To study the kinetics of decomposition at different acidities, HC solutions were placed in hermetically sealable glass jars, with the required acidity adjusted by introduction of an HCl solution. Changes in the acidity of the medium and in the concentration were determined at regular intervals of time. In all the experiments, the variation of the HC concentration was monitored iodometrically.

The experiments in which the stability of sodium HC solutions was studied were carried out with industrial and model solutions of close concentrations. The data obtained were used to calculate the order of the reaction by which the alkaline solution of sodium HC decomposes, using the known Van't Hoff formula

$$n = \frac{w_1/w_2}{\log(c_1/c_2)}.$$

This formula makes it possible to determine the reaction order n from the initial rates w_1 and w_2, i.e., from the reaction rates at different initial concentrations c_1 and c_2 of the starting HC.

The calculations demonstrated that spontaneous decomposition of sodium HC in alkaline solutions occurs as a second-order reaction at both 25 and 35°C. The second reaction order was also obtained by graphical differentiation from the slope of the dependence of the rate of HC decomposition on the logarithm of the concentration, $\log(-\Delta c/\Delta t) - \log c$. The rate constants of the decomposition reaction were calculated using second-order kinetic equations

$$k = 1/t \frac{c_0 - c}{c_0 c}.$$

The results obtained are listed in Table 1.

The second order of the reactions and the formal rate constants of decomposition were obtained using

the above-described procedures for a model HC solution with a concentration of 2.26 M at two temperatures: $k_{av} = 0.2060 \times 10^{-4}$ M at 25°C and $k_{av} = 0.1064 \times 10^{-3}$ M at 35°C.

The activation energies calculated using the Arrhenius equation

$$E = \frac{\log (k_2/k_1)}{(T_2 - T_1)/T_2T_1},$$

were 82.33 kJ mol^{-1} (19.67 kcal mol^{-1}) for a sodium HC solution with a concentration of 5.2 M and 79.53 kJ mol^{-1} (19.00 kcal mol^{-1}) for that with a concentration of 2.1 M. The results obtained are in an agreement with published data for alkaline HC solutions [10].

The decomposition of HC consists of two concurrent processes, oxygen and chlorate decompositions, which can be expressed by the following reactions

$$ClO^- + ClO^- = 2Cl^- + O_2, \quad \text{(I)}$$

$$ClO^- + ClO^- = ClO_2^- + Cl^-, \quad \text{(II)}$$

$$ClO_2^- + ClO^- = ClO_3^- + Cl^-. \quad \text{(III)}$$

The rate-determining reactions are (I) and (II), whereas reaction (III) is considerably faster than the first two [11].

As can be seen in Table 1, a certain deviation from the average kinetic parameters (reaction orders, reaction rate constants) is observed in the initial stage of the process (~216 h) at 25°C, which can be attributed to predominance of the oxygen decomposition [11]. At 35°C, the process is considerably faster: the chlorate decomposition predominates. The model solutions decompose in a similar way.

The experimental data were used to compare the decomposition rates of sodium HC in industrially manufactured and model solutions at 25 and 35°C. Figures 1 and 2 show kinetic curves that describe the self-decomposition of alkaline solutions of sodium HC. It can be seen that that the processes of spontaneous decomposition are autocatalytic at 25°C, with the process rates dependent on the initial concentration. The calculated rate constants of HC decomposition were used to compare the decomposition rates of HC in solutions with different concentrations at this temperature.

For example, sodium HC decomposes at 25°C in the solution with a concentration of 5.2 M approximately 1.5 times faster than in that with a concentration of 2.1 M. The temperature dependence of the decomposition rate is particularly strong. The decomposition is approximately 2.8 times faster at 35°C, compared with 25°C, for the solution with a sodium HC concentration of 5.2 M, and 2.65 times faster at a concentration of 2.1 M.

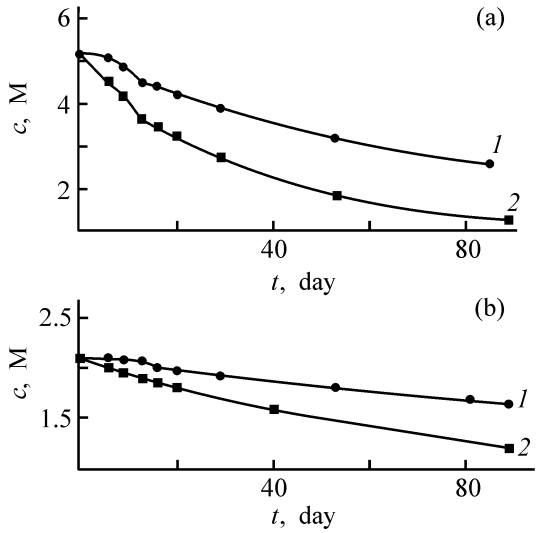

Fig. 1. Stability of industrially manufactured sodium hypochlorite solutions with a concentration of (a) 5.2 and (b) 2.1 M. (*c*) Concentration and (*t*) time; the same for Fig. 2. Temperature (°C): (*1*) 25 and (*2*) 35.

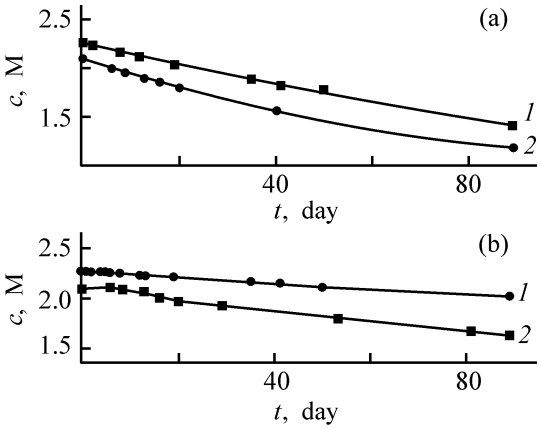

Fig. 2. Stability of (*1*) model sodium hypochlorite solutions with a concentration of 2.26 M and (*2*) industrially manufactured sodium hypochlorite solutions with a concentration of 2.1 M at (a) 35 and (b) 25°C.

Comparison with model solutions shows that decomposition of a diluted industrially manufactured sodium HC solution with a concentration of 2.1 M at 25°C is approximately 3 times faster than that of a model solution with a close concentration (c = 2.26 M). This can be attributed to presence in the industrial solution of mostly colloid particles of iron

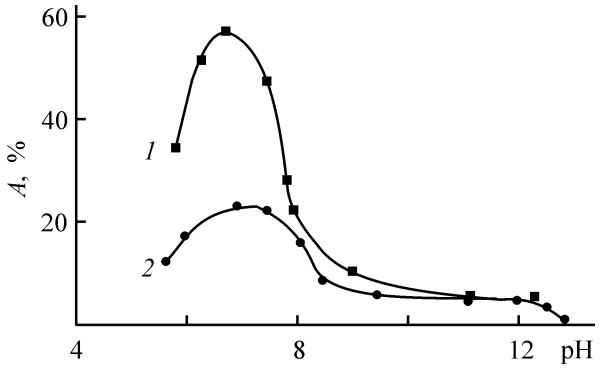

Fig. 3. Degree of sodium hypochlorite decomposition, *A*, vs. the pH value. (*A*) Ratio of the number of decomposed moles of HClO + ClO^- to their initial number. c_0 (M): (*1*) 1.24 and (*2*) 1.29. Temperature (°C): (*1*) 30 and (*2*) 25.

hydroxide $Fe(OH)_3$. These particles have an excess energy and accelerate the decomposition of HC, with the catalytic action of $Fe(OH)_3$ becoming less pronounced in the course of time, which is commonly accounted for by a decrease in dispersity, named "aging" [12]. At 35°C, the decomposition rate of the industrial solution exceeds that of the model solution only by approximately a factor of 1.5, because the accelerating effect of temperature equally tells upon the decomposition of both HC solutions. At the same time, the catalytic action of $Fe(OH)_3$ on the decomposition of the industrial becomes less pronounced as temperature increases, because a higher temperature favors coagulation, i.e., leads to coarsening of colloid particles and, consequently, to a decrease in their total surface area and excess energy.

The stability and oxidizing power of sodium HC solutions are strongly dependent on the activity of hydrogen ions in solution. Figure 3 shows how the degree of HC decomposition depends on the pH value at 25 and 30°C. It can be seen that the maximum degree of HC decomposition is observed at pH close to 7.

Table 2. Dynamics of variation of the pH value and concentration of sodium HC solutions

Solution no.	*t*, h	*c*, M	pH
1	0	1.188	8.06
	0.5	0.689	7.84
	1.0	0.437	7.52
	2.0	0.255	6.09
	3.0	0.207	6.05
	4.0	0.185	6.45
2	0	0.941	4.83
	96	0.323	5.01
	168	0.182	5.30
	384	0.132	5.25
	528	0.105	5.22

It is known that not only the mechanisms of HC decomposition in alkaline, neutral, and acid media, but also the rates of this process are different: the decomposition rate is at a minimum in a strongly acidic medium (pH < 1), increases with the pH value to reach a maximum in a nearly neutral medium, and then again decreases in an alkaline medium. Thus, the activity of hydrogen ions is one of the key factors affecting the composition and stability of HC solutions and, consequently, their oxidizing power [13–15].

The decomposition kinetics of industrial sodium HC solutions was studied at pH 6.5–8.0 (solution no. 1, c_0 = 1.188 M) and pH 4.8 (solution no. 2, c_0 = 0.941 M) at room temperature (21–22°C). A fast change in both the pH of the medium and the HC concentration was observed at pH 6.5–8.0. The experimental data obtained are listed in Table 2.

The order of the reaction of HC decomposition was determined from the variation of the HC concentration with time, and the rate constants of the reaction were calculated. The reaction order was found using the graphical variety of the method of substitution of experimental data (HC concentrations at different instants of time in the course of the reaction) into first-, second-, and third-order kinetic equations. For this purpose, time dependences of various functions of concentration were constructed. Each kinetic equation gives a straight line only in the appropriate coordinates [16]. Both for pH 6.5–8.0 and for pH 4.8, a linear plot was obtained for the $1/c$–t dependence, i.e., for a second-order kinetic equation. The reaction order was confirmed, as in the case of an alkaline medium, by graphical differentiation. The rate constants were calculated for a second-order kinetic equation:

pH	k, $l^{-1}\ mol^{-1}\ h^{-1}$
4.80	$(2.12 \pm 0.60) \times 10^{-2}$
8.0–6.5	1.34 ± 0.20
13.5	$(0.63 \pm 0.02) \times 10^{-4}$

It was noted in [8] that the reaction at pH 6.0–8.0 is so fast that the rate of self-decomposition increases by several orders of magnitude to become comparable with that of fast reactions.

The same dependence was observed in the present study.

The decomposition of sodium HC solutions at pH < 4.8 was not considered because preparation of solutions of this kind is accompanied by vigorous evolution of Cl_2, which leads to its waste and inefficient use of HC.

CONCLUSIONS

(1) An assessment of the stability of industrially manufactured sodium hypochlorite solutions revealed that dilute sodium hypochlorite solutions are the most stable in storage at temperatures not exceeding 25°C. It was shown that model hypochlorite solutions prepared with distilled water are more stable in storage than the industrially manufactured solutions.

(2) It was demonstrated that the spontaneous decomposition of industrial sodium hypochlorite solutions in a wide range of pH values (4.8–13.5) is a second-order reaction. The rate constants of the decomposition process, calculated at different pH values, confirmed the extremal type of the dependence of the decomposition rate on the pH value. It was shown that the decomposition pattern of dilute hypochlorite solutions is also valid for concentrated solutions.

Received December 16, 2004

Abstract—Dissolution of mercury in aqueous solutions of sodium hypochlorite at pH 5.9–8.5, the corresponding reaction order, and the mechanism of this process were studied. The ratio of the rates of mercury oxidation and sodium hypochlorite decomposition was analyzed.

Salts of hypochlorous acid, hypochlorites, find wide application as strong oxidizing agents, their oxidizing power being largely determined by the acidity of the medium.

The aim of this study was to assess the possibility of using a sodium hypochlorite (NaClO) solution at pH 5.9–8.5 for oxidation of mercury and to determine the rate constants of mercury dissolution via its oxidation to Hg^{2+} ions in the above-mentioned acidity range.

EXPERIMENTAL

Mercury was oxidized with an aqueous solution of NaClO at pH 5.9, 6.5, 6.9, and 8.5 and temperatures of 25 and 50°C; the concentration in terms of active chlorine was 0.3–0.8 M. The required acidity was created with a buffer phosphate solution obtained by adding orthophosphoric acid, potassium dihydrophosphate, and sodium hydrophosphate to the NaClO solution. The pH value was monitored with an EV-74 ionometer with glass and silver chloride electrodes.

The NaClO solution was produced by passing chlorine through a carbonate-free solution of sodium hydroxide at a temperature of –5…0°C. The reaction vessel was cooled with a mixture of sodium chloride and ice. Chlorine was obtained by reacting chemically pure hydrochloric acid with potassium permanganate. The concentration of the hypochlorite was determined iodometricaly.

A mercury drop of mass 0.05–0.15 g was placed in a hermetically sealable glass jars thermostated at 25 and 50°C, and 50 ml of a sodium hypochlorite solution with certain acidity was added. The Hg^{2+} concentration was determined at regular intervals of time by a selective spectrophotometric technique with dithizone [1]. The optical density of the solutions was determined with a KFK-2 photoelectric colorimeter.

Mercury is a metal that is liquid at room temperature. The high surface tension allows even comparatively large mercury drops to take the shape of a sphere, the body with the smallest relative surface area. Dissolution of mercury is a heterogeneous process that occurs at the interface and depends on the area and state of the surface. Kinetic characteristics of the process of mercury dissolution in sodium hypochlorite solutions were determined using the formula established experimentally by A.N. Shchukarev for the rate of dissolution of a solid body in a liquid [2, 3]. This formula made it possible to calculate the rate constant k of mercury dissolution:

$$w = kS(c_s - c),$$

where w is the dissolution rate; S, area of contact between the solid and liquid; c, concentration of the substance being dissolved in the bulk of the liquid; c_s, concentration of a saturated solution; and k, constant for the given experimental conditions.

As the concentration of a saturated solution was taken the maximum possible concentration of Hg^{2+} ions. The latter was determined from the mass of the mercury drop and the volume of the hypochlorite solution in which it dissolved. The rate of mercury dissolution was found from the concentration of mercury(II) at certain instants of time. The contact area was calculated from the mass of a spherical drop of mercury and its density [4] at a given temperature.

1070-4272/05/7804-0546 © 2005 Pleiades Publishing, Inc.

The order of the dissolution reaction was determined for two mercury drops with different masses by the Van't Hoff formula

$$n = (\log w_1 - \log w_2)/(\log c_1 - \log c_2),$$

which includes reaction rates for two concentrations of the starting substance.

The parameters of the reaction of mercury dissolution at pH 5.9–8.5 are listed in the table. The kinetic curves plotted as the Hg^{2+} concentration c vs. time t (Fig. 1a) and $\log c$ vs. t (Fig. 1b) confirm the first reaction order obtained by calculation, because the time dependence of the concentration of Hg^{2+} ions is exponential, and that of $\log c$, linear (see Fig. 1). The activation energies were calculated using the Arrhenius equation from the dissolution rate constants for 25 and 50°C. The results obtained are listed in the table.

The dissolution of mercury is a heterogeneous process in which a kinetic region, with the process rate determined by the chemical reaction, and a diffusion region, with the process rate determined by diffusion, can be distinguished. As a rule, the reaction occurs in the kinetic mode at low temperatures. As the temperature is raised, the rate constant of the chemical process rapidly increases and, at a certain temperature at which the rate constant of the chemical reaction becomes higher than that of diffusion, the heterogeneous process passes from the kinetic to the diffusion region. It has been noted in the literature [2] that, if the activation energy is 5–20 kJ mol^{-1}, the process can be identified as occurring in the diffusion mode. If the activation energy is 50–200 kJ mol^{-1}, then the heterogeneous process occurs in the kinetic region. In the intermediate region, the rate of the heterogeneous process is determined both by diffusion and by the chemical process at the phase boundary. The calculated activation energies suggest that the dissolution of mercury proceeds in the intermediate region, with its rate determined both by the rate of the chemical reaction and by the diffusion process.

The temperature dependence of the reaction rate is characterized by the temperature coefficient defined as the amount by which the rate increases on raising the temperature by 10°C. The temperature coefficients are 2–4 for the rate of the chemical reaction, $\gamma_{ch} = (k_{ch})_{T+10}/(k_{ch})_T$, and 1.1–1.4 for that of the diffusion process, $\gamma_D = (k_D)_{T+10}/(k_D)_T$, [2]. According to this rule, an increase in the reaction rate by at least a factor of 6 would be observed on raising the temperature by 25°C if the dissolution of mercury preferentially occurred in the kinetic region. However, the reaction rate actually increases by only a factor of 2.6–4, which points to a substantial influence exerted by the diffusion process on the dissolution of mercury. The same is indicated by the temperature coefficients of mercury dissolution, calculated for different pH values. The range pH 6–7 corresponds to the maximum decomposition rate of hypochlorite and, as a result, to a high rate of mercury oxidation by active chlorine evolved in the decomposition. Therefore, the key role in the dissolution process is played in the given case by diffusion. On passing to the alkaline region, the rate of hypochlorite decomposition markedly decreases and the chemical reaction of oxidation starts to exert a noticeable influence on the process at pH 8.5. The observed increase in the dissolution rate on raising the temperature to 50°C is small as compared with that expected. This is probably accounted for by a rise in the instability of the hypochlorite solution with increasing temperature, which is accompanied by a decrease in the concentra-

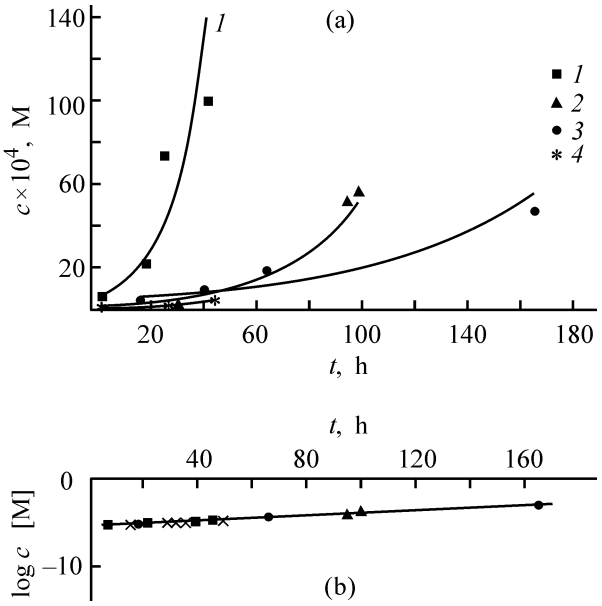

Fig. 1. Kinetic curves of mercury dissolution at 25°C. (c) Concentration of Hg^{2+} ions and (t) time. Variation of the Hg^{2+} concentration at pH: (*1*) 6.5, (*2*) 6.9, (*3*) 5.9, and (*4*) 8.5.

Parameters of the reaction of mercury dissolution

pH	k, cm^{-1} h^{-1}		γ^*	E, kJ mol^{-1}	Reaction order
	25°C	50°C			
5.90	2.17×10^{-3}	–			1.003
6.50	1.18×10^{-3}	3.65×10^{-2}	1.24	36.15	1.008
6.90	2.07×10^{-2}	5.38×10^{-2}	1.04	30.58	1.010
8.50	6.75×10^{-3}	2.68×10^{-3}	4.00	44.15	–

* γ, temperature coefficient of the dissolution process.

tion of active chlorine and the resulting decline in the oxidizing power.

It was established experimentally that the reaction of self-decomposition of hypochlorite occurs at the maximum rate at pH 6–8.5 and is first-order with respect to the concentration of hydrogen ions, i.e., the self-decomposition rate changes by a factor of 10 upon a unity change in the pH value. Therefore, the self-decomposition rate increases at pH 6–8.5 by several orders of magnitude, to become comparable with the rate of fast reactions [5–7]. The maximum rate of mercury dissolution is observed at pH 6.5–6.9, which correlates well with published data for the maximum rate of hypochlorite decomposition (pH ~7) [8]. The rate constant of mercury dissolution at pH 5.9–8.5 is $(0.2–2.0) \times 10^{-2}$, i.e., the decomposition rate of the hypochlorite is many times that of mercury oxidation. Therefore, in the authors' opinion, use of sodium hypochlorite for oxidation of mercury in this pH range is inadvisable because most part of active chlorine is wasted without having enough time for entering into the reaction.

CONCLUSIONS

(1) The rate constants of mercury dissolution in hypochlorite solutions at pH 5.9–8.5 were calculated. It was shown that the maximum rate of mercury dissolution is observed at pH 6.5–6.9.

(2) It was established that the reaction of mercury dissolution is first-order. The apparent activation energies of 30–44 kJ mol^{-1} indicate that the heterogeneous dissolution occurs in the intermediate region, in which both the chemical reaction and diffusion affect this process.

(3) It was found that the rate of mercury oxidation by sodium hypochlorite at pH 5.9–8.5 is considerably lower than the decomposition rate of the hypochlorite itself.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

A New Method for Study of Magnetic Suspensions

A. I. Zhernovoi and V. N. Naumov

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received October 13, 2004

Abstract—A procedure for determining the magnetization of a ferrofluid from the shift of ^{1}H NMR signal of the solvent by rotating a sample having the shape of an oblate ellipsoid is suggested. The possibility of using the NMR spectroscopy for evaluating the size of magnetite particles and for examining the distribution of the local magnetization of the ferrofluid in a magnetic field is analyzed. The NMR method is compared with the classical Gouy technique.

Magnetic fluids (colloid solutions of magnetite particles), which have found a wide application in various fields of technology, medicine, and chemical technology, have been attracting a considerable interest in recent years. The possibility of controlling the shape and structure of the surface of a magnetic fluid make it a promising technological medium for mass-exchange apparatus. The important part in the behavior of a magnetic fluid in a magnetic field is played by the size of magnetic particles and their distribution in the bulk. Control over these parameters, which is necessary in manufacture and application of magnetic fluids, is hindered by the lack of methods that can be used to measure them in sufficiently small volumes of a fluid. This control is enabled by measuring the shift of the ^{1}H NMR signal.

When placed in a magnetic field, a ferrofluid with a volume magnetite concentration c_0 acquires a magnetization

$$J_0 = c_0 (J_m - J_s) + J_s, \quad (1)$$

where J_m and J_s are the magnetizations of magnetite and the fluid substrate (solvent).

Commonly, a concentrated ferrofluid has $c_0 \approx 2$–4 vol %. At this magnetite concentration, it is difficult to record a ^{1}H NMR signal because of the too large line width, and, therefore, the ferrofluid should be diluted with the solvent to a volume magnetite concentration $c \approx 0.01$–0.02 vol %. The magnetization of a diluted ferrofluid placed in a magnetic field can be expressed as

$$J(c) = (J_m - J_s) + J_s. \quad (2)$$

From Eqs. (1) and (2) follows a relationship between the magnetization of the initial ferrofluid, J_0, and that of a diluted ferrofluid, $J(c)$, measured by the NMR method:

$$J_0 = KJ(c) - J_s(K - 1), \quad (3)$$

where $K = c_0/c$ is the dilution factor.

When a sample of a ferrofluid with a concentration c is placed in a magnetic field of the NMR spectrometer, the effective magnetic field strength H experienced by solvent molecules differs from the field strength H_0 of the magnet [1–3]:

$$H = H_0 + \left(\frac{1}{3} - N + q\right) J(c), \quad (4)$$

where N is the demagnetization factor of the sample surface, and q is a coefficient introduced by Dickinson [1] to characterize the additional shift of the NMR signal in paramagnetic solutions, caused by their magnetic anisotropy.

According to Eq. (4), the difference of the field strengths H in samples with demagnetization factors N_1 and N_2 is given by

$$H(N_2) - H(N_1) = (N_1 - N_2)J(c), \quad (5)$$

whence follows that

$$J(c) = \frac{H(N_2) - H(N_1)}{N_1 - N_2}. \quad (6)$$

The difference of the field strengths in the numerator of expression (6) is found from the shift of the peak

1070-4272/05/7804-0549 © 2005 Pleiades Publishing, Inc.

NMR signal from the ferrofluid, measured on an NMR spectrometer with a uniform field at different demagnetization factors N of the sample surface. The demagnetization factor can be varied by using samples with different shapes. For example, $N = 1/3$ for a sphere, 1/2 for a cylinder with axis perpendicular to H_0, 1 for a cylinder with axis parallel to H_0, 1 for a thin disc with axis perpendicular to H_0 and 0 for a thin disc with axis parallel to H_0.

With the experimental value of $J(c)$ determined using formula (6) and substituted into Eq. (3), we can find the magnetization J_0 of the initial ferrofluid. The solvent magnetization $J_s = \chi_s H_0$, where χ_s is the volume magnetic susceptibility. If χ_s is unknown, the solvent magnetization can be found experimentally from the shift of the NMR signal, using a formula similar to (6):

$$J_s = \frac{H_s(N_2) - H_s(N_1)}{N_1 - N_2}, \quad (7)$$

where the numerator is the difference of resonance fields of the NMR signal of a pure solvent at two demagnetization factors of a sample.

If our samples have ideal shapes of ellipsoids of revolution, we can calculate their dipole moments [4]. Otherwise, the difference $N_1 - N_2$ can be determined experimentally by measuring the shift of the NMR signal of a certain reference substance whose magnetic susceptibility χ_r is known. In this case, by analogy with formulas (6) and (7), we have

$$N_1 - N_2 = \frac{H_r(N_2) - H_r(N_1)}{\chi_r H_0}, \quad (8)$$

where $H_r(N_2) - H_r(N_1)$ is the shift of the NMR signal from the reference sample on changing the sample shape.

Substituting formula (8) into (6) and (7), we obtain an expression for determining $J(c)$ and J_s at unknown demagnetization factors N_1 and N_2:

$$J(c) = \frac{H(N_2) - H(N_1)}{H_r(N_2) - H_r(N_1)}\chi_r H_0,$$
$$J_s = \frac{H_s(N_2) - H_s(N_1)}{H_s(N_2) - H_r(N_1)}\chi_r H_0. \quad (9)$$

For an experimental study, we took a colloid magnetite solution in water with a particle size of about 10 nm, a concentration $c_0 = 2.7$ vol %, and a stabilizer based on oleic acid. To record the NMR signal, we diluted the solution with water to a concentration $c = 0.0135$ vol % (dilution factor $K = 200$). We measured the shift of the ^{1}H NMR signal with a high-resolution spectrometer operating at 40 MHz (with a magnetic field strength $H_0 = 7.46 \times 10^5$ A m^{-1}). As a probe with a varied demagnetization factor of a sample served an oblate thin-walled glass spheroid (disc) 2 mm thick and 8 mm in diameter, filled with a fluid under study via a thin glass pipe.

We determined $J(c)$ by the method with a reference substance (water).

With the probe filled with the ferrofluid, turning the disc axis from the direction perpendicular to H_0 ($N_1 \approx 0$) to that parallel to H_0 ($N_2 \approx 1$) resulted in that the resonance frequency changed by –508 Hz, which corresponds to a change in the magnetic field strength, $H(N_2) - H(N_1) = -9.5$ A m^{-1}.

With the probe filled with water, a similar turning of the disc axis led to a change in the resonance NMR frequency by 143 Hz, which corresponds to a change in the magnetic field strength $H_r(N_2) - H_r(N_1) \approx 2.68$ A m^{-1}. Substituting the values obtained for the change in H(N), χ_r equal to the magnetic susceptibility of water $\chi_{H_2O} = -9.0 \times 10^{-6}$, and $H_0 = 7.46 \times 10^5$ A m^{-1} into expression (9), we obtain $J(c) = 25.2$ A m^{-1}. Substituting this value of $J(c)$, $K = 200$, and $J_s = \chi_{H_2O} H_0 = -7.1$ A m^{-1} into (3), we find the magnetization of the initial ferrofluid, $J_0 = 6.5$ kA m^{-1}.

The theoretical value of J_0 can be calculated by the formula

$$J_{0th} = J_m c_0 P_m, \quad (10)$$

where P_m is the volume fraction of a solid possessing magnetic properties, and J_m is the magnetization of magnetite.

The values of P_m, taken from [5], and the theoretical values of J_{0th}, calculated from these P_m by formula (10) for three presumed particle sizes d are listed in the table.

We can obtain by means of interpolation that the experimental value $J_0 = 6.5$ kA m^{-1} coincides with the theoretical value at $d = 6$ nm. As d decreases or increases, the theoretical values become lower or higher than the experimental value, respectively. This circumstance can be used for evaluating the particle size.

To measure the magnetization by the Gouy method, we suspended a test tube with the fluid under study from an arm of a beam balance and measured the ponderomotive force F appearing under the action

of a magnet that was mounted below the test tube and created a field gradient directed along its axis. Theoretically, the force F is given by the expression

$$F = S\int_{B_1}^{B_2} J(B)\mathrm{d}B, \quad (11)$$

where S is the inner cross-sectional area of the test tube; and B_1, B_2 are the magnetic inductions at the upper and lower boundaries of the fluid.

The dependence of the magnetization J on induction B is given by the Langevin formula, which can be represented at $B > 0.05$ T as [6]:

$$J(B) = J_0 - \frac{nKT}{B}, \quad (12)$$

where n is the concentration of colloid particles; K, Boltzmann constant; and T, temperature.

Substituting formula (12) into (11) and integrating, we obtain

$$F = S\left[J_0(B_2 - B_1) - nKT\ln\frac{B_2}{B_1}\right], \quad (13)$$

whence follows

$$J_0 = \frac{\frac{F}{S} + nKT\ln\frac{B_2}{B_1}}{B_2 - B_1}. \quad (14)$$

In an experimental setup, $S = 27.3 \times 10^{-6}$ m, $KT = 4 \times 10^{-2}$ J, $B_1 = 0.05$ T, and $B_2 = 0.25$ T. The particle concentration n is related to the volume concentration c of magnetite and particle size d by

$$n = \frac{6c}{3\pi d^3}.$$

From Eq. (14) follows a formula for the experimental value of the magnetization, obtained using the Gouy method at $c = c_0$:

$$J_{0G} = 1.8 \times 10^5 F + \frac{6.1 \times 10^{-20} c_0}{d^3}. \quad (15)$$

In an experiment performed at $c_0 = 0.027$, we obtained $F = 0.096$ H. Substitution of this value into (15) gives

$$J_{0G} = 1.98 \times 10^4 + \frac{1.6 \times 10^{-21}}{d^3}. \quad (16)$$

The values of J_{0G}, obtained using formula (16) at various d, are listed in the table. It can be seen that all the experimental values exceeds those yielded by the theory. This can be attributed to magnitophoresis resulting in a rise in the particle concentration at high field gradients. This assumption can be verified by measuring the local magnetization of the ferrofluid by the NMR method.

P_m and ferrofluid magnetizations J_{0th} and J_{0G} in relation to particle size d

d_0, nm	P_m (S) [5]	J_{0th}^*	J_{0G}^{**}
		kA m^{-1}	
5	0.5	6.05	32.4
10	0.67	8.11	20.2
15	0.8	9.68	20.07

* Obtained using the theoretical formula (10).

** Obtained using the experimental calculational formula (16) at $c = 2.7$ vol %.

The results obtained open up new opportunities for study of the structure of a ferrofluid placed in a gradient magnetic field. This is of practical interest in design of magnetic seals and other devices that employ ferrofluids.

Received October 22, 2004

Abstract—The iodometric titration of photographic fixing solutions can be simplified by masking sulfite anions with 3% aqueous formaldehyde in a weakly acidic medium, instead of their standard masking with concentrated aqueous formaldehyde in weakly alkaline solutions.

The concentrations of sodium thiosulfate and sodium sulfite in photographic fixing solutions are commonly determined by iodometric titration. In this method, two identical aliquots of a fixer are titrated with iodine. In the first aliquot, the sum of $S_2O_3^{2-}$ and SO_3^{2-} anions is determined. The second aliquot is titrated in the presence of an agent masking SO_3^{2-} anions to determine the content of $S_2O_3^{2-}$ anions. The sulfite anions can be masked with formaldehyde [1–5] or acetone [4, 6], or by precipitating poorly soluble strontium sulfite [7, 8]. The accuracy of sodium thiosulfate and sodium sulfite determination depends on the reliability of masking sulfite anions.

As a rule, acetone is not used for masking of sulfite anions because of its volatility and inflammability. Futuremore, in iodometric titration in water–acetone mixture, the color of the iodine-sensitive indicator is strongly weakened and the color transition at the equivalent point is puurly defined.

The precipitation of sulfite anions is expedient only if other interfering components of the fixer are coprecipitated. For example, in determination of sodium thiosulfate in bleaching fixers, the precipitation of strontium sulfite is apparently accompanied by coprecipitation of thiourea interfering with the thiosulfate titration.

As a rule, in iodometric titration of fixers, sulfite anions are masked with formaldehyde. Formaldehyde is bound with sulfite anions to form a complex unoxidizable with iodine. The formation of this complex is described by reaction (1) in an acidic medium [9] and by reaction (2) in a neutral or weakly alkaline medium [10]:

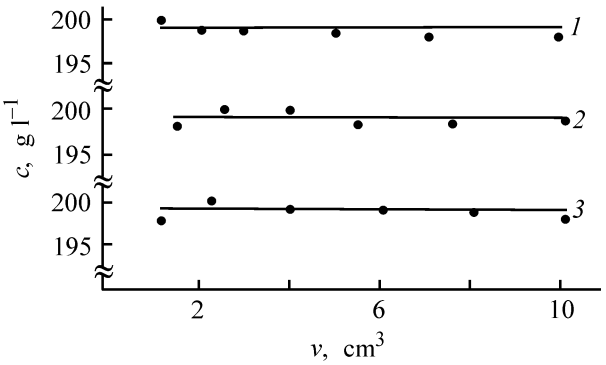
$$CH_2O + SO_3^{2-} + H^+ \rightarrow CH_2OHSO_3^-, \quad (1)$$

$$Na_2SO_3 + CH_2O + H_2O \rightarrow H_2COHSO_3Na + NaOH. \quad (2)$$

In iodometric titration of photographic fixers, sulfite anions are commonly masked in an alkaline medium. The initial aqueous solution of the fixer is diluted with water and alkalized to pH 8–10, with phenolphthalein as indicator. Thereafter, 37% aqueous formaldehyde is added, and the resulting mixture is allowed to stand for several minutes. This mixture is acidified with 10% aqueous acetic acid (10 ml), and a standard solution of iodine is added. The amount of formaldehyde, recommended for masking of sulfite anions (ml of formaldehyde solution per ml of fixer), varies over a wide range: 1.0 [2], 2.0 [3], 2.5 [1], 5 [5], and even 10 ml [4, 11]. It has also been reported [5] that sulfite anions can be masked in a weakly acidified fixer (pH 3–4) by adding a large excess of 37% aqueous formaldehyde.

Published data on masking of sulfite anions with formaldehyde in iodometric titration of fixers show that the recommended formaldehyde additions significantly exceed its stoichiometric amount required for complexation of sulfite anions by reactions (1) and (2). These reactions show that 1 mol of formaldehyde is bound with 1 mol of sulfite anions. The maximum content of sodium sulfite in the fixers does not exceed 40 g l^{-1} (0.32 M). Therefore, to mask sulfite anions present in 1 ml of this fixer, 0.027 ml of 37% (11.6 M) aqueous formaldehyde is required. In practice, the formalehyde addition exceeds its stoichiometric amount by a factor of 40–400.

1070-4272/05/7804-0552 © 2005 Pleiades Publishing, Inc.



It is known [12] that the complex of formaldehyde with sulfite anion is the most stable in weakly acidic solutions (pH 3–5). Therefore, we can suggest that sulfite anions can be masked in weakly acidic media with a smaller amount of formaldehyde than in commonly used alkaline solutions. The masking of sulfite anions in acidic medium could significantly simplify iodometric analysis of fixers.

In this study, we improved iodometric titration of fixers by masking sulfite anions with formaldehyde in weakly acidic solutions.

EXPERIMENTAL

The search for the optimal conditions of masking sulfite anions with formaldehyde was carried out with a fixer containing $Na_2S_2O_3 \cdot 5H_2O$ (199.5 g l^{-1}), Na_2SO_3 (20 g l^{-1}), and sulfuric acid. In our experiments sodium thiosulfate and sodium sulfite were determined by iodometric back-titration of 1-ml aliquots of the fixer. The first aliquot was diluted with distilled water (10 ml), and a 15 ml 0.1 N reference solution of iodine was added. The excess iodine was titrated with 0.1 aqueous thiosulfate in the presence of starch as indicator, and the iodine solution volume v consumed for oxidation of the sum of $S_2O_3^{2-}$ and SO_3^{2-} was determined. The second aliquot of the fixer was diluted with distilled water (10 ml) and alkalized to pH 9–10 with phenolphtalein as indicator, and then formaldehyde was gradually added, starting with a 1-ml portion, to its total volume equal to 10 ml. Along with commonly used 37% aqueous formaldehyde, we tested 14% and 10% aqueous formaldehyde. After adding each portion of formaldehyde, the mixture was kept for 5 min, and acidified with 10% aqueous acetic acid (5 ml), and a standard solution of iodine (15 ml) was added. Excess iodine was titrated with 0.1 M aqueous thiosulfate in the presence of starch, and the iodine solution volume v_1 consumed for oxidation of $S_2O_3^{2-}$ was determined. The iodine solution volume v_2 consumed for oxidation of SO_3^{2-} was determined as the difference $v - v_1 = v_2$.

In order to elucidate how the fixer acidity influences the efficiency of masking of sulfite anions with formaldehyde, the fixing solutions with different formaldehyde contents were iodometrically titrated at various pH. The fixing solutions were prepared by standard procedures [13, 14]. The reference solutions of iodine and sodium thiosulfate (0.1 N) were prepared from the reference samples. As indicator served 0.5% aqueous starch. All the solutions used in our experiments were prepared from chemicals analytically or chemically pure grades.

$Na_2S_2O_3$ content in a weakly acidic fixer, determined by iodometric back-titraition, vs. the formaldehyde volume added, v. Fixer: $Na_2S_2O_3 \cdot 5H_2O$ 200.0 g l^{-1}, Na_2SO_3 20 g l^{-1}, and H_2SO_4. (*c*) Sodium thiosulfate concentration. Formaldehyde concentration, %: (*1*) 37, (*2*) 14, and (*3*) 10.

The accuracy and reproducibility of sodium thiosulfate determination in fixers depend on the reliability of masking of sulfite anions. The figure shows how the iodometric determination of sodium thiosulfate in the fixer depends on the formaldehyde amount added. As seen from the figure (curve *1*), in masking of sulfite anions by successively adding 37% aqueous formaldehyde, starting with 1-ml portion to its total volume equal to 10 ml, the difference between the actual thiosulfate content and that determined iodometrically does not exceed 2 g l^{-1} (1%) within the entire range of formaldehyde volumes. Approximately the same difference between the actual and iodometrically determined thiosulfate content was obtained upon addition of 14% and 10% aqueous formaldehyde, starting with a 1.5-ml portion to the total volume of 10 ml (figure, curve *2*) and starting with a 2-ml portion to the total volume of addition 10 ml (figure, curve *3*). In masking of sulfite anions with 1 ml of 10% aqueous formaldehyde, the thiosulfate content was under-estimated by approximately 4%.

We found that small formaldehyde additions (1 ml of 37% aqueous formaldehyde or 1.5–2 ml of 10% aqueous formaldehyde) to 1 ml of the fixer completely mask sulfite anions. Thus, we can reliably mask sulfite anions in weakly acidified fixing solution by adding 5 ml of 3% aqueous formaldehyde to 1 ml of the fixing solution (see, e.g., the second point in curve *3* of the figure). Dilute solutions of formaldehyde are more stable and safer in handling in the course of analysis.

Our experiments showed that a 3% solution of formaldehyde in 10% aqueous acetic acid is the optimal masking mixture. Owing to the simultaneous presence of both the fixing and acidifying agents in a masking solution, this mixture is convenient in

Determination of sodium thiosulfate and sodium sulfite in various fixing solutions by (A) direct [OST (All Union Standard) 19-1–83] and (B) back iodometric titration as suggested in this study (n = 5, P = 0.95)

* (B*) Back-titration of a sum of thiosulfate and sulfite anions in a 1-ml aliquote of the fixer, acidified with 10% aqueous acetic acid (5 cm^3).

use. It should be noted that the possibility of reliable masking of sulfite anions with formaldehyde in weakly acidic media [Eq. (1)] follows from previous data [5, 12]. The adduct has been reported to be resistant to atmospheric oxygen in acidic media. The above-described masking of sulfite anions in weakly acidic solutions can be used in both direct and back iodometric titration of sodium thiosulfate in fixers.

Procedure for iodometric back-titration of sodium thiosulfate in fixer. A 1-ml portion of the fixer was placed in a 150-ml beaker, and distilled water (10 ml) and the masking solution (3% solution of formaldehyde in 10% aqueous acetic acid, 5 ml) were added. The resulting mixture was stirred, and right after that (without keeping for 5 min as prescribed by the standard protocol) a precisely measured volume of a reference 0.1 N solution of iodine (from 10 to 15 ml) was added. This mixture was stirred, and the excess iodine was titrated with a reference solution of thiosulfate in the presence of starch as indicator. The sodium thiosulfate concentration in the initial fixing solution was calculated by multiplying the iodine solution volume v_1 consumed for the oxidation of thiosulfate by 24.8.

In order to determine the content of the sulfite anion in the fixer, its 1-ml aliquot was placed in a 150-ml beaker and titrated with a standard iodine solution as described above, without masking of sulfite anions with formaldehyde. Under these conditions, the total volume of iodine solution v consumed for oxidation of $Na_2S_2O_3$ and Na_2SO_3 was determined. The iodine solution volume consumed for oxidation of sulfite anions was determined as the difference $v - v_1 = v_2$. The sodium sulfite content was determined by multiplying v_2 by 6.3.

A series of available fixers was analyzed by the above-described iodometric back-titration technique. In these experiments, the $Na_2S_2O_3$ and Na_2SO_3 content in the fixers, determined by our method, was compared with that determined by direct titration of these fixers in a weakly alkaline medium with masking of sulfite anions with 37% aqueous formaldehyde (10 ml) [11]. The amount of iodine consumed for oxidation of the sum of $Na_2S_2O_3$ and Na_2SO_3 was determined by titration of the fixer acidified with 10% aqueous acetic acid, without adding formaldehyde.

The results of determination of sodium thiosulfate and sodium sulfite in various fixers by the standard direct iodometric titration technique [11] and by the iodometric back-titration developed in this study are listed in the table. These data show that the standard method ensures correct determination of sodium sul-

fite in all the fixers tested. The sodium thiosulfate is correctly determined in all the fixers except the bleaching fixer containing thiourea, in which sodium thiosulfate is determined with a fixed error caused by the reaction of iodine with thiourea.

Our technique of iodometric back-titration in a weakly acidic medium also ensures a correct determination of sodium thiosulfate in all the fixers under consideration, except those containing thiourea. Both our and the standard [11] methods ensure correct determination of sodium sulfite for all the kinds of fixers except those containing bleaching agents. We found that, in determination of the sum of sodium thiosulfate and sodium sulfate in the acidified initial fixer (B^*), the back-titration of Na_2SO_3 is carried out without a fixed error. Under these conditions, the results obtained by our method have better reproducibility than those obtained by the standard direct titration [OST (Branch Standard) 19-1–83].

Thus, with masking of sulfite anions in a weakly acidified fixer with a dilute (3%) solution of formaldehyde, the accuracy of iodometric determination of sodium thiosulfate and sodium sulfite is not inferior to that ensured by standard iodometric titration (OST 19-1–83).

CONCLUSION

In iodometric titration of photographic fixers, sulfite anions can be masked with a 3% solution of formaldehyde in 10% aqueous acetic acid. Titration in an acidic medium simplifies the analytical procedures and improves the safety of handling formaldehyde. Under these conditions, the reproducibility and accuracy of sodium thiosulfate and sodium sulfite determination are not inferior to those ensured by the standard titration.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrochemical Precipitation of Dispersed Ni–Ag Powders in Ammonia Electrolytes

O. I. Kuntyi and R. R. Olenych

Lvivska Politekhnika National University, Lviv, Ukraine

Received September 20, 2004; in final form, January 2005

Abstract—The electrochemical precipitation of a dispersed Ni–Ag powder from aqueous systems $[Ni(NH_3)_6]^{2+}$–$[Ag(NH_3)_2]^{+}$–$(NH_4)_2SO_4$–$NH_3 \cdot H_2O$ was studied.

Electrochemical codeposition of metals is widely used for obtaining compact coatings [1–3]. Separation of two-component dispersed powders M(1)–M(2) has been little studied. The first attempt to generalize data of few studies devoted to the cathodic codeposition of dispersed metals has been made for the example of copper alloys [4]. The accelerating development of power metallurgy [5] stimulates design of new multicomponent formulations, increase in the dispersity and homogeneity of dispersed powder systems, and decrease in their cost. Mostly mechanical agitation is used to homogenize dispersed powder systems, with the homogeneity of their components not always attained [6]. For this reason, chemical, physicochemical, and electrochemical processes are also used to prepare a homogeneous multicomponent stock. The last method is used in two modifications: cladding of dispersed powders by electrolysis [7–9] and cathodic codeposition of metals in the form of dispersed precipitates [4]. Use of secondary raw materials [8, 10–12] is a promising way for decreasing the cost of powder systems. The present study continues an integrated investigation of the electrochemical precipitation of dispersed bimetal powders with the use of secondary raw material [8, 9].

EXPERIMENTAL

The electrolysis was performed at 30°C in ammonia electrolytes based on complexes of nickel(II) and silver(I) complexes [or only nickel(II)] at the following concentrations of the components (M): $NiSO_4$ ($NiCl_2$) 0.1–0.5, $AgNO_3$ 0.01–0.05 (or 0), $(NH_4)_2SO_4$ 0.5, and $NH_3 \cdot H_2O$ added to adjust pH to 10. The nickel and Ni–Ag powders were deposited onto cylindrical aluminum cathodes (diameter 10 mm and surface area 15 cm^2) in a 1-dm^3 electrolyzer (Fig. 1).

At the beginning of electrolysis the current I was set on the basis of the current density i_c and then electroprecipitation was performed at a constant potential in the laminar agitation mode. After 10–20 min the cathode with a deposit was removed from the electrolyzer and placed in a vessel filled with an ammonia solution. To make shorter the time of contact silver deposition onto the surface of a dispersed nickel-containing deposit, the current was not switched off in the process. The deposit was scraped from the cathode, washed with an ammonia solution, water, and ethanol under agitation, and dried in a vacuum. To study the morphology of the deposit, it was obtained on the edge of a cylindrical cathode with a fully insulated lateral surface and examined with a Tesla-BS-300 scanning electron microscope (Fig. 1, *1'*). After the electrolysis was complete,

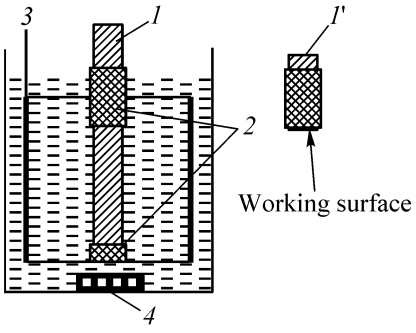

Fig. 1. Schematic of an electrolyzer for cathodic deposition of Ni–Ag alloy. (*1, 1'*) cylindrical cathodes, (*2*) hermetic fluoroplastic screens, (*3*) current lead to a concentric nickel anode, and (*4*) magnetic stirrer.

the powders, not removed from the support, were washed, dried (as described above), and mounted into the scanning microscope.

The powders obtained were analyzed on a DRON-3M diffractometer (Cu_{K_α} radiation, θ–2θ scanning mode, Bragg–Brentano method), with a stepwise recording of a diffraction pattern.

Solutions containing ammonia complexes of nickel(II) and ammonium salts are formed in processing of secondary raw materials [12] and can be used to prepare electrolytes for deposition of dispersed nickel and nickel alloys. The following reactions occur in the course of the electrolysis in the system $[Ni(NH_3)_6]^{2+}$–NH_4^+–NH_3 at the cathode and in the near-cathode layer:

$$[Ni(NH_3)_x]^{2+} + 2e \rightarrow Ni + xNH_3, \quad (1)$$

$$2H_2O + 2e \rightarrow H_2 + 2OH^-, \quad (2)$$

$$NH_4^+ + OH^- \rightarrow NH_4OH \rightarrow NH_3 \cdot H_2O. \quad (3)$$

The electrochemical reactions, the main reaction (1) directly and the conjugate reaction (2) indirectly via the chemical reaction (3), yield free ammonia and lead to its local concentration in the near-cathode layer. This prevents a considerable "alkalization" of the catholyte and deposition of $Ni(OH)_2$, which makes it possible to obtain pure dispersed powders without any admixture of nickel(II) hydroxide even at high current densities. Similarly, the components NH_4^+ and NH_3 favor precipitation of pure dispersed silver {Ag^+ forms $[Ag(NH_3)_2]^+$} complex and, accordingly, a dispersed nickel–silver deposit).

The silver concentration in the dispersed deposit depends nonlinearly on the concentrations of the $[Ni(NH_3)_6]^{2+}$ and $[Ag(NH_3)_2]^+$ ions (Fig. 2). It should be noted that, in electrolytes with a higher concentration of nickel(II), the composition of the dispersed deposit is less sensitive to the concentration of the silver salt. For example, the Ag concentration in the deposit depends nearly linearly on the $[Ag(NH_3)_2]^+$ concentration in 0.3–0.5 M solutions of $[Ni(NH_3)_6]^{2+}$ at $[Ag(NH_3)_2]^+$ concentrations of 0.01–0.05 M (Fig. 2a).

The coprecipitation of silver leads to a significant change in the morphology of the dispersed deposit and to an increase in its dispersity, compared with the dispersed nickel obtained in the ammonia electrolyte (Fig. 3).

The current density i_c in precipitation of dispersed deposit is a conventional value. It has a physical

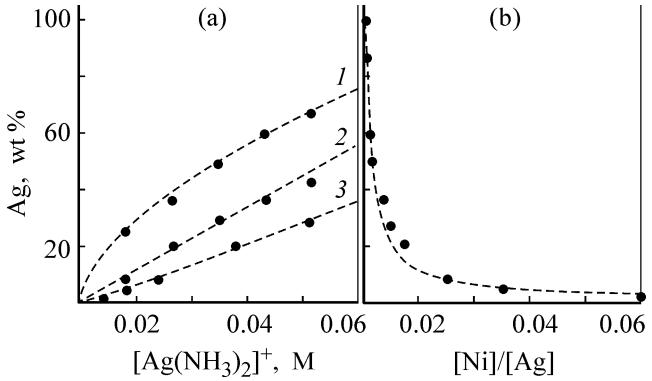

Fig. 2. Composition of dispersed cathodic Ni–Ag deposit vs. (a) $[Ag(NH_3)_2]^+$ concentration (M) and (b) [Ni]/[Ag] molar ratio in ammonia electrolyte. Temperature 30°C, i_c =20 A dm^{-2}, deposition duration 10 min. (Ag) Ag content in the deposit. $[Ni(NH_3)_6]^{2+}$ concentration (M): (*1*) 0.1, (*2*) 0.3, and (*3*) 0.5.

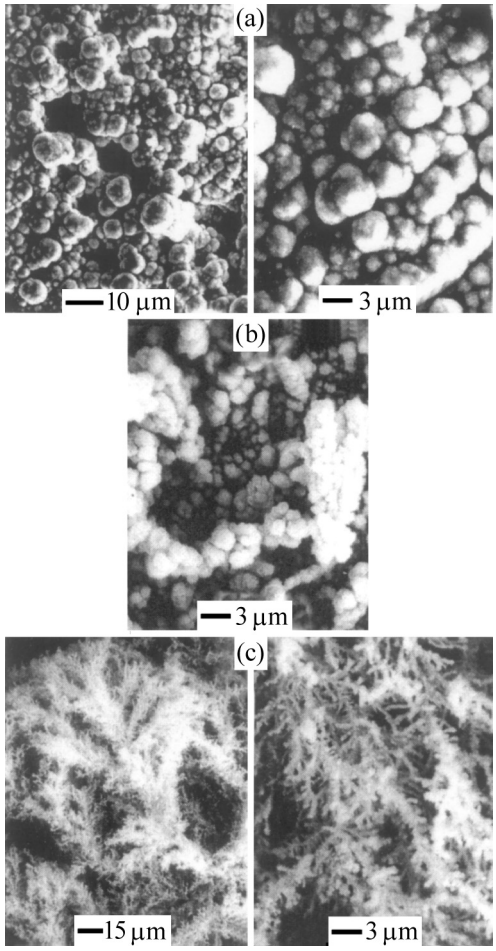

Fig. 3. Micrographs of dispersed cathodic deposits of (a, b) nickel and (c) Ni–Ag alloys obtained in electrolytes containing 0.5 M $(NH_4)_2SO_4$ and $NH_3 \cdot H_2O$ (up to pH 10) at T = 30°C. $NiSO_4$ concentration (M): (a) 0.5 and (b, c) 0.1; $AgNO_3$ concentration (M): (c) 0.02. i_c (A dm^{-2}): (a, c) 20 and (b) 100.

meaning only at the beginning of the electrolysis, since a kind of a "coat" is formed on the cathode in several minutes, and its electrochemically active area rapidly increases with time. Accordingly, the cathodic current at a constant potential increases. For example, in an electrolyte containing 0.1 M $[Ni(NH_3)_6]^{2+}$ and 0.02 M $[Ag(NH_3)_2]^+$ at the initial value i_c = 20 A dm^{-2} (U = const = 4.2 V), I increases virtually linearly from 3 to 7.5 A in 20 min. Thus, it may be concluded that, in electrochemical precipitation tion of a dispersed deposit at U = const, i_c stabilizes to a certain extent owing to an increase in the cathodic current. This electrolysis mode provides more favorable conditions for formation of a monodisperse deposit than that at I = const.

According to the results of an X-ray phase analysis, only nickel and silver are present in the cathodic deposits obtained. It is known [13] that nickel and silver form no intermetallic compounds and virtually no solutions with each other. As can be seen, the electrochemical codeposition of these metals in the form of dispersed deposits is not an exception. Therefore, the formation of a cathodic deposit can be regarded as a continuous formation of 3D nuclei of nickel and silver on the intrinsic and foreign bases. Taking into account that $E^0_{[Ni(NH_3)_6]^{2+}/Ni}$ and $E^0_{Ag(NH_2)]^+/Ag}$ = +0.373 V [14], it would be expected that the silver nucleation is faster in alternate deposition of nickel and silver. At the same time, a high concentration and diffusion overvoltage is observed for silver at high cathodic current densities and low concentrations of the $[Ag(NH_3)_2]^+$ complexes. Therefore, nucleation process dominates over the process of nucleus growth. This, in turn, also hinders growth of nickel nuclei, which results in the formation of an ultradispersed cathodic Ni–Ag deposit.

CONCLUSIONS

(1) It was established that coprecipitation of silver in ammonia electrolytes strongly affects the morphology of the Ni–Ag cathodic deposit, leading to its dispersion and formation of ultradispersed powders.

(2) The main parameter that can be used to control the composition of dispersed Ni–Ag deposit in ammonia electrolytes is the concentration of salts of these metals.

Abstract—A method for synthesis of metallofullerenes by electric-arc sputtering of graphite, in which lanthanum compounds are deposited on the surface of a graphite electrode, was suggested. The influence exerted by the amount of deposited lanthanum on the yield of lanthanum was studied.

At present, endohedral complexes of fullerenes [1] and higher fullerenes attract researchers' attention as potential objects of nanotechnologies [2], which possess nonlinear optical characteristics [3] and unique physicochemical properties [4]. Synthesis and identification of new forms of endofullerenes (various isomers, bi- and trinuclear complexes in encapsulation of the whole variety of the available elements in the void in the fullerene molecule) have been extensively studied [5–18]. The known methods for synthesis of metallofullerenes consist in bombardment of a fullerene-containing substrate with metal ions [19] or in evaporation of a metal–carbon composite in the atmosphere of an inert gas [16–23]. The composites are evaporated with lasers [21, 22] or by electric-arc sputtering [16, 22, 23].

Commonly, the composite is prepared as follows. A hole bored in a graphite rod is filled with a mixture of a metal oxide, powdered graphite, and binder resins. Then the rod (electrode) is annealed in a vacuum at a temperature of about 2000°C. As a result, the carbide of the starting metal is formed and fixed in the bulk of the electrode.

It should be noted that C_{60} and C_{70} are formed in synthesis of metallofullerenes. There is evidence [16, 21, 23] that the amount of a metal oxide introduced into the electrode affects the total yield of fullerenes. The ratio of yields of hollow fullerenes and metallofullerenes [16, 21, 24] suggests that the formation of an endocomplex is, in fact, the side process in synthesis of hollow fullerenes.

Use of a combined electrode results in that metal atoms are introduced into the discharge zone in sputtering of the electrode. Having a low ionization potential, metal atoms markedly change the discharge parameters, and, primarily, make lower the temperature of electrons in the arc and of the gas [25]. Using a combined electrode, as a rule, leads to a decrease in the yield of fullerenes [16, 25, 26].

The yield of metallofullerenes in synthesis is low and the procedure for preparing a composite is prolonged and complicated. This results in that the problem of obtaining industrial samples of metallofullerenes remains unsolved. The efficiency of synthesis of metallofullerenes is raised by varying the composition of the composite [22] and by improving the design of the reactors used for this purpose [23].

The aim of this study was to examine specific features of synthesis of metallofullerenes with a surface-modified electrode.

EXPERIMENTAL

The experimental installation for synthesis of fullerenes by electric-arc sputtering of graphite is shown schematically in Fig. 1. A combined electrode was fabricated from 10-cm-long rectangular graphite rods with a cross-section of 2×4 to 4×6 mm. The electrode was prepared by depositing an aqueous suspension of lanthanum carbonate on its surface. The deposited layer was dried in air to constant mass and then the electrode mounted into the reactor was an-

Schematic of the experimental installation for electricarc synthesis of fullerenes: (*1*) reactor, (*2*) reflector, (*3*) cooling circuit, (*4*) graphite rods, (*5*) microlift, (*6*) bell-jar, (*7*) vacuum station, (*8*) vacuum gage, (*9*) leak valve, (*10*) discharge feeding unit, (*11*) voltmeter, (*12*) ammeter, (*13*) current-carrying bar, (*14*) microlift-feeding unit, (*15*) vacuum cock, and (*16*) cylinder with helium.

nealed by passing a dc current of 50–70 A through short-circuited electrodes at a residual pressure in the reactor of 10^{-2} Pa or in the atmosphere of helium.

The cycle of reactor preparation to synthesis included the following stages: (1) mounting of graphite electrodes in the reactor, with their mass preliminarily determined; (2) evacuation of the reactor to a pressure of about 10^{-3} Pa; (3) heating of the electrode by passing an electric current; (4) filling of the reactor with helium to the working pressure and heating of the electrodes in this atmosphere; (5) repeated evacuation of the reactor to a pressure of 10^{-3} Pa; and (6) letting-in helium to a working pressure of 2×10^4 Pa.

The working pressure in synthesis of metallofullerenes has been experimentally determined previously [27]. This pressure corresponds to the maximum yield of hollow fullerenes.

To sputter the combined electrode, a voltage sufficient for arc initiation was applied across the electrodes and microlift displacement at a preliminarily adjusted velocity was switched on. In the course of sputtering, the arc current was 100–150 A at a voltage across the discharge gap equal to 20–25 V. The completion of the sputtering process was judged by visual inspection.

After the sputtering of the electrode, the carbon black obtained in the course of synthesis was collected and its mass was determined. Also weighed were the residue of the electrode being sputtered and the cathode deposit (carbon layer formed on the cathode in synthesis).

The fullerenes contained in the carbon black were extracted with *ortho*-xylene at a temperature of 40°C under agitation for 24 h. Then the solution was filtered on a glass filter and the carbon black was additionally washed with *ortho*-xylene to a colorless extract. The resulting filtrate was brought to a mark of 100 ml in the volumetric flask with *ortho*-xylene.

The concentration of individual fullerenes in solution was analyzed by HPLC and spectrophotometry. Chromatograms were obtained on a LIQUOCHROME 2010 chromatograph with a UV detector (analytical wavelength 330 nm), with hexane as eluent (residual content of water $\leq 6 \times 10^{-3}$%) and a column packed with SGX Separon adsorbent (grain size 7 μm). The chromatograms of reference solutions and those being analyzed were processed using Multichrom 1.5 software. The spectra were recorded with a Hitachi U2001 spectrometer.

A theoretical description of the synthesis of fullerenes has resulted in model concepts of the assembly of a carbon skeleton [28–31]. Also represented in the literature are the results of quantum-chemical calculations of the stability of various endocomplexes [32, 33]. An analysis of published data made it possible to maintain that both the C_{60} fullerene and the endocomplex are formed in the jet of a carbon vapor produced by sputtering in the electric-arc synthesis of fullerenes [30].

It is known that [34], in synthesis of the fullerene, the ions bombarding the cathode do not sputter it, but, conversely, are incorporated into its structure to give a cathode deposit. In this case, both the amount of the deposit formed and its structural features depend on the composition and energy of ions bombarding the cathode. Under the conditions of the synthesis performed, three sources are responsible for the composition of the near-cathode layer of plasma: buffer gas, sputtered graphite, and sputtered lanthanum. The lower the ionization energy, the larger the fraction of an ionized component. The ionization energy of helium is 24.587 eV [35]; that for components of the carbon vapor: C 11.260, C_2 12.10, C_3 11.65, and C_4 11.28 eV [36]; the energies of successive ionization

for lanthanum ions are 5.577, 11.06, and 19.17 eV [35]. It should be noted that the existence of high-energy metastable states of helium leads to ionization of easily ionized components of plasma by the Penning mechanism [36]:

$$A^* + B \rightarrow A + B^+ + e,$$

where A^* stands for helium in excited state, and B, for the easily ionized component.

Thus, it would be expected that the ionic composition of plasma is mainly represented by C_n^+ and La^+ ions. As the discharge current in the cathode region is carried by positive ions, the mass of the deposit is proportional to the quantity of electricity consumed in the process and to the accommodation coefficient of the incident ion. The amount of graphite being evaporated is also proportional to the charge passed [37]. As a result, the ratio of the mass of sputtered graphite to that of the deposit can be used to characterize an experiment.

The shape of the deposit obtained in the experiment (Figs. 2a and 2b) corresponds to that of the electrode being sputtered. The cross-section of the cathode deposit exceeds that of the initial electrode and a crater is always present in the central part of the cathode deposit. Use of both graphite and surface-modified electrodes leads to the same distribution of sputtered graphite among the fullerene black and the cathode deposit (Fig. 3). The lanthanum being evaporated does not change the nature of the ion flow toward the cathode surface and, consequently, does not enter into the near-cathode zone of the discharge. In the authors' opinion, this is an indication of the separate evaporation of graphite and lanthanum.

The decrease in the amount of the cathode deposit with respect to the amount of sputtered graphite on making smaller the cross-section of the electrode is understandable. There exists a considerable temperature gradient at the cathode from the axis of the arc toward its periphery, as well as a temperature gradient in the gas phase [37, 38]. As a result, the gas phase contains larger carbon clusters in the peripheral parts of the near-cathode region; the lower surface temperature leads to a higher accommodation coefficient, compared with that in the central parts of the cathode. Apparently, the area of the peripheral regions of the electrodes increases in proportion to a squared characteristic size (equivalent electrode diameter). The factors mentioned lead to an increase in the fraction of the cathode deposit on raising the cross-section area of the electrode being sputtered and provide the observed shape of the cathode deposit.

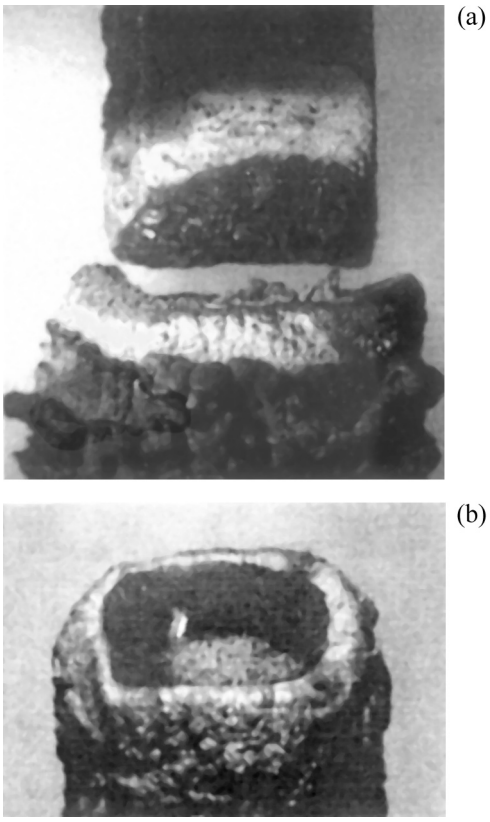

Fig. 2. Photographs of a typical cathode deposit upon completion of the synthesis. (a) Correspondence between the electrode being sputtered and the deposit formed, and (b) characteristic crater at the center of the deposit.

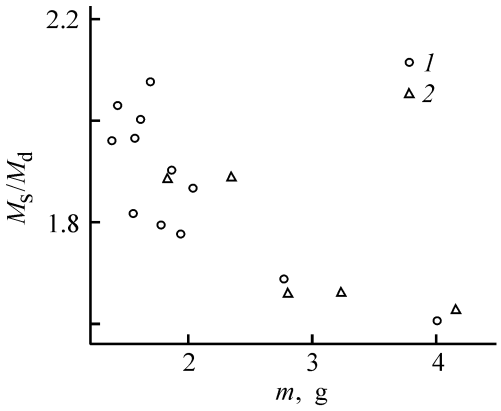

Fig. 3. Influence exerted by the mass m of the electrode being sputtered on the ratio M_s/M_d of the mass of the sputtered graphite to that of the cathode deposit for (*1*) graphite and (*2*) combined electrodes.

The flow of evaporated lanthanum is virtually not involved in the formation of the plasma composition in the arc, but affects the synthesis of fullerenes in the carbon vapor jet. This influence is primarily manifested in a change in the composition of the

carbon black being synthesized and extracts obtained (Figs. 4–6).

A typical chromatogram of an extract of the carbon black obtained using the combined electrode under study differs from chromatograms of samples obtained with a graphite electrode in that peak *6* appears (Fig. 4). The spectrum of the extract obtained with the combined electrode contains absorption bands coinciding with the characteristic absorption bands of metallofullerenes [39] (Fig. 5). The yields of the substance (Fig. 6c), calculated from the absorption band at around 1000 nm and from peak *6* of the chromatogram (Fig. 4) are in a good agreement for all syntheses, which makes it possible to attribute peak *6* in the chromatogram to metallofullerenes. The shapes of the chromatographic peak *6* and optical absorption peak at around 1000 nm indicate that several forms of endohedral fullerenes exist in the substrate synthesized.

The yield of the fullerene C_{60} increases as the fraction of lanthanum in the combined electrode becomes higher (Fig. 6a). It is noteworthy that a similar tendency has been observed previously in synthesis of metallofullerenes by electric-arc sputtering of a combined electrode [24]. The maximum total yield of fullerenes was observed at a C/La ratio in the combined electrode equal to 50. Surprisingly, the maximum yield of La@C_{82} has been observed at the same C/La

ratio in synthesis of metallofullerenes by laser evaporation of a combined electrode [21], although the influence exerted by lanthanum-doping of the electrode on the yield of hollow fullerenes was quite the opposite. It may be assumed that this is due to the existence of a temperature gradient in the carbon vapor jet. It has been shown in a study of how the synthesis temperature affects the yield of fullerenes that the yield of $La@C_{82}$ is the highest at 1200 K, whereas the maximum yield of C_{60} is obtained at lower temperatures. Apparently, the optimal conditions for stabilization of a certain structure of the carbon cluster can be satisfied in an expanding carbon vapor jet only locally.

The relative yield of C_{60} (Fig. 6b) remained virtually unchanged in a set of experiments, with the exception of that with a mass fraction of lanthanum carbonate equal to 0.75% (C_{60}/C_{70} of about 6.6). At the same time, the yield of metallofullerenes shows a significant scatter (Fig. 6c). This scatter is possibly due, as mentioned above, to presence of a mixture of various forms of metallofullerenes in a sample being analyzed, with the concentration of any particular form of metallofullerenes in the extract being low.

Experiments with a mass fraction of lanthanum carbonate equal to 0.75 and 2% (Fig. 6) cannot be explained in the same way as other experiments. Of a similar nature are the data of [16, 21, 23]. The possible reason for this phenomenon is that different steady states of the arc and structures of the gas-dynamic flows in the reactor are possible in the course of synthesis, even if the synthesis procedure is strictly observed. In the case under study, there exist at least two different dependences of the yield of fullerenes on the mass fraction of lanthanum in the combined electrode (Fig. 6a).

Apparently, it is necessary to take into account, in determining the yield of fullerenes and in comparing the results obtained with published experimental data, that studies of extracts provide only a limited knowledge of the structure and composition of the carbon black. It is known that the carbon substrate obtained by electric-arc sputtering of graphite contains a large amount of fullerene-like fragments [40]. In the course of extraction, the imperfect carbon structures are separated from the fullerenes synthesized. The aggregation susceptibility of fullerenes, including that with incomplete fullerene fragments, hinders extraction of fullerenes from the substrate. Therefore, the yield of the target product can be raised severalfold by changing the solvent used for extraction and the method for recovery of fullerenes from the substrate [42, 43].

CONCLUSIONS

(1) Use of a surface-modified electrode simplifies the electrode preparation procedure and makes it possible to synthesize by electric-arc sputtering a mixture of metallofullerenes in amounts comparable with those reported by other authors.

(2) Raising the amount of lanthanum carbonate contained in the electrode does not change the C_{60}/C_{70} ratio in the samples synthesized and leads to an increase in the total amount of fullerenes obtained at a mass fraction of lanthanum within the range studied. In addition, use of the electrodes suggested leaves unchanged the amount of graphite utilized into the cathode deposit. This fact supports the assumption that lanthanum and carbon evaporate separately in the case when surface-modified electrodes are used.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Influence of the Composition of Dilute Nickel-Plating Electrolytes on the Physicomechanical Properties of Electroplated Coatings

E. Binkauskene

Institute of Chemistry, Vilnius, Lithuania

Received June 23, 2004

Abstract—The influence of the composition of dilute nickel-plating electrolyte containing luster-forming additives on the leveling, plasticity, and internal stresses of coatings being electroplated was studied. The possibility of combining nickel sulfate, sodium chloride, and boric acid as the main composition of a dilute nickel-plating electrolyte was analyzed.

Technological solutions that would make lower the expenditure of nonferrous metals, such as nickel, tin, copper, and their alloys, are sought for in order to further develop the galvanic industries. Compositions of bright-nickel-plating electrolytes ensuring a common plating rate of 0.8–1.2 μm min^{-1} at the concentrations of salts of a metal being deposited lowered by a factor of 2–2.5 (with a total nickel concentration of up to 30–35 g l^{-1}) have been suggested [1–4]. The rate of nickel plating depends not only on the anionic composition of an electrolyte [5], but also on the luster-forming formulations used. The nature and cathodic behavior of luster-forming additives may lead to a redistribution of the rates of nickel deposition and hydrogen evolution in favor of the latter process. In this case, formation of nickel hydroxide compounds in a near-cathode layer and their inhibiting effect on nickel electrodeposition become more likely, and the microstructure of the resulting coatings is changed. The considerable increase in the hydrogenation of the deposits deteriorates the physicomechanical properties of the coatings obtained [6–8]. To improve the main characteristics of the bright-nickel-plating process, acetylene compounds are used in combination with ethylene and organosulfur additives [9].

The aim of this study, was to assess the influence exerted by the composition of a dilute nickel-plating electrolyte containing luster-forming additives based on β-oxyethyl cinnamide (OECAM) on the physicomechanical properties of the coatings being deposited.

EXPERIMENTAL

The study was performed in nickel-plating electrolytes containing (g l^{-1}): no. 1: 140 $NiSO_4 \cdot 7H_2O$, 30 $NiCl_2 \cdot 6H_2O$, and 30 H_3BO_3; no. 2: 33 $NiSO_4 \cdot 7H_2O$, 120 $NiCl_2 \cdot 6H_2O$, and 30 H_3BO_3; no. 3: 150 $NiSO_4 \cdot 7H_2O$, 50 NaCl, and 30 H_3BO_3. The electrolytes prepared were subjected to selective purification. Chemically and analytically pure reagents were used in the experiments. OECAM was synthesized and purified[1] mp 87°C. 2-butyne-1,4-diol (YN) was twice recrystallized from chloroform, mp 58°C; 2-butene-1,4-diol (EN) was purified chromatographically, mp 113°C at a pressure of 5 mm Hg. Saccharin was recrystallized from ethanol, mp 225–226°C. The temperature of the experiment was 50°C and pH 4.0. The pH value of the electrolytes was measured with an LPU-01 pH-meter and adjusted with hydrochloric acid or sodium hydroxide.

The microleveling power was determined by measuring profilograms of a titanium substrate with triangular grooves cut to a depth of about 4 μm (angle 120°). The microleveling factor B (%) was calculated from data on the average depth of the grooves before and after the nickel plating with the use of the formula:

$$B = \frac{h_1 - h_2}{h_1} \times 100, \quad (1)$$

where h_1 and h_2 are the depths of the substrate grooves (μm) before and after the deposition of a coating, respectively.

The plasticity of the coatings was evaluated by their ultimate tensile elongation, measured with a spiral elastometer.[2] Plates with coatings (170 × 10 mm in size and 1 mm thick) were placed on the elastometer having the form of a spiral template with a step-

Limiting current density i_c in a Hull cell for various nickel plating electrolytes for bright nickel plating

Electrolyte	Electrolyte no.	Luster-forming additive, g l^{-1}	i_c, A dm^{-2}
Sulfate	1	Saccharin, 1.5; OECAM, 0.5; YN, 0.05	1.9
Chloride	2	The same	2.8
	3	"	2.0
	2	Saccharin, 1.5; YN, 0.08; EN, 0.16	3.2

wise changing radius of curvature. The critical elongation, at which coatings cracked, was determined with a special paste containing *o*-phenanthroline chloride indicator, which could reveal an uncoated steel substrate.

The elongation l (%) was calculated by the formula

$$l = [d/(2r + d)] \times 100, \quad (2)$$

where d is the thickness of a plate with a coating (mm), and r, the radius of curvature at the critical point of the spiral surface.

The internal stresses (IS) in the nickel coatings were measured by the method of a flexible cathode with a device that could measure the cathode curvature after its being coated in a stirred electrolyte [10].

It is known that chloride nickel-plating electrolytes ensure a higher rate of nickel deposition, compared with sulfate electrolytes [5]. Introduction of sodium salts as supporting additives, which are used to improve the throwing power of nickel-plating electrolytes [6], makes lower the electrodeposition rate. The table lists the electrolyte formulations and estimates of the nickel-plating rates, found by the fast method [5] with a Hull cell. The formulation suggested is similar to the technological solution of [9], which consists in that small concentrations of YN are used in combination with an ethylene compound, EN, with the key role played by the competition of acetylene and ethylene groups in hydrogenation. β-Oxyethyl cinnamide is described by the formula $C_6H_5CH{=}CH{-}CONHCH_2CH_2OH$ and, unlike EN, contains a phenyl radical and nitrogen. A comparative study of the known bright-nickel-plating electrolyte based on a mixture of YN and EN [9] in an untypical formulation of a dilute electrolyte no. 2 demonstrated that the rates of metal plating in a dilute chloride solution differ only slightly for the additives used.

The coatings obtained in a chloride electrolyte have a factor of 1.5–2.0 lower internal compression stresses over the entire range of the current densities i_c (Fig. 1a).

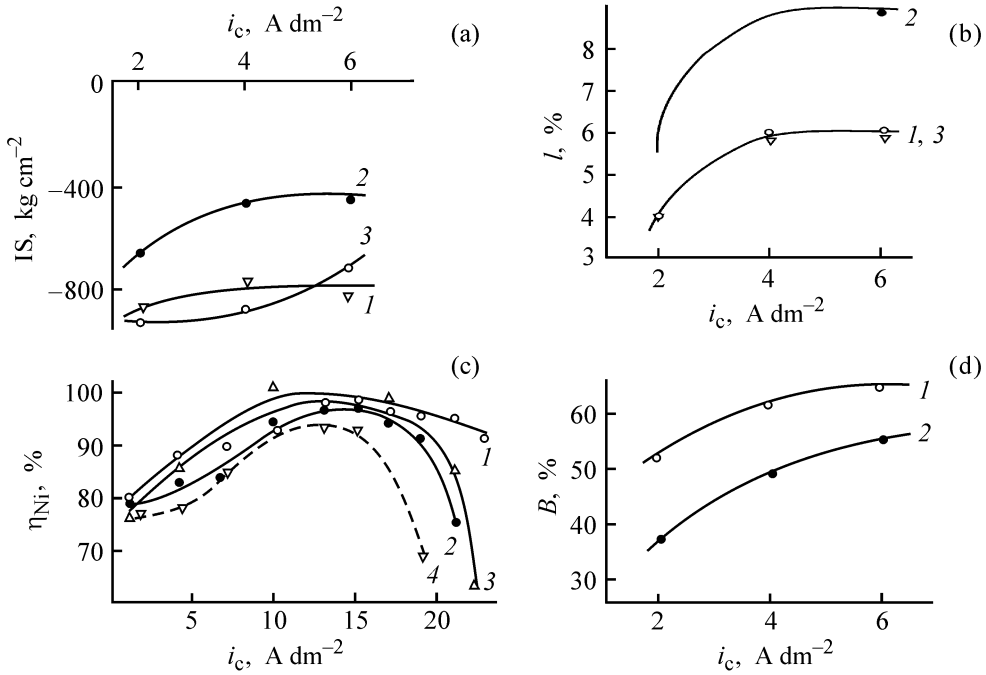

Fig. 1. (a) Internal stresses IS, (b) plasticity l, (c) current efficiency η_{Ni}, and (d) microleveling factor B vs. the current density i_c in various nickel-plating electrolytes. Temperature 50°C and pH 4.0. (a, b, d) Digits at curves are the electrolyte numbers; Additive to the electrolytes (g l^{-1}): saccharin 1.5, OECAM 0.5, and YN 0.05. (c) Electrolyte (g l^{-1}): (*1*) no. 2; (*2*) no. 2 + saccharin, 1.5; (*3*) $NiCl_2 \cdot 6H_2O$, 27; Na_2SO_4, 70; H_3BO_3, 30; and (*4*) no. 1 + saccharin, 1.5.

The plasticity of a lustrous nickel coating formed under the same conditions reaches a value of 9% (Fig. 1b), which is very high, compared with that obtained previously (up to 6%) for the technological solutions suggested in [9]. It should be noted that sufficiently plastic deposits (6%) are also obtained from dilute nickel-plating electrolyte nos. 1 and 3 (Fig. 1b). Presumably, the possible reason for the smaller elongation is the lower current efficiency by nickel in sulfate electrolytes, compared with chloride electrolytes. A similar effect is produced by sodium ions (Fig. 1c). In this case, a stronger alkalization of the near-cathode space is observed and the amount of impurities incorporated into the nickel deposit is larger. The best leveling power is observed for sulfate electrolyte no. 1 (Fig. 1d). This may be due to different catalytic activities of the renewed nickel surface in reactions of cathodic conversion of ethylene and acetylene compounds. Therefore, the choice of the electrolyte composition depends on whether a higher plasticity or leveling is required for a particular coating.

The data in the table indicate that the rates of nickel plating in dilute nickel-plating electrolytes, sulfate electrolyte no. 1 and chloride electrolyte no. 3, are nearly the same and the coatings obtained from these electrolytes have the same internal stresses and plasticities (Figs. 1a, 1b). This shows that nickel sulfate, sodium chloride, and boric acid can be combined in the formulation of a dilute nickel-plating electrolyte based on OECAM if nickel chloride is completely replaced with sodium chloride.

CONCLUSION

A study of the influence exerted by the composition of a dilute nickel-plating electrolyte containing β-oxyethyl cinnamide as luster-forming additive on the physicomechanical properties of the coatings deposited demonstrated that nickel sulfate, sodium chloride, and boric acid can be used in combination in the formulation of a dilute nickel-plating electrolyte.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Polymeric Sensors Based on Extraction Systems for Determination of Rare-Earth Metals

D. O. Kirsanov, A. V. Legin, V. A. Babain, and Yu. G. Vlasov

St. Petersburg State University, St. Petersburg, Russia

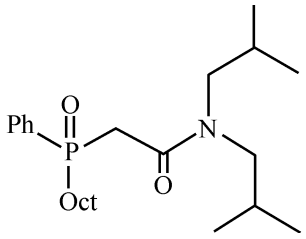
Received February 14, 2005

Abstract—New polymeric sensors based on bidentate neutral organophosphorus compounds of varied structure with addition of chlorinated cobalt dicarbollide, which are highly sensitive to Fe^{3+}, Y^{3+}, La^{3+}, Pr^{3+}, Nd^{3+}, and Eu^{3+} cations in a wide range of concentrations at pH 2, were suggested. The selectivity, detection limits, and pH-dependence of the potential of the sensors developed were studied. The influence of chlorinated cobalt dicarbollide on the electrochemical characteristics of the sensors was demonstrated.

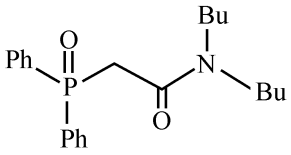
At present, the areas of analytical chemistry associated with design of chemical sensors of various types are being intensively developed. A particular place is occupied by studies concerned with such sensors as ion-selective electrodes (ISE), which are very convenient in measurements, do not require any complex and expensive apparatus, and can be used in field conditions. Film-type ISEs with a matrix of plasticized polyvinyl chloride (PVC) open up wide opportunities for variation of their sensor properties by modifying the chemical structure of the active substance of the membrane (ionophore), by changing the concentration ratio between the ionophore and the ion-exchange additive, and by using various solvents-plasticizers. A particularly topical task is to create sensors for determining stable isotopes of metals in liquid radioactive wastes. This is so because sensors of this kind can be used to create systems that enable on-line monitoring without direct involvement of an operator, which diminishes the health hazard for the personnel working with sources of ionizing radiation.

A rather large number of potentiometric sensors reversible to ions of cesium, barium, and other elements present in liquid radioactive waste have been developed. However, a considerably smaller number of studies have been devoted to development of film-type ISEs sensitive to triple-charged metal cations. Film-type ISEs reversible to the cations La^{3+}, Ce^{3+}, Nd^{3+}, Sm^{3+}, etc. have been created [1–6]. As a rule, macrocyclic organic compounds with various heteroatoms are used as membrane-active components in sensors of this kind. The sensitivity of such sensors is commonly close to the theoretical value of 19 mV decade^{-1}; however, the working pH range lies above pH 3 for most of the ISEs described, which is an important limitation in analyses for rare-earth elements (REE). At higher proton concentrations, the sensitivity markedly decreases, which gives no way of using sensors of this kind in strongly acidic solutions. In addition, the detection limits for most of the ISEs developed are rather high (4.5–5.5 pM^{3+}), which makes markedly narrower the variety of possible practical applications of sensors of this kind.



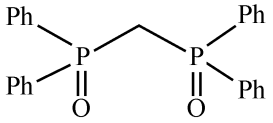
A possible way to overcome these difficulties is to search for new active compounds that can form strong complexes with multicharged metal cations.

The authors' approach to development of polymeric sensors sensitive to triple-charged metal cations consists in that various bifunctional neutral organophosphorus compounds (BNOPC) and the anion of chlorinated cobalt dicarbollide (CCD) are used as active substances. Compounds of this kind and their synergetic mixtures with CCD are used with success in extraction for separating and concentrating rare-earth elements from a strongly acidic radioactive waste formed from spent nuclear fuel [7–9]. Carboranes and substituted carboranes have been suggested as membrane components for ISEs sensitive to cesium [10, 11]. Carboranes and, in particular, CCD have the form of a large lipophilic anion and act in extraction systems as a cation-exchanger, similarly to potassium tetra(*p*-chlorophenyl)borate (PTCPB) conventionally used in ionometry. However, CCD is a con-



1070-4272/05/7804-0568 © 2005 Pleiades Publishing, Inc.

siderably stronger acid than PTPB and is stable against acid hydrolysis. Consequently, CCD is more stable when used with acid solutions. In addition, CCD shows a high radiation-hardness, which enables its effective use in extraction of various radioactive elements.



The aim of this study was to develop, on the basis of BNOPC and CCD, new polymeric sensors reversible to triple-charged metal cations. The working characteristics of the sensors, such as sensitivity, detection limits, selectivity, and pH-dependence of the potential, were examined. On the basis of extraction data, the following BNOPC were chosen as membrane-active substances: octylphenyl-*N*,*N*-di-isobutylcarbamoylmethylphosphine oxide (**I**), diphenyl-*N*,*N*-di-*p*-butylcarbamoylmethylphosphine oxide (**II**), tetraphenylmethylenediphosphine dioxide (**III**), and CCD:

Octylphenyl-*N*,*N*-diisobutylcarbamoylmethylphosphine oxide, diphenyl-*N*,*N*-di-*p*-butylcarbamoylmethylphosphine oxide, and tetraphenylmethylenediphosphine dioxide were synthesized at the Institute of Chemical Reagents and Special-Purity Chemical Substances (IREA, Moscow). The cesium salt of CCD was purchased from Katchem (Czech Republic) and converted into the H^+ form prior to use in a membrane. Yttrium, praseodymium, neodymium, and europium nitrates were provided by the Khlopin Institute of Radium in the form of 0.5 M solutions in 0.1 M nitric acid. Other inorganic salts and organic solvents of chemically pure grade were purchased from Reaktiv Co. (St. Petersburg). All the solutions were prepared using twice-distilled water.

The compositions of the polymeric sensor membranes studied are listed in Table 1. Composition nos. 1–3 contained BNOPC in a concentration of 50 mmol kg^{-1} membrane; composition nos. 4–6, BNOPC in the same concentration and CCD (10 mmol kg^{-1} membrane); composition nos. 7–9, CCD in a concentration of 100 mmol kg^{-1} membrane; and composition no. 10, no BNOPC and only CCD in a concentration of 100 mmol kg^{-1} membrane. These relative concentrations of the active substances of the membranes were chosen on the basis of the following considerations: a considerable excess of the concentration of a neutral ligand over that of an ion-exchange additive is traditionally used in developing the composition of a membrane in inonometry [12], with the particular ratio of the concentrations chosen in accordance with the stoichiometry of the complex constituted by the ligand and the target ion. It has been established in studies of extraction that the maximum

extracting capacity for rare-earth elements is observed for 1 : 2 mixtures of BNOPC and CCD [13]. The membrane composition nos. 1–3, 10 were prepared for determining the individual contributions of the active components to the electrode characteristics of the sensors.

The sensor membranes were fabricated using the standard procedure. Weighed portions of the membrane components were poured over with tetrahydrofuran (THF) and the mixture was agitated with a magnetic stirrer to complete dissolution of the components. The resulting cocktail was poured into a Teflon weighing bottle with a flat bottom and allowed to stay to complete evaporation of THF (~24 h). Discs 7 mm in diameter were cut from the membrane obtained and glued into electrode cases. Three sensors with a membrane of each type were fabricated. The numerical values of various parameters of the electrodes, presented below, were obtained by averaging over sensors of the same type.

Potentiometric measurements were performed with the following galvanic cell

Ag | AgCl, KCl_{sat} | Solution under study | Membrane | 0.01 M NaCl | AgCl, KCl_{sat} | Ag

The readings were taken with a high-input-resistance multichannel digital voltmeter connected to a personal computer for data acquisition and processing. An EVL 1M 3.1 silver chloride reference electrode was used. The sensitivity of the sensors was studied at metal cation concentrations in the range 10^{-7}–10^{-2} M. At least four calibrations were made in solutions of each cation. The slopes of the linear portions of the electrode functions were calculated for the concentration range 10^{-5}–10^{-3} M. The cation concentrations were not recalculated into activities because of the deficiency of comparable data on the activity coefficients of triple-charged metals. For all the triple-charged metals studied the pH value of the calibration solutions was adjusted by addition of nitric acid to pH 2 in order to suppress hydrolysis.

The pH values of the solutions were monitored using an ESL 43-07 glass pH-electrode.

Table 2. Electrode sensitivity of sensors in solutions of triple-charged metal cations at fixed pH 2

Sensor no.	Electrode sensitivity, mV decade^{-1}					
	Fe^{3+}	Y^{3+}	La^{3+}	Pr^{3+}	Nd^{3+}	Eu^{3+}
1	12 ± 1	9 ± 1	26 ± 1	24 ± 3	24 ± 2	22 ± 2
2	6 ± 2	13 ± 1	11 ± 1	17 ± 2	15 ± 1	11 ± 2
3	17 ± 1	16 ± 1	17 ± 1	20 ± 3	18 ± 1	15 ± 2
4	15 ± 2	18 ± 1	22 ± 1	26 ± 1	22 ± 1	21 ± 1
5	32 ± 1	25 ± 1	26 ± 3	32 ± 1	23 ± 2	23 ± 2
6	34 ± 1	16 ± 3	24 ± 2	28 ± 2	18 ± 1	18 ± 2
7	11 ± 1	10 ± 2	5 ± 2	6 ± 1	8 ± 2	6 ± 1
8	10 ± 1	10 ± 1	5 ± 1	7 ± 1	8 ± 1	7 ± 1
9	10 ± 2	7 ± 2	2 ± 1	7 ± 2	7 ± 1	5 ± 1
10	7 ± 1	5 ± 1	2 ± 1	6 ± 2	5 ± 2	3 ± 1

The selectivity of the sensors was studied by the method of mixed solutions at a fixed concentration of La^{3+} ions (interfering ions) and a constant pH value of 2.

The pH dependence of the potential of the sensors was determined in two ways: (i) in a 0.01 M solution of tris(hydroxymethyl)aminomethane (TRIS), with gradual addition of nitric acid (pH 1.5–9), and (ii) in a 0.0001 M solution of lanthanum nitrate, also with gradual addition of nitric acid (pH 1.5–6).

The sensors fabricated were calibrated against solutions of the cations Fe^{3+}, Y^{3+}, La^{3+}, Pr^{3+}, Nd^{3+}, and Eu^{3+} at a fixed pH 2, and the slopes of the linear portions of the electrode functions of the sensors were calculated. The data obtained are listed in Table 2. The major attention is attracted by the high electrode sensitivities of most of the sensors, which exceed in some cases the theoretical value of 19.7 mV/pM^{3+} for triple-charged cations. For example, sensor nos. 5 and 6, which are based on diphenyl-*N*,*N*-di-*p*-butylcarbamoylmethylphosphine oxide, and tetraphenylmethylenediphosphine dioxide with addition of CCD with a molar ratio BNOPC : CCD = 5 : 1, exhibit a super-Nernst sensitivity to Fe^{3+}, La^{3+}, and Pr^{3+} cations, with the slope ratios of the electrode functions close to the theoretical values for double-charged cations (29.5 mV decade^{-1}). Sensor nos. 1 and 4 also exhibit a super-Nernst response for some cations. The closeness of the sensor sensitivities in M^{3+} solutions to the theoretical values for M^{2+} is presumably due to the following: compounds of the type $M(X)_n^{m+}$ (where X is an inorganic anion, NO_3^- in the given case), with a formal charge of +2, rather than M^{3+} cations, enter into the reaction of complexation with BNOPC. This is indirectly confirmed by electro-

spray-mass-spectrometric experiments in systems constituted by BNOPC and an aqueous solution of an REE nitrate [14].

The influence exerted by the CCD concentration in a sensor membrane on the sensor sensitivity is clearly seen. Membrane nos. 1–3, based on BNOPC without CCD additive, possess, on the whole, lower sensitivities to all of the cations studied, compared with membrane nos. 4–6. The increase in sensitivity upon addition of CCD is the most clearly pronounced for composition nos. 5 and 6. Further increase in the CCD concentration from 10 to 100 mmol kg^{-1} leads to the opposite effect and composition nos. 7–9 exhibit only an insignificant sensitivity to the triple-charged cations studied. Composition no. 10 also shows very low slope rates of the electrode functions. Composition nos. 7–10 were excluded from further consideration.

In addition to the cations listed in Table 2, the sensor responses were studied in solutions of Al^{3+}, Cr^{3+}, Cu^{2+}, Ba^{2+}, and Pb^{2+}. It was found that the sensors developed show no sensitivity to these cations at pH 2. The only exception is sensor no. 1, based on octylphenyl-*N*,*N*-diisobutylcarbamoylmethylphosphine oxide, which has a response of 29 ± 1 mV $decade^{-1}$ with a detection limit of 6 pM^{2+} in lead solutions and a response of 20 ± 1 mV $decade^{-1}$ with a detection limit of 4 pM^{2+} in barium solutions.

The detection limits of the sensors are listed in Table 3. La^{3+} can be determined with the lowest detection limits for all of the sensors studied. Compared with those reported in [5, 6], the sensors developed in the present study open up wider opportunities of practical application. For example, it was established in [5] that electrodes with polymeric membranes containing monoaza-12-crown-4 as a neutral ligand can be used to determine La^{3+} cations at concentrations exceeding 3×10^{-5} M (4.5 pLa^{3+}) and satisfactorily work in the pH range 3–7. A detection limit of 6.3 pLa^{3+} was reported in [6] for sensors based on dicyclohexano-18-crown-6, which can be used in the pH range 4–9. The developed composition nos. 2 and 6 have lower detection limits and are applicable to determination of La^{3+} in acid media with pH 2. This is an important practical conclusion, because the elements to be determined exist in the ionic form only at low pH values. The detection limits of a number of the sensors developed for the cations Pr^{3+}, Nd^{3+}, and Eu^{3+} are also significantly lower than any of the previously known values.

The results obtained in determining the sensitivity of the sensors by the method of mixed solutions are presented in Fig. 1. Most of the sensors developed are more selective toward lanthanum cations. For composition nos. 2 and 3, the selectivity coefficients measured in Fe^{3+}/La^{3+} and Y^{3+}/La^{3+} solutions exceed 4. Introduction of CCD additive makes lower the sensitivity of the sensors to La^{3+} (composition nos. 4–6), and in the case of composition no. 4, there even occurs sensitivity reversal in favor of Nd^{3+} and Pr^{3+} and equalization of the sensitivities in the pair Eu^{3+}/La^{3+}. The most discriminated for all the sensors studied is the iron ion Fe^{3+}.

Table 3. Detection limits of sensors

Sensor no.	Detection limit, ±0.1 pM^{3+}					
	Fe^{3+}	Y^{3+}	La^{3+}	Pr^{3+}	Nd^{3+}	Eu^{3+}

Figure 2a shows the results obtained in determining the pH-dependence of the sensor potential in the absence of lanthanum ions in solution, with the response of a standard glass pH-electrode presented for comparison. For sensors with composition nos. 2, 3, and 6, the pH response in an acid medium becomes of the Nernst type, and composition no. 5 exhibits a considerable pH sensitivity in the alkaline region. On pass-

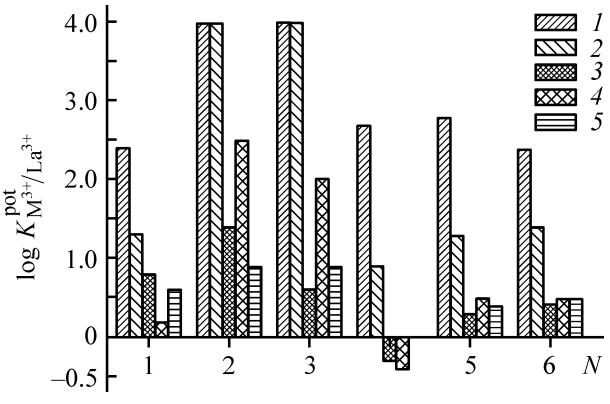

Fig. 1. Logarithms of the selectivity coefficients of the sensors, $\log K^{pot}_{M^{3+}/La^{3+}}$, determined by the method of mixed solutions. Typical determination error $\pm 0.1 \log K^{pot}_{M^{3+}/La^{3+}}$. (*N*) Sensor number. (*1*) Fe^{3+}, (*2*) Y^{3+}, (*3*) Pr^{3+}, (*4*) Nd^{3+}, and (*5*) Eu^{3+}.

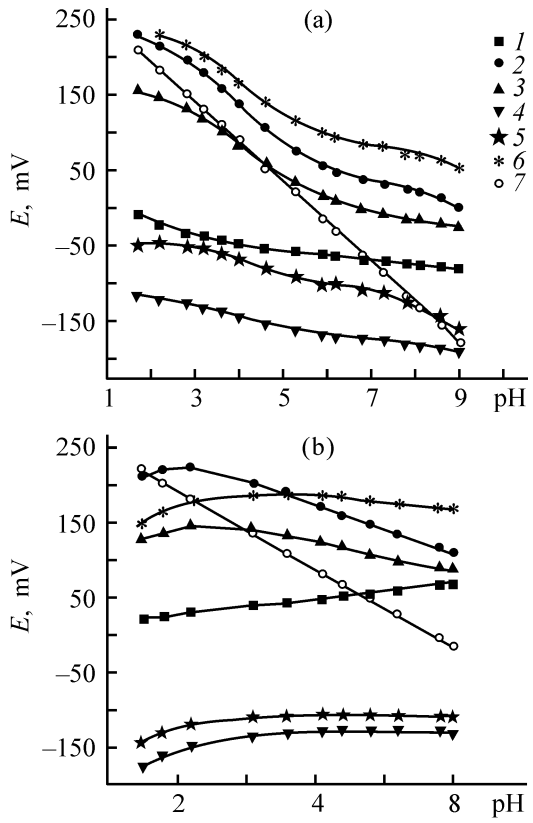

Fig. 2. Type of the pH-dependence of the potential E of (*1–6*) sensor nos. 1–6 (a) in the absence of metal cations in solution and (b) in a 0.0001 M solution of lanthanum nitrate. (*7*) Response of a standard glass pH-electrode.

ing to lanthanum-containing solutions, the type of the pH-dependence of the sensor potential changes significantly (Fig. 2b). At pH 2–6, the dependence for sensor nos. 4–6, which contain BNOPC and CCD in a concentration ratio of 5 : 1, virtually vanishes, which points to a high (>10) value of the selectivity coefficient $K^{pot}_{H^+/La^{3+}}$.

The published data [1–6] for the lower limit of the pH range in which polymeric sensor membranes reversible to triple-charged metal cation can successfully operate is no less than pH 3–4. At pH < 3, the influence exerted by protons on the electrode function becomes unacceptably strong and the sensitivity of the sensors to metals in acid solutions falls dramatically. It should be particularly noted that the sensors developed can be used to determine the concentrations of triple-charged metal cations at pH 2, which lifts a number of restrictions on practical application of such sensors, e.g., in analysis of solutions and wastes in radiochemical industry.

Of particular interest as regards possible analytical applications in analysis of liquid radioactive wastes are, in the authors' opinion, sensors with composition nos. 4–6, based on a mixture of BNOPC and CCD. Sensors of this kind, studied for the first time, surpass all the existing analogues in the whole set of their electrochemical characteristics.

CONCLUSIONS

(1) New polymeric sensors based on bidentate neutral organophosphorus compounds of varied structure, with addition of a chlorinated cobalt dicarbollide, were developed. It was established that the new sensors have a high sensitivity to Fe^{3+}, Y^{3+}, La^{3+}, Pr^{3+}, Nd^{3+}, and Eu^{3+} cations in a wide range of concentrations at pH 2.

(2) The detection limits of the sensors were determined, which lie below 6 pM^{3+} for La^{3+}, Pr^{3+}, and Eu^{3+} cations for a number of sensor compositions.

(3) It was established that, in the presence of the triple-charged metal cations under study, most of the membrane formulations are selective toward lanthanum cations. It was shown that addition of a chlorinated cobalt dicarbollide affects various electrochemical properties of the sensors.

(4) It was found that high H^+ concentrations do not interfere with determination of triple-charged cations.

(5) The efficiency of the approach suggested for sensor development was confirmed. This approach can be used to create convenient analytical instruments for practical monitoring of liquid radioactive wastes.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrodialysis Separation of Copper(II) and Platinum(IV) with Liquid Membranes Based on Di(2-Ethylhexyl)Phosphoric Acid

T. Zh. Sadyrbaeva

Institute of Inorganic Chemistry, Riga Technical University, Salaspils, Latvia

Received November 25, 2004

Abstract—Separation of copper(II) and platinum(IV) in extraction from binary acid chloride solutions with liquid membranes containing technical-grade di(2-ethylhexyl)phosphoric acid with addition of tri-*n*-octyl amine in 1,2-dichloroethane under the conditions of the galvanostatic electrodialysis was studied. The influence exerted by the current density and composition of aqueous solutions and liquid membranes on the rate and selectivity of copper(II) extraction was analyzed. The optimal conditions of metal separation were determined.

Membrane extraction is a promising technology for extraction and separation of metal ions. Acid organophosphorus reagents and, in particular, di(2-ethylhexyl)phosphoric acid (D2EHPA), are widely used for extraction of copper(II) ions from neutral and weakly acid solutions with impregnated and emulsion-type liquid membranes [1]. The membrane extraction is performed by the scheme of a counterflow transport of Cu^{2+} and H^+ ions and involves the interphase cation-exchange reaction

$$Cu^{2+}_{(a)} + 2HA_{(o)} \rightleftarrows CuA_{2(o)} + 2H^{+}_{(a)}, \qquad (1)$$

where HA stands for D2EHPA; (a), for the aqueous phase; and (o), for the organic phase.

The re-extraction of copper(II) from the organic phase is provided by the high acidity of the receiving solution. On applying a dc electric field, the transport of copper(II) ions across liquid D2EHPA-containing membranes occurs in the same direction as that of hydrogen ions. Under the conditions of electrodialysis, the transport of ions across bulk liquid membranes is intensified and extraction of metals into weakly acid solutions of mineral acids becomes possible [2]. Previously, electrodialysis extraction of copper(II) with liquid membranes containing pure and technical-grade D2EHPA in 1,2-dichloroethane has been studied [3, 4]. It was shown that, upon introduction of a tri-*n*-octyl amine (TOA) additive to raise their electrical conductivity, membranes of this kind provide an effective purification of dilute acid sulfate solutions to remove copper(II) and enable a thorough separation of copper(II) and palladium(II) in extraction from binary acid chloride mixtures.

The aim of this study was to examine the electrodialysis extraction of copper(II) from acid chloride solutions containing platinum(IV) with liquid membranes based on technical-grade D2EHPA with TOA additives and to determine the optimal conditions of metal ion separation.

EXPERIMENTAL

The electrodialysis transport of metal ions was studied using a five-compartment cell with a liquid membrane confined between vertical cellophane films in the system

(+) Pt, H_2SO_4	$CuCl_2$ H_2PtCl_6	D2EHPA TOA	HCl	H_2SO_4, Pt (–)
	MA		MA	

A dc current was passed across planar platinum electrodes in the galvanostatic mode. The volume of the liquid membrane was 2 cm^3, its thickness was 0.2 cm, and the phase contact area, 7.1 cm^2. The cellophane films confining the liquid membrane were preliminarily soaked in water.

The electrode compartments filled with a 0.15 M H_2SO_4 solution (17 cm^3) were separated from the compartments filled with a donating and receiving solution (13 cm^3) with MA-40 solid anion-exchange membranes.

1070-4272/05/7804-0574 © 2005 Pleiades Publishing, Inc.

As liquid membranes served 1,2-dichloroethane solutions of technical-grade D2EHPA (containing about 63% main substance) with addition of pure grade tri-*n*-octyl amine (containing 95% main substance). The donating solution, which, as a rule, contained 0.04 M copper(II) and 0.018 M platinum(IV), was prepared by dissolving hydrogen hexachloroplatinate hexahydrate $H_2PtCl_6 \cdot 6H_2O$ (pure grade) and a salt $CuCl_2 \cdot 2H_2O$ (analytically pure grade) in a 0.01 M hydrochloric acid. In most cases, 0.1 M HCl was used as receiving solution. The concentration of metal ions in the aqueous solutions was determined spectrophotometrically: copper(II), with NH_4OH [5], and platinum(IV), with tin chloride [6]. The optical density was measured on an SF-46 spectrophotometer.

In organic solutions of D2EHPA, an ionic pair is formed in the presence of tri-*n*-octyl amine (R_3N). This pair comprises an organic cation and organic anion, i.e., a binary extractant is formed [7].

$$R_3N_{(o)} + HA_{(o)} \rightleftarrows R_3NH^+A^-_{(o)}. \quad (2)$$

Copper(II) ions are extracted into the phase of the liquid membrane by the cation-exchange mechanism:

$$Cu^{2+}_{(a)} + 2Cl^-_{(a)} + 2R_3NH^+A_{(o)} \rightleftarrows CuA_{2(o)} + 2R_3NHCl_{(o)}. \quad (3)$$

The CuA_2 complex being extracted is transferred across the organic layer, to be decomposed at the interface with the receiving solution under the action of the electric field via a reaction reverse to reaction (3). The transport of Cu^{2+} ions across liquid D2EHPA membranes in the zero-current mode is virtually absent, since the receiving solution of 0.1 M hydrochloric acid does not provide copper(II) re-extraction from the organic phase. Platinum(IV) is present in the acid chloride solutions mainly in the form of an anionic chlorocomplex $PtCl_6^{2-}$ [6] and is extracted with tri-*n*-octyl amine by the interphase anion-exchange mechanism [8]:

$$H^+_{(a)} + Cl^-_{(a)} + R_3N_{(o)} \rightleftarrows R_3NHCl_{(o)}, \quad (4)$$

$$2R_3NHCl_{(o)} + PtCl^{2-}_{6(a)} \rightleftarrows [(R_3NH)_2PtCl_6]_{(o)} + 2Cl^-_{(a)}. \quad (5)$$

The effect of the current density on the rate of transmembrane transfer of the metal ions was studied with liquid membranes containing 20 vol % D2EHPA and 0.1 M TOA in dichloroethane. The flow rate of copper(II) ions is directly proportional to the current density in the range 4.2–10.6 mA cm^{-2} (Fig. 1).

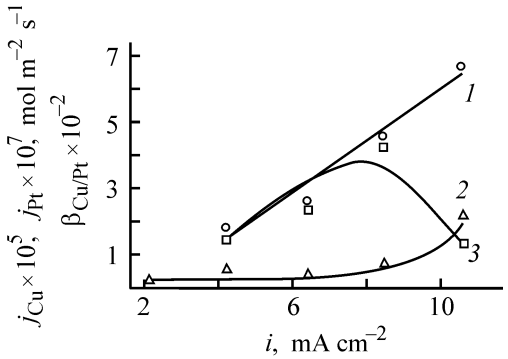

Fig. 1. Transfer rate of (*1*) copper(II) J_{Cu} and (*2*) platinum(IV) J_{Pt} and (*3*) separation coefficient $\beta_{Cu/Pt}$ vs. the current density i. c_{D2EHPA} = 20 vol %, c_{TOA} = 0.1 M, and τ = 60 min.

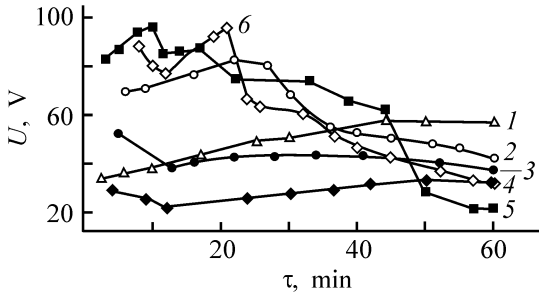

Fig. 2. Variation of the voltage U with time τ at different current densities and concentrations of TOA additive. i (mA cm^{-2}): (*1*) 4.2, (*2–5*) 8.5, and (*6*) 10.6. c_{TOA} (M): (*1, 2, 6*) 0.1, (*3*) 0.15, (*4*) 0.2, and (*5*) 0.05.

The current efficiency by Cu^{2+} during 1 h of electrodialysis in the given system is <13%. The current is mainly carried across the liquid membrane by hydrogen and chloride ions. The re-extraction of platinum(IV) from tri-*n*-octyl amine solutions is hindered by the high stability of the forming compounds [8]. In addition, the flow of $PtCl_6^{2-}$ anions through the membrane is impeded by the polarity of an electric current applied in the experiments. For this reason, metal ions are effectively separated in the course of electrodialysis. The degree of platinum(IV) extraction into the receiving solution is, as a rule, <0.1%. At the same time, the transfer of copper(II) during 1 h of electrodialysis at the highest current density is about 33%. The separation coefficient of metal ions is as high as 430 at a current density of 8.5 mA cm^{-2} (Fig. 1, curve *3*). Therefore, further experiments were performed at this current density.

In the course of the galvanostatic electrodialysis, a peak or a gradual increase in voltage is observed in the kinetic curves describing how the voltage varies at different current densities and compositions of the liquid membrane (Fig. 2). The rise in voltage is

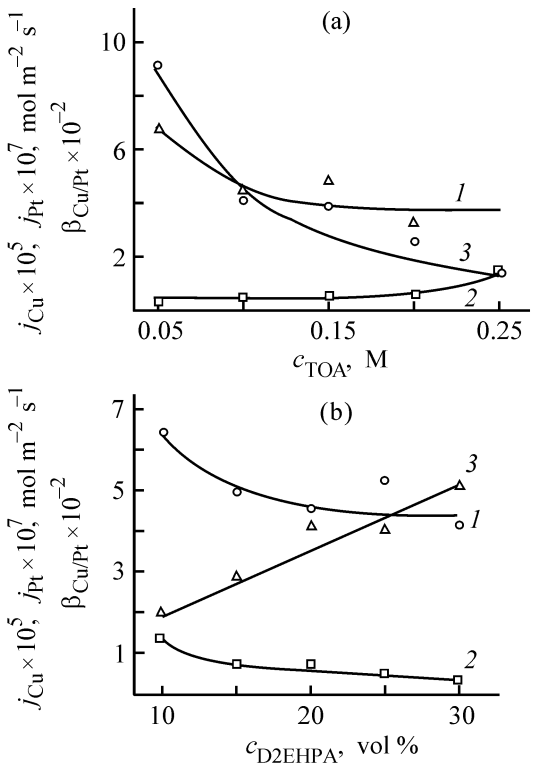

Fig. 3. Transfer rates of (*1*) copper(II) J_{Cu} and (*2*) platinum(IV) J_{Pt} and (*3*) separation coefficient of metals $\beta_{Cu/Pt}$ vs. the concentrations of (a) additive, c_{TOA}, and (b) transferring agent, c_{D2EHPA}. i = 8.5 mA cm^{-2}, and τ = 60 min.

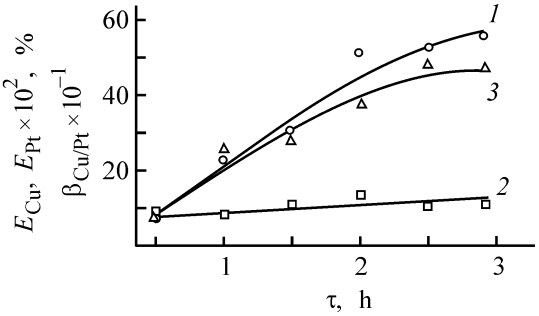

Fig. 4. Degree of extraction of (*1*) copper(II) E_{Cu} and (*2*) platinum(IV) E_{Pt}, and (*3*) separation coefficient $\beta_{Cu/Pt}$ vs. the process duration τ. i = 8.5 mA cm^{-2}, $c_{Cu} = 4.0 \times 10^{-2}$ M, $c_{Pt} = 1.8 \times 10^{-2}$ M in a 0.01 M HCl solution.

presumably due to formation of a deposit at the phase boundary between the donating solution and the liquid membrane in the interaction of Cu^{2+} with D2EHPA. Such a light blue deposit, containing copper(II), was observed on a cellophane film on the side of the organic phase. The decrease in voltage, following its increase, is due to accumulation of water in the liquid membrane. In some cases, the voltage decreases in steps, i.e., an "electric breakdown" is observed (Fig. 2, curve *5*). It has been suggested [2] that the reason for electric breakdowns in the liquid membrane is supersaturation of the organic phase with water to form through aqueous channels. The electrical conductivity of the membrane system is largely determined by the concentration of the tri-*n*-octyl amine additive and grows as its concentration increases (Fig. 2). Solutions of technical-grade D2EHPA in dichloroethane have a low electrical conductivity and cannot be used in electrodialysis extraction without additives, because it is impossible to maintain high current densities in these solutions.

Raising the TOA concentration in the liquid membrane somewhat decreases the rate of copper(II) transfer and increases that of platinum(IV) (Fig. 3a). Probably, this is associated with enhancement of the flow of chloride ions across the liquid membrane, which leads to a decrease in the current efficiency by copper(II). The maximum separation coefficient of the metal ions in the system containing 0.05 M TOA exceeds 900 and considerably decreases as the concentration of the amine additive becomes higher. However, the voltage is insufficiently stable in electrodialysis at the minimum concentration of TOA in the liquid membrane (Fig. 2, curve *5*), and it is more convenient to use D2EHPA solutions containing 0.1 M amine when studying the fundamental aspects of the membrane extraction of copper(II).

During 3 h of electrodialysis at a current density of 8.5 mA cm^{-2}, more than 55% of copper(II) is transferred across the liquid membrane from a solution containing 0.04 M $CuCl_2$ and 0.018 M H_2PtCl_6 (Fig. 4). Cu^{2+} ions are extracted at the highest rate during the first 2 h of process, after which the kinetic curve levels off. The content of platinum(IV) in the receiving solution is about 0.1% and remains virtually unchanged in the course of time in the interval 0.5–3 h. The highest separation coefficient of copper(II) and platinum(IV) is reached after 2.5 h of electrodialysis ($\beta_{Cu/Pt}$ ~500).

The influence exerted by the D2EHPA concentration on the rates of copper(II) and platinum(IV) extraction across the liquid membrane is demonstrated in Fig. 3b (curve *1*). Raising the concentration of the transport agent in the organic phase within the range 10–30 vol % lowers the transmembrane flows of both metal ions and improves the selectivity of Cu^{2+} extraction. The adverse influence exerted by excess D2EHPA on the electrodialysis extraction of copper(II) with liquid membranes is due to competition of copper and hydrogen ions in current transport

Table 1. Influence of the composition of the receiving solution on the electrodialysis transport and separation of metals* (c_{D2EHPA} = 20 vol %, c_{TOA} = 0.1 M, i = 8.5 mA cm^{-2}, τ = 60 min)

across the interface between the liquid membrane and the receiving solution. Raising the concentration of the transport agent, which acts as the supporting electrolyte, hinders the stage of copper(II) re-extraction from the organic phase.

Under the action of an electric field, the nature of an acid in the receiving solution does not, as a rule, affect to any significant extent the transmembrane flow of the component being extracted (Table 1). Copper(II) is extracted at approximately equal rates into dilute solutions of hydrochloric, sulfuric, nitric, and perchloric acids and into water. In all these cases, with the exception of HNO_3, a thorough separation of copper(II) from platinum(IV) is reached. HNO_3 solutions can re-extract platinum(IV) from organic solutions of salts of tertiary amines [8]. When 0.1 M HNO_3 is used as the receiving solution, the rate of copper(II) extraction is virtually the same as that with the other systems studied. However, the rate of platinum(IV) extraction increases and the separation coefficient of the metal ions decreases dramatically.

The influence exerted by the copper(II) concentration in the initial solution on the rate of transmembrane transfer of Cu^{2+} ions was studied using individual solutions of $CuCl_2$ in water. At copper(II) concentrations less than 0.07 M, the voltage across the membrane system steeply increases in the course of electrodialysis at a current density of 8.5 mA cm^{-2} (Fig. 5). Hypothetically, the drop in the electrical conductivity is due to desalting of the donating solution through extraction of copper(II) into a liquid membrane and to transfer of Cl^- ions across a solid anion-exchange membrane into the anode compartment.

At higher concentrations of copper(II) in the donating solution, the degree of extraction into the receiving solution is about 65% and independent of the concentration of metal ions within the range 0.02–0.04 M. At the same time, the transmembrane flow of copper(II) and the current efficiency proportionally increase under these conditions (Table 2). At higher $CuCl_2$ concentrations, the rate of copper(II) trans-

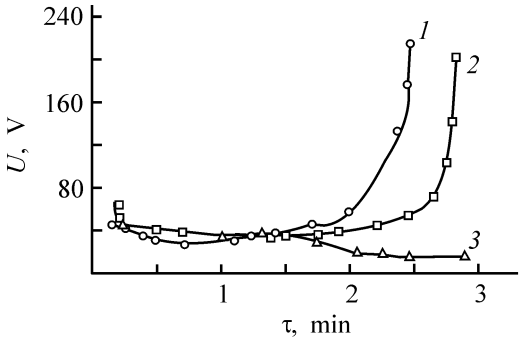

Fig. 5. Variation of the voltage U with the process duration τ at different copper(II) concentrations in the donating solution. i = 8.5 mA cm^{-2}, c_{D2EHPA} = 20 vol %, c_{TOA} = 0.1 M. c_{Cu} (M): (*1*) 0.02, (*2*) 0.04, and (*3*) 0.07.

fer into the cathode compartment somewhat decreases, which may be due to enhancement of copper(II) extraction with tri-*n*-octyl amine to form a complex containing $CuCl_4^{2-}$ anions [9].

CONCLUSIONS

(1) Liquid membranes based on technical-grade di(2-ethylhexyl)phosphoric acid in 1,2-dichloroethane ensure extraction of Cu^{2+} into dilute solutions of mineral acids and provide a single-stage separation of copper(II) from platinum(IV) in extraction from binary acid chloride mixtures under the conditions of the galvanostatic electrodialysis.

(2) The rate of transmembrane transfer of copper(II) is determined by the current density of electrodialysis, concentrations of transport agent and tri-*n*-octyl amine additive in the liquid membrane, and copper(II) concentration in the donating solution, and is virtually independent of the composition of the receiving solution.

(3) The selectivity of the copper(II) extraction from binary solutions is improved as the current density, duration of electrodialysis, and concentration of di(2-ethylhexyl)phosphoric acid become higher and the concentration of tri-*n*-octyl amine in the liquid membrane is lowered. Under the optimal conditions, the separation coefficient of the metals exceeds 900.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Regeneration of a Solution for Electroless Copper Plating

D. Yu. Turaev and S. S. Kruglikov

Mendeleev Russian University of Chemical Technology, Moscow, Russia

Received September 15, 2004; in final form, February 2005

Abstract—The possibility of electrochemical regeneration of a solution for electroless copper plating by membrane electrolysis was studied. The conditions of anodic dissolution of copper in a spent solution for electroless copper plating, under which the concentration of copper ions increases at a rate exceeding by an order of magnitude that of their deposition in the course of electroless copper plating, were examined. A scheme for regeneration of spent solutions for electroless copper plating was suggested.

Metals are commonly deposited from aqueous solutions to obtain metal coatings with various functional properties by the electrochemical method. However, the method of chemical reduction is used in some cases (electrically nonconducting support, intricate shape of articles). An electrically conducting sublayer for subsequent electrodeposition of metals and alloys is most frequently deposited by electroless copper plating. When in use, solutions for electroless copper plating accumulate reaction products and this restricts their service life. In this study, the method of membrane electrolysis was used to develop a process for complete regeneration of a tartrate-formaldehyde solution for electroless copper plating, widely used in Russia.

The reduction of copper ions is described by the equation

$$Cu^{2+} + 2HCOH + 4OH^- = Cu^0 + 2HCOO^- + H_2 + 2H_2O. \quad (1)$$

Equation (1) expresses the overall result of the conjugated cathodic and anodic reactions:

$$[CuT_4]^{6-} + 2e = Cu^0 + 4T^{2-}, \quad (2)$$

$$2HCOH + 4OH^- = 2HCOO^- + 2H_2O + H_2 + 2e, \quad (3)$$

where T^{2-} stands for the tartrate ion $C_4H_4O_6^{2-}$.

The equilibrium potential of reaction (3) depends on the solution pH:

$$E = 0.372 - 0.118\,\mathrm{pH}. \quad (4)$$

It was shown in [1] that the anodic reaction (3) occurs in a number of stages to form unstable intermediates. A side reaction in electroless copper plating is the disproportionation of formaldehyde (Cannizzaro reaction) [2, 3]:

$$2HCOH + OH^- = HCOO^- + CH_3OH. \quad (5)$$

When in use, the solution is to be adjusted at regular intervals of time by addition of copper sulfate, alkali, and formaldehyde, in order to compensate for the consumption of these components. However, SO_4^{2-}, $HCOO^-$, and CO_3^{2-} ions are simultaneously accumulated, which impairs the plasticity of the copper films obtained. For example, additional introduction of 0.28 M SO_4^{2-} into the working solution leads to a decrease in the relative elongation at break of a copper film by a factor of 6–12 [4]. Therefore, the incapacitation of solutions for electroless copper plating is due to accumulation of reaction products, rather than to consumption of the starting reagents.

In [5], a method for regeneration of solutions for electroless copper plating with a three-chamber electrolyzer having two anion-exchange membranes was described. The middle chamber of the electrolyzer contains a solution to be regenerated, and the cathode and anode chambers, a sodium hydroxide solution and dilute sulfuric acid, respectively.

In the present study, copper ions were introduced into a solution for electroless copper plating by anodic dissolution of copper, which yields solutions containing the minimum amount of copper sulfate.

EXPERIMENTAL

Two- and three-compartment cells with cation- and anion-exchange membranes, working volume of each compartment equal to 25–30 ml, and working surface area of each membrane of 16 cm^2 were used in

the study. Nickel served as the cathode, and copper and platinum-plated titanium (PTA), as the anode. The solutions were analyzed for the content of copper and alkali by titrimetry. The current efficiency by copper was determined gravimetrically and titrimetrically. Polarization curves in the solutions under study were measured with a PI-50-1 potentiostat. All the potentials are given relative to a standard hydrogen electrode. The study was carried with model solutions containing $CuSO_4 \cdot 5H_2O$, $KNaC_4H_4O_6 \cdot 4H_2O$, and NaOH.

The rate of electroless copper plating in tartrate-formaldehyde solutions is about 1 μm h^{-1}, which is equivalent to a cathode current density of 7.5 A m^{-2}. Therefore, it is necessary to choose such conditions of anodic copper dissolution at which the rate of copper dissolution will exceed that of electroless copper plating by no less than an order of magnitude. The results obtained in studying the anodic dissolution of copper in solutions containing 0.28 M $KNaC_4H_4O_6$ and 0.4–2.0 M NaOH are presented in Fig. 1a and Table 1.

It follows from Fig. 1 and data of Table 1 that, at a constant concentration of tartrate ions, the current density of passivation onset strongly depends on the concentration of free alkali: 40 A m^{-2} at 0.4 M and 180 A m^{-2} at 2.0 M.

The increase in the current density of passivation onset, observed as the alkali concentration becomes higher, may be due both to involvement of OH^- ions in the anodic reaction and to formation of complex compounds with two ligands, hydroxy and tartrate ions:

$$Cu + T^{2-} + 2OH^- - 2e \rightarrow [Cu(OH)_2T]^{2-}. \quad (6)$$

Presence of sulfate and chloride ions in minor concentrations (0.1 M) has no significant effect on

the rate of anodic dissolution of copper. These ions are already contained in a freshly prepared solution for electroless copper plating, because this solution is obtained using copper sulfate or (more rarely) copper chloride.

Formate ions can be accumulated in a solution for electroless copper plating in considerably greater amounts via reactions (1), (3), and (5). To study the influence exerted by the concentration of formate ions on the rate of anodic dissolution of copper in a tartrate-alkaline solution, these ions were introduced, from the very beginning, in a high concentration (2 M) in the form of sodium formate into a solution containing 0.75 M NaOH and 0.28 M $KNaC_4H_4O_6$. It was found that presence of an excess amount of formate ions in a solution results in that the current density of the passivation onset of copper increases only slightly.

Also, the influence exerted by a change in the concentration of tartrate ions on the rate of anodic dissolution of copper was studied. Figure 1b shows anodic polarization curves obtained under the conditions similar to those for the curves in Fig. 1a, but at a higher concentration of tartrate ions (0.57 M). Comparison of the curves in Figs. 1a and 1b shows that raising the concentration of the ligand did not lead to any significant decrease in the current density of passivation onset.

It follows from the polarization curves that copper may be passivated in the solutions under study. Therefore, it is necessary to determine the current efficiency of the target reaction, anodic dissolution of copper, for various portions of the anodic polarization curve (Table 2).

The data of Table 2 were obtained under potentiostatic conditions with control over the current strength in a solution containing 0.283 M $KNaC_4H_4O_6$ and 0.75 M NaOH.

The results obtained demonstrate that the current efficiency by copper is close to 100% only in the regions of active dissolution and active-passive transition. In the repassivation region, the current efficiency by copper decreases dramatically (to 3% at 20 A m^{-2}), with the current efficiency by copper decreasing as the current density becomes higher (to 0.7% at 70 A m^{-2}).

To determine the rates of transfer of formate and tartrate ions from a solution for electroless copper plating into the anode chamber, experiments were carried out in a two-chamber cell with an anion-exchange membrane and a three-chamber cell with two anion-exchange membranes (Tables 3, 4). The spent

	NaOH		$CuSO_4$, initial	Cu^{2+}, final			
	initial	final					
1	0.61	0.65	0.075	0.21	20	100	7.24
2	0.78	0.76	0	0.09	20	100	4.94
3	0.78	0.76	0	0.09	20	97	5.0
4	0.78	0.77	0	0.085	40	99	4.60
5	0.53	0.56	0.005	0.11	40	103	5.46
6	0.34	0.19	0.005	0.08		91	4.40
7	0.35	0.39	0	0.075	20	91	4.41

solution was placed in the cathode chamber in the first case, and in the middle chamber in the second; a sulfuric acid solution served as catholyte in both cases. An alkali solution served as catholyte in experiments with a three-chamber cell.

It can be seen from Tables 3, 4 that the rate of transfer of formate ions into the anolyte is several times higher than that of formate ions.

Under industrial conditions, it is more difficult to control the anode potential of the electrode than to maintain a certain anode current density. Therefore, the possibility of introducing copper ions by anodic dissolution of copper in a solution based on sodium hydroxide and Rochelle salt (0.28 M) at a constant current strength (density) was analyzed in this study. To preclude deposition of copper at the cathode, it was separated from the solution for electroless copper plating by an anion-exchange membrane, with the process carried out in a two-chamber cell. A 0.1 M NaOH solution was used as the catholyte. The results of the experiments are listed in Table 5.

It was found that, after electrolysis, the catholyte contains no compounds of bivalent copper and no copper is deposited at the cathode, which points to a negative charge of complex compounds of the tartrate ion with the Cu^{2+} ion. Copper is dissolved anodically with a current efficiency of 91–100% at a low (20–40 A m^{-2}) current density both in the presence and in the absence of sulfate ions.

The results obtained served as a basis for the development of a technological scheme (Fig. 2) of operation of a regeneration unit.

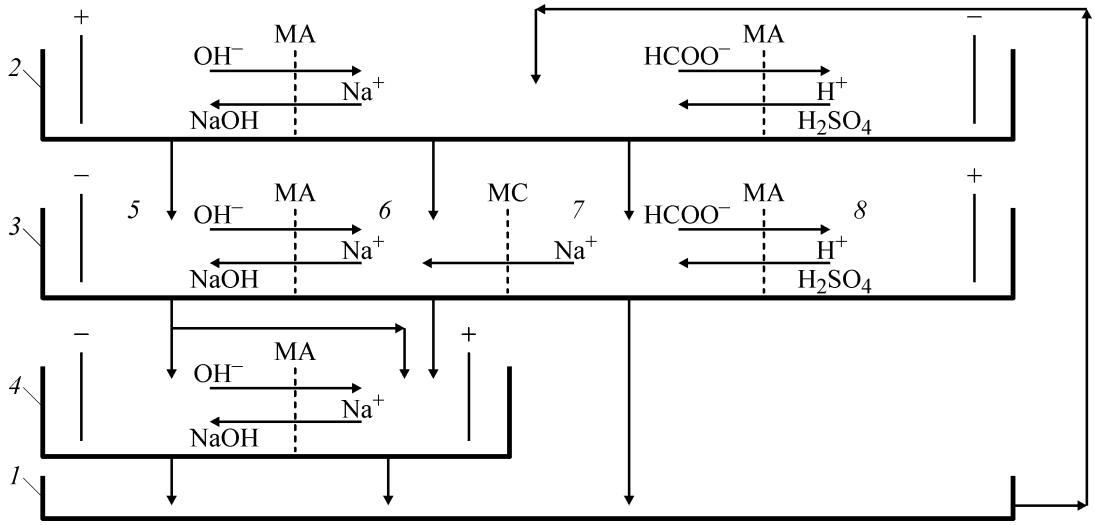

Fig. 2. Scheme of regeneration of a spent solution for electroless copper plating: (*1*) working bath; (*2*) three-chamber cell with two anion-exchange membranes; (*3*) four-chamber cell with two anion-exchange and one cation-exchange membranes; (*4*) two-chamber cell with an anion-exchange membrane; (*5*, *8*, *6*, *7*) cathode, anode, and auxiliary compartments of cell *3*.

CONCLUSIONS

(1) A technology for regeneration of a spent solution for electroless copper plating was developed on the basis of the experiments performed.

(2) A scheme of a membrane electrolysis unit for regeneration of a spent solution for electroless copper plating was suggested.

Abstract—Electrocatalytic reduction of the nicotine alkaloid in the presence of skeletal nickel catalysts was studied.

Natural nicotine, the main alkaloid contained in tobacco (2–10 wt % in a plant), is an (*S*)-isomer [1] and acts as an exceedingly strong poison upon the peripheral and central nervous systems. For this reason, it does not find any wide use, even in the form of a sulfate, as an insecticide for pest control in agriculture and for curing parasitic skin diseases in veterinary medicine. An attempt to apply this alkaloid in curing Alzheimer [2] or Parkinson diseases [3] proved to be unsuccessful because of the strong side effects [4].

The discovery of the bactericide and pesticide activity of synthetic analogues of nicotine and products of its reductive transformations [5] attracted the attention of researchers to development of methods for synthesis of compounds of this kind. However, nicotine itself was not was used for synthetic purposes. This was done using not nicotine itself, but a product of its metabolism in mammal organisms, the cotinine alkaloid whose skeleton transforms to the structure of the corresponding nicotine derivative [6–9]. In this context, it may be assumed that hydrogenated and partly hydrogenated nicotine derivatives are of interest as syntons for obtaining new physiologically active compounds. As for sources of nicotine, it should be emphasized that it is important to utilize wastes from the tobacco industry, whose stock may be as large as tens of thousands of tons, with this alkaloid and its analogues contained in an amount of 2–3 wt %.

It is well known that hydrogenation of pyridine bases requires noble metal catalysts and rather severe conditions: high temperature and hydrogen pressure [10, 11]. A fully hydrogenated nicotine, hexahydronicotine, can be obtained either by reduction of nicotine with metallic sodium or catalytically, by hydrogenation in the presence of platinum black [12], Adams catalyst in acetic acid [13], or skeletal nickel [14]. The yield of hexahydronicotine under these conditions is as high as 23–25%.

Undoubtedly advantageous in reduction of the pyridine ring is the reaction of electrocatalytic hydrogenation. It proceeds on a skeletal nickel catalyst under atmospheric pressure at low temperature [15, 16].

For this reason, the electrocatalytic reduction of nicotine on a skeletal nickel catalyst under conditions closely similar to those in reduction of pyridine bases was studied in order to develop a technique for synthesis of hexahydronicotine.

EXPERIMENTAL

The skeletal nickel catalyst was obtained by the Rayney method from a 50 : 50 alloy of nickel and aluminum [15].

Experiments on reduction of nicotine were carried out in a thermostated electrocatalytic diaphragm cell. As the cathode served a stainless steel disc with a surface area of 0.05 dm^2, which was closely adjacent to the cell bottom. A skeletal nickel catalyst was placed on the cathode and kept in the reaction zone by the field of a permanent magnet. A stainless steel plate was used as the anode. An MA-40 anion-exchange membrane served as the diaphragm. The anolyte was a 20% solution of sodium hydroxide; the alkali concentration in the catholyte was selected experimentally. The gases evolved were collected into graduated burettes.

Nicotine well dissolves in aqueous solutions of sodium hydroxide in the temperature conditions studied. Therefore the electrolytic hydrogenation was performed without agitation.

The composition of the reduction products was determined by gas–liquid chromatography with marker

Table 1. Results of hydrogenation of nicotine **I**

Catalyst	Amount of absorbed H_2, ml	Total yield, %		Unchanged nicotine, %
		of hexahydronicotine isomers	of side products	
Ni_{skel}	200	57	0.8	40
Pd/Ni, 5% Pd	110	42	1.8	54
Pt/Ni, 5% Pt	60	Trace amounts	Trace amounts	98
Re/Ni, 5% Re	40	″	″	99
Mo/Ni, 5% Mo	110	42	1.6	55
V/Ni, 5% V	230	62	0.8	36

substances [Chrom-5 chromatograph; flame-ionization detector; 3.5-m-long stainless steel column with an inner diameter of 3.0 mm, packed with Chromaton NAW-HMDS with a grain size of 0.315–0.400 mm, supporting an SE-30 silicone elastomer (5 wt %)]. The temperature of the column, detector, and evaporator was 200, 240, and 240°C, respectively; the flow rate of the carrier-gas (argon) was 40 ml min^{-1}. An analysis of the catalyzates formed on skeletal nickel demonstrated that the main reduction product of nicotine (**I**) is hexahydronicotine in the form of two 2*S*,3*S*'- (**II**) and 2*S*,3*R*'-diastereomers (**III**).

The electrocatalytic reduction is accompanied by hydrogenolysis leading to decomposition of compound **I** and to formation of pyridine (**IV**) and *N*-methylpyrrolidine (**V**). Also, piperidine (**VI**) was found, which could be formed both via hydrogenation of nicotine **I** and via hydrogenolysis of hexahydronicotine **II** and **III**:

Diastereoisomers obtained in hydrogenation of compound **I** were isolated from the catalyzates by extraction with diethyl ether and separated on a column packed with Al_2O_3 (II degree of activity), with successive elution with petroleum ether and chloroform. The constants of these compounds were in an agreement with published data [14]; however, the ratio of diastereoisomers **II** and **III** was 5.1 : 1 in the case in question, as opposed to the 4 : 1 ratio in [14]. The total yield of side reaction products (pyridine, piperidine, methylpyrrolidine) did not exceed 1–3%.

The rate of electrocatalytic reduction of substance **I** increases with its concentration, reaching the highest value of 1.3 mol H_2/min at a content of alkaloid of 0.185 M in the catholyte. The highest utilization coefficient of hydrogen is observed at the same concentration. Raising further the concentration of nicotine **I** does not change the process rate and the coefficient of hydrogen utilization. However, an analysis of the catalyzates by gas–liquid chromatography demonstrated that this leads to an increase in the content of side products of hydrogenolysis of the starting molecule. For example, as the concentration of substance **I** increases from 0.185 to 0.250 M, the yield of pyridine grows from 0.8 to 3.0%.

The optimal hydrogenation parameters are as follows: temperature, within the range 20–30°C; the current density, 20 A dm^{-2}; alkali concentration in the catholyte, 1–2 wt %; and alkaloid **I** : catalyst ratio, 1.5 : 1.0. The total yield of diastereoisomers of hexahydronicotine **II** and **III** under these conditions is 57%.

It is known that promotion of a skeletal nickel catalyst with other metals favors occurrence of many difficultly performable reactions [17]. Therefore, it seemed reasonable to use, in order to raise the activity and selectivity of skeletal nickel, binary skeletal catalysts containing, in addition to nickel, such metals as Pt, Pd, Re, mo, and V, which are themselves used in hydrogenation processes as catalysts. Platinum and palladium were deposited onto a nickel catalyst by cementation; rhenium, molybdenum, and vanadium were introduced in the form of salts NH_4ReO_4, K_2MoO_4, and NH_4VO_3, respectively, into a 20% aqueous solution of sodium hydroxide intended for leaching of the Ni–Al alloy. The concentration of the salts corresponded to a 5% content of a metal added, relative to the mass of nickel in the catalyst.

The experimental results listed in Table 1 indicate that of particular interest among the six skeletal nickel

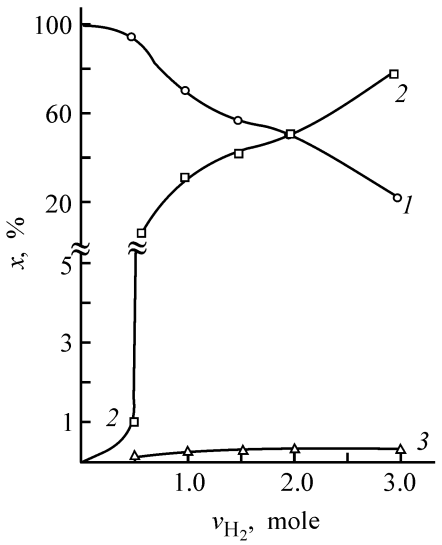

Table 2. Yield of the sum of hexahydronicotine isomers **II** and **III** in relation to the content of vanadium in the catalyst

V content, wt %	Yield, %		Unchanged nicotine, %	V content, wt %	Yield, %		Unchanged nicotine, %
	of the final product	of side products			of the final product	of side products	
–	57	0.8	40	15	70	0.9	27
5	62	0.8	36	20	76	0.8	22
10	65	0.9	32	25	65	0.8	32

catalysts studied under comparable conditions is the nickel-vanadium catalyst in whose presence 62% of alkaloid **I** was converted into hexahydronicotine **II** and **III**.

A study of how the yield of a sum of hexahydronicotine isomers **II** and **III** depends on the amount of ammonium *meta*-vanadate added in preparing a skeletal nickel catalyst (Table 2) demonstrated the following. As the content of vanadium in solution increases from 5 to 20 wt %, the yield grows from 57 to 76%, whereas the amount of side products in the catalyzate remains virtually unchanged.

Possibly, the mechanism of promotion of the skeletal nickel catalyst consists in formation of phase surface vanadium oxides with lower degrees of oxidation, which have high isosteric heat of adsorption, Q_{M-H}. Such oxidized forms can be formed on the cathode components of the initial nickel-aluminum alloys, where the anion VO_3^- is reduced. For example, it is known that a saltlike product is deposited at the cathode in electrolysis of alkaline solutions of vanadates. The cation of this product contains V^{4+}, and its anion, V^{5+} [17].

Catholyte composition x vs. amount v_{H_2} of hydrogen absorbed in electrocatalytic reduction of nicotine **I** on a nickel catalyst promoted with the VO_3^- anion. (*1*) Nicotine, (*2*) 2*S*,3*R*-hexahydronicotine, and (*3*) 2*S*',3*S*-hexahydronicotine.

The figure shows the dependence of the catholyte composition on the amount of hydrogen absorbed in electrocatalytic reduction of nicotine **I** on a nickel catalyst promoted with the VO_3^- anion. The concentration of nicotine (curve *1*) steadily decreases to become 24% upon absorption of 3 mol of hydrogen. Simultaneously, a sum of hexahydronicotine isomers **II** and **III** is accumulated (curves *2* and *3*). Only the yield of isomer **II** increases with the amount of absorbed hydrogen (curve *2*), whereas the content of 2*S*,3*R*'-isomer **III** remains virtually unchanged (curve *3*), so that their ratio becomes 26 : 1 by the end of the process.

The results of the study also demonstrated that the promotion of a skeletal nickel catalyst with vanadium not only raises its activity, but also leads to a nearly twofold increase in its service life, from 40 to 72 h.

CONCLUSIONS

(1) It was established that hexahydronicotine is formed in electrocatalytic reduction of nicotine on an unpromoted skeletal nickel catalyst and that promoted with various metals.

(2) The best results are obtained with a Ni-skeletal catalyst promoted with ammonium *meta*-vanadate, in whose presence the selectivity of the process grows and the yield of a sum of hexahydronicotine diastereoisomers increases from 57 to 76%. The yield of the 2*S*',3*S*-isomer is 75%, and the service life of the catalyst increases from 40 to 72 h.

Abstract—The phase composition, thermal stability, and electrical conductivity of a compound formed by a polymethylsiloxane lacquer and copper were studied in relation to the temperature of formation of a coating on its basis.

At present, development of heating elements with a large heating surface area and high efficiency is a topical task. The most effective solution to this problem is deposition of an electrically conducting coating onto the surface of an article to be heated. A coating of this kind can be created in the simplest way by depositing a suspension based on an electrically conducting powder and a polymer binder by the paint-and-varnish technology. The electrical conductivity of such composite coatings (compounds) is provided by the contact between particles of the conducting phase [1]. Apparently, the electrical conductivity of a compound is affected both by the nature of particles and the phase composition of their surface and by the properties of the polymeric matrix.

As an electrically conducting phase was used powdered copper of the PM 1 brand. It is known that a considerable oxidation of copper starts at 180–200°C, depending on the dispersity of the metal. However, it may be assumed, based on the data of [1], that incorporation of the metal into the polymeric matrix should prevent its oxidation.

Compounds based on most of organic polymers have a low working temperature (not higher than 150°C) because of the destruction of macromolecules. It has been suggested to use as a binder for the electrically conducting compound an organosilicon polymer stable against oxidation up to 400°C [3].

The present study is concerned with properties (electrical conductivity, thermal resistance, phase composition) of the system constituted by a polysiloxane lacquer and copper.

EXPERIMENTAL

The compound was prepared by mixing a toluene solution of the polymer (15 wt %) with powdered copper in a 2 : 1 ratio (by weight). The mixture was ground in a porcelain mortar and applied on glass plates, the resulting coatings were dried at 50–350°C for 1 h. The thermal destruction of the compound was studied by differential thermal analysis (DTA) on a Q-1500 instrument.

The phase composition of the metal in the compound was determined by X-ray phase analysis (DRON-UM1, Co_{K_α} radiation) and voltammetric (VA) analysis with a carbon paste (CP) electrode in the cyclic voltammetry (CVA) mode [4].

The coating surface was analyzed by a nondestructive VA method with an all-in-one sampling and indicator electrode (Hg and HgNa) [5–7]. The voltammograms were recorded in the differential mode of potential variation on a PU-1 polarograph. The phase composition of the surface and bulk of the compound was studied using two methods of solid-phase voltammetry (see table).

The electrical conductivity of a coating largely depends on the particle packing density and the uniformity of distribution of Cu particles in the bulk. Mechanical grinding of a Cu powder in a solvent,

Methods of solid-phase voltammetry

VA method	Type of electrode	Electrochemical process	Application field
CVA	CP	Reduction of oxidized forms of the metal from the bulk of the composite and oxidation of the reduced metal into the solution	Identification of the phase composition in the bulk of the composite and determination of ratio between the elementary and oxidized forms of the metal
VA	Hg	Oxidation of the metal that formed an amalgam when brought in contact with the surface	Determination of the elementary form of the metal on the surface
	HgNa	The same (with account of the phase exchange)	Determination of the bulk content of the elementary and oxidized forms of the metal

with its subsequent mixing with a polymer, makes it possible to obtain a lower electrical resistance of the coating. It can be seen in micrographs obtained with an MIM-8 optical microscope at a magnification of 400 that, in this case, the distribution of Cu in the coating is more uniform and the number of agglomerates of Cu particles is smaller.

The dependence of the resistance of formulations on the formation temperature is shown in Fig. 1. The resistance remains virtually unchanged in the range 100–200°C, and decreases to 10–20 Ω at 200–250°C. As the formation temperature increases, the resistance becomes higher.

To identify the phase composition of the conducting component (copper), X-ray phase and VA analyses of samples formed at temperatures of 100 to 300°C were made. The results of a VA analysis of the surface of the polysiloxane–copper compound with mercury and amalgam electrodes are shown in Fig. 2. The error in determining the metal on the surface was too large in most cases for evaluating the phase composition of the surface. However, comparison of the signals obtained by means of VA (semi-quantitative approach) suggests that the content of copper on the surface of the samples studied increases with temperature. This is due to the following. As the temperature becomes higher, the polymeric matrix contracts because of the evaporation of the solvent and cross-linking of polysiloxane, and, therefore, part of Cu atoms "emerge" to the surface. The currents of Cu oxidation, obtained on the mercury and amalgam electrodes brought in contact with the surface of the compound differ only slightly. Consequently, mainly the elementary form of Cu is present on the surface. The differences in the currents obtained after bringing the electrodes in contact with the surface of compounds formed at different temperatures are insignificant. Consequently, the polymeric matrix "retains" copper particles rather firmly and is an appropriate binder.

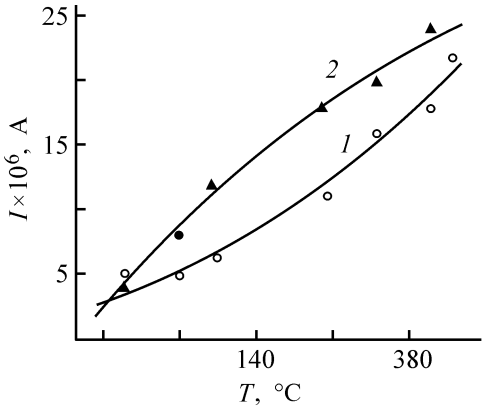

Fig. 2. Copper oxidation currents *I* obtained on (*1*) mercury and (*2*) amalgam electrodes brought in contact with the surface of polymethylsiloxane–copper samples formed at a temperature *T*.

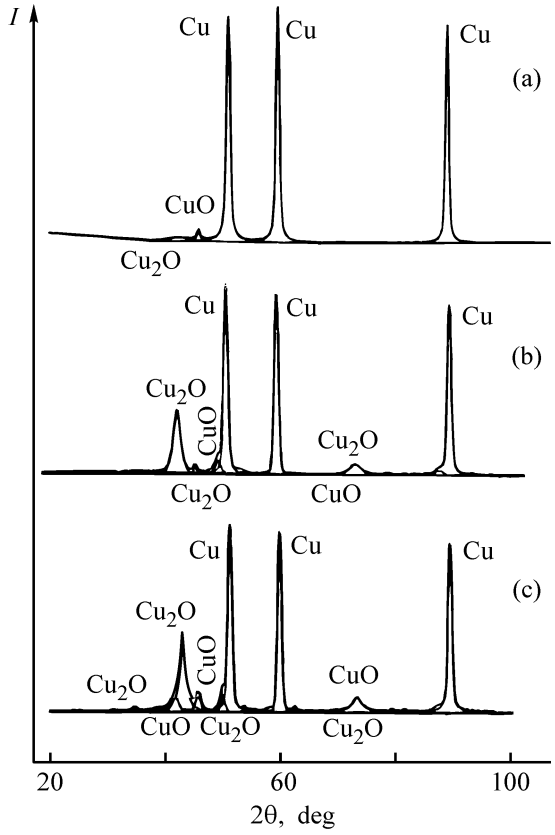

Fig. 3. X-ray diffraction patterns of a polyorganosiloxane–copper compound formed at a temperature *T*. (*I*) Intensity and (2θ) Bragg angle. Temperature (°C): (a) 70, (b) 250, and (c) 300.

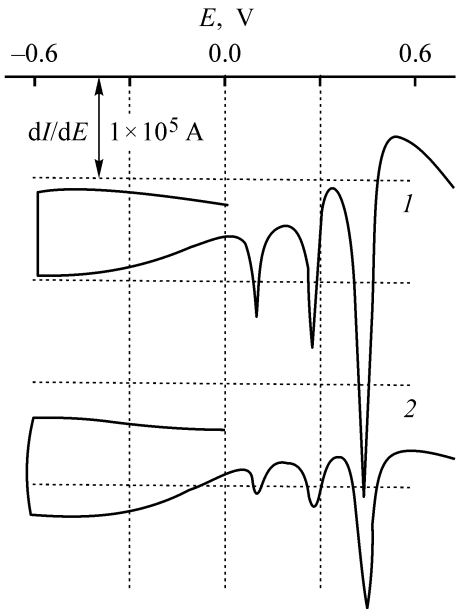

Fig. 4. CVA curves for a CP electrode containing samples formed at (*1*) 250 and (*2*) 100°C. (*E*) Potential.

The X-ray diffraction patterns of samples obtained at 70–200°C are similar; noticeable changes begin at above 250°C (Fig. 3). It can be seen that Cu is the main phase below 300°C. The weak reflections associated with Cu(I) and Cu(II) oxides can be only attributed to phases on the surface of copper particles. As the temperature is raised to 250°C, the content of the Cu(I) oxide phase starts to grow and a Cu(II) oxide phase appears at 300°C. For comparison, the initial Cu powder was analyzed. It was found that, in this case, a considerable amount of the Cu_2O phase is present at 250°C.

The cyclic voltammograms of the CP electrode containing samples formed at different temperatures do not differ in the spectra of the signals obtained (Fig. 4). The anodic curve shows three peaks at 0.06, 0.28, and 0.40 V, which correspond to oxidation of copper from the surface annd bulk layers of the compound. The difference in the oxidation current can be attributed to different electrical conductivities of compounds formed at 100 and 250°C. The absence of signals in the cathodic curve (reduction current) can be attributed to the fact that the content of oxidized forms of copper in the compound is less than 5%. The data obtained using CVA with a CP electrode confirm the results of the X-ray phase analysis.

To elucidate the mechanism of coating formation, the compound and the starting components, polysiloxane and copper powder, were subjected to a thermal analysis (Fig. 5). Analysis of the initial copper powder shows that the oxidation of Cu begins at around 200°C and occurs in several successive stages. Thermolysis of polymethylsiloxane also occurs in a number of stages: the polymer is cross-linked at 130–450°C to form a three-dimensional network structure and then (at 450–700°C) side groups burn-out, with the process accompanied by strong exothermic effects. A mass gain corresponding to oxidation of Cu contained in the composite is observed at above 400°C, with the nature of this process coinciding with that of oxidation of the copper powder.

Thus, the run of the dependence of the electrical resistance of the coating on the thermal treatment temperature can be explained as follows. In the temperature range 100–200°C, the resistance remains constant until the cross-linking of polymethylsiloxane begins. In the process, the matrix contracts and Cu particles come in direct contact with one another to form a continuous conducting "network," with the resistance of the composite decreasing. As the heating temperature is raised to above 300°C, the resistance again increases, which is due to oxidation of the surface of copper particles.

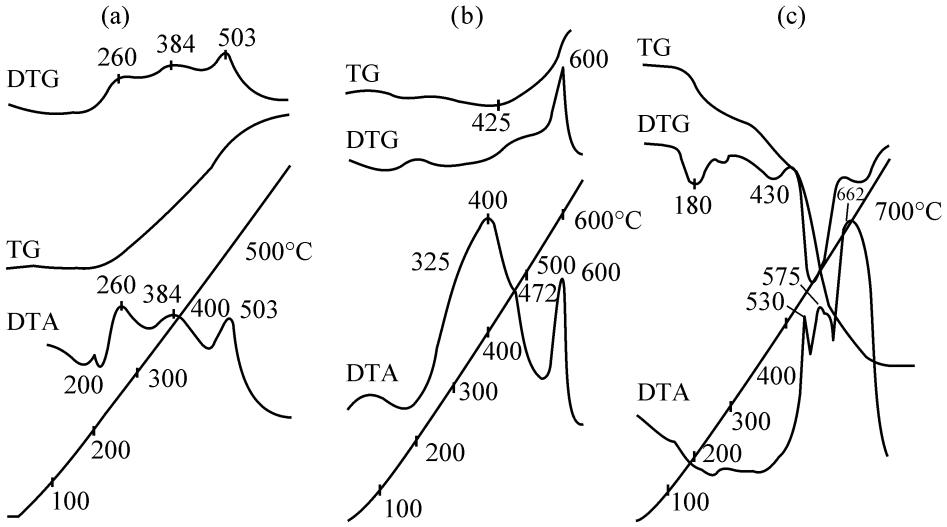

Fig. 5. Thermograms of (a) copper powder, (b) compound, and (c) polyorganosiloxane.

CONCLUSIONS

(1) It was found, using voltammetry and X-ray phase and termogravimetric analyses, that polymethylsiloxane prevents oxidation of copper at temperatures of up to 250°C.

(2) It was demonstrated that the optimal formation temperature of a polymethylsiloxane–copper coating is 250°C.

(3) It was shown that the compound can be used to develop heating elements with a large heating surface area and high efficiency.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Sorption of Iron(II) on Ferromanganese Nodules

D. E. Chirkst, O. V. Cheremisina, M. V. Ivanov, and A. A. Chistyakov

St. Petersburg State Mining Institute, St. Petersburg, Russia

Received May 26, 2004; in final form, October 2004

Abstract—The dynamic capacity, specific surface area, grindability, and wearability of filter materials based on pyrolusite were determined. The dynamic capacity of ferromanganese nodules was compared with the capacity of imported filter materials.

Treatment of wastewater from many metallurgical plants to remove various iron species and removal of iron(II) ions, which are not precipitated in a neutral medium, from artesian water are important environmental problems.

Owing to the low pH of hydrate formation at neutralization, iron(III) ions present in water are precipitated as $Fe(OH)_3$. Iron(II) is precipitated in the form of low-soluble hydroxide to a residual concentration corresponding to the maximum permissible concentration (MPC) (0.1 mg ml^{-1}, MPC for fish breeding reservoirs) only at pH 9.5, which is confirmed by the following calculation:

$$Fe(OH)_2 \rightleftarrows Fe^{2+} + 2OH^-,$$

$$L = [Fe^{2+}][OH^-]^2 = 1.6 \times 10^{-15} \quad [1],$$

where $[Fe^{2+}] = MPC = 1.79 \times 10^{-6}$ M.

Hence, $[OH^-] = 3 \times 10^{-5}$, pH 9.5. This result explains why Fe^{2+} ions remain in solution. Hence, Fe^{2+} should be converted to Fe^{3+} with oxidants (e.g., ozone or chlorine), but the oxidation procedures are rather expensive [2, 3].

The aim of the treatment procedures is to decompose pollutants and remove decomposition products, which requires additional material costs.

Various ion-exchanging resins provide a high degree of purification of water, but the required sorbents are rather expensive and, thus, the cost of this procedure is very high [4]. For this purpose, inorganic filter materials are promising. These materials, exhibiting high thermal, chemical, and radiation stability, allow treatment of hot solutions and wastewater from radiochemical plants [5]. At present, treatment of wastewater to remove Fe(II) is frequently performed using imported pyrolusite-containing sorbents, such as Aquamandix filler for bulk filters, which is a crushed material with a particle size of 0.5–1.0 mm (78–80% MnO_2 content, 3.5–4.0 g cm^{-3} density, and 2.0 g cm^{-3} bulk density). Pyrolusite oxidizes Fe(II) to Fe(III), and then iron(III) hydroxide precipitates even from weakly acidic solutions. The oxidative effect of the sorbent is described by the reaction

$$MnO_2 + 2Fe^{2+} + 5H_2O \rightarrow MnO + 2Fe(OH)_3\downarrow + 4H^+.$$

It should be noted that there are no pyrolusite deposits in Russia. Because of the high cost of the imported sorbent, it is advisable to substitute it with a domestic analog. The use of ferromanganese nodules (FMNs) as sorbents for Fe(II) ions seems to be promising.

The FMN deposits are rather widespread in the Gulf of Finland of the Baltic Sea, occurring predominantly on the bottom surface. Search for new deposits available for mining is actively performed [6].

The deposits in this region can be subdivided into two types. Deposits of the first type occur in the southern and northern parts of the Gulf of Finland at a depth of about 60 m. Nodules of this type are spherical particles 1–2 to 30 mm in size [1–16 mm predominant diameter, 100 kPa (1 kg cm^{-2}) strength, and 1.6 g cm^{-3} density). The resources of ferromanganese nodules in these regions are tentatively estimated as 25–30 million tons, which corresponds to a continental deposit of a medium profitability [7].

Another deposit lies in the Luga Bay and Kopor'e Bay at a smaller depth (25–30 m). The predominant particle size in this deposit is 3–5 mm, with nodules

1070-4272/05/7804-0592 © 2005 Pleiades Publishing, Inc.

of size 15–30 mm being rare. In 2000, the first 2500 tons of the nodule-containing material were uplifted in prospecting of the Kopor'e Bay[1] from a depth of 30 m.

The nodules can be separated from silt ashore, using a conical hydraulic screen, which allows separation of a gravel with a particle size exceeding 20 mm and nodule particles 2–20 mm in size. The chemical composition of the nodules from the Kopor'e Bay is given in Table 1 [9]; they contain todorokite $(Mn^{2+}, Ca, Mg)Mn_3^{4+}O_7 \cdot H_2O$ and vernadite $MnO_2 \cdot H_2O$ and minor amounts of pyrolusite MnO_2, psilomelane $(M, Mn)O \cdot mH_2O$ (where M = K, Ca, Ba, Ni, etc.), and rancieite $(Ca, Mn^{2+})Mn_4^{4+}O_8 \cdot 3H_2O$ [10]. The parameters of selected minerals are listed in Table 2.

Iron predominantly occurs as hydrated goethite FeO(OH) and double silicates with aluminum of ferrihydrite type $Fe_5Al_2(Al_2Si_6O_{22})(OH)_2$ [10].

A study of the FMN composition [10] demonstrated that the main ore fraction is constituted by iron and manganese hydroxides, and non-ferrous metals are isomorphically bound with manganese and iron minerals. Owing to strongly developed surface area (porosity of up to 58%), the FMN material is highly hygroscopic. The environmentally safe FMN material is a finished granulated material with round particles and particle-size distribution suitable for bulk filters.

The total content of manganese in various forms is shown in Table 1; data on the oxidation states of manganese in these forms are lacking. We assume that the average content of MnO_2 in the nodules, minus MnO inactive in water treatment, is nearly 20%, which is lower than that in pyrolusite Aquamandix sorbent by a factor of 4. However, the significantly larger surface area of the nodules compensates for the lower content of MnO_2 on the surface as compared to the pyrolusite sorbent.

The strength of FMNs can be raised by their grinding, mixing with bentonite (colloidal clays), and subsequent granulation.

The dynamic capacity, specific surface area, and strength were studied to compare the properties of the filter materials.

The dynamic capacity of the sorbents for Fe(II) was determined by the procedure similar to that given in [11]. A sorbent sample was placed in a column (300 mm bed height and 16 mm diameter); the elution rate was 0.5–1.0 ml min^{-1}. All the sorbents were preliminarily washed with distilled water (5 l). We studied the following samples: FMN (1.0–1.6 mm) washed with 2 l of 0.01 M oxalic acid (FMN 1), FMN without washing (FMN 2), Aquamandix sorbent (Aqu.), and Chinese sorbent based on pyrolusite (Pyr.). An aqueous NaOH solution was added to the ini-

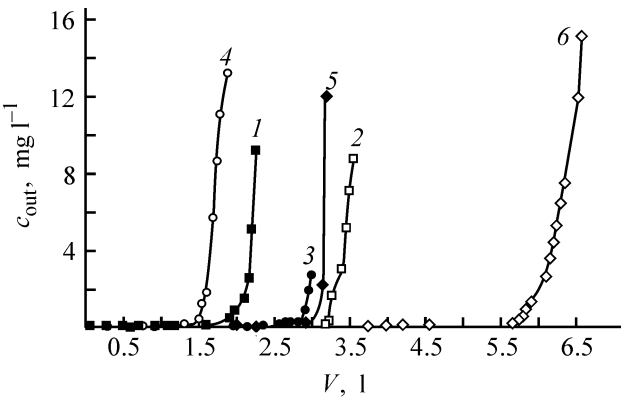
tial solution of $(NH_4)_2Fe(SO_4)_2 \cdot 6H_2O$ with a Fe^{2+} concentration of 0.7–7.5 mg l^{-1}, to attain pH 7–8. The dynamic capacity to breakthrough (DC) of the 0.1 mg l^{-1} Fe(II) solution (3.57 mg-equiv l^{-1}, i.e., MPC for fish breeding reservoirs) and the total dynamic capacity (TDC) with respect to Fe(II) were determined by analyzing 50-ml aliquots taken at the column outlet. The total content of Fe(II) and Fe(III) in the samples was determined spectrophotometrically with KSCN by absorption at λ 420 nm, and the content of Fe(III), at λ 536–540 nm with sulfosalicylic acid in an acidic medium. The content of Fe(II) was determined as the difference between the total content of iron and that of Fe(III). The dynamic capacity to breakthrough of the Fe(II) solution with a concentration of 0.1 mg l^{-1} and the total dynamic capacity of the sorbents, evaluated as the amount of Fe(II) ions adsorbed by unit weight or unit volume of the air-dried sorbent, are listed in Table 3. The initial concentrations of Fe(II) at the column inlet in the course of determination of DC and TDC were 0.026 and 0.134 equiv l^{-1}, or 0.728 and 7.504 g l^{-1}, respectively.

The model solutions sampled at the column outlet in the course of DC determination contained only Fe(II) ions, because no reaction was observed between Fe(III) ions and sulfosalicylic acid in the acidic medium.

The experimental results showed that the FMN capacity is higher than that of the imported fillers owing to its higher porosity and lower bulk density.

With the aim to enhance the FMN strength, we studied the modified nodules from the Gulf of Finland, prepared by granulation with bentonite clays, polyvinyl acetate glue (PVA), or water glass at various component ratios and temperatures (Table 4).



The mechanical strength was studied using the procedure given in [12]. First the particle-size distribution was determined and the major fraction was separated ($-d_1$; $+d_2$), where d is the side of the sieve mesh. Then the sample of the selected material was washed with distilled water, dried at 110°C, placed in a 250-ml conical flask, and poured over with distilled water. The flask was sealed and shaken for 24 h. After this procedure, the solutions were transferred

into porcelain dishes, water was evaporated, and the samples were dried at 110°C in air. The dried samples were successively sifted on sieves (d_2 and $d_2/2$) at a shaking frequency of 50 Hz for 10 min. The weight of the material that passed through sieve d_2 (percentage relative to the total weight of the material sample) characterizes the material grindability, and the weight of the material that passed through sieve $d_2/2$, its wearability. The strength characteristics of modified FMN samples are listed in Table 5.

As can be seen, the strength properties of several samples meet the requirements of GOST (State Standard) [12], according to which the grindability and wearability should not exceed 4.0 and 0.5%, respectively.

The dynamic capacity of the modified nodules to breakthrough of 0.1 mg l^{-1} Fe(II), determined as the content of Fe(II) ions adsorbed by unit weight or unit volume of the air-dried sorbent, is given in Table 6 (300 mm bed height and 16 mm diameter, 0.5–1.0 ml min^{-1} elution rate).

As can be seen from the experimental results, the capacity of the majority of the modified sorbents is higher than that of unmodified FMN samples by a factor of 2–3. This is apparently due to an increase in the specific surface area in the course of grinding and granulation with the binder. The saturation curves of sorbents exhibiting the highest dynamic capacity are shown in the figure.

Table 7. Specific surface area of ferromanganese nodules and Aquamandix sorbent (5-g samples)

Sorbent	MB concentration, equiv l^{-1}		S, m^2 g^{-1}
	initial	equilibrium	
FMN	0.01	2.341×10^{-3}	43.809
Aquamandix	0.002	1.665×10^{-3}	1.915

To understand the origin of high dynamic capacity of the sorbents, we evaluated their specific surface area by sorption of Methylene Blue (MB) from solution. A weighed portion of an air-dried sorbent (5 g) was placed in a 100-ml conical flask, and a 50-ml portion of a 0.001–0.01 M solution of MB was added. The flask was shaken, and the dispersion was stored for 12–14 h.

Then, the colored suspension was filtered twice through a "blue band" paper filter. The first two filtrate fractions (~10 ml) were rejected because of the MB sorption on the filter. Aliquots of the resulting filtrate and initial solution (1 ml) were diluted with water to 100 ml, and their optical density was measured at λ 665 nm. The MB concentration in the filtrate was calculated by the equation

$$c_f = c_{ini} D_f / D_{ini},$$

where D_f and D_{ini}, and c_f and c_{ini} are the optical densities and concentrations of the filtrate and initial solution, respectively.

The capacity (equiv g^{-1}) was calculated with an accuracy of up to 0.1 mg-equiv. from the following equation:

$$E = \Delta c V \times 10^{-3}/m, \quad (1)$$

where Δc is the difference between the concentrations of the initial and equilibrium MB solution (equiv l^{-1}); V, volume of the initial MB solution (cm^3); and m, weight of the sorbent sample.

From the exchange capacity, we calculated the specific surface area. According to X-ray diffraction analysis [13], the area occupied by a single MB molecule is 95.6×10^{-20} m^2. If we assume that the maximum amount of MB sorbed on the sample surface forms a monomolecular layer, then the specific surface area S (m^2 g^{-1}) can be calculated as

$$S = E N_A W_0, \quad (2)$$

where E is the sorbent capacity for MB (equiv g^{-1}); N_A, Avogadro constant; and W_0, area occupied by a single MB molecule.

Data on the specific surface area of FMNs and Aquamandix sorbent are listed in Table 7.

Table 8. Dynamic capacity to breakthrough of 0.1 mg l^{-1} of Fe(II) and mechanical strength of pyrolusite-containing filter materials

Sample no.	Bulk density, kg dm^{-3}	DC				Strength, %	
		equiv l^{-1}	equiv kg^{-1}	g kg^{-1}	g l^{-1}	grindability	wearability
1	0.53	1.66	0.87	46.34	24.47	4.01	1.27
3	0.51	2.81	1.42	78.65	39.84	3.04	0.78
11	0.70	3.63	2.56	101.72	71.71	5.09	0.43
12	0.92	1.50	1.38	41.94	38.70	2.08	0.31
14	0.55	1.85	1.02	51.77	28.59	12.02	6.20
17	0.62	2.00	1.25	56.03	34.92	2.85	0.35
20	0.80	4.15	3.31	116.17	92.76	3.76	0.30
21	0.73	4.41	3.21	123.56	89.80	3.87	0.21
Pyr.	0.61	0.74	0.45	20.66	12.57	<4	<0.5
Aqu.	1.08	0.12	0.13	3.35	3.63	<4	<0.5
FMN I	0.35	2.41	0.85	67.30	23.74	7.4–9.8	1.3–1.4
FMN II	0.35	2.54	0.89	70.93	24.85	7.4–9.8	1.3–1.4

As can be seen, the specific surface area of FMNs exceeds that of Aquamandix by more than a factor of 20. Hence, although the content of pyrolusite in FMNs is lower by a factor of 3–4, the large specific surface area compensates for the low content of MnO_2 on the nodule surface as compared to the imported pyrolusite-containing sorbent. The presence of goethite and other iron-containing minerals, which act as nucleation centers for precipitation of iron(III) hydroxide, is also an important factor.

Data on the capacity and mechanical strength of some pyrolusite-containing filter materials are summarized in Table 8.

As can be seen from Table 8, the capacity for Fe(II) of all the FMN samples is higher than that of the imported pyrolusite-containing sorbents. In general, the strength properties of the FMN samples do not meet the requirement of GOST. Sample no. 17 has the highest mechanical strength, and its capacity is close to that of the natural unmodified nodules. Sample nos. 3,11,12, 20, and 21 also have a satisfactory strength and a high capacity. These samples were prepared by granulation of ground nodules with appropriate binders (Table 4). Our experimental data suggest that the FMNs from the Gulf of Finland allow preparation of a filter material with a high capacity for Fe(II), meeting the requirements of GOST [12]. The low bulk density, developed porosity, and large specific surface area are the advantages of this environmentally safe material exhibiting sufficient strength, which can be controlled by grinding and mixing with bentonite. In this context, the low content of manganese oxides cannot be regarded as an essential disadvantage. For sorbents, it is advisable to use the fine fraction of nodules with a size of 1–3 mm, which are less valuable for metallurgy. The low cost of these inorganic sorbents makes them attractive for use.

The process for FMN recovery was developed by V.B. Dobretsov at the St. Petersburg Mining Institute [14]. The possibility of utilization of spent nodules is being examined [14, 15]. This utilization can be performed by means of pyrometallurgy at metallurgical plants, using a procedure that can recover nonferrous metals, such as manganese, copper, cobalt, and nickel [16].

CONCLUSIONS

(1) Treatment of wastewater to remove Fe(II) with ferromanganese nodules was studied.

(2) The dynamic capacity of the nodules for Fe(II) to breakthrough of 0.1 mg l^{-1} exceeds that of the imported pyrolusite-containing filter materials by a factor of 12–36. The high sorption capacity of ferromanganese nodules is determined by their large specific surface area, which is greater than the specific surface area of Aquamandix sorbent by a factor 20, and by the presence of goethite and iron-containing minerals on the sample surface, which act as nucleation centers for the precipitation of iron(III) hydroxide.

(3) Grinding and granulation of ferromanganese nodules with binders increases their capacity by a factor of 2–3 and enhances their strength characteristics to the level prescribed by the GOST.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Application of the Nanofiltration Method in Systems for Recycling of Washing Water in Photographic Development of Motion-Picture Films

K. B. Grekov

St. Petersburg State University of Cinema and Television, St. Petersburg, Russia

Received April 26, 2004; in final form, February 2005

Abstract—The possibility of using the nanofiltration method for purification of washing water in photographic development of professional motion-picture films is analyzed. Characteristics of domestic membranes, OPMN-K of nanofiltration type and OFAM-KN of low-pressure reverse-osmosis type, obtained in desalting of silver-containing washing water, are presented.

The amount of wastewater produced at motion picture and photolaboratories is small as compared with that formed at plants of other industries, but their complex composition necessitates development of techniques for their detoxication [1, 2]. According to some estimates, photographic development is a process with rather high water consumption because it exceeds in this regard (per unit mass of manufactured products) even such industries as tanneries, manufacture and rolling of steel, etc.

As shown by an analysis of published data and by the results of the author's own studies, the ecological problems of the technology of photographic development of motion picture and photographic materials can be solved in an integrated way virtually only by the membrane techniques, which can be used to create a closed-loop recirculation system of water consumption.

The most widely used among membrane methods are baromembrane techniques, whose main parameters are listed in Table 1. However, the boundaries between various baromembrane processes are rather conditional, and, in some cases, their applicability regions may overlap in practice.

The reverse osmosis method is applicable to purification of various kinds of thiosulfate-containing washing water, formed in fixation procedures. It is recommended to maintain the working pressure at 6 MPa and more, and the permissible $Na_2S_2O_3$ concentrations in the initial solution depend on the scheme of a reverse-osmosis installation used and vary within the range 10^{-3}–1.0 M [2].

The nanofiltration method occupies an intermediate position between ultrafiltration and reverse osmosis (Table 1). The applicability regions of nanofiltration and low-pressure reverse osmosis partly overlap and, occasionally, these two terms are used as synonyms [3].

Recently, a publication "Nanofiltration in Professional Cinematography" has appeared. This paper is

devoted to the possibility of application of this membrane technique for desalting of washing and wastewater discharged in photographic development of negative and positive color films (ECN-2 and ECP-2 processes).[1] The experimental data presented have been obtained by TECHNO-MEMBRANES Co. In performing the tests, a membrane installation equipped with nanofiltration units (MPSW-11 brand) was used; each of the three stages of the unit had a filtrate throughput of up to 0.5 m^3 h^{-1}. It was shown that the retention capacity (RC) of nanofiltration membranes for various components (with the exception of chloride and bromide ions) was 80% and more, and the concentration of Ag^+ in the filtrate did not exceed 2 and 0.1 mg l^{-1} for the ECN-2 and ECP-2 processes, respectively.

Analogous data for nanofiltration membranes of domestic manufacture cannot be found in the literature. Therefore, model thiosulfate- and silver-containing solutions, as well as the industrial silver-containing washing water produced in the fixation procedure, were chosen as the main object for preliminary studies. The concentration of $Na_2S_2O_3$ in the model solutions were in the range from 0.007 to 0.8 M. It was shown in preliminary experiments performed at a working pressure P = 0.5 MPa in an FM-02-200 laboratory cell that the RC of the OPMN-K domestic nanofiltration membrane is too low for effective desalting at $Na_2S_2O_3$ concentrations in solution exceeding 0.17 M.

The next set of experiments was carried out in a flow-through flat-chamber cell with a working surface area of the membrane equal to 38 cm^2, at a temperature of 18–20°C. It was found (Table 2) that the RC and specific throughput of the membrane start to decrease substantially when the $Na_2S_2O_3$ concentration becomes higher than 0.14 M. The dependence of the same type for reverse-osmosis membranes is qualitatively similar to a certain extent, but there still are rather significant differences due, on the one hand, to the large pore size in the nanofiltration membrane and, on the other, to the enhanced role of electrochemical factors (negative charge of the membrane and the ion being retained) in the retention mechanism. The higher RC for Ag^+ (in the form of thiosulfate complexes) is due to both steric and electrochemical factors.

Raising the working pressure from 0.8 to 1.4 MPa makes the RC higher and leads to a substantial increase (by approximately a factor of 2) in throughput (Table 3).

If a linear approximation similar to that used for reverse-osmosis membranes is applied to a nanofiltration membrane, the constants b_1 and b_2 can be found to be 31 and 85.4, respectively, for a solution with $Na_2S_2O_3$ concentration of 0.014 M, and 7.8 and 28.4 for that with 0.08 M.

In addition, the experimental results obtained demonstrated that the RC (for $Na_2S_2O_3$ and Ag^+) falls dramatically when the transmembrane volumetric flow rate decreases to 8–10 l m^{-2} h^{-1}, which also makes it possible to evaluate the applicability limits of the nanofiltration method.

The data in Table 4 also show that introduction of gelatin into the model solution leads to an increase in

[1] Internet site of KODAK Co. (www.kodak.com).

Table 5. Desalting of silver-containing solutions with membranes for nanofiltration and low-pressure reverse osmosis (P = 1.4 MPa)

Membrane	Concentration, g l^{-1}		Π, l m^{-2} h^{-1}	RC, %	
	$Na_2S_2O_3$	Ag^+		for $Na_2S_2O_3$	for Ag^+
OPMN-K	30	0.1	15	32	52
OFAM-KN	30	0.1	2.1	70	82
	5.1	0.0043	5.4	79	88

the RC of the membrane, which is accompanied by a considerable (by more than a factor of 2) decrease in its throughput, caused by the formation of a gel-like layer on the membrane surface [2].

Also, experiments on desalting of silver-containing spent solutions taken from a 40P3 developing machine processing an MZ-3 positive black-and-white film were carried out. In these experiments, the already studied OPMN-K nanofiltration membrane and an OFAM-KN membrane for low-pressure reverse osmosis were tested (Table 5).

CONCLUSION

Domestic nanofiltration membranes can be used in industrial units for desalting of washing water. However, they fail to provide a high degree of solution concentration. At the same time, their indisputable advantage is that, in contrast to reverse-osmosis membranes, they can effectively work at pressures of up to 1.5 MPa.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Recovery of Heavy Metals from Excess Active Sludges with Aeration

I. V. Zykova and V. P. Panov

St. Petersburg State University of Technology and Design, St. Petersburg, Russia

Received December 9, 2004

Abstract—The fundamental aspects of recovery of heavy metal ions from excess active sludges produced at biological treatment plants with the use of various calcium-containing materials (chemically pure, of natural and technological origin) upon introduction of biogenic elements with aeration were studied.

Previously, it has been shown that the problem of detoxication of excess active sludges to remove heavy metal ions (HMI) and utilization of these sludges in agriculture as fertilizers are matters of current interest and new engineering solutions have been suggested as an alternative to deposition or burning of sludges [1–3].

Introduction of sparingly soluble compounds containing Ca(II) into a humid excess sludge leads to immobilization of microorganisms from the sludge on solid surfaces and adsorption of humic acids, amino acids, proteins, and vitamins. In this case, HMI are desorbed by the ion-exchange mechanism from the cell surface, extracted from the cytoplasm of bacterial cells, and replaced by Ca(II) ions in humates. The immobilization of microorganisms on the surface of calcium-containing materials intensifies physical and biochemical processes leading to replacement of HMI in sludge components by Ca(II) ions. Aeration of the system and introduction of phosphate ions, which are necessary for stimulation of the vital functions of microorganisms, may favor a deeper extraction of HMI from sludges [4]. It would be expected that the recovery of HMI should be also more complete when calcium-containing materials containing phosphate components, e.g., phosphogypsum and phosphorite ores, are used.

HMI were recovered from samples of excess sludges from the biological treatment plant (BTP) (Velikii Novgorod) with the use of Kingissep phosphorite, technical-grade $Ca_3(PO_4)_2$, natural gypsum, phosphogypsum, and conversion chalk. To study the influence exerted by phosphate ions on the process, $CaHPO_4$ or NaH_2PO_4 was introduced into the excess sludge before its being mixed with a calcium-containing material in order to create PO_4^{3-} ions in a concentration of 1–100 mg l^{-1}. The volumetric flow rate of air supply was 16 h^{-1}. The concentration of HMI was analyzed on a Perkin–Elmer spectrophotometer by the procedure described in [5].

If the system is agitated with air, the surface of the calcium-containing material becomes more accessible for immobilization of microorganisms and adsorption of organic substances and enzymes. Presence of oxygen in the system leads to partial oxidation of organic compounds, including that occurring via development of an aerobic microflora, which decomposes compound complex substances [6, 7]. As a result, the degree of recovery of HMI from sludges into the aqueous phase increases by 10– 30%, compared with that in the case of mechanical agitation (Table 1).

In the case of aeration, HMI are recovered at a high rate during 1 h, with further agitation (for up to 3 h) having virtually no effect on the completeness of recovery.

Introduction of phosphate ions into the system in a concentration of up to 50 mg l^{-1} at an agitation duration of 3 h and a concentration of the calcium-containing material of no less than 25 g l^{-1} leads to a 10–50% increase in the degree of recovery of Cu(II), Pb(II), Ni(II), Cr(III), and Zn(II) ions from the "solid" phase of the sludge into the "aqueous" phase (includ-

ing that in the form of colloids) under mechanical agitation (Table 2).

According to experimental data, aeration of the system and introduction of phosphate ions markedly accelerate the replacement of HMI by Ca(II) ions in the solid phase of the sludge. Residual HMI concentrations in the treated sludge (per unit mass of dry sludge) that are below the standard concentrations established by GOST (State Standard) R 17.4.3.07–2001 [8] for group-I sediments, which are allowed for use as fertilizers in agriculture, can be reached by agitating the system for 1 h. The data obtained served as a basis for the method suggested for intensifying the process of sludge detoxication [9].

The intensification of HMI recovery from components of the active sludge is also favored by presence of phosphate ions in the starting calcium-containing material. With most of the above-mentioned calcium-containing materials used, the rate of HMI recovery from the sludge is higher during the first 30 min of a process performed with mechanical agitation, compared with that in the case of aeration. However, already 1 h of agitation of systems by aeration results in that the total rate and the degree of recovery exceed (and remain at this level for 3 h) the parameters obtained with mechanical agitation.

Any calcium-containing material introduced into a sludge changes the pH of the medium. For example, the pH of the medium changes, depending on the dose, by 0.7–0.9, 0.5–0.7, 0.5–0.8, and 0.7–0.8 upon introduction of $CaCO_3$, phosphogypsum, natural gypsum, and phosphorite, respectively. Attracting ions of

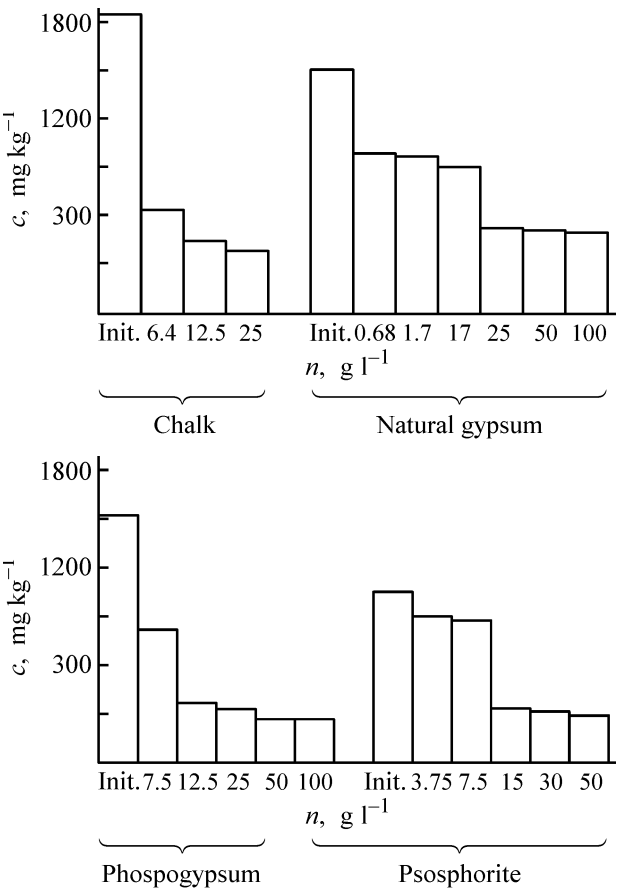

Fig. 1. Comparison of the residual concentrations c of copper ions in the sludge at various doses n of calcium-containing materials. T = 22–25°C, pH 6.8, aeration duration 1 h.

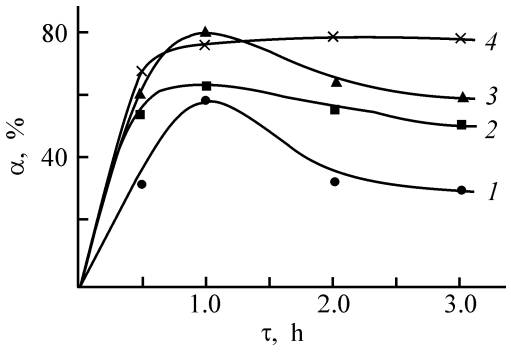

Fig. 2. Degree of copper ion recovery, α, vs. the process duration τ with (*1*, *3*) phosphorite and (*2*, *4*) phosphogypsum used in doses of 15 and 12.5 g l^{-1} of sludge, respectively. T = 22–25°C, pH 6.8. Agitation: (*1*, *2*) mechanical and (*3*, *4*) with air.

the opposite sign from solution, the charged surface of the calcium-containing material changes the conditions of occurrence and the rate of surface reactions. At the interface between the positively charged surface of the material and the liquid medium, the pH may increase by 0.5–2.0 to become 8.5–9.0, which changes the stability of humus complexes [6] and the possibility of replacement of HMI in these complexes and other organic substances by Ca(II) ions.

According to experimental data, the residual concentration of, e.g., copper(II) ions in a dehydrated sludge is the lowest, all other conditions being the same, when phosphogypsum and phosphorite are used as a calcium-containing material (Fig. 1). Some differences are observed when the process is performed using phosphorite and phosphogypsum under mechanical agitation or phosphorite under aeration (Fig. 2). The maximum degree of recovery is observed after 1 h of agitation. If the process duration is made longer, the degree of recovery decreases, This is due to the presence of a considerable amount of fluoride ions in phosphorite, which may lead to loss of microorganisms, with the resulting, after a certain time, biosorption of HMI by "dead" microorganisms and a decrease in the degree of recovery. Phosphogypsum also contains an admixture of fluoride ions, but in a lower concentration and in the form of complex silicofluorides, which results in that its action on microorganisms is not so fatal.

The results of this study demonstrate the possibility of effective detoxication of active sludges from biological treatment plants to remove HMI with the use of various sparingly soluble calcium-containing materials of natural and technological origin. If the process is carried out under certain physicochemical conditions (pH value, temperature, dose of calcium-containing materials, aeration of the system, introduction of biogenic materials, duration of agitation of a system constituted by the sludge and a calcium-containing material), the residual concentration of HMI in a dehydrated sludge can be brought to a standard level that permits use of sludges and sediments from wastewater as fertilizers.

CONCLUSIONS

(1) Introduction of phosphate ions into a system constituted by an excess active sludge and a calcium-containing material and agitation of the heterogeneous system with air intensify the extraction of heavy metals and substantially diminish their residual concentrations.

(2) The rate of replacement of heavy metal ions by calcium ions depends on the composition of the calcium-containing materials used, presence of impurities, and pH value at the phase boundary.

(3) The residual concentrations in the active sludge from biological treatment plants can be brought, by using the method suggested, to a level permissible in utilization of the excess sludge as an organomineral fertilizer in agriculture.

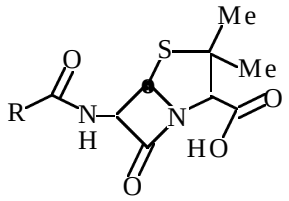
ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Determination of Benzylpenicillin, Ampicillin, and Carbenicillin by Paper Chromatography



V. G. Alekseev, A. F. Nersesova, and Ya. M. Khalyapina

Tver State University, Tver, Russia

Received June 16, 2004

Abstract—A mobile phase was developed for selective determination of benzylpenicillin, carbenicillin, and ampicillin in drugs by paper chromatography.

Antibiotics of the penicillin group are widely used in the medical practice for treatment of infectious diseases. Numerous agents of this group are used today [1, 2]. The molecular structures of penicillins are as follows [3, 4]:

where R = $PhCH_2$ (benzylpenicillin), $PhCH(CO_2H)$ (carbenicillin), or $PhCH(NH_2)$ (ampicillin).

These antibiotics significantly differ in performance, spectrum of the antimicrobial effect, and price. In particular, carbenicillin (CC) differing from benzylpenicillin (BP) only in the presence of one more carboxy group is 9–10 times more expensive than BP. Thus, a risk arises that an expensive drug can be adulterated by replacement with a cheaper drug of the same group. In this case, the drug identification is of crucial importance [5, 6]. Therefore, an urgent problem is the development of selective methods for analysis of antibiotics, as their adulteration is more frequent [7]. Titrimetric [8, 9], spectrophotometric [10–13], and ionometric (with membrane ion-selective electrodes [14, 15] and biosensors [16]) methods, as well as flow injection analysis [17], can be successfully used for quantitative determination of penicillin of a known chemical structure, but are unsuitable for identification of particular penicillins. According to recent studies, high-performance liquid chromatography (HPLC) can be successfully used for selective determination of penicillins [18, 19]. However, this procedure requires expensive apparatus. Thin-layer chromatography (TLC) and paper chromatography (PC) are simpler but also efficient methods; they are widely used in the analytical chemistry of drugs [20].

The possibility of using TLC and PC for the determination of penicillins was examined in numerous studies [21–29]. As eluents were used alcohols, ethers, esters, ketones, and their mixtures with addition of acetic or formic acid, or of aqueous buffer solutions (phosphate, carbonate, citrate). It should be noted, however, that many studies were performed with outdated drugs (heptylpenicillin, propionylpenicillin, ethylmercaptomethylpenicillin, etc.). Furthermore, the results obtained by different authors are inconsistent and sometimes even contradictory.

The goal of this study was to develop a procedure for qualitative determination of three penicillin drugs widely used today: BP, ampicillin (AP), and CC, using such a simple and cheap method as paper chromatography.

EXPERIMENTAL

Experiments were performed with antibiotics in the form of powders in vials: benzylpenicillin sodium salt (Biokhimik, Saransk, Mordovia, Russia), ampicillin sodium salt (Krasfarma, Krasnoyarsk, Russia), and carbenicillin disodium salt (Ferane, Moscow, Russia). Acetone, ethanol, 2-propanol, 1-butanol, diethyl ether, ethyl acetate, carbon tetrachloride, chloroacetic acid, and crystalline iodine were of analyticaly pure grade. Borate buffer solution (pH 9.18), a 0.01 M solution of sodium tetraborate, was prepared from a reference sample.

1070-4272/05/7804-0606 © 2005 Pleiades Publishing, Inc.

In the first step, we examined the possibility of separation of BP, AP, and CC on filter paper using several solvent systems [20, 26]: acetone–ethanol (1 : 1), 1-butanol–ethanol–water (4 : 1 : 5), 1-butanol–acetic acid–water (4 : 1 : 5), 2-propanol–ethanol (3 : 7), and diethyl ether.

The development of the chromatograms with the Bouchard and Dragendorff reagents [26] failed. Better results were obtained with an iodine vapor; the antibiotics always gave dark orange spots against a light yellow background. Unfortunatelly, the R_f values obtained significantly differed from published data. The results are listed in the table.

It is seen that all the mobile phases tested are unsuitable for determination of BP, AP, and CC because of very low R_f. Therefore, we decided to use a denser material, SvetoCopy office paper (80 g m^{-2}, Svetogorsk Joint-Stock Company, Russia), on which the eluent front moved more slowly. The R_f values were the same, but the chromatograms became clearer. However, foreign spots appeared, apparently originating from wash-out of certain components from the paper with the eluent. Therefore, the SvetoCopy paper was preliminarily washed with the eluent to be used for chromatographing. Paper strips (200 × 25 mm) were placed in a chromatographic chamber with an eluent and kept for 8 h. Then the paper was removed and dried in air.

We performed two series of experiments: (1) separation of penicillins in the form of anions, using a mixture of an organic solvent and aqueous borate buffer solution (pH 9.18), volume ratio 95 : 5; (2) separation of penicillins in the form of acids, with addition of chloroacetic acid (5 wt %) to the solvent system.

The choice of chloroacetic acid was governed by its good solubility in organic solvents and sufficiently strong acidity for converting the antibiotics into the acid form: for chloroacetic acid pK_a 2.87 [30], whereas for the carboxy group of penicillins pK_a 3.04 (BP), 2.79 (CC), and 2.96 (AP) [31].

Freshly prepared 5 mg ml^{-1} solutions of the antibiotics were applied to the start line on the pretreated paper with a glass capillary. The paper was dried and placed in a chromatographic chamber for 6 h. The eluent front moved in this time by 75–85 mm. The resulting chromatogram was dried in air and developed in iodine vapor by placing it for a few minutes in a closed vessel containing crystalline iodine on the bottom. The developed chromatogram contains spots ~8 mm in diameter of almost regular round shape.

Chromatographic mobility (R_f) of penicillins

Mobile phase	AP	BP	CC
Acetone–ethanol (1 : 1)	0.05	0.04	0.06
1-Butanol–ethanol–water (4 : 1 : 5)	0.09	0.10	0.09
1-Butanol–acetic acid–water (4 : 1 : 5)	0.43	0.44	0.45
2-Propanol–ethanol (3 : 7)	0.44	0	0
Diethyl ether	0.08	0.09	0.08
CCl_4–chloroacetic acid (95 : 5)	0.16	0.18	0.20
Diethyl ether–chloroacetic acid (95 : 5)	0.10	0.08	0
Ethyl acetate–chloroacetic acid (95 : 5)	0.13	0.19	0.17
Acetone–chloroacetic acid (95 : 5)	0.07	0.10	0.09
Ethanol–chloroacetic acid (95 : 5)	0.89	0.87	0.93
Ethyl acetate–CCl_4–chloroacetic acid (47.5 : 47.5 : 5)	0.15	0.18	0.19
Ethanol–CCl_4–chloroacetic acid (47.5 : 47.5 : 5)	0.18	0.18	0.21
Ethanol–ethyl acetate–chloroacetic acid (47.5 : 47.5 : 5)	0.16	0.18	0.20
Ethanol–water–chloroacetic acid:			
20 : 75 : 5	0.61	0.62	0.55
35 : 60 : 5	0.65	0.67	0.59
47.5 : 47.5 : 5	0.69	0.71	0.61
60 : 35 : 5	0.71	0.72	0.63
75 : 20 : 5	0.83	0.75	0.70

We tested the following individual organic solvents: CCl_4, diethyl ether, ethyl acetate, acetone, and ethanol. With the borate buffer solution, the results were unsuccessful; R_f was zero in all the cases. Separation of the antibiotics was attained in acidic mobile phases (see table). The best results were obtained with the ethanol–chloroacetic acid (95 : 5) system. The use of mixed organic solvents afforded no significant advantages, compared to the individual solvents. We tested the following systems: ethyl acetate–CCl_4–chloroacetic acid (47.5 : 47.5 : 5), ethanol–CCl_4–chloroacetic acid (47.5 : 47.5 : 5), and ethanol–ethyl acetate–chloroacetic acid (47.5 : 47.5 : 5). The larger difference between BP, AP, and CC in R_f was attained only with the ethanol–water–chloroacetic acid system. The best component ratio is 75 : 20 : 5.

CONCLUSION

Penicillins are better separated by paper chromatography in the form of acids rather than anions. A procedure was developed for selective determination of benzylpenicillin, ampicillin, and carbenicillin by paper chromatography.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Changes in the Structure of Wool Fiber in Dyeing in a Redox Medium

O. V. Petrova, S. F. Grebennikov, and A. A. Burinskaya

St. Petersburg State University of Technology and Design, St. Petersburg, Russia

Received December 29, 2004

Abstract—The suitability of redox systems for wool dyeing with acid and active dyes at temperatures below the boiling point of the dyeing solutions was studied. The influence of the hydrogen peroxide–reductant (glucose, ethylene glycol, 1,2,3-propanetriol, polyoxymethylene, and hexamethylenetetramine) systems on the surface of wool roving was elucidated.

Finishing of wool fiber fabrics governs to a significant extent the quality and competitiveness of ready-for-use textile articles. As is known, wool preliminarily damaged by dyeing, light exposure, and high temperatures, as well as by alkalis, chlorine, and oxidants, is especially sensitive to mechanical loads (pressure, twisting, shear). Mechanical treatment of wool fibers causes various transverse and longitudinal cracks, depending on the moisture content of the fibers. These cracks are responsible for dust formation upon degradation of the cuticle when treated on fast rotating machines, which poses risks on human health. Most of the wool lint is formed in the yarn production stage. However, wool dyeing causes respiratory tract diseases more often than other jobs do, because dyed yarn exceeds undyed yarn in the dust content [1].

Wool is traditionally dyed at the boiling temperature of the dyeing solution, which may lead to inefficient use of raw materials and energy. Therefore, it is of great practical importance to develop processes for low-temperature dyeing of wool, which damage the fiber and contaminate the environment to a lesser extent and are more energy-efficient. Low-temperature dyeing can be performed with the use of redox systems, tems, which allows the temperature at which the wool fiber is dyed with acid and active dyes to be lowered from the boiling point of the solution to 80°C, and the treatment time, to be made a factor of 1.5–2 shorter [2].

In this study, we took as dyeing intensifiers hydrogen peroxide–reductant systems with glucose (system no. 1), ethylene glycol (system no. 2), 1,2,3-propanetriol (system no. 3), polyoxymethylene (system no. 4), and hexamethylenetetramine (system no. 5) as reductants.

When introduced into a dye bath, reagents with high redox potentials cause degradation of the wool fiber and, possibly, of the chromophore system of the dyes. In this context, we studied how the above systems affect the structure of the wool substrate. To determine the optimal oxidant : reducer ratio in the systems, we estimated the redox potentials of a number of intensifiers. The optimal concentration of the reductant, favoring the maximum sorption of acid and active dyes, is 0.0075–0.015 M [3]. The figure shows the electrochemical potentials at the actual concentrations of hydrogen peroxide and the reductant.

Undyed sample	15.55			

The concentrations of the components in the systems constituted by hydrogen peroxide and a reducing agent correspond to the stoichiometric ratios in the equations of the redox reactions at the initial H_2O_2 concentrations of 0.0075 (system no. 1), 0.03 (system nos. 2 and 3), and 0.022 M (system nos. 4 and 5). The optimal concentration of the reductant in the redox systems corresponds to the electrochemical potential of 129–210 mV.

We studied by sorption methods (sorption of benzene and water vapors, as well as of iodine from a 0.2 wt % solution) how the redox systems affect the surface properties of the wool fiber [4]. The choice of specifically these substances was dictated by the fact that benzene is an inert sorbate for wool [5], characterizing the total volume of micro- and mesopores. Water causes wool to swell, and the sorption at a relative pressure P/P_0 = 0.3–0.4 is proportional to the amount of active (polar) centers in the free volume of the wool. At $P/P_0 \to 1$, like in the case of aqueous solutions in dyeing, swelling is accompanied by cleavage of intermolecular physical bonds, and the sorption value characterizes the total amount of polar groups in the amorphous domains of the polymer [6]. Tables 1 and 2 present the measured sorption of benzene and water vapor by the wool fiber dyed with Acid Bordeaux and Active Scarlet 4ZhT dyes at 80°C using the redox systems and by boiling of dyeing solutions without intensifiers.

The data in the tables show that, in the presence of the intensifiers, sorption of benzene vapor by the wool fiber dyed at 80°C with acid and active dyes is lower than that in the case of samples dyed with the same dyes by boiling the solution without intensifying ad-

Table 3. Sorption *a* of iodine by the wool fiber

5	16.38	10.88	10.6

ditives. This suggests strengthening of the surface of the wool fiber dyed in the presence of the redox systems, since the dye and the intensifier have filled a significant pore volume. The redox systems act, presumably, via generation of free radicals in the reaction of the reductant with hydrogen peroxide, which detach labile hydrogen atoms from the amine and carboxy groups of the polymer substrate and dye molecules. Recombination of the macroradicals on the wool fiber surface strongly increases its activity, and the dye sorption by the fiber tends to grow. This is supported by the results of our previous studies [3].

A decrease in the water sorption by the dyed wool fiber, compared to the undyed fiber, suggests that the dye and the intensifiers penetrate into the polymer bulk. They block polar groups, both those occurring in the free volume of the polymer and "released" by the wool fiber swelling. It is also possible that, in the presence of the redox systems, the hydrophobic scaly layer (exocuticle) of the wool fiber partly degrades (as it occurs under the action of a low-temperature plasma [7]), which leads to an increase in the size of the hydrophilically bound segments on the fiber. The diffusion barrier for dye molecules is mainly due to the hydrophobic nature of the exocuticle, resulting from the presence of a large number of disulfide bridges, and to the lipid material {isodipeptide bonds [ε-(γ-glutamyl)lysine]} whose degradation allows spreading of dye molecules and their retention on the fiber surface, which can also be responsible for the enhanced sorption and diffusion of the dyes into the fiber.

The possible degradation of the scaly layer is suggested by the value of iodine sorption from a 0.2% solution by the undyed wool fiber pretreated with the redox systems and dyed in the presence of these systems (Table 3).

The enhanced iodine sorption by the undyed wool fiber pretreated with the redox systems, compared to the untreated fiber, also confirms the influence of the intensifiers on the polymer, which causes its swelling. A decrease in the iodine sorption by the wool fiber dyed at 80°C in the presence of the redox systems, compared to the fiber treated by the conventional procedure (boiling of the dyeing solution without intensifiers), suggests that additional active centers in the wool fiber and new bonds are formed. The performance of the intensifiers tends to improve in the series H_2O_2–hexamethylenetetramine < H_2O_2–polyoxymethylene < H_2O_2–1,2,3-propanetriol < H_2O_2–ethylene glycol < H_2O_2–glucose. However, the strength properties of the wool fiber do not decrease, compared to that treated at the boiling temperature of the dyeing solution. This is due to the fact that the radicals yielded by the reaction between the reductant and oxidant favor formation of new cross-links both within the fiber and with the dye molecules, as confirmed by our previous studies [8, 9].

CONCLUSION

The redox systems studied, taken in the revealed optimal concentrations, intensify wool dyeing and allow the wool to be dyed with acid and active dyes at temperatures below the boiling temperature of the dyeing solution, with the fiber strength preserved.

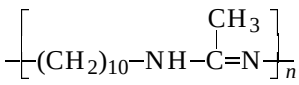
MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Supramolecular Structure of the Polyamidine–Bisphenol System

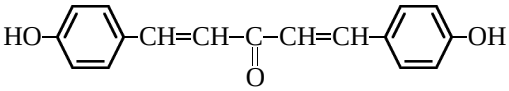
M. N. Nikolaeva and A. Yu. Osadchev

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia



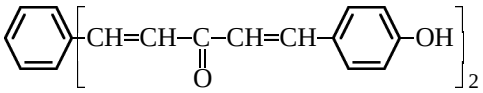
Received December 9, 2004

Abstract—Supramolecular organization of poly-1,10-decamethyleneacetamidine complexes with low-molecular-weight bisphenols was studied by the ^{1}H nuclear magnetic relaxation and UV spectroscopy.



Noncovalent bonded networks are promising materials for development of new type polymer systems exhibiting nonlinear optical properties [1]. It is known that hydrogen-bonded polymer networks formed in the interaction of polymers of the polyamidine type with dyes of the bisphenol type can also exhibit nonlinear optical properties [2]. Therefore, a study of the supramolecular structure of these polymer systems is of particular interest. It is known [3, 4] that the hydrogen bond is formed between polyamidine molecules and also between polyamidine and bisphenol (**II**) molecules both through the peripheral hydroxo group of the dye and through the lateral hydroxo group of the quinoid form of the dye or keto group of its main form [5] (structural formulas **IIa** and **IIb**). However, the mobility and strength of interchain interactions of the polyamidine are mainly governed by the interactions of the peripheral hydroxy groups of bisphenols.

EXPERIMENTAL



We studied the interaction of poly-1,10-decamethyleneacetamidine (hereinafter, polyamidine)

with the following low-molecular-weight additives: phenol (**I**), bis-(4-hydroxybenzylidene)acetone (**II**)

and 1,4-bis[5-(4-hydroxyphenyl)-3-oxopenta-1,4-dien-1-yl]benzene (**III**)

Synthesis and characteristics of poly-1,10-decamethyleneacetamidine were described in [6].

The degree of polymerization of the polyamidine n = 50; glass transition point 4°C; melting point approximately 60°C [3]. The melting points of phenol **I**, bisphenol **II**, and bisphenol **III** are 43, 220, and 169°C, respectively.

We used the NMR relaxation method, which allows estimation of the mobility of polymer chains with proton-containing groups. Introduction of new compounds into the polymer composition alters the mobility of macromolecules and, hence, the NMR relaxation time. The relaxation data offer information on how the interaction of polymer chains changes [7]. Here, we studied the spin–spin relaxation time of polyamidine and its mixtures with low-molecular-weight additives. Bisphenols dissolve in the polyamidine melt. Poly-1,10-decamethyleneacetamidine and its mixtures with bisphenols and phenol were heated to 180°C and allowed to stand at this temperature for 15 min; then the samples were cooled to the melting point of polyamidine and the measurements began.

The mole fraction of the bisphenols in the mixture with the polyamidine was varied from 0.05 to 0.35. At these concentrations, the bisphenols are compatible with the polymer.

The spin–spin relaxation times of protons T_2 for polyamidine and a mixture of polyamidine with addition of low-molecular-weight bisphenols were measured in melts on an RRP-1 relaxometer in the temperature range 70–140°C. Each measurement was made

1070-4272/05/7804-0613 © 2005 Pleiades Publishing, Inc.

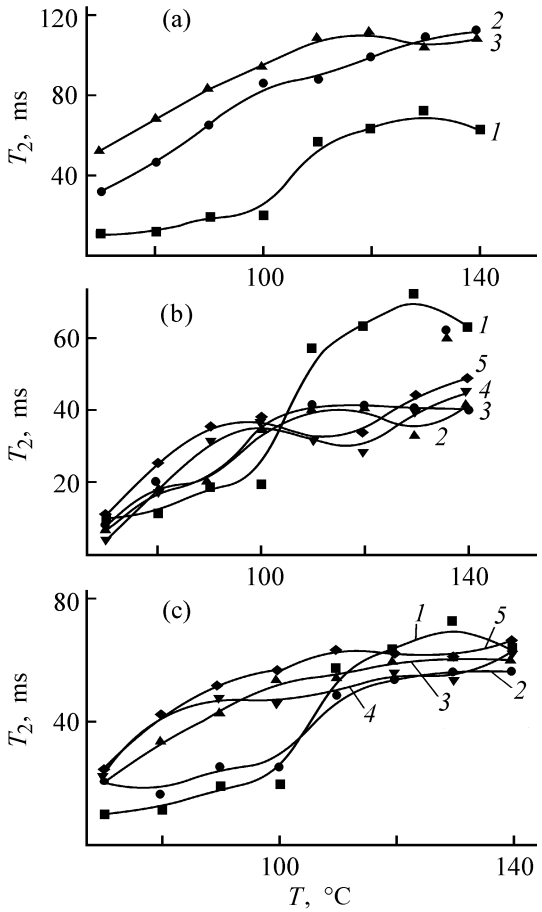


Fig. 1. Spin–spin relaxation time T_2 for mixtures of poly-1,10-decamethyleneacetamidine with (a) phenol **I**, (b) bisphenol **II**, and (c) bisphenol **III** vs. temperature T. (a) Mole fraction of phenol **I**: (*1*) 0, (*2*) 0.15, and (*3*) 0.3. (b) Mole fraction of bisphenol **II**: (*1*) 0, (*2*) 0.1, (*3*) 0.2, (*4*) 0.3, and (*5*) 0.35. (c) Mole fraction of bisphenol **III**: (*1*) 0, (*2*) 0.05, (*3*) 0.1, (*4*) 0.15, and (*5*) 0.2.

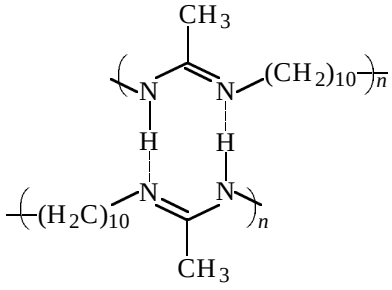
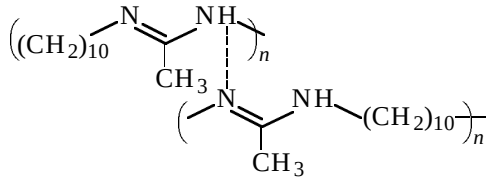
after a sample was kept at a given temperature for 15 min. The measurement error did not exceed 10%.

The spin–spin relaxation time T_2 was found from the decrease in magnetization after the action of a train of RF pulses $(\pi/2–\pi)_n$. The decrease in magnetization is usually described by one or two exponentials:



$$A(t) = A_1 \exp(-t/T_{2(1)}) + A_2 \exp(-t/T_{2(2)}),$$

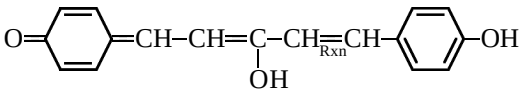
where $A_{1,2}$ are the initial amplitudes of the NMR signal and $A(t)$ is the amplitude of the NMR signal at instant of time t.



When the relaxation curve is described by one exponent, the medium is homogeneous in molecular mobility. Superposition of two exponents suggests the appearance of a component with a different molecular mobility [6].

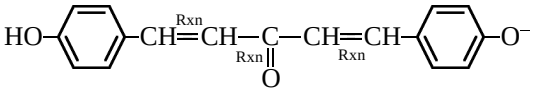
The UV spectrum was obtained on an SF-2000-01 spectrophotometer.

It is well known [7] that polyamidine forms interchain hydrogen bonds in *E-syn* (**a**) and *E-anti* (**b**) conformations of the amidine groups:



(**a**)

(**b**)



In the solid state, polyamidine has predominantly the *trans* conformation (**b**) [7].

For bisphenol **II**, the quinoid structure is

IIa

The deprotonated nonquinoid structure is

IIb

To estimate the influence of interchain hydrogen bonds in straight polyamidine on the spin–spin relaxation time, polyamidine was modified with phenol. Because of the presence of a hydroxy group, phenol can compete with interchain hydrogen bonds of polyamidine for formation of new hydrogen bonds. As a result of this interaction, comb-shaped polymer structures are formed. Addition of phenol to the melt decreases the viscosity of the polymer blend and the correlation time decreases. This is indicated by an increased relaxation time T_2 for polyamidine with addition of phenol as compared to straight polyamidine (Fig. 1a). Hence, a decrease in the spin–spin relaxation time for the straight polyamidine at a temperature above 130°C (Fig. 1a) suggests most likely a change

in the polyamidine conformation from *trans* to *cis*, since the prototropic tautomerism characteristic of the *cis* conformation [6] can accelerate the proton relaxation and, correspondingly, decrease T_2. The prototropic tautomerism is characterized by fast hoppings of proton through two bonds, and in the case of the polyamidine studied, from one nitrogen atom in the amidine group to another. On addition of phenol **I** (Fig. 1a) and bisphenols **II** and **III** to a polyamidine melt (Figs. 1b, 1c), a decrease in T_2 above 130°C was not observed or was insignificant, since it is likely that molecules of low-molecular-weight compounds, forming comb-shaped polymers and network structures, prevent mutual approach of the polyamidine polymer chains.

Rigid linear molecules of bisphenols in the polyamidine melt alter the strength of noncovalent interchain interactions in the polymer and thus the stability of the resulting network structure. These changes depend on the molecular weight of bisphenols. For example, with the molecular weight of bisphenol increasing from 274 (bisphenol **II**) to 422 (bisphenol **III**) (molecular weight of monomeric unit of polyamidine, 196), the relaxation time T_2 increases (Figs. 1b, 1c), since long molecules of bisphenol **III** can strongly separate the polymer chains. As shown previously [8], the relaxation time increases also upon addition of dihydroxydiphenyl, whose molecular weight is lower than that of bisphenol **II**. In this case, addition to the polymer of dihydroxydiphenyl, which has a lower acidity constant in comparison with polyimidine, so that only one group can be deprotonated, favors formation of comb-shaped structures rather than of a hydrogen-bonded polymer network.

The estimation of the thermodynamic compatibility of polyamidine with the bisphenols by the procedure described in [9] showed a high degree of compatibility of bisphenol **II** with polyamidine. The Hildebrand solubility parameter δ was calculated by the formula

$$\delta = \rho \Sigma F_i / M,$$

where ρ is the polymer density; M, molecular weight of the monomeric unit; and ΣF_i, sum of all molecular constants of attraction of chemical groups in the monomeric unit.

The calculated difference in solubility parameters δ for bisphenols **II** and **III** in polyamidine was approximately 7% (the solubility of bisphenol **II** is higher). The parameter of interaction, χ, of polyamidine with bisphenol **II** is 0.0027, which corresponds to the compatibility of the compounds at their ratio of 1 : 1 up to the degree of polymerization of approximately 750.

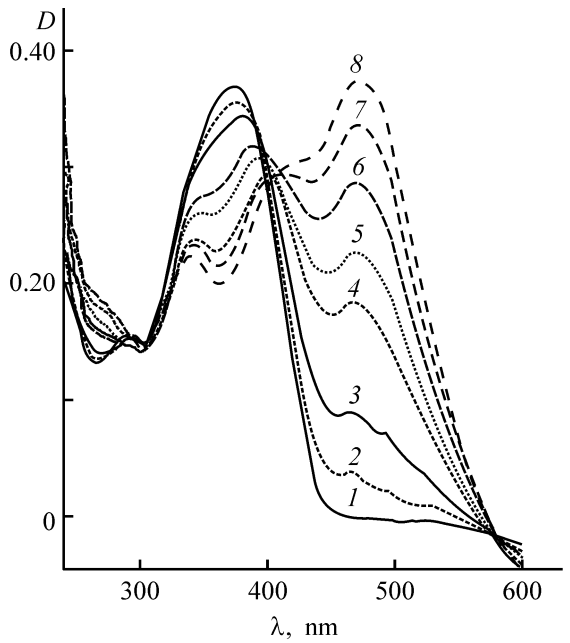


Fig. 2. Electronic spectra of bis(4-hydroxybenzylidene)-acetone in ethanol at various contents of poly-1,10-decamethyleneacetamidine. Concentration of bis(4-hydroxybenzylidene)acetone 1.97×10^{-7} M. (*D*) Optical density and (λ) wavelength. Molar ratio of hydroxy and amidine groups: (*1*) 1.9 : 0, (*2*) 1 : 2.6, (*3*) 1 : 5.2, (*4*) 1 : 7.8, (*5*) 1 : 10.4, (*6*) 1 : 13, (*7*) 1 : 15, and (*8*) 1 : 18.2.

Since the degree of polymerization of one of the components in the system is 50 and the second component is a monomer, the calculated value should differ from the true value. The presence of hydrogen bonds in the system complicated evaluation of the thermodynamic compatibility; therefore dynamic methods were to be used for its estimation. Here we used as such method NMR relaxation. Variation of the shape of the relaxation curve, with a second component appearing as the content of bisphenols in the polymer blend becomes higher suggests that phase segregation of the mixture occurs. This critical concentration (mole fraction) in polyamide is 0.3 for bisphenol **II**, and 0.2 for bisphenol **III**, i.e., the solubility of bisphenol **III** in the polymer is lower, which agrees with the calculation. The differences found can be caused by different molecular weights of the low-molecular-weight dyes, since they are closely related in their structure. The T_2 relaxation time was measured under the conditions of a thermodynamic compatibility of the components. Thus, an increase in the relaxation time T_2 upon addition of bisphenol **III** to polyamidine to a mole fraction of 0.20 is not caused by formation of the individual phase of dye, but is most likely due to an increase in the distance between the polymer chains.

The measured relaxation time is a quantity averaged over all the proton-containing groups in the sample, since the method is nonselective. Therefore, to elucidate the nature of interaction of bisphenols molecules with polyamidine, we used UV spectroscopy, with bisphenol **II** as an example. As shown previously [10], there are two absorption peaks at a 10^{-5} M concentration of dye **II** in an ethanol solution: the first with a maximum at 380 nm is due to absorption by free bisphenol **II**, and the second, to formation of a complex of polyamidine with the quinoid form of the dye. The spectra obtained in a dilute solution contain two peaks in the absorption band of bisphenol **II** (Fig. 2). One of these peaks is assigned to free dye molecules (330 nm), and the second, to monodeprotonated dye molecules of nonquinoid form bonded to the polymer (390 nm). This assignment of the resulting bands is quite reasonable, since the energy difference between these states (approximately 4.5 kcal mol^{-1}) is sufficiently large for a new intermolecular complex to be formed. In addition, it is known [7] that the content of the quinoid form of the dye in deuterated methanol at a sufficiently high concentration of the polyamidine is only 10%. Thus, the interaction of polyamidine and low-molecular-weight bisphenol in solution results in the formation of both comb-shaped polymers and network structures. Most likely, the similar structures should also exist in melts of polyamidine with bisphenols.

CONCLUSIONS

(1) The interaction of polyamidine and low-molecular-weight bisphenols in solutions and melts results in the formation of both comb-shaped polymers and network structures.

(2) The molecular sizes of rigid linear bisphenols are responsible for the differences in molecular mobility between the resulting network hydrogen-bonded polymer structures. The most stable hydrogen-bonded network of polyamidine is formed upon addition of bis-(4-hydroxybenzylidene)acetone to its melt. Addition of bisphenols with a higher {1,4-bis[5-(4- hydroxyphen-1-yl)-3-oxopenta-1,4-dienyl]benzene} or lower (dihydroxydiphenyl) molecular weight results in weakening of hydrogen bonds between the polymer chains and thus in lower stability of the resulting network structure.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Use of an Acrylic Dendron-containing Monomer in the Synthesis of a Macroporous Polymeric Material

G. N. Khimich and T. B. Tennikova

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

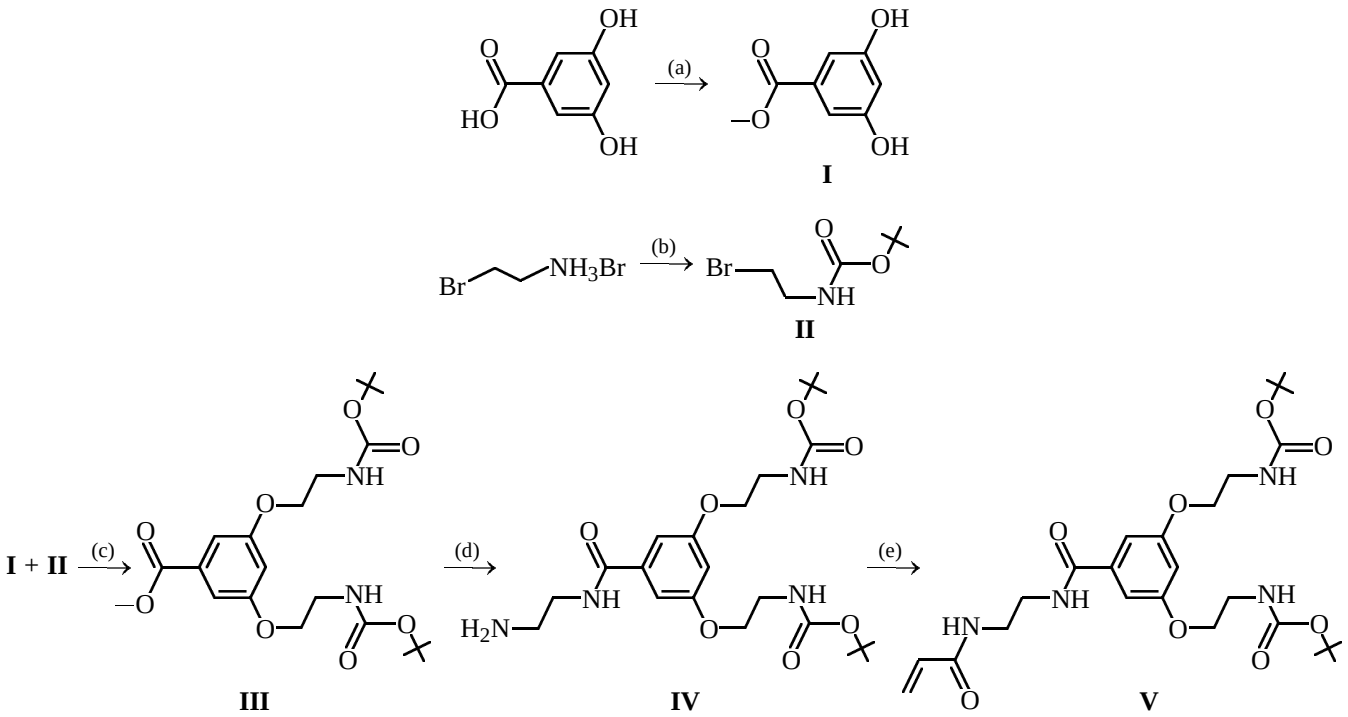
Received July 26, 2004; in final form, December 2004

Abstract—A procedure was developed for preparing a monolithic macroporous material by photoinitiated copolymerization of glycidyl methacrylate, ethylene glycol dimethacrylate, and an acrylic comonomer containing a dendron with protected terminal amino groups. The macropore formation is provided by a blowing agent.

Dendrimers and superbranched polymers were synthesized in the late 1980s. Active efforts are made today to find applications for dendrimers. For this purpose, numerous modified dendrons and dendrimers have been synthesized. The use of dendritic monomers as building blocks, along with linear monomers, substantially expanded the possibilities of macromolecular design and led to macromolecules of unusual architecture [1]. Incorporation of bulky dendrons into the polymer structure is of both basic and applied interest. The high degree of functional substitution of such polymers opens virtually unlimited opportunities for further transformations, which can lead to novel materials. Modification of the surface of macromolecules, with the aim to impart to them pronounced lyophilic or lyophobic properties, is also possible.

Dendron-containing polymers of several types have been synthesized: monodendrons with a polymer chain in the focal point [2]; dumbbell-like hybrids containing a polymer chain between two monodendrons [3, 4]; and dendron-containing polymers prepared by polymerization of dendron-containing monomers [5, 6].

The interest in dendron-containing polymers is due to the possibility of obtaining new speciality materials and using them in biology, medicine, and medical diagnostics [7, 8]. In particular, dendrimers are used for detecting oligonucleotides in DNA diagnostics [9, 10], and polynucleotide dendrimers with fluorescent markers, in microchip DNA diagnostics [11]. Dendritic polyvalent ions can be used to bind proteins [12].



However, only very few studies have been concerned with the possibility of using dendrimers and dendron-containing monomers for preparing modified sorbents [13, 14]. In particular, aliphatic highly branched poly alcohols were used for preparing polymeric chiral stationary phases by postmodification of a macroporous copolymer [13].

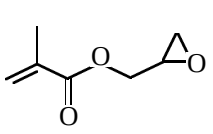
The use of vinyl monomers linked through spacers to dendrons containing various terminal groups may be a promising route to adsorption-active macroporous polymers.

Monolithic sorbents, a new generation of stationary phases, are prepared by copolymerization of monomers containing active groups whose high reactivity provides for easy functionalization of the internal surface of the sorbent [15, 16]. Macroporous flow-through layers based on a monolithic copolymer of glycidyl methacrylate (GMA) and ethylene glycol dimethacrylate (EDMA) were developed in the late 1980s–early 1990s [17–21]. Dendron-containing monomers seem promising for preparing functionalized macroporous polymers, since addition of even a small amount of a dendron-containing monomer allows the content of functional groups in the sorbent to be sharply increased. By varying the level of generation and the chemical nature of substituents on the external surface of a dendron molecule, and also by varying the length of a spacer linking the dendron to the acryloyl group, it is possible to control the characteristics of the resulting sorbents.

In the first step, we prepared an acrylic derivative of a dendron containing Boc-protected amino groups by controllable multistep synthesis:

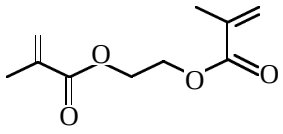
1070-4272/05/7804-0623 © 2005 Pleiades Publishing, Inc.

Steps: (a) MeOH, H^+; (b) Boc_2O; (c) $KHCO_3$, DMF; (d) $NH_2(CH_2)_2NH_2$; and (e) CH_2=CHCOCl, NEt_3.



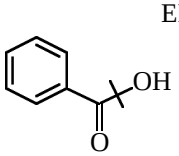
Methyl 3,5-di(2-*tert*-butoxycarbonylaminoethoxy)-benzoate **III** was prepared by alkylation of methyl 3,5-dihydroxybenzoate **I** with 2-(*tert*-butoxycarbonyl-amino)ethyl bromide **II**. It is known that compound **III** can be prepared in the presence of various catalysts [15, 16, 22, 23]. We performed alkylation in the presence of potassium carbonate, with DMF as solvent [15]. The reaction occurs at 40°C within 16 h; yield about 80%.

The starting compounds, methyl 3,5-dihydroxybenzoate **I** and 2-(*tert*-butoxycarbonylamino)ethyl bromide **II**, were prepared as follows: **I**, by esterification of 3,5-dihydroxybenzoic acid with methanol in acid solution [15]; **II**, by protection of the amino group of 2-bromoethylamine hydrobromide with di-*tert*-butyl pyrocarbonate [16].



We prepared previously unknown dendron of the first generation **IV** with the amino group at the focal point and terminal Boc-amino groups. To do this, methyl 3,5-di(2-*tert*-butoxycarbonylaminoethoxy)benzoate was treated with excess ethylenediamine at room temperature. The subsequent acylation of the NH_2 group in **IV** with acryloyl chloride in anhydrous methylene chloride in the presence of triethylamine at low temperature yielded dendritic monomer **V**. The structures of the compounds prepared were confirmed by ^{1}H NMR spectroscopy.

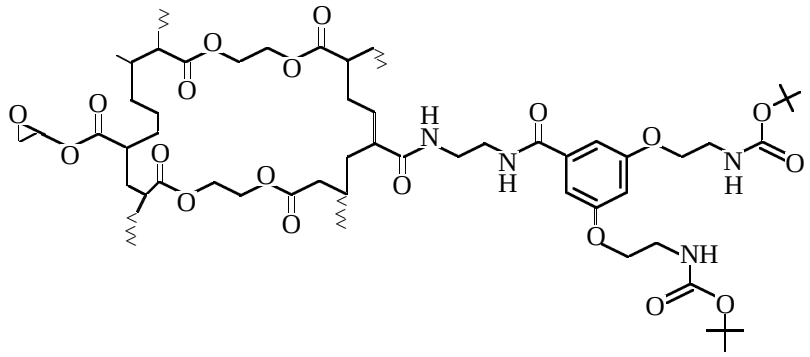
The porosity of monolithic sorbents depends on the monomer ratio, blowing agents used, and polymerization conditions [18]. Therefore, the participation of a dendron-containing monomer in copolymerization can affect the pore structure of the resulting material and, in particular, cause its ordering.



Monolithic macroporous polymers were prepared by radical photoinitiated copolymerization of EDMA, GMA, and acrylic comonomer **V** containing a dendron of the first generation. The reaction was performed in cyclohexanol (a solvent acting as blowing agent [19]) using 2,2-dimethyl-2-hydroxyacetophenone (Darocure 1173) as initiator of radical polymerization [24, 25]:

GMA

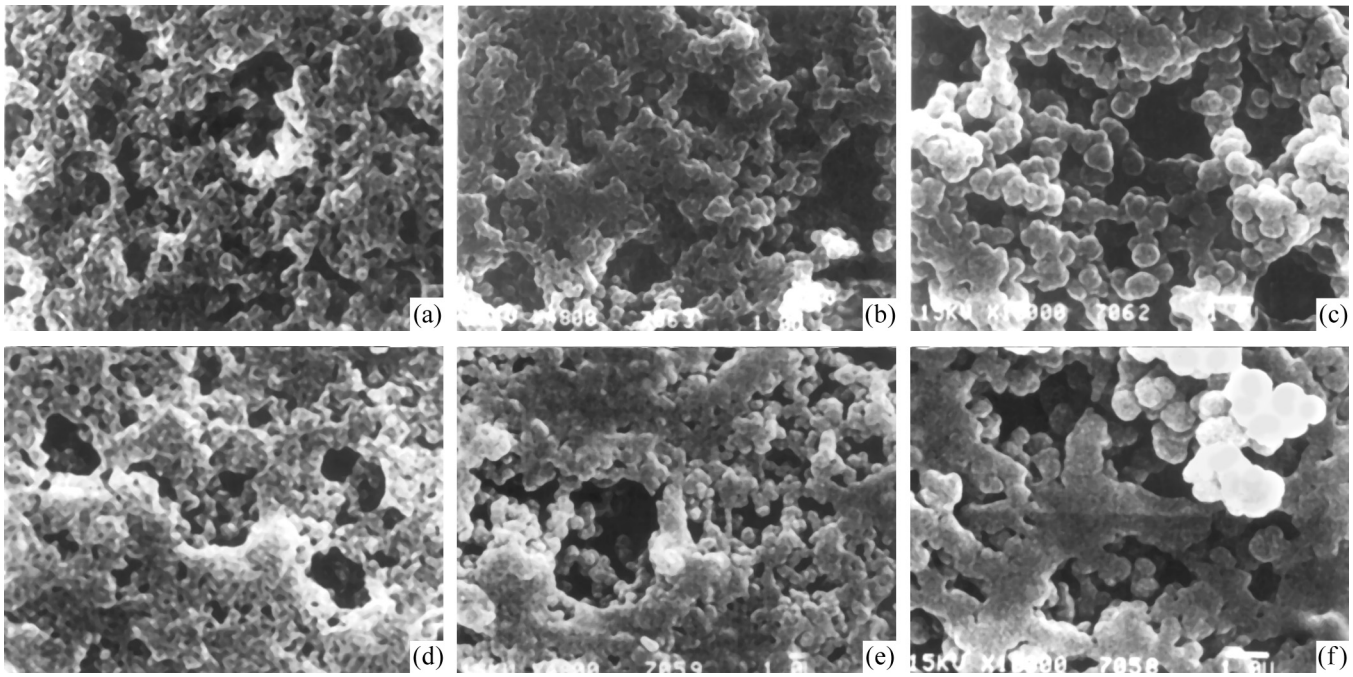
EDMA



Darocure 1173

We prepared the copolymers containing 10 and 20 mol % **V**.

The IR spectrum confirmed the involvement of the acrylic dendron-containing monomer in the copolymerization. The IR spectrum of the hybrid material contains absorption bands of the N–H (3340 cm^{-1}) and CO (1690 cm^{-1}, amide I; 1520 cm^{-1}, amide II) bonds.



A fragment of the assumed chemical structure of the resulting macroporous polymer is shown below:

The pore structure of the materials obtained was examined by electron microscopy. The polymer layers have a homogeneous internal morphology of the pores. Figure shows plane and cross-sectional electron micrographs of the samples. The polymer containing 10 wt % dendritic monomer has a looser structure. The time required for formation of such monolythic macroporous materials is longer than that for synthesis of GMA–EDMA polymers.

EXPERIMENTAL

GMA was purchased from Fluka (Switzerland); 2,2-dimethyl-2-hydroxyacetophenone, from Merck–Schuchard (Germany); EDMA, cyclohexanol, 3,5-dihydroxybenzoic acid, (2-bromoethyl)amine hydrobromide, and di-*tert*-butyl pyrocarbonate, from Sigma–Aldrich (Germany); and acryloyl chloride, from Reakhim (Russia).

Electron micrographs of microporous monolithic layers prepared by ternary copolymerization of GMA, EDMA, and acrylic monomer. Acrylic monomer content, wt %: (a–c) 10 and (d–f) 20. (a, d) Planar and (b, c, e, f) cross-sectional. Magnification: (a, b, d, e) ×4800 and (c, f) ×10000.

The ^{1}H NMR spectra were recorded on a Bruker AC300 spectrometer (300 MHz), with deuterated acetone as solvent.

The structural homogeneity of the monoliths was examined by scanning electron microscopy using a JSM-35CF device with cathodic sputtering of a 50–100-Å gold layer.

The IR spectra were measured with a Bruker IFS 88 spectrophotometer (KBr pellets). UV irradiation was performed with a 125-W mercury lamp having a broad radiation spectrum and constant intensity.

Methyl 3,5-di(2-*tert*-butoxycarbonylaminoethoxy)benzoate III. A mixture of 2.82 g (0.017 mol) of methyl 3,5-dihydroxybenzoate, 10.0 g (0.045 mol) of 2-(*tert*-butoxycarbonylamino)ethyl bromide, 10.58 g (0.0765 mol) of potassium carbonate, and 25 ml of DMF was stirred at 80°C for 4 h and left overnight. The precipitate was filtered off, and the solution was concentrated. The product was purified by preparative adsorption column chromatography. Yield 5.08 g (81.5%); colorless crystalline substance. ^{1}H NMR spectrum (acetone-d_6), δ, ppm: 1.47 s [18H, 2C(C$\underline{H}_3$)$_3$], 3.47 m (4H, 2C$\underline{H}_2$NH), 3.86 s (3H, CO$_2$C$\underline{H}_3$), 4.10 m (4H, 2OC$\underline{H}_2$), 6.25 br.s (1H, N$\underline{H}$Boc), 6.76 t (1H, Ar–H), 7.13 d (2H, Ar–H).

Found, %: C 57.98, H 7.81, N 6.21.

$C_{22}H_{34}N_2O_8$.

Calculated, %: C 58.14, H 7.54, N 6.16.

Dendron IV. A solution of 1.5 g (3.28 mmol) of methyl 3,5-di(2-*tert*-butoxycarbonylaminoethoxy)benzoate **III** in 15 ml of methanol was slowly added dropwise to 20 ml of ethylenediamine. The mixture was kept in the dark at room temperature for 3 days, after which the solvent and excess ethylenediamine were distilled off in a vacuum. The residue was dissolved in chloroform, washed with water, dried with sodium sulfate, and concentrated. Yield 1.06 g (67%); oily substance. ^{1}H NMR spectrum (acetone-d_6), δ, ppm: 1.45 s [18H, 2C(C$\underline{H}_3$)$_3$], 3.42 (6H, 2C$\underline{H}_2$NH), 3.60 m (2H, 2CH$_2$NH$\underline{H}_2$), 4.04 t (4H, 2OC$\underline{H}_2$), 6.64 t (1H, Ar–H), 7.05 d (2H, Ar–H).

Found, %: C 57.51, H 8.03, N 11.47.

$C_{23}H_{38}N_4O_7$.

Calculated, %: C 57.24, H 7.94, N 11.61.

Acrylic monomer V. To a solution of 0.31 g (0.64 mmol) of dendron **IV** in 5 ml of anhydrous methylene chloride, we added 0.073 g (0.72 mmol) of triethylamine and then, slowly with cooling to 0°C, 0.06 ml (0.66 mmol) of acryloyl chloride. The mixture was stirred for 30 min at 0°C and then for 3 h at room temperature. The reaction course was monitored by TLC. After the reaction was complete, 5 ml of methylene chloride was added, and the mixture was washed with water, dried over sodium sulfate, and concentrated; 0.151 g (44%) of **V** was obtained. ^{1}H NMR spectrum (acetone-d_6), δ, ppm: 1.45 s [18H, 2C(C$\underline{H}_3$)$_3$], 3.46 t (4H, 2C$\underline{H}_2$NH), 3.60 m (2H, 2CH$_2$NH$\underline{H}_2$), 3.82 s (4H, NHC$\underline{H}_2$C$\underline{H}_2$NH), 4.07 t (4H, 2OC$\underline{H}_2$), 5.52 d.d (1H, C$\underline{H}_2$=CH), 5.88 d.d (1H, CH$_2$=C$\underline{H}$), 6.3 d.d (1H, C$\underline{H}_2$=CH), 6.62 t (1H, Ar–H), 7.05 d (2H, Ar–H).

Found, %: C 58.23, H 7.68, N 10.27.

$C_{26}H_{40}N_4O_8$.

Calculated, %: C 58.19, H 7.51, N 10.44.

The radical polymerization of GMA, EDMA, and acrylic monomer (molar ratios 5.4 : 4 : 0.6 and 4.8 : 4 : 1.2) in cyclohexane in the presence of 0.5% Darocure 1173 was performed under the photoinitiation conditions for 1 h. After the reaction was complete, the polymers obtained were washed with ethanol and dried at 100°C.

CONCLUSIONS

(1) A procedure was developed for preparing dendron of the first generation with the amino group at the focal point and terminal Boc-amino groups and an acrylic monomer derived from it.

(2) A monolithic material can be prepared by photoinitiated ternary copolymerization of glycidyl methacrylate, ethylene glycol dimethacrylate, and an acrylic dendron-containing monomer in the presence of Darocure in a cyclohexanol solution.

(3) Scanning electron microscopy shows that the layers obtained have a homogeneous internal morphologhy of pores.

Abstract—Microheterogeneous structure and morphology of epoxy-based polymeric composites modified with polyvinylidene fluoride were studied.

Epoxy resins (ERs) are widely used as adhesives, structural materials, and coatings [1–8]. To accomplish the desired performance characteristics, both ER blends [8–11] and epoxy hardener mixtures [12–15] are used, with low- and high-molecular-weight organic and inorganic compounds as fillers [1, 3, 16–18]. Because of the broadening application area of such polymeric composites, more stringent requirements are imposed on their hardening conditions, physicochemical and mechanical properties, and, first of all, environmental safety. The latter is of particular importance for coatings and, specifically, for self-leveling floor finishes [16–20], which are used in immediate contact with humans.

Here we report on a study of composites based on blends of ERs of the epoxy-diphenylolpropane and aliphatic nature, which can be used as self-leveling floor finishes [18]. We studied the microheterogeneous structure and morphology of cured polymeric composites (PCs) modified with polyvinylidene fluoride (PVDF).

EXPERIMENTAL

In the study, we examined the epoxy resin blend composed of ED-20 (100 wt parts), DEG-1 (20 wt parts), and Oksilin (7 wt parts) (Ufakhimprom, Russia). Polyethylenepolyamine (PEPA) (RIAP, Ukraine) was used as an epoxy hardener (ER : PEPA = 1.0 : 0.17). The epoxy resin and hardener were used without further purification. Polyvinylidene fluoride (Aldrich) was added to the epoxy resin as a 10% solution in DMF, and the resulting mixture was stirred for 1 h. Then PEPA was added dropwise and the mixture was stirred for additional 30 min. The mixture was cast onto a Teflon support and cured for 72 h. The PVDF concentration in the system varied from 0.1 to 10 wt % (see table).

The microheterogeneous structure of the initial and PVDF-modified composites as $1.0 \times 0.50 \times 0.02$ cm plates was studied by small-angle X-ray scattering, using a KRM-1 camera with a collimating system meeting the condition of the infinite height of the primary beam [21, 22]. The measurements were carried out with monochromated Cu_{K_α} radiation (Ni foil filter), using a Kratky slit collimator [21]. The diffraction pattern was recorded with a scintillation detector in the automatic step-by-step scan mode. The measured scattering intensity was corrected for the primary beam attenuation factor for the test sample, which was followed by subtraction of the background scattering of the collimating system. Finally, the intensity thus

obtained was normalized to the scattering volume. The scattering profiles were then reduced to the point collimation by the Schmidt method [23, 24].

The surface morphology of the samples was studied on an REMMA-102 scanning electron microscope (X-ray electron probe microanalyzer) in the secondary electron emission mode (accelerating potential 15 kV; normal excitation of the condenser; horizontal arrangement of the sample; magnification in the range from 1000 to 10 000). The SEM micrographs were recorded in the format 512 × 512 pixels (512 scans per point), which provided optimal signal filtering and high-quality imaging.

Sample preparation for a morphological examination included pouring-over with a binder so that the sample face could be seen at the base of the washer thus obtained. Then the washer base was ground with emery-papers of progressively decreasing grain size and polished on opal glass and silk. The resulting "disturbed" surface layer of the composite was converted into the vapor phase by plasma ablation in a JEOL JFC-1100 device operating at 1.2 keV. The ablation products were removed from the surface during 2 h. The samples were etched for 1 h in a plasma with a low concentration of high-energy particles.

The sample surface was coated with a 30–50-nm gold layer (99.99 wt % purity) by cathode sputtering to enhance the contrast of the surface and also to remove the surface charge.

Figure 1 shows that the small-angle X-ray scattering intensity grows with increasing PVDF concentration in the composites, which is probably due to transition from the network structure of the polymer to the microheterogeneous structure of the composite. In this case, the nature of the polymeric composite changes from a strongly cross-linked polymer to a semi-interpenetrating polymer network (s-IPN), in which fragments of the PVDF macrochains penetrate into the network formed by the epoxy resins.

Generally, the microheterogeneity of the structure of the composites under study can be assessed by comparison of the scattering invariants Q (arb. units) of the initial and PVDF-modified composites, using Eq. (1) [25].

$$Q = \int_0^\infty q^2 I(q)\,\mathrm{d}q, \qquad (1)$$

where $q = (4\pi/\lambda)\sin\theta$ is the scattering vector (nm^{-1}); λ, X-ray wavelength (nm); 2θ, scattering angle (deg); and I, scattering intensity in the case of a point collimation of the primary beam (arb. units).

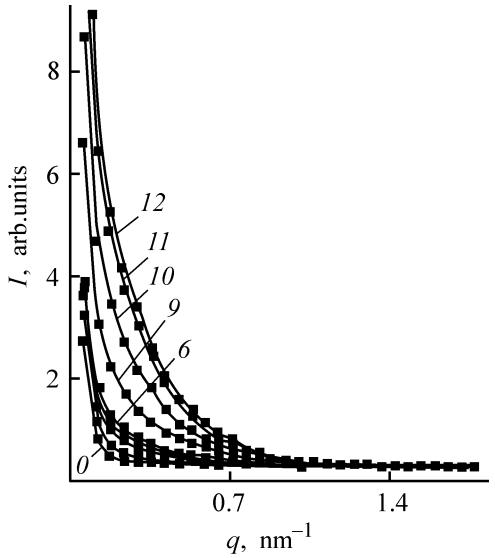

Fig. 1. Small-angle X-ray diffraction patterns of polymeric composites. (I) Scattering intensity and (q) scattering vector. *The numerals at the curves* correspond to the sample numbers in the table.

It is known that the parameter Q characterizes the scattering capacity of an object, being directly dependent on the mean-square fluctuation of the electron density $\overline{\Delta\rho^2}$, $(\mathrm{e\,nm^{-3}})^2$, in the bulk of two-phase systems, such as s-IPN.

$$Q = 2\pi^2 I_e V \overline{\Delta\rho^2}, \qquad (2)$$

where V is the scattering volume of the sample (nm^3); I_e, X-ray scattering intensity on single electron (nm^2); and $\overline{\Delta\rho}$, the parameter determined by Eq. (3).

$$\overline{\Delta\rho^2} = \varphi_1\varphi_2(\rho_1 - \rho_2)^2, \qquad (3)$$

where φ_i and ρ_i are the volume fraction ($\varphi_1 \le 1$) and electron density ($\mathrm{e\,nm^{-3}}$) of the ith phase [8].

The calculated concentration dependences of Q_i are shown in Fig. 2. The heterogeneity of the polymeric composites increases starting from the PVDF concentration in the matrix of 0.5 wt % and reaches the first maximum (Q_I) at 1.5 wt %. A decrease in the heterogeneity of the composites containing 1.75–2 wt % PVDF can be attributed to the onset of microphase segregation between the network and the foreign linear polymer.

At the same time, the lack of the interference peak in the scattering profiles of s-IPNs characterized by clearly pronounced steady rise in the heterogeneity for the composites containing 2.5–10 wt % PVDF sug-

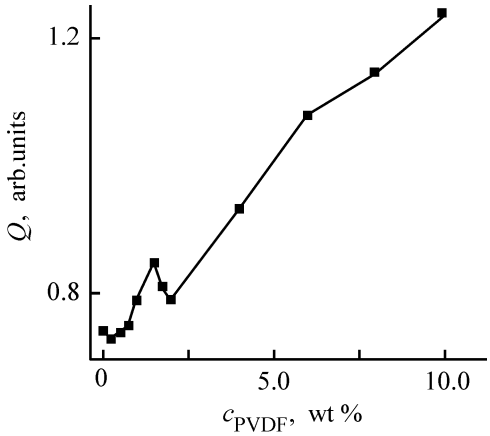

Fig. 2. Concentration dependence of the heterogeneity of the polymeric composites expressed via parameter *Q*. (c_{PVDF}) PVDF concentration in the composite.

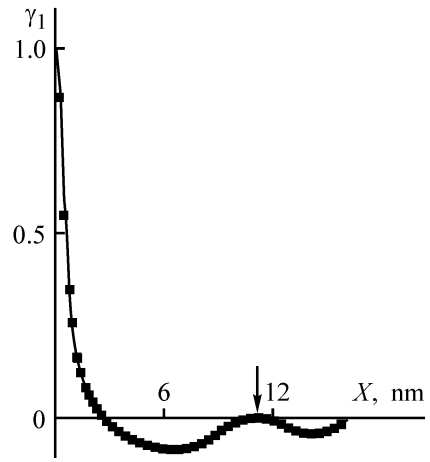

Fig. 3. One-dimensional correlation function γ_1 of the sample with 10 wt % PVDF. (*X*) Projection of the vector *r* in the real space onto the *x* axis.

gests a topological distribution of microheterogeneous domains in the bulk of the composites. Since PVDF is a partially crystalline polymer, and it can crystallize under microphase segregation conditions to form an individual phase, the lack of the diffuse peak in the scattering curve of the polymeric composites was somewhat surprising. However, this result can be accounted for by the plane anisotropy of PVDF crystallites. In this case, the 2*D* order controlled by the crystallization conditions in the network structure could give no peak in the small-angle scattering curve.

We analyzed the structure of the s-IPN with the optimally high level of heterogeneity (in accordance with Fig. 2 and table, this is sample no. 13 containing 10 wt % PVDF) using the one-dimensional correlation function for the electron density γ_1 [26]:

$$\gamma_1(x) = \frac{\int_0^\infty q^2 I(q)\cos(Xq)\,dq}{\int_0^\infty q^2 I(q)\,dq}, \quad (4)$$

where *X* is the projection of the vector *r* in the real space onto the *x* axis.

Figure 3 shows the one-dimensional correlation function of sample no. 13 (10 wt % PVDF). The lack of the positive maximum suggests no 1*D* order in arrangement of the domains of heterogeneity. However, the occurrence of the maximum with a peak value lying on the *x* axis at $X \sim 12$ (marked with an arrow in Fig. 3) shows that the most probable one-dimensional distance d_{1D} between the microdomains of heterogeneity amounts to 12 nm.

The size of the heterogeneity microdomains were estimated using two different approaches. First of all we determined the coherence length l_c (nm) from Eq. (5) [25]:

$$l_c = \frac{1}{\pi}\frac{\int_0^\infty \tilde{I}(q)\,dq}{\int_0^\infty q\tilde{I}(q)\,dq}, \quad (5)$$

where $\tilde{I}(q)$ is the intensity of primary beam scattering (arb. u.) for the slit collimation.

It follows from the table that l_c increases in parallel with the PVDF concentration in the composite.

The second parameter characterizing the microheterogeneous structure of the polymeric composites is the heterogeneity range l_g (nm), which is directly related to the mean diameter of the heterogeneity microdomains with different electron densities via Eq. (6) [25, 27]:

$$l_g = \varphi_2\langle l_1\rangle = \varphi_1\langle l_2\rangle, \quad (6)$$

where φ_1, φ_2 and l_1, l_2 (nm) are the volume fractions and sizes of the heterogeneity microdomains of the first and second kinds.

The parameter l_g was estimated by the method described in [27]. It also follows from the estimated l_g for s-IPNs containing 4–10 wt % PVDF (see table) that the size of the heterogeneous microdomains with increasing fraction of the linear polymer.

It is well known that curing of polyepoxides is front-propagating after the system reaches the gelation point [28]. It is clear that, after a time, the abruptly increasing viscosity of the 3*D* network starts to decel-

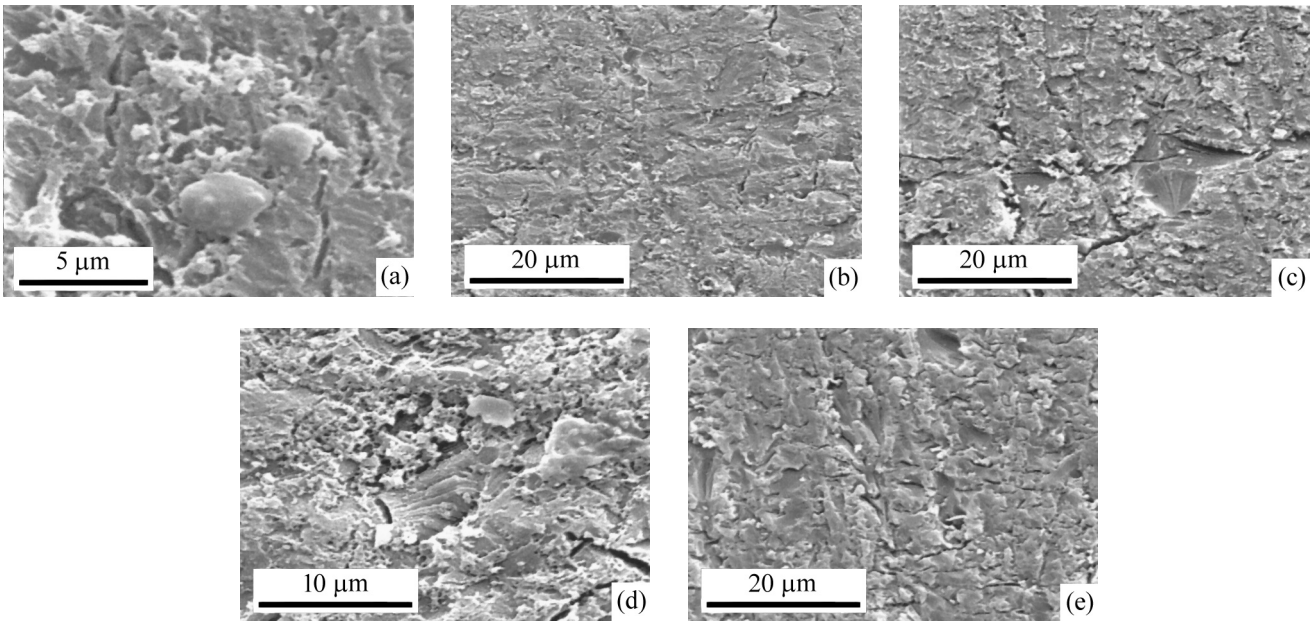

Fig. 4. Micrographs of polymeric composites. PVDF concentration (wt %): (a) 0, (b) 1.5, (c) 2, (d) 6, and (e) 8.

erate the polyaddition reaction between the diamines and polyepoxides, and, unless additional measures are taken, the reaction stops at a conversion level of about 69 mol %. Here two points should be taken into account. First, the high reactivity of the epoxy groups and aliphatic amines can warm the reaction mass up to 200°C in the initial stage [28], which will result in build up of stresses in the cured composite and in microcracking. This is illustrated by Fig. 4a, in which microcracks are clearly seen on the surface of the initial composite. Analysis of the morphology of the composites shows that its structure is inhomogeneous. This conclusion is supported by the second fact manifested in the course of propagation of the gelation front: the front of addition polymerization by passes some regions, which remain in the sol state, i.e., uncured. The size of the sol domains is about 4 μm (Fig. 4a).

Figure 4b shows the surface morphology of sample no. 5. It is seen that the structure of this composite includes not only the epoxy matrix, but also ordered regions and dips of various sizes and shapes. The ordered domains can be identified as PVDF inclusions. The dips most likely correspond to uncured zones of the epoxy resin, which is consistent with the conclusions drawn in [29] that, in the first 48–72 h, the conversion of epoxy resins based on Bisphenol A diglycidyl ether with aliphatic diamines does not exceed 60–70% recalculated to the amount of reactive group. It may be also suggested that some of the elements of the morphological profile are composed of the PVDF phase, which is confirmed by the X-ray diffraction data. This conclusion is also supported by the fact that the constituents of the composite, epoxy resin and PVDF, are strongly different in their molecular weight (MW 400 – 600 and 7×10^4, respectively), and, being thermodynamically incompatible [30], tend to undergo microphase seqregation, which is illustrated by Fig. 4c (2 wt % PVDF).

The microdomains of the PVDF phase in the 3*D* network of the epoxy resin are clearly seen in the micrograph of the sample with 6 wt % PVDF (Fig. 4d). In this case, the morphological elements have an individual structure in the form of divergent lamellas (× 3000). At a larger magnification (× 6000), it is seen that the inclusion is formed by scalene trapezia delimited from one side by the boundary (crack) between incompatible microphases.

Comparison of the micrographs presented in Figs. 4e and 4b shows how an increase in the PVDF concentration in the epoxy matrix to 8 wt % fundamentally changes the composite surface. First of all, it is seen that, with increasing PVDF concentration, its microphases are fused and run to the surface, forming layers and healing the microcracks in the polymer matrix.

CONCLUSIONS

(1) A steady increase in the polyvinylidene fluoride concentration in the epoxy matrix from 0.1 to 10 wt % is accompanied by an abrupt change in

the degree of heterogeneity in the concentration range 1–1.75 wt %, which is probably due to incompatibility of the 3*D* chemical network with the linear high-molecular-weight polymer.

(2) Further increase in the polyvinylidene fluoride fraction in the matrix is accompanied by a rise in the heterogeneity of the polymeric composite material as a result of transition from the network polymer, having a typical homogeneous structure, to a polymeric composite with clearly pronounced microheterogeneity.

(3) Fragments of the polyvinylidene fluoride chains displaced by the network elements can fill up cracks in the epoxy matrix, thus forming a microphase. In this case, a distortion of the network structure will result not in degradation, but in healing of its defects, as demonstrated by the morphological data.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Curing of Epoxy-containing Oligomers with Oxidized Carbon Black

S. A. Imankulova, N. B. Kondrashev, and V. A. Val'tsifer

Institute of Technical Chemistry, Ural Division, Russian Academy of Sciences, Perm, Russia

Received October 5, 2004; in final form, February 2005

Abstract—The physical properties of polymeric composites based on polydieneurethane-diepoxide and filled with particles of carbon black of various degrees of oxidation were studied.

Modern composite materials are not only multiphase in the polymeric composition but also contain mineral fillers, which determines nonuniformity of the polymer–inorganic phase boundary. Thus, filled composites can be regarded as a micrononuniform and microheterophase system.

The activity of a filler depends on its specific surface area, morphology, and chemical and energy characteristics of the surface; the interphase interaction with the polymer is determined by the specific surface area.

Since carbon black (CB) is widely used as highly active filler of polymeric materials [1–3], it seemed advisable to study the mechanical properties of the polymer as influenced by the acidity and content of oxygen-containing groups on the CB surface. Certain parts of the CB particle surface can be occupied by various functional groups appearing in the course of oxidation of the filler surface by atmospheric oxygen; just these parts can form strong chemical bonds with polymers. The chemical principles of formation of highly filled materials are poorly understood yet.

The goal of this study was to prepare epoxy-containing polymeric composites cured with surface functional groups of the filler (e.g., carbon black). This is a particular case of such a fundamental problem as study of processes in complex dispersion systems with a high content of the solid phase.

EXPERIMENTAL

The CB samples with similar particle-size distributions, but different degrees of the surface oxidation were prepared from low-active furnace carbon black (P-803 brand) prepared by thermal oxidative decomposition of liquid hydrocarbon raw materials. The CB samples were supplied by the Temp Scientific and Technical Center (Yaroslavl, Russia).

By varying the time of thermal oxidation of the initial CB by atmospheric oxygen at 500°C, we prepared samples with varied oxygen content (CB-1)–(CB-6).

The procedure for determining the content of oxygen-containing groups on the CB surface was based on the difference in their chemical activity. The total content of surface oxygen-containing acidic groups was determined by potentiometric titration with a strong (hydrochloric) acid of a CB suspension with an aqueous NaOH solution, and the content of carboxy groups, by titration of the CB suspension with an aqueous Na_2CO_3 solution, using an EV-74 pH-meter.

The mechanical tests were carried out with oligodiene-urethane–diepoxide (M 5000), which was mixed with a CB filler (30 wt %) and stirred for 30 min at 50°C under reduced pressure. The composition was cured for 10 days at 80°C, with no additional curing agents used.

The mechanical properties (elongation at break and strength) of the filled CB composites based on polydiene-urethane–diepoxide were determined on an R-5 2099 tensile-testing machine at various temperatures, with the measurement error of 5% according to GOST (State Standard) 270–75.

The degree of oxidation of the CB particle surface stongly affects the surface (sorption) properties and the structuring power of the CB [4]. The strength of the CB particles depends both on the micromosaic structure of the oxidized particle surface and on the

* Total acidity.

content of the initial aggregates formed by unchanged CB particles [4].

The surface layer of a CB particle can contain various chemical groups affecting its properties [5]. The chemical properties are determined by functional groups containing oxygen, hydrogen, and sulfur. The chemical composition of the surface is often characterized by the total content of oxygen and some individual oxygen-containing groups. Oxygen on the CB surface can occur in carboxy, phenol, quinoid, and lactone groups.

As can be seen from the table, the moderate CB oxidation increases the content of all the oxygen-containing groups. Further, more profound oxidation first increases the content of carboxy groups to 0.24% (CB-6), but then causes breakdown to CO and CO_2, which agrees with the following scheme of CB oxidation [6]

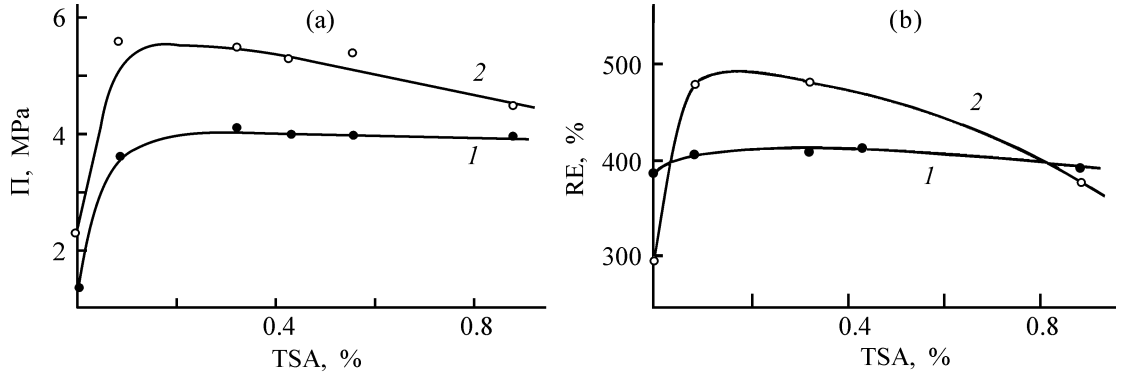
* Hydrocarbon radical from another molecule.

Our experimental data show that the strength of epoxy composites cured with CB depends on both the total acidity and the content of carboxy groups on the CB particle surface.

The dependences of the strength and strain of the cured epoxy samples on the total surface acidity are shown in Figs. 1a and 1b. As seen, the strength of cured composites is rather high, which suggests a chemical interaction between the functional surface groups on the CB particle surface and active functional groups of the oligomer to give a three-dimensional (3*D*) network of chemical bonds in the resulting material.

As can be seen from Fig. 1a, the strength of all the samples filled with CB particles is appreciable. However, the data on the swellability of the polydiene-urethane–diepoxide samples filled with unoxidized CB particles (CB-1) in various solvents show that they rapidly swell and dissolve in 3 days at room temperature. This fact indicates that there is no chemical interaction between unoxidized CB particles and epoxy oligomer, and the strength of these samples is probably due to their structuring caused by physical interactions.

The samples filled with CB particles with a total surface acidity of about 0.1% contain 3*D* networks of chemical bonds and show limited swelling in various solvents (the equilibrium swelling in toluene is 280%). Slight changes in the mechanical properties of the samples as influenced by the degree of surface oxidation agree with the insignificant changes in their swellability (from 270 to 290%). This fact confirms that the total acidity of 0.1% is sufficient to provide formation of a network of chemical bonds in the cured polymer, and its further increase does not affect noticeably the composite strength, i.e., only some frac-



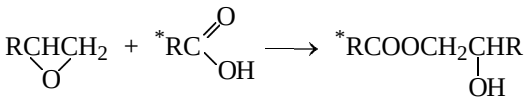


Fig. 1. (a) Strength Π and (b) relative elongation RE of cured epoxy oligomer filled with CB particles vs. the total surface acidity TSA at (*1*) 25 and (*2*) 40°C.

tion of the CB functional groups are involved in the formation of the 3*D* network in the polymer.

Most probably, the oligomer is cured by the reaction of the carboxy groups on the CB surface with epoxy groups of the oligomer [7, 8]

* Hydrocarbon radical from another molecule.

Thus, it is feasible to prepare filled epoxy composites cured only by functional groups present on the CB particle surface (without any other curing agents).

CONCLUSIONS

(1) Samples of carbon black with various degrees of surface oxidation were prepared by thermal oxidation with atmospheric oxygen.

(2) Functional groups formed on the surface of the carbon black affect curing of epoxy composites without addition of other curing agents.

Abstract—Features of radical copolymerization of *N*-vinyl-2-pyrrolidone with 2-hydroxyethyl methacrylate in the presence of azobis(isobutyronitrile) were studied. The copolymerization constants of these monomers were calculated. The structure of the resulting copolymer was confirmed. The composition, microstructure, and molecular-weight parameters of the copolymers were determined.

Polymeric *N*-vinylpyrrolidone (VP), polyvinylpyrrolidone, is widely used in medicine as detoxicant [1] and modifier of morphine, iodine [2], and silver [3]. VP copolymers are studied as carriers for antimicrobial [4], hormone-containing [5], and other pharmaceuticals [6] and haptens [7]. At the same time, poly-(2-hydroxyethyl methacrylate) (HEMA) exhibits a number of valuable medical and biological properties: its hydrogels can be used to immobilize various pharmaceuticals [8] and to produce contact lenses [9].

VP–HEMA copolymers with a combination of VP and HEMA units can be used as carriers of biologically active compounds since they are hydrophilic, low toxic, and biocompatible with blood and tissues of a living body. These properties are provided by primary hydroxy groups in the side unit of the copolymers.

At the same time, features of copolymerization of VP and HEMA and the microstructure and molecular-weight parameters of VP–HEMA copolymers are poorly understood. Here we studied these issues.

As can be seen from Fig. 1a, the copolymerization rate strongly depends on the initial concentration of the monomer mixture. The higher this concentration, the faster the copolymerization. The copolymerization of VP with HEMA in isopropanol (Fig. 1b) also accelerates as the HEMA concentration $[M_2]$ in the initial mixture becomes higher, which indicates that HEMA (M_2) is more reactive than VP in copolymerization.

In the first copolymerization steps, the concentration of HEMA (M_2) units in the copolymer is substantially higher than the HEMA concentration in the initial mixture. In the course of copolymerization, this

* In 2 h. ** Insoluble in water.

difference sharply decreases, which is typical of copolymerization of monomers strongly differing in polymerization activity (Fig. 2). The copolymers isolated at high conversions (83–88%) are enriched in HEMA units (Table 1). As can be seen from Fig. 2, the intrinsic viscosity of the copolymers increases with the monomer conversion. This is probably due to deceleration of unit termination at high viscosity of the reaction mixture. Water-soluble VP–HEMA copolymers containing 15.5 to 33.6 mol % HEMA (M_2) units can be obtained by varying the molar ratio of the monomer in the initial mixture (Table 1).

The copolymer structure was confirmed by IR and ^{1}H NMR spectroscopy. The IR spectrum of copolymer **Id** contains a strong absorption band of stretching vibrations of the carbonyl group of the pyrrolidone ring of VP units at 1674 cm^{-1} and the band of the C=O group of HEMA units at 1722 cm^{-1}. The bands of asymmetric and symmetric stretching vibrations of the ether $-\overset{|}{C}-O-\overset{|}{C}-$ group of HEMA units appear at 1079 and 1167 cm^{-1}, respectively. The broad band at 3411 cm^{-1} is due to stretching vibrations of the associated hydroxy group.

The ^{1}H NMR spectrum of copolymer **Ia** contains of both VP and HEMA units. The signals at 0.95 and 1.25 ppm are assigned to the methyl protons of HEMA units. A characteristic doublet at 2.0 and 2.5 ppm is due to protons of the $-CH_2-\overset{\|}{C}O-$ group of VP units. Strong signals at 3.2 and 3.65 ppm are assigned to the H_2C and $-CH-$ groups of VP units, respectively. The signal of the methylene protons of HEMA units is observed at 4.4 ppm. These data allow us to assign the following structure to the VP–HEMA copolymer

where m_1 = 66.4–84.5 and m_2 = 15.5–33.6 mol %.

At high conversions, M_{SD} of the copolymers containing up to 25–30 mol % HEMA is about 50 000 (Table 1). As the HEMA content increases to 40 mol %, MW grows by a factor of 2. This is due to the higher copolymerization activity of HEMA as compared to that of VP. When polymerization was terminated in 2 h, M_{SS} of the copolymer with a fairly high HEMA content (25.8 mol %) was 31 000. This molecular weight does not exceed the threshold molecular weight

40 : 60	0.016	0.082	0.821	1.19	11.00
25 : 75	0.004	0.045	0.907	1.09	21.1
10 : 90	0.0005	0.016	0.967	1.03	62.01

(40 000) of polymers used as carriers of biologically active compounds (BAC). The intrinsic viscosity of the copolymers prepared by 24-h copolymerization (Table 1) grows from 0.17 to 0.25 dl g^{-1}, in parallel with MW, with increasing the HEMA content.

The initial parameters for calculation of the copolymerization constants of VP (M_1) with HEMA (M_2) in isopropanol at 60°C, $[M_1^0 + M_2^0]$ = 10 wt % and [AIBN] = 1.0 wt % are listed in Table 2.

The copolymerization constants were calculated by Naio-Lewis differential equation [10] and by Fineman-Ross [11] and Kelen-Tudos [12] procedures. In the last two cases, the linear regression was computed by the least-squares method. In all cases, the calculated linear correlation coefficients were 0.998–0.999.

The copolymerization constants calculated taking into account the influence of the terminal unit are close in all the three cases (Table 3). These constants confirm that HEMA is more reactive than VP. The rate constant of the reaction of HEMA macroradical with HEMA monomer is approximately a factor of 23 higher than that of the reaction of VP macroradical with VP monomer. The parameter $1/r_1$, ehich characterized the ratio of the reactivity of HEMA to that of VP macroradical, shows that the reaction of HEMA with VP macroradical is faster than that with HEMA macroradical. The high values of the product r_1r_2 (Table 3) suggest that M_1 and M_2 units in the macromolecule do not tend to alternate (Table 4). By contrast, the probability of formation of HEMA microblocks separated by single VP units is high. This

assumption is confirmed by a calculation [13] of the probability of formation of the M_1–M_1, M_1–M_2, M_2–M_1, and M_2–M_2 structures in the polymeric unit at low conversion and of the average lengths $\bar{L}_1$ and $\bar{L}_2$ of the blocks consisting of M_1 and M_2, respectively. The results of these calculations are listed in Table 4. It can be seen that the probability of formation of the M_1–M_1 diad at $[M_1^0] : M_2^0] > [50] : [50]$ mol % sharply decreases, and $\bar{L}_1$ approaches unity. The probability of formation of M_2–M_2 diads sharply increases at the indicated molar ratio of the monomers and so does $\bar{L}_2$. At $[M_1^0] : M_2^0] = [10] : [90]$ mol %, $\bar{L}_2$ is 62. Analysis of the structure and composition of the copolymers reveals their compositional nonuniformity.

EXPERIMENTAL

N-Vinylpyrrolidone was three times distilled in a vacuum from KOH. HEMA (Fluka) was double-distilled from molecular sieves in the presence of hydroquinone. Monomers of chromatographically pure grade were used. A gas-chromatographic analysis of the monomers was performed by the procedure described in [14]. Azobis(isobutyronitrile) was three times recrystallized form a chloroform–ethanol (1 : 5) mixture at temperatures lower than 40°C (mp 103°C).

VP–HEMA copolymer was prepared as follows. Weighed portions of the initiator, VP, HEMA, and isopropanol were loaded in a glass ampule pretreated with live steam. The ampule was purged with argon, sealed, and placed in a thermostat. The copolymerization was performed at 60°C. Then the ampule was cooled and opened. The viscous copolymer solution was poured dropwise into diethyl ether (200 ml). The precipitated copolymer was collected on a Schott filter and dried in a vacuum to constant weight. The yield and composition of the copolymer were determined. The composition was calculated from the nitrogen content, which, in turn, was determined on a Perkin–Elmer analyzer. When the conversion-vs.-time dependence was studied (Figs. 1, 2), the copolymerization was monitored gravimetrically.

The ^{1}H NMR spectrum of copolymer **Ia** was recorded in $CDCl_3$ on a Bruker AC-200 spectrometer. The IR spectrum of copolymer **Id** in a chloroform film was recorded on a JFS spectrometer.

The molecular properties of the copolymer in DMF solutions were studied by methods of molecular hydrodynamics. The intrinsic viscosity was measured on an Ostwald viscometer. Centrifugal sedimentation was performed on an MOM 3180 analytical ultracentrifuge (Hungary) at 45 000 rpm, using a refractometric registration system. The sedimentation boundary was produced by layering of a solvent onto the solution. The sedimentation coefficient was determined from the time dependence of the average shift of the sedimentation curves. The diffusion experiments were performed in a Tsvetkov diffusometer equipped with a polarization optical system. The diffusion coefficient D was calculated by the methods of areas and maximal ordinates. The molecular weights were calculated by the Svedberg equation [15]

$$M_{SD} = \frac{kT}{1 - \bar{\nu}\rho_0}\frac{S_0}{D},$$

where S_0 is the sedimentation constant; T, temperature; k, Boltzmann constant; ρ_0, solvent density; and $\bar{\nu}$, partial specific volume of the polymer.

The partial specific volume of copolymers, measured pycnometrically, was independent of the copolymer composition within the experimental error. The average partial specific volume ($\bar{\nu} = 0.84 \pm 0.06$ cm^3 g^{-1}) was close to that of PVP in various solvents [16].

CONCLUSIONS

(1) A copolymer of *N*-vinylpyrrolidone (M_1) with 2-hydroxyethyl methacrylate (M_2), prepared in isopropanol at 60°C in the presence of azobis(isobutyronitrile), is enriched in M_2 units.

(2) The constants of copolymerization of M_1 with M_2, determined by three methods, are as follows: $r_1 = 0.30 \pm 0.02$, $r_2 = 6.72 \pm 0.34$; $r_1 = 0.29 \pm 0.01$, $r_2 = 6.68 \pm 0.37$; $r_1 = 0.29 \pm 0.02$, $r_2 = 6.66 \pm 0.01$.

(3) The compositions, molecular weights, and microstructure of the copolymer confirm their compositional nonuniformity.

Abstract—Radical copolymerization of 1-vinylazoles with vinyl chloride and the composition and properties of the resulting copolymers were studied.

Polyvinyl chloride (PVC) and its copolymers (CPVCs) are among the most important macromolecular compounds. They are widely used for preparing plastic items, insulating materials, flexible films, pipes, and sheets. Copolymers of PVC with vinyl acetate and other monomers are starting substances for production of varnishes and adhesives [1, 2].

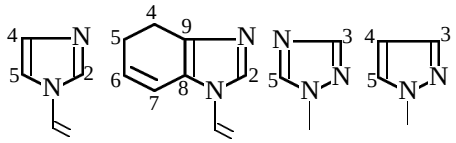
The applications and performance of copolymers are largely determined by their chemical nature. In particular, it is known that introduction of nitrogen-containing monomeric units into the PVC macromolecule improves the adhesive properties [3, 4]. Furthermore, nitrogen-containing monomeric units, as a rule, are internal plasticizers and are readily cross-linked at elevated temperatures, enhancing the cohesion of the material, which is particularly important for pasty formulations. At the same time, nitrogen-containing compounds can promote dehydrochlorination of PVC [1, 5]. Nevertheless, no special studies have been performed up to now to elucidate the influence exerted by the chemical nature of a comonomer on the degree of dehydrochlorination in the course of copolymerization.

In this study, we examined how the structure of the azole ring in 1-vinylazoles (VAZs) and the compositions of the starting mixture and the copolymer affect the dehydrochlorination in the course of copolymerization of vinyl chloride (VC) with 1-vinyl imidazole (VIM), 1-vinylbenzimidazole (VBI), 1-vinyl-1,2,4-triazole (VTA), and 1-vinylpyrazole (VPA).

EXPERIMENTAL

Copolymerization of the monomers in the bulk and in dimethylformamide (DMF) was performed in sealed ampules at 60°C in the presence of azobis(isobutyronitrile) (AIBN) under argon. After the polymerization was complete, the mixture was dissolved in DMF, and the copolymer was precipitated with ice-cold water. The reprecipitation was repeated twice. The copolymer composition was determined by elemental analysis, following the standard procedure [4].

The IR spectra were taken on a Specord IR-75 spectrometer in KBr and in mineral oil. The ^{13}C NMR spectra of copolymer samples were recorded on a Varian VXR-500S spectrometer (working frequency 125.5 MHz, relaxation delay 2.5 s, 90° pulse, solvent DMSO-d_6). As relaxant we used 0.02 M chromium tris(acetylacetonate). The relative error in quantitative determination of the comonomer content by NMR and elemental analysis of the copolymers did not exceed 6.7%.



The TG curves were taken on an MOM derivatograph (Hungary) in air at a heating rate of 5 deg min^{-1}. The maximum temperature was 700°C, and the DTA sensitivity, 1/5–1/10.

The IR spectra of the CPVCs contain stretching vibration bands of the azole rings and C–Cl bond (1480–1500 and 680 cm^{-1}, respectively); the bands of the VAZ vinyl fragments are absent. In the ^{13}C NMR spectra of the CPVCs, the signals of the vinyl groups of VAZs and VC are absent, but there are broadened signals assignable to the carbon atoms of the azole ring and the >CHCl, >N–CH_2–, and >CH_2 fragments. The chemical shifts of the carbon atoms in the VAZ and VC units of CPVCs are listed in Table 1.

The occurrence of dehydrochlorination in the course of the copolymerization was judged from the group of signals of the ~CH=CH~ fragment (128.03–127.58 ppm) in the ^{13}C NMR spectra of the samples.

The degree of dehydrochlorination Z is defined as follows [3]:

$$Z = A/(B + A),$$

where A is the content of the ~CH=CH~ units, and B, content of VC units.

The content of VC and ~CH=CH~ units in CPVCs was determined by quantitative ^{13}C NMR analysis (spectra, Table 1; anaytical data, Table 2).

Table 2 shows that the dehydrochlorination occurs in the copolymerization of VC with VIM and VBI. In the copolymerization of VC with VTA, HCl is eliminated only at a high content of the azole comonomer. The copolymerization of VC with VPA involves no side processes; in the ^{13}C NMR spectrum of the reaction products, the group of signals of the ~CH=CH~ fragment is absent. Thus, the occurrence of the dehydrochlorination depends on the nature of the comonomer (VAZ), specifically, on its basicity [4, 6].

Since VIM is the most basic (pK_{BH^+} 7.52) among the VAZs studied, the degree of dehydrochlorination in the VIM–VC system is the highest. Apparently, the dehydrochlorination occurs via formation of an intermediate complex in the macromolecular chain (for the scheme, see [3]). As the basicity of the pyridine-like nitrogen atom in VAZ increases, the hydrogen atom of the CH_2 group in VC becomes more labile, and the HCl elimination is facilitated.

It should be noted that the degree of dehydrochlorination in the systems of VC with VIM, VBI, and VTA (Table 2, run nos. 1, 2) grows as the VAZ content (both in the starting mixture and in the copolymer) increases.

1-Vinylpyrazole is the weakest base (pK_{BH^+} 1.70); therefore, the pyridine-like nitrogen atom of the pyrazole ring does not promote the HCl elimination. The absence of dehydrochlorination in the copolymerization of VPA and VTA (Table 2, run nos. 3 and 4) with VC indicates that DMF does not promote dehydrochlorination. At the same time, DMF is a polar aprotic solvent with appreciable basic properties, which should not be disregarded. Available data show that the dehydrochlorination of PVC in DMF is due to the presence in DMF of amine impurities (dimethylamine, ammonium formate) and to accumulation of the reaction products (HCl, Cl^-) in solution [5, 7]. Release of HCl is observed at high temperatures (>90°C). Freshly distilled DMF contains only minor amounts of dimethylamine and dimethylammonium formate (10^{-3}–10^{-2} M) [7]. In our experiments, we used freshly distilled DMF, and, apparently, minor amounts of these impurities did not promote the dehydrochlorination. Also, the copolymerization was performed at a lower temperature (60°C) than in [5, 7]. Examination of the composition of the VBI–VC copolymer showed that the eliminated HCl is fully bound to the pyridine-like nitrogen atom [3]. In the VTA–VC copolymers, HCl is also fully trapped by the heterocycle, with the formation of quaternized VTA units. This conclusion is based on a comparison of the copolymer compositions determined by chemical analysis (run no. 1, Table 2, found, %: C 48.85, H 5.81, N 39.74, Cl 5.60; run no. 2, Table 2, found, %: C 50.32, H 6.40, N 37.18, Cl 5.80) and by ^{13}C NMR spectroscopy on the assumption of complete binding of the eliminated HCl with the triazole ring (run no. 1, found, %: C 49.44, H 5.22, N 40.25, Cl 5.09; run no. 2, found, %: C 52.09, H 4.99, N 37.02, Cl 5.90).

Thus, experiments on radical copolymerization of VAZs with VC showed that the degree of dehydrochlorination depends on a particular VAZ, and with VPA the copolymers contain no polyene structures, i.e., ~CH=CH~; the eliminated HCl is fully trapped by the pyridine-like nitrogen atom in the heterocycle, which excludes the autocatalytic effect of HCl on the dehydrochlorination and is important for processing and use of VC-based copolymers.

To evaluate the modifying effect of VAZs on the properties of polyvinyl chloride materials, we studied some physicochemical and mechanical characteristics of the CPVCs prepared.

Introduction of units containing bulky heterocyclic substituents increases the distance between the main polymer chains and thus decreases the rigidity and the temperature of transition to the viscous-flow state; the solubility grows owing to distortion of the intermolecular interactions of the polar C–Cl groups.

Copolymerization of VAZs with VC in DMF yielded powdered products soluble in dimethyl sulfoxide (DMSO), DMF, C_6H_6, cyclohexanone, and a 1 : 2 : 3 (by volume) mixture of acetone, butyl acetate, and toluene. These polymers can be processed under milder conditions, compared to VC and vinylidene chloride homopolymers.

It is known that PVC and polyvinylidene chloride (PVDC) can form only dilute solutions (≤5 wt %) [1]. The limited solubility of these polymers makes their solutions unsuitable for preparing varnish coatings. The new CPVCs dissolve in a wider range of solvents and can form 50 wt % solutions, which meets the requirements to paint-and-varnish materials.

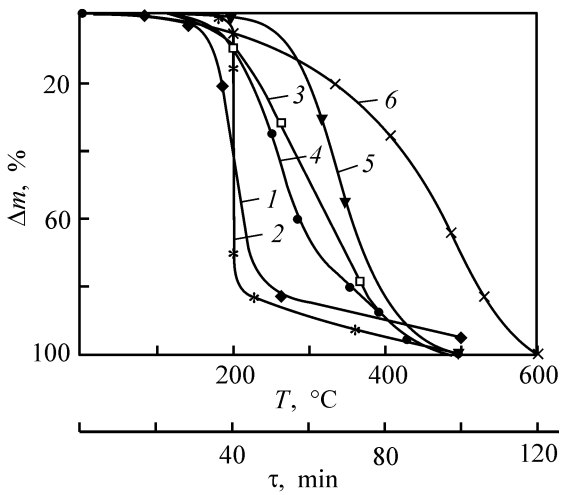

Table 3. Properties of coatings based on VC–VAZ copolymers

VAZ mole fraction in copolymer	Impact strength, kg cm	Bending strength, mm	Adhesion (notching method), points	
			grid	parallel
VTA–VC				
0.25	50	4	1	1
0.45	40	1	1	1
0.75	35	1	1	2
VPA–VC				
0.61	45	1	1	1
0.73	50	2	1	1
0.84	50	2	1	2

The varnish coaatings based on VTA–VC, VPA–VC, VBI–VC, and VIM–VC copolymers were tested for the strength and adhesion properties by standard procedures [8].

The best results, which are or practical interest, were obtained with coatings prepared from solutions of VTA–VC and VPA–VC copolymers. These coatings show good strength and adhesion properties (Table 3). Their impact strength is 40–50 kg cm, and bending strength, 1–2 mm. The adhesive properties of the varnish coatings were evaluated in points by the method of grid and parallel notchings.

Table 3 shows that the best results are obtained at the VTA mole fraction in VTA–VC copolymer of 0.25–0.45 and at the VPA mole fraction in VPA–VC copolymer of 0.61–0.73. The adhesion of the varnish coatings (method of parallel notchings) was 1 point, i.e., the copolymer coatings have high adhesion to metal surfaces.

Weight loss Δm by CPVCs. (T) Temperature and (τ) time. (*1*) PVC, (*2*) VBI–VC, (*3*) VTA–VC, (*4*) VPA–VC, (*5*) VIM–VC, and (*6*) VTGI–VC.

One of the most significant disadvantages of PVC is its instability at temperatures required for normal reprocessing. Degradation of PVC involves a set of different chemical processes occurring simultaneously in several directions. The main reaction is the intramolecular elimination of HCl resulting in formation of polyene systems, altering the color and impairing the performance of PVC.

The initial step of degradation of PVC and VC copolymers is autocatalytic elimination of HCl. Therefore, it becomes necessary to stabilize PVC with toxic agents (compounds of lead, cadmium, barium) belonging to hazard class 1, which is undesirable from the environmental viewpoint.

Raskulova *et al.* [9] studied the heat resistance of copolymers of VC with butyl vinyl ether (BVE). Despite the fact that BVE contains no functional groups that could bind the eliminated HCl, the heat resistance of VC–BVE copolymers appeared to be higher than that of suspension PVC (decomposition point 162.5°C). Raskulova et al. believe that the enhanced heat resistance of VC–BVE copolymers is exclusively due to the structural features (short VC blocks are separated by single units of the comonomer); this phenomenon was termed structural stabilization.

The presence in the copolymer of functional groups that can bind the released HCl should enhance its heat resistance. This was demonstrated by the example of VC copolymers with unsaturated glycidyl ethers [9]. The epoxy groups trap HCl, and the decomposition point of the copolymer is as high as 252°C.

The thermograms (see figure) show that the heat resistance of CPVCs is higher than that of suspension PVC. This is indicated by both the higher decomposition point of CPVCs (up to 193–217°C) and lower rate of their degradation. The cross-linked VIM–VC copolymer prepared in the bulk is thermally stable up to 290°C. For comparison, we also show the TG curve for a copolymer of VC with *N*-vinyl-4,5,6,7-tetrahydroindole (VTHI).

The enhanced heat resistance of the copolymers, compared to PVC, is apparently due to both internal and structural stabilization. It is known [4, 9] that the HCl elimination rate decreases with shortening of VC blocks. The internal stabilization is due to the pres-

ence of a nitrogen-containing heterocycle efficiently trapping HCl.

CONCLUSIONS

(1) Copolymers of vinyl chloride with 1-vinylazoles were prepared. The activity of the monomers in copolymerization with vinyl chloride increases in the order 1-vinylpyrazole, 1-vinylimidazole, 1-vinylbenzimidazole, 1-vinyl-1,2,4-triazole, as the polarity of the vinyl group, which depends on the number and mutual arrangement of the nitrogen atoms in the heteroring, becomes higher.

(2) Formation of the copolymers is accompanied by dehydrochlorination; its degree grows in parallel with an increase in the content of a 1-vinylazole and in its basicity. The released HCl reacts with the pyridine-like nitrogen atoms to form quaternized products, which suppresses the autocatalytic pathway of dehydrochlorination.

(3) The copolymers prepared surpass commercial polyvinyl chloride in heat resistance and solubility in organic solvents. Varnish coatings based on these copolymers exhibit good adhesion to metal surfaces and high strength.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Thermochemical Analysis of Cyanoethyl Ethers of Cellulose Blended with Polyacrylonitrile

Yu. N. Sazanov, L. I. Kutsenko, and A. V. Novoselova

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received January 11, 2005

Abstract—Thermochemical reactions of cyanoethyl ethers of cellulose with polyacrylonitrile in the temperature range of its cyclization were studied.

It is well known that polyacrylonitrile (PAN) is a unique polymer allowing production of carbon materials with a high coke number (CN) and shows by a high reactivity in polymer-analogous transformations in combinations with other macromolecular compounds. This feature has been noted in studying thermochemical reactions of PAN blended with nitrogen-containing polysaccharides (chitin, chitosan) and in a series of graft copolymers with cellulose ethers [1–5]. The above studies revealed the leading role of cyano groups in the formation of a carbon skeleton in the temperature range of increased reactivity of these groups, in which a series of occurring heterogeneous reactions initiate formation of a precursor of the carbonized network structure. The well-known procedures of directional cross-linking of the reaction mixture of copolymers and intermediates of thermal degradation allow the initial structures of carbonizates to be fixed and the yield of low-molecular-weight products to be minimized. Thus, real prerequisites arise for a noticeable increase in CN, for a decrease in the temperature and energy barrier of carbonizate formation, and for use of the potential of nitrogen atoms which, as shown previously [6–8], play a decisive role in formation of aromatic carbonizates from heteropolymers.

With the aim to raise the thermal stability of cellulose derivatives and also to produce carbonization products therefrom with specific characteristics and increased CN, we considered thermochemical reactions of cyanoethyl ethers of cellulose (CEC) and their blends with PAN. For this purpose, we used PAN synthesized in the presence of catalysts of the radical type and cyanoethyl derivatives of cellulose, synthesized by the well-known procedure [9] involving the reaction of viscose fiber CEC_1 [degree of substitution (DS) 2.8, degree of polymerization (DP) 300], CEC_2 (DS 2.3, DP 300), and finely crystalline cellulose with acrylonitrile.

Initially, to reveal the influence of cyano group on thermochemical transformations of cellulose, we used its cyanoethyl derivatives. As shown by TGA and DTA [10, 11] under conditions of heating of the sample (50 mg) at a constant rate of 10 deg min^{-1} in the self-generated medium (SGM), up to 225–250°C there is only insignificant weight loss (approximately 1.5–2.5%) caused by removal of adsorbed volatiles. Above these temperatures, thermal degradation starts, and its rate abruptly increases with heating. In this stage, we observed avalanche-like release of low-molecular-weight degradation products whose amount reached 70–75% of the total weight of the sample. Above 360–370°C, the residue gets carbonized, and this stage proceeds with a low and constant rate of weight loss until complete burning-out of the sample at approximately 800°C (Fig. 1a). For CEC_1 and CEC_2 samples, which differ in the degree of substitution with cyanoethyl groups, we observed small deviations from the above temperature-weight characteristics of the process, which did not noticeably affect the kinetics of CEC thermal degradation. Thermal effects for CEC_1 and CEC_2 samples in the range of 400–500°C can be assigned to melting of separate ordered fragments of the precarbonizate formed by transformations of the sample residue after completion of the oxidative reactions at 295–355°C. The reasons for its appearance should be looked for in studying spectral characteristics of these products in the initial stage of carbonization.

1070-4272/05/7804-0646 © 2005 Pleiades Publishing, Inc.

Returning to the problem of cocarbonization of CEC with PAN, we should note that, according to the DTA and TG curves of both polymers, the most favorable temperature range of these reactions is the range of intense degradation of the main chains of CEC and cyclization of PAN at 200–300°C. A blend of powdered CEC and PAN in a weight ratio of 1 : 1 (sample 1) and films prepared from mixed solutions at CEC : PAN weight ratios of 0.25 : 0.75 and 1 : 1 (sample nos. 2–4) were thermally treated under the same dynamic conditions. The TG and DTA curves of the blends recorded during heating in SGM are shown in Figs. 1a and 1b. It is seen that, in thermal degradation of the blends, there are stages of weight loss typical of both components of the blend. However, depending on the composition and aggregative state of the samples, the kinetics of their thermal degradation show significant differences, compared to the initial polymers. For example, the difference in CN for PAN and CEC at 800°C is almost 50%, and, for the blends at the CEC : PAN ratio of 1 : 1, CN varies from 40 to 30% (samples nos. 2–4). This difference indicates that PAN reacts with CEC during thermal cocarbonization and the degree of substitution of CEC strongly affects the process. In addition, the blends in the form of a powder and a film show a noticeable difference both in CN and in the weight loss Δm in the first stage of thermal degradation. Δm is 35% for sample no. 2, 14% for sample no. 3, and almost 40% for sample 4; this can be caused by differences in the procedure of preparation of the samples obtained by precipitation of a CEC–PAN blend from the solution (powdered precipitate) and by dry forming of a composite film from the dimethylformamide solution. In the thermochemical characteristics, sample no.1 is similar to PAN, since the weight fraction of CEC in this sample is 0.25; however, the influence of CEC is noticeable only in the first stage of thermal degradation (there is no abrupt weight loss at 200°C). In the subsequent stages of cocarbonization, the kinetics of weight loss (beginning at 300°C) almost exactly coincide with the kinetics of carbonization of PAN, and CN at 800°C even exceeds CN for PAN by 4%, i.e., for this sample the CEC structure is completely realized in the carbonized residue with PAN.

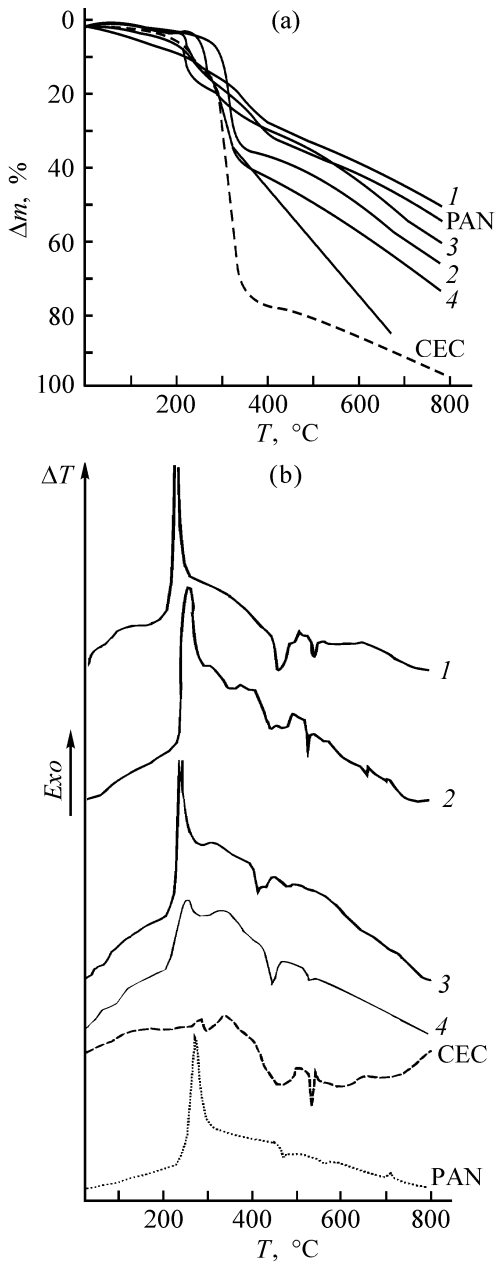

Fig. 1. (a) TG and (b) DTA curves for samples of CEC–PAN blends at component ratios of (*1*) 0.25 : 0.75 and (*2–4*) 1 : 1. (Δm) Weight loss by the sample and (T) temperature; the same for Fig. 2. Samples: (*1*, *3*, *4*) films and (*2*) powder. Degree of substitution of CEC: (*1–3*) 2.3 and (*4*) 2.8. (*Dotted line*) CEC and (*dashed line*) PAN.

When analyzing the thermal effects accompanying thermal transformations of CEC, PAN, and their mixtures in the range 20–800°C (Fig. 1b), we can note the following features of behavior of mixed compositions: (1) For all the samples, the exothermic peaks of PAN cyclization are observed at temperatures lower by 50–60°C than those for pure PAN; (2) the absolute values of this effect (kcal mol^{-1}) differ insignificantly, except for sample no. 4; (3) in the carbonization stage (above 400°C), the endothermic effects are significant; these effects can be assigned to formation of carbonizate with various degrees of ordering.

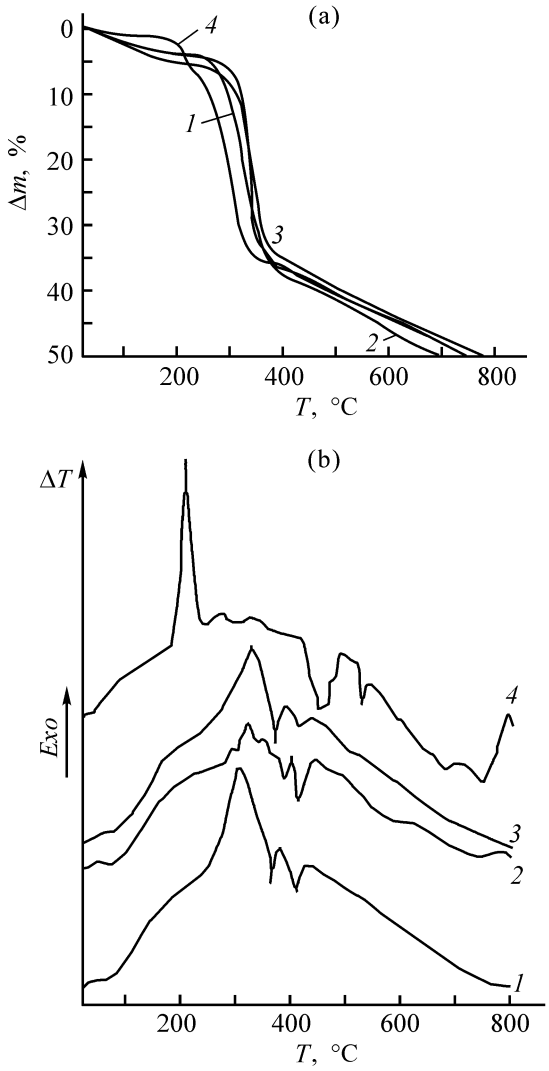

Fig. 2. (a) TG and (b) DTA curves of the samples of (*1*) long staple cotton, (*2*) cotton linter, (*3*) flax fiber, and (*4*) cyanoethyl nitrocellulose (DS 2.3 with respect to cyanoethyl groups and 0.7 with respect to nitro groups).

The modifying role of PAN, which not only favors a significant increase in CN of its blends with CEC but also noticeably enhances their thermal stability, is illustrated by Figs. 2a and 2b. The TG and DTA curves of long staple cotton, cotton linter, and flax fiber show that the kinetics of thermal degradation involves two major stages, similar to CEC. After an insignificant weight loss below 250°C, thermal rearrangements of the main chain of the polymers start in the range 250–360°C. This stage is characterized by a significant rate of release of volatiles in the amount of 60–65% of the initial weight of the sample and by a noticeable exothermic effect. Furthermore, in the carbonization stage, the residue gradually burnts out and the sample is completely evaporated at 700–800°C. An attempt to introduce additional nitrogen-containing groups (cyanoethyl group, nitro group, or both) into cellulose or its ethers did not noticeably affect the carbonization of the polymers examined.

Thus, it can be concluded that PAN is a certain reinforcing skeleton, around which, under favorable carbonization conditions (as mentioned above) the carbonizate of concomitant heterostructures is formed by intermolecular and intramolecular layering.

CONCLUSIONS

(1) In combined thermal treatment of polyacrylonitrile and cyanoethyl ethers of cellulose, cyclyzation of polyacrylonitrile noticeably decreases (by 50–60°C).

(2) Cocarbonization of the polymers studied results in a noticeable increase in the coke number of the blends as compared to the homopolymers of cellulose ethers.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Use of Amines as Complex-Action Additives to Butadiene–Vinylidene Chloride Latex

A. A. Ivanova and I. Yu. Averko-Antonovich

Kazan State Technological University, Kazan, Tatarstan, Russia

Received July 26, 2004; in final form, December 2004

Abstract—The suitability of amines with different structures for modifying ready-for-use butadiene–vinylidene chloride latexes was examined. The influence of the amines on the main physicochemical properties of the latexes was elucidated.

Butadiene–vinylidene chloride latexes have been manufactured for more than 60 years; their synthesis technology is streamlined, and the raw materials for their production are readily available. The currently produced commercial[1] butadiene–vinylidene chloride latexes are DVKhB-70 [TU (Technical Specifications) 38.303-04-03–90] and DVKhB-Sh (TU 2294-049-05 766 764–02).

The polymer of the DVKhB-70 latex (butadiene : vinylidene chloride 30 : 70) contains a large amount (35–37 wt %) of bound chlorine imparting to it a set of valuable properties [1]. However, application of the polymer is substantially restricted by the inadequate aggregative stability of the latex, as well as by the low stability upon introduction of fillers and the possible dehydrochlorination of the polymer in the latex stage. Elimination of these drawbacks will make DVKhB-70-based compositions suitable for application in building industry as adhesives, coatings, building materials, etc. [2].

The manufacture of the DVKhB-Sh latex (butadiene : vinylidene chloride 90 : 10) with 7.3 wt % bound chlorine, intended for tire cord impregnation, was commenced only recently.

The specific features of emulsion polymerization do not allow efficient use of additives of modifying chemical reagents in synthesis of the latex. It seems more reasonable to introduce them into latex with particles already coated with a protective surface layer [3].

As complex-action additives can serve amines with various structures, used previously for preparation of synthetic latexes [4]. Many of these amines are surfactants and, moreover, affect structuring of aqueous solutions.

In this context, we examined here the suitability of additives of some amines for improving the colloidal chemical characteristics of butadiene–vinylidene chloride latexes and elucidated how the structure of the amine affects its performance in modification of ready-for-use latexes.

EXPERIMENTAL

The latexes under study were liquids with a specific odor, dark brown in the case of DVKhB-70 and light in the case of DVKhB-Sh. Selected parameters of the latexes are listed in the table.

As additives for DVKhB-70 and DVKhB-Sh latexes we used a number of readily available amines: diethanolamine, ethanolamine, and diethylamine. Ethanolamine and diethanolamine are viscous hygroscop-

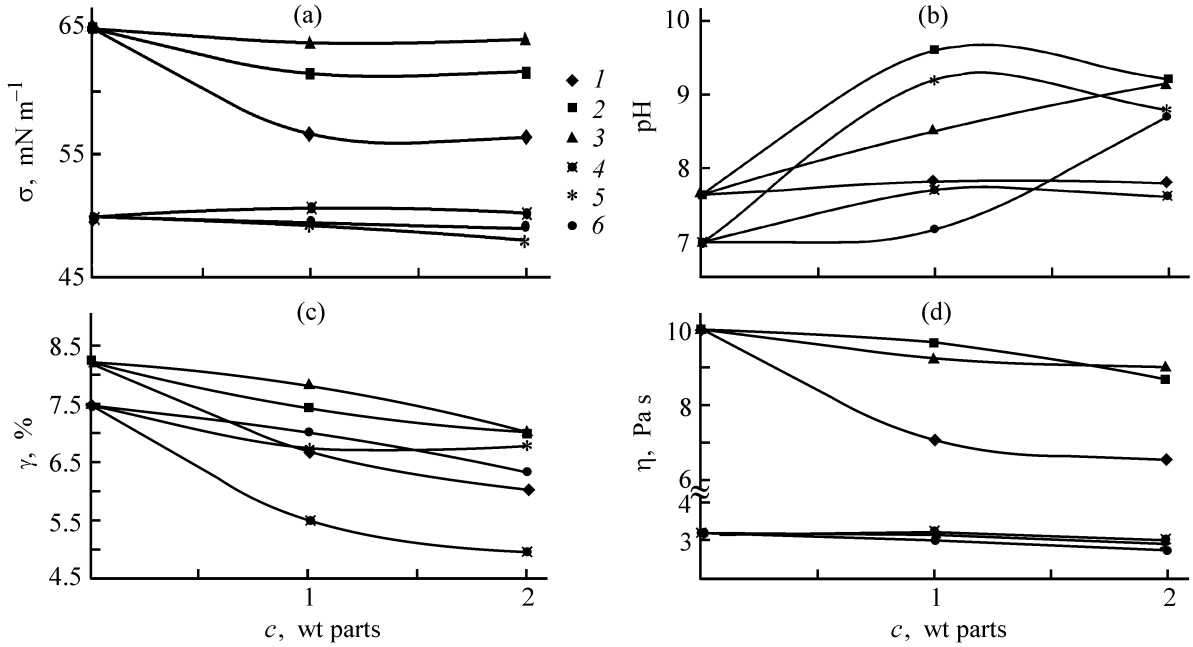

Fig. 1. (a) Surface tension σ, (b) pH, (c) mechanical stability γ, and (d) Hoeppler viscosity η of (*1–3*) DVKhB-Sh and (*4–6*) DVKhB-70 latexes vs. the amine content *c*. (*1*, *4*) Diethanolamine, (*2*, *5*) ethanolamine, and (*3*, *6*) diethylamine.

ic liquids, well soluble in water, ethanol, and chloroform; these are weak bases combining the properties of amines and alcohols. By contrast, diethylamine is a strong base ($K_b = 9.6 \times 10^{-4}$) with the properties of amines solely.

The amines were introduced at room temperature into a commercial butadiene–vinylidene chloride latex in various amounts. The resulting mixture was stirred; after the adsorption equilibrium was established, we studied by the known procedures [5] how the amines affect the properties of the latexes.

The surface tension was determined by the Du Nouy ring method [GOST (State Standard) 20216–74]. The surface tension σ characterizes the degree of saturation of the adsorption shells of the rubber globules in the latex and, hence, the stability of the latex, as well as its wetting power with respect to hydrophilic surfaces. The results of replicate measurements agreed within 0.2 mN m^{-1}.

Viscosity is an important characteristic of latexes, which are colloid systems. It depends on the properties of the protective layers on the surface of a rubber particle in the latex, all other conditions being the same. The viscosity was determined on a Hoeppler rheoviscometer. The results of replicate measurement agreed within 0.3 s.

The mechanical stability of the latexes was tested on a Maron instrument.

As is known, the low stability of butadiene–vinylidene chloride latex is due to the elimination of HCl from the latex polymer macromolecules with time. This changes the pH, thereby destabilizing the latex. The pH of the latexes was measured on a pH-meter with glass electrodes. The results of replicate measurements agreed within 0.2.

The surface tension of the DVKhB-Sh latex is much, lower compared to DVKhB-70, and this parameter for the latexes differently varies with increasing amount of the amines introduced (Fig. 1a). Since both latexes were synthesized in the presence of the same emulsifier taken in identical amounts, the difference in the surface tension can be due to the latex polymer composition only. Evidently, more polar (because of a high content of bound chlorine in the polymer) surface of the DVKhB-70 latex particles absorbs the emulsifier less effectively than do the hydrophobic particles of DVKhB-Sh. This increases the amount of the emulsifier dissolved in the aqueous phase and decreases the surface tension of the latex.

The same factor is the reason why the surface tension of the DVKhB-70 latex remains virtually unchanged upon introduction of various amines (Fig. 1a, curves *4–6*). The surface tension of the DVKhB-Sh latex in the presence of the amines tends to decrease (Fig. 1a, curves *1–3*). The influence of the amines on the surface tension decreases in the order diethanolamine > ethanolamine > diethylamine. This suggests,

first, that the amines are differently adsorbed on the latex particle surface and, second, that not only the nitrogen atom, but also the alcoholic functional group are involved in the latex modification. Indeed, the behavior of ethanolamine in the butadiene–vinylidene chloride latex is similar to that of diethanolamine, but is manifested more weakly. Diethylamine contains no OH groups and exhibits no prominent surface activity, which is responsible for a minor decrease in the surface tension of the latex with increasing amount of diethylamine.

Also, the surface tension of the latex can be affected by formation of a new surfactant via the reaction of the alcoholic groups of the amine with the free carboxylic acid yielded by hydrolysis of the emulsifier, potassium soap of synthetic fatty acids. As is known, salts of diethanolamine and carboxylic acids are much more effective emulsifiers than potassium or ammonium soaps of the corresponding acids. Formation of a more effective emulsifier decreases the surface tension of the latex; diethanolamine is more actively involved in the formation of a soap with synthetic fatty acids, and the resulting surfactant is more effective.

During synthesis, storage, and processing of the latex, HCl can be spontaneously eliminated from the polymer macromolecules and can dissolve in the aqueous phase of the latex, thus decreasing its pH. Therefore, DVKhB-70 latex with a fivefold, compared to DVKhB-Sh, amount of bound chlorine has a smaller pH (Fig. 1b). Amines are capable of binding free HCl into quaternary ammonium salts with an enhanced surface activity, compared to the initial amines. Upon introduction of ethanolamine and diethylamine, pH of the DVKhB-Sh and DVKhB-70 latexes tends to increase (Fig. 1b, curves *2*, *3*, *5*, *6*). Evidently, binding of the eliminated HCl intensifies dehydrochlorination; the relative change in the pH is 0.15 and 0.63 pH units for DVKhB-Sh and DVKhB-70 latexes, respectively, which is almost four times that for DVKhB-Sh and suggests binding of a larger amount of free HCl. Diethanolamine virtually does not affect the pH of the latex, which suggests its reduced activity in binding of HCl.

The above-described processes should be responsible for the enhanced stability of the latexes. Indeed, adding the amines of interest in amounts of 1 and 2 wt parts per 100 wt parts of dry substance of the latex increases its mechanical stability (leads to a decrease in the percentage of coagulum) (Fig. 1c). The maximum enhancement of the mechanical stability is observed for diethanolamine-modified latexes (both DVKhB-Sh and DVKhB-70).

Additional adsorption of the amines on the latex particle surface, formation of new surfactants of different types in the system, increase in the pH of the latexes, and the known effect of the amines on the water structure will necessarily affect the viscosity of the latexes. The Hoeppler viscosity depends both on the type of the latex and on the nature and amount of the amine introduced (Fig. 1d). The viscosity of the DVKhB-70 latex remains virtually unchanged on introducing any type of amine (Fig. 1d, curves *4*–*6*). At the same time, the viscosity of the DVKhB-Sh latex decreases most significantly upon addition of diethanolamine in amounts exceeding 1 wt part per 100 wt parts of the dry latex.

CONCLUSIONS

(1) Introduction of amines into a ready-for-use butadiene–vinylidene chloride latex can improve its characteristics.

(2) Diethanolamine is the best modifier for DVKhB-70 and DVKhB-Sh latexes; ethanolamine and diethylamine improve the properties of these latexes to a smaller extent. The optimal amount of the modifier introduced is not larger than 1 wt part per 100 wt parts of the latex polymer. The amine-modified latexes exhibit reduced surface tension, as well as increased pH and improved mechanical stability.

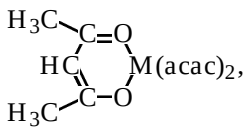
Abstract—The film-forming properties of divinyl triethylene glycol bis-*o*-phthalate in air in the presence of a redox system and β-diketonates of transition metals were studied.



Oligoether acrylates are widely used in production of homopolymer and composite materials. Much attention is given today to photopolymerization of oligomers containing double bonds, because of the possibility of combining the polymerization and curing in a single process cycle and of using such compounds in production of optical disks, in protective and adhesive coatings, in polygraphy, and in stomatology [1, 2]. Promising photoinitiators (PIs) are transition metal β-diketonates because of their availability and high stability in storage [3]. There are virtually no data on the use of these photoinitiators for curing of films of vinyl oligomers.

In this study, we examined the photopolymerization of divinyl triethylene glycol bis-*o*-phthalate (DPT) in the presence of transition metal β-diketonates, with the aim to search for new applications of this vinyl oligomer.

DPT was prepared by the reaction of ethylene chlorohydrin with phthalic anhydride, followed by dehydrochlorination of the resulting monoester in the presence of alkali. The monovinyl *o*-phthalate thus obtained was brought into the reaction with triethylene glycol, which was performed by the azeotropic method in the presence of catalytic amounts of H_2SO_4. The properties of DPT agreed with those described in [4].

As PIs we used Co(III) and Fe(III) acetylacetonates

where M = Fe^{3+}, Co^{3+}.

The properties of the transition metal acetylacetonates agreed with those described in [5, 6]. The choice of these PIs was governed by their absorbing power, examined in [7].

Films (15–35 μm thick) were applied by casting a toluene solution onto quartz glass plates. Initially the samples were kept at 298–343 K and UV-irradiated with a DRT-400 quartz lamp, placed at a distance of 10 cm from the film surface, for 300 s at 298–343 K. To eliminate the inhibiting effect of atmospheric oxygen in the surface layer of DPT films, the films to be irradiated were covered with quartz glass (thickness ≤0.1 μm).

For comparison, we studied polymerization of DPT films in air at 353 K in the presence of a redox system consisting of 0.55% cyclohexanone hydroperoxide

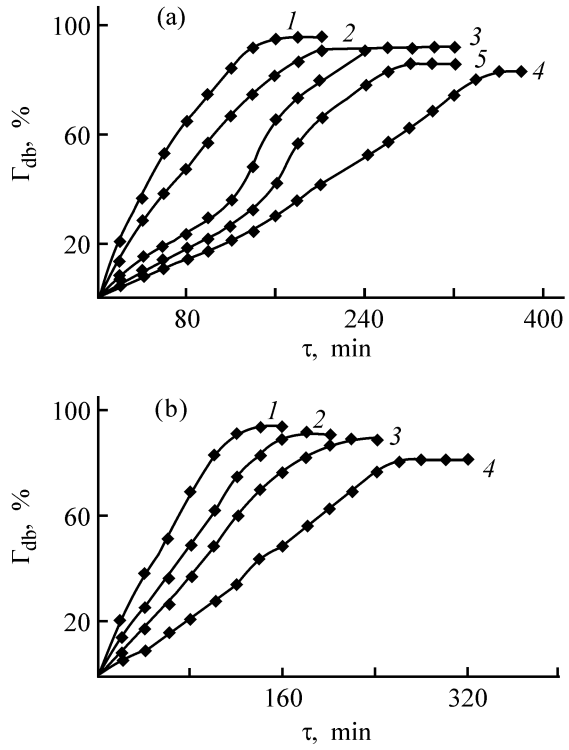

Fig. 1. Curing of DPT films at 353 K as influenced by the film thickness and concentrations of (a) iron(III) and (b) cobalt(III) acetylacetonates. Exposure time 300 s; photoinitiation temperature 298 K. (Γ_{db}) Conversion of double bonds and (τ) time; the same for Fig. 2. Film thickness, μm: (a) 15 and (b) 35. M(III) concentration, %: (*1*) 5, (*2*) 4, (*3*) 3, and (*4*) 2.5; (*5*) redox system 0.55% CHP + 0.1% CN.

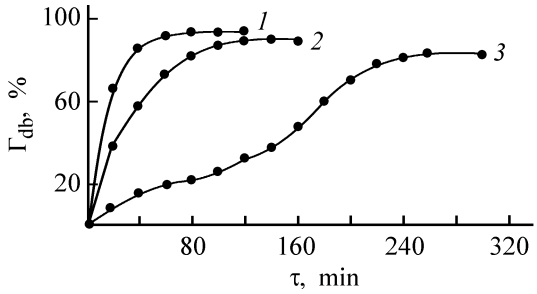

Fig. 2. Curing of DPT at 353 K in 35-μm films as influenced by the kind of photoinitiator. Exposure time 300 s, photoinitiation temperature 343 K, photoinitiator concentration 3%. Photoinitiator: (*1*) cobalt(III) acetylacetonate, (*2*) iron(III) acetylacetonate, and (*3*) redox system 0.55% CHP + 0.1% CN.

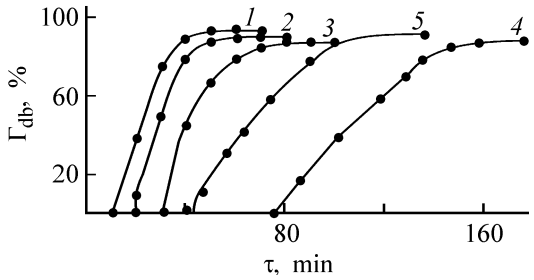

Fig. 3. Yield of three-dimensional polymer Γ_{td} in photopolymerization of DPT in 35-μm films vs. time τ. Exposure time 300 s, photoinitiator concentration 3%, drying at 353 K. Photoinitiation temperature, K: (*1, 2*) 343 and (*4, 5*) 298. Photoinitiator: (*1, 5*) cobalt(III) acetylacetonate, (*2, 4*) iron(III) acetylacetonate, and (*3*) redox system 0.55% CHP + 0.1% CN.

(CHP) and 0.1% cobalt naphthenate (CN) in terms of metal.

The conversion of double bonds in the films, Γ_{db}, was determined bromatometrically. The content of the three-dimensional polymer, Γ_{td}, was determined gravimetrically after extraction with boiling acetone for 6 h. The samples were dried at 353 K. The results are shown in Figs. 1–3.

The curing of DPT in films, irrespective of the initiation mode, photoinitiation temperature, and film thickness, occurs without any induction period (Figs. 1 and 2). The absence of the induction period in curing of DPT in the presence of the redox system in air (Fig. 1a, curve *5*; Fig. 2, curve *3*) is due to the free air access. Starting from the lowest conversions, double bonds are consumed under the conditions of film curing not only in the reactions $HO_2^{\bullet} + M \rightarrow MOOH$, but also in destructive oxidative transformations. The high conversion of the double bonds can be accounted for by the plasticizing effect of the –O–O– groups in the three-dimensional polymer formed in air.

The limiting degrees of film curing are close, 92–96% (Figs. 1a, 1b, curves *1–3*; Fig. 2, curves *1*, *2*) and exceed Γ_{db} in DPT polymerization in the presence of the redox system in air (Fig. 1, curve *5*; Fig. 2, curve *3*), irrespective of the film thickness and photoinitiation temperature, except in the experiments at the lowest PO concentration, 2.5 wt % (Figs. 1a, 1b, curves *4*).

The film curing rate grows with an increase in the PI concentration, irrespective of its nature, film thickness, and photoinitiation temperature.

The curing time is the shortest at a PI concentration of 5 wt % (Figs. 1a, 1b, curves *1*), but the physicomechanical characteristics of the resulting films are worse (Table 1). The photocuring of DPT film in the presence of $Co(acac)_3$ occurs faster (Fig. 2, curve *1*; the limiting Γ_{db} is attained in 80 min) than that in the presence of $Fe(acac)_3$ (Fig. 2, curve *2*; the limiting Γ_{db} is attained in 110 min).

Table 1. Physicochemical characteristics of DPT coatings (photoinitiation temperature 298 K, film thickness 15 μm)

$Fe(acac)_3$ content, wt %	Curing time at 353 K, min	Aging time at 298 K, h	Γ_{db}, %	Bending strength, mm	Impact strength, N m	Relative hardness
2.5	360	24	84	4	4.5	0.66
		168	88	4	4.5	0.65
		720	89	3	4.0	0.65
3	240	24	93	5	4.5	0.66
		168	94	5	5.0	0.66
		720	95	4	5.0	0.67
4	200	24	92	3	4.0	0.53
		168	94	3	4.0	0.55
		720	95	4	3.5	0.55
5	150	24	96	3	3.5	0.50
		168	97	3	3.5	0.53
		720	97	4	3.5	0.55

Table. 2. Physicochemical characteristics of DPT coatings (photoinitiation temperature 298 K, film thickness 35 μm)

Photo-initiator	Curing time at 353 K, min	Aging time at 298 K, h	Γ_{db}, %	Bending strength, mm	Impact strength, N m	Relative hardness
$Co(acac)_3$	220	24	92	5	5.0	0.66
		168	93	5	5.0	0.68
		720	95	5	5.0	0.68
$Fe(acac)_3$	260	24	92	5	5.0	0.66
		168	93	5	5.0	0.66
		720	93	5	4.5	0.67
Redox system	240	24	90	5	5.0	0.66
		168	90	5	4.0	0.66
		720	92	5	4.0	0.68

As can be seen from Table 1, the impact strength and relative hardness of the films decrease with an increase in the content of $Fe(acac)_3$. The film elasticity decreases in the course of thermal aging. The curing time decreases by a factor of 2.4 (from 360 to 150 min) with an increase in the PI concentration by a factor of 2. The coatings obtained at a PI concentration of 3 wt % meet the requirements to paint-and-varnish materials (Γ_{db} 94%, bending strength 5 mm, impact strength 5.0 N m, relative hardness 0.66 at a curing time of 240 min and aging time of 168 h); similar parameters are attained when a DPT film is cured in the presence of the redox system).

We examined the DPT film curing at a PI concentration of 3 wt %, photoinitiation temperature of 343 K, and film thickness of 35 μm. Figure 2 (curves *1*, *2*) shows that the general trends in the film curing are preserved, irrespective of the photoinitiation temperature and film thickness. The physicomechanical characteristics of the films cured at the optimal PI concentration of 3 wt % are listed in Table 2. It is seen that the films have a bending strength of 5 mm and a relative hardness of 0.66–0.68, irrespective of the initiation procedure. The impact strength of the photocured DPT films (4.5–5 N m) exceeds that of DPT films cured in the presence of the redox system (4–5 N m) and meets the requirements to protective coatings. Comparison of Tables 1 and 2 shows that, in photocuring of DPT films of different thicknesses in the presence of $Fe(acac)_3$, the curing time at the same photoinitiation temperature is longer in thicker films: 35 μm, 260 min; 15 μm, 240 min.

An important characteristic of curing is the kinetics of accumulation of the three-dimensional polymer. Figure 3 shows that the induction period of the three-dimensional polymerization is observed in all the cases,

irrespective of the initiation procedure. It is believed that, during the induction period, intermediate soluble polymers are formed, and the viscosity of the film-forming material increases. The induction period of the three-dimensional polymerization depends on the photoinitiation temperature. As the photoinitiation temperature is raised, the induction period becomes shorter. In particular, with $Co(acac)_3$, the induction period is 38 min at the photoinitiation temperature of 298 K and as short as 10 min at 343 K (Fig. 3, curves *1*, *5*). The same trend is observed with $Fe(acac)_3$ (Fig. 3, curves *2*, *4*). The induction period depends on the initiation procedure and kind of PI; at the photoinitiation temperature of 343 K, it increases in the order $Co(acac)_3 < Fe(acac)_3 <$ redox system.

The rate of the three-dimensional polymerization at a photoinitiation temperature of 343 K in the presence of $Co(acac)_3$ and $Fe(acac)_3$ (Fig. 3, curves *1*, *2*) is higher than the rate of the three-dimensional polymerization of DPT initiated with the redox system (Fig. 3, curve *3*), but at 298 K the rate is considerably lower (Fig. 3, curves *4*, *5*). The limiting degrees of conversion in the DPT photopolymerization (92–95%) differ insignificantly from those attained with the redox system.

The DPT photocured in the presence of $Fe(acac)_3$ has found use as a film-forming material in preparation of dentures by compression molding.

CONCLUSION

The rate of curing of divinyl triethylene glycol bis-*o*-phthalate films largely depends on the kind and concentration of the photoinitiator. As the photoinitiator concentration is increased, the physicomechanical characteristics of coatings based on divinyl triethylene glycol bis-*o*-phthalate get worse. The optimal photoinitiator concentration for the photopolymerization of divinyl triethylene glycol bis-*o*-phthalate is 3 wt %. The photocuring of divinyl triethylene glycol bis-*o*-phthalate is more efficient at elevated photoinitiation temperatures.

Abstract—Radical polymerization of hydroquinone was studied in an aqueous medium. Black polymers of low molecular weight (up to 1500 Da), poorly soluble in water and alcohols, are formed. *Ab initio* calculations of the steric and electronic structure and vibrational and electronic spectra of molecules containing 1 to 5 hydroquinone units were performed.

It is known that polymerization of hydroquinone under the action of alkali or atmospheric oxygen in alkaline medium gives low-molecular-weight oligohydro- and oligooxyhydroquinones [1, 2]. As compared to phenol and naphthol, hydroquinone is more reactive [3], which is caused by the mutual influence of two hydroxy groups. It has been shown [2] that oligomerization of hydroquinone yields semiquinone radical ions

which are further involved in recombination dimerization followed by hydrogen transfer from the core to carbonyl groups. Molecules of the reaction product consist of hydroquinone units in-series connected by C–C bonds. The structural studies performed did not confirm formation of the polymers in which adjacent aromatic rings are bound by C–O–C bridges [1].

Polyhydroquinones and polyphenols substantially differ in their properties from monomeric analogues; in particular, they show acidic properties [4] and exist as stable semiquinone-type polyradicals. It is believed that the unusual properties of the polymers are caused by conjugation in the polymeric chain, strong intra- and intermolecular bonds, and high local concentration of the hydroxy groups. Polymeric products with unusual black color are heat-resistant nonvolatile compounds, whose electrical properties can widely range and exhib biological activity.

It is interesting that the similar products can be prepared by *p*-benzoquinone polymerization [5–8]. Both the starting monomers, hydroquinone and *p*-benzoquinone, exist in equilibrium with each other in water or an organic solvent [9]. Crystalline quinone–hydroquinone complexes (so-called quinhydrone) undergo redox transformations with an increase in the difference between the hydroquinone ionization potential and quinone electron affinity [10]. It has been shown that transfer of two hydrogen atoms from hydroquinone to quinone occurs in the electron-excited state of quinhydrone [11].

p-Benzoquinone polymerizes under the action of an alkali or acid, and also under the action of Lewis acids, e.g., anhydrous $AlCl_3$ [7, 8]. Black oligomeric products (M_n = 810–1120) are well soluble in acetone and ethanol and melt at low temperatures (85–120°C). A study of *p*-benzoquinone polymerization products in all the cases revealed hydroquinone structure of units [6, 8] with *o*-substitution in the aromatic ring.

In this study, we performed radical polymerization of hydroquinone in an aqueous solution and examined the steric and electronic structure of polyhydroquinone by molecular spectroscopy and *ab initio* quantum-chemical calculations.

EXPERIMENTAL

The ESR spectra of polyhydroquinones were recorded on a BER-418 spectrometer both in the solid

1070-4272/05/7804-0656 © 2005 Pleiades Publishing, Inc.

state and as an aqueous solution (Fig. 1). The concentration of unpaired electrons (spins) was determined with a known reference, diphenylpicrylhydrazyl, which was taken as a mixture with an inert matrix; the concentration was 5×10^{18} per gram of substance. As compared to solids, the intensity of the ESR signal decreases in solution by approximately a factor of 10. In both cases, the signal is a single line with a 5-G width without resolved hyperfine structure, which is indicative of a complete delocalization of the unpaired electron and the lack of its magnetic interaction with protons.

The molecular weights of the polymer were determined by liquid exclusion chromatography in dimethylformamide with addition of trifluoroacetic acid (TFAA) and sodium trifluoroacetate (STFA) on a GMA Gel G-5 column (Fig. 2). Two fractions were studied. One of them (major) is limitedly (40 g l^{-1}) soluble in water, and its retention time τ = 45.5 min corresponds to a molecular weight of 650–700 Da. The second fraction is a water-insoluble precipitate; it is precipitated with water from the polymer solution in dimethylformamide and has shorter τ = 43.5 min corresponding to the molecular weight of 1500 Da (calibration against polystyrene).

Quantum-chemical calculations of the structure of molecules in the singlet S_0 and triplet T_1 states were performed with GAMESS software within RHF, ROHF/6-31G*, and SBK schemes. The electronic absorption spectra were calculated by the CNDO/S or ZINDO/S methods (HyperChem soft-ware); for *ab initio* calculations of the vibrational spectra, we used the GAMESS software. The theory and methods of quantum-chemical calculations were considered in more detail in [12].

Polymerization of hydroquinone under the action of a radical initiator is essentially nonequilibrium, which is apparently responsible for the polymer nonuniformity in molecular weights. The IR spectra of both isolated fractions in the solid state (Fig. 3) are similar, suggesting similar structures of the molecules.

The strong low-frequency shift of the bands of ν_{OH} stretching vibrations (2600 and 2300 cm^{-1}) indicates a very strong intrachain hydrogen bond OH…OH (Fig. 3, spectrum *2*). In the IR spectrum of the water-soluble fraction, these bands are less intense, probably, due to a shorter conjugated chain (Fig. 3, spectrum *1*). The band at 3380 cm^{-1} belongs to ν_{OH} stretching vibrations of absorbed water, which is always present in air-dry polyhydroquinone. The band at 3300 cm^{-1} belongs to hydroxy groups involved in moderately strong intrachain and intermolecular hydrogen bonding, O–H…OH.

chain. This conclusion is confirmed by *ab initio* calculations of the vibrational spectrum of the first members of the polyhydoquinone series (Table 1):

$n = 0–4.$ (I)

Table 1 shows that the calculated intensities of IR transitions related to stretching $\nu_{C=C}$ vibrations at 1600 cm^{-1} increase with lengthening of the polymeric chain. Values of *I* in Table 1 are comparable with *I* for the most intense transitions in the IR spectra, such as, e.g., $\nu_{C=O}$ stretching vibrations. The calculated data confirm the assignment of the broad and intense band at 1600 cm^{-1} to $\nu_{C=C}$ stretching vibrations of the conjugated aromatic rings.

Bands at 1530 and 1470 cm^{-1} are also associated with $\nu_{C=C}$ stretching vibrations. The high-frequency shoulder at 1730 cm^{-1} of the 1640 cm^{-1} band can be assigned to $\nu_{C=O}$ stretching vibrations of the terminal units of the polyhydroquinone molecules bearing an unpaired electron. The strongest band at 1200 cm^{-1} belongs to $\nu_{C–OH}$ stretching vibrations of the polymer. The structured band at 825 cm^{-1}, belonging to out-of-plane bending vibrations of C–H bonds of aromatic rings, should also be noted.

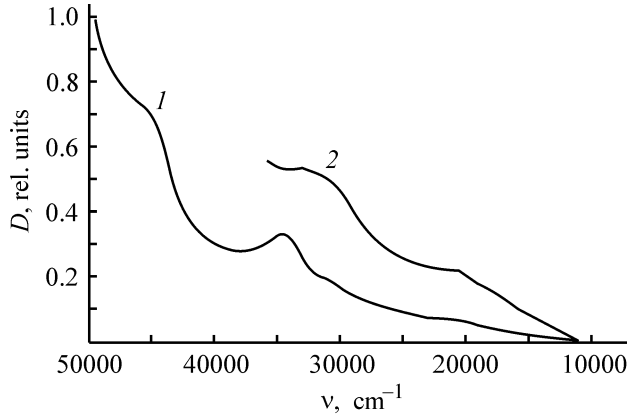

Fig. 4. Absorption spectra of polyhydroquinone: (*1*) solution in water and (*2*) precipitate from aqueous solution in dimethylformamide.

In the electronic absorption spectrum of polyhydroquinone in the UV–VIS region, several broad bands are observed (Fig. 4). The black (brown in dilute solution) color of the polymer is caused by a broad band ($\pi–\pi^*$ transition) peaked at 34500 cm^{-1}, which extends throughout the visible region of the spectrum (Fig. 4, spectrum *1*). At least two bands at 30700 and 28000 cm^{-1}, probably assigned to minor components of polyhydroquinone, are seen on the low-frequency wind of this broad band. Finally, a structured band at 20000 cm^{-1} is observed. In the high-molecular-weight fraction studied in dimethylformamide (Fig. 4, spectrum *2*), these bands are shifted to lower frequencies, to 30000, 28000 and less than 28000 cm^{-1}. This shift is caused in part by the specific effect of dimethyformamide as a solvent, but the main reason is the lengthening of the polyhydroquinone polymeric chain.

Generally, the ^1H and ^{13}C NMR spectra furnish the most complete information on the polymer structure. However, NMR spectra cannot be measured in the case in question because of the presence of paramagnetic particles, which broaden the signal and the spectrum. Therefore, we used quantum-chemical calculations to gain insight into three structural characteristics: (1) mode of binding of the adjacent aromatic rings, C–C or C–O–C; (2) intrachain conjugation be-

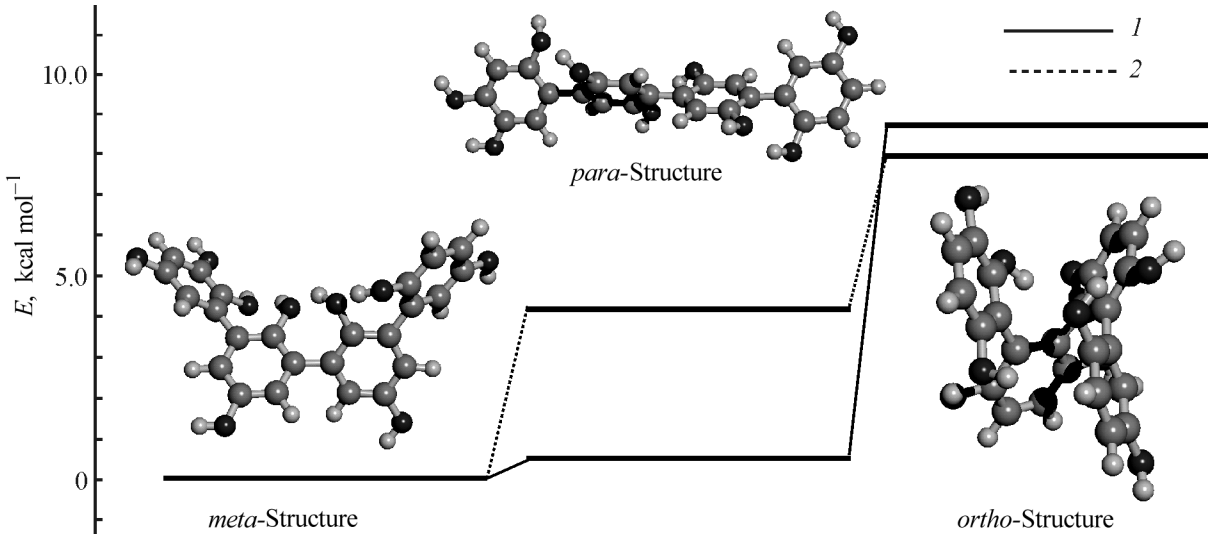

Fig. 5. Relative energies *E* of model polyhydroquinone molecules consisting of four units in *ortho*, *meta*, and *para* configurations, according to (*1*) PM3 and (*2*) RHF/SBK calculations.

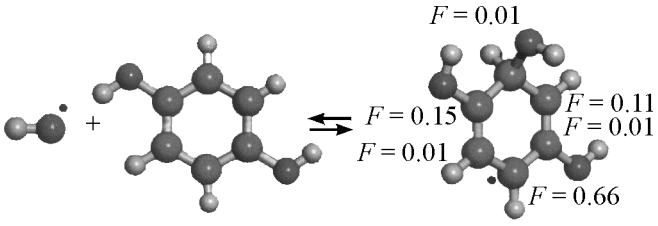


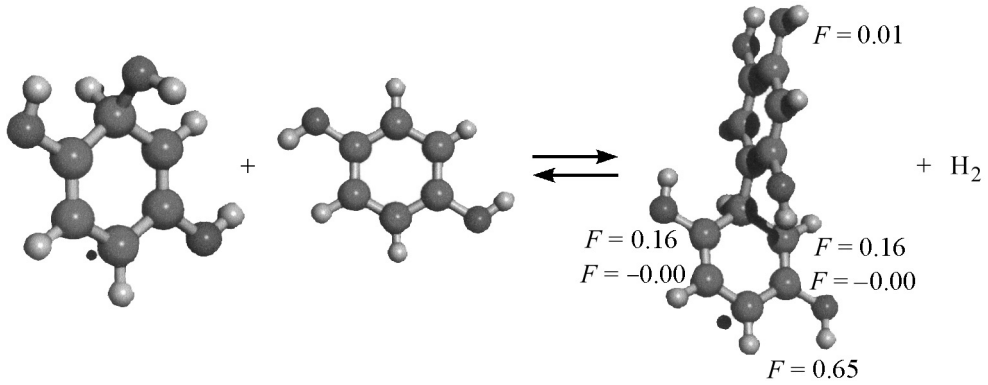
tween adjacent units; and (3) mechanism of chain termination during polymerization. The last item is directly associated with the nature of the paramagnetic species. Elucidation of these questions is necessary for understanding of both the polymerization mechanism and the structure and properties of the polymerization product.

Assuming that the monomeric units in polyhydroquinone are bound with each other by the C–C bonds, let us consider three probable kinds of binding of two adjacent rings: 1) *ortho*, 2) *meta*, and 3) *para* (Fig. 5). In the first case, a compact spiral structure of the polymeric chain with close contacts (< 3 Å) between the atoms of the distant rings is formed. Such a strained structure is the least favorable energetically, being inferior to the *para* structure by 3.76 kcal mol^{-1} and to the *meta* structure at n = 4 by 7.94 kcal mol^{-1} (RHF/SBK calculation). A semiempirical PM3 calculation gives somewhat different relative energies (Fig. 5): the *ortho* structure lies higher than the most stable *meta* structure by 8.73 kcal mol^{-1}, and the *para* and *meta* structures are close to in energy.

In the *ortho* structure, the distance between the adjacent hydroxy groups OH…OH is the longest: 1.9–2.2 Å. This value corresponds to a weak H bond. Conjugation along the molecular chain is characterized by the dihedral angle γ, which determines the mutual orientation of the adjacent aromatic rings. In this parameter, the *ortho* structure is also less favorable than the other two structures: γ = 57°–70°. These results allow us to rule out an *ortho* addition as a way of junction of adjacent aromatic rings in polyhydroquinone.

The *para* structure is characterized by a moderately strong intrachain H bond OH…O ($R_{OH...O}$ = 1.83–1.85 Å); dihedral angles γ are 49.2°–49.8°. For the most stable *meta* structure, we obtained by RHF/SBK method the shortest, and hence the strongest, H bonds OH…H ($R_{OH...O}$ = 1.76–1.82 Å). According to the available data, *ab initio* RHF/SBK method may overestimate the contribution of H bond to the total energy of the molecule, which may be responsible for the lower (by 4.18 kcal mol^{-1}) energy of *meta* structure, compared to *para* structure. When calculated by the semiempirical PM3 method, which is usually used for theoretical estimation of the H bond strength, both structures have close energies and the same lengths of the H bond, 1.83 Å (Fig. 5).

Along with the energetic criterion, the probability of formation of a chemical compound is determined by the spin population, or by indices of free valence on the atoms of the reaction structure. Equation (1) reflects the initial step of polymerization of hydroquinone in which the OH• radical adds to the carbon atom of the aromatic ring to give a radical-type σ complex:



Scheme 1.

The enthalpy ΔH of reaction (1) is negative and equal to –2.2 kcal mol^{-1} (RHF and ROHF/6-31G* calculations), i.e., the initiation is thermodynamically feasible. The spin populations or indices of free valence in Scheme (1) reveal the reactive carbon atoms of the σ complex. The C_{para} atom (F = 0.66) is the most active, and the hydroquinone molecule should be attacked just through this atom to give a dimeric product.

The unsubstituted C_{ortho} atom is less reactive (F = 0.11), while the C_{meta} atom with the zero index of free valence is inactive. Hence, in the radical polymerization of hydroquinone, addition to the *meta*-carbon atom is forbidden by the spin control principle.

The next step of the reaction, addition of the hydroquinone molecule to the primary radical σ complex, is shown in Scheme (2):

Scheme 2.

This step yields a dimeric radical σ complex and a hydrogen molecule. The distibution of the indices of free valence is the same as that for the primary complex: the carbon atom in the *para* position (F = 0.65) is the most reactive; addition to it of the next hydroquinone molecule should give the trimeric σ complex. As in the case of the monomeric σ complex, the carbon atom in the *ortho* position is less reactive (F = 0.16). Hence, propagation of the polymeric chain through this center is unlikely. In addition, the *ortho* structure is, as already mentioned, energetically less favorable relative to the other two structures. The C_{meta} carbon atom in the dimeric complex is characterized by a zero index of free valence and is inactive in addition. The propagation of the polymeric chain stops in the stage of chain termination, which is probably caused by the substantial decrease in the reactivity of the radical center. The polymerization of hydroquinone stops in a rather early stage, after addition of only 10–15 units. In this context, a question arises concerning the termination mechanism of polymerization.

We believe that the propagation of the polymeric chain stops because of the rapid increase in degree of conjugation along the polyhydroquinone chain with its lengthening in the initial step of the reaction, which results in delocalization of the unpaired electron and its stabilization with loss of reactivity of the propagating radical center. The degree of conjugation can be characterized by the frequency and intensity of the low-frequency electronic transition.

The calculated electronic spectra of the series of molecules differing in chain length and kind of junction between the monomeric units are listed in Table 2. The number of π–π^* transitions in the low-frequency region of the spectrum is equal to the number of aromatic rings, but the lowest (in energy) transition is delocalized and related to the whole molecule. It can be seen that, in the case of *para* junction, the frequency of the lowest transition monotonically decreases, and its intensity sharply increases at the expense of high-frequency transitions, reaching a value that is limiting for ZINDO/S at a chain length of five units. For molecules containing five and more units, this transition lies in the visible region and, because of the very high intensity, should impart dark color to the substance.

The *ortho* substitution does not produce any conjugation in the molecular chain or in the system of H bonds. In this case, the spectrum of the spectrum should be similar to the spectrum of the initial hydroquinone, i.e., a substance with such a chain structure should be colorless. As can be seen from Table 2, the *meta* substitution also cannot be responsible for the observed deep color of polyhydroquinone because of the low intensity of low-frequency transitions. In

addition, as noted above, formation of the *meta* structure is forbidden by the spin control principle.

After oxidation of polyhydroquinone and substitution of one of the four units of the *para* structure by the quinoid unit (Fig. 6, structure **I**), a substantial long-wave shift of the intense electronic transition at 32435 (0.715) cm^{-1} is observed (Table 2), with its intensity somewhat decreasing. The appearance of the absorption at 25000 cm^{-1} should impart dark color to the substance. At the same time, polybenzoquinone (which is the product of complete polyhydroquinone oxidation) (Fig. 6, structure **II**) should have, in accordance with the calculated absorption spectrum, a weak yellow color, similarly to *para* benzoquinone. Probably, in partially oxidized polyhydroquinone, inclusion of the quinoid ring in the conjugation chain provides more efficient interaction of the monomeric units than in the initial polymer.

Thus, the above analysis showed that the oxidation of polyhydroquinone and conversion of a certain amount of hydroquinone units into quinoid units is accompanied by a shift of intense π–π^* transitions into

I **II** **III**

Fig. 6. Optimized (RHF/SBK) structure of the model molecules: (**I**) partially oxidized polyhydroquinone (*n* = 3, *m* = 1), (**II**) polybenzoquinone (*n* = 0, *m* = 4), and (**III**) polyhydroquinone with an ether bond between units (*n* = 4).

the visible region, which can account for the experimentally observed black color of the polymer.

Table 2 can clarify the question being discussed in the literature, concerning the possibility of formation of ether bonds C–O–C in the polyhydroquinone chain. For instance, Anderson *et al.* [1], based on the ESR spectra, suggest formation of a dimeric product with the ether bond between the rings during oxidation of fluoro- and chloro-substituted hydroquinones. We calculated the structure and absorption spectra of polyhydroquinones with an ether bond between the units (Fig. 6, structure **III**; Table 2). In agreement with the later published results, the calculated data do not confirm the existence of any substantial amounts of units bound by ether bridges. In such structures, the electronic transitions should have low intensity and lie in the UV region; they cannot be responsible for the experimentally observed black color of the polymer.

CONCLUSIONS

(1) Black polyhydroquinones with a molecular weight less than 1500 Da, weakly soluble in water and alcohols, were prepared by polymerization of hydroquinone in water under the action of a radical initiating system.

(2) Polyhydroquinones are characterized by long-lived paramagnetism (existing for no less than a year). In the solid state and in water, the ESR signal is a single line with a 5-G width and without resolved hyperfine structure.

(3) *Ab initio* quantum-chemical calculations of polyhydroquinone molecules with a chain length of up to six units with *ortho*, *meta*, and *para* substitution in the aromatic ring were performed. The *para* structure with the single C–C bond between the hydroquinone rings is the most probable configuration of the polymeric chain.

(4) Termination of the chain propagation in the early stage of polymerization of hydroquinone is probably caused by a sharp decrease in the reactivity of the propagating radical center because of the delocalization of the unpaired electron in the polyconjugated molecular chain.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Toms Effect as Influenced by the Glass Capillary Length and Diameter

S. V. Chichkanov and V. A. Myagchenkov

Kazan State Technological University, Kazan, Tatarstan, Russia

Received September 16, 2004; in final form, February 2005

Abstract—The degree of reduction of the hydraulic resistance was studied as influenced by the concentration of the anionic copolymer of acrylamide, geometric parameters of the contour, and turbulent flow velocity.

High-speed transportation of oil-containing dispersed systems via main pipelines with the use of polymeric additives, such as, e.g., polyolefins, for reducing the hydraulic resistance of turbulent oil streams (Toms effect) has recently demonstrated a high economic efficiency [1–4].

The prospects for use of water-soluble polar polymers, e.g., (co)polymers of acrylamide, for intensifying the mass transfer of oil-containing dispersed system still remain to be elucidated more precisely. The use of water-soluble (co)polymers for reducing the hydraulic resistance of oil streams under turbulent flow mode is especially urgent in view of the fact that the water content of the extracted crude oil tends to increase [5]. For real objects, the dispersion media are mostly complex systems with variable parameters, including pH, ionic strength, concentration of active components, etc. All this affects the resulting macroscopic Toms effect. Quantitative studies of the Toms effect as influenced by various factors (parameters of the medium and of the restricting contour and characteristics of the polymeric additive) become increasingly important.

We have demonstrated earlier [6–9] that the Toms effect is strongly dependent on the chemical nature, molecular parameters, and concentration of the polymeric additives, pH, ionic strength of the medium, and the content of active components (polymers, surfactants, electrolytes) in it. We assumed that, near the inner surface of the capillary, there is a special near-wall zone of the stream [6, 9], in which the optimal concentration of the polymeric additive is created, preventing the spread of turbulent waves from the wall to the core of the stream. A rather thin electrical double layer (EDL) is formed on the inner wall of the tubes (capillaries), whose parameters strongly affect the resulting balance of the attraction and repulsion forces between the charged macroions of the polymer and the capillary wall. Changes in such parameters of the medium as pH or ionic strength affect the conformation and size of the polymer macromolecules, as well as the ratio between the sizes of the near-wall layer and EDL, thus affecting the Toms effect.

Also, the performance of polymeric additives in reducing the hydraulic resistance of turbulent streams is governed by the diameter, length, and the degree of branching of the pipeline network. Clearly, conducting numerous experiments on real pipelines is a difficult and, in most cases, impossible task. Theoretical studies of the transportation of crude oil via pipelines have not received wide acceptance, since they are suitable only for selected special cases and require some simplifying prerequisites and assumptions. Now, hydraulic processes are being studied fairly successfully by the experimental method based on the similarity theory: A pipeline is simulated in a reduced, compared to the original, scale, so that the process of interest is reproduced "in miniature," with all the relationships being preserved. Specifically this approach was taken in developing the experimental procedure in this study.

Here, we examined how the concentration of acrylamide (co)polymers and the geometric parameters of the contour (capillary diameter and length) affect the degree of reduction of the hydraulic resistance of turbulent water streams. The experiments were run in a modified turbulent rheometer.

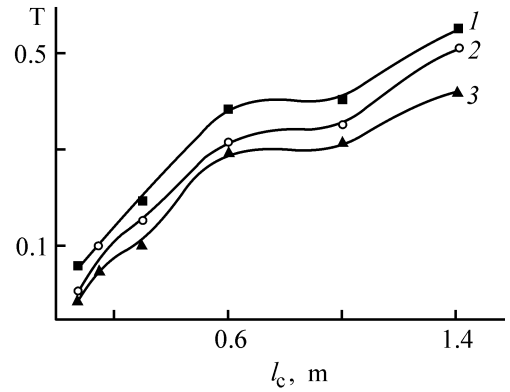

Fig. 2. Variation of the Toms effect T with the capillary length l_c at $c = 0.08$ kg m^{-3}. $d_c = 0.84 \times 10^{-3}$ m. p, atm: (*1*) 5, (*2*) 10, and (*3*) 15.

EXPERIMENTAL

In experiments on studying the direct-current turbulent flow of aqueous media with polymeric additives, we used Alcoflood 1175A acrylamide–sodium acrylate anionic copolymer available from Allied Colloids, the United Kingdom, with the molecular weight $M = 10.8 \times 10^6$ and 21.5 wt % of ionic (acrylate) units.

The experimental setup (modified turbulent rheometer) consisted of a thick-walled reservoir, into which the liquid under study was poured, and a glass capillary connected to the reservoir. Under excess pressure of a gas (nitrogen) in the reservoir, the liquid flowed via the capillary into the receiver which was weighed on a one-arm electronic balance (for details, see [10]). An advantage offered by this setup is operation with a set of separate glass capillaries, which allowed the capillary length and diameter to be easily varied within the desired range. During the experiment, the capillary length l_c was widely varied from 0.075 to 1.410 m, and the diameter d_c, from 0.84×10^{-3} to 2.61×10^{-3} m.

The Toms effect was estimated by the formula

$$T = (m - m_0)/m_0,$$

where m_0 and m are the gravimetric flow rates of the liquid without and with a polymeric additive, respectively [6].

Let us consider the dependence of T on the polymer concentration c (Fig. 1) for capillaries with a fixed diameter $d_c = 0.84 \times 10^{-3}$ m and different lengths l_c of 0.075, 0.15 and 0.60 m.

Figure 1 shows that, first, the concentration dependences of T are virtually identical for all the capillary lengths and differ only in the scale (magnitude of T). The fact that the $T = f(c)$ dependences are similar has been noted by the majority of researchers [1, 11]. With increasing polymer concentration, T initially tends to increase and then, upon achieving certain optimal concentration, approaches a constant value or begins to smoothly decrease. Second, T clearly tends to decrease with increasing pressure (at constant l_c and d_c) and with decreasing l_c.

To get a more specific and clearer insight into the dependence of the Toms effect on l_c, we carried out a special series of experiments, taking the capillary with the diameter $d_c = 2.61 \times 10^{-3}$ m and initial length $l_c = 1.41$ m as the initial capillary. After the experiment, we prepared from this capillary other capillaries with smaller l_c. We gradually reduced the capillary length and thus obtained a set of experimental data on how the Toms effect T is influenced by l_c. This excluded complications caused by the use of different capillaries, associated, above all, with different surface characteristics.

Figure 2 shows how the Toms effect T varies with l_c at $c = 0.08$ kg m^{-3}. It is seen that, with increasing l_c, the polymeric additive tends to perform better. Such a run of the curves is fairly unusual and even paradoxical. With increasing length and unchanged diameter of the capillary, the liquid flow rate tends to decrease, since the pressure loss by turbulent friction of the stream tends to grow with increasing l_c. This is also confirmed by our experimental data: The Reynolds number (Re) for water tends to decrease with increasing l_c (see table).

The Reynolds number of water for various capillary lengths l_c and pressures p ($d_c = 2.61 \times 10^{-3}$ m)

l_c, m	Re at indicated p, atm			l_c, m	Re at indicated p, atm

As to the rheological relationships revealed in this study for aqueous solutions of the polymers, there is an essential difference in the T-vs.-Re and T-vs.-l_c experimental dependences obtained by different authors [12, 13]. Kulik carried out the most systematic study in this field [13] and, taking polyoxyethylene as an example, showed that the degree of reduction of the hydraulic resistance of a turbulent stream tends to grow with increasing l_c.

We qualitatively explain the results presented in Fig. 2 on the basis of the fundamental concepts of hydraulics. From this viewpoint, the reservoir–glass capillary joint can be regarded as a kind of a local hydraulic resistance of the "internal nozzle" type, when the liquid outflows under pressure [14] (Fig. 3).

When coming out of the reservoir into the capillary with diameter d_c, a liquid jet is first compressed, then gradually expands, and at a certain length once again fills the entire cross section of the capillary. The jet can be compressed by 20 % [15]. The higher the flow rate of the liquid, the longer the section with the length l_1 within which the jet is compressed. In the zone of compression of the jet, an area with vortical movement of the liquid is formed (Fig. 3, zone *A*). However, after passing the section with length l_1, the stream of the liquid is not yet in equilibrium, since the hydraulics of turbulent streams should also take into account the length of the straight section of the pipe l_2, within which the local resistance ceases to exert a disturbing impact on the stream. The length of this section depends on the type of local resistance, Re, l_c, and roughness and generally can reach (20–50)d_c [15]. Thus, the near-wall zone of a turbulent stream with stable characteristics is formed only after this section with the length l_2 is passed, and in capillary sections 1 and 2 (Fig. 3) the polymer either does not act at all as a turbulence quencher or executes this function only partially.

For the pressures p of interest (5, 10 and 15 atm), we tentatively estimated at 0.05–0.13 m the length of the section where the local resistance is important. This suggests that, in 0.075-and 0.15-m-long capillaries, the Toms effect should either be small or completely lacking, which is really the case, as can be seen from Fig. 2. Naturally, the lengths of the unstable zones of stream l_1 and l_2 tend to become shorter with decreasing flow velocity (and Re), most prominently near the transition area from turbulent to laminar mode of the liquid flow. With increasing l_c, the relative length of the stable section, where the polymer performs at full power, tends to increase, thus improving the performance of the polymeric additive. Figure 2 shows that, already at $l_c = 0.30$ m, the Toms effect T begins to increase and becomes appreciable. This can also account for the nature of the dependence of T on p: The Toms effect naturally decreases with increasing p.

This assumption is also confirmed by the results reported by Gnativ [16], who analyzed how polymeric additives affect the local hydraulic resistances, for which abrupt expansions and constrictions of the pipeline are responsible. He showed that the capability of the additives to reduce the hydraulic friction resistance, lacking (or weakly manifested) when a polymer solution flows through local resistance, is restored downstream.

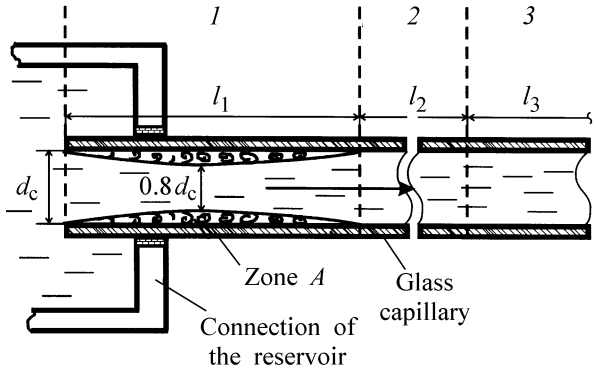

Fig. 3. Schematic structure of the turbulent stream in a capillary. Section: (*1*) compression of jet, (*2*) stabilization of the flow mode, and (*3*) working section.

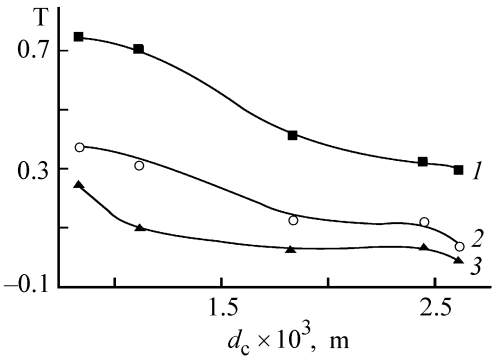

Fig. 4. Variation of T with the capillary diameter d_c at the pressure in the reservoir p = 15 atm. l_c, m: (*1*) 0.6, (*2*) 0.15, and (*3*) 0.075.

This is also validated indirectly by our studies of the Toms effect T as influenced by d_c (Fig. 4). For all the three capillary lengths studied, T clearly tends to decrease with increasing d_c (i.e., with decreasing l_c/d_c), especially in the initial segments of the curves. Common knowledge suggests that, with increasing d_c, the length of the capillary sections characterized by unstable mode of the liquid flow will also increase (Fig. 3, sections *1* and *2*). As a result, the polymeric additive performs worse in reducing the hydraulic resistance of a turbulent stream of liquid throughout the capillary length ($l_1 + l_2 + l_3$), which eventually decreases the Toms effect T.

CONCLUSIONS

(1) The degree of reduction of the hydraulic resistance of turbulent water streams was studied on a modified turbulent rheometer as dependent on the concentration of a polymeric additive and the geometric parameters of the contour (capillary diameter and length). For all the capillary diameters and lengths studied, these dependences are virtually identical, with the only difference in the scale.

(2) A probable reason for the rise in the Toms effect with increasing length and decreasing diameter of the capillary is the instability of the turbulent stream of the liquid in the initial section of the capillary.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Simulation of Wood Impregnation with Oligomer Solutions

S. S. Glazkov and I. P. Biryukova

Voronezh State Academy of Forestry Engineering, Voronezh, Russia

Received January 26, 2004; in final form, February 2005

Abstract—An adequate model is developed for the impregnant distribution along the fibers of a small-dimension crosscut end under conditions of isothermal diffusion impregnation with oligomer solutions.

Synthetic materials are widely used for modification of wood and wooden articles [1, 2]. The properties of the resulting material are controlled by the nature of wood, type and content of impregnant, impregnant distribution in the matrix of the capillary-porous body of wood, and compatibility with wood material. In turn, the impregnant distribution is determined by various factors and process parameters. Capillary-diffusion impregnation of wood remains practical for goods with high end surface fraction, particularly, for friction assembly bushings, compressed-wood frictionless bearings, and end face parquet and wall panels [3–5]. In accomplishing a specific task of impregnation, it is advisable to develop an adequate mathematical model for the impregnant distribution along the fibers of a sample, as influenced by the process time and characteristics of the impregnant.

EXPERIMENTAL

To describe the impregnant distribution in a wood sample with thickness h, which is small compared to the sample length and width, the second Fick's law for 1D diffusion along the x axis is used:

$$\frac{\partial c}{\partial t} = D_M \frac{\partial^2 c}{\partial x^2}, \quad (1)$$

where D_M is the effective mass-transfer coefficient along the x axis; t, impregnation time; and c, impregnant concentration per unit volume (or weight) of the sample.

Assume that at $t = 0$ the material contains no impregnant and the impregnant concentration in solution is constant.

In the study, we used Eq. (1) at the following initial and boundary conditions: at $t = 0$ $c(x, 0) = 0$, $c(\pm h/2, t) = c^*$. In this case, we obtain

$$c(x, t) = c^* \left[1 - \sum_{n=1}^{\infty} \frac{2}{\mu_n}(-1)^{n+1} \cos \mu_n \frac{x}{R_2} \exp(-\mu_n^2 F_0)\right], \quad (2)$$

where $\mu_n = (2n - 1)\pi/2$ are the characteristic series roots; n is a natural number; R_2, half-width of the sample; $F_0 = D_M t/R_2^2$, Fourier criterion (dimensionless time); $c(x, t)$, current impregnant concentration in the wood (%); and c, equilibrium impregnant concentration in the wood (%).

Let us apply Eq. (2) to estimate the effective mass transfer coefficient. At a sufficiently long impregnation time ($t > 80$ min), we can take only the first term of the series, which introduces a relative error of no more than 1%.

We denote the impregnant content in the wood sample by $c(0, t) = A_m$ (mg g^{-1}); the maximal impregnant content in the sample, by $c^* = A_\infty$ (mg g^{-1}); and the degree of process completeness, by $F = A_m/A_\infty$. Then we obtain for D_M

$$D_M = -\frac{[0.24 + \ln(1 - F)]h^2}{\pi^2 t}. \quad (3)$$

In the study, we used samples of birch, pinetree, and oak with dimensions $a \times b \times h = 40 \times 40 \times 1.5$ mm, which corresponds to the infinite board model.

The current sorption was estimated by Eq. (4).

$$A(t) = \frac{m_0(t) - m_0}{m_0}, \quad (4)$$

where m_0 is the weight of the initial absolutely dry sample (g), and $m(t)$, current weight of the impregnated sample dried to constant weight (g).

In the study, we used synthetic oligomers of 4-vinylcyclohexene (VCH) with styrene [SKT-70 (numeral

denotes the bound comonomer content)], methyl methacrylate (OBMMA-15), maleic anhydride (OBMA-6), and sulfur (OBS-50), obtained using still bottoms from production of butadiene rubber. Characteristics of the oligomers and their solutions are summarized in Table 1.

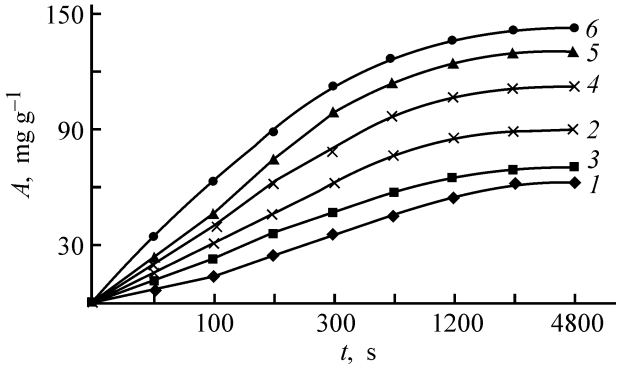

Fig. 1. Kinetic curves of impregnation of pine-tree with (*1*) SKOP, (*2*) drying oil, (*3*) OBMMA-15, (*4*) SKT-70, (*5*) OBMA-6, and (*6*) OBS-50. (*A*) Current absorption, and (*t*) time.

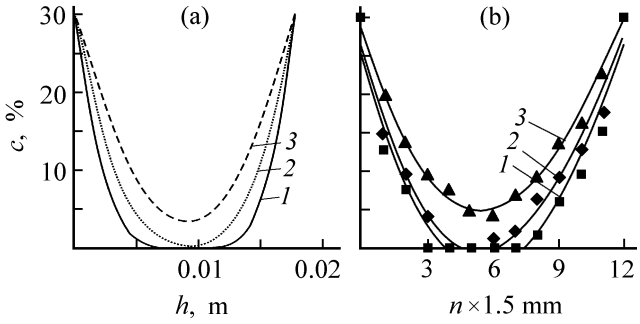

Fig. 2. (a) Theoretical and (b) experimental distribution of OBMA-6 impregnant across the sample. (*h*) Penetration depth and (*n*) number of 1.5-mm layers. Impregnation time (min): (*1*) 20, (*2*) 40, and (*3*) 80.

We experimentally verified the mass transfer model of essentially end-type impregnation for consistency. Test samples were prepared by successive cutting with a milling machine to obtain cuts 40 × 40 × 1.5 mm in size (mill cut thickness was 0.2 mm). Then the end cuts were closely jointed together in the initial order and fastened with a Teflon tape at the side faces. After impregnation the cuts were disjointed and weighed. The initial samples were dried to constant weight at 105 ± 3°C and stored in a desiccator over calcined $CaCl_2$.

Figure 1 shows the kinetic curves of impregnation of pine-tree, which correlate with the molecular weights of the cooligomers used and physical properties of their solutions (Table 1).

From the absorption data obtained at a sufficiently long impregnation time we estimated the effective mass-transfer coefficients by Eq. (3). The coefficients (Table 2) regularly change depending on the sort of wood and molecular and structural features of the oligomers used. D_M decreases in the order birch > pine-tree > oak and also with increasing molecular weight of the oligomers.

Let us use Eq. (2), which is a solution to Eq. (1), for the cases of two-end impregnation mode and fully immersed sample at the above-specified initial and boundary conditions. The distribution of OBMA-6 across the birch sample, estimated by Eq. (2) for various impregnation times (Fig. 2a), is well consistent with the experimental data (Fig. 2b). The theoretical data adequately reproduce the observed increase in the impregnant penetration to the center of the sample.

It should be pointed out that the model demonstrates sufficient adequacy only for thin end cuts

Table 3. Characteristics of end cuts of birch after bulk diffusion impregnation

and the two-end impregnation mode, when the sample thickness h is small as compared to its length and width, and the side-edge diffusion is comparable with the experimental error.

In the cases of the two-end impregnation mode and full immersion of the sample, the amount of one-side open pores, for which the capillary effect is negligible, increase as compared to the case of one-end impregnation.

Analysis of properties of the impregnated wood shows that raising the impregnant concentration in the wood increases the density of the resulting composite material and improves its water resistance (Table 3). The density demonstrates more pronounced tendency to increase with decreasing molecular weight of the impregnant, which is evidently caused by the ability of small macromolecules to be more closely packed in the porous matrix of wood.

The water resistance changes in proportion to the packing density of the macromolecules. At a relatively low impregnant concentration in the wood, the water absorption index W can be decreased by a factor of 2.0–2.5, and the volume swelling index, by a factor of 2–3 (Table 3). The best performance characteristics were obtained after impregnation with the sulfur-containing impregnant OBS-50 having the minimum molecular weight and a heterochain structure with labile sulfur atoms capable of structural rearrangement.

CONCLUSIONS

(1) An analytical solution of the differential equation for the mass transfer in the course of impregnation of thin end cuts of wood provided a relationship for estimating the effective diffusion coefficients.

(2) The impregnation kinetics was studied and the effective diffusion coefficients were determined for various oligomer solutions.

(3) It was found the theoretical and experimental effective diffusion coefficients correlate with the chemical and structural features of oligomers, as well as with the characteristics of the porous structure of wood.

(4) It was astablished that the mass-transfer model suggested reproduces well the experimental data on the distribution of oligomers across the wood fibers, allowing prediction of the impregnation kinetics and performance characteristics of the impregnated wood.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Model of a Polymeric Stabilizer and Optimization of Its Compatibility with Wood

S. S. Glazkov

Voronezh State Academy of Forestry Engineering, Voronezh, Russia

Received February 10, 2004

Abstract—The structure and functionality of a reactive oligomer are characterized in terms of the adhesion, cohesion, and diffusion theories. The dimensions and chain-length distribution of the stabilizer are calculated using the fundamental aspects of adsorption of macromolecules on porous supports and result of an analysis of the capillary-pore system of wood. The statistical model obtained adequately reproduces the properties of stabilized wood over the investigated ranges of the process parameters.

Stabilization of the dimensions of wood materials at varying humidity is, without question, a topical problem. The present-day Russian market of impregnants for wood is saturated with materials of this kind, which are mostly imported. These impregnants, even being highly effective, are, as a rule, expensive, and their use by Russian consumers is occasionally limited by specific process conditions [1]. Therefore, it is an urgent task to extend the range of impregnants for wood through synthesis of new materials from petrochemistry waste products and to characterize these materials [2, 3].

In this study, we developed a model for a thermoplastic polymeric impregnant produced from monomers of still bottoms from synthetic rubber production.

The basic concept of the model is the ability of a polymeric impregnant to penetrate the capillaries of the cell wall and to be involved in structural transformations via functional groups, residual moisture, and the siccative complex in the course of thermal treatment.

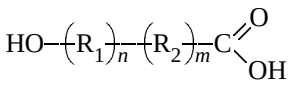
Let us consider the model of a macromolecule of a polymeric impregnant, including its structure, functionality, and molecular-weight distribution, which would be best suited for the problem in hand, i.e., would impart hydrophobicity to wood and provide the desired stability of shape.

In interaction of a solid (wood) with an impregnant solution, the adhesion F (N cm^{-1}) is described, as for two solids, by Eq. (1) [4]

$$F_{ad}(W_{ad}) = f(N_0,\ R_0,\ k,\ S_{eff},\ h,\ D), \qquad (1)$$

where N_0 (N) and R_0 (J) are the interaction strength and energy, referred to a single contact point; k is the number of contact points per unit effective contact surface area (per 1 cm^2); S_{eff}, effective contact surface area (cm^2); h, distance between the contact points (cm); and D, dielectric constant.

Impregnation of wood with a polymeric impregnant bearing polar oxygen-containing groups (carboxy groups at best) is strongly affected by the residual moisture contained in a sample (moisture promotes deprotonation of the carboxy groups).



Interaction of metal cations from the siccative with the anions of the acid residues of the hydrophobic polymeric fragments of the impregnant may result in formation of chemical bonds providing very high adhesion between the interacting bodies. This process is facilitated by raising the temperature in the stages of solvent removal and thermal hardening when an elevated temperature provides a closer contact between macromolecules of the polymeric impregnant.

The proportion between the aliphatic (hydrophobic) part of the macromolecule and the amount of functional groups of the hydrophilic part may vary with the kind of a wood article and purposes of processing. However, it is clear that, to improve the hydrophobicity of an article, it is necessary to minimize the amount of oxygen-containing functional groups, right up to

1070-4272/05/7804-0670 © 2005 Pleiades Publishing, Inc.

bifunctional macromolecules with terminal functional groups. These groups can be readily introduced at the stage of polymerization of vinyl compounds under the action of radical initiators of the peroxy and hydroperoxy types.

The structure of the model impregnant can be schematically represented as

where R_1 and R_2 are structural units of one or different types of vinyl monomers.

The chemical nature and composition of vinyl monomers will control the film-forming capacity of the polymeric impregnant and physicochemical properties of the resulting film.

The optimal molecular-weight distribution or the degree of polymerization P, and the parameters n and m in the general formula of the impregnant are determined, on the one hand, by the desired level of cohesion and, on the other, by the minimal pore space, which limits the permeability to macromolecules with a high molecular weight.

According to one of the known hypotheses, the macromolecules are arranged on the surface in the whole-chain contact mode. Therefore, the packing becomes the closest after the limiting adsorption is reached. However, this is the case only at a very high adsorption. The thickness of a molecule adsorbed on a plane surface D_a (Å) can be approximately estimated by the De Gennes equation [5]:

$$D_a \cong a_u \delta^{-3/2}, \quad (2)$$

where a_u is the averaged unit length in vinyl compounds (3.08 Å), and δ, dimensionless parameter (equation is exactly valid at $1 \ll \delta \ll P^{-2/5}$).

In simulating the structure, composition, and functionality of the polymeric impregnant, let us proceed from the basic cross dimensions of the conducting system at the macro- and microlevels (Table 1) [6].

Table 1 shows that the macro- and microstructures of the capillary-pore structure of both softwood and hardwood are considerably different in their pore diameter. The pore system of the cell wall and intercellular channels are smaller, primarily in their cross dimensions, by several orders of magnitude (by up to a factor of 10^5) as compared to the base conducting system. It is known [6] that changes in the linear dimensions of wood are primarily controlled by characteristics of the cell wall, whose dimensions are sensitive to the humidity. Therefore, only delivery of a polymeric impregnant to cell walls, specifically, to hydrophilic and amorphous parts of the cellulose and hemicellulose fibrils can provide a high stability of shape of wood articles.

Table 1. Cross dimensions of the major conducting elements in various sorts of wood [6]*

Conducting element	Inner diameter, Å		
	pine-tree	birch	oak
Micro level:			
tracheids	2.4×10^5	–	
vessels	–	7×10^5	$\frac{3 \times 10^6}{0.35 \times 10^6}$
fibers	–	1.6×10^5	5×10^4
Micro level:			
micropores in matrix	$\frac{300–400}{50–60}$	2.8×10^5	6×10^5
interfibrillar spacings	50–100	0.32	–
intercellular membrane channels	200	–	

* Averaged data obtained from the wood permeability; data for summerwood and latewood zones are given in the numerator and denominator, respectively.

Let us now approximately calculate the size of macromolecules of a polymeric impregnant that would be capable to reach the indicated structures of wood by comparison with the pore size of the wood conducting system (Table 1). Rearrangement of Eq. (2) gives Eq. (3) [5].

$$R_F \approx a_u P^{3/5}, \quad (3)$$

where P is the degree of polymerization, and R_F, size of the polymeric globule (Å) R_F is taken equal to approximately half the corresponding pore diameter, i.e., $R_F \approx D_a/2$). Then we obtain

$$P = \left(\frac{D_u}{2a_u}\right)^{5/3}. \quad (4)$$

As a simplified model we take an outstretched chain of the macromolecule of the polymeric impregnant, whose length (Å) is written as

$$L_{mol} = a_u P. \quad (5)$$

Table 2. Estimated molecular and thermodynamic characteristics of impregnant macromolecules capable of penetrating the micropores in pine-tree wood

Conducting element	P	L_{mol}, Å	ΔG_a, kJ mol^{-1}
Micropores in matrix	817* 37	2.5×10^3 117	2.7 2.4

SKOP	11000	31	25.6 ± 1.7	27	23
Drying oil	2300	30	26.3 ± 1.3	7	14

* (c) Impregnant concentration (solvent xylene), (σ) surface tension, (θ) contact angle, and (η) dynamic viscosity.

The calculated data for the intercellular and cell-wall capillary systems of pine-tree are given in Table 2.

Table 2 shows that the interfibrillar spacings having the narrowest pores show the lowest permeability to the impregnant. At the same time, these regions are responsible for the absorbed moisture content and, correspondingly, for the stability of shape of the cell wall and of a wood article as a whole. The free energy changes ΔG_a reflecting the changes in the flexibility of macromolecules vary slightly (Table 2), which can be attributed to both rough estimates and close sizes of the cellular micropores.

Turning back to the structure of the model polymeric impregnant, it may be suggested that the desired degree of polymerization $P = n + m$ ranges from 32 to 102 structural units.

Taking into account the indicated optimal range of the degree of polymerization and accepting the molecular weight of 4-vinylcyclohexen (MW 108) as the molecular weight of the basic structural unit, we obtain the average statistical molecular weight of the impregnant macromolecule of 3500–11 000.

EXPERIMENTAL

In the study, we used copolymers of VCH with styrene SKT-70 (numeral denotes the content of the bound comonomer), methyl methacrylate (OBMMA-15), maleic anhydride (OBMA-6), and sulfur (OBS-50), obtained using still bottoms from production of butadiene rubber [7]. The characteristics of the oligomers and their solutions are summarized in Table 3.

For OBMA-6 containing 6% MA units ($\overline{M}_n$ 900–1500), the degree of polymerization ($P = n + m$) is 8.4–14.1, which corresponds to the size of linear macromolecule of 2.6–4.2 nm.

Impregnated wood was prepared as follows. Pine-tree samples (20 × 20 × 30 mm; density 540 kg m^{-3}; moisture content 5–7%) were immersed in an impregnant solution with fixed impregnant and siccative concentrations. The samples were allowed to stand at room temperature and then were dried in an oven at 105–135°C for 1–2.5 h.

After statistical processing, we obtained the following regression equations (confidence probability $p < 0.05$) for the water absorption in 24 h, W_{24} (%):

$$Y_1 = 133.5 - 0.55X_1 - 5.75X_2 - 0.575X_3 - 6.625X_4 + 0.033X_2X_3,$$

for volume swelling in 24 h, h_v^{24} (%):

$$Y_2 = 56.57 - 0.25X_1 - 2.12X_2 - 0.35X_3 - 9.48X_4 + 0.04X_1X_4 + 0.01X_2X_3 + 0.22X_2X_4 + 0.06X_3X_4,$$

for the ultimate strength at break along the fibers, σ (MPa)

$$Y_3 = -16.59 + 0.56X_1 + 1.88X_2 + 0.61X_3 + 6.13X_4 + 0.81X_3X_4,$$

and for the oligomer concentration in wood c_{ol}^w (%):

$$Y_4 = -22.29 - 0.35X_1 - 1.11X_2 + 0.17X_3 + 3.16X_4 + 0.019X_1X_2 + 0.005X_1X_3 + 0.22X_2X_4 + 0.081X_1X_4.$$

The regression equations were tested for an extremum by the Fiacco–McCormick method [8] under the following constrictions: oligomer concentration in impregnating solution $20 \le A \le 40\%$; impregnation time $4 \le B \le 8$ h; temperature of the impregnating solution $60 \le C \le 90$°C; and siccative concentration $2 \le D \le 4\%$.

Optimization with the indicated ranges was performed using the internal penalty function method.

Comparison of the optimization data allowed determination of the optimal process conditions: oligomer concentration 40%, impregnation time 6 h, temperature 90°C, and siccative concentration 3%.

CONCLUSIONS

(1) A statistical model of a polymeric impregnant was experimentally verified for polymeric products obtained from still bottoms from synthetic rubber production.

(2) The wood stabilization process was optimized in a full factorial experiment 2^4. The resulting system of regression equations was tested for an extremum, and the optimal operation mode was found.

(3) For wood impregnated under the optimized conditions, the water absorption and volume swelling decreased by a factor of 5–7, and the ultimate strength at break along the fibers increases by a factor of 2.0–2.5, with all the other mechanical characteristics remaining no worse the before the impregnation.

Abstract—Experimental data on the thermal treatment and hydrophobization of components of fire-extinguishing powdered formulations in an apparatus with active hydrodynamics of a two-phase flow are presented.

Fire-extinguishing formulations have the form of a powdered mixture of various inorganic salts and dopants. Depending on the fire-extinguishing capacity of their components, the mixtures can contain ammonium sulfate, ammophos, carbon white, nepheline, talcum, sodium hydrocarbonate, aerosil, potassium chloride, sodium chloride, etc. The main active components of fire-extinguishing powdered mixtures are ammophos and ammonium sulfate, which form a fusion cake at 160–200°C and thereby screen an inflammation site from interaction with atmospheric oxygen. The rest of the additives, such as talcum and carbon white, impart fluidity to the fire-extinguishing powder and protect it from caking. The moisture content of the components of fire-extinguishing mixtures should not exceed 0.5 wt %.

To prevent caking and to raise the fluidity of powders, a mixture is hydrophobized. Such organosilicon liquids as GKZh-94, Penta-804, MN-15, *et al.* are used as water repellents [1]. Most frequently, either main active components or additives introduced into the formulation are subjected to hydrophobization [2]. In the industry, the components are dehydrated in various drying apparatus, and then some of the dried-up substances are subjected to hydrophobization. To save expensive water-repellent agents, that component of the mixture is treated, which has the highest capacity for moisture absorption under normal atmospheric conditions. It would be the most expedient to combine the processes of thermal treatment of a component and its hydrophobization. Such combined processes can be carried out effectively in vortex apparatus in a high-temperature heat carrier under conditions of a high relative velocity of the interacting phases, which provide an intensive removal of moisture from the material and a high degree of polymerization of a water repellent.

EXPERIMENTAL

The components of fire-extinguishing powdered formulation were heat treated and hydrophobized in an installation shown schematically in Fig. 1. The installation contained the following units: whirlpool

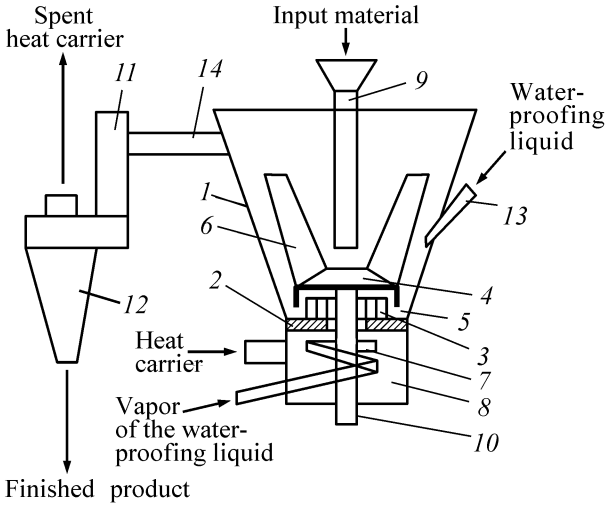

Fig. 1. Schematic of the experimental installation.

1070-4272/05/7804-0674 © 2005 Pleiades Publishing, Inc.

chamber *1*, end plate *2*, turbine section *3*, turbulator *4* in the form of a truncated cone with downwards-directed rim beaters *5* mounted on the periphery of its base, blades *6* attached to the conic surface, evaporator *7*, gas-intake box *8*, feed spout *9*, driving shaft *10*, ventilator *11*, cyclone discharger *12*, droppers *13*, and output fitting pipe *14*.

The device works as follows. The input product is conveyed by a feeder through a gutter *9* into the whirlpool chamber *1* onto the rotating turbulator *4* having blades *6* on its conic surface. When the turbulator rotates with such a rate that its peripheral velocity is equal to, or exceeds the flow velocity of the heat carrier leaving the turbine section *3*, a highly turbulized twirled gas-dispersion flow is formed in the whirlpool chamber. The agglomerates present in the input product are disintegrated by blades and then thrown by the centrifugal force to the periphery into the working zone of beaters *5*, to be partly crushed there. The heat carrier moves from the gas-intake box *8* through a central outlet in the end plate *2* into the turbine section *3*. The blades of the turbine section are arranged so as to ensure the tangential inflow of the heat carrier into the whirlpool chamber in the direction coinciding with the direction of rotation of the turbulator mounted on the driving shaft *10*. As a result, the material is crushed and heat-treated. Under the action of the whirling flow of the heat carrier and of the centrifugal force created by rotating blades of the turbulator, the material is dispersed and ascends to the top part of the whirlpool chamber along a spiral path, wherefrom it is delivered via an outlet fitting pipe *14* and a ventilator *11* into a cyclone discharger *12*. The gas-suspension is separated in the cyclone into a finished product and spent heat carrier, which is then delivered into a bag filter for additional purification. The waterproofing liquid can be fed into the evaporator *7*, where its vapor is formed and mixed with the heat carrier in the gas-intake box, or it is delivered in the form of a liquid through droppers directly into the layer of a material under treatment.

Crushed ammophos was hydrophobized and thermally treated in the experimental installation described above. The effect of heat carrier temperature on the moisture absorption by the finished product was studied. The consumed concentration of the solid phase, μ, was 0.04 kg kg^{-1}; the amount of waterproofing liquid was 3.5% relative to the mass of the solid phase; and the heat carrier temperature was varied within the range 100–150°C.

The curve of moisture absorption by the active component, shown in Fig. 2, was obtained using

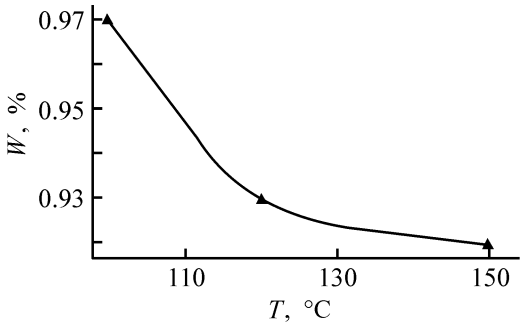

Fig. 2. Moisture absorption by the active component *W* vs. the heat carrier temperature *T*.

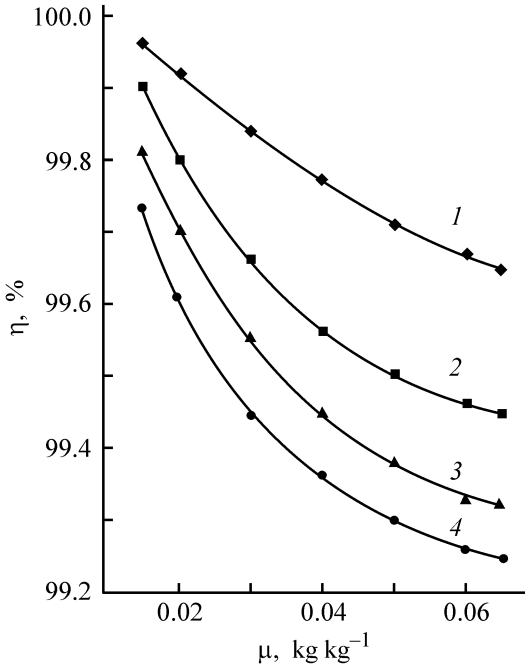

Fig. 3. Degree of silicon dioxide hydrophobization, ν, vs. the consumed concentration of the solid phase, μ. Temperature (°C): (*1*, *2*) 250, (*3*) 200, and (*4*) 150. Water repellent expenditure (kg kg^{-1} of a solid phase): (*1*, *3*) 0.96, (*2*) 0.7, and (*4*) 0.47.

a standard procedure after a treatment of the component in an apparatus with an active hydrodynamics of a two-phase flow. An analysis of the curve shows that the moisture absorption by the powder at a heat carrier temperature of 150°C is 0.92 wt %. As the temperature of the heat carrier decreases, the moisture absorption increases, which points to an incomplete polymerization of the waterproofing liquid. The humidity of the powder fed into the apparatus was 1 wt %. The permissible moisture absorption should not exceed 2 wt %.

Figure 3 shows how the degree of hydrophobization of a highly dispersed silicon dioxide depends on

the consumed concentration of the solid phase at various flow rates of the water repellent and heat carrier temperatures. The heat carrier flow rate L = 11.5 kg h^{-1}. Analysis of the curves in Fig. 3 shows that, as the temperature of the heat carrier increases, the hydrophobicity of the material being treated grows, whereas an increase in the consumed concentration of the solid phase leads to a decrease in the degree of powder hydrophobization.

Our calculations show that 0.028 kg of the waterproofing liquid is consumed for hydrophobization of 1 kg of the active component, which is contained in a powdered formulation in an amount of up to 80 wt %. When a highly dispersed hydrophobized silicon dioxide is introduced into a powdered mixture as a dusting additive in an amount of 2 wt %, 30 to 60% of the waterproofing liquid is saved, which considerably reduces the production costs at the same quality of a fire-extinguishing formulation [2].

CONCLUSIONS

(1) It was found experimentally that 0.035 kg of a water repellent per 1 kg of a solid phase is required to achieve a high hydrophobicity of the active component of a powdered formulation.

(2) The expenditure of the water repellent should be varied within the range 0.47–0.96 kg kg^{-1} of a solid phase for hydrophobization of a highly dispersed silicon dioxide. In this case, the hydrophobicity of the powder is 99.22–99.88%.

(3) If a highly dispersed hydrophobized silicon dioxide is introduced into a powdered fire-extinguishing formulation in an amount of 2 wt %, 30–60% of the water repellent can be saved.

On Raising the Corrosion Stability of Cement Stone

V. E. Akhrimenko

Kuban State Agrarian University, Krasnodar, Russia

Received June 21, 2004

Abstract—A water–paraffin slurry formulation was elaborated and sedimentation-stable cement mortars with low filter output were obtained on its basis.

Development of a quantitative theory of corrosion processes occurring in a cement stone placed in a corrosive liquid and the forecast of its longevity have been the subject of numerous studies [1–5].

The effect of salt additives on the corrosion stability of the cement stone has been considered earlier [6]. It was shown that addition of salts to a cement paste improves the corrosion stability of a cement stone against a salt aggression and that the main reason for destruction of a cement stone in a sodium sulfate solution is its reaction with unreacted tricalcium aluminate $3CaO \cdot Al_2O_3$ and calcium hydroxide $[Ca(OH)_2]$ to give calcium hydrosulfoaluminate (ettringite) $3CaO \cdot Al_2O_3 \cdot 3CaSO_4 \cdot 31H_2O$) which increases in volume upon its crystallization and destroys the cement stone.

Under conditions of polymineral aggression in the presence of hydrogen sulfide, cement stone samples reinforced with asbestine and basalt fibers are the most corrosion-resistant [7]. Cement stone is hydrated to a greater extent in the contact layer with filler fibers, newly formed particles in it are packed more densely, and filler fibers grow into its structure, making lower the overall permeability of the stone. As a result of an intensive clogging of the porous structure, an aggressive liquid cannot freely penetrate into a stone and initiate destruction corrosion processes in it.

The permeability of a cement stone can be diminished by lowering the water-to-cement ratio (w/c), which makes the crystal structure of the stone more dense and depresses diffusion processes occurring in the cement stone and leading to its corrosion. However, the decrease in the water-to-cement ratio changes the rheological characteristics and cementation time. Therefore, development of a formulation of a manufacturable grouting mortar hardening to form a strong corrosion-resistant stone is an important item in the general problem of building of concrete constructions and well casing.

EXPERIMENTAL

In this study, the effect of mudding of the porous structure of a forming cement stone on its permeability and corrosion resistance was examined. We used paraffin as a mudding agent, which was introduced into a cement mortar together with a tempering liquid having the form of a water–paraffin dispersion.

The water–paraffin dispersion was prepared by intensive stirring of paraffin fused in hot water. To stabilize the water–paraffin dispersion, we added to it high-molecular substances and surfactants of the type of oxoethylated alkyl phenols. To obtain a water–paraffin dispersion, we used a paraffin with a melting point of 50–55°C. Cement was tempered with the water–paraffin dispersion prepared (w/c=0.5), thoroughly stirred, and the resulting cement mortar [8] and the stone based on it were tested using the standard procedures (see table).

The resulting cement stone was tested for permeability and corrosion resistance. The permeability of the cement stone was estimated by the filtration coefficient K_f calculated by the formula

$$K_f = Q/S\tau.$$

Here Q is the amount of water filtered through a cement stone (g); τ, filtration time (s); and S, cross-section area of the cement stone (mm^2).

To determine the permeability of the cement stone, we poured the cement mortar under study into a 20-cm^3

medical syringe to a height of 1 cm and left it to harden. After the hardening of the cement stone for 3 days, distilled water was poured into the syringe and forced through the cement stone under a certain pressure created by placing a set of weights on the piston. The permeability of the cement stone was estimated by the volume of water passing through the stone sample in a certain time.

It follows from the table that addition of paraffin to a cement mortar makes it sedimentation-stable; dehydration of such a solution is 2–4 times less as compared with a paraffin-free solution. As to the filtration coefficient, it is an order of magnitude smaller in the case of a paraffin-containing cement stone.

The corrosion stability of the cement stone was estimated using the express gravitational procedure. For this purpose, the cement stone sample under study was kept for 1 h in distilled water, then immersed in a vessel with water, and weighed on an electronic balance. After weighing, the stone sample was placed in a 10 wt % solution of hydrochloric acid. After a certain time, the sample was taken from the acid, placed in a vessel with water, and weighed again. The loss of mass was determined from the difference of sample masses before and after immersion in the acid solution, and the corrosive destruction coefficient K_{destr} was calculated from this loss. The corrosive destruction coefficient is defined as the ratio of the mass of the dissolved stone to the initial mass of the stone (see table).

It follows from the table and figure that sample no. 1 of pure portland cement is subject to strong destruction in an acid medium, as well as cement stone sample no. 2 with an addition of polyvinyl alcohol (PVA) and a surfactant, and their corrosive destruction coefficients are 0.13 and 0.12, respectively. As to the cement stone samples containing paraffin (sample nos. 3 and 4), they were found to be corro-

Changes in cement stone samples. (*1*) Pure portland cement; portland cement with an additive: (*2*) PVA and surfactant, (*3*) 1.0% paraffin, and (*4*) 1.5% paraffin.

sion-resistant, their corrosive destruction coefficients are 0.08 and 0.05, respectively. Thus, our study demonstrated that finely dispersed paraffin contained in a tempering liquid leads to mudding of the porous structure of the forming cement stone and makes it low-permeable and corrosion-resistant.

CONCLUSIONS

(1) A novel water–paraffin tempering liquid was developed.

(2) It was shown that the water–paraffin tempering liquid affects rheological characteristics of a cement mortar.

(3) It was found that introduction of paraffin into a cement mortar leads to mudding of the porous structure of the resulting stone and makes it low-permeable and corrosion-resistant.

Kinetic Aspects of Dimethylamine Hydroxyethylation in the Presence of Water

S. M. Danov, V. A. Kolesnikov, R. V. Efremov, and D. Yu. Mezhenin

Nizhni Novgorod State Technical University, Dzerzhinsk Branch, Dzerzhinsk, Nizhni Novgorod oblast, Russia

Received June 30, 2004; in final form, January 2005

Abstract—The kinetics of dimethylamine hydroxyethylation at an ethylene oxide : dimethylamine : water molar ratio of 1 : 3 : (0.1–0.5) was studied in the temperature range 20–50°C. A kinetic model of the reaction, which adequately describes the experimental data, was suggested.

Dimethylethanolamine (DMEA) is produced industrially by hydroxyethylation of dimethylamine (DMA) with ethylene oxide (EO) in the liquid phase. At one of the existing plants, the synthesis is carried out in a "tube-in-tube" reactor at 80–175°C, pressure of 5–6 MPA, and DMA : EO molar ratio of 3 : 1 in the presence of water (6% relative to the total weight of the starting reagents).

Previously, the kinetic aspects of DMA hydroxyethylation in the absence of water have been studied [1]. It was shown that the reaction is autocatalytic and accelerated by DMEA. The parameters of the Arrhenius equation for noncatalytic and autocatalytic reactions were found.

It is known from published data that the reaction is accelerated by proton donors (water, alcohols, phenols, and acids) [2–6]. Therefore, the aim of the present study was to examine previously unstudied kinetic aspects of DMA hydroxyethylation in the presence of water. The data obtained can be further used in choosing the optimal equipment and operation mode of a reaction unit. As to other amines, the kinetics of aniline hydroxyethylation in the presence of water was studied in [3]. It was shown that the reaction is first-order with respect to water, and the rate constant of the catalytic reaction at 100°C and water concentration of 0.5 M is 4.7×10^{-4} l mol^{-1} s^{-1}.

It is also known that dimethylaminoethoxyethanol (DMAEE) is formed as a by-product, in addition to DMEA, in hydroxyethylation of DMA, with EO isomerized to give acetaldehyde and also dimerized and polymerized [7]. Furthermore, glycols can be formed in an alkaline medium in the presence of water [8]. The products obtained can undergo further transformations. Preliminary studies have shown that the side reactions proceed to an insignificant extent at 20–60°C, DMA : EO molar ratio of 3 : 1, and low water content. The synthesis in industrial reactors is carried out at the same ratio, and, therefore, the kinetics of DMA hydroxyethylation in the presence of water was studied under the same conditions.

The reaction rate was monitored by the accumulation of DMEA in the reaction mass, with the concentration of DMEA determined by gas–liquid chromatography.

In developing the kinetic model, the reaction orders with respect to EO, DMA, and DMEA were taken to be unity in accordance with the authors' [1] and published [3–6] data. The reaction order with respect to water was calculated from the experimental data obtained. Thus, the rates of noncatalytic (r_1), autocatalytic (r_2), and catalytic (r_3) reactions were described by the following equations

$$r_1 = k_1 c_1 c_2,\ r_2 = k_2 c_3 c_1 c_2,\ r_3 = k_3 c_4^n c_1 c_2.$$

Here k_1, k_2, and k_3 are the rate constants of the noncatalytic, autocatalytic, and catalytic reactions, respectively; c_i, molar concentration of ith component (1, EO; 2, DMA; 3, DMEA; and 4, water); and n, reaction order with respect to water.

The reaction proceeds with a decrease in the number of moles of reagents, which becomes 12% at a complete EO conversion. Therefore, the material balance equations for each component

$$\mathrm{d}(Vc_i)/\mathrm{d}\tau = \nu_i V(r_1 + r_2 + r_3),\ i = 1, 2, 3, 4$$

[where V is the volume of the reaction mass; τ, time; and ν_i, stoichiometric coefficient of ith component

1070-4272/05/7804-0680 © 2005 Pleiades Publishing, Inc.

($\nu_1 = -1$, $\nu_2 = -1$, $\nu_3 = 1$, $\nu_4 = 0$)] were solved simultaneously with the equation describing the change in the volume in the course of the reaction:

$$dV/d\tau = \sum_{i=1}^{4} \nu_i V(r_1 + r_2 + r_3)/\rho_i.$$

Here ρ is the molar density of a component.

The order of the catalytic reaction with respect to water was estimated using the kinetic curves obtained at various initial concentrations of water in the reaction mass (Fig. 1a). The system of equations was numerically integrated by the fourth-order Runge–Kutta method. In the integration of the system, the values of k_1 and k_2 were fixed and corresponded to the previously obtained values of the coefficients A and E (J mol^{-1}) of the Arrhenius equation [1]: k_1 9.25×10^5, 58 800; k_2 1.75×10^5, 49 800. The reaction order n with respect to water and the constant k_3 of the catalytic reaction at 30°C were calculated from the condition that the sum of squared deviations F of the calculated DMEA yields b_i^c from the experimental values b_i^e at each point i is at a minimum for all the kinetic curves, with account of the weighting factors w_i (T = 30°C):

$$\min_{n,\,k_3} F = \sum_{i=1}^{N} w_i (b_i^c - b_i^e)^2.$$

Here N is the number of experimental points.

The minimum of the function F was found using the modified gradient method.

The following values of the sought-for parameters were obtained: n = 1.62 and k_3 = 4.58×10^{-4} $l^{2.62}\,mol^{-2.62}\,min^{-1}$. As can be seen from Fig. 1a, the calculated and experimental values of the yield are in a good agreement.

The kinetic curves of DMEA formation at various temperatures and equal initial water concentrations are shown in Fig. 1b.

The parameters A_3 and E_3 (J mol^{-1}) of the temperature dependence of rate constant of the catalytic reaction [$k_3 = A_3 \exp(-E_3/RT)$] were calculated from the condition that the sum of squared deviations F of the experimental DMEA yields from the calculated values for all the experimental points shown in Fig. 1b is at a minimum:

$$\min_{A_3,\,E_3} F = \sum_{i=1}^{N} w_i (b_i^c - b_i^e)^2, \quad T \ 20, 30, 40, 50°C.$$

For a water-catalyzed reaction (k_3), the following parameters of the Arrhenius equation were obtained: A_3 13.79×10^5 and E_3 54 700 J mol^{-1}.

(b) $q^0_{EO} \times 10^4$ (mol): (*1*) 430.5, (*2*) 345.8, (*3*) 462.8, (*4*) 431.2. $q^0_{DMA} \times 10^4$ (mol): (*1*) 1321.6, (*2*) 1006.3, (*3*) 1346.7, (*4*) 1302.2. $q^0_{water} \times 10^4$ (mol): (*1*) 89.0, (*2*) 69.1, (*3*) 92.0, (*4*) 87.4. *Points*, experiment; *lines*, calculation.

Thus, the experimental data are well described in terms of the kinetic model suggested, which can be used to optimize a reaction unit for DMEA production.

EXPERIMENTAL

In the experiments, EO [GOST (State Standard) 7568–88] and DMA (GOST 9967–74) without additional purification and twice-distilled water were used. The experimental procedure and the method of analysis are similar to those described earlier [1].

Catalytic Activity of a Mordenite Catalyst in Alkylation of Xylenols with Methanol

A. A. Agaev and K. M. Madatzade

Sumgait State University, Sumgait, Azerbaijan

Received July 26, 2004; in final form, February 2005

Abstract—The catalytic activity of a palladium-containing mordenite catalyst in alkylation of 2,6-, 2,4-, 2,5-, 2,3-, 3,4-, and 3,5-xylenols with methanol was studied. The main and by-products of catalysis and the activity of the catalyst in synthesis of individual trimethylphenols were determined.

Methyl derivatives of phenol are consumed in considerable amounts because of their being the most important half-products of small- and medium-tonnage chemistry. However, the last decade exhibited not only an absolute increase in the amount of their manufacture, but also, and to a greater extent, an expansion of their assortment [1].

Catalytic alkylation of phenols with methanol, which is employed with success in manufacture of *ortho*-cresol and 2,6-xylenol [2–4] or recommended for use in synthesis of other isomers of mono- and dimethyl derivatives of phenol, virtually has not been systematically studied in synthesis of individual trimethylphenols.

The aim of this study was to examine the catalytic activity of a mordenite catalyst in alkylation of isomeric xylenols with methanol.

EXPERIMENTAL

Experiments on alkylation were performed in a laboratory reactor under stationary conditions with a fixed catalyst bed of volume 10 cm^3. Synthetic mordenites (SiO_2 : Al_2O_3 molar ratio x = 25), containing Pd-H-mordenite, served as catalysts. The mordenites were obtained by treating a Na-mordenite (x = 10) with a 1 N NH_4Cl solution, with the subsequent washing and drying. Palladium was introduced in an amount of 1.0 wt % into grains of a mixture of a zeolite and γ-aluminum oxide with an aqueous solution of $[Pd(NH_3)_4]Cl_2$. Before delivering the raw material, the catalysts were calcined at 450°C in a flow of dry air (1 h, 1000 h^{-1}) and then kept for 1 h in a flow of hydrogen (1000 h^{-1}) at 410°C and a pressure of 0.1 MPa. The products formed were condensed in a refrigerator-separator and analyzed by gas-liquid chromatography on a Khrom-5 chromatograph with a column (3.6 m × 4 mm) packed with dimenthylphthalate (18 wt %) on Chromocorb W and catharometer as detector. Dimenthylphthalate was synthesized using an accelerated procedure from menthol and phthalic anhydride.

To reveal the role of noncatalytic transformations, preliminary experiments were performed under the reaction conditions, but without a catalyst. In this case, more than 98% of methanol and 100% of isomeric xylenols (virtually all the isomers) were recovered in an unreacted state, which indicated that there was no reaction in the after-catalyst space [6]. In addition, it was established that isomeric xylenols are isomerized and disproportioned over the Pd-H-mordenite catalyst under the conditions studied (350°, 0.8 h^{-1}) to only a slight extent, because a study of transformations of 2,6-, 2,4-, 2,5-, and 3,5-xylenols in the presence of Pd-H-mordenite without methanol demonstrated that their conversion does not exceed 3.2%.

Analysis of the results obtained in alkylation of isomeric xylenols with methanol shows that this reaction occurs by the concurrent-consecutive mechanism. In this case, the alkylation of isomeric xylenols at the carbon atom of the benzene ring is far ahead of the methylation at the hydroxy group of a particular xylenol. Formation of trimethylphenols via intramolecular conversion of the resulting methyl esters of the respective xylenols is unlikely at the given temperature. According to the previously obtained data [5, 7], such a scheme of formation of methyl homologues of phenol in the presence of mordenite and other zeolite catalysts is accompanied by a low selectivity with respect to the target isomers.

It can be seen from the table that trimethylphenols are formed rather selectively with respect to some of the isomers. For example, 2,4,6-trimethylphenol is

1070-4272/05/7804-0683 © 2005 Pleiades Publishing, Inc.

Alkylation of xylenols with methanol in the presence of a Pd-containing mordenite (T = 350°C, v = 0.8 h^{-1}, xylenol : methanol molar ratio 2 : 1)

Xylenol–methanol	Conversion of xylenol, %	Yield of trimethylphenol in terms of a xylenol taken, %	Yield of reaction products in terms of reacted xylenol, %							
			dimethylanisole	2,4,6-trimethylphenol	2,3,6-trimethylphenol	2,4,5-trimethylphenol	2,3,4-trimethylphenol	2,3,5-trimethylphenol	3,4,5-trimethylphenol	tetramethylphenols
Xylenol:										
2,6-	35	28	2	80	8	–	–	–	–	8
2,4-	48	35	0.5	73	–	13	–	–	–	11
2,5-	40	32	–	–	79	3	–	–	–	13
2,3-	51	41	–	–	80	–	5	5	–	7
3,4-	53	45	–	–	–	40	45	–	1	10
3,5-	58	40	1	–	–	–	–	70	6	17

the main reaction product in methylation of 2,4- and 2,6-xylenols, mainly 2,4,6-trimethylphenol is formed in methylation of 2,5- and 2,3-xylenols, and predominant formation of 2,3,6-trimethylphenol is observed in the catalytic system constituted by 3,5-xylenol and methanol. In contrast to other xylenols, the 3,4-isometer is methylated less selectively on the mordenite catalyst. Methylation of 3,4-xylenol yields two isomers, 2,4,5- and 2,3,4-trimethylphenols in a virtually equimolar ratio. However, the total yield of these isomers in terms of reacted 3,4-xylenol is rather high (95%), and the conversion of 3,4-xylenol in a single pass is practically important (53%).

It can also be seen in the table that the Pd-containing mordenite exhibits a sufficiently high selectivity in methylation of isomeric xylenols. The highest selectivity of the reaction with respect to the target trimethylphenols is observed in the case of methylation of 2,6- and 2,3-xylenols (80%), and the lowest (70%), in the case of a 3,5-xylenol. It should be noted that the yield of trimethylphenols in terms of reacted methanol is also high (74–88%).

In addition to the main isomers listed above, other trimethylphenols are also formed under the reaction conditions, but in a considerably lower yield. The concentration of the main trimethylphenol in the mixture of its isomers varies rather widely (47–82%).

The composition of the tetramethylphenols obtained is not complex and depends on the starting xylenol only slightly. The 2,3,5,6-isomer predominates in the tetramethylphenol fraction obtained in the case of 3,5-xylenol, and mostly 2,3,4,6-tetramethylphenol is formed in other cases.

A comparison of the yields of the main reaction products (trimethylphenols) in terms of a xylenol taken demonstrated that, on the whole, the catalytic activity of the Pd-containing mordenite decreases in the following order: 3,4-xylenol > 2,3-xylenol > 3,5-xylenol > 2,4-xylenol > 2.5-xylenol > 2.6-xylenol.

Under the conditions of catalysis, methanol is transformed only slightly: it undergoes dehydration, dehydrogenation, decarbonylation, and decomposition. Methyl ether, CO, CO_2, and trace amounts of formaldehyde and ethylene were found in the gaseous reaction products.

CONCLUSIONS

(1) A sufficiently high catalytic activity of a Pd-containing zeolite catalyst in synthesis of individual trimethylphenols and their mixtures from xylene isomers and methanol was demonstrated.

(2) It was shown that, under the conditions studied, the conversion of xylenols is 35–57% and the yield of the main trimethylphenol in terms of a reacted xylenol, 70–80%.

Decreasing the Content of Free Formaldehyde in Urea–Formaldehyde Resins

V. Z. Maslosh, V. V. Kotova, and O. V. Maslosh

Institute of Applied Chemistry, Ministry of Science and Education of the Ukraine, Rubezhnoe, Lugansk oblast, Ukraine

Received June 14, 2004

Abstract—The possibility of decreasing the content of free formaldehyde in urea–formaldehyde resins by varying the pH and urea–formaldehyde ratio in various synthesis steps was examined. Urea–formaldehyde resins containing no free formaldehyde were prepared.

Urea–formaldehyde resins (UFRs) are widely used binders. Their significant drawback is the toxicity caused by the presence of free formaldehyde (FA); its content depends on the preparation conditions [1].

The influence of process parameters on the properties and structure of UFRs was examined in numerous studies [2–4], but the problem is far from being solved because of the complexity of the reactions involved in UFR formation. Polycondensation in the urea–FA system is accompanied by many side reactions (hydrolysis, cyclization, addition, etc.), affecting the functional composition of the product. The kinetic features and mechanisms of these reactions are different [5]. An additional factor complicating the mechanism of UFR formation is the polyfunctional nature of urea and FA.

In this study, we examined how the process parameters affect the content of free FA in UFRs prepared at varied pH values and urea : FA ratios in particular reaction steps.

EXPERIMENTAL

UFRs were prepared at 82 ± 3°C and varied pH in three steps. The urea : FA molar ratio in these steps was 1 : 4, 1 : 1.45, and 1 : 1.33. In the course of the synthesis, we monitored the content of free FA and methylol groups (MGs) [6]. The experimental results are shown in Fig. 1. In run nos. 1 and 2, step I was performed in an acidic solution (pH 4.5–5.0), and steps II and III, in an alkaline solution (pH 9.5–10.0). In run nos. 3 and 4, step I was performed in an alkaline solution (pH 9.5–10.0); step II, in an acidic solution (pH 4.5–5.0); and step III, again in an alkaline solution (pH 9.5–10.0). In run nos. 5 and 6, steps I and III were performed similarly to run nos. 3 and 4, and step II, at pH 2.0–2.5. In run nos. 7 and 8, all the three steps were performed in an alkaline solution (pH 9.5–10.0). In run nos. 1, 3, 5, and 7, urea was loaded in a single portion in each step; in run nos. 2, 4, 6, and 8, the same amounts of urea were loaded uniformly in equal portions during the course of the process step. A detailed protocol of UFR preparation and the UFR structure were reported in [7, 8].

Experimental data show that the properties and toxicity of UFRs are appreciably influenced by such process factors as the mode of loading urea, pH of the medium, and reaction time, and also by the concentrations of urea and FA. In the UFR synthesis in an alkaline solution, when urea is loaded in a single portion, the content of free FA is 0.13–0.14, and that of MGs, 18.6–19.8 wt % (Fig. 1d, curves *1* and *1*'); when urea is loaded uniformly, the content of free FA is 0.05–0.09, and that of MGs, 18.5–19.7 wt % (Fig. 1, curves *2* and *2*'). A longer reaction in alkaline solution does not result in an appreciable decrease in the free FA content.

In the synthesis of UFR in an alkaline solution, a steady decrease in the free FA content is accompanied by a smooth increase in the MG content, which reaches 23.0–23.5 wt % (Fig. 1, curves *1*' and *2*'). It has been shown previously [7] that the UFR formed under such conditions is of mostly linear structure, with a high content of methylene ether bonds. The ready hydrolysis of the methylene ether bonds and the equilibrium character of MG formation account for the reproducibly high content of free FA in UFR samples prepared in alkaline solution.

1070-4272/05/7804-0685 © 2005 Pleiades Publishing, Inc.

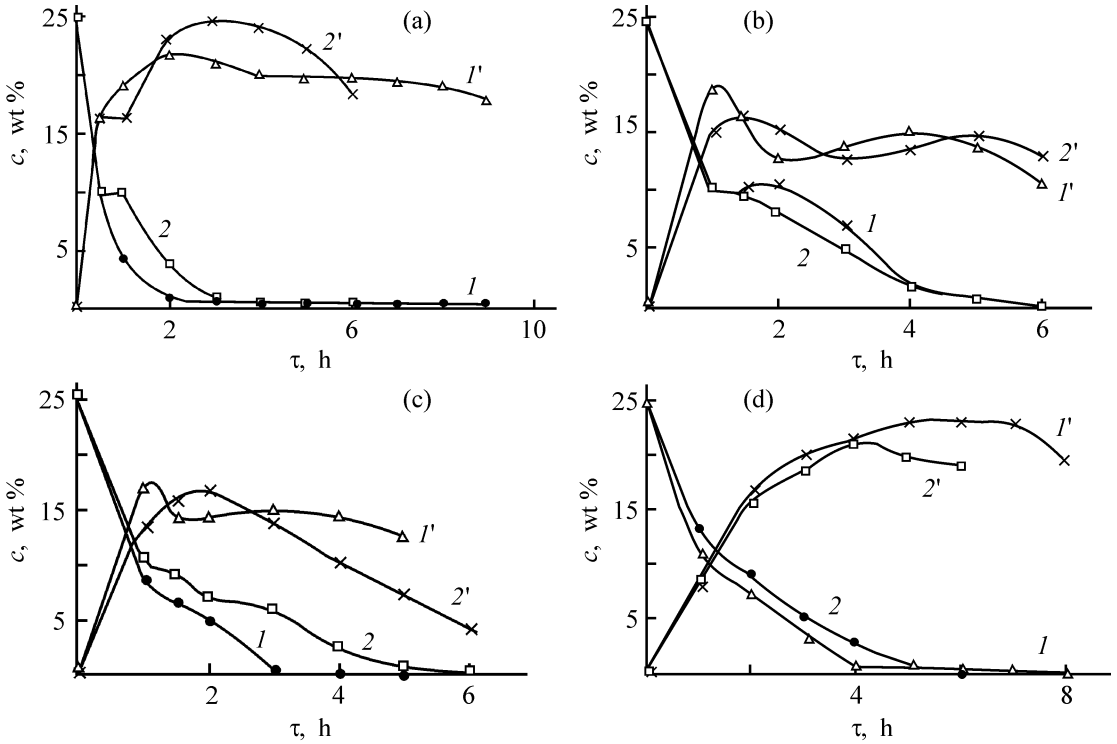

Fig. 1. Concentrations *c* of (*1*, *2*) free FA and (*1*', *2*') MGs vs. time τ in synthesis of UFR at varied pH. (a) Step I, pH 4.5; steps II and III, pH 9.5–10.0; urea loaded in a single portion in each step; (b) steps I and III, pH 9.5–10.0; step II, pH 4.0–4.5; (c) steps I and III, pH 9.5–10.0; step II, pH 2.0; and (d) whole synthesis in aklaline solution. MA loading mode: (*1*, *1*') in a single portion in each step and (*2*, *2*') uniformly in equal portions.

In the UFR prepared in acidic solution in step I and alkaline solution in steps II and III, the free FA content is high, 0.23–0.39 wt % (Fig. 1, curves *1* and *2*). A longer reaction does not result in a noticeable decrease in the free FA content. The MG content is considerably lower than in the preceding case, 18.0–18.5 wt % (Fig. 1, curves *1*' and *2*'). The UFR prepared under these conditions is characterized by the linear structure with small branchings and by the presence of MGs and methylene ether bonds [7], which are potential sources of free FA. Apparently, the main source of free FA in this case is unchanged FA.

The free FA content in UFRs was the lowest (0.03 wt %) when the resins were prepared in alkaline solution in step I, in acidic solution in step II, and again in alkaline solution in step III (Figs. 1b and 1c, curves *1* and *2*). When urea is added in a single portion in each step, the trends in variation of the FA concentration at pH 2.0–4.5 in step II are different (Figs. 1b and 1c, curves *1*). As pH 2.0–4.5 is established and a new portion of urea is added, the free FA content ceases to decrease until the pH is changed and a new portion of urea is added, after which the free FA content appreciably decreases again. When UFR is prepared under similar conditions but with uniform addition of urea, the free FA content decreases without interruptions (Figs. 1b and 1c, curves *2*). According to spectroscopic data, uronic rings are formed in step I in alkaline solution when urea is loaded in a single portion; upon completion of step II, these rings are cleaved with the release of free FA and its subsequent addition to amino and imino groups of urea derivatives. In the synthesis with uniform addition of urea, uronic rings are also formed in step I, but they are preserved in all the subsequent steps and in the final product. The alkaline–acidic–alkaline sequence provides conditions for formation of branched products, which are mainly formed in step II. The subsequent condensation in alkaline solution favors lengthening of the molecular chain of the reaction products formed in the preceding steps. Such a sequence of the pH variation at the chosen molar ratio of urea and FA results in formation of products with stronger bonds (including cyclic products). The residual release of free FA in these resins may be due to equilibrium reactions involving MGs and FA, and in the resins prepared by uniform addition of urea, also to reactions involving amino groups of urea which is present in the free state according to the spectroscopic data [7]. A longer reaction can yield under these conditions resins containing

no free FA. In storage of such resins, the equilibrium processes can cause fluctuations in the free FA content within the range 0.00 – 0.02 wt %.

CONCLUSION

The influence of process factors on the free formaldehyde content in urea–formaldehyde resins was revealed. The lowest content of free formaldehyde is attained when the first and third steps of the synthesis are performed in an alkaline solution, and the second step, in an acidic solution. Uniform addition of urea results in a larger extent of polycondensation, both in acidic and in alkaline solutions.

Professor Nikolai Nikolaevich Lyubavin (To 160th Anniversary of His Birthday)

Nikolai Nikolaevich Lyubavin, a graduate from St. Petersburg University and a pupil of N.N. Sokolov (1826–1877) and D.I. Mendeleev (1834–1907), is primarily known as the author of the book *Fizicheskaya khimiya* (Physical Chemistry) (first issue 1876, second issue 1877) and of a seven-volume textbook of technical chemistry.

Lyubavin was born on April 10 (22), 1845, into a wealthy merchant's family in St. Petersburg. He received his secondary education at St. Petersburg College of commerce. In 1867, he graduated from the natural department of the physicomathematical faculty of St. Petersburg University with a Ph. D. Beginning in early 1868, Lyubavin worked on his own initiative at a number of German chemical laboratories of the following scientists: H. Kolbe (1818–1884) in Leipzig, A. Baeyer (1835–1917, Nobel Prize in 1905) in Berlin, R. Bunsen (1811–1899) A. Ladenburg (1842–1911) in Heidelberg, and I. Hoppe-Seyler (1825–1895) in Tubingen. He also worked for a short time at M. Berthelot's (1827–1907) laboratory in Paris. During his stay in Germany, Lyubavin published results of his studies in the field of organic chemistry in four papers in German journals [1, 2].

In August 1870, the young scientist returned to St. Petersburg and at the beginning of 1871, occupied, by invitation of professor N.A. Menshutkin (1842–1907), a position of a laboratory assistant at the analytical department of his laboratory. Till the summer of 1886, Lyubavin supervised practical training in quantitative analysis. In 1874, he received his master's degree on passing appropriate examinations and defending a dissertation "Ammonia Compounds of Valeric Aldehyde." As a privatdocent, Lyubavin delivered a special course of lectures "Glycines and Amides of Carbonic Acid" in 1880–1882 and a general course of technical chemistry in 1885–1886. During his work at St. Petersburg University, Lyubavin continued experimental investigations in the field of organic chemistry. Among objects of his studies were valeric and other aldehydes, glyoxal, glyoxamine, cinchonine, glycines and amines of carbonic acid, and many other compounds. During the period

from 1871 to 1886, he published about 20 papers in *Zhurnal Russkogo fiziko-khimicheskogo obshchestva* (Journal of Russian Physicochemical Society). In the early 1880s, the scientist performed a number of investigations in the field of technical chemistry and studied iron-manganese ores and phosphorites. The first issue of Lyubavin's monograph *Fizicheskaya khimiya* (Physical Chemistry) was published in 1876, and the second issue, in 1977 (both issues combined include 20 chapters with a total volume of 806 pages). Lyubavin wrote the book on the assumption that theoretical chemistry, concerned with various chemical phenomena, can be divided into three sections: physical chemistry, descriptive chemistry, and analytical chemistry. In terms of this approach, physical chemistry is understood as a part of theoretical chemistry, which is concerned with fundamental aspects of chemical phenomena and chemical processes, irrespective of the nature of substances involved in these processes. The material is presented on the basis of a large number of diverse experimental investigations, with references given to original studies. The whole presentation is of nearly exclusively descriptive nature. Detailed descriptions of processes and phenomena, permanent references to experimental studies by various authors, the manner of presen-

1070-4272/05/7804-0688 © 2005 Pleiades Publishing, Inc.

tation, and the volume of the book give no way of referring this Lyubavin's work to merely the category of textbooks.

In 1886, having accepted an offer by professor V.V. Markovnikov (1837–1904), Lyubavin became a staff member at Moscow University and started to deliver the basic course of lectures in technical chemistry. The lectures were delivered during two semesters twice a week. The basic curse included the following topics: chemistry of combustibles; technical chemistry of heavy metals; silicates and cements; salts, alkalis, and acids; nutrients (including studies of fermentation); fats; oils and tars; and fibrous substances [3]. The chair of technical chemistry included two laboratories, of technical and agricultural chemistry. According to the Statute of Imperial Russian Universities, approved in 1863, chairs of technical chemistry were established at physicomathematical faculties. Even having no knowledge of certain engineering disciplines, students specialized in technical chemistry could well work in chemical industry. This was largely due to Lyubavin's efforts.

On having defended his doctoral dissertation "Pyridine Compounds, Lyubavin was appointed an extraordinary professor at the chair of technology and technical chemistry. In 1897 was published the first volume of the scientist's fundamental work *Tekhnicheskaya khimiya* (Technical Chemistry). In all, he wrote and published six volumes before 1914. The seventh volume remained unfinished and was published in parts in 1922–1926, under the editorship of a Lyubavin's pupil, professor A.M. Nastyukov (1868–1941). The first four volumes presented technical chemistry of inorganic substances, and the last three, that of organic substances.

In 1901, Lyubavin completed his 30-years term as a State employee and, in conformity with the regulations of that time, lost his position as a professor on the staff, but "retained his professor's status and right to teach at the University." He continued to deliver lectures and supervised practical training. In 1907, Lyubavin retired, terminated his teaching activities and concentrated his attention on writing next volumes of Technical Chemistry. During 20 years of his work at Moscow University, from 1886 to 1906, Lyubavin always delivered the basic course of technical chemistry himself. Privatdocents invited by him delivered separate special courses of lectures in varius sections of chemical technology. The position of the head of the chair of chemical technology at Moscow University was inherited by Nastyukov, who defended his doctoral dissertation in 1906 and was appointed professor in 1908.

Lyubavin did much for the improvement of the quality of teaching of technical chemistry at Moscow University and played an important role in training of specialists for industry. The construction of a new building for the laboratories of technical chemistry and agricultural chemistry was commenced in 1903 and completed in 1905 under Lyubavin. For Lyubavin, teaching at Moscow University was the main kind of activity; he did not occupy any positions not associated with his work at the University. The teaching of technical chemistry at Moscow University in 1855–1905 was described in detail by the scientist himself [3]. The organization of teaching and Lyubavin's contribution were discussed in [4–6]. Lyubavin's many-volume book Technical Chemistry was highly appreciated in P.M. Luk'yanov's monograph [7].

Lyubavin died on December 17, 1918.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Specific Features of Chemical Interactions in Atmospheric Purification of a Nickel–Cobalt Solution To Remove Copper

Converter-Matte Plant, Norilsk Nickel Mining-and-Smelting Combine, Open Joint-Stock Company, Norilsk, Russia

Received February 24, 2005

Abstract—Atmospheric purification of a nickel–cobalt solution to remove copper with a high-copper converter matte was studied. The structural and textural characteristics and the phase and chemical composition of the high-copper converter matte and of the solid residue remaining after atmospheric copper removal were examined. The mechanism of copper precipitation and leaching-out of elements belonging to the iron triad was determined, and the extents of the main chemical reactions were calculated.

The technology of manufacture and hydrometallurgical processing of a granulated high-copper converter matte, developed for polymetallic raw materials with a high content of platinum-group metals from Norilsk,[1] has been rather thoroughly worked over in laboratory and, as regards certain procedures, on enlarged-laboratory and semicommercial scales.

It has been experimentally established that the key influence on parameters of the autoclave procedures of the technology is exerted by the mode of the leading procedure, copper removal. This fact, opening up an opportunity to control in rather simple ways the autoclave operations, has attracted the researchers' attention and has become a powerful stimulus to a comprehensive study of the fundamental aspects and specific features of chemical interactions occurring in purification of a nickel–cobalt solution to remove copper ions. Another factor requiring an in-depth analysis of copper removal processes is the need to calculate the distribution of metals and sulfur in the initial stages of converter matte hydrometallurgy, which are associated with development of process schedules and choice of apparatus.

The first stage of hydrometallurgical processing of the converter matte, selective purification of a nickel–cobalt solution to remove copper, is performed under atmospheric conditions with vigorous agitation of the slurry and aeration with air. The solution delivered from the stage of autoclave refining is purified with the initial crushed converter matte. In this case, the mode parameters of the process ensure that a final nickel–cobalt solution with a prescribed residual copper concentration (0.001 g dm^{-3}) is obtained. The main goal of this procedure consists in the maximum possible recovery of copper from solution into a solid precipitate directed into the stage of autoclave oxidative leaching (AOL). Another goal is to leach-out readily removable components of the converter matte, metallic alloy and, in part, heazlewoodite (Ni_3S_2). The leaching occurs in this procedure in the same chemical event as copper precipitation. Therefore, both these tasks are inseparably linked with each other.

It is known [1–4] that the most chemically active component of the converter mattes is the metallic phase. Leaching-out of its components mainly occurs by the reaction

$$M + H_2SO_4 + 0.5O_2 \rightarrow MSO_4 + H_2O, \qquad (1)$$

where M stands for Ni, Fe, Co, or Cu.

Because the recirculated solution delivered to the copper removal stage contains a considerable amount of free sulfuric acid, the acid leaching of heazlewoodite is possible [5–7]:

$$Ni_3S_2 + H_2SO_4 + 0.5O_2 \rightarrow NiSO_4 + 2NiS + H_2O. \qquad (2)$$

Despite that the atmospheric copper removal has been used for several decades in many schemes of atmospheric hydrometallurgy of converter matte, the mechanism of copper precipitation has not been conclusively elucidated. Published data on the mech-

[1] Developed by specialists from the Converter-Matte Plant of Norilsk Nickel Mining-and-Smelting Combine, Open Joint-Stock Company.

1070-4272/05/7805-0691 © 2005 Pleiades Publishing, Inc.

anism of this process are rather contradictory. This suggests the existence of several possible mechanisms of copper removal, with one or another dominating, depending on the composition of the converter matte and on operation conditions. In particular, the atmospheric purification of Ni–Fe–Co solutions to remove copper with a high-nickel converter matte (Ni : Cu ≈ 13 : 1), implemented at Harjavalta plant (Finland), occurs at pH values exceeding 4.5. In [4], the mechanism of this process, in which hydrolytic purification of the solution to remove iron occurs simultaneously with copper removal, is described by the following reactions:

$$CuSO_4 + (Ni \cdot Cu) + 0.5O_2 \rightarrow Cu_2O + NiSO_4, \quad (3)$$

$$2CuSO_4 + 2Ni_3S_2 + 0.5O_2 \rightarrow Cu_2O + 2NiSO_4 + 4NiS, \quad (4)$$

$$3CuSO_4 + 2Ni_3S_2 + O_2 + 2H_2O \rightarrow Cu_3SO_4(OH)_4 + 2NiSO_4 + 4NiS, \quad (5)$$

$$2CuSO_4 + (Ni \cdot Cu) + O_2 + 2H_2O \rightarrow Cu_3SO_4(OH)_4 + NiSO_4. \quad (6)$$

Iron present in the initial solution as Fe^{2+} is oxidized and precipitated mainly as FeOOH, in accordance with the equation

$$FeSO_4 + Ni_3S_2 + 0.75O_2 + 0.5H_2O \rightarrow FeOOH + NiSO_4 + 2NiS. \quad (7)$$

It can be seen from Eqs. (3)–(7) that, in the conditions under consideration (pH > 4.5), copper precipitates from solution in the form of cuprite (Cu_2O) and basic copper sulfate, whose composition corresponds to the formula of antlerite, $Cu_3SO_4(OH)_4$.

A study of the phase composition of solid residues formed in copper removal with a high-copper converter matte (Cu : Ni ≈ 2 : 1) at final pH values ~4.2–4.8 revealed noticeable amounts of basic copper sulfate described by the formula $Cu_5(SO_4)_2(OH)_6$[2]; among other newly formed phases of copper, produced in its precipitation from solution, secondary djurleite and covellite were found. X-ray diffraction studies of the residues revealed the absence of magnetite and bornite. Transfer of sulfide iron into solution in the course of copper removal may proceed by the following reaction to give elementary sulfur:

$$FeS + H_2SO_4 + 0.5O_2 \rightarrow FeSO_4 + S + H_2O. \quad (8)$$

[2] Carried out by specialists from Gipronikel' Institute, Open Joint-Stock Company.

Data on the process kinetics suggest the possibility of direct reaction between the freshly formed millerite and oxygen:

$$NiS + 2O_2 \rightarrow NiSO_4, \quad (9)$$

which also continues in the final stages of copper removal in the absence of copper and acid in solution.

The schedule of the copper removal process, developed for autoclave hydrometallurgy of high-copper converter matte, involves separate purification of nickel–cobalt solution to remove copper and iron. For this purpose, the copper precipitation is carried out at pH values not exceeding 3, which precludes formation of oxides and hydroxy compounds of copper (cuprite, basic sulfates) and coprecipitation of iron oxides. This specific feature of the copper removal mode leads to a fundamentally different course of the process, compared with that described above. The ability of copper–nickel converter mattes to precipitate copper ions has been used in hydrometallurgical practice for a comparatively long time. This effect has been attributed to a specific metallic property of a nickel atom in the heazlewoodite lattice, whence the term "cementation" has appeared. According to this concept, heazlewoodite is a complex in which nickel atoms are in different oxidation states, $Ni \cdot (2Ni_2 + S)$. Reznik *et al*. [8] assume that the copper precipitation with heazlewoodite can be represented as an exchange reaction

$$Ni_3S_2 + CuSO_4 \rightarrow Ni_2CuS_2\downarrow + NiSO_4, \quad (10)$$

according to which two of the three atoms of nickel contained in heazlewoodite remain in the precipitate in a complex intermediate phase. In accordance with the suggested mechanism, copper is in the atomic state in the complex intermediate phase. If the solution contains free acid and an oxidizing agent (oxygen) is present, reverse transfer of the active copper atom into solution is inevitable:

$$2NiS \cdot Cu + H_2SO_4 + 0.5O_2 \rightarrow 2NiS + CuSO_4 + 2H_2O. \quad (11)$$

The occurrence of reaction (11) leads to a paradoxical conclusion that precipitation of copper, which acts in the given process as a "mediator" that carries electrons from atomic nickel to oxygen molecules, is impossible.

The mechanism of copper precipitation by cementation with a converter matte from sulfate solutions was considered in [1, 2, 4, 5, 9]. According to the

results of these studies, the heazlewoodite leaching with simultaneous copper precipitation mainly occurs by the reaction

$$Ni_3S_2 + 2CuSO_4 \rightarrow NiS + 2NiSO_4 + Cu_2S. \quad (12)$$

The cementation reaction (12) is, undoubtedly, an overall reaction, because it is impossible to imagine congruent dissolution of a nickel metal atom from the heazlewoodite lattice and nickel ions chemically bound with sulfur. In addition, the mechanism of direct sulfidization of the copper(2+) atom remains unclear.

Rademan *et al.* [1] explained the interaction as occurring via the stage of formation of hydrogen sulfide:

$$Ni_3S_2 + 2H^+ \rightarrow H_2S + NiS + 2Ni^{2+} + 2e, \quad (12a)$$

$$2Cu^{2+} + H_2S + 2e \rightarrow Cu_2S + 2H^+, \quad (12b)$$

$$Ni_3S_2 + 2Cu^{2+} \rightarrow Cu_2S + NiS + 2Ni^{2+}. \quad (12)$$

There exists a concept that this reaction can proceed by the redox mechanism, without intermediate formation of hydrogen sulfide:

$$2NiS \cdot Ni \rightarrow 2NiS + Ni^{2+} + 2e, \quad (13a)$$

$$2Cu^{2+} + 2e \rightarrow 2Cu^+, \quad (13b)$$

$$Ni_3S_2 + 2CuSO_4 \rightarrow NiSO_4 + Cu_2SO_4 + 2NiS. \quad (13)$$

The active copper(1+) sulfate reacts with millerite to give copper(1+) sulfide:

$$NiS + Cu_2SO_4 \longrightarrow NiSO_4 + Cu_2S \quad (14)$$

In this case, the resultant reaction described by a sum of Eqs. (13) and (14) has the form corresponding to Eq. (12).

If this mechanism is operative, it follows from Eq. (12) that the stoichiometric recovery of copper into solution is 66%. At the same time, extensive studies of the process of copper removal, carried by us on real products, demonstrated that the actual level of copper recovery into solution does not exceed 25–30%.

EXPERIMENTAL

To determine the maximum recovery of nickel into solution in copper removal, laboratory studies of how the procedure duration and l/s ratio affect the parameters of the copper removal process were carried out.

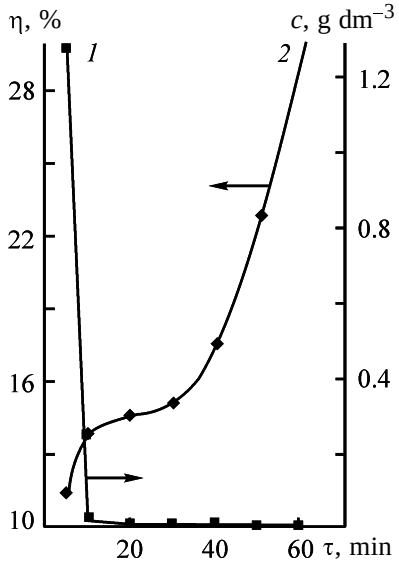

Fig. 1. (*1*) Residual content *c* of copper in solution and (*2*) nickel recovery η into solution vs. the duration of the copper removal process, τ.

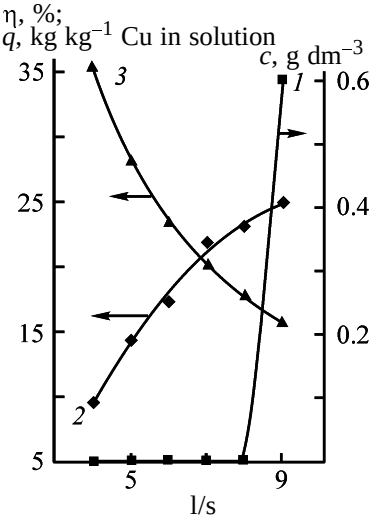

Fig. 2. (*1*) Residual content *c* of copper in solution, (*2*) nickel recovery η into solution, and (*3*) specific expenditure *q* of the converter matte vs. the l/s ratio in the initial sludge.

As starting ingredients were used a model solution of the composition simulating that of the recirculation solution from autoclave refining and sample no. 1 of a granulated high-copper converter matte of composition (%): Ni 26.20, Cu 46.6, Co 0.61, Fe 3.21, and S 21.4, crushed in a laboratory ball mill to a 90% content of particles of the –45-μm fraction. The copper removal was performed in a 1.0 dm^3 titanium reactor with mechanical agitation and electric heating. Air was supplied through a dispersant under a sludge bed, with its flow rate controlled with a calibrated rotameter. The results of these experiments are shown in Figs. 1, and 2.

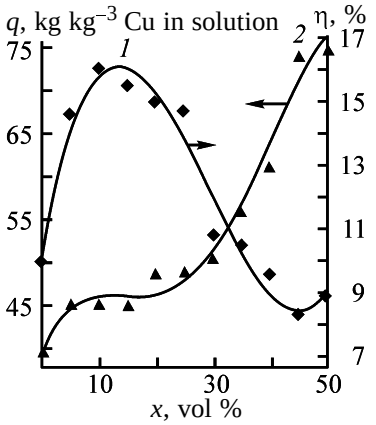

Fig. 3. (*1*) Nickel recovery η into solution and (*2*) specific expenditure *q* of the converter matte vs. the amount *x* of anolyte added.

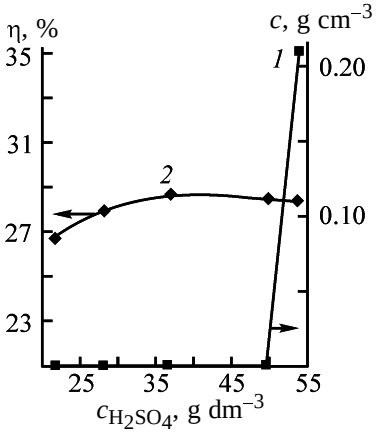

Fig. 4. (*1*) Residual content *c* of copper in the final solution and (*2*) nickel recovery η into solution vs. the content $c_{H_2SO_4}$ of the acid in the initial solution.

Figure 1 shows that sufficiently deep precipitation of copper occurs already in 20 min, with its residual concentration in solution equal to 1 mg dm^{-3}. The maximum recovery of nickel into solution was 30.19% at 60 min of copper removal.

Figure 2 shows how the recovery of nickel into solution depends on the l/s atio, i.e., on the amount of copper and sulfuric acid delivered to the process of copper removal with the recirculated solution.[3] The amount of copper and acid involved in the process grows simultaneously with an increase in the l/s ratio. Therefore, it is impossible to make an unambiguous conclusion about what mechanism, cementation (12) or acid dissolution (1) and(or) (2), predominantly affects the extent of nickel recovery into solution.

A possible way to raise the nickel recovery into solution was to deliver an additional amount of the acid into the copper removal process. In laboratory experiments, the acid was introduced into the process as a component of a nickel anoyte at a fixed l/s ratio. The laboratory experiments were performed with sample no. 2 of a granulated high-copper converter matte of composition (%): Ni 25.42, Cu 48.9, Co 0.72, Fe 2.27, and S 22.3, crushed in a laboratory ball mill to a 90% content of particles of the –45-μm fraction. The specific expenditure of the converter matte was raised, compared to that in preceding experiments, in order to diminish the influence exerted by copper arriving with the solution on the extent of nickel recovery from the converter matte. The experiment duration was the maximum possible, 60 min. In all the experiments, the required residual copper concentration in solution ($c \le 1$ mg dm^{-3}) was reached. The results obtained in copper removal are shown in Fig. 3.

Figure 3 shows that the dependence of the extent of nickel recovery on an anolyte addition shows an extremum. At small volumes of the anolyte, the nickel recovery into solution grows to reach a maximum at an anolyte expenditure of 10 vol %. However, further increase in the fraction of the anolyte in the liquid phase of the initial sludge leads to a decrease in the extent of nickel recovery into solution. The observed decline in the recovery may be due to a decrease in the amount of copper delivered into the process and to the resulting increase in the specific expenditure of the converter matte.

In the next stage of the study, it was necessary to determine how the nickel recovery into solution depends on the initial concentration of the acid in the recirculated solution. The duration of copper removal was 60 min. The initial solution with a fixed content of copper was acidified with concentrated sulfuric acid. The specific expenditure of the converter matte was 20.68 kg kg^{-1} copper in solution in all the experiments. The results obtained are shown in Fig. 4. It can be seen that, all other conditions being the same, introduction of an additional amount of the acid does not exert any decisive influence on the nickel recovery into solution, because the value of this parameter is about the same within experimental error.

The results of the study are summarized in Fig. 5. The data obtained indicate that the key influence is exerted on the extent of nickel recovery into solution by the ratio between the mass of the converter matte and amount of dissolved copper, delivered to the process of copper removal. In addition, the nickel recovery into solution is strongly affected by the degree of metallization of the converter matte, which, in turn,

[3] The duration of copper removal in experiments with varied l/s ratio was 40 min.

Table 1. Results of semicommercial tests of the atmospheric copper removal process (T = 85–90°C, air space velocity 2.2 $nm^3\ m^{-3}$ solution min^{-1}, τ = 60 min)

Phase	Content in precipitate, %, and in solution, g dm^{-3}					Recovered into solution, %			Degree of copper precipitation, %
	Ni	Cu	Co	Fe	S_{tot}	Ni	Co	Fe	
Solid residue	21.20	48.1	1.71	0.26	21.4	–	–	–	–
Solution	115.16	<0.001	0.89	5.78	86.0	18.18	59.54	43.55	99.99

depends on the content of sulfur in it. At a lowered content of sulfur in the converter matte, the amount of metallic nickel in the matte increases, reaction (1) of dissolution of the metallic component develops, and the dependence of nickel recovery into solution on the specific expenditure of the converter matte is less pronounced.

The minimum specific expenditure of the converter matte, which ensures that a prescribed residual concentration of copper in solution (0.001 g dm^{-3}) is reached, was 17.78 kg kg^{-1} Cu (Fig. 2); the maximum extent of nickel recovery into solution, achieved in the experiments, was 30.2% (Fig. 1). To determine the composition and structure of products formed in copper precipitation in atmospheric copper removal, samples of the initial and final solid products formed in this procedure were subjected to a mineralogical analysis.[4] In particular, the initial granulated high-copper converter matte (Ni 26.8, Cu 46.8, Co 0.67, Fe 3.1, and S 22.2%) and a solid residue formed in semicommercial purification to remove copper (Table 1) were analyzed. Composition of the initial solution (g dm^{-3}): Ni 114.1, Cu 7.19, Fe_{tot} 3.0, Co 0.01, and H_2SO_4 13.5.

A study of a sample of granulated high-copper converter matte demonstrated that the material contains three phase components: copper sulfide, nickel sulfide, and a metallic phase. Among the phases identified were djurleite, a tetragonal modification of $Cu_{1.96}S$, and heazlewoodite, Ni_3S_2, which are the main constituents of the converter matte. Also, a primary low-temperature chalcosine, an orthorhombic modification of Cu_2S, and a minor amount of low-temperature bornite (Cu_5FeS_4) were revealed. No independent mineral forms of iron and cobalt were established. Because of its extremely small dimensions, the composition of the metallic phase was determined semiquantitatively (wt %): Ni 75–80, Fe 10, Cu 10, and Co 2–3. The content of the metallic phase in a sample of the high-copper converter matte was approximately 3–5 wt %.

Coarse particles of the solid residue formed in purification to remove copper were close in their mineralogical composition to grains of the initial crushed converter matte. The finely dispersed component of the residue was mainly composed of copper sulfide (of predominantly secondary origin). A sample of the solid residue was composed both of particles containing all the three components and of those in which there was already no metallic phase. These latter had voids of a characteristic shape reproducing that of the initial metallic component, and these voids indicated that leaching of chemically free metals is selective. An unexpected and difficultly understandable fact was that the metallic phase simultaneously disappeared throughout the particle volume without any noticeable indications of their decryptation or formation of open pores. The main phase component of the sample formed in copper removal was relict djurleite ($Cu_{1.96}S$), containing virtually no iron. The composition of the metallic phase remained unchanged, but

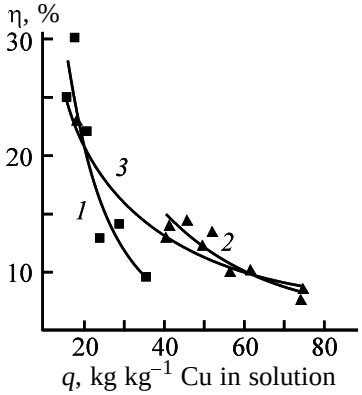

Fig. 5. Influence of the specific consumption q of the converter matte on the nickel recovery η into solution in atmospheric copper removal. Sulfur content (%) in the converter matte: (*1*) 21.4 and (*2*) 22.3; (*3*) generalized curve.

[4] Carried out by L.N. Ertseva using the conventional diagnostic techniques: X-ray diffraction and optical analyses and a set of modern methods for studying the composition of substances, including scanning electron microscopy and X-ray fluorescence microanalysis (Converter-Matte Plant, Norilsk Nickel Mining-and-Smelting Combine, Open Joint-Stock Company and Gipronikel' Institute, Open Joint-Stock Company).

Table 2. Calculated extents of the main chemical reactions in copper removal

Reaction	Metal being recovered	Extent of reaction with respect to metal being recovered into solution, %	Recovery of metal from converter matte, %	Fraction in total recovery of component, %
$Ni + H_2SO_4 + 0.5O_2 \rightarrow NiSO_4 + H_2O$	Ni	80.00	10.83	59.64
$Ni_3S_2 + 2CuSO_4 \rightarrow NiS + 2NiSO_4 + Cu_2S$	Ni	11.60	6.68	36.78
$Ni_3S_2 + H_2SO_4 + 0.5O_2 \rightarrow NiSO_4 + 2NiS + H_2O$	Ni	2.25	0.65	3.58
$Fe + H_2SO_4 + 0.5O_2 \rightarrow FeSO_4 + H_2O$	Fe	80.00	12.49	28.78
$Fe_2S_3 + 2CuSO_4 + Cu_2S \rightarrow 2FeSO_4 + 4CuS$	Fe	66.00	30.91	71.22
$Co + H_2SO_4 + 0.5O_2 \rightarrow CoSO_4 + H_2O$	Co	80.00	13.98	23.44
$Co_3S_2 + 2CuSO_4 \rightarrow CoS + 2CoSO_4 + Cu_2S$	Co	83.00	45.66	76.56
$Cu + H_2SO_4 + 0.5O_2 \rightarrow CuSO_4 + H_2O$	Cu	80.00	0.80	–

dissolution of its major part resulted in a decrease in the total content of iron and cobalt in the solid residue, compared with the initial converter matte. The decrease in the content of iron in the solid phase in the course of purification to remove copper is also due to its leaching-out from the bornite component, which probably yielded secondary copper sulfide. The phase component of nickel sulfide contained considerable amounts of copper impurity and, for the most part, had a formula close to $Ni_{50}Cu_{10}S_{40}$, which stoichiometrically corresponded to a mixture of $Cu_{2-x}S$ and Ni_3S_2. A minor amount of nickel sulfide was present in the form of millerite.

The possibility of copper precipitation in the course of copper removal by mechanism (12) is in good agreement with the results obtained when studying the phase composition of the product formed in the process, but this mechanism cannot be used to explain the effect of limited copper precipitation from solution. At the minimum specific expenditure of the converter matte equal to 17.78 kg kg^{-1} Cu in the recirculated solution, the calculated recovery of nickel from the solid phase by reaction (12) is 21.7%, in good agreement with the experimental results. However, it is unclear why the degree of solution purification decreases dramatically at a specific expenditure of the converter matte of less than 17.78 kg kg^{-1} Cu, despite that a considerable amount of heazlewoodite is still contained in the solid residue and there are no apparent reasons why reaction (12) cannot proceed further. It may be assumed that these reasons are of kinetic, rather than thermodynamic, origin.

The probable reasons for the hindrance to reaction (12) are as follows: diffusion hindrance associated with copper deposition onto the surface of converter matte particles in the form of dense films that preclude penetration of leaching agents into the reaction zone; kinetic hindrance of electrochemical nature, associated with the primarily occurring leaching-out of the metallic phase from the whole volume of a converter matte particle.

Elucidating the mechanism of hindrance and developing methods for its inhibition are a matter of current interest because, if the extent of reaction (12) is raised, the nickel recovery into solution in the atmospheric stage will substantially increase. A solution to this problem will markedly diminish the amount of expensive equipment required in the other stages of autoclave leaching.

The formation of a secondary copper sulfide with a composition close to Cu_2S suggests that the copper removal occurs under domination of the cementation mechanism by reaction (12). The extent of this reaction is determined from the amount of nickel recovered into solution, which is found in direct experiments with account of the dissolution of the metallized phase by reaction (1).

It may be assumed that the behavior of cobalt, which is isomorphically incorporated into the composition of heazlewoodite, in the reaction with copper sulfate is similar to that of nickel. This reaction yields higher cobalt monosulfide and chalcosine:

$$Co_3S_2 + 2CuSO_4 \rightarrow CoS + 2CoSO_4 + Cu_2S. \quad (15)$$

The acid fed into the process as a component of the initial solution is spent for dissolution of the metallic phase and oxidative leaching of heazlewoodite by reaction (2).

According to the results of mineralogical studies, the solid residue formed in copper removal contains virtually no bornite. This may be due to decomposition of iron and copper sulfides contained in it ($Cu_4^{1+}Cu_{0.5}^{2+}Fe^{3+}S_4 \rightleftarrows 2Cu_2S + 0.5CuS + 0.5Fe_2S_3$) to give iron sulfate and covelline:

$$Fe_2S_3 + 3CuSO_4 = Fe_2(SO_4)_3 + 3CuS, \quad (16)$$

$$Fe_2(SO_4)_3 + Cu_2S = 2FeSO_4 + CuS + CuSO_4, \quad (17)$$

$$Fe_2S_3 + 2CuSO_4 + Cu_2S = 2FeSO_4 + 4CuS. \quad (18)$$

The extent of this reaction was determined from the iron recovery into solution with account of the amount of iron dissolved by reaction (1). The main chemical reactions occurring in the course of copper removal and their extents are listed in Table 2.

The procedure for calculating the extent of the chemical reactions was based on the best possible fitting of the theoretical quantitative characteristics of the copper removal process to the parameters obtained in direct experiments (Table 1). The calculations were performed with account of the data obtained in an instrumental analysis of the structure and composition of the products under study.

CONCLUSIONS

(1) It was established experimentally and confirmed by calculation that the cementation precipitation of copper is incomplete despite the presence in the system of considerable amounts of the starting ingredients.

(2) The cementation mechanism of precipitation from solution is characteristic of copper; iron is leached-out both from the metallic phase of the converter matte and from the complex copper sulfide with a composition of bornite with predominance of the second mechanism; the recovery of nickel into solution is primarily due to leaching-out of the metallic phase and copper precipitation by the cementation mechanism, with the acid dissolution of heazlewoodite proceeding to only a minor extent.

(3) The results obtained in calculating the extent of the main chemical reactions were used for preliminary design and feasibility study of hydrometallurgical processing of a high-copper converter matte.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Use of Wastes from Soda Production To Produce Nonshrinking Oil-Well Cement

T. V. Kuznetsova, A. A. Shatov, M. A. Dryamina, and R. N. Badertdinov

Soda Open Joint-Stock Company, Sterlitamak, Bashkortostan, Russia

Received September 20, 2004

Abstract—The possibility of using soda wastes to obtain sulfated clinkers was analyzed. The phase composition of the clinkers synthesized was determined. Processes of hydration of the cements obtained were examined. Semicommercial tests of formulations of nonshrinking oil-well cements were performed.

Disintegration of a cement ring in the annular space is largely due to its shrinkage stresses [1]. Therefore, the problem of development of an oil-well material with a compensated shrinkage in the course of hardening is still a matter of current interest.

As objects of study we chose raw materials used at the Podol'sk experimental cement plant: limestone, clay, cinders, gypsum, and materials of industrial origin, produced at the Soda Open Joint-Stock Company: carbonized and noncarbonized slurries [2]. The chemical compositions of the chosen components are listed in Table 1.

X-ray diffraction and petrographic analyses revealed that the limestone is mainly represented by calcite (>50%) and the clayey component mostly contains montmorillonite and a certain amount of hydromicas.

The slurries have close compositions. According to the results of an X-ray diffraction analysis, the material also contains calcium sulfate, calcium and aluminum oxychlorides, and a minor amount of magnesium hydroxychloride.

To examine the possibility of using carbonized and noncarbonized slurries, the compositions of raw mixes used to obtain sulfoferrite clinkers were calculated. The data obtained show that the chosen materials of industrial origin, wastes from the Soda Open Joint-Stock Company, can be used as a carbonate component. The presence of calcium sulfate in the wastes leads to a significant decrease in the amount of gypsum necessary for preparing the mixture (from 9.8% for mixtures prepared from the conventional components to 4.5% for a mixture prepared from a carbonized slurry) [3].

EXPERIMENTAL

To study processes of mineral formation, mixtures intended for production of low- and high-basic sulfoferrite clinkers and a clinker of intermediate composition were prepared. A control clinker was synthesized

Table 1. Chemical composition of raw components

Material	Content of oxides, wt %						
	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	SO_3	calcination loss
Limestone	6.56	1.58	0.86	50.02	1.18	–	39.80
Clay	51.93	15.17	6.86	7.29	1.75	2.92	11.27

from raw materials used at the Podol'sk cement plant. The raw mixes were prepared by wet grinding in a laboratory porcelain mill for 6 h. Then the slurries obtained were dried in a drying box at 60±5°C to a residual moisture content of 1–2%.

The prepared raw mixes were used to form on a hydraulic press at a pressure P = 400 kg cm^{-2} cylindrical samples 5 cm in diameter and 3 cm high. The samples were calcined in a high-temperature furnace with lanthanum chromite heaters at 1100, 1150, 1180, and 1200°C, with isothermal heating for 5, 10, 15, 20, 30, and 60 min.

We found that the temperature of complete assimilation of CaO in heating of raw mixes depends on the basicity of a clinker. In a low-basic clinker, the degree of binding equal to 0.98–1.0 is reached at 1180°C. The degree of CaO assimilation is 0.73–0.78 upon an isothermal keeping for 5 min (T = 1180°C) and becomes as high as 0.98–1.0 when the time of heating is raised to 30 min.

Binding of calcium oxide in raw mixes for high-basic clinkers requires heating to a higher temperature of 1250°C, with a degree of limestone assimilation equal to 0.98–0.99 reached upon heating for 30 min. In clinkers of intermediate composition, the degree of CaO assimilation equal to 0.98–1.0 is reached at 1200°C (τ = 30 min). Data on the degree of assimilation of calcium oxide are listed in Table 2.

Comparison of the kinetics of CaO assimilation in mixtures based on solid residues formed in soda production and in control mixtures based on the conventional components shows that synthesis of minerals contained in the sulfoferrite clinker is considerably faster in the formulations developed, compared with control mixtures. The acceleration of the reactions of mineral formation is apparently due to the presence in slurries of chloride compounds, which act as mineralizers in calcination of a clinker [4, 5].

These results were used to calculate the rate constants of the reactions of CaO assimilation in formation of sulfated clinkers. An analysis of the data obtained demonstrated that the rate of CaO binding is limited by diffusion processes and is described by the Jander equation.

X-ray diffraction and petrographic analyses were used to determine the phase composition of the clinkers synthesized. It was established that the phase composition of a clinker produced by calcination of low-basic sulfoferrite raw mixes based on materials of industrial origin at a temperature of complete assimilation of CaO (T_c ≈ 1180–1200°C) significantly differs from that calculated. This is due to the appearance of a large amount of a melt and to the preferential formation of high-basic phases via the liquid phase. The content of phases in clinkers prepared from high-basic mixtures and those of intermediate composition was close to to that obtained by calculation (Table 3).

A study of hydration of the resulting clinkers by the petrographic method in micropreparations confirmed the conclusion that the hydration activity of products based on materials of industrial origin is higher [2]. Already in the first hours of hydration, ferruginous ettringite is formed in the samples studied;

it remains stable for up to 14 days. This makes it possible to preserve the expansion effect in a system being hardened during a rapid buildup of strength and to eliminate the shrinkage deformations. In further hydration, the recrystallization of the ferruginous ettringite into a monosulfate form and the formation of a gel of iron hydroxide lead to reinforcement of the cement stone through mudding of the pore space.

The results obtained served as a basis for development of optimal compositions of zero-shrinkage oil-well cements.

Cements of various compositions (Table 4) were prepared on the basis of sulfoferrite clinkers (Table 3) and portland cement clinker (PCC) in an MBL laboratory mill.

The cements obtained were tested in conformity with the requirements imposed on oil-well materials at the following characteristics: w/c 0.45 and flowability within 205–230 mm. The results of physicomechanical tests are listed in Table 5.

Thus, the linear expansion of the samples increases from 0.03 to 0.24% as the amount of sulfoferrite clinker introduced into the cement is raised from 5 to 15 wt %. The strength of the cement stone remains virtually unchanged at small SFC doses (5–10%). As the amount of the sulfoferrite clinker in the cement is raised to 15 wt %, the strength characteristics deteriorate. This is due to formation of a greater amount of calcium hydrosulfoferrite of trisulfate form in hydration of the sulfoferrite clinker, with the expansion of the hardening system reaching such a level that destruction processes impair the strength characteristics.

Electron-microscopic examination of the cement stone demonstrated that, in the course of hydration of sulfoferrite phases, mainly ferruginous ettringite, calcium monohydrosulfoferrites and hydroferrites, and a gel of iron hydroxide are formed. In joint hydration of the minerals contained in portland cement and sulfoferrite clinkers, these phases are responsible for the expansion of the hardening system and densification of the cement stone.

Estimates of the rates of cement hydration make it possible to arrange the sulfoferrite-containing cements in the following order: low-basic SFC, that of intermediate composition, and high-basic SFC. This enables a considerable decrease in the amount of the sulfoferrite additive introduced, at the same linear expansions of the system.

These results served as a basis for tests at the Pilot Cement Plant of NIItsement (Research Institute of Cement).

Table 5. Strength of cement stone

Cement no.	Strength, MPa, at indicated age, days				Expansion, %, at indicated age, days	
	bending		compression		2	28
	2	28	2	28		
1	2.3	4.9	5.8	11.3	0.03	0.08
2	2.2	4.5	5.2	10.7	0.05	0.10
3	1.7	3.4	4.0	8.7	0.11	0.18
4	2.7	5.6	6.6	13.4	0.07	0.12
5	2.4	5.3	6.2	13.0	0.10	0.15
6	1.8	3.2	4.1	8.8	0.14	0.24
7	2.5	5.1	6.0	12.1	0.05	0.09
8	2.3	5.0	6.1	11.6	0.08	0.11
9	2.2	4.7	5.2	10.4	0.10	0.18

The tests were performed with the developed compositions of nonshrinking oil-well cements based on sulfated clinkers. The sulfoferrite clinker was obtained by calcination of a raw mix composed of limestone, pyrite cinders, and gypsum from the Podol'sk experimental cement plant and carbonized slurry from the Soda Open Joint-Stock Company in a forge at 1180°C.

A physicochemical analysis of the clinker obtained revealed that it is close in composition to high-basic sulfoferrite clinkers. The content of sulfated dicalcium ferrite is 38 wt %.

The oil-well cement was prepared by grinding in a batch mill of a stock composed of 80 wt % portland cement clinker, 10 wt % sulfoferrite clinker, and 10 wt % gypsum. The fineness of grinding of the cement was characterized by a 13% residue on sieve no. 008 at a specific surface area of about 3300 $cm^2\ g^{-1}$.

The physicomechanical properties of the cement obtained, determined in accordance with GOST (State Standard) 1581–78, are as follows: flowability at w/c = 0.44 equal to 195 mm; time of setting: onset 8 h 15 min, end 9 h 30 min; mortar density 1940 $kg\ m^{-3}$; ultimate strength of a 2-days-old cement stone: bending 3.0 MPa, compression 11.2 MPa; linear expansion of the cement stone 0.06%.

Thus, the cement tested can be classed with nonshrinking oil-well cements.

CONCLUSIONS

(1) The chemical and mineralogical composition of materials of industrial origin (carbonized and noncarbonized slurry), produced by the Soda Open Joint-Stock Company, enable their use as a raw mix component for obtaining sulfoferrite clinkers.

(2) A physicochemical analysis established the optimal compositions of the sulfoferrite clinker used as an expanding additive in production of nonshrinking cements. The clinker containing high-basic sulfated minerals is the most effective as regards the degree of hydration and physicomechanical properties of the resulting cements.

(3) The physicomechanical properties of sulfoferrite-containing cements demonstrated the possibility of development of a high-quality nonshrinking oil-well cement. The optimal cement formulations should not contain the sulfoferrite clinker in amounts exceeding 10 wt %.

(4) The pilot industrial tests performed at the Pilot Cement Plant of NIItsement confirmed the results of the laboratory studies.

Abstract—The crystal structure parameters of solid solutions $YBaCuFe_{1-x}Co_xO_5$ ($0 \le x \le 1$) were determined, and their thermal stability, thermal expansion, conductance, thermoelectromotive force, dielectric properties, and magnetic sensibility were studied.

At present, layered perovskite-like oxides $A'A''B_2O_{5.5\pm\delta}$ (A' is Y or rare-earth element; A'' is alkaline-earth element; B is 3*d* metal) attract appreciable interest. One of such compounds is yttrium barium ferrocuprate $YBaCuFeO_{5+\delta}$, which was described for the first time in [1].

The compound $YBaCuFeO_5$ has a tetragonal unit cell with the parameters $a = 0.3867$ and $c = 0.7656$ nm (space group $P4mm$, $z = 1$) [2], though, according to [3], this compound belongs to space group $P4/mmm$. At room temperature, $YBaCuFeO_5$ is antiferromagnetic (Neel temperature T_N is 440–475 K); its magnetic structure changes at 190–240 K [3–5] (a commensurate $\leftrightarrows$ incommensurate phase transition). The compound $YBaCuFeO_5$ is a *p*-type semiconductor [6] and shows anomalies of dielectric properties near 460 and 560 K [7]. The effect of iron replacement by nickel on the structure and properties of $YBaCuFe_{1-x}Ni_xO_5$ solid solutions was examined in [6]. Solid solutions $YBaCu_{1-x}Co_xFeO_{5+\delta}$, $YBaCu_{1-x}Fe_xFeO_{5+\delta}$, and $YBaCuFe_{1-x}Co_xFeO_{5+\delta}$ were obtained in [8], and their thermal stability in various gaseous media was examined in [9].

Here we report data on the crystal structure, thermal expansion, and electrophysical and magnetic properties of solid solutions $YBaCuFe_{1-x}Co_xO_5$.

EXPERIMENTAL

Samples of $YBaCuFe_{1-x}Co_xO_5$ ($0 \le x \le 1$) were prepared by a ceramic technique [6, 7] from Y_2O_3 (ItO-LYuM7), Fe_2O_3 (ultrapure 2-4 grade), CuO (ultrapure 9-2 grade), Co_3O_4 (analytically pure grade), and $BaCO_3$ (pure grade). The mixture was heated in air at 1173 K for 40 h. To study the thermal expansion, conductance, and thermoelectromotive force, the powders obtained were pressed in pellets 10 mm in diameter and 3–5 mm thick and bars of size $5 \times 5 \times 30$ mm, which were then sintered in air for 2–8 h at 1273 K. The density of the samples after sintering was no less than 80% of the X-ray density. The X-ray phase analysis (XRPA) of the resulting samples was carried out on a DRON-3 diffractometer (CuK_α radiation) at room temperature. The IR absorption spectra of the synthesized compounds in KBr (chemically pure grade) pellets in the frequency range 200–1500 cm^{-1} were recorded on Specord M-80 and Nexus (Thenno Nicolet) instruments. The thermal stability, thermal expansion, conductance, thermoelectromotive force, inductivity, and dielectric loss of the samples were studied in air according to the procedures described in [6, 7]. Before measuring the electrophysical properties, electrodes were applied onto end faces of the samples by burning-in a silver paste at 1073 K for 15 min. The temperature dependence of the magnetic susceptibility of $YBaCuFe_{0.8}Co_{0.2}O_5$ and $YBaCuFe_{0.7}Co_{0.3}O_5$ samples was studied by a ponderomotive method in a magnetic field H = 8.6 kOe in the temperatures range 77–1200 K, and that of $YBaCuFeO_5$ and $YBaCuFe_{0.9}Co_{0.1}O_5$ samples, by the Faraday method in a magnetic field of 4.5 kOe in the range 77–700 K.

The crystal structure of $YBaCuFe_{1-x}Co_xO_5$ solid solutions corresponded to the structure of $YBaCuFeO_5$. Figure 1 shows that the replacement of

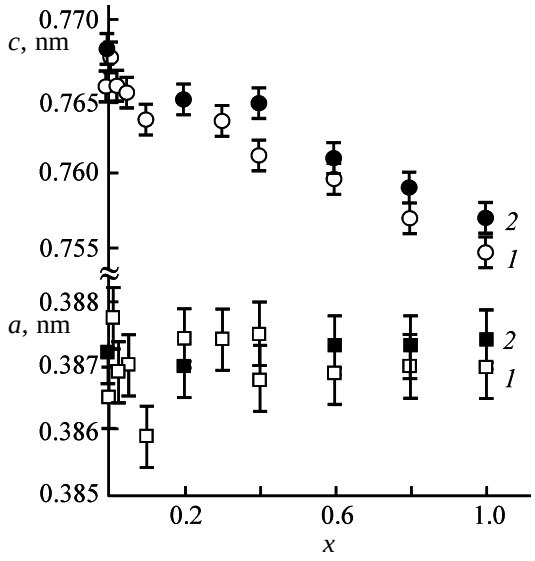

Fig. 1. Unit cell parameters a and c of $YBaCuFe_{1-x}Co_xO_5$ solid solutions as functions of the cobalt content x in $YBaCuFe_{1-x}Co_xO_5$ samples. Data: (*1*) this work and (*2*) [5].

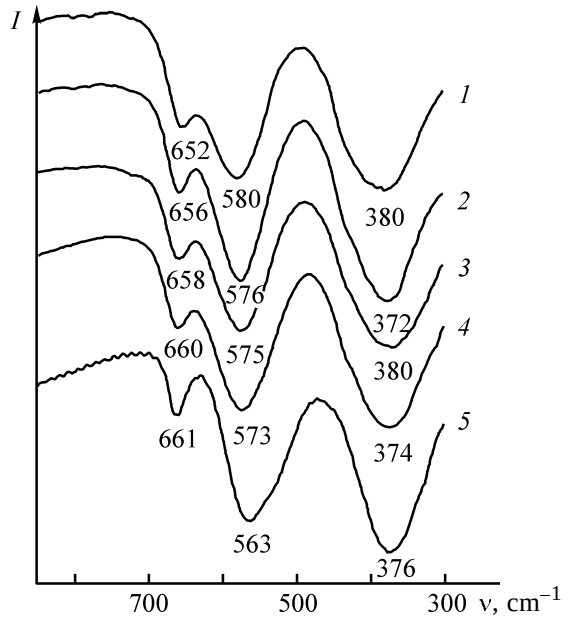

Fig. 2. IR absorption spectra of $YBaCuFe_{1-x}Co_xO_5$ solid solutions. (T) Transmittance and (ν) wave number. x: (*1*) 0, (*2*) 0.1, (*3*) 0.2, (*4*) 0.3, and (*5*) 1.0.

iron by cobalt results in an appreciable decrease in the unit cell parameter c, whereas the parameter a of $YBaCuFe_{1-x}Co_xO_5$ solid solutions remains practically constant up to $x = 1.0$. The data obtained agree well within the error limits with the results of [8]. Anomalies in the concentration dependences $a = f(x)$ and $c = f(x)$ at small ($x \le 0.1$) degrees of replacement are attributable to the fact that, in this case, cobalt in the lattice of $YBaCuFe_{1-x}Co_xO_5$ is in the form of Co^{3+} both in the high-spin (HS) and low-spin (LS) states, and at $x = 0.01$, partly or completely in the form of Co^{2+} ($r_{Fe^{3+}(HS)} = 0.0645$, $r_{Co^{3+}(HS)} = 0.0630$, $r_{Co^{3+}(LS)} = 0.0545$, $r_{Co^{2+}(HS)} = 0.0720$ nm for coordination number 6 [10]).

The IR absorption spectra of $YBaCuFe_{1-x}Co_xO_5$ solid solutions (Fig. 2) contain three absorption bands with maxima at 370–380 (ν_1), 560–580 (ν_2), and 650–660 cm^{-1} (ν_3), corresponding [11] to stretching (ν_2) and bending (ν_1) Cu(Fe)–O–Cu(Fe) vibrations of bonds in basal planes $[Cu(Fe)_2]_\infty$ and also to stretching vibrations of apical oxygen atoms of Cu–O–Fe bonds (ν_3). The replacement of iron by cobalt results in the shift of ν_1 and ν_2 bands to lower frequencies and of ν_3, to higher frequencies (Fig. 2). Thus, the increase in x in $YBaCuFe_{1-x}Co_xO_5$ results in a gradual decrease in the energy of metal–oxygen bonds in basal planes of $-[Cu(Fe)O_2]_\infty-$ layers. The energy of metal–oxygen bonds in the Cu–O–Fe-chains of the $YBaCuFe_{1-x}Co_xO_5$ crystal structure increases, which agrees with a decrease in the unit cell parameter c of $YBaCuFe_{1-x}Co_xO_5$ solid solutions as the degree of iron replacement by cobalt increases.

Samples of the compositions $YBaCuFeO_5$ and $YBaCuFe_{0.9}Co_{0.1}O_5$ were thermally stable in air in the range 293–1273 K, which agrees with the data of [9]. No anomalies were found in the temperature dependences of specific elongation for $YBaCuFe_{1-x}Co_xO_5$ solid solutions (Fig. 3a) within the entire temperature range under study, which points to the absence of structural transitions in these phases in air in this temperature range. A small hysteresis observed in the heating–cooling curves of certain solid solutions (Fig. 3a) is probably due to a low rate of reaching a thermal equilibrium in the samples under conditions of dynamic heating or cooling at a rate of 4–5 deg min^{-1}. The linear thermal expansion coefficient (LTEC) α of $YBaCuFe_{1-x}Co_xO_5$ solid solutions remains unchanged within the error limits when iron is replaced by cobalt (Table 1).

The conductance of $YBaCuFe_{1-x}Co_xO_5$ solid solutions is of the semiconductor nature ($d\sigma/dT > 0$) and tends to increase on replacing iron by cobalt (Fig. 4a). Anomalies in the $\sigma = f(x)$ dependences for $YBaCuFe_{1-x}Co_xO_5$ compounds (Fig. 4b), which are most strongly pronounced at near-room temperatures, can be caused by differences in the charge and spin states of cobalt ions in the composition of $YBaCuFe_{1-x}Co_xO_5$ solid solutions and also by different degrees of order-

Table 1. Coefficients of linear thermal expansion α, temperatures of bends T_{α_1} and T_{α_2}, and activation energies E_σ, E_s, E_p, E_m of charge-transfer processes in $YBaCuFe_{1-x}Co_xO_5$ solid solutions, calculated from the data on conductance and thermoelectromotive force

ing of 3*d*-metal ions in the structure of these compounds. The activation energies of conductance E_σ calculated from the linear portions of the $\ln(\delta T) = f(1/T)$ dependences, and also the temperatures of bends T_{σ_1} and T_{σ_2} in these dependences are given in Table 1. The E_σ of $YBaCuFe_{1-x}Co_xO_5$ solid solutions at $T < T_{\sigma_1}$ decreases (except for the composition with $x = 0.1$), and at $T > T_{\sigma_1}$, increases as compared to E_σ of $YBaCuFeO_5$.

The thermoelectromotive force coefficient S of $YBaCuFe_{1-x}Co_xO_5$ phases in the entire temperature range under study was positive (Fig. 5). This indicates that "holes" are the main charge carriers in $YBaCuFe_{1-x}Co_xO_5$ and $YBaCuFeO_5$, i.e., these solid solutions are also *p*-type conductors (Fig. 4). A maximum near 480 K in the $S = f(T)$ dependence for $YBaCuFe_{1-x}Co_xO_5$ solid solutions can be caused by a change in the charge ($Co^{2+} \rightarrow Co^{3+}$) or spin [$Co^{3+}$(LS) $\rightarrow$ Co^{3+}(HS)] states of cobalt ions, though additional studies are necessary to elucidate unambiguously the causes of this anomaly. The thermoelectromotive force activation energies E_s calculated from the $S = f(1/T)$ dependences are presented in Table 1.

By applying the model of small-radius polarons (SRPs) [12] to the description of electrotransport properties of $YBaCuFe_{1-x}Co_xO_5$ solid solutions and comparing their measured conductance with the thermoelectromotive force, we can determine the activation (excitation) energy of charge-carrying SRPs (E_p, $E_p = E_s$) and also the activation energy of SRP

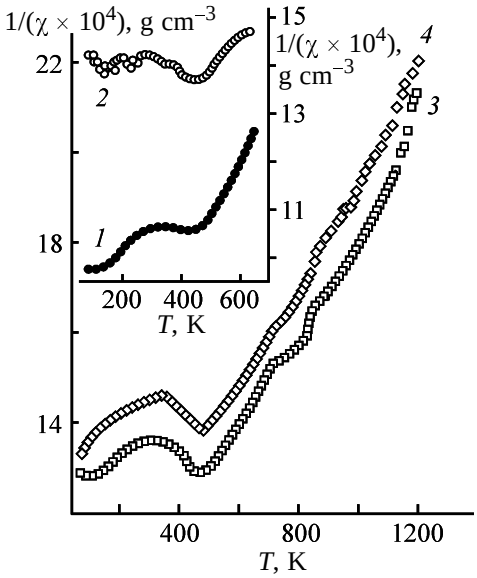

Fig. 6. Temperature dependence of reciprocal magnetic susceptibility 1/χ of $YBaCuFe_{1-x}Co_xO_5$ solid solutions. x: (*1*) 0, (*2*) 0.1, (*3*) 0.2, and (*4*) 0.3.

mobility (E_m, $E_m = E_\sigma - E_p$). Table 1 shows that the replacement of iron by cobalt slightly affects the excitation energy of the main charge carriers, "holes" (E_p); however, it result in hampering of their migration (E_m increases).

Partial replacement of iron by cobalt results in a shift of the permittivity anomalies (Fig. 3b) and of the tangent of the dielectric losse angle (Fig. 3c) toward lower temperatures (455 K for $YBaCuFeO_5$ and 380 K for $YBaCuFe_{0.9}Co_{0.1}O_5$).

The replacement of iron by cobalt noticeably reduces the magnetic susceptibility χ of $YBaCuFe_{1-x}Co_xO_5$ solid solutions (Fig. 6) compared to the compound $YBaCuFeO_5$ and does not appreciably affect their Neel temperature (Table 2). The χ is virtually independent of the degree of iron replacement by cobalt. In the paramagnetic region, the temperature dependence of the magnetic susceptibility for $YBaCuFe_{1-x}Co_xO_5$ solid solutions is described by the Curie–Weiss law $\chi = C/(T + \Theta)$, with C and Θ constants given in Table 2.

Table 2. Constants C and Θ and Neel temperature T_N of $YBaCuFe_{1-x}Co_xO_5$ solid solutions

x	$C \times 10^3$, $cm^3\ K\ g^{-1}$	Θ	T_N
		K	
0.0	8.90	–460	480
0.1	13.3	–1345	480
0.2	10.1	–808	460
0.3	9.27	–775	480

A preliminary test of the catalytic properties of $YBaCuFe_{1-x}Co_xO_5$ solid solutions has shown that they can be used as catalysts of the oxidation of hydrocarbons with atmospheric oxygen [13]. The fact that hydrocarbons are completely converted to CO_2 and H_2O on $YBaCuFe_{0.9}Co_{0.1}O_5$ makes this material promising as an afterburning catalyst (for example, in internal-combustion engines).

CONCLUSION

The effect of replacement of iron ions by cobalt ions on the crystal structure parameters and physical and chemical properties of solid solutions $YBaCuFe_{1-x}Co_xO_5$ ($0.0 \le x \le 1.0$) was studied. The parameters of electrotransport processes and constants of Curie–Weiss equations for the compounds studied were determined. The replacement of iron by cobalt leads to an increase in the conductivity and to a decrease in the thermoelectromotive force and magnetic susceptibility of samples and does not appreciably affect the coefficient of linear thermal expansion and temperatures of antiferromagnetic–paramagnetic transition of $YBaCuFe_{1-x}Co_xO_5$ solid solutions.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Thermodynamics of Reaction of Carbon with Oxygen

A. I. Demidov and I. A. Markelov

St. Petersburg State Polythechnic University, St. Petersburg, Russia

Received April 7, 2005

Abstract—The standard Gibbs energies of reactions proceeding in the C–O system are calculated per mole of carbon dioxide, per mole of the reaction product, and per mole of atoms of the initial substances. A comparative analysis of the calculation results is made.

The reactions of carbon with oxygen can be described by the following equations [1–5]:

$$2C + O_2 = 2CO, \quad (1)$$

$$C + O_2 = CO_2, \quad (2)$$

$$C + CO_2 = 2CO, \quad (3)$$

$$2CO + O_2 = 2CO_2. \quad (4)$$

These reactions are of practical significance for metallurgical, chemical, and fuel industry. The input data for calculating the standard Gibbs energy of the reactions were taken from a reference book [1]. The thermodynamic calculation of the Gibbs energy of reactions (1)–(4) per mole of oxygen [reactions (1), (2), (4)] or per mole of carbon dioxide [reaction (3)], as it was done in [2–6], yields the results given in Table 1 and Fig. 1.

In the range 298–2500 K, reactions (1), (2), and (4) are characterized by the negative standard Gibbs energy, and, consequently, by the high yield of the reaction products. The more negative the ΔG^0 values, the higher the yield of the reaction products [7]. The standard Gibbs energy of reaction (3) (straight line *3*) is negative above 1000 K. At the same time, the positive ΔG^0 values do not show that the reaction is improbable; they only show that the yield of the reaction products is very low [7].

Straight lines *1*, *2*, and *4* (Fig. 1) intersect at a temperature of about 1000 K. To the right from the interception point, straight line *1* passes below two others. This means that, above 1000 K, the chemical affinity of carbon for oxygen under conditions of CO formation is maximal. To the left from the interception point, i.e., below 1000 K, the most negative is the standard Gibbs energy of reaction (4). At temperatures of about 2100 K, straight lines *3* and *4* intersect. Above 2100 K, CO rather than CO_2 becomes the thermodynamically stable oxide.

The reactions in the C–O system can also be related to 1 mol of the reaction product [8, 9]:

$$C + 1/2O_2 = CO, \quad (1')$$

$$C + O_2 = CO_2, \quad (2')$$

$$1/2C + 1/2CO_2 = CO, \quad (3')$$

$$CO + 1/2O_2 = CO_2. \quad (4')$$

The results of the thermodynamic calculation of the standard Gibbs energy of reactions (1')–(4') are given in Table 1 and Fig. 2. As seen from Fig. 2, reaction (2') (straight line *2*') is characterized by the lowest standard Gibbs energy in the range 298–2500 K. This means that, in the reaction of carbon with oxygen over the entire temperature range studied,

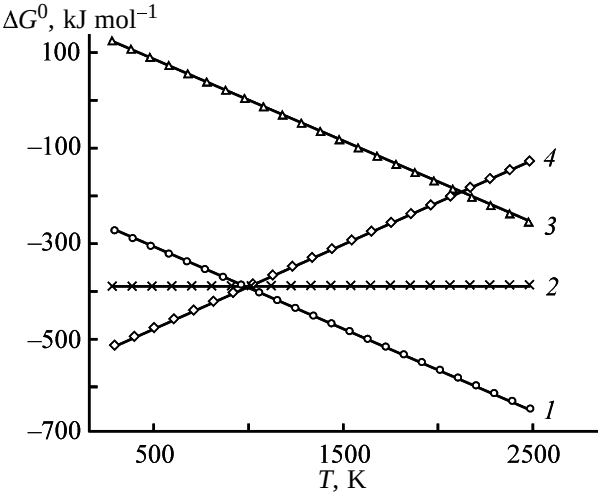

Fig. 1. Standard Gibbs energies ΔG^0 of reactions (1)–(4) vs. temperature *T*.

2500	–655.3	–396.0	–259.3	–136.7	–327.6	–396.0	–129.7	–68.3

the most thermodynamically stable oxide is CO_2. Straight lines *1'*, *2'*, and *4'*, characterizing the standard Gibbs energies of reactions (1'), (2'), and (4'), do not intersect in the temperature range studied. The difference in the results of a comparative thermodynamic analysis of reactions (1)–(4) and (1')–(4') is due to the fact that the Gibbs energy is an extensive quantity and depends on the amounts of substances participating in the reaction. When the reactions are related to 1 mol of oxygen, the number of moles of the reaction products is different from the case when they are related to 1 mol of carbon dioxide. When a reaction is related to 1 mol of the reaction product, the number of moles of the initial substances is different. Therefore, the equations of the chemical reactions related to 1 mol of oxygen [reactions (1), (2), (4)], 1 mol of carbon dioxide [reaction (3)], or 1 mol of the reaction product [reactions (1')–(4')] yield different results. In thermodynamic analysis of heterogeneous condensed systems, the thermodynamic characteristics are commonly calculated per mole of the alloy or the solution, or per gram-atom of a substance incorporated in the compound [10, 11]. Therefore, the standard Gibbs energies of the reactions between carbon and oxygen were calculated per mole of atoms of the initial substances:

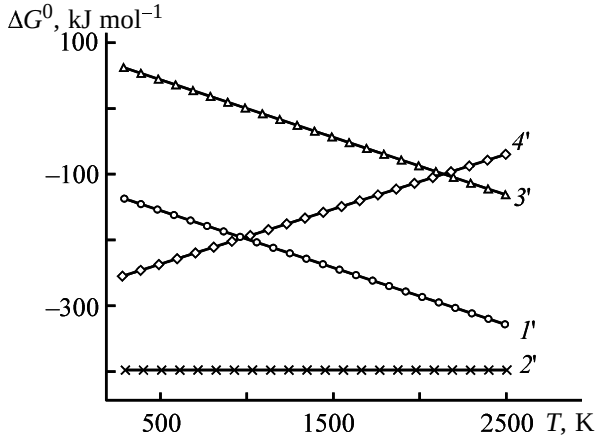

Fig. 2. Standard Gibbs energies ΔG^0 of reactions (1)–(4) (*1'–4'*, respectively) vs. temperature *T*.

$$1/2C + 1/4O_2 = C_{0.5}O_{0.5}, \quad (1'')$$

$$1/3C + 1/3O_2 = C_{0.333}O_{0.667}, \quad (2'')$$

Table 2. Standard Gibbs energies of reactions (1")–(4") within 298–2500 K

2100	–147.3	–132.1	–48.2	–33,9
2200	–151.4	–132.1	–52.4	–31.1
2300	–155.6	–132.0	–56.6	–28.3
2400	–159.7	–132.0	–60.7	–25.5
2500	–163.8	–132.0	–64.8	–22.8

$$1/4C + 1/4CO_2 = C_{0.5}O_{0.5}, \quad (3")$$

$$1/3CO + 1/3O_2 = C_{0.333}O_{0.667}. \quad (4")$$

The results of the calculation are given in Table 2 and Fig. 3.

As seen from Fig. 3, the dependences depicting the standard Gibbs energy of reactions (1")–(4") markedly differ from those considered above. Straight line *1*" [reaction (1")] intersects with line *2*" [reaction (2")] at 1750 K. To the right from the interception point, straight line *1*" lies below line *2*". This shows that, in the range of high temperatures (above 1750 K), the chemical affinity of carbon for oxygen under the conditions of CO formation is maximal. At about 500 K, straight line *1*" intersects with straight line *4*" [reaction (4")]. Consequently, CO_2 is the most thermodynamically stable oxide below 500 K. As the temperature increases, the equilibrium of reaction (3") shifts further toward the formation of carbon monoxide, and the equilibrium of reaction (4"), toward the formation of carbon monoxide and oxygen. Above

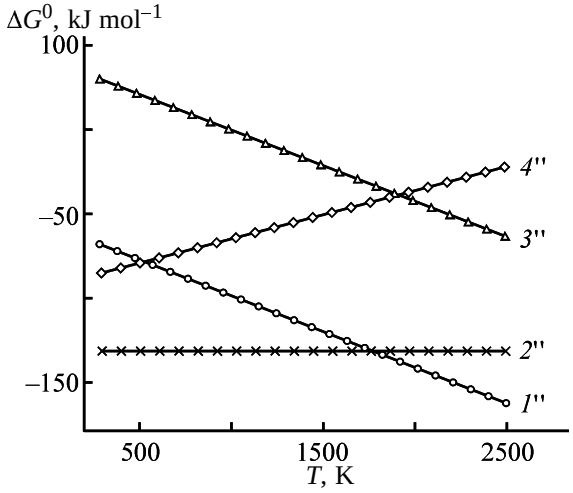

Fig. 3. Standard Gibbs energies ΔG^0 of reactions (1")–(4") (*1*"–*4*", respectively) vs. temperature T.

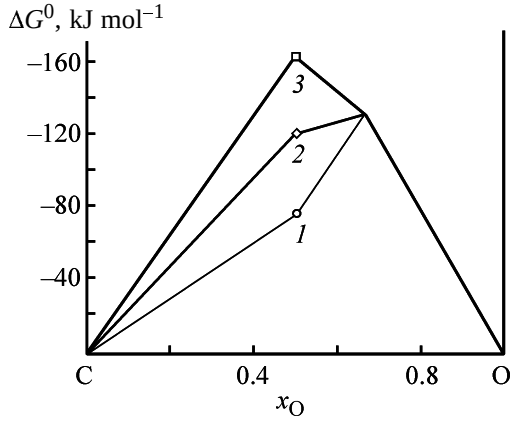

Fig. 4. Standard Gibbs energies ΔG^0 of reactions (1") and (2") vs. mole fraction of oxygen x_O at (*1*) 500, (*2*) 1500, and (*3*) 2500 K.

1900 K, the most thermodynamically stable oxide is CO. The dependences describing the Gibbs energy in the C–O system on the composition (x_O is the mole fraction of atomic oxygen) at 500, 1500, and 2500 K (Fig. 4) demonstrate how temperature affects the stability of carbon(II) and carbon(IV) oxides. At 2500 K, the most stable compound is carbon monoxide.

CONCLUSIONS

A comparative analysis of the Gibbs energies of the reactions occurring in the C–O system, calculated per mole of oxygen or carbon dioxide, per mole of the reaction product, and per mole of atoms of the initial substances shows that the results of the thermodynamic calculation and the conclusions about preferential formaiton of one or another product depend on the form of the equations of chemical reactions. To perform a comparative analysis, it is suggested to

relate the equations of chemical reactions to 1 mol of atoms of the initial substances.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Polythermal Study of Solubility of *N*-[4-(Difluoromethylthio)phenyl]-2-Aminobenzoic Acid in the System Water–1,2-Propanediol

O. Yu. Sytnik, A. P. Krasnoperova, V. A. Lebedinets, and K. M. Sytnik

Received August 18, 2003; in final form, January 2005

Abstract—The solubility of *N*-[4-(difluoromethylthio)phenyl]-2-aminobenzoic acid in the system water–1,2-propanediol was studied over the entire range of the concentrations of the mixed solvent at 288.15–328.15 K.

Anthranilic acid derivatives are commonly used in modern pharmacology. *N*-[4-(Difluoromethylthio)-pheny]l-2-aminobenzoic acid (Difluorant, hereinafter DF), a nonsteroid antiphlogistic with antipsoriasis activity, is among them.

Difluorant is a hydrophobic organic compound, sparingly soluble in water, which makes it difficult to create on its basis water-containing medicines in the form of ointments, foams, and emulsions. Therefore, a study of the DF solubility in nonaqueous solvents, which can homogenize hydrophobic and hydrophilic compounds and their mixtures with water, is one of the main stages of development of highly effective and inexpensive drugs. The most commonly used solvent in soft medicines is 1,2-propanediol (1,2-PD) [1].

This study is concerned with the DF solubility in the water–1,2-PD system over the entire range of the concentrations of the mixed solvent at 288.15–328.15 K.

EXPERIMENTAL

The water–1,2-PD system was prepared gravimetrically. 1,2-Propanediol was preliminarily treated by double vacuum distillation [2]. The quality of 1,2-PD was checked by the density (ρ_4^{25} = 1032.8 kg m^{-3}) and dielectric permittivity (ε = 29.0 at 25°C). As second component was used double-distilled water. Prior to use, DF was dried for 2 h at 353 K under a pressure of 2.7 kPa. The quality of the preparation was checked by the melting point (T_m = 397 K).

The DF solubility was studied by the isothermal method, and the concentration of the saturated solution was determined by the electronic spectroscopy. To do this, excess amount of the substance under study was placed in flasks with ground-glass stoppers, the solvent of the required composition was added, and the mixture was kept at a constant temperature controlled to within $\pm$0.1 K with continuous agitation until the thermodynamic equilibrium was attained. The attainment of the equilibrium was monitored by taking the solution samples and measuring their optical density. The equilibrium was assumed to be attained when the optical density A of a series of successively taken solution samples became constant. Then, the solutions were allowed to settle for 3–4 h at the given temperature, after which they were sampled for the analysis. The saturation time was from 10 to 100 h, depending on the concentration of the nonaqueous component.

The optical density A was measured on a Specord M-40 spectrophotometer at λ = 310 nm. To do this, 2 ml of the transparent saturated solution was diluted with ethanol so that A of the solutions obtained was within 0.3–0.7. Each value of the solubility is the average of 3–4 measurements. The maximum average error in determining the solubility was 2–3% at a confidence probability of 0.95. The results obtained are presented in the table.

Our results show that the DF solubility varies within a wide range depending on the solvent composition and temperature and is not a linear dependence of the solvent composition.

Amino acids in strongly polar solvents are in the form of zwitterions [3, 4]. Since the zwitterions have

high dipole moments [5], the electrostatic interactions should largely contribute to the dissolution of bipolar compounds. It appeared, however, that the DF solubility in water is lower by four orders of magnitude than in 1,2-PD, despite the fact that the dielectric permittivity of water is considerably higher than that of 1,2-PD (ε = 80.1 against 30.8 at 20°C). In addition, the logarithm of the solubility $\log L$ in solvents of the same chemical nature is a linear function of reciprocal dielectric permittivity ε^{-1} [6], which is not the case in the system studied (Fig. 1). Hence, the solubility of the substance studied is primarily govened by interactions other than electrostatic.

The results obtained show that the specific interactions in the solute–solvent system and the specificity of the interparticle interactions in a binary solvent play the decisive role in DF dissolution. The fact that the DF solubility in water is lower than in 1,2-PD and in its aqueous mixtures is typical of a compound with large hydrophobic ions, which tend to structurization

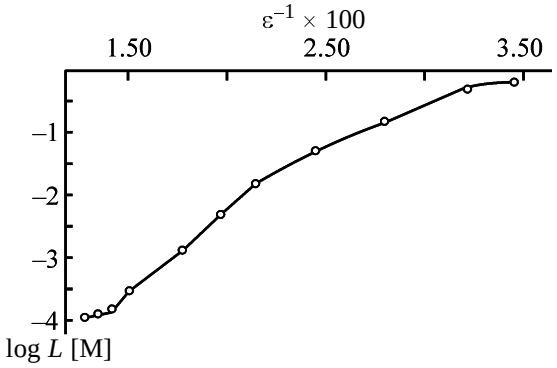

Fig. 1. Logarithm of the DF solubility $\log L$ vs. reciprocal dielectric permittivity ε^{-1} of the mixed solvent water–1,2-PD at 298.15 K.

in aqueous solvent owing to the enhancement of hydrogen bonding between the surrounding water molecules.

The deviations of the logarithm of the solubility from the additive values in the solvent studied were calculated from the data on the DF solubility [7]:

$$(\ln L)^E = \ln L - \sum_{i=1}^{2} \varphi_i \ln L_i, \qquad (1)$$

where L is the solubility of a substance in a mixed solvent (M); L_i, solubility of a substance in individual solvent i; $(\ln L)^E$, deviation of the logarithm of the solubility from the additive value; and φ_i, calculated volume fraction of individual solvent i in a mixed solvent in the water–1,2-PD system [8].

The logarithm of the DF solubility shows negative deviations from the additivity at all the studied temperatures and compositions of the mixed solvent (Fig. 2). Increasing temperature decreases the absolute values of $(\ln L)^E$. The $(\ln L)^E$ value is more than 10%, which shows that the features of the interparticle interaction in the binary mixed solvent considerably affect the DF solubility.

The heats of mixing of water and 1,2-PD in the water–1,2-PD system containing about 20 mol % 1,2-PD are maximal [9]. This fact suggests formation of relatively stable water–1,2-PD associates in which the water–dihydric alcohol bond is stronger than the water–water and diol–diol bonds, which is also confirmed elsewhere [8, 10–12].

The formation of mixed associates even more impedes dissolution of the third component. Apparently,

this fact explains why $(\ln L)^E$ at about 20 mol % 1,2-PD passes through a deep minimum.

A more detailed information about the processes affecting formation of saturated solution can be obtained from the thermodynamic characteristics of DF solution.

The solubility of substances is determined by two competing factors: changes in the Gibbs energy upon solvation and upon destruction of the crystal lattice [13]:

$$\Delta G_s^0 = \Delta G_{lat}^0 + \Delta G_{solv}^0, \quad (2)$$

where ΔG_s^0 is the Gibbs energy of solution (kJ mol^{-1}); ΔG_{lat}^0, Gibbs energy of crystal lattice destruction (kJ mol^{-1}); and ΔG_{solv}^0, Gibbs energy of solute solvation (kJ mol^{-1}).

Since the Gibbs energy ΔG_{lat}^0 of DF is the constant in Eq. (2), the decisive effect on the solubility in solvents with varied 1,2-PD concentration is exerted by ΔG_{solv}^0.

The lack of data on the thermodynamic characteristics of the crystal lattice formation prevents estimation of the thermodynamic characteristics of DF solvation from the solubility data. Therefore, the thermodynamic characteristics were calculated for the DF transfer from water into the water–1,2-PD mixed solvent [14].

The isotherms of the Gibbs energy of transfer ΔG_t^0 are nonlinear. The ΔG_t^0 is negative in the whole range of compositions of the mixed solvent (Fig. 3). Therefore, the DF solubility in 1,2-PD and in the binary solvent is higher than in water.

At the same time, when the concentration of the nonaqueous solvent in water is low, ΔG_t^0 depends only slightly on the solvent composition, and this is typical of low temperatures. Such a dependence of ΔG_t^0 on the composition of the mixed solvent is determined by a number of factors.

According to the physicochemical analysis [8], at low concentrations of 1,2-PD in water (5 mol %) the structure of water is stabilized with methyl radicals of 1,2-PD. The DF molecules in this region may undergo solvophobic solvation, which results in enhanced hydrogen bonding between the solvent molecules and their minimal contact with DF molecules. The solvophobic solvation of DF is typical of water, which explains the low solubility of DF in water. For a mixed solvent water–1,2-PD it is also typical in the regions of low 1,2-PD concentrations, where a small

plateau disappearing at higher temperatures is observed in the isotherm of ΔG_t^0 of DF.

The ΔG_t^0 decreases with a further increase in the 1,2-PD concentration in the binary solvent. The large negative values of ΔG_t^0 in the 1,2-PD-rich binary solvent show that the solvates formed in the binary

solvent and in individual 1,2-PD are more stable than in water. The solvate stability in this region is of entropy origin, and the large negative values of $-T\Delta S_t^0$ confirm this conclusion.

The ΔH_t^0 and ΔS_t^0 isotherms have extrema; to the endothermic peak at about 20 mol % 1,2-PD in water corresponds the ΔS_t^0 maximum. Apparently, the extrema in the ΔH_t^0 and ΔS_t^0 curves in this region are due to the formation of water : 1,2-PD mixed associates of the composition 4 : 1.

CONCLUSION

The dependences of the Difluorant solubility in the water–1,2-PD system, dielectric permittivity, deviation of the logarithm of the solubility from additive values, and thermodynamic characteristics of Difluorant transfer from water into the mixed solvent on the composition of the mixed solvent, studied over the entire range of concentrations of the mixed solvent at 288.15–328.15 K, show that the specific interactions in the binary solvent and the Difluorant solvophobic solvation are the major factors affecting the Difluorant solubility.

SORPTION AND ION-EXCHANGE PROCESSES

Chemisorption of Platinum(II) and Platinum(IV) Chloride Complexes on Fibrous Sorbents Derived from Polyacrylonitrile Modified with Aminoguanidine

Abstract—Sorption of platinum(II) and platinum(IV) chloride complexes on nitrogen-containing fibrous sorbents derived from polyacrylonitrile with aminoguanidine groups (GLIPAN-3) was studied as influenced by the temperature, platinum concentration in the solution, and pH of the solution. The kinetic sorption parameters and the sorption capacities of the sorbents in hydrochloric acid and chloride solutions were determined. The sorption mechanism and the composition of platinum compounds formed in the sorbent phase were suggested.

Complexing polyfunctional sorbents with various nitrogen-containing groups (aliphatic and aromatic amines, pyridine, pyrazole, and other nitrogen-containing heterocycles) are widely used to concentrate platinum metals in solutions and to recover them from solutions [1–4]. High sorption capacity of these sorbents for platinum metals in acidic solutions is due to, on one hand, protonation of the nitrogen-containing functional groups which facilitates their interaction with anionic complexes of platinum metals [1–3], and on the other hand, formation of strong platinum complexes with nitrogen-containing ligands [1, 2, 4].

As shown previously [5], polystyrene resin with sulfoguanidine groups sorbs quantitatively K_2PdCl_4 and does not sorb K_2PtCl_4 from perchloric acid solutions with different pH under the static conditions and under the dynamic conditions at constant stirring. Palladium(II) was desorbed with 3–4 M HCl [5]. The results of elemental analysis and IR spectroscopic study showed that the sorption could be described by the following equation:

Our previous study on sorption of palladium(II) chloride complexes on GLIPAN-3 fiber showed [6] that the apparent equilibrium in the palladium distribution between 1 M HCl and the fiber was attained within 40–60 min and the sorption half-time in this solution was 6 min. Onium palladium(II) complexes like $[RNHNHC(NH_2)NH_2]_2[PdCl_4]$ are formed in the fiber. Sorption of other metals including platinum on GLIPAN-3 fiber was not studied.

In this study we examined sorption of platinum(II) and platinum(IV) chloride complexes on nitrogen-containing GLIPAN-3 sorbent, composition and structure of platinum complexes formed in the fiber, and possibility of recovering platinum(II) from solutions containing Al(III), Fe(III), Ni(II), Co(II), and Cu(II) in a 1000-fold excess.

EXPERIMENTAL

Complexing fibrous sorbent GLIPAN-3 was prepared by Yu.E. Kazakevich (St. Petersburg State University of Technology and Design) by treatment of PAN fiber with aminoguanidine in ethylene glycol solution containing sodium hydroxide [6]. The fiber is yellow and contains aminoguanidine [NH_2–NH–C(=NH)–NH–] and carboxy (–COOH) groups. The static exchange capacity (SEC) for HCl and NaOH is 2.96 and 2.48 mmol g^{-1}, respectively. The sorbent is stable in 2 M H_2SO_4, 6 M HCl, and 0.5 NaOH for 24 h: the weight loss is 2–3 wt %. The aminoguani-

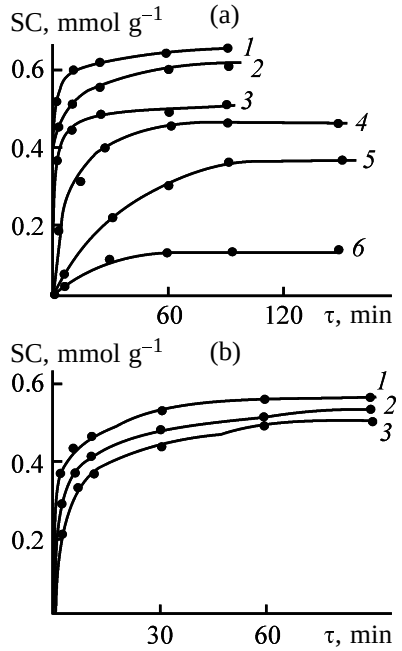

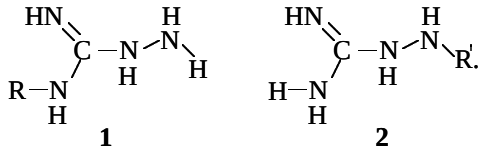

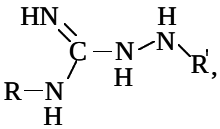

Fig. 1. Kinetic curves of (a) K_2PtCl_4 and (b) K_2PtCl_6 sorption from (*1–3*) 0.5 M HCl and (*4–6*) 0.5 M NaCl on GLIPAN-3 at (*1*, *4*) 90, (*2*, *5*) 50, (*3*, *6*) 18°C. (SC) sorption capacity and (τ) time. Platinum content (mM): (a) (*1–3*) 3.1 and (*4–6*) 3.3; (b) 2.9.

dine functional groups of the fiber have two structures:

1 **2**

Theoretically, guanidine can be bound to the matrix via both amino groups, but the content of these structures should be significantly smaller since the probability of reaction of two amino groups of an aminoguanidine molecule with the nitrile groups of the sorbent matrix is lower. Thus, the general structural formula of the fiber can be described as follows:

where R and R', in a particular case, can be hydrogen atoms.

We studied sorption of Pt(II) and Pt(IV) chloride complexes on GLIPAN-3 fiber under static conditions at continuous stirring (250 rocking min^{-1}, a T-22 rocker) at 18, 50, 76, and 90°C. The initial complexes $K_2[PtCl_4]$ and $K_2[PtCl_6]$ were prepared by the procedure in [7]. Sorption experiments were performed in freshly prepared 1–20 mM solutions of $K_2[PtCl_4]$ and $K_2[PtCl_6]$ in 0.1–4 M HCl and 0.5 M NaCl. In all cases, the solution volume was 20 ml and the sorbent weight was 0.1 g. The platinum content in the solutions before and after sorption was determined spectrophotometrically with a hydrochloric acid solution of tin(II) chloride [8]. The platinum sorption was determined as a difference between the platinum content in the solution before and after sorption. The IR spectra of fibers in the 400–4000 cm^{-1} range were recorded on an IKS-29 spectrophotometer and in the 140–400 cm^{-1} range (far IR region), on an FIS-3 spectrophotometer (Hitachi).

The procedure of sample preparation is described in our previous work [9]. Thermal analysis curves were recorded on an MOM derivatograph (Hungary) in the range 20–800°C at a heating rate of 10 deg min^{-1}. Isothermal hating of the sorbents was performed on a special installation equipped with a unit for qualitative analysis of gaseous thermolysis products. Thermal transformations of the samples (onset decomposition temperature, etc.) was visually observed with the aid of a Koefler stage [10]. The X-ray photoelectron spectra (XPS) of the platinum-containing samples were measured on a Kratos Axis Ultra electron spectrometer using AlK_α X-ray radiation with a power of 180 W. The sample was bombarded with slow electrons to compensate the surface charging. The measurements were performed at a residual pressure of 3×10^{-7} Pa. The quantitative analysis of the spectra and resolution of the spectra into separate lines were performed by conventional programs. The spectra were normalized to the C1*s* energy taken as 285.0 eV. The atomic concentrations were calculated from the corresponding peak areas.

The kinetic curves of K_2PtCl_4 and K_2PtCl_6 sorption from 0.5 M solutions of HCl and NaCl are shown in Figs. 1a and 1b. The equilibrium distribution of platinum(II) between the sorbent and hydrochloric acid and chloride solutions of K_2PtCl_4 at 50°C is attained in 60 and 120 min, respectively. The sorption half-time $\tau_{1/2}$ is 1 and 7 min, respectively. The degree of platinum(II) recovery from 0.5 M HCl (Fig. 1a, curve *2*) and 0.5 M NaCl (Fig. 1a, curve *5*) at 50°C is 95 and 54%, respectively.

In the case of K_2PtCl_6 (Fig. 1b), the sorption is somewhat slower and the degree of platinum recovery is lower than in the case of K_2PtCl_4. In acidic solutions at 50°C, τ_{app} is 80 min (Fig. 1b, curve *2*) and $\tau_{1/2}$ is 1.5 min. The degree of platinum(IV) recovery in 80 min is about 87%. The sorption from NaCl solutions is so slow that the apparent equilibrium between

the fiber and the solutions is not attained within 180 min and the degree of platinum recovery even on heating does not exceed 28%.

Generally, the rate-determining steps of the heterogeneous reaction can be (1) diffusion of reagents to the solid surface, (2) chemical reaction proper, and (3) diffusion of the reaction products from the solid phase into the solution. Since the sorption rate in hydrochloric acid solution is high and is almost independent of temperature, we suggest that the sorption of K_2PtCl_4 and K_2PtCl_6 occurs mainly by the anion-exchange mechanism to form onium complexes containing protonated amino groups [1, 2]. According to a large body of experimental data [1–4], slow sorption from chloride solutions suggests formation of intraspherical platinum complexes with aminoguanidine groups of GLIPAN-3 fiber.

Usually the type of diffusion kinetics is determined as follows: the dependence of the diffusion rate on the stirring rate (external diffusion) is studied; diffusion experiment is interrupted to determine the internal diffusion mechanism [1]]; and the F vs. $\tau^{0.5}$ and $-\ln(1 - F)$ vs. sortion time τ (where F is the degree of exchange, $F = Q_\tau/Q_\infty$, where Q_τ is the sorption of ions from solution in time τ and Q_∞ is the equilibrium sorption) are constructed. In the case of external diffusion kinetics, the $-\ln(1 - F)$ vs. τ curve is linear in the range from 0 to $\tau_{1/2}$. When the diffusion kinetics is external, the F vs. $\tau^{0.5}$ dependence is linear up to $F = 0.5$ [11]. The complex shape of the F vs. $\tau^{0.5}$ and $-\ln(1 - F)$ vs. τ dependence (Figs. 2a, 2b) and the presence of a linear section in them suggest [12] a mixed diffusion kinetics of sorption of platinum(II) and platinum(IV) chloride complexes from acidic solutions on GLIPAN-3. The apparent activation energies calculated by the Arrhenius equation [13] (7.1 and 7.5 kJ mol^{-1} for K_2PtCl_4 and K_2PtCl_6, respectively) confirm that the rate-determining step of the sorption is diffusion [12].

The kinetic curves of K_2PtCl_6 sorption from 0.5 M HCl at different stirring rates are shown in Fig. 3a. As seen from Fig. 3a, the sorption rate depends on the

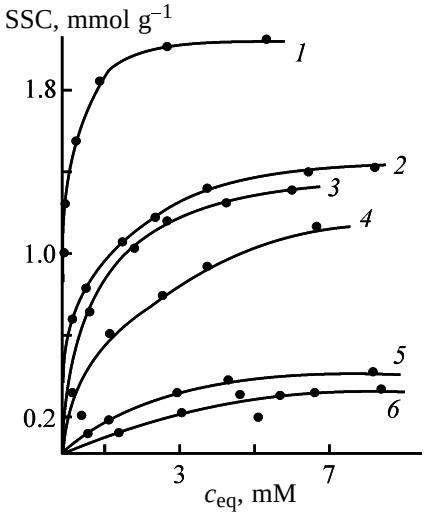

Fig. 4. Sorption isotherms of (*1, 2, 5, 6*) K_2PtCl_4 and (*3, 4*) K_2PtCl_6 at (*2, 4, 6*) 18°C and (*1, 3, 5*) 76°C from (*1–4*) 0.5 M HCl and (*5, 6*) 0.5 M NaCl. (SSC) Static sorption capacity and (c_{eq}) equilibrium Pt(II, IV) concentration.

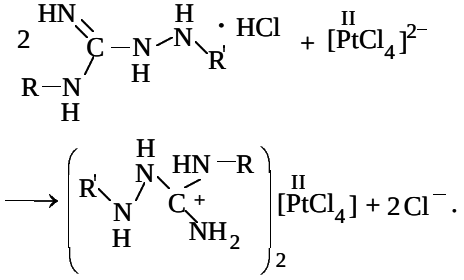
stirring rate, which suggests diffusion control of the process. The sorption accelerates only insignificantly when the stirring rate increases in the range 112–250 rocking min^{-1}. The kinetic curves of K_2PtCl_6 sorption from 0.5 M HCl without interruption (curve *1*) and with a 40-min interruption (curve *2*) are shown in Fig. 3a. The fact that the SC measured in the experiment with interrupted sorption increases by 7% (Fig. 3b) suggests that not only external but also internal diffusion contribute to the sorption [12, 14]. Thus, these results also confirm mixed-diffusion mechanism of K_2PtCl_6 sorption on GLIPAN-3 from hydrochloric acid solutions.

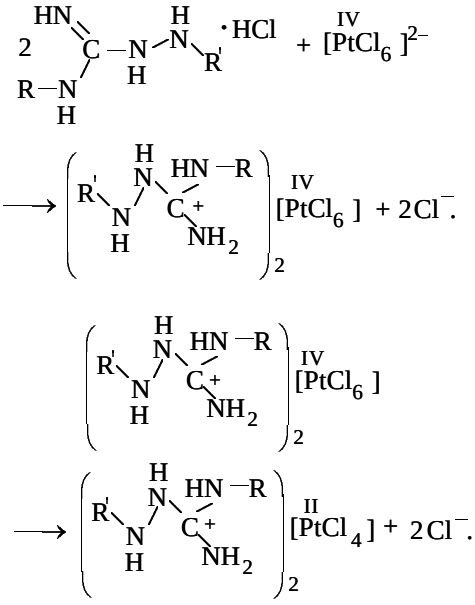
The sorption isotherms of K_2PtCl_4 and K_2PtCl_6 from 0.5 M HCl and 0.5 M NaCl are shown in Fig. 4 (the initial platinum concentrations in the solutions are 1–20 mM). The shape of the sorption isotherm measured in hydrochloric acid solutions shows that GLIPAN-3 fiber can be used for platinum recovery from both dilute and concentrated solutions. The static sorption capacities (SSC) for K_2PtCl_4 and K_2PtCl_6 in 0.5 M HCl and 0.5 M NaCl are presented in the table. It should be noted that SSC for K_2PtCl_6 is almost independent of temperature, whereas SSC for K_2PtCl_4 increases by a factor of 1.5 on heating from 18 to 76°C, reaching 2.02 mmol g^{-1} at 76°C.

Table 1. Parameters of sorption of platinum(II) and platinum(IV) chloride complexes on GLIPAN-3



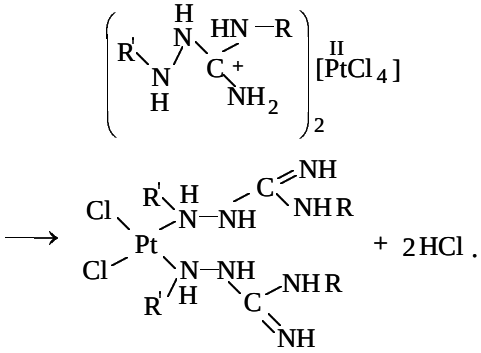
T, °C	Solution, 0.5 mM	Adsorbate	SSC, mmol g^{-1}
18	HCl	K_2PtCl_6	0.98
76			1.04
18	HCl	K_2PtCl_4	1.34
76			2.02
18	NaCl	K_2PtCl_4	0.33
76			0.38

Sorption of K_2PtCl_4 and K_2PtCl_6 substantially decreases with increasing HCl concentration. In the case of K_2PtCl_4, almost 100% of platinum(II) (SC = 0.94 mmol g^{-1}) is sorbed from 0.2 M HCl, whereas only 57% of Pt(II) (SC = 0.55 mmol g^{-1}) is sorbed at elevated temperature and 30% at room temperature (SC = 0.29 mmol g^{-1}) from 4 M HCl. Thus, sorption of platinum(II) and platinum(IV) chloride complexes from 0.2–0.5 M HCl is optimal.



Comparison of the kinetic parameters of sorption of K_2PtCl_4 and K_2PtCl_6 on GLIPAN-3 and the capacity of this fiber for these complexes shows that the sorption of square planar tetrachloroplatinate on GLIPAN-3 is faster that that of hexachloroplatinate and the sorption capacity of the fiber for K_2PtCl_4 is higher than that for K_2PtCl_6. This is probably due to the fact that platinum(IV) complexes with $5d^5$ configuration of the central metal are more kinetically inert and the steric hindrance in sorption of larger $[PtCl_6]^{2-}$ anion with greater delocalization of the negative charge is stronger.

About 20% of platinum(II) and 25% of platinum(IV) can be desorbed from GLIPAN-3 fiber with 5 M HCl. Desorption of K_2PtCl_4 and K_2PtCl_6 with 0.5 M HCl does not exceed 5 and 10%, respectively. It should be noted that in all cases hexachloroplatinate is more readily desorbed than tetrachloroplatinate.



Analysis of the sorption kinetics of K_2PtCl_4 and K_2PtCl_6 on GLIPAN-3 and the capacity of this fiber for these complexes in acidic solution suggests that the complexes are sorbed mainly by the ion-exchange mechanism. Indeed, the FIR spectra of the fiber after sorption of K_2PtCl_4 from 0.5 M HCl (Fig. 5, curves *5*, *6*) suggest formation of onium platinum(II) complexes $[R'NHNHC(NH_2)NHR]_2[PtCl_4]$ (ν_{Pt-Cl} = 326 cm^{-1}) by the reaction

As determined by XPS, hexachloroplatinate is partially reduced to tetrachloroplatinate in the course of its sorption on GLIPAN-3 fiber [Pt4$f_{7/2}$ BE 72.9 and 75.0 eV agree well with the known BE for K_2PtCl_4 (73.1 eV) and K_2PtCl_6 (75.7 eV)] [15]. The Pt : Cl ratio on the fiber surface is 1 : 4.6 and the Pt(IV) : Pt(II) ratio is approximately 1 : 3. Formation of both onium platinum(II) chloride complexes and onium platinum(IV) chloride complexes, $[R'NHNHC(NH_2)\cdot NHR]_2[PtCl_6]$ is confirmed by the presence of a ν_{Pt-Cl} band at 330–334 cm^{-1} in the FIR spectra of the firber after sorption of K_2PtCl_6 from 0.5 M HCl. Platinum(IV) compounds can be reduced to platinum(II) compounds with hydrazine groups of aminoguanidine. Thus, sorption of K_2PtCl_6 can be described by the following scheme:

Formation of onium complexes of Pt(II) and Pt(IV) was also confirmed in special experiments. Intense liberation of hydrogen chloride was observed on isothermal heating of the sorbent that was washed with water to remove chloride ions and then was air-dried. The onium complex is converted to diamino chloride complex like $\{Pt[R'NHNHC(=NH)–NHR]_2Cl_2\}$ [10]:

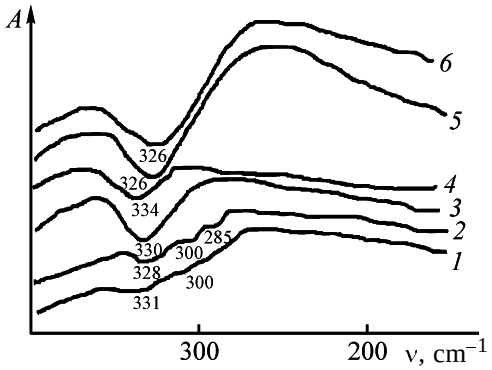


Fig. 5. Far IR spectra of GLIPAN-3 fiber after sorption of K_2PtCl_4 and K_2PtCl_6 for 3 h from (*1*, *2*) 0.5 M NaCl and (*3*–*6*) 0.5 HCl. C_{Pt} = 10 mM. (*A*) Absorption and (ν) frequency; the same for Fig. 3.

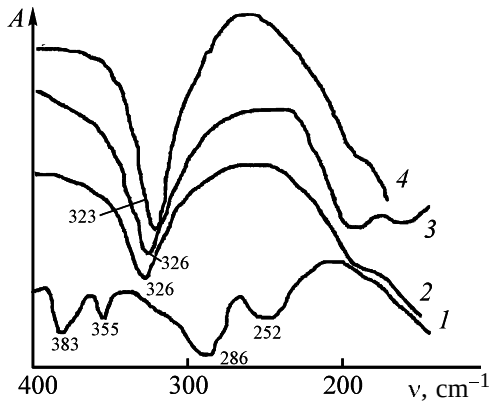
The temperature of this rearrangement cannot be accurately determined by thermal analysis, since it occurs simultaneously with water elimination and fiber degradation. The decomposition is complete at about 700°C with the formation of Pt metal.

Sorption of K_2PtCl_4 and K_2PtCl_6 from NaCl solutions is essentially different. Low sorption rate of these complexes and strong temperature dependence of the sorption rate and sorption capacity suggest formation of $\{Pt[R'NH–NH–C(=NH)–NHR]_2Cl_2\}$ complexes. Formation of these complexes is also confirmed by more complex shape of the FIR spectra of the fiber after sorption of K_2PtCl_4 from 0.5 M NaCl (Fig. 5, curves *1*, *2*) [16].

To confirm formation of these complexes by reaction of the platinum chloride complexes with aminoguanidine groups of the fiber, we prepared model Pt(II) complexes with aminoguanidine hydrochloride and guanidine hydrochloride. Solutions of K_2PtCl_4 and guanidine hydrochloride or aminoguanidine hydrochloride in a 1 : 2 ratio in 6 and 0.5 M HCl and water were heated on a boiling water bath for 5 h. Evaporation of the hydrochloric acid solutions gave red crystals of onium salts $[NH_2–NH–C(NH_2)–NH_2]_2\cdot[PtCl_4]$ or $[NH_2–C(NH_2)–NH_2]_2[PtCl_4]$. The FIR spectra of these complexes are similar to those of the fiber after sorption of K_2PtCl_4 from 0.5 M HCl and contain Pt–Cl bands at 323 and 326 cm^{-1} (Fig. 6) [17].

Prolonged heating of K_2PtCl_4 with aminoguanidine hydrochloride in an aqueous solution yields a dark finely crystalline product poorly soluble in water and ethanol. Elemental analysis of the product agrees with the formula $\{Pt[NH_2NHC(=NH)NH_2]_2Cl_2\}$: calculated M_w = 414.15, C 5.80, H 2.92, N 27.06; found: C 6.23, H 3.22, N 26.94. The FIR spectrum of this



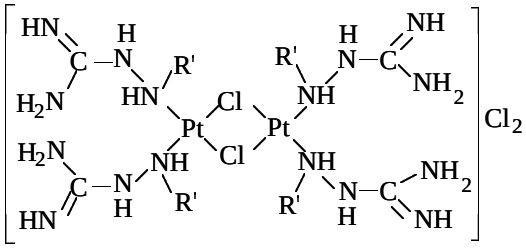


Fig. 6. FIR spectra of platinum(II) complexes with (*2*) guanidine and (*1*, *3*, *4*) aminoguanidine prepared from (*1*, *2*) 6 M HCl, (*3*) 0.5 M HCl, and (*4*) water.

compound is similar to the spectrum measured in [16]; the Pt–Cl stretching bands at 286 and 252 cm^{-1} are due to bridging chloride ions. The bands of terminal chloride ions are absent (Fig. 6, curve *1*). The structure of this complex can be described by the formula

Comparison of these data with the FIR spectra of the fiber after sorption of K_2PtCl_4 from neutral chloride solutions (Fig. 5, curves *1*, *2*) suggests that complexes containing bridging chloride ions (ν_{Pt-Cl} = 285 cm^{-1}), which are similar to the model compounds formed in aqueous solutions, are present in the polymeric matrix along with the amino chloride complexes.

We studied the possibility of using GLIPAN-3 fiber for separation of platinum metals from nonferrous metals and iron. Sorption was performed from 0.5 M HCl at 18 and 76°C for 3 h. The content of nonferrous metals and iron in the solution before and after sorption was determined by atomic emission spectroscopy (analysis was performed by S.N. Zimina, Mekhanobr Joint-Stock Company). The platinum content was determined by atomic absorption spectroscopy after precipitation on tellurium (L.A. Ushinskaya, Mekhanobr Joint-Stock Company). The main components of platinum-containing process solutions are nickel(II), copper(II), cobalt(II), and iron(III) chlorides. We studied sorption of tetrachloroplatinate(II) from model solutions of 1 M $NiCl_2$, $CuCl_2$, $CoCl_2$, and $FeCl_3$ in 0.5 M HCl (c_{Pt} = 1 mM) and sorption of K_2PtCl_4 against the background of a 1000-fold excess of $AlCl_3$ (solutions simulating process solutions formed in recovery of platinum metals from catalysts of gasoline afterburning). The solutions contained 1 M $AlCl_3$, 1 mM K_2PtCl_4, and 0.5 M HCl.

We found that about 25% of platinum was sorbed at 18 and 76°C. The main portion of nonferrous metals remained in the solution; their total recovery was no higher than 6–7%. At room temperature, about 83% of platinum and 13% of aluminum were sorbed, which allowed effective platinum concentration. Thus, GLIPAN-3 fiber can be used for platinum recovery at room temperature from solutions formed in processing of gasoline afterburning catalysts containing $AlCl_3$.

CONCLUSIONS

(1) Sorption of tetrachloroplatinate and hexachloroplatinate from hydrochloric acid solutions at the platinum concentration of 1–10 mM on GLIPAN-3 fibrous sorbent prepared by modification of polyacrylonitrile with aminoguanidines is fast and quantitative. In neutral solutions, the sorption is slow and is not quantitative [20–40% recovery of platinum(II)].

(2) Platinum chloride complexes are sorbed on GLIPAN-3 fiber from hydrochloric acid solutions by the anion-exchange mechanism to form $[R'NHNH \cdot C(NH_2)NHR]_2[PtCl_4]$ and $[R'NHNHC(NH_2)NHR]_2 \cdot [PtCl_6]$. Sorption from chloride solutions involves complexation with functional groups of the fiber.

(3) GLIPAN-3 fiber can be used to recover tetrachloroplatinate(II) from solutions containing 1000-fold excess of aluminum chloride and from solutions formed in processing of gasoline afterburning catalysts.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of Uranium from Sulfuric Acid Leaching Solutions by Strongly Basic Anion Exchangers

Abstract—The equilibrium and kinetic characteristics of uranium sorption from simulated sulfuric acid leaching solutions by AMP, Lewatit K 6367, Purolite A 500, Purolite A 600, and AM-p gel-like and porous strongly basic anion exchangers were studied.

Underground leaching is widely used in uranium mining. In leaching uranium with aqueous sulfuric acid, the leaching solutions containing neutral $[UO_2SO_4]^0$ and anionic $[UO_2(SO_4)_2]^{2-}$ and $[UO_2 \cdot (SO_4)_3]^{4-}$ complexes are formed. The yield of these complexes depends on the content of sulfuric acid and sulfate anions in the leaching solution [1].

The sorption recovery of uranium from sulfuric acid leaching solutions by strongly basic anion exchangers can be described by reactions of complexation and ion exchange [2]:

$$(R_4N^+)_2SO_4 + [UO_2SO_4]^0 \rightleftarrows (R_4N^+)_2[UO_2(SO_4)_2]^0,$$

$$2(R_4N^+)_2SO_4 + [UO_2(SO_4)_2]^{2-} \rightleftarrows (R_4N^+)_4[UO_2(SO_4)_3] + SO_4^{2-},$$

$$2(R_4N^+)_2SO_4 + [UO_2(SO_4)_3]^{4-} \rightleftarrows (R_4N^+)_4[UO_2(SO_4)_3] + 2SO_4^{2-}.$$

In this study we examined the equilibrium and kinetic characteristics of uranium sorption by anion exchangers from sulfuric acid solutions simulating the leaching solutions for underground uranium mining. Along with common AMP and AM-p anion exchangers, we tested new Lewatit K 6367, Purolite A 500, and Purolite A 600 strongly basic anion exchangers.

EXPERIMENTAL

In our experiments we studied sorption of uranium from simulated leaching solutions by commercial strongly basic anion exchangers in the SO_4^{2-} form. Anion exchangers of various brands were tested: AMP, AM-p (Smoly State Company, Ukraine); Purolite A 500, Purolite A 600 (Purolite International Limited, the United Kingdom); Lewatit K 6367 (Bayer AG, Germany). The main physicochemical characteristics of these resins, listed in Table 1, were published [3], taken from certificates (Lewatit K 6376, Purolite A 500, and Purolite 600), or determined in accordance with OST (Branch Standard) recommendations.

The factors for recalculating the mass sorption capacity (mg g^{-1}) of resins to their volume sorption capacity (mg cm^{-3}) were determined by the method reported in [4]. For the anion exchangers under consideration, these factors are as follows:

Anion exchanger	Recalculation factor, $cm^3\ g^{-1}$
AMP	1.9
Lewatit K 6367	1.8
Purolite A 500	2.7
Purolite A 600	2.5
AM-p	2.6

The sorption of uranium from simulated leaching solutions was studied at room temperature (20°C). The composition of these solutions was as follows (g dm^{-3}): uranium(VI) 0.058–0.063, sulfuric acid 4.8–5.0, iron (total) 1.50–1.65, aluminum(III) 1.30–1.35, calcium 0.50–0.57, magnesium 0.40–0.45, chloride anion 0.50–0.58, and sulfate anion (total) 19.5–20.5. The solid and liquid phases were stirred with a mechanical stirrer at a rate of 340 rpm.

The isotherms of uranium sorption were obtained at the uranium concentration in the solution ranging from 5 to 204 mg dm^{-3}. For solutions containing

5–30, 60–80, and 150–204 (mg U) dm^{-3}, the solution to sorbent ratio $V_l : V_s$ was 5000, 3000 and 1000, respectively. The time of contacting the sorbent and liquid phase was 24 h.

The isotherms of uranium sorption were treated with the Langmuir equation [5].

The kinetics of uranium sorption was studied at room temperature under static limited-volume conditions. The integral sorption kinetic curves were obtained at the contacting time of 1–24 h and the solution to sorbent ratio $V_l : V_s = 3000$.

The external uranium diffusion was estimated using a simplified approach [7] based on an assumption that, in the initial period of contact of the sorbent and solution, the solute content on the sorbent surface is zero and its diffusion into sorbent can be neglected:

$$\ln\frac{c(\tau)}{c_0} = -k\frac{A}{V}\tau, \qquad (1)$$

where $c(\tau)$ is the solute concentration (mg dm^{-3}) at time τ; c_0, initial solute concentration (mg dm^{-3}); A, exchanging surface area of the sorbent (m^2); and V, solution volume (dm^3).

The initial external mass transfer factor k (m s^{-1}) was determined from the plot of $\ln c(\tau)/c_0$ vs. the phase contact time.

The A/V ratio was calculated by the equation

$$A/V = 6m/d\rho_a, \qquad (2)$$

where m is the sorbent to solution ratio (g dm^{-3}); d, diameter of the sorbent granule (m); and ρ_a, apparent sorbent density (g dm^{-3}).

The average diameter of anion exchanger granules, as determined by dry sieving, was as follows (mm): AMP, 0.9; Lewatit K 6367, 0.7; Purolite A 500, 0.8; Purolite A 600, 0.7; and AM-p, 0.9. The apparent density of these sorbents was 1.15, 1.11, 1.12, 1.11, and 1.08 g cm^{-3}, respectively. In our kinetics sorption experiments, the A/V ratio, on the average, was 0.75, 0.72, 0.87, 1.00 and 0.74 m^{-1} for AMP, Lewatit K 6367, Purolite A 500, Purolite A 600, and AM-p anion exchangers, respectively.

The uranium diffusion within gel-like resins was analyzed by the equation deduced by Boyd, Adamson, and Myers [8]:

$$F = a_\tau/a_\infty = 1 - \frac{6}{\pi^2}\sum_{n=1}^{\infty}\frac{1}{n^2}\exp(\bar{D}\pi^2 n^2\tau/r_0^2), \qquad (3)$$

where $\bar{D}$ is the coefficient of internal diffusion ($m^2\ s^{-1}$); r_0, average radius of sorbent granule (m); a_τ and a_∞, sorption capacity of the resin for uranium

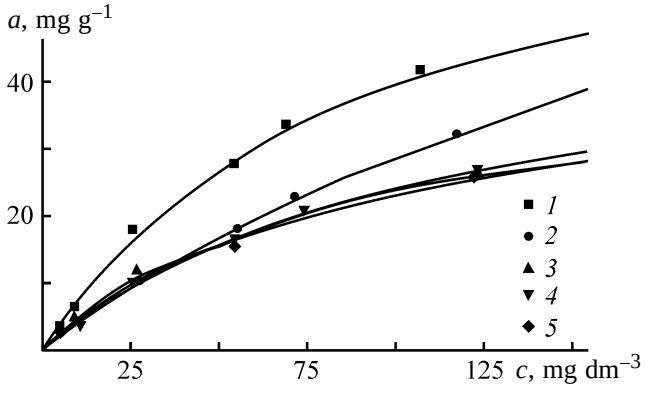

Fig. 2. Isotherms of uranium sorption by (*1*) AMP, (*2*) Lewatit K 6367, (*4*) Purolite A 600, and (*5*) AM-p anion exchangers and (*3*) apparent isotherm of uranium sorption by Purolite A 500 from simulated leaching solutions. (*a*) Volume sorption capacity of anion exchangers for uranium and (*c*) uranium concentration in solution.

Table 2. Parameters of isotherms of uranium sorption by AMP, Lewatit K 6367, Purolite A 500, Purolite A 600, and AM-p anion exchangers, calculated by the Langmuir equation

Anion exchanger	K, $dm^3\ g^{-1}$	A_∞, $g\ dm^{-3}$	R^2	$S \times 10^4$
AMP	8.5	86.4	0.962	1.4
Lewatit K 6367	3.1	123	0.977	0.8
Purolite A 500	10	45.8	0.988	1.7
Purolite A 600	6.5	61.3	0.949	2.6
AM-p	9.1	48.8	0.974	2.3

at the moment τ and at equilibrium ($mg\ g^{-1}$); and F, degree of the resin saturation depending only on the dimensionless parameter $B = \bar{D}\pi^2/r_0^2$.

At the degree of resin saturation $F > 0.7$, the terms of higher orders in Eq. (3) become small, and this equation is simplified:

$$F = 1 - \frac{6}{\pi^2}\exp(-B\tau). \quad (4)$$

After taking the logarithm, Eq. (4) is converted to a linear semilogarithmic equation $\ln(1 - F) = \ln(6/\pi^2) - B\tau$. This equation can be presented as the plot of $\log(1-F)$ vs. τ, whose slope is the B factor. After substitution of this factor into Eq. (3), the diffusion coefficient D was calculated.

The simplest and the most reliable procedure for determining the limiting stage of sorption is based on interruption of sorption [9]. According to this technique, after contact for 1 h, a resin is separated from the solution by vacuum filtration through a Schott filter, and both the sorbent and solution are kept separately. After the lapse of 3 h, the solution and sorbent are brought in contact again.

In sorption of uranium(VI) from model leaching solutions containing from 5 to 150 $(mg\ U)\ dm^{-3}$, the mass sorption capacity of anion exchangers for uranium decreases in the order AMP > AM-p, Purolite A 600, Purolite A 500 > Lewatit K 6367 (Fig. 1). Under the same conditions, the volume sorption capacity of these resins decreases in the order AMP > Lewatit K 6367 > AM-p, Purolite A 600, and Purolite A 500 (Fig. 2).

The residual uranium content in the leaching solution after the sorption is determined by the residual sorption capacity of regenerated resins for uranium. With the sorbents under consideration, the residual uranium concentration of 2 $mg\ dm^{-3}$ is attained at the following residual sorption capacities, $mg\ cm^{-3}$: AMP, 1.1–1.3; Lewatit K 6367, 0.6–0.8; Purolite A 500, 0.7–0.9; Purolite A 600, 0.6–0.8; and AM-p, 0.7–0.9.

Our sorption isotherms are well described by the Langmuir equation. The k and A_∞ parameters of the Langmuir equation for anion exchangers under consideration and also the approximation reliability factors R^2 and the residual variances S are listed in Table 2.

The rate of uranium sorption from simulated leaching solutions by the anion exchangers under consideration decreases in the order Lewatit K 6367 >

Table 3. Mass-transfer coefficient k and diffusion coefficient D of uranium(VI) in its sorption by AMP, Lewatit K 6367, Purolite A 500, Purolite A 600, and AM-p anion exchangers

Anion exchanger	$k \times 10^5$, m s^{-1}	R^2	S	$\bar{D} \times 10^{12}$, m^2 s^{-1}	R^2	S
AMP	2.10	0.957	0.0061	1.69	0.983	0.3247
Lewatit K 6367	2.00	0.990	0.0025	1.12	0.995	0.1189
Purolite A 500	0.54	0.954	0.0017	0.66	0.983	0.2062
Purolite A 600	0.83	0.983	0.0018	0.89	0.997	0.1136
AM-p	1.05	0.980	0.0018	0.98	0.981	0.1994

AMP > Purolite A 600, AM-p > Purolite A 500. The complete saturation of sorbents with uranium in sorption from its dilute sulfuric acid solutions was attained within the following time (h): Lewatit K 6367 6–10; AMP, Purolite A 600, 14–16; and AM-p, 20–24. In sorption of uranium by Purolite A 500, the sorption equilibrium was not attained within 25 h. Therefore, in this case the apparent isotherms of uranium sorption were obtained (Figs. 1, 2). Under the identical experimental conditions, the mass sorption capacity of AMP anion exchanger for uranium exceeds that of the other resins under consideration by 10–40%, and the volume sorption capacity, by 5–7%.

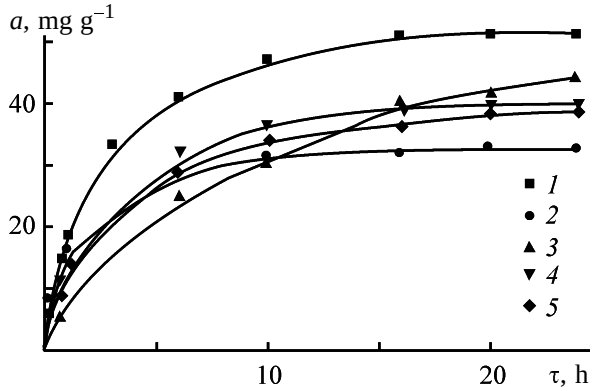

Fig. 3. Integral kinetic curves of uranium sorption by (*1*) AMP, (*2*) Lewatit K 6367, (*3*) Purolite A 500, (*4*) Purolite A 600, and (*5*) AM-p from simulated leaching solutions. (*a*) Mass sorption capacity for uranium and (τ) phase contact time; the same for Fig. 4.

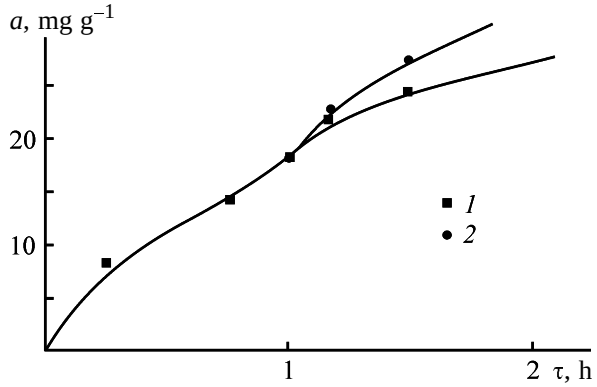

Fig. 4. Kinetic curves of uranium sorption from simulated leaching solutions: (*1*) without interruption and (*2*) with interruption.

Experiments on interruption of sorption showed that, in sorption of uranium with AMP, the intragranular (gel-like) diffusion starts to contribute to the total rate of uranium sorption at $\tau > 1$ h.

Under these conditions, after repeated phase contact, the rate of uranium sorption increases as compared to the rate of sorption before interruption. This effect is caused by the fact that, after interrupting the phase contact, uranium gets evenly distributed within the granule and, as a result, in the moment of repeated contact, the gradient of uranium concentration between the solution and the sorbent surface increases (Fig. 4). Whereas at a contact time $\tau < 1$ h uranium mainly diffuses by the film mechanism, at $\tau > 6$ h the intragranular gel-like diffusion of uranium predominates. At a contact time of 1–6 h, uranium is sorbed by the mixed mechanism.

The mass-transfer coefficients of uranium at a contact time $\tau < 1$ h and the uranium diffusion coefficients at the degree of sorbent saturation $F > 0.7$, calculated by Eqs. (1) and (4), are listed in Table 3.

The best kinetic characteristics of uranium sorption from simulated leaching solutions were exhibited by AMP and Lewatit K 6367 anion exchangers. The mass-transfer coefficients and the diffusion coefficients decrease in the order AMP > Lewatit K 6367 > AM-p > Purolite A 600 > Purolite A 500.

CONCLUSIONS

(1) Among anion exchangers used for uranium sorption from simulated leaching solutions for underground uranium mining (Lewatit K 6367, Purolite A 600, Purolite A 500, AMP, and AM-p), the highest sorption capacity for uranium is exhibited by standard

AMP anion exchanger. The isotherms of uranium sorption are well described by the Langmuir equation.

(2) AMP and Lewatit K 6367 anion exchangers show the best kinetics of uranium sorption from simulated leaching solutions. The experiments on interruption of uranium sorption showed that, whereas at a contact time $\tau < 1$ h uranium mainly diffuses by the film mechanism, at $\tau > 6$ h the intragranular gel-like diffusion predominates. At a contact time within 1–6 h, uranium diffuses by the mixed mechanism.

SORPTION AND ION-EXCHANGE PROCESSES

Specific Features of 1,3-Diazole Adsorption on the Surface of NiO and Fe_2O_3

I. B. Dmitrieva, K. P. Tikhomolova, and A. S. Chukhno

Received October 20, 2004; in final form, March 2005

Abstract—Variation of the electrokinetic potential of the surface of the oxides and of the amount of adsorbed diazole and its concentration in solution in systems constituted by aqueous solutions of 1,3-diazole and NiO and Fe_2O_3 adsorbents was studied in the course of a long time after bringing the phases in contact.

In this study, we proceed with analysis of the fundamental aspects of adsorption of nitrogen-containing five-membered heterocyclic organic compounds, azoles, from their aqueous solutions onto the surface of transition metal oxides [1–5]. Azoles are fragments of biologically important objects responsible for binding of metals in living bodies and show considerable promise for use in pharmacology and medicine. It is noteworthy that azole-containing fragments are incorporated in blood cells; numerous medical preparations (Analgin, antipyrine, pyramidone, etc.) and vitamins (B_1) are derivatives of azoles [6–8]. A study of adsorption of azoles on the surface of transition metal oxides will make it possible to understand and explain the mechanism of specific adsorption, which governs such biological processes as introduction of vitally important metals and removal of those with toxic properties from living bodies.

We chose as basic objects of study 1,3-diazole (imidazole) and Ni(II) and Fe(III) oxides. It is known that iron is the "metal of life" and nickel is a highly toxic metal.

The presence of nitrogen(III) in the imidazole molecule in position 1 (pyrrole-type nitrogen) determines its acid–base properties and the possibility of its existence in the anionic form, and nitrogen in position 3 (pyridine-type nitrogen) enables positive charging of the diazole molecule in its protonation. Imidazole can exist in aqueous solutions in three forms: neutral, cationic, and anionic. Consequently, the imidazole molecule can form, depending on conditions, an electrostatic bond with the charged surface of the oxide as a cation (at negatively charged surface) or anion (at a positive charge). It should, however, be noted that imidazole dissociates in water mainly by the basic type; the anionic form appears in noticeable amounts (>3%) at pH > 12 (pK_a 14, pK_{BH^+} – 6.99 [5]).

The imidazole cation is rather stable and can form, under the optimal conditions, large aggregates in the form of long chains with 20 and more molecules linked by hydrogen bonds $N_1 \cdots H \cdots N_3$. The neutral form of the molecules can also produce chains, which are, however, considerably shorter; the anionic form typically shows no aggregation [9].

At the same time, nitrogen atoms can be involved in bonding by the donor–acceptor mechanism with the metal ion belonging to an active center on the oxide surface. It is noteworthy that the property of aromaticity, generally characteristic of heterocycles, is rather poorly pronounced in imidazole.

The iron(III) and nickel(II) ions we chose for the study belong to metal ions exhibiting a variable acceptor power [10]. Depending on the pH value, the surface of their oxide may be charged both positively (at low pH) and negatively (at higher pH values), which is determined by its adsorption capacity for $[H^+]$ and $[OH^-]$ ions. The pH value at the isoelectric point (pH_{IEP}), found from electrokinetic measurements, depends on the acid–base properties of the active center on the oxide surface. For the oxides used in the study, these values were 7.6 for NiO and 6.1 for Fe_2O_3.

The interaction of azoles with an oxide surface can be judged from the manner in which the electrokinetic potential ζ, position of pH_{IEP}, and amount Γ of adsorbed nitrogen (found from its loss from solution) vary with the pH value of the system, intial nitrogen

1070-4272/05/7805-0727 © 2005 Pleiades Publishing, Inc.

concentration c_N^0, and time t_c of contact between the phases.

The powder of iron(III) oxide, used in the study, was composed of crystalline particles of three modifications, γ-Fe_2O_3, δ-Fe_2O_3, and α-Fe_2O_3; powdered nickel oxide was composed of particles of a single modification. To remove surface impurities, we repeatedly washed the metal oxides with distilled water to a constant electrical conductivity and pH value of washing water and dried in an oven at 105°C.

We studied the adsorption properties of the oxides, as regards the parameter Γ (henceforth, "adsorption properties" without specifying the characteristic parameter), on powders with a particle size of 0.5–10.0 μm, fractionated by sedimentation in water. The specific surface areas S_{sp} of this fraction, determined by BET, were ($m^2\ g^{-1}$) 3.3 for NiO and 2.8 for Fe_2O_3. To study the adsorption properties as regards the parameter ζ (henceforth "electrokinetic properties"), a powder fraction with a particle size of 0.5–10.0 μm was separated by sedimentation.

The concentrations of imidazole solutions were, before the solutions were brought in contact with the oxides, 1×10^{-3} and 1×10^{-4} M. We used solutions with various pH values: that corresponding to an imidazole solution of a given concentration without any additives during the entire experiment; pH 3; and, in the case of electrokinetic experiments, also pH 4. The initial pH of the aqueous imidazole solutions was 7.6 (solution no. 1). Solutions with pH 3 and 4 (solution nos. 2 and 3, respectively) were obtained by adding a certain amount of 1×10^{-1} M HCl, and these values were maintained constant during the entire experiment by adding an acid or an alkali. With solution no. 1, the pH values varied in the course of an experiment, but only slightly, by 0.3–0.4 pH units; they decreased during the first hour and then increased in the course of 120 h. In the latter case, they reached pH 8.0 when working with NiO, and 7.7, with Fe_2O_3.

All the solutions were prepared using distilled water with an electrical conductivity of $(1–2) \times 10^{-6}$; the 1×10^{-1} M HCl solution was prepared from a reference sample; all the chemicals used were of analytically pure grade. According to the speciation diagram calculated from K_a and K_{BN^+} [2, 3], at pH 7.6 about 30% of imidazole molecules carry a positive charge and about 70% are neutral; at pH 7.3 about 35–40% are in the cationic form; at pH 8.0 only 10% are charged positively and about 90% are neutral. In all the cases considered, only trace amounts of the anionic form are found.

The electrokinetic potential was determined by the microelectrophoretic method [11, 12]. The dispersion contained 0.5 g of a metal oxide and 200 ml of a solution. The electrophoretic mobility of dispersion particles was measured in a plane-parallel cell (cross-sectional area of the channel 17.8 mm^2). The ζ potential was calculated by the procedure corresponding to that repeatedly described in the literature [2, 3, 12].

To determine the adsorption of imidazole, weighed portions of NiO (Fe_2O_3) were poured over with 0.15 l of its solution ($c = 1 \times 10^{-3}$ M).[1] After 15, 30, and 45 min, and 1, 1.25, 1.5, 2, 3, and 24 h the solution was separated from the solid phase by filtration. The adsorption Γ was calculated from the difference of the imidazole concentrations (initial c_a^0 and that in a sample being measured, c_a) by the formula

$$\Gamma = \frac{(c_a^0 - c_a)V}{mS_{sp}},$$

where Γ is the adsorption (mol m^{-2}); c_a^0, concentration of the initial solution (M); c_a, running concentration of the solution in the course of adsorption (M); V, solution volume (l); m, mass of the adsorbent (g); and S_{sp}, specific surface area of NiO (Fe_2O_3) ($m^2\ g^{-1}$).

The concentration of imidazole in the solution bulk in adsorption on iron(III) oxide was determined spectrophotometrically with an SF-24 spectrophotometer at λ = 220 nm using 10-mm-thick quartz cells. Prior to measurements, the dispersion was exposed to a strong magnetic field to achieve a more complete separation of iron(III) oxide particles. In studying the adsorption on nickel oxide, the imidazole concentration was determined using the Kjeldahl method [13].

Let us first discuss the results obtained with solutions with $c_a^0 = 1 \times 10^{-3}$ M. Figures 1a and 1b show the $\zeta = f(t_c)$ dependences for Ni(II) and Fe(III) oxides at all of the above-mentioned pH values. For comparison, curves describing similar dependences for imidazole-free systems are presented. The corresponding solutions having the same pH values as solution nos. 1–3 (henceforth, solution nos. *1*'–*3*') are termed "background" solutions.

Here and hereinafter, the scale of the time variable (abscissa axis) in all the figures describing the kinetics of the processes under study as regards the ζ potential gives no way of plotting the potentials (ordinate axis) for $t_c < 0.25$ h. Therefore, two points are plotted on

[1] It is noteworthy that the relative amounts of the adsorbent and solution, as well as the above-mentioned particle sizes, are different in experiments in which Γ and ζ are measured.

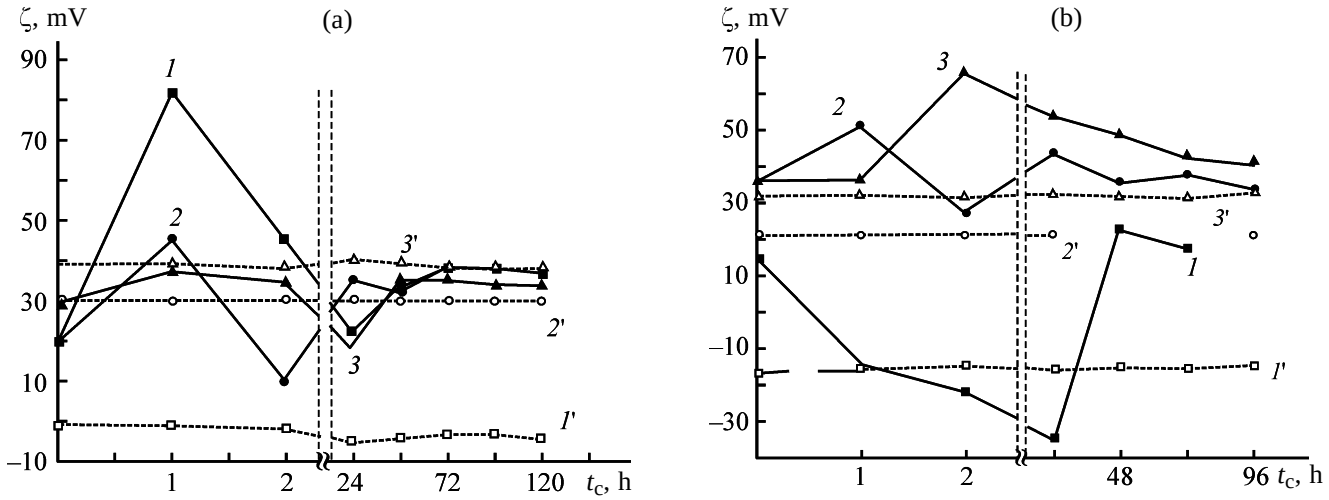

Fig. 1. The ζ potential of (a) NiO and (b) Fe_2O_3 particles vs. the time t_c of their contact with aqueous imidazole solutions with $c_a = 1 \times 10^{-3}$ M (solid lines) and with background solutions (HCl and KCl) (dashed lines) at different pH values. pH: (*1*, *1*') 7.6 (solution nos. *1*, *1*'), (*2*, *2*') 4 (solution nos. *2*, *2*'), and (*3*, *3*') 3 (solution nos. *3*, *3*').

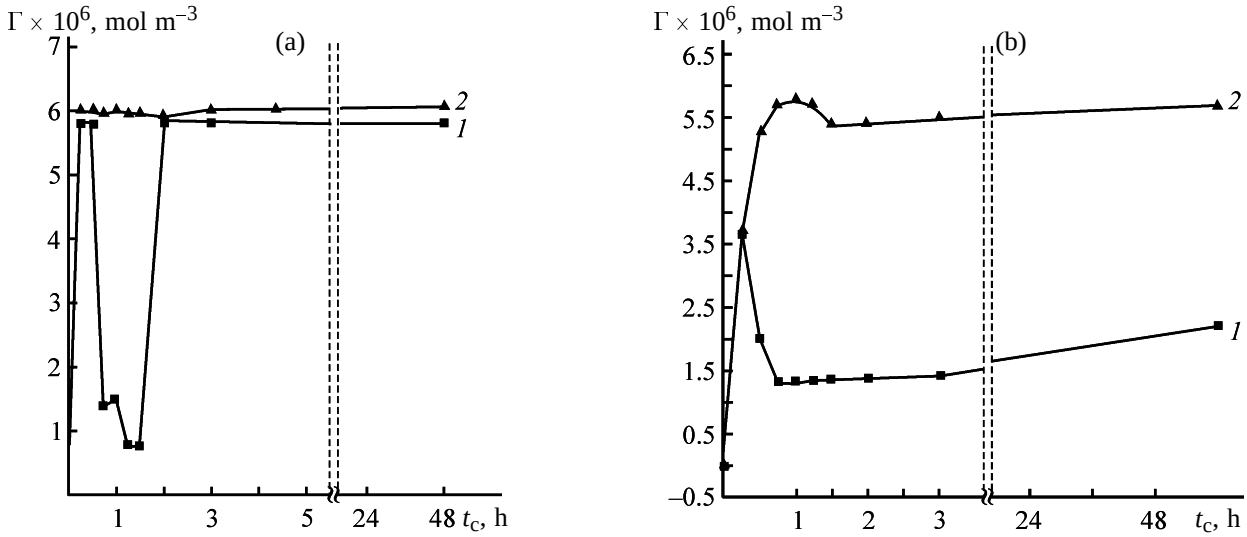

Fig. 2. Γ vs. time t_c of phase contact in systems constituted by aqueous imidazole solutions with $c_a = 1 \times 10^{-3}$ M and (a) NiO and (b) Fe_2O_3. pH: (*1*) 7.6 (solution no. 1) and (*2*) 3 (solution no. 3).

the ordinate axis at $t_c = 0$ in each run: that for a background solution and that with imidazole. The noncoincidence of these points suggests the occurrence of the adsorption governed by electrostatic forces.

It can be seen that the ζ potentials in simple electrolytes rapidly reach their steady-state values and further remain virtually unchanged in the course of time. In imidazole solutions, the ζ potential vs. time plots show extrema at all pH values. Qualitatively, the $\zeta = f(t_c)$ dependences are similar. In all cases, the potential substantially grows during the first hour of contact (in the system constituted by Fe_2O_3 and solution no. 1, already in the first few minutes) and then equally substantially decreases during several hours and after that either flattens out or slowly increases. However, the extrema are the more pronounced, the higher the pH, and at a given pH they are somewhat more pronounced in the case of NiO, compared to Fe_2O_3.

The experimental dependences of Γ on t_c are shown in Fig. 2a (NiO dispersion) and 2b (Fe_2O_3 dispersion). It can be seen that the $\Gamma = f(t_c)$ dependences obtained in solution no. 1 show a behavior differing from that of the corresponding $\zeta = f(t_c)$ dependences, which, however, also show pronounced maxima. In the case under consideration, Γ substantially grows

during a certain initial interval of time and then steeply decreases, after which it again starts to grow [relatively steeply in the case of nickel(II) oxide and rather gradually for iron(III) oxide], and the curve flattens out. It is noteworthy that the differences between the $\zeta = f(t_c)$ and $\Gamma = f(t_c)$ dependences at those t_c values for which the direction of the run of the corresponding curve shows the most pronounced changes can be, in principle, attributed to the above-mentioned difference of the grain-size distribution of the objects in electrokinetic and adsorption experiments. In the case of systems with low pH (pH 3), the run of the curves is rather smooth, with Γ substantially changing only in the first several minutes.

Let us now discuss the experimental results concerning the $\zeta = f(t_c)$ dependence. We are primarily interested in the noncoincidence of points on the ordinate axis that correspond to systems with imidazole ("zero points") and without it (background curves) at the same pH value. The increase in the positive potential upon appearance of imidazole in the system indicates that the imidazolium cation is adsorbed. Figure 1b shows that, in the case of a system constituted by Fe_2O_3 and imidazole solution no. 1, the sign of the ζ potential changes from negative to positive. This fact can be qualitatively understood as resulting from adsorption of the imidazolium cation onto the originally negatively charged surface of the adsorbent under the action of Coulomb forces; this process comes to saturation very rapidly (within fractions of second or several seconds). However, the noncoincidence of zero points in all other cases cannot be attributed to a simple electrostatic interaction. The adsorption of the cation on a positive (or neutral) surface indicates that specific adsorption forces are important already in the first minutes of contact.

The more or less prolonged rise in the ζ potential, observed during the first hours of the phase contact (Figs. 1a, 1b; 1 h for systems with NiO and 1–2 h in the case of Fe_2O_3), indicates that the specific adsorption of imidazolium cations continues. We believe that the absence of a portion of this kind in curve *1* in Fig. 1b is due to the active involvement of Coulomb forces (the only case of an originally negatively charged surface of the oxide), and the corresponding rise in the positive potential occurs in full measure within a few minutes.

We call attention to two facts characteristic of the interval of time from zero to 1 h when working with a NiO dispersion. The first is that the $\Delta\zeta$ corresponding to this time of the experiment is rather large in the case of solution no. 1. The second is that $\Delta\zeta$ decreases as the pH value becomes lower, but remains significant in more acidic solutions. A substantial rise in the ζ potential in solution no. 1 has been observed previously [3]. In our opinion, the increase in positive values of the ζ potentials in the initial period of time is due to adsorption of the already mentioned long chains formed in solution from protonated forms of imidazole molecules. These chains can be adsorbed on the oxide surface via formation of donor–acceptor bonds between a metal ion in the oxide and a molecular unit at the end of a chain. The appearance of such "polycations" in the surface layer introduces into it a large positive charge fixed on the oxide surface.

In addition to the specific adsorption of positively charged chains, the anionic form of imidazole can also be adsorbed. The adsorption of the anionic form must, in principle, lead to an increase in magnitude of the negative ζ potential; however, the contribution of this form is negligible under the experimental conditions. In addition to charged forms, the neutral form can also be adsorbed, which somewhat increases the magnitude of the ζ potential because of the steric effect on the distribution of counterions in the electrical double layer [14]. However, their role is incomparable with that of positive chains. A positive chain formed by protonated forms of imidazole molecules can have one its end attached to the oxide surface and the other (tail) directed into the solution, or both of its ends attached to the surface, with its shape resembling in this case a loop or a bridge. It should be added that a large number of counterions (inorganic anions in the given case) are situated between the tails and within the loops formed by the positive chains, and these counterions contribute to the electrokinetic flow.

The calculated values of the ζ potential are a consequence of the overall effect of all the forms.

The fact that $\Delta\zeta$ becomes lower with increasing solution acidity apparently reflects a decrease in aggregation between imidazole molecules at a higher concentration of H^+ ions. The aggregation of imidazole occurs via formation of hydrogen bonds between nitrogen atoms in one imidazole molecule and hydrogen atoms in the other. In the presence of a large number of hydrogen cations in solution, there occurs competition between free hydrogen cations and hydrogen atoms in a diazole molecule.

The results obtained for the interval of time from 0 to 2 h when working with iron(III) oxide dispersions can, on the whole, be explained from the same standpoint, although the influence of pH is manifested in an increase in the time interval after the maximum is observed, rather than in its magnitude.

We now pass to that portion of the curve in which the ζ potential falls. As before, we primarily choose for more clarity systems with solution no. 1. We attribute the behavior in this case to prevalence of the effect of chain disintegration over adsorption of long aggregates. This process is due to the relay-race mechanism of rupture of hydrogen bonds, i.e., formation of strong donor–acceptor bonds at chain ends leads to subsequent disintegration of the whole chain. As a result, a large number of imidazolium cations not bound with the surface can be found in its vicinity. This means that the equivalent amount of counterions previously contributing to the electrokinetic flow cease to be electrokinetically active [14]. As a result, the ζ potential decreases.

The rather fast, with account of the occurrence of the components in the bulk of the aqueous phase, rise in the ζ potential in the first period of interaction between the active centers of the surface and the solution components and its decrease in the second period are in full qualitative agreement with the experimental results obtained in determining the adsorbed amount, which reflect the fast increase in Γ in the first 15–20 min and an equally rapid decrease in Γ in the subsequent 30 min. The fact that the duration of these periods of fast growth and decrease in the amount of adsorbed diazole does not coincide with that estimated from the ζ potential is in all probability due to the above-emphasized difference in the relative amounts of phases in the dispersions used in ζ and Γ measurements.

It should be noted that the result of the interaction between the metal ions of a surface center and imidazole in the stages of rise and decrease of ζ and Γ is determined by the dynamic nature of attainment of their final values and the prevalent state of imidazole in solution.[2]

The abscissas of the minimum values indicate that, by the given time, the processes of chain adsorption and disintegration are complete and all the possible (in accordance with the Langmuir theory) active centers of the surface are bound with separate imidazole molecules or small associates only.

[2] The chains, being adsorbed, disintegrate; separate molecules from the surface layer find their way into solution bulk to form there new chains, which come to free surface centers to be again disintegrated, etc. The stage of rise in ζ and Γ means that, during this period, there still is a large number of long chains in solution, whereas the stage of a decreasing height of the peak in the ζ–t_c curve and a dip in the Γ–t_c curve corresponds to disintegration of long chains, whose number becomes small by that time.

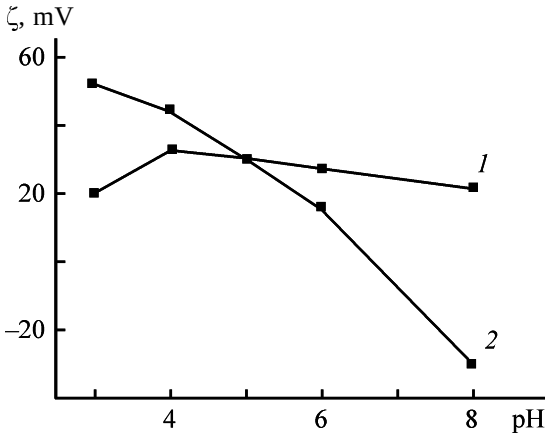

Fig. 3. The ζ potential of (*1*) NiO and (*2*) Fe_2O_3 particles vs. pH of aqueous imidazole solutions with $c_a = 1 \times 10^{-3}$ M.

The last stage of rise in the ζ potential in the absence of changes in Γ apparently indicates that there occur surface chemical reactions with the already formed surface compound [15]. In this context, it should be noted that, in the case of Fe(III) oxide, the pH values of solution no. 1 correspond to the region of strong hydrolysis, whereas in the case of Ni(II), the hydrolysis is considerably weaker [16].

To conclude, we note that the increments in the absolute values of the parameters in the stage of their rise and decrease are less pronounced in the case of Fe_2O_3, compared to NiO. These facts are in agreement with the repeatedly published concept that the energy of interaction between the ligand and Fe(III) is lower than that with Ni(II) [17]. The above concept suggesting the key role of specific interaction between nickel(II) or iron(III) ions of an active surface center and imidazole molecules is confirmed by the shift of pH_{IEP} values in imidazole solutions, compared to those in solutions containing no organic ligands (with HCl or KOH). According to the data obtained (Fig. 3), the pH_{IEP} value in systems with imidazole is shifted, for both NiO and Fe_2O_3, into the alkaline region, compared to systems with HCl, suggesting specific adsorption of the imidazolium cation. The shift in the system with Ni(II) oxide is so strong that pH_{IEP} lies far in the alkaline region (ΔpH_{IEP} markedly exceeds 2–3 pH units). In the system with Fe(III) oxide, the shift is considerably smaller (ΔpH_{IEP} = 0.5–0.6 units). The strong shift of pH_{IEP} in the case of Ni(II) oxide and the weak shift for Fe(III) oxide suggest that imidazole is a ligand with a rather low electrostatic component of the ligand field.

The main specific features of the dependences described, $\zeta = f(t_c)$ and $\Gamma = f(t_c)$, and their influence

on pH were qualitatively manifested also at a lower imidazole concentration of 1×10^{-4} M. As for the quantitative aspect, changes in the parameters were markedly smaller in this case. Such an influence of the imidazole concentration on $\Delta\zeta$ and $\Delta\Gamma$ is apparent and requires no special discussion.

CONCLUSIONS

(1) It was found that, in NiO and Fe_2O_3 dispersions in aqueous solutions of 1,3-diazole, the dependences of the electrokinetic potential and amount of adsorbed substance on the time of contact between the phases pass through a clearly pronounced maximum and a minimum following immediately after, and then show a prolonged ascent and flatten out.

(2) The height of the corresponding peak and depth of the dip in the curves depend on pH (higher and deeper, respectively, at pH 6.7–7.6, and less so at lower pH), initial imidazole concentration (stronger effect at higher concentrations), and kind of a metal oxide (considerably better pronounced in a dispersion with NiO, compared to Fe_2O_3).

(3) In the dispersions under study, pH_{IEP} is shifted, for both NiO and Fe_2O_3, into the alkaline region, compared to the pH_{IEP} of these oxides in HCl and NaOH solutions. The shift of pH_{IEP} exceeds 3 pH units for NiO, but is considerably smaller in the case of Fe_2O_3 (0.5–0.6 pH units).

SORPTION AND ION-EXCHANGE PROCESSES

Adsorption of Aliphatic Acids from Aqueous Solutions at the Interface with the Gas Phase

V. A. Malov

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received October 15, 2004; in final form, March 2005

Abstract—The type of the dependence of the Gibbs relative adsorption on the concentration of an ideal solution of a surfactant was studied. The applicability of the hypothesis of monomolecular adsorption at the interface between an aqueous solution of aliphatic acids and the gas phase was assessed.

An important role in studying the adsorption from solutions at the interface with the gas phase is played by the dependence of the surface tension σ on the solution concentration x. Among a number of $\sigma = f(x)$ equations that have been suggested (for reviews, see [1, 2]), the best known and the most frequently cited is the equation empirically obtained by Shishkovskii [3]:

$$\Delta\sigma = B\ln(1 + xA), \quad (1)$$

where $\Delta\sigma = \sigma_0 - \sigma$; σ_0 and σ, surface tensions of the solvent and solution, respectively; and A and B, constants.

Equation (1) was theoretically substantiated in [4, 5] as the $\sigma = f(x)$ dependence for an ideal solution.

The interest in Eq. (1) is largely due to the fact that its application in the Gibbs adsorption equation yields the equation of the Langmuir isotherm for monomolecular adsorption. Therefore, the adequacy of Eq. (1) to experimental data gives reason to believe that the adsorption is monomolecular and to identify the Gibbs surface excess with the surface concentration. The applicability of Eq. (1) is most frequently judged from the presence of a linear portion in the surface tension isotherm plotted on the semilog scale. In this portion, the specific adsorption and the solution concentration in the surface layer reach their limiting values.

In a number of studies [6, 7], the experimental $\sigma = f(x)$ dependence was processed graphically or by numerical differentiation without using Eq. (1) and adsorption isotherms with a peak, untypical of monomolecular adsorption, were obtained. Adsorption isotherms with such a specific feature can be obtained from an approximate form of Eq. (1), which was not analyzed in [4].

Equation (1) can be written as

$$\Delta\sigma = -B\ln[1 - Ax/(1 + Ax)] = -B\ln(1 - \theta). \quad (2)$$

If the quantity $Ax/(1 + Ax) = \theta$, which characterizes the filling of the surface with the adsorbate in the case of monomolecular adsorption, is considerably less than unity ($\theta \ll 1$), then it is possible to keep in the power series expansion of the logarithmic function only the first term and to take that

$$\Delta\sigma = BAx/(1 + Ax). \quad (3)$$

Published data show that an equation of a fractionally linear function (3) was semiempirically obtained and experimentally verified in four studies [8–11]. In these cases, the $\sigma = f(x)$ dependences were represented in a form different from that of Eq. (3), but can be readily reduced to it. It was shown in [12] that introduction into Eq. (2) of an additional term $a\theta^2$, which accounts for the attractive interaction of adsorbed molecules, improves the agreement between the experimental and calculated data. Noteworthy is the fact that, upon this transformation of Eq. (1), the $\sigma = f(x)$ dependence becomes closer to the fractionally linear function (3).

In [9], Eq. (3) was derived on the assumption that the surface tension of a solution linearly depends on the solute concentration y in the surface layer:

$$\sigma = \sigma_0(1 - y) + \sigma_1 y, \quad (4)$$

where σ_0 and σ_1 are the surface tensions of the solv-

Caproic	–14.6	2459.8 ± 13.0	0.05205 ± 0.0021

ent and solute, respectively; *y* is the mole fraction of the solute in the surface layer.

To Eq. (3) leads substitution into formula (4) of the following known equation relating the solution compositions in the surface layer and in the bulk [4, 9]:

$$y = \frac{kx}{1 + (k - 1)x}, \quad (5)$$

where *y* and *x* are the mole fractions of the solute in the surface layer and in the solution bulk, respectively; $k = A + 1$ is the constant of equilibrium between the surface layer and the bulk of the solution.

The adsorption isotherm equation derived from the Gibbs adsorption equation and Eq. (3) has the form

$$\Gamma = \frac{B}{RT}\frac{Ax}{(1 + Ax)^2}. \quad (6)$$

Analysis of Eq. (6) for an extremum shows that, graphically, this adsorption isotherm is a curve with a peak of height $\Gamma_{max} = [B/(4RT)]$, lying at $x_0 = 1/A$. As follows from Eq. (5), the mole fraction of the solute in the surface layer is given by $y = (A + 1)/(2A)$ at $x = 1/A$ and equals 0.5 at $A \gg 1$. In the case of monomolecular adsorption, the mole fraction $y = 0.5$ corresponds to half-filling of the surface layer if the area occupied by a solute molecule is equal to the molecular area of the solvent. Therefore, the capacity of a saturated monolayer must be $\Gamma_\infty = 2\Gamma_{max} = B/(2RT)$ for a solution of this kind.

As known, the shape of an adsorption isotherm depends on various types of intermolecular interactions responsible for nonideality of solutions. The influence exerted by the nonideality of solutions on the adsorption can be analyzed using the Gibbs equation written as

$$\Gamma = -\frac{x}{RT}\frac{d\sigma}{dx}\left(1 + x\frac{d\ln\gamma}{dx}\right)^{-1}, \quad (7)$$

where Γ is the relative adsorption, and γ is the activity coefficient of the solute.

In [6], adsorption isotherms with a peak were obtained in a study of adsorption from aqueous solutions of aliphatic acids. In these systems, the influence exerted by nonideality of solutions was weak, which can be judged from the $\ln\gamma/dx$ values taken from this paper (Table 1). Therefore, it was of interest to compare the results obtained in processing of the experimental dependence $\sigma = f(x)$ by Eq. (3) with the results of [6].

A verification of the applicability of Eq. (3) demonstrated that the experimental dependences $\sigma = f(x)$ plotted in the coordinates of the linear form of Eq. (3), i.e., $x/\Delta\sigma = f(x)$, are straight lines with a satisfactory accuracy. The intercepts and slopes of these straight lines were used to calculate constants *A* and *B* listed in Table 1. It can be seen from Table 1 that constant *A*, which characterizes the slope of the adsorption isotherm at low concentrations, increases by, on average, a factor of 3 on passing from one homolog to another (in accordance with the Traube rule). As follows from Eq. (6), at $x > x_0$ the adsorption decreases as constant *A* becomes larger. Such a behavior was experimentally revealed in [7] in a study of adsorption of alcohols from aqueous solutions.

To illustrate the capabilities of Eq. (3), Table 2 lists the experimental [6] and calculated (from constants *A* and *B*) values of the surface tension of aqueous solutions of aliphatic acids. The specific adsorption Γ_c, calculated by Eq. (6) with a correction for the nonideality of the solutions, is given in Table 3.

As seen from Tables 3 and 4, the agreement between the results of [6] and data calculated by Eq. (6) is satisfactory at $x \le x_0$, i.e., in that concentration range in which the accuracy of numerical differentiation, used in [6] to calculate the specific adsorption Γ, is sufficiently high.

An assumption was made in [6, 13, 14] that the adsorption of butyric, valeric, and caproic acids cannot be understood in terms of the concept of monomolecular adsorption. As a criterion for monomolecular nature of the adsorption layer can serve the area S_0 occupied by a molecule in a saturated monolayer with molecules oriented perpendicularly to the surface:

$$S_0 = 1/(\Gamma_\infty N_A). \quad (8)$$

S_0 can also be calculated using the formula relating the relative adsorption Γ and the mole fraction *y* of the adsorbate in the surface layer. It was shown in [15]

Table 4. Areas S_0 calculated by formulas (8) and (9)

Acid	y	x	$\Gamma_{max} \times 10^6$, mol m^{-2}	$S_0 \times 10^{20}$, m^2	
				(8)	(9)
Acetic	0.5147	0.0321	3.570	24.5	23.2
Propionic	0.5048	0.0107	4.285	20.4	19.4
Butyric	0.5017	0.0035	4.457	19.2	18.6
Valeric	0.5004	0.0009	4.201	19.9	19.7
Caproic	0.5002	0.0004	5.280	15.8	15.7

that, if the molar surface areas of the solvent and solute are equal, the following expression is valid for the ideal solution:

$$y = S_0 N_A \Gamma + (1 - S_0 N_A \Gamma)x, \quad (9)$$

where N_A is the Avogadro number.

The results of calculation of S_0 by formulas (8) and (9) at x and y corresponding to the maximum adsorption Γ_{max}, listed in Table 4, give reason to assume that the adsorption of aliphatic acids, with the exception of caproic acid, has a monomolecular nature because, according to [16], $S_0 = 20.5 \times 10^{-20}$ m^2 for aliphatic acids.

CONCLUSIONS

(1) An isotherm equation for the relative adsorption at the liquid–gas interface for ideal solutions was derived. A distinctive feature of this equation is that it gives an adsorption isotherm with a peak. It was shown that the suggested adsorption isotherm satisfactorily describes, with account taken of the nonideality of solutions, the adsorption of aliphatic acids from aqueous solutions.

(2) The areas occupied by molecules of a number of aliphatic acids in the surface layer were calculated. For all the acids, except caproic acid, the molecular areas suggest monomolecular adsorption.

Received September 1, 2004; in final form, February 2005

Abstract—The effect of Ca^{2+}, Mg^{2+}, Fe^{3+}, and Al^{3+} ions on the deposition of electrolytic manganese dioxide from chloride solutions was studied.

In the world practice, the raw materials for production of electrolytic manganese dioxide (EMD) and electrolytic manganese metal (EMM) are rich manganese ores, which are virtually lacking in Russia. Therefore, it is of specific interest to use lean manganese ores, e.g., manganese limestones, for the production of manganese compounds. The largest deposit of manganese limestone ores is the Ulu-Telyak deposit (Bashkortostan). Manganese limestones have the following average chemical composition (wt %): Mn 9–15, SiO_2 5–10, Al_2O_3 3–5, Fe 1.2–1.5, CaO 30–40, S 0.04–0.06, P 0.02–0.04, MgO 3–5, and H_2O 1.0–1.5.

In hydrometallurgical reprocessing of lean manganese ores, as leaching agents are used mineral acids, H_2SO_4, HCl, and HNO_3. The choice of the acid is mainly determined by its cost and accessibility rather than by leaching power. For example, a large volume of a 20–25% hydrochloric acid is formed at chlorine production plants as waste, which can be utilized for ore leaching.

It should also be noted that leaching of manganese ores with hydrochloric acid has a number of advantages. For example, in leaching of manganese from limestone ores with hydrochloric acid, in contrast to sulfuric acid leaching, no sparingly soluble compounds adversely affecting the process equipment are formed. Moreover, in reprocessing of ores containing manganese in higher oxidation states, chlorine can be obtained, which is a valuable chemical raw material.

At the same time, in hydroelectrometallurgical reprocessing of manganese ores, there is also a number of problems, first of all, the problem of purification of leaching solutions to remove undesirable impurities. As a rule, the processing solutions of hydrochloric acid leaching contain, apart from $MnCl_2$, also $CaCl_2$, $MgCl_2$, $FeCl_3$, and $AlCl_3$ as main impurities. Prior to use for the electrolysis, they should be treated to remove the impurities that adversely affect the electrolysis and the composition and properties of the products. A common treatment method is the hydrolytic purification [1], which allows the content of readily hydrolyzable compounds, Fe^{3+} and Al^{3+} chlorides, to be decreased to the acceptable value. However, presumably, these compounds would not adversely affect the electrodeposition of MnO_2 and its properties.

Therefore, it was of practical significance to study the effect exerted by calcium, magnesium, aluminum, and iron ions on the composition of electrolytic manganese dioxide and the electrolysis parameters.

EXPERIMENTAL

The electrolysis was performed in an electrolyzer with parallel-plate Plexiglas electrodes. A VT-1-00 titanium was anode and NKh18N10T stainless steel, a cathode. The electrodes were polarized with a stabilized B5-47 current source. The electrode potentials were measured relative to a silver chloride reference electrode.

The change in the acidity of the electrolyte solutions before and after the electrolysis was determined with a portable microprocessor HI-9025 pH/mV/°C meter (Portugal).

The experiments were performed at 75°C and a current density of 5 mA cm^{-2}.

$FeCl_3$:							
0.05	0.35	0.13	64	8.0	2.82	1.84	1.33
0.25	0.08	0.02	Solution after electrolysis is turbid. Breakdown of anode surface. Voltage across the electrolyzer increased from 2.43 to 6 V.				

The time of all the experiments was 60 min. Under the given conditions, the current efficiency was 95–97% and the degree of manganese electrodeposition, 18–20%. To retain the relatively constant composition of the components in the electrolytes, the process was not performed to greater extents of manganese electrodeposition. The electrolytes were prepared from chemically pure and analytically pure grade chemicals.

The product obtained was analyzed for the content of MnO_2 and of calcium, magnesium, iron, and aluminum impurity ions. The manganese content was determined by Volhard's method [2]. The microimpurities of calcium, magnesium, aluminum, and iron ions were determined by emission spectroscopy on an ISP-30 spectrometer. The apparent density was determined by the volumetric-gravimetric method [3].

In Ca^{2+}-containing electrolytes, the current efficiency (CE) is 75–93%, and it decreases with growing Ca^{2+} concentration (see table). As the concentration of the calcium ions in the electrolyte increases, the voltage across the electrolyzer and the anode potentials increase. For example, in the electrolyte containing 0.05 M Ca^{2+}, the voltage across the electrolyzer is 2.6 V, whereas in that containing 1 M Ca^{2+} it is 3.2 V.

In the course of the electrolysis, the anode potential first decreases and then increases, whereas the cathode potential always decreases (Fig. 1a).

Irrespective of the Ca^{2+} concentration in the electrolyte, MnO_2 is deposited onto the anode in the form of a black lustrous flaky film easily exfoliating from the electrode. The weight fraction of MnO_2 in the product obtained was 99.7% and the calcium concentration, less than 0.01%.

In magnesium-containing electrolytes, the current efficiency was 90–95% (see table). The behavior of the anode and the cathode potentials and of the voltage across the electrolyzer was similar to that in calcium-containing electrolytes (Fig. 1b), with the anode potential and voltage across the electrolyzer being somewhat lower. For example, the voltage across the electrolyzer was 2.4 and 2.85 V at 0.05 and 1 M Mg.

At any concentration of Mg^{2+} in the electrolyte, MnO_2 was deposited onto the anode in the form of a black flaky film easily exfoliating from the surface. The deposited film contained 99.7% MnO_2 and no more than 0.01% magnesium.

When the electrolysis was performed in the presence of aluminum ions, the current efficiency was 75–80%, and it decreased as the Al^{3+} concentration was increased (see table). For example, at an Al^{3+} concentration of 0.05 M, the current efficiency was 80% and at 0.25 M, 75%. In an electrolyte containing 1 M Al^{3+}, the anode was damaged and the electrolyte became turbid.

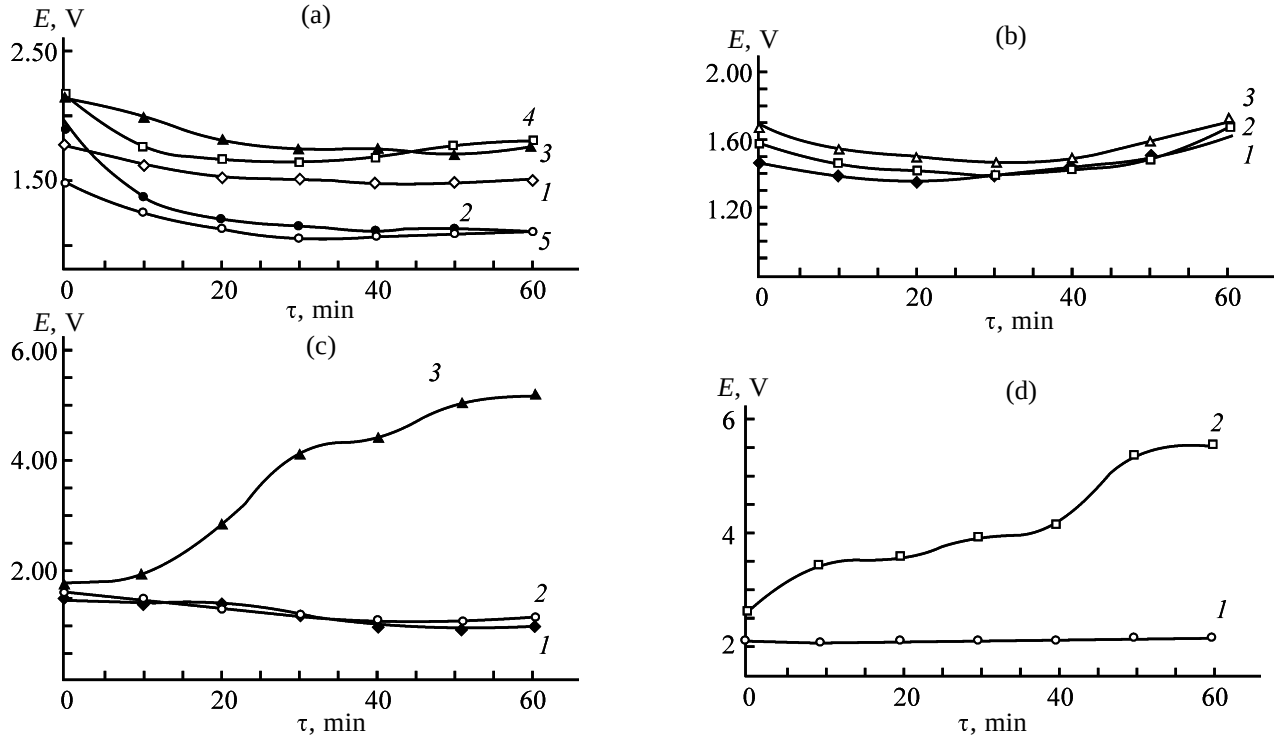

Fig. 1. Influence of the concentrations of (a) Ca^{2+}, (b) Mg^{2+}, (c) Al^{3+}, and (d) Fe^{3+} ions on variations of the anode potential E with time τ. Electrolyte (M): 1.0 $MnCl_2$ and 0.05 HCl. (a) $CaCl_2$ concentration (M): (*1*) 0.05, (*2*) 0.25, (*3*) 1.0, (*4*) 2.0, and (*5*) 0.0. (b) $MgCl_2$ concentration (M): (*1*) 0.05, (*2*) 0.25, and (*3*) 1.0. (c) $AlCl_3$ concentration (M): (*1*) 0.05, (*2*) 0.25, and (*3*) 1.0. (d) $FeCl_3$ concentration (M): (*1*) 0.05 and (*2*) 0.25.

In electrolytes with a low concentration of Al^{3+} ions (0.05 M), variations of the anode potential and voltage across the electrolyzer in the course of the electrolysis were similar to those in the Ca^{2+}- and Mg^{2+}-containing electrolytes. With the Al^{3+} concentration increased from 0.25 to 1 M, the anode potential (Fig. 1c) and voltage across the electrolyzer increased.

The manganese dioxide film deposited onto the anode was dense and difficult-to-detach from the surface. The film contained 99.5 wt % MnO_2 and no more than 0.03 wt % aluminum.

In the electrolytes containing Fe^{3+}, the current efficiency by MnO_2 was only 64% even at small iron concentrations (0.05 M Fe^{3+}) (see table). With increasing iron concentration, the voltage across the electrolyzer and the anode potential sharply increased (Fig. 1d).

The electrolyte containing 0.25 M $FeCl_3$ became turbid after the electrolysis. In the course of the electrolysis, the damage of the anode was observed, with its small areas coated with a fine MnO_2 deposit.

Manganese dioxide was deposited onto the anode as a dense dull black film difficult-to-detach from the surface. The deposited film contained 99 wt % MnO_2 and no more than 0.03–0.1 wt % iron.

The electrolysis of chloride solutions yields manganese tetrachloride, which hydrolyzes to form manganese dioxide [4, 5]:

$$MnCl_4 + 2H_2O \rightarrow MnO_2\downarrow + 4HCl. \quad (1)$$

The study showed that the effects exerted by calcium, magnesium, iron, and aluminum salts on the electrolysis of manganese chloride solutions differ essentially. The Ca^{2+} and Mg^{2+} ions do not noticeably affect the voltage across the electrolyzer, current efficiency, and chemical composition of MnO_2. On the contrary, the Fe^{3+} and Al^{3+} ions exert a very strong effect on both the electrolysis parameters and the chemical composition of the forming products. Probably, this is due to their different acid–base properties.

The Al^{3+} and Fe^{3+} ions are strong Lewis acids. In acid solutions, they form metallic acids:

$$FeCl_3 + HCl \rightarrow HFeCl_4, \quad (2)$$

$$AlCl_3 + HCl \rightarrow HAlCl_4. \quad (3)$$

Therefore, in electrolyte solutions they compete with Mn^{4+} ions for chloride ions. The binding of chloride ions with Al^{3+} and Fe^{3+} ions can accelerate the $MnCl_4$ hydrolysis. Therefore, MnO_2 is formed both in the bulk of the solution and on the anode surface, forming strong films with a poorly developed crystal structure.

The fact that CE considerably decreases in the presence of Fe^{3+} ions can be accounted for as follows. The iron ions in electrolytes are reduced on the cathode and oxidized on the anode in the course of electrolysis [6]. This results, on the one hand, in a decrease in the current efficiency of the MnO_2 electrodeposition owing to Fe^{2+} oxidation on the anode and, on the other hand, in a decrease in the Mn^{4+} concentration owing to the redox reactions

$$Fe^{2+} + Mn^{4+} \rightarrow Mn^{3+} + Fe^{3+}, \quad (4)$$

$$2Fe^{2+} + Mn^{4+} \rightarrow Mn^{2+} + 2Fe^{3+}. \quad (5)$$

A fast increase in the anode potential and, consequently, in the voltage across the electrolyzer may be due to formation on the anode of a dense passivation film with a low electrical conductivity. On the damaged areas of this film, the current densities increase, which results in the damage of the anodes by electroerosion.

Continuous electrolysis of electrolytes containing calcium and magnesium compounds will result in the formation of spent electrolytes with relatively high concentrations of Ca^{2+} and Mg^{2+} ions and hydrochloric acid. The results of this study showed that spent electrolytes can be used for leaching manganese compounds. In the process, a part of Ca^{2+} and Mg^{2+} ions passes into the leaching sludge by an ion-exchange reaction. The leaching of manganese compounds from ores with calcium chloride solutions has been described in [7, 8]. Moreover, the concentration of calcium ions in the spent electrolyte can be decreased to a required value by adding sulfuric acid. Calcium sulfate formed in the process can be used in building industry.

Thus, our results show that electrolytic MnO_2 with a low concentration of impurities can be prepared directly from processing solutions of hydrochloric acid leaching of manganese ores without their exhaustive purification.

CONCLUSION

Calcium and magnesium ions do not affect adversely the electrolysis of manganese chloride electrolytes and the quality of manganese dioxide being formed. The presence of iron and aluminum ions in the electrolyte solutions markedly deteriorates electrolysis process and the quality of the MnO_2 deposit.

Abstract—The temperature–concentration dependence of the conductivity in glasses of the system Li_2O–P_2O_5 was studied. The content of extrinsic hydrogen in the structure of glasses was estimated by IR transmission spectra. The effect of hydrogen on the electrical properties and structure of the glasses studied was considered.

A large interest in the development of chemical power sources (CPSs) with a high specific energy is accompanied by active search for substances with a high conductivity. This is apparently responsible for researchers' interest in interrelations between physicochemical (especially electrical) properties and structures of model glasses such as M_2O–P_2O_5 (M = Li, Na,). Particular attention is given to glasses of the system Li_2O–P_2O_5 [1–10], allowing development of CPSs with a solid electrolyte (SEL), exhibiting unipolar conductance caused by migration of lithium ions. Furthermore, lithium glasses are promising materials for studying the effect of the ratio Li_2O/P_2O_5 = *R* on their structure and physicochemical properties [9]. Metaphosphate structural units (SUs) are formed in the glass at *R* = 1. These units consist of oxygen tetrahedra $[PO_4]$ connected in chains by bridging oxygen atoms. In this case, the following SUs can be distinquished [9]:

(1) "single" $[PO_4]^{3-}$ group sharing three oxygen atoms with adjacent $[PO_4]$ groups, thus forming "branching points" (B);

(2) "middle" $[PO_4]^{-}$ group sharing two oxygen atoms with adjacent $[PO_4]$ groups (M);

(3) "terminal" $[PO_4]^{2-}$ group sharing one oxygen atom with an adjacent $[PO_4]$ group, with two negative charges localized on two oxygen atoms (T).

Reactions of the following type proceed in phosphate melts [9]:

$$2MPO_3(M) \leftrightarrows PO_{2.5}(B) + MPO_{3.5}(T).$$

These reactions were studied later for seven binary mixtures, and it was shown that the equilibrium constant is virtually independent of the rate of cooling the melt when synthesizing the glasses [11]. These data suggest that the structure of the anionic matrix of the glasses being prepared is maximally close to the structure of the equilibrium melt at a preset temperature of the synthesis and depends only on the $[M_2O]/[P_2O_5]$ ratio. Compared to glasses of the systems M_2O–P_2O_5 (M = Na, K), in the lithium system the number of branchings is larger, and their concentration is less dependent on *R*.

At *R* > 1, the number of terminal oxygen atoms grows. The length of phosphate chains decreases, which results in increasing SU mobility. The number of pyro- and orthophosphate groups in the structure of glasses increases. An attempt to estimate quantitatively how the degree of polymerization of phosphate SUs forming the glass anionic matrix depends on *R* was undertaken in [12]. The results obtained confirm the assumed gradual depolymerization of the glass anionic matrix and formation of shorter-chain SUs [6].

To obtain high specific characteristics of a chemical power source, the electrolyte should have a minimal resistance. One way to increase SEL conductivity is to increase the concentration of lithium ions, which are current carriers in glasses of the Li_2O–P_2O_5 system. Another way for increasing the conductivity can be modification of the glass anionic matrix with the aim of decreasing the tightness of fixation of current-carrying ions in the structure. It will increase the degree of dissociation of polar structural chemical units (SCUs). According to [13], a three-dimensional network of a binary glass, e.g., Li_2O–P_2O_5, can be presented as a combination of polar $Li^+O^-PO_{3/2}$ $\begin{bmatrix} O_{3/2}P–O^-Li^+ \\ H^+O^–PO_{3/2} \end{bmatrix}$, $[O_{3/2}P–O^-Li^+]$, $[O_{2/2}P–O^-H^+]$ and nonpolar ($PO_{4/2}$) SCUs. At $[Li^+] < 8 \times 10^{-3}$ mol cm^{-3} ($R \cong 0.15$), polar SCUs are separated from each other by a nonpolar medium. When polar

1070-4272/05/7805-0741 © 2005 Pleiades Publishing, Inc.

SCUs dissociate, lithium ions should come out into the nonpolar medium and migrate in it. An increase in the concentration of lithium ions ($R > 1$) results in decreasing length of phosphate chains, as it was mentioned above, whereas polar SCUs form tie chains threading the entire glass volume. In this case ($[Li^+] < 8 \times 10$ mol cm^{-3}), polar SCUs dissociate much more easily, and dissociated lithium ions migrate in the medium of polar SCUs [6, 13]. The conductivity itself sharply increases owing to a decrease in the activation energy of conductivity [4].

In view of the aforesaid, it seemed appropriate to study glasses of the system Li_2O–P_2O_5 with the aim to obtain more specific information on the nature of current carriers and on the effect of anionic matrix on the electric current transport.

EXPERIMENTAL

Glasses were synthesized in crucibles made from SU-2000 carbon glass under dry argon. We used chemically pure grade Li_2CO_3 and H_3PO_4 as starting reagents. To study the effect of synthesis conditions on the physicochemical properties, the charge was prepared by two techniques. In the first case, the mixture of the components was heated in steps up to the temperature of glass founding. The charge was prepared by the sol–gel method. Lithium carbonate was mixed with orthophosphoric acid, and the resulting solution was evaporated to form a highly homogeneous charge.

In the second case, the charge was prepared from lithium oxide and metaphosphate preliminarily calcined to constant weight under dry argon.

In both cases, the glass melt was kept at 800–850°C for approximately 30 min. This time ensured good reproducibility and was sufficient for complete fusion of the glass. Samples of glasses were obtained by casting the melt on a steel plate, which was followed by annealing for 1 h in a muffle oven at temperatures lower than T_g by 10–15°C and cooling with the oven. Annealed samples were ground and polished to a thickness of 1.50 ± 0.01 mm and stored in a desiccator.

In view of the data of [10, 11], the structure of the anionic component of the resulting glasses can be considered as maximally approaching that of the equilibrium melt at the synthesis temperature.

The density of the glasses was determined by hydrostatic weighing in toluene. The reproducibility of the data obtained was no worse than ± 0.01 g cm^{-3}. The IR absorption spectra were recorded on a Perkin–Elmer 156 instrument. A weighed glass sample (~10 mg) was preliminarily crushed in an agate mortar to a dispersity of about 0.1 mm, and then it was transferred into a vibration mill and treated for 3 min. A weighed portion (~3 mg) of the resulting powder with a grain size of 5–40 μm was mixed with a weighed portion of KBr (~700 mg) in a vibration mill for 3 min, after which the mixture was pressed in pellets. The water content in the glasses were monitored by comparing their transmission spectra (1600–4000 cm^{-1}) with the spectra of samples prepared by as Nujol mulls.

The estimation of the electronic conduction component (Liang–Wagner polarization procedure [14]) showed that the contribution of the electronic component to the overall conductivity does not exceed 10^{-2}% (sensitivity of the procedure). The stationary conductivity was studied on direct current using active electrodes [4, 6]. The voltage applied to the samples ensured implementation of Ohm's law (electric field strength less than 10 kV cm^{-1}), which is a particular case of the general dependence between the current strength and voltage. The measurement was carried out in the temperature range from room temperature to temperatures lower than T_g by 15–20°C, using an ED-05M electrodynamic dc amplifier. The voltage was taken from a B5-49 stabilized dc source or a PI-50-1.1 potentiostat. To eliminate the surface conduction arising from the interaction of samples with the environment, the measurements were carried out using protective electrodes according to GOST (State Standard) 6433.2–71. The relative measurement error was 5–7%. Within the entire temperature range, a linear dependence $\log\sigma = f(1/T)$ was observed. The measurement of the conductivity in the heating and cooling modes showed the absence of hysteresis. The activation energy of conductivity E_σ was calculated by the equation

$$\sigma = \sigma_0 \exp[-E_\sigma/(2kT)].$$

The results of studying the temperature–concentration dependence of the conductivity are given in Table 1. The concentration dependence of the conductivity and the activation energy of conductivity of glasses of the system Li_2O–P_2O_5, obtained in this study, are compared with the published data [1, 4, 7] in Fig. 1. It is seen that an increase in the volume concentration of lithium ions from 2.12×10^{-2} to 3.08×10^{-2} mol cm^{-3} (from 30 to 58 mol % Li_2O) is accompanied by the growth of the conductivity by approximately four orders of magnitude (at 25°C). In

* Data of [4].

this case, the activation energy of the conductivity decreases from 1.65 to 1.12 eV, the density of the glasses under study increases, and their molar volume decreases (Table 2). The results obtained agree well with the data of [4, 7] on the conductivity of glasses of the system Li_2O–P_2O_5 for the molar ratio $[Li_2O]/[P_2O_5]$ from 0.7 to 1.22.

It was shown that an increase in the content of lithium oxide is accompanied by a linear increase in the conductivity. The fulfillment of Faraday's laws in glasses of this system was studied by Pronkin *et al*. [4]. They found that 99.1% of lithium was precipitated on the cathode in the electrolysis of the glass $0.425Li_2O$–$0.45P_2O_5$. Plyshevskii *et al*. [15] studied the removal of water from bulk phosphate glasses by a thermal method and showed that it was impossible to remove water completely from the glass by this technique. The content of hydrogen ("water") in lithium metaphosphate was qualitatively estimated in [16] (Table 3). It is evident from these data that, although the content of residual water is reduced as the temperature and the duration of the synthesis increase, it remains quite measurable, which should essentially affect the physicochemical and especially electrical properties of glasses. On this basis, Pronkin *et al*. [4] assumed that protons take part in the current transport in glasses of the system Li_2O–P_2O_5 along with lithium ions, with the contribution of protons to current transport decreasing as the Li_2O content increases. The participation of OH^- groups and hydrated protons (H_3O^+) in the current transport is improbable.

It is seen from the above data that a noticeable difference in the electrical properties of glasses is ob-

* Bubbling of dry oxygen through the melt.

served at the concentrations of lithium oxide less than 50 mol % ($R < 1$), whereas at $R \geq 1$ they are rather constant. This fact seems to be caused by the presence of appreciable amounts of extrinsic hydrogen in the structure of the glasses under study, the content of which depends on their composition and synthesis conditions.

According to Van Wazer [9], the structure of phosphoric anhydride is formed by $[PO_{4/2}]$ tetrahedra linked to each other in infinite chains by bridging oxygen ions. The introduction of lithium oxide into P_2O_5 is accompanied by depolymerization of polyphosphate chains. Thus, according to the ^{31}P NMR data, as the content of lithium in glasses of the $Li_2O–P_2O_5$ system increases, the mean length of polyphosphate ions decreases from 22 (for the glass $0.5Li_2O–0.5P_2O_5$) to 7 units (for the glass $0.55Li_2O–0.45P_2O_5$) [17]. Thus, the introduction of lithium oxide in P_2O_5 is accompanied by cleavage of bridging P–O–P bonds according to the scheme

$$O_{3/2}P–O–PO_{3/2} + Li_2O \rightarrow 2[Li^+O^- – PO_{3/2}].$$

As mentioned above, Plyshevskii *et al*. [15] believe that it is impossible to remove hydrogen completely from the glass structure by thermal methods. This seems to be due to different positions of hydrogen in the structure of glasses. Water can be removed virtually completely from the glass only by chemical methods [4]. Therefore, the fact that the hydrogen content in the structure of glasses of the system $Li_2O–P_2O_5$ decreases as the concentration of lithium oxide increases is attributable to the substitution of lithium ions for hydrogen in the glass structure according to the scheme

$$2[O_{3/2}P–O^-H^+] + Li_2O \rightarrow [O_{3/2}P–O^-Li^+] + H_2O\uparrow.$$

Thus, according to [13], the structure of glasses of the system $Li_2O–P_2O_5$ can be presented as a combination of polar $\begin{bmatrix} O_{3/2}P–O^-Li^+ \\ H^+O^–PO_{3/2} \end{bmatrix}$, $[O_{3/2}P–O^-Li^+]$, $[O_{2/2}P–O^-H^+]$ and nonpolar $[PO_{4/2}]$ SCUs.

The dissociation energy of lithium SCGUs $O_{3/2}P–O^-Li^+$ is lower than that of mixed quadrupoles; $Li^+O^–PO_4$ therefore, the amount of current-carrying lithium ions and the conductivity of the glasses increase. At $R < 1$, the structure of the glasses is mainly determined by a combination of $[O_{3/2}P–O^-Li^+]$, $\begin{bmatrix} O_{3/2}P–O^-Li^+ \\ H^+O^–PO_{3/2} \end{bmatrix}$, and $[PO_{4/2}]$ SCUs. The structure of lithium metaphosphate ($R = 1$) consists mainly of polar SCUs $[O_{3/2}P–O^-Li^+]$ and of a small amount of $\begin{bmatrix} O_{3/2}P–O^-Li^+ \\ Li^+O^–PO_{3/2} \end{bmatrix}$ and $\begin{bmatrix} O_{3/2}P–O^-Li^+ \\ H^+O^–PO_{3/2} \end{bmatrix}$ SCUs. In this case, the concentration of quadrupoles $\begin{bmatrix} O_{3/2}P–O^-Li^+ \\ H^+O^–PO_{3/2} \end{bmatrix}$ decreases as the Li_2O content increases. At $R > 1$, only polar SCUs are formed in the structure of glasses, and the concentration of lithium quadrupoles increases as the concentration of lithium oxide increases.

Changes occurring in the structure of the glasses are proved by IR spectra, which correlate with the results of an IR study of glasses of the system $Li_2O–P_2O_5$ [7, 10, 12]. Broad bands with maxima near 3300 and 2600 cm^{-1} are observed in the IR transmission spectra in the region of vibrations of hydroxy groups. Their intensity increases as the content of lithium oxide decreases in glasses of both series examined in this study. However, in samples prepared by the first procedure, the relative content of water was somewhat less than in samples prepared by the second procedure. The IR absorption spectra of the samples prepared by the first procedure are given in Fig. 2. It is seen that the absorption in the range 910–1160 cm^{-1} changes essentially as the Li_2O content increases. The intensity of bands in the range 1050–1160 cm^{-1} in-

creases, which seems to be due to the appearance of pyrophosphate groups [$\nu_{as}(PO_3)$]. At the same time, the intensity of the band at 1270 cm^{-1} [$\nu_{as}(PO_2)$] slightly decreases, and also the intensity of the band of bending vibrations (~500 cm^{-1}) decreases. Thus, as the content of Li_2O increases from 40 to 50 mol %, the position and shape of a number of bands change slightly, suggesting the preservation of the main metaphosphate motif of the glass. A sharp decrease in the intensity of the $\nu_{as}(PO_2)$ band and an increase in the intensity of $\nu_{as}(PO_3)$ are observed in the glass with 55 mol % Li_2O, which is due to increasing content of pyro- and orthophosphate groups and agrees well with the NMR data for the glasses of this system [17].

These conclusions are supported by the data on the density of the glasses: as the content of Li_2O increases, the density of the glasses increases (Table 2), which is attributable to more compact packing of the newly formed short-chain SCUs. Simultaneously the molar volume decreases (Table 2).

The effect of synthesis conditions on the electrical properties of glasses is illustrated by Table 4, in which the data of several authors on the conductance of lithium metaphosphate are compared. The observed discrepancy seems to be due to different techniques of the charge preparation and different thermal conditions of glass founding, as these factors determine the content of residual water in the glass structure, which noticeably affects the electrical properties of the glasses.

CONCLUSION

The temperature–concentration dependence of the conductivity in glasses of the system Li_2O–P_2O_5 was interpreted in terms of the structure-chemical microheterogeneity of the glass structure: in the region of low Li_2O concentrations, extrinsic hydrogen forms mixed quadrupoles $\begin{bmatrix} O_{3/2}P–O^-Li^+ \\ H^+O^–PO_{3/2} \end{bmatrix}$, retaining lithium ions more strongly than do homogeneous quadrupoles $\begin{bmatrix} O_{3/2}P–O^-Li^+ \\ Li^+O^–PO_{3/2} \end{bmatrix}$, and thus eliminating these ions from the electricity transfer. As the con-

centration of lithium oxide increases, the amount of extrinsic hydrogen decreases, which is accompanied by an increase in the conductance due to an increase in the concentration of current carriers and to a change of the mechanism of their migration.

Abstract—The temperature–concentration dependence of the conductivity in glasses of the system Li_2O–P_2O_5 was studied. The content of extrinsic hydrogen in the structure of glasses was estimated by IR transmission spectra. The effect of hydrogen on the electrical properties and structure of the glasses studied was considered.

A large interest in the development of chemical power sources (CPSs) with a high specific energy is accompanied by active search for substances with a high conductivity. This is apparently responsible for researchers' interest in interrelations between physicochemical (especially electrical) properties and structures of model glasses such as M_2O–P_2O_5 (M = Li, Na,). Particular attention is given to glasses of the system Li_2O–P_2O_5 [1–10], allowing development of CPSs with a solid electrolyte (SEL), exhibiting unipolar conductance caused by migration of lithium ions. Furthermore, lithium glasses are promising materials for studying the effect of the ratio Li_2O/P_2O_5 = *R* on their structure and physicochemical properties [9]. Metaphosphate structural units (SUs) are formed in the glass at *R* = 1. These units consist of oxygen tetrahedra $[PO_4]$ connected in chains by bridging oxygen atoms. In this case, the following SUs can be distinquished [9]:

(1) "single" $[PO_4]^{3-}$ group sharing three oxygen atoms with adjacent $[PO_4]$ groups, thus forming "branching points" (B);

(2) "middle" $[PO_4]^{-}$ group sharing two oxygen atoms with adjacent $[PO_4]$ groups (M);

(3) "terminal" $[PO_4]^{2-}$ group sharing one oxygen atom with an adjacent $[PO_4]$ group, with two negative charges localized on two oxygen atoms (T).

Reactions of the following type proceed in phosphate melts [9]:

$$2MPO_3(M) \leftrightarrows PO_{2.5}(B) + MPO_{3.5}(T).$$

These reactions were studied later for seven binary mixtures, and it was shown that the equilibrium constant is virtually independent of the rate of cooling the melt when synthesizing the glasses [11]. These data suggest that the structure of the anionic matrix of the glasses being prepared is maximally close to the structure of the equilibrium melt at a preset temperature of the synthesis and depends only on the $[M_2O]/[P_2O_5]$ ratio. Compared to glasses of the systems M_2O–P_2O_5 (M = Na, K), in the lithium system the number of branchings is larger, and their concentration is less dependent on *R*.

At *R* > 1, the number of terminal oxygen atoms grows. The length of phosphate chains decreases, which results in increasing SU mobility. The number of pyro- and orthophosphate groups in the structure of glasses increases. An attempt to estimate quantitatively how the degree of polymerization of phosphate SUs forming the glass anionic matrix depends on *R* was undertaken in [12]. The results obtained confirm the assumed gradual depolymerization of the glass anionic matrix and formation of shorter-chain SUs [6].

To obtain high specific characteristics of a chemical power source, the electrolyte should have a minimal resistance. One way to increase SEL conductivity is to increase the concentration of lithium ions, which are current carriers in glasses of the Li_2O–P_2O_5 system. Another way for increasing the conductivity can be modification of the glass anionic matrix with the aim of decreasing the tightness of fixation of current-carrying ions in the structure. It will increase the degree of dissociation of polar structural chemical units (SCUs). According to [13], a three-dimensional network of a binary glass, e.g., Li_2O–P_2O_5, can be presented as a combination of polar $Li^+O^-PO_{3/2}$ $\begin{bmatrix} O_{3/2}P–O^-Li^+ \\ H^+O^–PO_{3/2} \end{bmatrix}$, $[O_{3/2}P–O^-Li^+]$, $[O_{2/2}P–O^-H^+]$ and nonpolar ($PO_{4/2}$) SCUs. At $[Li^+] < 8 \times 10^{-3}$ mol cm^{-3} ($R \cong 0.15$), polar SCUs are separated from each other by a nonpolar medium. When polar

1070-4272/05/7805-0741 © 2005 Pleiades Publishing, Inc.

SCUs dissociate, lithium ions should come out into the nonpolar medium and migrate in it. An increase in the concentration of lithium ions ($R > 1$) results in decreasing length of phosphate chains, as it was mentioned above, whereas polar SCUs form tie chains threading the entire glass volume. In this case ($[Li^+] < 8 \times 10$ mol cm^{-3}), polar SCUs dissociate much more easily, and dissociated lithium ions migrate in the medium of polar SCUs [6, 13]. The conductivity itself sharply increases owing to a decrease in the activation energy of conductivity [4].

In view of the aforesaid, it seemed appropriate to study glasses of the system Li_2O–P_2O_5 with the aim to obtain more specific information on the nature of current carriers and on the effect of anionic matrix on the electric current transport.

EXPERIMENTAL

Glasses were synthesized in crucibles made from SU-2000 carbon glass under dry argon. We used chemically pure grade Li_2CO_3 and H_3PO_4 as starting reagents. To study the effect of synthesis conditions on the physicochemical properties, the charge was prepared by two techniques. In the first case, the mixture of the components was heated in steps up to the temperature of glass founding. The charge was prepared by the sol–gel method. Lithium carbonate was mixed with orthophosphoric acid, and the resulting solution was evaporated to form a highly homogeneous charge.

In the second case, the charge was prepared from lithium oxide and metaphosphate preliminarily calcined to constant weight under dry argon.

In both cases, the glass melt was kept at 800–850°C for approximately 30 min. This time ensured good reproducibility and was sufficient for complete fusion of the glass. Samples of glasses were obtained by casting the melt on a steel plate, which was followed by annealing for 1 h in a muffle oven at temperatures lower than T_g by 10–15°C and cooling with the oven. Annealed samples were ground and polished to a thickness of 1.50 ± 0.01 mm and stored in a desiccator.

In view of the data of [10, 11], the structure of the anionic component of the resulting glasses can be considered as maximally approaching that of the equilibrium melt at the synthesis temperature.

The density of the glasses was determined by hydrostatic weighing in toluene. The reproducibility of the data obtained was no worse than ± 0.01 g cm^{-3}. The IR absorption spectra were recorded on a Perkin–Elmer 156 instrument. A weighed glass sample (~10 mg) was preliminarily crushed in an agate mortar to a dispersity of about 0.1 mm, and then it was transferred into a vibration mill and treated for 3 min. A weighed portion (~3 mg) of the resulting powder with a grain size of 5–40 μm was mixed with a weighed portion of KBr (~700 mg) in a vibration mill for 3 min, after which the mixture was pressed in pellets. The water content in the glasses were monitored by comparing their transmission spectra (1600–4000 cm^{-1}) with the spectra of samples prepared by as Nujol mulls.

The estimation of the electronic conduction component (Liang–Wagner polarization procedure [14]) showed that the contribution of the electronic component to the overall conductivity does not exceed 10^{-2}% (sensitivity of the procedure). The stationary conductivity was studied on direct current using active electrodes [4, 6]. The voltage applied to the samples ensured implementation of Ohm's law (electric field strength less than 10 kV cm^{-1}), which is a particular case of the general dependence between the current strength and voltage. The measurement was carried out in the temperature range from room temperature to temperatures lower than T_g by 15–20°C, using an ED-05M electrodynamic dc amplifier. The voltage was taken from a B5-49 stabilized dc source or a PI-50-1.1 potentiostat. To eliminate the surface conduction arising from the interaction of samples with the environment, the measurements were carried out using protective electrodes according to GOST (State Standard) 6433.2–71. The relative measurement error was 5–7%. Within the entire temperature range, a linear dependence $\log\sigma = f(1/T)$ was observed. The measurement of the conductivity in the heating and cooling modes showed the absence of hysteresis. The activation energy of conductivity E_σ was calculated by the equation

$$\sigma = \sigma_0 \exp[-E_\sigma/(2kT)].$$

The results of studying the temperature–concentration dependence of the conductivity are given in Table 1. The concentration dependence of the conductivity and the activation energy of conductivity of glasses of the system Li_2O–P_2O_5, obtained in this study, are compared with the published data [1, 4, 7] in Fig. 1. It is seen that an increase in the volume concentration of lithium ions from 2.12×10^{-2} to 3.08×10^{-2} mol cm^{-3} (from 30 to 58 mol % Li_2O) is accompanied by the growth of the conductivity by approximately four orders of magnitude (at 25°C). In

* Data of [4].

this case, the activation energy of the conductivity decreases from 1.65 to 1.12 eV, the density of the glasses under study increases, and their molar volume decreases (Table 2). The results obtained agree well with the data of [4, 7] on the conductivity of glasses of the system Li_2O–P_2O_5 for the molar ratio $[Li_2O]/[P_2O_5]$ from 0.7 to 1.22.

It was shown that an increase in the content of lithium oxide is accompanied by a linear increase in the conductivity. The fulfillment of Faraday's laws in glasses of this system was studied by Pronkin *et al*. [4]. They found that 99.1% of lithium was precipitated on the cathode in the electrolysis of the glass $0.425Li_2O$–$0.45P_2O_5$. Plyshevskii *et al*. [15] studied the removal of water from bulk phosphate glasses by a thermal method and showed that it was impossible to remove water completely from the glass by this technique. The content of hydrogen ("water") in lithium metaphosphate was qualitatively estimated in [16] (Table 3). It is evident from these data that, although the content of residual water is reduced as the temperature and the duration of the synthesis increase, it remains quite measurable, which should essentially affect the physicochemical and especially electrical properties of glasses. On this basis, Pronkin *et al*. [4] assumed that protons take part in the current transport in glasses of the system Li_2O–P_2O_5 along with lithium ions, with the contribution of protons to current transport decreasing as the Li_2O content increases. The participation of OH^- groups and hydrated protons (H_3O^+) in the current transport is improbable.

It is seen from the above data that a noticeable difference in the electrical properties of glasses is ob-

* Bubbling of dry oxygen through the melt.

served at the concentrations of lithium oxide less than 50 mol % ($R < 1$), whereas at $R \geq 1$ they are rather constant. This fact seems to be caused by the presence of appreciable amounts of extrinsic hydrogen in the structure of the glasses under study, the content of which depends on their composition and synthesis conditions.

According to Van Wazer [9], the structure of phosphoric anhydride is formed by $[PO_{4/2}]$ tetrahedra linked to each other in infinite chains by bridging oxygen ions. The introduction of lithium oxide into P_2O_5 is accompanied by depolymerization of polyphosphate chains. Thus, according to the ^{31}P NMR data, as the content of lithium in glasses of the $Li_2O–P_2O_5$ system increases, the mean length of polyphosphate ions decreases from 22 (for the glass $0.5Li_2O–0.5P_2O_5$) to 7 units (for the glass $0.55Li_2O–0.45P_2O_5$) [17]. Thus, the introduction of lithium oxide in P_2O_5 is accompanied by cleavage of bridging P–O–P bonds according to the scheme

$$O_{3/2}P–O–PO_{3/2} + Li_2O \rightarrow 2[Li^+O^- – PO_{3/2}].$$

As mentioned above, Plyshevskii *et al*. [15] believe that it is impossible to remove hydrogen completely from the glass structure by thermal methods. This seems to be due to different positions of hydrogen in the structure of glasses. Water can be removed virtually completely from the glass only by chemical methods [4]. Therefore, the fact that the hydrogen content in the structure of glasses of the system $Li_2O–P_2O_5$ decreases as the concentration of lithium oxide increases is attributable to the substitution of lithium ions for hydrogen in the glass structure according to the scheme

$$2[O_{3/2}P–O^-H^+] + Li_2O \rightarrow [O_{3/2}P–O^-Li^+] + H_2O\uparrow.$$

Thus, according to [13], the structure of glasses of the system $Li_2O–P_2O_5$ can be presented as a combination of polar $\begin{bmatrix} O_{3/2}P–O^-Li^+ \\ H^+O^–PO_{3/2} \end{bmatrix}$, $[O_{3/2}P–O^-Li^+]$, $[O_{2/2}P–O^-H^+]$ and nonpolar $[PO_{4/2}]$ SCUs.

The dissociation energy of lithium SCGUs $O_{3/2}P–O^-Li^+$ is lower than that of mixed quadrupoles; $Li^+O^–PO_4$ therefore, the amount of current-carrying lithium ions and the conductivity of the glasses increase. At $R < 1$, the structure of the glasses is mainly determined by a combination of $[O_{3/2}P–O^-Li^+]$, $\begin{bmatrix} O_{3/2}P–O^-Li^+ \\ H^+O^–PO_{3/2} \end{bmatrix}$, and $[PO_{4/2}]$ SCUs. The structure of lithium metaphosphate ($R = 1$) consists mainly of polar SCUs $[O_{3/2}P–O^-Li^+]$ and of a small amount of $\begin{bmatrix} O_{3/2}P–O^-Li^+ \\ Li^+O^–PO_{3/2} \end{bmatrix}$ and $\begin{bmatrix} O_{3/2}P–O^-Li^+ \\ H^+O^–PO_{3/2} \end{bmatrix}$ SCUs. In this case, the concentration of quadrupoles $\begin{bmatrix} O_{3/2}P–O^-Li^+ \\ H^+O^–PO_{3/2} \end{bmatrix}$ decreases as the Li_2O content increases. At $R > 1$, only polar SCUs are formed in the structure of glasses, and the concentration of lithium quadrupoles increases as the concentration of lithium oxide increases.

Changes occurring in the structure of the glasses are proved by IR spectra, which correlate with the results of an IR study of glasses of the system $Li_2O–P_2O_5$ [7, 10, 12]. Broad bands with maxima near 3300 and 2600 cm^{-1} are observed in the IR transmission spectra in the region of vibrations of hydroxy groups. Their intensity increases as the content of lithium oxide decreases in glasses of both series examined in this study. However, in samples prepared by the first procedure, the relative content of water was somewhat less than in samples prepared by the second procedure. The IR absorption spectra of the samples prepared by the first procedure are given in Fig. 2. It is seen that the absorption in the range 910–1160 cm^{-1} changes essentially as the Li_2O content increases. The intensity of bands in the range 1050–1160 cm^{-1} in-

* The activation energy was recalculated by the equation $\sigma = \sigma_0 \exp[-E_0/(2kT)]$.

** Synthesis in an induction oven: heating to 900°C within approximately 5 min followed by exposure for 15 min; starting reagent: polycrystalline $LiPO_3$ of chemically pure grade.

creases, which seems to be due to the appearance of pyrophosphate groups [$\nu_{as}(PO_3)$]. At the same time, the intensity of the band at 1270 cm^{-1} [$\nu_{as}(PO_2)$] slightly decreases, and also the intensity of the band of bending vibrations (~500 cm^{-1}) decreases. Thus, as the content of Li_2O increases from 40 to 50 mol %, the position and shape of a number of bands change slightly, suggesting the preservation of the main metaphosphate motif of the glass. A sharp decrease in the intensity of the $\nu_{as}(PO_2)$ band and an increase in the intensity of $\nu_{as}(PO_3)$ are observed in the glass with 55 mol % Li_2O, which is due to increasing content of pyro- and orthophosphate groups and agrees well with the NMR data for the glasses of this system [17].

These conclusions are supported by the data on the density of the glasses: as the content of Li_2O increases, the density of the glasses increases (Table 2), which is attributable to more compact packing of the newly formed short-chain SCUs. Simultaneously the molar volume decreases (Table 2).

The effect of synthesis conditions on the electrical properties of glasses is illustrated by Table 4, in which the data of several authors on the conductance of lithium metaphosphate are compared. The observed discrepancy seems to be due to different techniques of the charge preparation and different thermal conditions of glass founding, as these factors determine the content of residual water in the glass structure, which noticeably affects the electrical properties of the glasses.

CONCLUSION

The temperature–concentration dependence of the conductivity in glasses of the system Li_2O–P_2O_5 was interpreted in terms of the structure-chemical microheterogeneity of the glass structure: in the region of low Li_2O concentrations, extrinsic hydrogen forms mixed quadrupoles $\begin{bmatrix} O_{3/2}P–O^-Li^+ \\ H^+O^–PO_{3/2} \end{bmatrix}$, retaining lithium ions more strongly than do homogeneous quadrupoles $\begin{bmatrix} O_{3/2}P–O^-Li^+ \\ Li^+O^–PO_{3/2} \end{bmatrix}$, and thus eliminating these ions from the electricity transfer. As the con-

centration of lithium oxide increases, the amount of extrinsic hydrogen decreases, which is accompanied by an increase in the conductance due to an increase in the concentration of current carriers and to a change of the mechanism of their migration.

CATALYSIS

Reactivity of Copper Nanopowders in a Model Reaction of Isopropylbenzene Oxidation

T. S. Skorokhodova, N. S. Kobotaeva, and E. E. Sirotkina

Institute of Petrochemistry, Siberian Division, Russian Academy of Sciences, Tomsk, Russia

Received July 27, 2004; in final form, December 2004

Abstract—The reactivity of copper nanopowders produced by an electric explosion of a conductor or mechanochemically was studied. Oxidation of isopropylbenzene was used as a model reaction. The dependence of the oxygen uptake rate on the specific surface area of a copper nanopowder and on the method used for its production is discussed. A possible mechanism of isopropylbenzene oxidation in the presence of copper nanopowders is suggested.

The intermediate position occupied by nanoparticles in passing from a bulk metal to a separate atom predetermines the deviation of their physicochemical properties from those of bulk metals, on the one hand, and from the properties of isolated atoms, on the other. This deviation is manifested in electronic, magnetic, optical, and other properties of nanoparticles with a characteristic size of several tens of nanometers to several nanometers [1]. Numerous summarizing papers concerning methods for preparation and stabilization of nanoparticles and their optical and other properties have already appeared, whereas studies of chemical transformations involving nanoparticles are only in their initial stage [2].

It is known [3] that nanosize powders (NPs) of metals show an increased reactivity, compared to compact metals. For example, reactions that do not occur in the presence of some metals or require severe conditions readily proceed in the presence of metal nanopowders. In particular, synthesis of complex compounds (phthalocyanines and tetraphenylporphyrins) with the use of copper and indium NP [4, 5] is performed under milder conditions (room temperature and atmospheric pressure) than the conventional synthesis with metal salts. Use of metal NPs as catalysts for oxidation of organic compounds is known. It was shown in [6] that the uptake of oxygen in oxidation of isopropylbenzene (IPB) in the presence of NPs of copper and cobalt proceeds at a sufficiently high rate even at 30°C without any initiator.

In this study we examined the reactivity of copper NP, obtained by an electric explosion of a conductor (EEC) or mechanochemically, in a model reaction of IPB oxidation.

EXPERIMENTAL

As objects of study served copper NP obtained by an electric explosion of a conductor in the atmosphere of nitrogen, argon, and xenon, as well as copper NP produced mechanochemically on an AGO-2 installation in the presence of organic and inorganic additives.[1] The additives were used to raise the specific surface area of the mechanochemically produced NP [7]. Copper nanopowders were produced by mechanical treatment (MT) in AGO-2 planetary-centrifugal high-energy-intensity mills in the presence of an organic surfactant (2,2,3,3,4,4,5,5-octafluorovaleramide) in an amount of 10% for 10 (Cu I), 20 (Cu II), and 30 min (Cu III). Copper powders were also prepared by mechanical treatment in the presence of 15 wt % $CuCl_2$ ($CuCl_2$ was washed out with ethanol after MT) on an AGO-2 installation for 10 (Cu 1), 20 (Cu 2), and 30 min (Cu 3). The physicochemical parameters and the preparation conditions of copper NPs used in this study are listed in Table 1.

IPB was oxidized on a gasometric installation [8]. A 0.7-M portion of IPB and 0.12 wt % copper NP were placed in the reactor. The reaction was performed at 30 and 60°C without initiator (azodiisobutyronitrile, AIBN). The reaction was stopped at the minimum rate of oxygen uptake (10–15 μl min^{-1}), which is determined by the scale factor of the buret in the gasometric installation. In some cases, repeated oxidation was performed 24 h after the end of the first

[1] Electric-explosion Cu NPs were obtained at the Institute of High-Current Electronics, Siberian Division, Russian Academy of Sciences, Tomsk; mechanochemical Cu NPs, at the Institute of Solid-State Chemistry and Mechanochemistry, Siberian Division, Russian Academy of Sciences, Novosibirsk.

** W_{max}, maximum rate of oxygen uptake.

oxidation. Liquid reaction products (acetophenone, AP, and dimethylphenylcarbinol, DMPC), were analyzed by gas–liquid chromatography on a Perkin–Elmer Sigma 2B chromatograph with a flame-ionization detector on an SE-52 column (column length 33 m) in the programmed-temperature mode: initial thermostat temperature 80°C, temperature raised at a rate of 3 deg min^{-1} to 150°C. Carrier gas helium. Quantitative analyses were performed with an internal reference (*n*-hexane). IPB hydroperoxide (IPB HP) was determined iodometrically by the standard procedure [9].

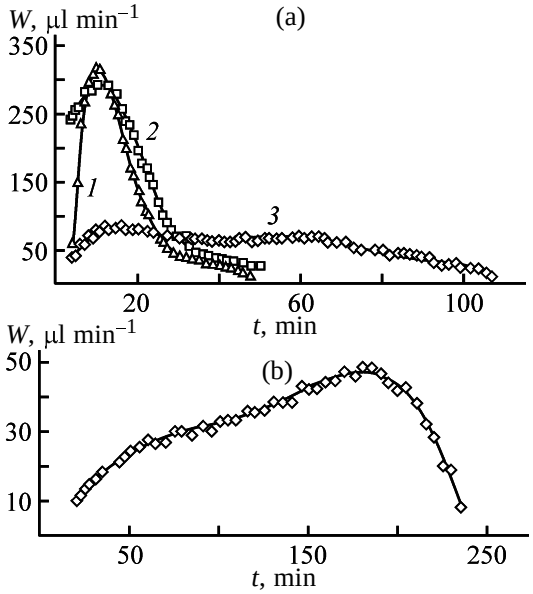

Fig. 1. Rate W of oxygen uptake vs. time t in oxidation of IPB in the presence of nanopowders. Nanopowder: (a) (*1*) Cu 8, (*2*) Cu 11, and (*3*) Cu 13; (b) Cu II. Temperature 60°C; the same for Fig. 2.

X-ray diffraction analysis was made on a DRON-1 instrument with a cobalt radiation source.[2] The X-ray diffraction patterns were recorded by point-by-point scanning with a step of 0.05°, with recording into a file for further computer processing.

The efficiency of copper NPs as catalysts for IPB oxidation was judged from the rate of oxygen uptake by a system constituted by IPB and Cu NP. Figure 1a shows the most typical kinetic curves of oxygen uptake in oxidation of IPB in the presence of 0.12 wt % Cu NP produced by EEC in various inert gases. Curves *1* and *2* are characteristic of Cu NP possessing a sufficiently large specific surface area [Cu 18(2), Cu 8, Cu 19, and Cu 11]. The run of the kinetic curves is about the same irrespective of the medium in which a powder was obtained: an exceedingly high rate at the beginning of the reaction and an abrupt fall in 10–15 min (Fig. 1). In the system constituted by IBP and Cu 13 NP with a small specific surface area (S_{sp} = 2.2 $m^2\ g^{-1}$), oxygen is taken up at a low rate during the entire reaction course (Fig. 1, curve *3*). For Cu NP produced by EEC, the following tendency can be noted: the larger the specific surface area of Cu NP, the higher the rate of oxygen uptake by the system constituted by IBP and Cu NP (Table 1).

A somewhat different behavior is exhibited in IBP oxidation by Cu NP produced mechanochemically. Irrespective of an additive, the rate of oxygen uptake gradually increases with time (Fig. 1b), with this type of curves characteristic of all mechanochemical Cu

[2] X-ray studies were carried out at the Institute of Strength Physics and Materials Science, Siberian Division, Russian Academy of Sciences, Tomsk.

NPs. The powders are as if "shaken up" in the course of time. The oxygen uptake in IPB oxidation in the presence of mechanochemical Cu NP begins only after a certain induction period (Table 1).

The time in which the minimum rate of oxygen uptake (10–15 μl min^{-1}) is reached depends on the method by which Cu NPs are obtained: for NP produced by EEC, the minimum oxidation rate is reached rather rapidly (in 30–40 min), and this occurs the faster, the larger the specific surface area of the powder. For mechanochemical Cu NP, the time in which the minimum rate of oxygen uptake is reached is long and independent of the specific surface area of the powder. After the minimum rate of oxygen uptake is reached, the reaction may continue during an infinitely long time until the whole amount of IPB enters into the reaction or the reaction terminates because of recombination processes.

IPB oxidation in the presence of a Cu powder with a particle size of 40 μm and a specific surface area of 0.016 $m^2 g^{-1}$ (Cu 0) deserves separate consideration. Copper with such a specific surface area does not catalyze the IPB oxidation at 60°C. At 80°C, the reaction starts in 15 min, and then oxygen is adsorbed at a very low, nearly constant rate.

A chromatographic analysis of the reaction products formed in IPB oxidation in the presence of Cu NP demonstrated the presence of not only IPB HP, but also AP and DMPC (Table 2), irrespective of the preparation method, specific surface area, preparation medium, and other physicochemical properties of NP (Table 1). When used in the form of shavings, metallic copper decomposes hydroperoxides [10]; probably, the same behavior is characteristic of Cu NPs because it was impossible to selectively obtain only IPB HP in the presence of Cu NP. For electric-explosion Cu NPs, which have a large specific surface area and exhibit a high rate of oxygen uptake at the beginning of the reaction, the amount of reaction products is insignificant, in contrast to those characteristic of mechanochemical Cu NPs, at the same oxygen uptake. For example, the conversion is 1.36% (0.60 IPB HP, 0.32 AP, 0.44 DMPC) for electric-explosion copper Cu 11 with a specific surface area of 6 $m^2 g^{-1}$ and 2.9% (0.80 IPB HP, 0.88 AP, 1.25 DMPC) for mechanically treated Cu II NP. An increase in the mass of Cu NP by a factor of nearly 10 does not lead to any significant rise in the yield of the reaction products.

It is known [11] that IPB oxidation in the presence of a copper catalyst occurs by the radical-chain mechanism, with the primary radicals appearing on the surface of copper. This makes it possible to suggest a heterogeneous-homogeneous mechanism of the reaction by the scheme

$$\begin{aligned} (M) + O_2 &\rightarrow (M^+)\cdots(O\text{–}O)^-, \\ (M^+)\cdots(O\text{–}O)^- + RH &\rightarrow (M^+) + (OOH)^- + R^\bullet, \\ (M^+) + (OOH)^- &\rightarrow (M) + HO_2^\bullet, \\ HO_2^\bullet + RH &\rightarrow H_2O_2 + R^\bullet. \end{aligned} \quad (1)$$

The performance of a catalyst depends on the rate at which the active centers on the catalyst surface can adsorb reactants, retain them during the chemical transformation, and then release the reaction products to be free to perform a new catalytic cycle [1].

Probably, fast sorption of oxygen at the first instant of time is natural for Cu NPs with a sufficiently large specific surface area. After the surface of copper is saturated with oxygen, the rate of uptake decreases significantly because three processes start to compete: oxygen uptake, formation of reaction products on the surface, and desorption of the reaction products into solution. Chromatographic analysis for the reaction products, made immediately after the reaction ter-

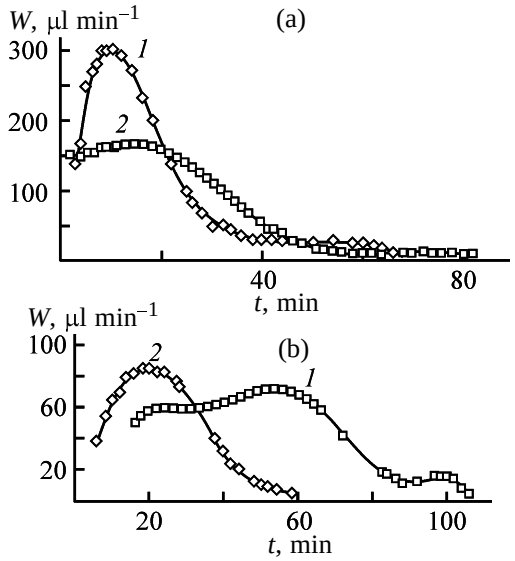

Fig. 2. Rate *W* of oxygen uptake vs. time *t* in oxidation of IPB in the presence of (a) Cu 8 and (b) Cu I nanopowders. Oxidation: (*1*) first and (*2*) repeated in 24 h.

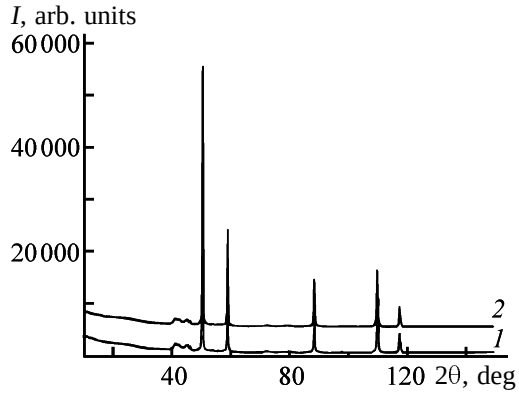

Fig. 3. X-ray diffraction patterns of Cu 11 powder (*1*) before and (*2*) after the oxidation. (*I*) Intensity and (2θ) Bragg angle.

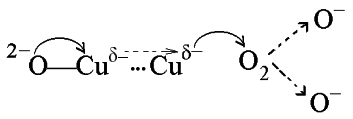

minated, reveals trace amounts of AP and DMPC. This means that the oxygen sorption is faster than formation of the reaction products and their desorption from the surface into the bulk. Nevertheless, after a certain time, when all the products would have diffused from the surface into the bulk, the conversion in the oxidation in the presence of electric-explosion Cu NPs with a large specific surface area is considerably lower than that with mechanochemical NPs. Probably, part of oxygen involved in oxidation is irreversibly sorbed on these NPs. Repeated oxidation of the system constituted by IPB and Cu NPs was performed in 24 h. The rate of oxygen uptake in the repeated oxidation of the system constituted by IPB and Cu NP prepared by the EEC method is always lower than that in the first oxidation of the same system, irrespective of the specific surface area of the NP (Fig. 2a). This means that the surface is not "freed" of oxygen even in the course of time. The curve of oxygen uptake in the repeated oxidation in the presence of mechanochemical Cu NP runs somewhat higher than that of the first oxidation (Fig. 2b). It was assumed that oxygen is consumed for oxidation of copper, and an X-ray diffraction analysis was carried out. However, an X-ray diffraction analysis did not reveal any additional formation of copper oxides after the reaction. Oxygen sorbed on the surface does not oxidize copper, but, probably, can be rather firmly retained on the surface of powder particles, without being involved in IPB oxidation to give reaction products; for example, it may form charge-transfer complexes with copper.

Figure 3 shows X-ray diffraction patterns of Cu 11 NP before and after the oxidation. The patterns reveal no difference between the structures of the initial NP and that isolated after the reaction. For example, the lattice constants (fcc unit cell) differ by less than 0.01% and the size of crystallites, determined from the angular broadening of the lines, was 60 and 62 nm in the initial and treated states, respectively. The only difference that could be revealed in the X-ray diffraction patterns is that the intensity of weak lines at 40°–48°, which, according to a phase analysis made on the basis of the ASTM file, belong to CuO (tenorite structure, 41-254 card), changes: after treatment of the powder, their intensity increases.

It was of interest to reveal the nature of the active center in Cu NPs, which can activate oxygen by scheme (1) and give rise to radical-chain transformations. A study was carried out[3] in order to elucidate the reasons for the increase in the reactivity of a mechanochemically treated copper powder, compared to the same powder in the initial state. It was demonstrated by X-ray photoelectron spectroscopy (XPS) that the intensity of oxygen peaks with a binding energy of 530.9–531.1 eV, which is not characteristic of adsorbed oxygen or copper oxides, increases in mechanochemically treated copper NPs [12]. The authors of this study believe that this peak may belong to the lattice, or suboxide, oxygen bound with defective sites in copper powder particles. In view of the fact that the bonding energy of the lattice oxygen exceeds that in the oxides CuO and Cu_2O, it may be stated that the bonding of copper atoms with the lattice oxygen is largely covalent, i.e., the suboxide oxygen donates its excess electron density to a copper atom bonded with it. The authors assume that the role of active centers in a copper sample activated by

[3] At the Institute of Solid-State Chemistry and Mechanochemistry, Siberian Division, Russian Academy of Sciences.

mechanical treatment or other methods leading to saturation with the lattice oxygen is played by oxygen atoms covalently bonded to copper atoms. Therefore, they suggest the following model of interaction of such an active center with molecular oxygen:

The lattice oxygen donates its excess electron density to the neighboring Cu atom, whose charge rapidly reaches the surface atom. The presence of an excess electron density on surface atoms leads to activation of molecular oxygen, which can then initiate radical-chain transformations in the catalytic oxidation of IPB.

The data of [12] can be used to explain the results obtained in this study. The copper NPs mechanically treated in ball mills in air probably contain a larger amount of suboxide oxygen capable of formation of active centers giving rise to radical chain reactions, because a 2 times greater amount of reaction products is formed. In addition, it is possible that the mechanochemical Cu NP treated in the presence of organic additives has on its surface a smaller number of free active sites at which oxygen not involved in the oxidation could be adsorbed. This is so because these sites, represented by various dislocations and structural surface defects, are already occupied in part by surfactants (e.g., by an organic surfactant, 2,2,3,3, 4,4,5,5-octafluorovaleramide), which can themselves form complexes with copper.

For copper NP produced by EEC in an inert atmosphere, presence of a large amount of suboxide oxygen is unlikely, and, therefore, it may be assumed that most part of absorbed oxygen is not activated and is not involved in the oxidation, being irreversibly sorbed at defective sites on the surface.

CONCLUSIONS

(1) In oxidation of isopropylbenzene in the presence of electric-explosion copper nanopowders obtained in an inert atmosphere, the maximum rate of oxygen uptake depends on the specific surface area of the nanopowders. The rate of oxygen uptake in the first oxidation run exceeds that in the case of a repeated oxidation run.

(2) With mechanochemically produced copper nanoparticles, the rate of oxygen uptake in the repeated oxidation runs exceeds that in the first oxidation of isopropylbenzene, which may be due to the high degree of caking of these powders and their "shake-up" in the course of time.

(3) The final products are isopropylbenzene hydroperoxide, acetophenone, and dimethylphenylcarbinol. The relative amounts of the reaction products depend on the method used to produce the nanopowders.

(4) A possible mechanism of isopropylbenzene oxidation in the presence of Cu nanopowders was suggested. This mechanism is associated with the presence of suboxide oxygen, which is involved in the oxidation and activates molecular oxygen.

CATALYSIS

New Catalytic Reactions in the Presence of Mo–V-Phosphoric Heteropoly Acid Solutions

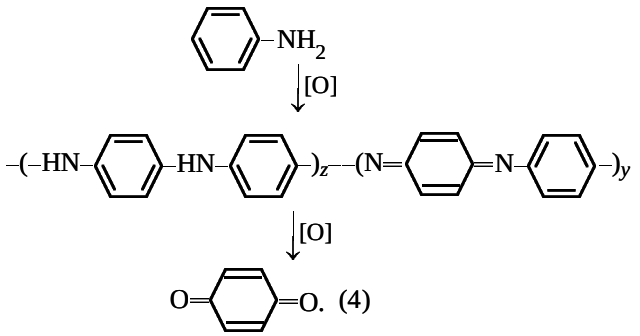
Abstract—The possibility of performing new catalytic reactions in the presence of solutions of $H_{x+3}PMo_{12-x}V_xO_{40}$ Mo–V-phosphoric heteropoly acids was examined.

Solutions of Mo–V-phosphoric heteropoly acids (HPAs) of the Keggin structure and the composition $H_{x+3}PMo_{12-x}V_xO_{40}$ (HPA-*x*, *x* = 2–6) find expanding application as effective catalysts of oxidation of organic compounds with oxygen [1–3]. In the presence of HPAs, these reactions often proceed in two steps performed in different reactors. In step (1), substrate H_2Su is oxidized with HPA to form the reaction product SuO and reduced HPA H_mHPA. In step (2), HPA is regenerated with oxygen. Catalytic reaction (3) is a sum of these reactions; it proceeds in the mode of non-steady-state catalysis. In these reactions, HPA acts as reversible oxidant.

$$m/4H_2Su + m/4H_2O + HPA \rightarrow m/4SuO + H_mHPA, \quad (1)$$

$$H_mHPA + m/4O_2 \rightarrow HPA + m/2H_2O, \quad (2)$$

$$H_2Su + O_2 \xrightarrow{HPA} SuO + H_2O. \quad (3)$$



In HPA solutions, only vanadium ions undergo reversible redox transformations: V(V) → V(IV). Separate performance of reactions (1) and (2) provides high selectivity of reaction (1).

In this work we studied the oxidation of new substrates [aniline (An), *o*-toluidine (TD), hydroquinone (HQ), and partially hydrogenated quinones of naphthalene and anthracene series] in the presence of 0.2–0.25 M aqueous solutions of HPAs-*x* (*x* = 3–6, where *x* is the number of vanadium atoms in the molecule). Also, synthesis of 9,10-anthraquinone (AQ) was performed by combining the diene synthesis and oxidation of the adducts.

EXPERIMENTAL

In all the processes, HPA solutions were regenerated at 150–160°C and oxygen pressure of 6–9 atm [4, 5]. Almost complete regeneration of the activity of HPA solutions allowed their multiple reuse.

Oxidation of aniline and *o*-toluidine. Aniline and other aromatic amines are often oxidized with strong oxidants such as $NaClO_3$, $K_2Cr_2O_7$, etc. Depending on the oxidant and conditions, the reaction can yield 1,4-benzoquinone (BQ) or polyaniline (PAn), a product of oxidative polymerization {scheme (4) [6–8]}. Polyaniline can be quantitatively oxidized to BQ [8]:

(4)

Being a conducting polymer, PAn is widely used in chemical current sources [9, 10] and as stable black dye [11]. Development of environmentally safe procedures for catalytic oxidation of aniline to form PAn is an urgent problem.

We attempted to solve this problem using solutions of HPAs-*x* (*x* = 3, 4). Here we report the data on oxidation of AN and TD in HPA solutions; depending on the reaction conditions, either PAn or BQ can be obtained.

1070-4272/05/7805-0758© 2005 Pleiades Publishing, Inc.

Aromatic amines were oxidized in a 100-ml flask at stirring with a magnetic stirrer. Aniline (5.5 mmol) was added to a 0.2 M aqueous solution of HPA-3 (3.66 mmol), and a black precipitate (0.4858 g) that formed upon stirring of the reaction mixture for 30 min at 22°C was filtered off. The properties of this black compound correspond to those of PAn prepared by noncatalytic oxidation of aniline [7, 12]. This product is insoluble in organic solvents, organic acids (e.g., acetic, oxalic, and tartaric acids), and concentrated HCl, and is poorly soluble in concentrated KOH and NaOH. It is soluble only in concentrated H_2SO_4 and, with oxidation, in concentrated HNO_3. Except the 1000–800 cm^{-1} range, the IR spectrum of this compound essentially coincided with the IR spectrum of PAn [poly(*p*-phenylenaminimine)] [12].

The composition of this product is as follows, %: C 59.36, H 4.39, and N 11.98. Calculated composition of PAn {$z = y$ in scheme (1) [7]}, %: C 79.56, H 4.97, and N 15.47. The C/N ratio in our compound and in those prepared in [7] is 4.95 and 5.14, respectively. This difference is probably due the fact that x and z in the formula of the PAn obtained in our work differ from those in the formula $C_6H_{4.5}N$ {$z = y$, scheme (1) [7]}.

o-Toluidine was oxidized under the similar conditions (22°C, 30 min). For this purpose, the substrate (5.5 mmol) was added to a 0.2 M aqueous solution of HPA-3 (3.66 mmol). As a result, we obtained methylated PAn (0.5620 g) of the following composition, %: C 60.62, H 6.30, and N 6.59 [calculated, %: C 82.76, H 3.45, and N 13.79]. Higher content of H and C in the product is due to the additional methyl group in the monomer.

The GLC and ^1H NMR data show that, at 90–100°C, PAn prepared by low-temperature oxidation of An dissolves in excess HPA-3 or HPA-4 to form BQ at the molar ratio HPA-x : aniline = 3, recalculated to the initial An concentration. This result agrees with published data [8] and additionally confirms formation of PAn. If An is oxidized directly in excess HPA-x (x = 3, 4) at temperature higher than 70°C, BQ is formed in a quantitative yield.

As seen from Table 1, the yield of PAn depends on the HPA-3 : An molar ratio. The yield of PAn is low at HPA-3 deficiency due to incomplete An conversion, whereas at HPA-3 excess it decreases owing to partial oxidation of An to BQ. In HPA-4 solutions the highest yield of PAn is observed at the molar ratio HPA-4 : An = 0.5, which is due to larger number of vanadium(V) atoms than in HPA-3, i.e., to greater oxidative power.

Table 1. Yield of PAn in oxidation with HPA-3 solution at 22°C for 30 min; An content 0.5115 g (5.5 mmol)

Amount of An, mmol	HPA-3 : AN molar ratio	Amount of PAN, g	PAn : An weight ratio
4.58	0.83	0.3802	0.74
3.66	0.67	0.4858	0.95
1.83	0.33	0.0912	0.18

* PAn was separated from HPA-3 solution by filtration, washed, and dried over $CaCl_2$.

Our data show that, depending on the experimental conditions, An and TD are oxidized in HPA-x solutions yielding either the corresponding PAn or the corresponding 1,4-quinone. Regeneration of HPA-x with oxygen by reaction (2) [4, 5] closes the catalytic cycle and thus allows development of a catalytic process for synthesis of PAn in the presence of HPA solutions.

Preparation of 1,4-benzoquinone, 1,4-naphthoquinone, and 9,10-anthraquinone by oxidative dehydrogenation. *p*-Quinones are usually obtained by oxidation of appropriate substrates with strong oxidants. For example, BQ is prepared by oxidation of hydroquinone with salts of copper(II) [13], iron(III) [14], chromium(VI) [15], and sodium nitrosodisulfonate (Fremy salt) [16]. 1,4-Naphthoquinone (NQ) is prepared by oxidation of naphthalene with salts of chromium(VI) and cerium(IV) [17]. Anthraquinone is most often prepared from anthracene by oxidation with air at 360–380°C in the presence of V_2O_5 catalyst [18] or with such strong oxidants as $ZnCr_2O_7 \cdot 3H_2O$ or AcO_2H [17]. These processes are economically inefficient because of high cost of the oxidant; moreover, they are environmentally hazardous because of significant amount of wastes requiring utilization. Therefore, development of environmentally safe catalytic processes to prepare *p*-quinones is urgent. Owing to high oxidative power and reversible redox cycle [1, 19], the use of HPA-x solutions as oxidation catalysts seems promising.

It was found [20–22] that alkyl-substituted phenols of the benzene and naphthalene series can be oxidized in the presence of HPA solutions to form the corresponding *p*-quinones with high selectivity (85–99%). These reactions are usually carried out in two-phase systems (e.g., HPA aqueous solution + solution of substrate and reaction products in organic solvent). In this study, we also used HPA solutions for catalytic oxidation with air (oxidative dehydrogenation) of partially hydrogenated phenols of benzene, naphthalene, and anthracene series to prepare the corresponding *p*-quinones [23].

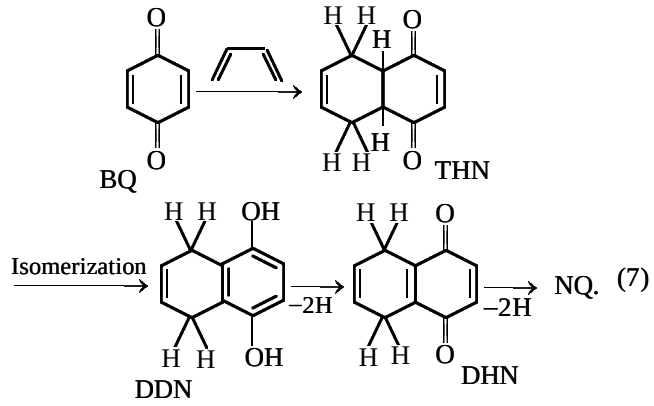
* Experiment was performed with 0.25 M solution of HPA-6 ($H_9PMo_6V_6O_{40}$, 25 ml, 5.62 mmol).

Oxidative dehydrogenation was carried out with stirring in a 100-ml temperature-controlled conical flask equipped with a reflux condenser. In the case of two-phase systems, the reaction products are separated from the catalyst by phase separation. If the reaction was performed in the absence of organic solvent, the solid products were filtered off from the HPA solution. For more complete isolation of the reaction products, they were extracted with an organic solvent (chloroform, benzene); the extracts were dried over $CaCl_2$ and evaporated to dryness. The components of the residue were separated chromatographically (SiO_2, hexane, benzene, and chloroform eluents). The yields of the products were determined from the ^1H NMR spectra. The data on the oxidative dehydrogenation of several compounds studied are listed in Table 2.



The oxidative dehydrogenation of 1,4-dihydroxy-5,8-dihydronaphthalene (DDN) in 0.25 M solution of HPA-4 at 50–70°C gives NQ in a yield from 30 to 82% and 5,8-dihydronaphthalene-1,4-dione (DHN) in a yield of up to 59% [scheme (5)]. With increasing temperature, the yield of NQ increases:

$$\mathrm{DDN} \xrightarrow[50\text{–}70^\circ\mathrm{C},\ 1\text{–}2.5\ \mathrm{h}]{\text{HPA-4}} \underset{\leq 59\%}{\mathrm{DHN}} + \underset{30\text{–}82\%}{\mathrm{NQ}}. \qquad (5)$$

This reaction can be performed without organic solvent. A solid substrate is added into an HPA solution heated to a required temperature before switching on stirring. As the initial substrate we can use 4a,5,5,8a-tetrahydronaphthalenedione (THN), and not the product of its isomerization (DDN). In this case, the yield of NQ reached 96%. No DHN was found in the reaction mixture (Table 2):

$$\mathrm{THN} \xrightarrow[70^\circ\mathrm{C},\ 1\ \mathrm{h}]{\text{HPA-4}} \underset{\leq 96\%}{\mathrm{NQ}}. \qquad (6)$$

These data suggest that the known procedure [24, 25] for preparing NQ [scheme (7)], which requires preliminary isomerization of THN in DDN and subsequent two-stage oxidation first into DHN and then into NQ using two different oxidants, can be significantly simplified and performed in one stage in the presence of HPA solutions:

(7)

The oxidative dehydrogenation of 1,4,4a,9a-tetrahydro-9,10-anthraquinone (THA) to 1,4-dihydro-9,10-anthraquinone (DHA) (Table 2) in the presence of HPA-4 solutions proceeds under more severe conditions than hydrogenation of THN and DDN:

$$\underset{}{\text{THA}} \xrightarrow[60\text{–}90^\circ\text{C},\ 1\text{–}3\ \text{h}]{\text{HPA-4}} \underset{37\text{–}67\%}{\text{DHA}} + \underset{5\text{–}49\%}{\text{AQ}}. \qquad (8)$$

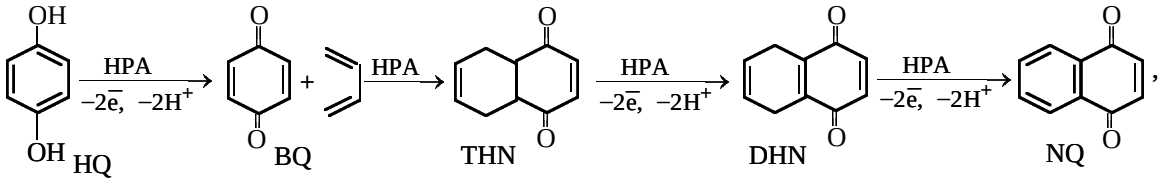
On the contrary, hydroquinone is readily oxidized into BQ even at room temperature with a high yield (up to 98%), and with increasing temperature the yield of BQ decreases:

$$\underset{}{\text{HQ}} \xrightarrow[24\text{–}25^\circ\text{C},\ 0.5\ \text{h}]{\text{HPA-4}} \underset{82\text{–}98\%}{\text{BQ}}. \qquad (9)$$

The above data show that *p*-quinones of the benzene, naphthalene, and anthracene series can be prepared by oxidation of their partially hydrogenated derivatives in HPA solutions. Since DDN and THA are rather expensive, commercial synthesis of NQ and AQ should be based on more available substrates. However, the successful oxidative dehydrogenation of various substrates (Table 2) shows that the HPA solutions can be used as bifunctional catalysts for preparing 1,4-naphthoquinone and 9,10-anthraquinone.

Diene synthesis of 9,10-anthraquinone. Anthraquinone and its derivatives are intermediate products in synthesis of dyes, analytical reagents, and drugs [26]. 9,10-Anthraquinone is used as a catalyst of redox reactions, in particular, in production of hydrogen peroxide [27]. Moreover, AQ and its derivatives catalyze wood delignification and increase the yield of cellulose, degree of its bleaching, and its strength properties [28]. For this purpose, "soluble AQ," i.e., sodium salt of THA (intermediate product in the diene synthesis of 9,10-anthraquinone), is widely used [29].

Known procedures for preparing AQ can be subdivided in two groups. The first group includes oxidation of anthracene into AQ with atmospheric oxygen and other oxidants at 350–400°C [17, 26], and the second group is based on the cyclization reactions involving inter- and intramolecular acylation and Diels–Alder diene synthesis [26]. In the case of acylation, benzene and phthalic anhydride are the initial reagents and synthesis is carried out in several steps. The first stage yields 2-benzoylbenzoic acid, which is then dehydrated in the presence of various heterogeneous catalysts to form AQ [30].



Diene synthesis is one of the commercial procedures for preparing THA, DHA, and AQ. It is based on the catalytic gas-phase oxidation of naphthalene into NQ and its subsequent reaction with 1,3-butadiene [26]. The primary addition products (adducts) are obtained in organic solvents either at elevated pressure of 1,3-butadiene of 0.3–2.0 MPA or in the presence of organic acids to decrease the pressure. In the presence of oxygen or alkalis, THA (adduct of diene synthesis) isomerizes to form 1,4-dihydro-9,10-dihydroxyanthracene, and this product is then oxidized in DHA and AQ with strong oxidants in acidic solutions or with atmospheric oxygen in an alkaline medium.

All modern procedures for preparing AQ and its derivatives are multistage and environmentally hazardous; each step produces significant amount of wastes including strong acids, spent acid catalysts, and oxidants, e.g., toxic compounds of chromium(VI) and (III), which require recycling.

Growing demand for AQ and its derivatives cannot be complied using outmoded and environmentally hazardous processes. Russia has no large-scale commercial production of AQ, and only foreign companies supply the required reagent. Hence, development of the domestic environmentally safe production of AQ and its derivatives is a very urgent problem.

Catalysts based on HPA show promise for this purpose. For example, condensation of NQ with 2,3-dimethyl-1,3-butadiene (Diels–Alder reaction) in the presence of tungsten HPA ($H_3PW_{12}O_{40}$ and $Ce_{0.87}H_{0.4}PW_{12}O_{40}$) yields substituted THA (70–80%) [31]. No oxidation of this product was observed because these HPAs exhibit no oxidative power [1, 31].

In the diene synthesis, we used solutions of HPA-*x* (*x* = 4–6) [23], which are both strong acids catalyzing Diels–Alder reaction and strong reversible oxidants. In contrast to Meuzelaar *et al*. [31], we succeeded in combining the diene synthesis with oxidation of the adducts in the presence of HPA solutions [23]. 9,10-Anthraquinone and its derivatives were prepared by one-pot synthesis:

(11)

Hydroquinone was used as the initial substrate [schemes (10), (11)]. It was oxidized to BQ and then condensed with 1,3-butadiene. The adducts of the diene synthesis were oxidized to NQ in the same HPA-*x* solution. In the second step of the process [scheme (11)], NQ was condensed with 1,3-butadiene to form THA, which was then oxidized to DHA and AQ. All the above reactions were performed as one-pot process owing to bifunctional properties of HPA acting as both acid and oxidation catalyst. In the course of this process, HPA was reduced to H_mHPA, where *m* is the number of electrons accepted by the HPA molecule. After the reaction completion, poorly soluble products (AQ, DHA, THA) were filtered off from the aqueous solution of H_mHPA. The solution of HPA-*x* was regenerated at 150–160°C under oxygen pressure, as in the case of oxidation of aniline, which allows multiple reuse of the HPA solutions.

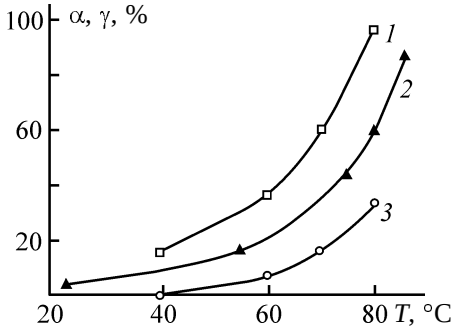

Fig. 1. (*1, 2*) Conversion of NQ γ and (*3*) yield of AQ α as functions of temperature *T*. 1,3-Butadiene medium, 0.2 M HPA-4 (25 ml), NQ 0.79 g. Conversion of NQ: (*1*) after 7 h (^{1}H NMR data) and (*2*) after 5 h (GLC data); (*3*) yield of AQ in 7 h (^{1}H NMR data).

First we studied preparation of AQ and its hydrogenated derivatives THA and DHA from HQ in HPA solutions by reaction schemes (10) and (11). The experimental results are listed in Table 3. As seen, with increasing temperature and HPA-6 : HQ molar ratio, the content of AQ in the reaction mixture increases, whereas addition of a solvent decreases the AQ yield.

For better understanding of processes (10) and (11), we studied separately step (11), i.e., preparation of a mixture of AQ, THA, and DHA from NQ. These data are also of independent importance. For example, if NQ as initial substrate will be acceptable by a cheap method (e.g., by oxidation of naphthalene), then the one-pot process for preparing AQ from NQ will be competitive, because at present HQ is a cheaper substrate as compared to NQ.

We found that the rate of reaction (11) strongly depends on temperature. At 40°C, the rate of the diene synthesis is low, but with increasing temperature to 80°C the conversion of NQ and the yield of AQ rapidly increase (Fig. 1). Simultaneously the solubility of NQ in HPA-*x* solution also increases, which promotes

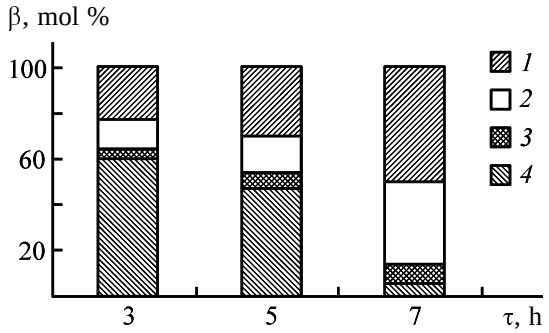

Fig. 2. Changes in the composition of the reaction products β with reaction time τ. 1,3-Butadiene medium, 80°C, 0.2 M HPA-4 (25 ml), NQ 0.79 g. (*1*) AQ, (*2*) DHA, (*3*) THA, and (*4*) NQ.

the reaction. The NQ conversion and AQ yield increase with time. The dependence of the precipitate composition on the reaction time (based on the ^{1}H NMR data) is shown in Fig. 2. As seen, the fraction of DHA in the reaction mixture is greater than that of THA. This suggests that the oxidation of DHA in AQ is slower than the oxidation of THA to DHA.

We also studied the condensation of HPA-4 with 1,3-butadiene as influenced by some organic solvents. We found that such solvents as toluene, benzene, and chloroform do not noticeably affect the NQ conversion and AQ yield. These results agree with the data on the diene synthesis of NQ with 1,3-butadiene in HPA-6 solution (Table 2).

We also studied how the HPA-4 : NQ molar ratio affects the composition of the reaction products of the diene synthesis of NQ with 1,3-butadiene and subsequent oxidation of the adducts [scheme (11)]. The HPA-4 : NQ molar ratio was varied by changing the content of NQ at constant content of HPA-4; the results are listed in Table 4.

As seen, with increasing HPA-4 : NQ molar ratio the yield of AQ increases. At high molar ratios (HPA-4 : NQ > 2), the catalysts retains high oxidative potential for a longer period, which provides higher conversion in reaction (11).

Table 4. AQ yield in the diene synthesis as influenced by HPA-4 : NQ molar ratio. 1,3-Butadiene medium, 0.2 M HPA-4 (25 ml), time 5 h, temperature 80°C

Weighed portion of NQ, g	HPA-4 : NQ molar ratio	AQ yield, %
1.58	0.5	7.2
0.79	1	12.9
0.40	2	38.2
0.20	4	40.3

CONCLUSIONS

(1) Aniline and *o*-toluidine in solutions of Mo–V-phosphoric heteropoly acids are oxidized to 1,4-benzoquinone or undergo oxidative polymerization to form polyanilines.

(2) The adducts of the Diels–Alder reaction are oxidized with heteropoly acid solutions to the corresponding *p*-quinones.

(3) Solutions of heteropoly acids can be used as bifunctional catalysts, i.e., acid catalysts in the Diels–Alder reaction and oxidation catalysts. In the presence of HPA-*x* (x = 4–6) solutions, a mixture of the products is obtained with a high content of 9,10-anthraquinone and 1,4,4a,9a-tetrahydro-9,10-anthraquinone at nearly quantitative conversion of the initial substrate (hydroquinone, 1,4-benzoquinone, or 1,4-naphthoquinone). The one-pot process combines reactions of diene synthesis and oxidation of its products.

CATALYSIS

Decrease in Content of Insoluble Fraction in *cis*-1,4-Polyisoprene in Formation of Titanium Catalyst in Turbulent Flow

Received October 14, 2004

Abstract—The effect caused by using a tubular prereactor of the diffuser–confuser design operating in the turbulent flow mode on the content of the insoluble gel fraction in *cis*-1,4-polyisoprene obtained on a Ti/Al catalyst is studied.

SKI-3 large-scale synthetic isoprene rubber is synthesized on Ti/Al Ziegler–Natta catalysts on the basis of the *cis* isomer and is used primarily in production of tires, conveyer belts, and other industrial and medical goods. Performance of goods manufactured from *cis*-1,4-polyisoprene and their application areas are controlled to a considerable extent by the molecular characteristics of the macrochains, particularly, by the content of the insoluble fraction (gel fraction) in the polymer, which may be as large as 20–30% [1]. Rubber stocks based on *cis*-1,4-polyisoprene with decreased insoluble fraction can be processed by molding, and SKI-3-based rubber stocks with low gel fraction content demonstrate better adhesiveness and lower shrinkage [1].

Muzhai *et al*. [2] suggested that formation of the gel fraction in stereoregular polymerization of dienes on Ziegler–Natta catalysts is initiated by secondary cationic reactions involving the macrochain at the solid surface of the heterogeneous catalyst. Most likely, these reactions are intra- and intermolecular interactions between the double bonds of the ready polymer chain and also chain propagation. At the same time, we have demonstrated previously that, in polymerization of isoprene on $TiCl_4$–$Al(i\text{-}C_4H_9)_3$, the use of a tubular turbulent prereactor installed before the bulk polymerizer with longer residence time affects the catalyst particle size distribution, particularly, reduces the particle size in the catalytically active precipitate. Evidently, this alters the insoluble fraction content in *cis*-1,4-polyisoprene, allowing development of a procedure aimed at decreasing the gel fraction content in isoprene rubber and improving performance characteristics of the products.

Therefore, in this study we examined the effect of the stereoregular polymerization procedure, namely, of the formation of the $TiCl_4$–$Al(i\text{-}C_4H_9)_3$ catalyst in a turbulent flow provided by the use of a tubular turbulent prereactor of the diffuser–confuser design on the content of the insoluble fraction in *cis*-1,4-polyisoprene.

The experimental setup for isoprene polymerization was described elsewhere [3]. The starting reactants were purified by standard methods accepted in stereoregular polymerization on Ziegler–Natta catalysts. In the experiments we varied the process procedure, the polymerization conditions remaining unchanged.

Method no. 1 simulated the traditional industrial polymerization process. Separately prepared solutions of the catalytic system [binary $TiCl_4$–$Al(i\text{-}C_4H_9)_3$ or ternary (modified) $TiCl_4$–$Al(i\text{-}C_4H_9)_3$–piperylene (piperylene as a modifier was introduced in the catalytic complex solution at the stage of its preliminary keeping)] kept for 30 min at 273 K and of the monomer were directly introduced into the apparatus (flask) with gentle stirring.

Method no. 2. The preliminarily kept catalytic system and the solvent were mixed in a tubular apparatus operating in the turbulent flow mode. Then the catalyst solution was fed to a stirred vessel. The monomer was added with gentle stirring.

Method no. 3. Separately prepared solutions of $TiCl_4$ and $Al(i\text{-}C_4H_9)_3$ were mixed in the tubular apparatus. The fast formation of the catalytically active precipitate proceeded in a turbulent flow, followed by keeping for 30 min with gentle stirring in the vessel at 273 K. Finally, the monomer was added.

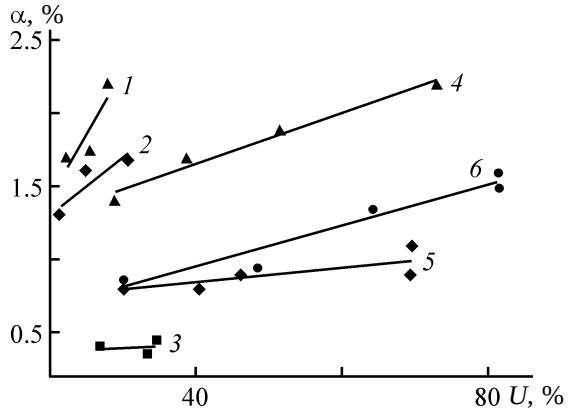

Fig. 1. Content of the gel fraction α as a function of the yield of *cis*-1,4-polyisoprene *U* on (*1*–*3*) $TiCl_4$–Al(*i*-C_4H_9)$_3$ and (*4*–*6*) $TiCl_4$–Al(*i*-C_4H_9)$_3$–piperylene catalysts. Ti : Al : piperylene molar ratio 1 : 1.25 : 2; solvent toluene; c_{Ti} = 6 mM; c_M = 1.5 M; 298 K. Polymerization conditions: (*1*, *4*) method no. 1 (conventional), (*2*, *5*) method no. 2 (exposure of the catalyst particles to turbulent flow), (*3*) method no. 3 (formation of the catalytic system in turbulent flow), and (*6*) method no. 4 (formation of the reaction mixture in turbulent flow).

Method no. 4. Separately prepared solutions of the preliminarily kept ternary catalytic system and monomer were mixed in the tubular apparatus and then fed into the bulk reactor. In this case, the catalyst particles were exposed to the turbulent flow. The procedure ensured fast initiation (addition of the first monomer molecule to the active center) and uniform distribution of the growth centers on the surface of the heterogeneous catalyst throughout the bulk of the reaction mixture.

In method nos. 2–4, the residence time of the reaction mixture in the tubular turbulent prereactor of the diffuser–confuser design was about 2–3 s.

The insoluble fraction in *cis*-1,4-polyisoprene was determined by extraction with hot toluene for 150 h [4]. For extraction, a 0.2-g sample was placed in cambric bag. The content of the insoluble fraction was determined gravimetrically.

Grechanovskii and Poddubnyi [5] have demonstrated that the insoluble fraction in polyisoprene consists of conglomerates of particular molecules, representing a physical gel rather than a cross-linked polymer. In this case, the conglomerates pass into solution upon stirring. The catalyst deactivation procedure used in this study involved vigorous mechanical action on both the polymer solution and polymer at the stage of precipitation with methanol. In this case, the physical gel is broken down, and the analysis for the insoluble fraction content in *cis*-1,4-polyisoprene reflects the content of the gel fraction formed by cross-linked macromolecules (chemical gel). As a result, the content of the insoluble fraction in *cis*-1,4-polyisoprene appears to be small, being below 3% (Fig. 1).

The content of the insoluble fraction increases with increasing polymer yield. Exposure of the catalyst system to turbulent flow (Fig. 1, curve *2*) slightly decreases the gel fraction content in the polymer as compared to the conventional method (Fig. 1, curve *1*). The minimal content of the gel fraction in *cis*-1,4-polyisoprene was observed when the fast reaction of the starting $TiCl_4$ and Al(*i*-C_4H_9)$_3$ solutions was conducted in a tubular turbulent prereactor with formation of a finely dispersed catalyst (Fig. 1, curve *3*). Modification of the $TiCl_4$–Al(*i*-C_4H_9)$_3$ catalyst by addition of piperylene decreases the gel fraction content under the same polymerization conditions (Fig. 1, curves *1* and *4*, and *2* and *5*). Furthermore, in the case of the modified catalyst, the effect of the turbulent flow on the gel fraction content is more pronounced.

It was demonstrated in our previous paper [6] that the polymerization procedure, particularly, the use of a tubular turbulent prereactor influences the molecular weight distribution of *cis*-1,4-polyisoprene, growth center concentration, and polymerization rate. An integral characteristic of the process is the amount of macrochains per active center. Therefore, it appeared advisable to examine the interrelation between the insoluble fraction content in the polymer and this integral parameter.

The amount of polymer chains in the reaction mixture *N* is written as

$$N = c_M U/P_n, \quad (1)$$

where c_M is the initial monomer concentration; *U*, polymer yield; and P_n, number-average degree of polymerization.

In turn, the amount of polymer chains *n* per active center is written as

$$n = c_M U/P_n c_a, \quad (2)$$

where c_a is the concentration of active centers.

In accordance with Eq. (1), with increasing polymer yield, the amount of macrochains in the reaction mixture increases as well as the probability of secondary processes, particularly, cross-linking, in the polymer chains. All this results in formation of a polymer with a high gel fraction content, as demonstrated experimentally (Fig. 1). At the same time, analysis

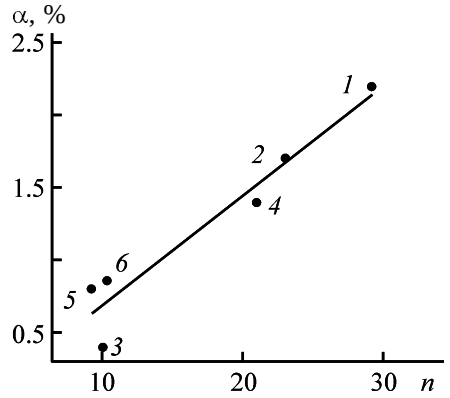

Fig. 2. Content of the gel fraction in *cis*-1,4-polyisoprene α as a function of the amount of macromolecules *n* per active center in polymerization on (*1–3*) $TiCl_4$–$Al(i\text{-}C_4H_9)_3$ and (*4–6*) $TiCl_4$–$Al(i\text{-}C_4H_9)_3$–piperylene catalysts. Polymerization conditions: (*1, 4*) conventional method, (*2, 5*) exposure of the catalyst particles to turbulent flow, (*3*) formation of the catalytic system in turbulent flow, and (*6*) formation of the reaction mixture in turbulent flow (polymer yield 30%).

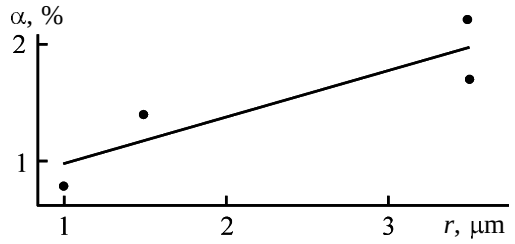

Fig. 3. Content of the gel fraction α as a function of the radius of the particles of the Ti/Al catalyst *r*.

of data on the insoluble fraction in *cis*-1,4-polyisoprene synthesized on $TiCl_4$–$Al(i\text{-}C_4H_9)_3$ and $TiCl_4$–$Al(i\text{-}C_4H_9)_3$–piperylene catalytic systems under various polymerization conditions revealed a general trend in this parameter as a function of the amount of macrochains per active center (Fig. 2).

It is known that active centers of stereoregular polymerization of isoprene on $TiCl_4$–$Al(i\text{-}C_4H_9)_3$ catalyst are located on the defects of the β-$TiCl_3$ crystal lattice [7]. In accordance with Eq. (2), this implies the interrelation between the insoluble fraction content in the polymer and the particle size of the heterogeneous catalyst as obtained by the sedimentation analysis [3] (Fig. 3). Decreasing radius of the catalyst particles results in a decrease in the insoluble fraction in *cis*-1,4-polyisoprene. In turn, the catalyst particle size and, as follows from Fig. 3, the insoluble fraction content can be affected by addition of a diene to the catalytic system and also by modification of the procedure of formation of the $TiCl_4$–$Al(i\text{-}C_4H_9)_3$ catalyst using the effect of a turbulent flow [3, 6]. Indeed, the minimal amount of macrochains per active center as well as the minimal gel fraction content are observed in formation of the catalytic system in a turbulent flow, when a fast chemical reaction proceeds with formation of a finely dispersed catalytically active precipitate (Fig. 2). It is clear that further decrease in the catalyst particle size should result in a decrease in the insoluble fraction in the polymer (Fig. 3). This is confirmed by the lack of the gel fraction in the polymers obtained on pseudohomogeneous lanthanide-based catalysts [8].

Evidently, the trend observed in this study (Fig. 3) is caused by the fact that, with decreasing particle size of the catalyst, the polymeric shell on its surface, consisting of growing macromolecules, becomes close to a monomolecular adsorption layer. In this case, the probability of cross-linking through collision of internal double bonds near the active center on the catalyst surface decreases, as evidenced by the results obtained in [7, 9] that the smaller the catalyst particle size, the thicker the polymeric shell (in a monomolecular layer the thickness of the adsorption layer approaches the length of the macromolecule), and the macromolecules growing in these shells are one-end connected to the catalyst surface. It is obvious that the indicated trends in evolution of the gel fraction formed by chemically cross-linked macromolecules (chemical gel) are valid also for the insoluble fraction formed by physically bound macrochains (physical gel).

CONCLUSIONS

(1) A correlation is found between characteristics of the $TiCl_4/Al(i\text{-}C_4H_9)_3$ heterogeneous catalyst and the particle size and content of the insoluble fraction in *cis*-1,4-polyisoprene. Modification of the catalytic system with a diene and hydrodynamic effects in a tubular prereactor of the diffuser–confuser design operating in the turbulent flow mode decrease the catalyst particle size as well as the content of the insoluble gel fraction in the polymer.

(2) The minimal content of the gel fraction in *cis*-1,4-polyisoprene was observed when the fast reaction of the starting $TiCl_4$ and $Al(i\text{-}C_4H_9)_3$ solutions was conducted in a tubular turbulent prereactor with formation of a finely dispersed catalyst.

CATALYSIS

Modification with *d* Metals of Zeolite Catalysts for Conjugated Conversion of Methanol and Lower Alkanes

Abstract—Joint conversion of methanol and lower alkanes on modified zeolites of the ZSM-5 type was studied.

A promising method for processing of hydrocarbon raw materials is conjugated conversion of alkanes C_3–C_4 and methanol. The most efficient catalysts in this process are zeolite catalysts of the Pentasil family, modified with various elements. The modifying elements strongly affect the selectivity and catalytic activity of zeolites, depending on their nature and method of introduction into the initial zeolite. A combination of unique structural and acid properties of Pentasils with the dehydrogenating capacity of modifiers makes it possible to develop the most selective catalysts for obtaining the desired conversion products.

The aim of this study was to examine the conjugated conversion of methanol and lower alkanes on high-silica zeolites (HSZs) modified by various methods with Group IV *d* metals and to determine how their acid and catalytic properties are related.

EXPERIMENTAL

High-silica zeolites of the ZSM-5 type with a mass ratio $SiO_2 : Al_2O_3 = 50$ (NVLTs-50) were prepared by the procedure developed in [1].

Modified HSZs (MHSZs) were produced by ion exchange (IE) and mechanical mixing (MM). In introducing a modifying element by the IE technique, a calculated amount of a soluble salt of a metal was added to an HSZ under vigorous agitation. The volume of the salt solution added was chosen so that the degree of proton exchange for metal cations was 95–100%. The modification by the MM method was performed by adding the oxide of an appropriate metal to HSZ, with subsequent mechanochemical activation in a ball mill at 293 K for 24 h. Thus, Zr-HSZ and Hf-HSZ were obtained by the IE method, and 5% TiO_2–HSZ, 5% ZrO_2–HSZ, and 5 wt % HfO_2–HSZ, by that of mechanical mixing; Ti-HSZ was produced by impregnation to saturate the moisture capacity.

As a raw material for joint conversion we used a gas mixture consisting (wt %) of methane (0.5), propane (80), and butane (19.5) and methanol. The catalytic conversion of lower alkanes and methanol was performed under atmospheric pressure, with the reaction temperature varied from 723 to 873 K. Methanol and the alkanes were fed at space velocities of 1.4 and 240 h^{-1}, respectively.

The catalytic properties of the modified zeolites are presented in Table 1.

The modification technique strongly affects the distribution of the products of joint conversion and the conversion of the raw material. As seen in Table 1, raising the reaction temperature from 773 to 873 K favorably affects the conversion of the starting alkanes for samples modified both by IE and by MM. For MHSZ produced by the IE technique, raising the temperature in the above range leads to an increase in the conversion γ from 34 to 63%. Similarly to the conversion of the starting substances, the selectivity α with respect to alkenes increases with temperature from 3.7 to 28.9 wt %; accordingly, the value of α for aromatic hydrocarbons, on the whole, falls from 13.6 to 4.5 wt %.

The maximum values of γ and α for alkenes are observed for MHSZ modified by IE in the case of Zr-HSZ: 63 and 28.9%, respectively.

For samples modified by MM (Table 1), raising the temperature from 773 to 873 K favors a more pronounced rise in γ of the starting alkanes, from 40 to 73%, compared both with the initial HSZ and with zeolites modified by IE. The selectivity of these catalysts with respect to alkenes increases with temperature to a considerably greater extent, from 12.1 to 36.2 wt %. The selectivity with respect to alkenes is the highest at 873 K for catalysts modified by the MM method (wt %): 33.4 for 5% TiO_2–HSZ, 36.2 for 5%

ZrO_2–HSZ, and 23.3 for 5% HfO_2–HSZ, which markedly exceeds the selectivity of the initial zeolite and samples modified by IE. A specific feature of the joint conversion of methanol and lower alkanes C_3–C_4 on MHSZ is the low content of benzene in the products (0.5–1.5 wt %), compared to alkylbenzenes, i.e., the role of methanol as an alkylating additive is apparent.

The difference in the catalytic activity between MHSZs obtained in different ways is due to the fact that acid centers differing both in concentration and strength and in nature are formed on the catalyst surface, depending on the modification technique. The acid parameters of the surface of the samples studied were evaluated by temperature-programmed desorption (TPD) of ammonia. The TPD spectra of all

Table 2. Acid parameters of modified HSZ

* Total amount of type I and type II acid centers.

the samples show two types (I, II) of acid centers, with the low-temperature form identified [2–4] as weak type I acid centers with predominance of Lewis centers (LCs) and the high-temperature peak corresponding to strong type II acid centers mostly represented by Brønsted centers (BCs).

The amount of ammonia desorbed in the temperature ranges mentioned above, which can serve as a measure of the number of both types of centers, and the positions of peaks in the TPD spectra of ammonia, which indirectly characterize the strength of the acid centers present on the surface of MHSZ, are listed in Table 2.

Introduction of modifying elements into the initial zeolite changes to a certain extent the acid properties of its surface, depending on the modification technique. As seen in Table 2, introduction of Zr and Hf into the initial zeolite by IE leads to a decrease in the temperatures of peak I and II by 30 and 15°C, respectively. Also, the concentration of type II centers, to which BCs are predominantly attributed, decreases. The decrease in the temperatures of the peaks for the samples produced by IE indicates that the strengths of acid centers of both types decrease, which is also confirmed by the lower activation energy of desorption, E_a, as compared to the initial HSZ-50. For the samples modified by MM method, a significant increase in the concentration of type II acid centers is observed, by a factor of approximately 1.5 as compared to the catalysts produced by IE; the increase in E_a of desorption also indicates that the strength of these acid centers becomes higher. The concentration of type I centers (LCs) remains virtually the same as that for the initial zeolite, but the strength of these centers is somewhat higher than that for the samples modified by IE.

It is known [5] that a polyvalent modifier introduced by IE is incorporated in the cationic positions of the initial HSZ in the form of $MO(OH)^+$ species. Isolated $MO(OH)^+$ species have a coordination sphere of a larger radius and create steric hindrance, with the result that the acid centers become less accessible.

In explaining the enhanced surface acidity and high catalytic activity exhibited in alkene formation by samples modified by MM, it was suggested that isomorphic substitution of aluminum by a modifying element occurs in the mechanochemical activation in the solid phase. As a consequence, the concentration of LCs remains virtually the same as that in the initial zeolite, but their strength somewhat decreases. It may be suggested, based on the hypothesis that dehydrogenation of alkanes involves strong LCs incorporating ions of the modifying metals [6, 7] and on the experimental data obtained, that, for catalysts modified by MM, the strength of LCs is the optimal strength for formation of alkenes without their further aromatization.

CONCLUSIONS

(1) With modified high-silica zeolites used in joint conversion of methanol and lower alkanes (C_3–C_4), the chemical nature of the modifying agent and the method of modification strongly affect the distribution of conversion products.

(2) The active centers present on the surface of zeolites modified by ion exchange and mechanical mixing differ in chemical nature.

(3) The maximum selectivity with respect to alkenes is observed for a zirconium-containing zeolite catalyst modified by mechanical mixing. The resulting concentration and strength of various acid centers are optimal for formation of olefins.

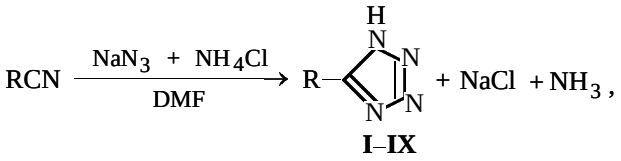
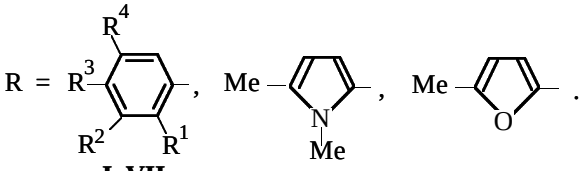
Abstract—Acetylation of 5-aryltetrazoles, 5-(5-methyl-2-furyl)tetrazole, and 5-(1,5-dimethyl-2-pyrrolyl)tetrazole with chloroacetyl chloride was studied.



1,3,4-Oxadiazoles are key fragments of various drugs, from antiviral agents to antidepressants; they are used as organic scintillators and are components of specialty polymerizing formulations, etc. [1].

The goal of this study is the development of a one-pot procedure for preparing 5-aryl-2-chloromethyl-1,3,4-oxadiazoles and previously unknown 2-chloromethyl-5-(5-methyl-2-furyl)- and 2-chloromethyl-5-(1,5-dimethyl-2-pyrrolyl)-1,3,4-oxadiazoles from appropriate tetrazole derivatives. These 1,3,4-oxadiazoles are of interest as biologically active substances and reagents for further fine organic synthesis. Similarly to other 1,3,4-oxadiazoles [2], they can be involved in the peptide synthesis by the subsequent reactions with amino acids.



2,5-Disubstituted 1,3,4-oxadiazoles of various structures can be prepared by several procedures. The starting compounds can be carboxylic acids and hydrazine; they are converted into diacylhydrazides via several intermediates. The cyclodehydration of diacylhydrazides under the action of $POCl_3$ yields 1,3,4-oxadiazoles; these compounds can also be prepared by cyclodehydration of diaroylhydrazines and diacylhydrazines under the action of various dehydrating agents (organic acid anhydrides, PCl_5, H_2SO_4 [2–5]).

A procedure developed in [6] for preparing 2,5-diaryl-1,3,4-diazoles by the reactions of tetrazoles with benzoyl chlorides in *o*-xylene or toluene on heating was applied here to the synthesis of 2-chloromethyl-5-aryl-, 2-chloromethyl-5-(5-methyl-2-furyl)-, and 2-chloromethyl-5-(1,5-dimethyl-2-pyrrolyl)-1,3,4-oxadiazoles from tetrazoles and chloroacetyl chloride.

Tetrazoles are prepared starting from aromatic and heterocyclic nitriles [7]. Their azidation with NaN_3 is performed in the presence of NH_4Cl in DMF at 110–120°C. Following the procedures from [8–10], we prepared 5-phenyltetrazole **I**, 5-(2-chlorophenyl)tetrazole **II**, 5-(2-nitrophenyl)tetrazole **III**, 5-(2-ethoxyphenyl)tetrazole **IV**, 5-(3-methylphenyl)tetrazole **V**, 5-(2,4-dimethoxyphenyl)tetrazole **VI**, 5-(3,4,5-trimethoxyphenyl)tetrazole **VII**, and also previously unknown 5-(1,5-dimethyl-2-pyrrolyl)tetrazole **VIII** and 5-(5-methyl-2-furyl)tetrazole **IX**. The reaction conditions, yields, melting points, and analytical data for **VIII**, **IX**, and products of their further transformations (**X**–**XVIII**) are given in Table 1, and the ^1H NMR data, in Table 2.

I–**IX**

$R^1 = R^2 = R^3 = R^4 = H$ (**X**); R^1 = Cl, $R^2 = R^3 = R^4 =$ H (**XI**); $R^1 = NO_2$, $R^2 = R^3 = R^4 =$ H (**XII**); $R^1 =$ OEt, $R^2 = R^3 = R^4 =$ H (**XIII**); R^2 = Me, $R^1 = R^3 = R^4 =$ H (**XIV**); $R^1 = R^3 =$ OMe, $R^2 = R^4 =$ H (**XV**); $R^2 = R^3 = R^4 =$ OMe (**XVI**).

1,3,4-Oxadiazoles **X**–**XVIII** were prepared in 80–93% by a one-pot procedure involving the reaction of **I**–**IX** with chloroacetyl chloride in *o*-xylene at 110–120°C for 3–10 h. The structures of **VIII**–**XVIII** were confirmed by elemental analysis and ^{1}H NMR spectroscopy. The melting points given in the literature for **X**–**XII** and **XVI** are different and depend on the synthesis procedure. We determined the melting points of **VIII**–**XVIII** (Table 1) on a PTP device at a heating rate of 1 deg min^{-1}.

EXPERIMENTAL

The ^{1}H NMR spectra were recorded on a DPX-300 spectrometer (300 MHz), solvent DMSO-d_6, internal reference TMS. The elemental analysis was performed on a Hewlett–Packard automatic C, H, N analyzer. The melting points were determined on a PTP device. The TLC analyses were performed on Silufol UV-254 plates (eluent $CHCl_3$–methanol, 90/10 by volume); development by UV light or with iodine vapor.

5-(1,5-Dimethyl-2-pyrrolyl)tetrazole VIII and 5-(5-methyl-2-furyl)tetrazole IX. To a solution of 3.6 g of NaN_3 in 25 ml of DMF, we added 5 g of 1,5-dimethyl-2-cyanopyrrole or 2-cyano-5-methylfuran and 3 g of NH_4Cl. The mixture was cooled, and excess DMF was distilled off at 20 mm Hg. The remaining solution was slowly poured into water with cooling and stirring and then was acidified with 10% HCl. The precipitate thus formed was filtered off, dried in air, and recrystallized from ethanol.

5-Aryl-2-chloromethyl-1,3,4-oxadiazoles X–XVI, 2-chloromethyl-5-(1,5-dimethyl-2-pyrrolyl)-1,3,4-oxadiazole XVII, and 2-chloromethyl-5-(5-methyl-2-furyl)-1,3,4-oxadiazole XVIII. A 5-g portion of **I**–**IX** was dissolved in 30 ml of *o*-xylene. The solution was heated with stirring to 30–40°C, and 3.6 g of chloroacetyl chloride in 10 ml of *o*-xylene was added. The mixture was cooled, and excess *o*-xylene was distilled off at 20 mm Hg. The remaining solution was slowly poured with cooling into 10% NaOH. The precipitate thus formed was filtered off, dried in air, and recrystallized from ethanol.

CONCLUSION

5-Aryl- and 5-heteryltetrazoles react with chloroacetyl chloride in *o*-xylene to form 5-aryl-2-chloromethyl-1,3,4-oxadiazoles, 2-chloromethyl-5-(1,5-dimethyl-2-pyrrolyl)-1,3,4-oxadiazole, and 2-chloromethyl-5-(5-methyl-2-furyl)-1,3,4-oxadiazole in 80–93% yields.

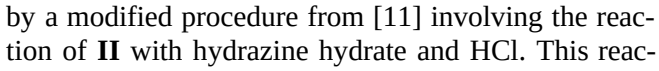
Abstract—Acylation of 3,5-diamino-1,2,4-triazole with anhydrides and chlorides of alkane- and arenecarboxylic acids and arenesulfonyl chlorides in aqueous solutions and under phase-transfer catalysis was studied.

Acyl, aroyl, and arenesulfonyl derivatives of 3,5-diamino-1,2,4-triazoles are used as intermediates for preparing nitro and azido derivatives of 1,2,4-triazoles [1–3], and also drugs and herbicides [4–7]. The most general route to acyl derivatives of 3,5-diamino-1,2,4-triazole is acylation of 3,5-diamino-1,2,4-triazole **I**, which can yield mono-, di-, and triacetyl derivatives depending on the reaction conditions [1, 4, 8–10]. However, triazole **I** is expensive, despite the fact that it is prepared from available substances: dicyanodiamide **II** and hydrazine [11]. The high cost of **I** is due to its difficult isolation from reaction mixtures. Our previous studies [12, 13] showed that some derivatives of **I** can be prepared from dicyanodiamide and hydrazine without isolation of **I**.

In this study we developed a procedure for preparing 1-acyl-, 1-aroyl-, and 1-arenesulfonyl-3,5-diamino-1,2,4-triazoles by acylation of products of the reaction of nitrile **II** with hydrazine without isolation of **I**:



where R = Ac (**III**), EtCO (**IV**), PrCO (**V**), BuCO (**VI**), PhCO (**VII**), $PhSO_2$ (**VIII**), *p*-$MeC_6H_4SO_2$ (**IX**), *p*-$ClC_6H_4SO_2$ (**X**).

The reaction mixtures for acylation were prepared by a modified procedure from [11] involving the reaction of **II** with hydrazine hydrate and HCl. This reaction gave hydrochloride of **I** in 92–97% yield (determined according to [14]), with NH_4Cl as by-product.

Initially we studied acylation of the reaction mixtures with acetic anhydride, since 1-acetyl-3,5-diamino-1,2,4-triazole **III** is widely used as a reagent for preparing various 1,2,4-triazole derivatives, and, among the existing routes to **III**, the most convenient is acylation of **I** with acetic anhydride in aqueous solution [1].

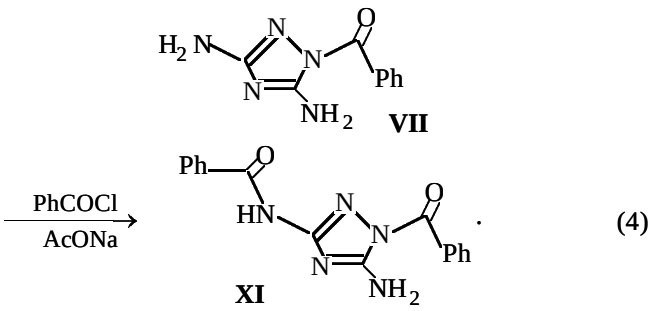
Since triazole **I** occurs in the reaction mixture in the protonated form (pH 2–3), which does not react with acylating agents, the mixture should be preliminarily alkalized to convert the salt of **I** into the free base. However, for the acylation to be selective, ammonia should remain in the salt form. According to published data, for the equilibrium $\mathbf{I}\cdot H^+ \rightleftarrows \mathbf{I} + H^+$ $pK_a = 4.43$ [15], and for $NH_4^+ \rightleftarrows NH_3 + H^+$, $pK_a = 9.27$ [16]. Hence, pH 6.4–7.3 is an optimum at which the salt $\mathbf{I}\cdot H^+$ is virtually fully deprotonated but ammonia remains in the salt form. As bases in acylation with acetic anhydride, we used NaOH, Na_2CO_3, $NaHCO_3$, and sodium acetate.

At the equimolar ratio of **I** and base (pH 4.6–8.4), the major product of the reaction with acetic anhydride is **III**; its yield is virtually independent of particular base. Other acyl derivatives of **I** were not detected in the reaction mixtures. With sodium carbonate, hydrocarbonate, or acetate taken in excess, the reaction selectivity and yield of **III** remain unchanged. With excess NaOH (pH > 10), the yield of **III** decreases to 10–15%, because of the hydrolysis of ammonium chloride and competing reaction of the more nucleophilic ammonia with acetic anhydride:

1070-4272/05/7805-0776 © 2005 Pleiades Publishing, Inc.

Free ammonia can also cause ammonolysis of the target product:

$$\mathbf{III} + NH_3 \longrightarrow \mathbf{I} + AcNH_2. \quad (3)$$



As the molar ratio $\mathbf{I} : Ac_2O$ is changed from 1 : 1 to 1 : (1.25–1.5), the yield of **III** increases from 62–71 to 78–80% (Table 1); larger excess of Ac_2O does not cause a further increase in the yield of **III**.

It is noteworthy that heating does not appreciably affect the selectivity of acylation with acetic anhydride and the yield of the target product (Table 2). In contrast to the majority of *N*-acyl azole derivatives, compound **III** shows enhanced resistance to hydrolysis, which may be due to the electron-donor effect of the 3,5-amino groups.

Thus, it is advisable to perform acylation with acetic anhydride at the molar ratio $\mathbf{I} : \text{base} : Ac_2O$ = 1 : (1–1.2) : 1.25. As in the range 0–50°C the acylation selectivity varies insignificantly, all the steps can be performed at the same temperature as one-pot synthesis. The use of NaOH is not appropriate, because excess NaOH can cause hydrolysis of NH_4Cl and decrease the reaction selectivity because of competing ammonolysis of the acylating agent.

Compounds **IV**–**VII** were prepared under similar conditions using appropriate anhydrides (Table 3). Compound **VII** is isolated from the reaction mixture together with benzoic acid. Benzoic acid can be readily removed by recrystallization from ethanol; yield of purified compound **VII** 35–40%.

With carboxylic acid chlorides and arenesulfonyl chlorides as acylating agents, it is necessary to introduce an additional amount of a base to bind the released HCl. Acylation with aliphatic acyl chlorides resulted only in their hydrolysis. Acylation with benzoyl chloride, which is more resistant to hydrolysis, at 20°C in the presence of sodium acetate gave a mixture of products consisting, according to liquid chromatography, of 14% **VII**, 42% 5-amino-3-benzamido-1-benzoyl-1,2,4-triazole **XI**, and 44% benzoic acid. Compound **XI** is apparently formed by acylation of **VII**:

(4)

Table 1. Yield of **III** at 20°C and pH 4.6–8.4

Molar ratio $\mathbf{I} : Ac_2O$	Yield, %	Molar ratio $\mathbf{I} : Ac_2O$	Yield, %
1 : 1.0	62	1 : 1.5	80
1 : 1.1	71	1 : 1.75	80
1 : 1.25	78	1 : 2.0	75

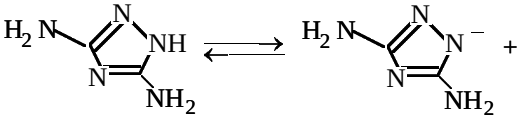


Table 2. Yield of **III** at the molar ratio $\mathbf{I} : Na_2CO_3 : Ac_2O$ = 1 : 1 : 1.25

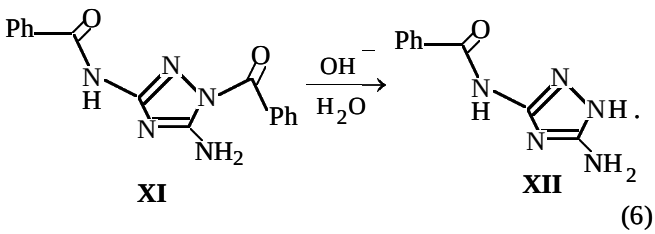
T, °C	Yield, %	*T*, °C	Yield, %
0	79	50	77
30	78	70	72
40	77	90	68

Apparently, the rate of formation of **VII** is comparable with the rate of its subsequent acylation with benzoyl chloride into **XI**. We failed to prepare **VII** selectively even at a twofold excess of **I** relative to benzoyl chloride. This may be due to the fact that benzoyl chloride and compound **I** occur in different phases. Benzoyl chloride is poorly soluble in water, whereas triazole **I** is very well soluble; therefore, compound **VII** is mainly formed at the phase boundary. After being formed, compound **VII** dissolves in benzoyl chloride and undergoes further acylation.

The reaction with benzenesulfonyl chloride under the same conditions yielded compound **VIII** but was very slow; the yield of the target product did not exceed 35% in 72 h. Crystalline *p*-toluenesulfonyl chloride and *p*-chlorobenzenesulfonyl chloride under the same conditions gave **IX** and **X**; their yield in 3 days did not exceed 10%, and the major isolated compounds were unchanged arenesulfonyl chlorides.

We suggested that the selectivity of acylation with carboxylic acid chlorides and arenesulfonyl chlorides could be increased by converting triazole **I** into the anion and performing the reaction with phase-transfer catalysis. The anion should be considerably more nucleophilic and reactive as compared to the neutral molecule. For equilibrium (5), pK_a = 12.12 in water at 20°C [17]. Hence, at pH > 14.12, compound **I** in water occurs in the anionic form:

(5)



To provide the required basicity, no less than 3 mol of NaOH per mole of **II** should be added to the reac-

Table 3. Synthesis conditions, yields, and properties of acylation products **III**–**XII** (molar ratio **I** : acylating agent = 1 : 1)

[1] Compounds **III**–**VII** and **XI** were crystallized from ethanol; **VIII**–**X** and **XII**, from ethanol–DMF. [2] Additional 2 mol of NaOH was introduced per mole of **II**. [3] mp 228–230°C [9]. [4] According to liquid chromatography. [5] mp 225°C [18].

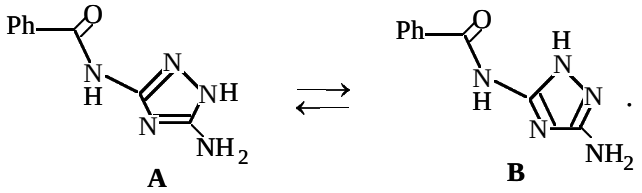
tion mixture [see scheme (1)]. Since NH_4Cl is fully hydrolyzed under these conditions, the released ammonia was removed by boiling the reaction mixture. The subsequent acylation with acetyl and butyryl chlorides in a CH_2Cl_2–water mixture in the presence of benzyltriethylammonium chloride yielded only 1-acyl derivatives **III** and **V**, and the reaction with benzoyl chloride, along with the major product **VII**, yielded also **XI** or 5-amino-3-benzamido-1,2,4-triazole **XII** depending on the molar ratio **I** : NaOH (Table 3, method *b*). Compound **XII** is apparently formed by hydrolysis of **XI**:

XI **XII** (6)

In particular, at an equimolar ratio of triazole **I** to NaOH, compound **XI** was isolated in 15% yield

(Table 3), and compound **XII** was not detected. At a 20% excess of alkali, compound **XI** was absent in the reaction products, and compound **XII** was isolated from the aqueous phase in 12% yield. Hence, compound **VII** formed under the conditions of phase-transfer catalysis is subsequently "slowly" acylated to dibenzoyl derivative **XI**, which is hydrolyzed to product **XII** with excess alkali. Probably, the hydrolysis of **XI** is promoted by an acidic proton of the benzoylamino group, responsible for the dissociation of **XI** in an alkali solution with the dissolution of **XI** in the aqueous phase and its subsequent hydrolysis.

The low yields of the acetyl (**III**) and butyryl (**V**) derivatives and the lack of acylamino derivatives in the reaction products may be due to the high rate of hydrolysis of aliphatic acyl chlorides.



Acylation of **I** under the phase-transfer conditions is also an efficient route to 1-arenesulfonyl-3,5-diamino-1,2,4-triazoles. Under these conditions, from appropriate arenesulfonyl chlorides, we prepared compounds **VIII**–**X** in 50–70% yields (Table 3). The main substance content in the crude products was no less than 90% according to the ^{1}H NMR data.

The composition and structure of the compounds synthesized were confirmed by elemental analysis (Table 3) and by IR, UV, and ^{1}H NMR spectroscopy.

In the IR spectra of acyl derivatives **III**–**VII** and **XI**, the stretching vibration bands of the carbonyl group bonded to the nitrogen atom of the triazole ring are manifested at 1680–1710 cm^{-1}, whereas the vibration frequencies of the "amide" carbonyl group in **XI** and **XII** are lower: 1650–1660 cm^{-1}. The spectra of arenesulfonyl chlorides **VIII**–**X** contain a strong absorption band at 1150–1160 cm^{-1}, which was assigned to the symmetric vibrations of the SO_2 group.

The UV spectra of **III**–**VII** are similar to the spectra of 5-amino-1-acyl-1,2,4-triazoles reported in [9] and exhibit two maxima at 217–230 and 273–290 nm. The spectra of 1-arenesulfonyl-3,5-diamino-1,2,4-triazoles **VIII**–**X** are also characterized by two maxima in the ranges 220–234 and 261–269 mn. The UV spectrum of 5-amino-3-benzamido-1,2,4-triazole **XII** differs from that of isomeric 1-benzoyl-3,5-diamino-1,2,4-triazole **VII** by the absence of the long-wave maximum at about 290 nm and the presence of a shoulder at about 253 nm; this is consistent with the data for 3-R-5-acylamino-1,2,4-triazoles [9].

The NMR spectra of 1-acyl- and 1-arenesulfonyl-3,5-diamino-1,2,4-triazoles **III**–**X** contain two singlets from protons of amino groups. The 3-NH_2 protons give a signal at 5.36–5.65 ppm, and the 5-NH_2 protons, a signal at 7.32–7.55 ppm for acyl derivatives **III**–**VII** and at 6.90–6.97 ppm for arenesulfonyl derivatives **VIII**–**X**. The spectrum of **XI** does not contain the 3-NH_2 signal but contains a singlet of the amide proton at 10.67 ppm; the 5-NH_2 signal is shifted downfield relative to **VII** owing to the electron-withdrawing effect of the additional benzoyl group. According to the NMR spectrum, compound **XII** in DMSO occurs in the form of tautomers **A** (major) and **B**:

A **B**

EXPERIMENTAL

The ^{1}H NMR spectra were recorded on a Varian Unity-300 spectrometer (300 MHz) in DMSO-d_6, internal reference TMS. The IR spectra were recorded on a Specord IR-75 spectrometer from mulls in mineral oil. The UV spectra (aqueous solutions) were taken on an SF-26 spectrophotometer. High-performance liquid chromatography was performed on a Milikhrom chromatograph equipped with a UV detector and a 60 × 3-mm column (sorbent Silasorb C_{18}, 5 μm, mobile phase methanol, elution rate 5 μl min^{-1}, detection at 230 nm).

1-Acyl- and 1-arenesulfonyl-3,5-diamino-1,2,4-triazoles III–X and 5-amino-3-benzamido-1-benzoyl-1,2,4-triazole XI. (*a*) To 0.0333 mol of hydrazine hydrate (55% solution), we added dropwise with stirring at a temperature not exceeding 50°C 0.0666 mol of HCl (30% solution) and 0.0333 mol of **II** over a period of 10–15 min; the mixture was heated for 1 h at 50°C. Then the required amount of a base was added, and the acylating agent was added dropwise with stirring at the required temperature (Tables 1–3). The mixture was stirred for a period indicated in Table 3; the precipitate was filtered off, washed with water, dried, and analyzed by ^{1}H NMR and HPLC. The precipitates of **III**–**VI**, according to ^{1}H NMR, contained no less than 90% main substance, and compound **VII**, according to HPLC, contained ~50% benzoic acid. Compounds **III**–**VII** were purified by recrystallization from ethanol. To separate mixtures from acylation with benzoyl chloride, the precipitate was dissolved in 60 ml of boiling ethanol, and the solution was cooled. The precipitate of **XI** was filtered off, recrystallized, and analyzed. The mother liquor after the separation of **XI** was evaporated to a volume

of 15 ml and cooled; the precipitate of **VII** was recrystallized and analyzed. Compounds **VIII**–**X** were washed with chloroform to separate unchanged arenesulfonyl chloride, recrystallized, and analyzed.

(*b*) To the solution from the reaction of hydrazine hydrate, HCl, and compound **II** by method *a*, we added the required amount of NaOH (Table 3) and boiled until the evolution of NH_3 was complete (30–40 min); water was added to compensate for the evaporation. The mixture was diluted with distilled water to a volume of 12.5 ml and cooled; 0.003 mol of benzyltriethylammonium chloride and a solution of the acylating agent in 6 ml of CH_2Cl_2 were added. The mixture was stirred for 20 min; the precipitate of the target product was filtered off, washed successively with water and methylene chloride, dried, and analyzed. Compounds **III**–**XI** were purified similarly to method *a*.

5-Amino-3-benzamido-1,2,4-triazole XII. (*a*) The reaction mixture after the separation of compound **VII** prepared by method *b* at the molar ratio **I** : NaOH = 1 : 1.2 was neutralized with 10% HCl to pH 7–8. The precipiptate thus formed was filtered off, washed with 5 ml of boiling ethanol to separate benzoic acid, and crystallized from DMF–ethanol.

Compound **XII** was also prepared in 86% yield by independent synthesis: hydrolysis of 0.001 ml of **XI** in 10 ml of 1 M NaOH at 5°C for 2 h.

CONCLUSIONS

(1) One-pot procedures were developed for acylation and arenesulfonylation of 3,5-diamino-1,2,4-triazole in reaction mixtures from the reaction of dicyanodiamide with hydrazine.

(2) It is advisable to prepare 1-acyl-3,5-diamino-1,2,4-triazoles by acylation of 3,5-diamino-1,2,4-triazole with carboxylic acid anhydrides in aqueous solution (70–80% yields), and 1-arenesulfonyl-3,5-diamino-1,2,4-triazoles, by acylation of 3,5-diamino-1,2,4-triazole with arenesulfonyl chlorides under conditions of phase-transfer catalysis (50–70% yields).

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis and Antioxidative Activity of *N*,*N*-Dialkyl-ω-[4-hydroxy(methoxy)aryl]alkylamines and Their *N*-Oxides

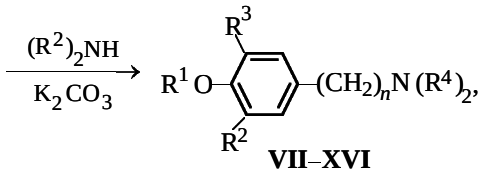
Received September 1, 2004; in final form, January 2005

Abstract—Aminoalkylphenols of various structures were prepared by reactions of ω-[4-hydroxy(methoxy)-aryl]haloalkanes with dialkylamines. The corresponding *N*-oxides were prepared by oxidation of aminoalkylphenols with hydrogen peroxide and cumene hydroperoxide. The inhibiting activities of these compounds in a model reaction of thermal autooxidation of lard were compared.



Aminoalkylphenols containing a phenolic fragment and an alkylamino group are highly effective inhibitors of free-radical oxidation of various organic substrates. According to patent data [1–3], they can be used as stabilizers of polymeric materials, rubbers, lubricating oils, and diesel and jet fuels. Furthermore, aminoalkylphenols show a wide spectrum of biological activity; in particular, they exhibit antiphlogistic, antirheumatic, antiallergic, antidiabetic, and other properties [4–10]. The mechanism of the antioxidative effect of aminoalkylphenols responsible for their high performance is not yet fully elucidated; for its better understanding, it is necessary to study the structure–inhibiting activity relationship for aminoalkylphenols and to examine their oxidation products in which one of the groups responsible for the antioxidative power is inactivated.

Therefore, in this study we prepared aminoalkylphenols differing in the extent of steric shielding of the phenolic OH group, structure of the *N*-substituents, and distance between the amino group and aromatic core; also we prepared the corresponding *N*-oxides and compared the inhibiting powers of the compounds synthesized in the model reaction of thermal autooxidation of lard.

By the reaction of ω-[4-hydroxy(methoxy)aryl]-haloalkanes **I**–**VI** with dialkylamines, we prepared the corresponding alkylphenols **VII**–**XVI**:

I–**VI**

VII–**XVI**

where R^1 = H, R^2 = R^3 = *t*-Bu: *n* = 2, Hlg = Cl (**I**); *n* = 2, R^4 = Me (**VII**), Et (**VIII**); *n* = 3, Hlg = Cl (**II**); *n* = 3, R^4 = Me (**IX**), Et (**X**), Pr (**XI**); *n* = 4, Hlg = Cl (**III**); *n* = 4, R^4 = Me (**XII**), Et (**XIII**); R^1 = R^2 = H, R^3 = *t*-Bu, *n* = 3: Hlg = Cl (**IV**), R^4 = Me (**XIV**); R^1 = R^2 = R^3 = H, *n* = 3: Hlg = Br (**V**), R^4 = Me (**XV**); R^1 = Me, R^2 = R^3 = H, *n* = 3: Hlg = Br (**VI**), R^4 = Me (**XVI**).

The syntheses were performed in ampules in ethanol in the presence of K_2CO_3 at 120°C for 7 h; the molar ratio of the starting haloalkane, dialkylamine, and K_2CO_3 was 1 : 2 : 2. Yields of **VII**–**XVI** 60–93%.

It is known [11–14] that tertiary aliphatic amines react with peroxy compounds to form *N*-oxides. We performed the oxidation of aminoalkylphenols **IX**–**XI** with hydrogen peroxide and cumene hydroperoxide in 2-propanol at 60°C for 3 h and obtained the corre-

* R = 3,5-di-*tert*-butyl-4-hydroxyphenyl, R' = 3-*tert*-butyl-4-hydroxyphenyl, and R'' = 4-hydroxyphenyl.

sponding *N*-oxides **XVII**–**XIX** in 43–90% yields:

IX–**XI**

XVII–**XIX**

where X = H, $PhC(Me)_2$; R = Me (**XVII**), Et (**XVIII**), Pr (**XIX**).

The compositions and structures of aminoalkylphenols **VII**–**XVI** and their *N*-oxides **XVII**–**XIX** were confirmed by elemental analysis and spectroscopy. In the ^1H NMR spectra of *N*-oxides **XVII**–**XIX**, compared to the corresponding aminoalkylphenols **IX**–**XI**, the signals of the methylene protons of the *p*-alkyl substituent are shifted downfield, which suggests an increase in the polarizing power of the N-containing fragment, i.e., its oxidation. The IR spectra of **XVII**–**XIX** contain absorption bands at 950–970 cm^{-1}, characteristic of the N–O stretching vibrations. These bands are absent in the spectra of the corresponding aminoalkylphenols **IX**–**XI**.

A search in the STN International database showed that compounds **VIII**, **XI**–**XIV**, and **XVII**–**XIX** were unknown previously. Aminoalkylphenol **VII** is mentioned in [6] without spectral characteristics, and amines **XV** and **XVI** are reported in [8] only as hydrochlorides.

The antioxidative activity (AOA) of aminoalkylphenols **VII**–**XV** and their *N*-oxides **XVII**–**XIX** was evaluated from their inhibiting effect on thermal autooxidation of lard. As references we used commercial inhibitors 2,6-di-*tert*-butyl-4-methylphenol (Ionol) and *N*,*N*-dimethyl(3,5-di-*tert*-butyl-4-hydroxybenzyl)amine **XX**, and also a 1 : 1 synergistic mixture of Ionol and *N*,*N*-dimethyldodecylamine (DMDA).

We found that di-*tert*-butyl-substituted aminoalkylphenols **VII**–**XIII** are effective inhibitors of lard oxidation (see table); in their antioxidative power they appreciably surpass the commercial antioxidants and the Ionol–DMDA mixture.

A previous study of the antiradical activity of 2,6-di-*tert*-butyl-substituted aminoalkylphenols **VII**, **IX**, and **XX** in a model reaction of initiated oxidation of methyl oleate in chlorobenzene at 60°C showed that these compounds are highly reactive toward peroxy radicals [15]. The rate constants k_7 of their reaction with peroxy radicals

$$PhOH + ROO^{\bullet} \longrightarrow PhO^{\bullet} + ROOH \qquad (1)$$

were similar to those characteristic of Ionol. This fact suggests that the higher inhibiting power of aminoalkylphenols **VII**–**XIII**, compared to Ionol, in autooxidation of lard is due to the bifunctional mechanism of theit antioxidative effect, namely, to a combination of the antiradical activity of the phenolic group and antioxidative activity of the alkylamino group. The significance of the contribution of the alkylamino group to AOA of aminoalkylphenols is also confirmed by the fact that the corresponding *N*-oxides **XVII**–**XIX** are comparable with, or even inferior to Ionol as inhibitors of lard oxidation. The low AOA of benzylamino derivative **XX** compared to aminoalkylphenols **VII**–**XIII** in oxidation of lard at 130°C is apparently caused by the thermal instability of **XX** [16].

It is known [17, 18] that aliphatic amines in mixtures with phenolic antioxidants can act as synergistic agents. The synergistic effect is usually evaluated by the induction period and characterized by $\Delta\tau_{syn}$ [19]:

$$\Delta\tau_{syn} = \tau_{1,2} - (\tau_1 + \tau_2),$$

where $\tau_{1,2}$ is the induction period in the presence of two inhibitors; τ_1 and τ_2, induction periods in the presence of individual inhibitors.

In the experiments on lard oxidation, the nonadditive effect of coinhibitors was revealed for the system Ionol–DMDA; the synergistic effect, calculated by the formula

$$\Delta\tau_{syn} = (\tau_{PhOH+DMDA} - \tau_0) - (\tau_{DMDA} + \tau_{PhOH} - 2\tau_0),$$

where τ_0 is the induction period of the noninhibited oxidation of lard; τ_{DMDA} and τ_{PhOH}, induction periods in the presence of DMDA and Ionol, respectively; and $\tau_{PhOH+DMDA}$, induction period in the presence of the Ionol–DMDA mixture, amounted to 33 min. For 2,6-di-*tert*-butyl-substituted aminoalkylphenols **VII**–**XIII**, the synergistic effect was more pronounced, and $\Delta\tau_{syn}$, calculated as

$$\Delta\tau_{syn} = (\tau_{AAP} - \tau_0) - (\tau_{DMDA} + \tau_{PhOH} - 2\tau_0),$$

where τ_{AAP} is the induction period of lard oxidation in the presence of aminoalkylphenols, ranged from 112 to 270 min. Thus, we can state that the high antioxidative acitivity of aminoalkylphenols in lard oxidation is associated not only with the bifunctional mechanism of their antioxidative effect but also with the pronounced synergistic effect which, most likely, is of intramolecular origin and is due to structural features of these molecules.

The occurrence of intramolecular synergism in bifunctional inhibitors, in particular, in sulfur-containing derivatives of sterically hindered phenols, was repeatedly discussed in [20–22]; however, its origin was not elucidated. The intramolecular synergism may be due to favorable steric arrangement of the phenolic and sulfur-containing fragments, allowing the hydroperoxide formed by reaction (1) to be deactivated with the sulfur-containing fragment without escaping into the bulk of the substrate [22]. A similar pattern can be expected for aminoalkylphenols.

Since the extent of the intramolecular synergism can depend on the distance between the alkylamino group and aromatic core, the difference in the AOA of aminoalkylphenols **VII**–**X**, **XII**, **XIII**, and **XX** containing different number of carbon atoms in the *p*-alkyl chain becomes quite understandable. In the series of *N,N*-dimethyl- and diethyl-substituted aminoalkylphenols, in the most effective inhibitors of lard oxidation the alkylamino group was separated from the aromatic core by four carbon atoms. Apparently, in this case the mutual arrangement of the phenolic and alkylamino groups is the most favorable for the intramolecular synergism.

The antioxidative activity of aminoalkylphenols also strongly depended on the structure of *N*-substituents and extent of steric shielding of the phenolic OH group. In going from *N,N*-dimethyl-substituted amine **IX** to its diethyl (**X**) and dipropyl (**XI**) analogs, the inhibiting activity decreased.

Aminoalkylphenols differing in the extent of steric shielding of the phenolic OH group can be ranked in the following order with respect to the capability to inhibit lard oxidation: **IX** > **XIV** > **XV**. A decrease in AOA of aminoalkylphenols in this series corresponds to an increase in the reactivity of the corresponding phenoxy radicals in the reaction

$$PhO^{\bullet} + RH \longrightarrow PhOH + R^{\bullet}. \qquad (2)$$

In particular, according to the existing estimates, *o*-unsubstituted phenoxyls are 10^3–10^4 times (at 60°C) more active than 2,6-di-*tert*-butyl-substituted phenoxy radicals [23]. Compound **XV** at the *o*-positions contains no bulky *tert*-butyl substituents sterically hindering reaction (2), which accounts for the lowest AOA of this compound in the examined series.

EXPERIMENTAL

The ^{1}H NMR spectra were recorded on a Bruker spectrometer (500 MHz), solvents $CDCl_3$ and CD_3OD, internal reference TMS; the IR spectra were taken on a Specord M80 spectrometer in $CHCl_3$. The melting points were determined on a PTP device. The starting ω-[4-hydroxy(methoxy)aryl]haloalkanes **I**–**VI** were prepared as described previously [24], and *N,N*-dimethyl(3,5-di-*tert*-butyl-4-hydroxybenzyl)amine **XX**, by the procedure described in [3].

***N,N*-Dimethyl-2-(3,5-di-*tert*-butyl-4-hydroxyphenyl)ethylamine VII.** A 50-ml ampule was charged with 5.0 g (18.6 mmol) of chloride **I**, 5.1 g of dimethylamine solution (37.2 mmol), 5.1 g (37.2 mmol) of K_2CO_3, and 10 ml of ethanol. The ampule was sealed, placed in a thermostat equipped with a shaker, and heated for 7 h at 120°C. After cooling, the ampule was opened, and the reaction mixture was treated with alkali and extracted with toluene. The extract was washed with water and dried over Na_2SO_4; the solvent was distilled off, and the residue was distilled in a vacuum. Yield of amine **VII** 4.0 g (78%), bp 140–142°C (1 mm Hg), mp 84–85°C. ^{1}H NMR spectrum, δ, ppm: 1.44 s (18H, *t*-Bu), 2.32 s [6H, $N(CH_3)_2$], 2.55 m (2H, CH_2N), 2.69 m (2H, $ArCH_2$), 4.91 s (1H, OH), 6.99 s (2H, H_{arom}). ***N,N*-Dipropyl-3-(3,5-di-*tert*-butyl-4-hydroxyphenyl)propylamine *N*-oxide XIX was prepared similarly by oxidation of 1.0 g (2.9 mmol) of amine XI** with 0.35 ml of hydrogen peroxide solution (4.3 mmol). Yield 0.8 g (80%), mp 105°C. ^{1}H NMR spectrum ($CDCl_3$), δ, ppm: 0.92 t [6H, $N(CH_2CH_2CH_3)_2$], 1.40 s (18H, *t*-Bu), 1.70 m [4H, $N(CH_2CH_2CH_3)_2$], 2.02 m (2H, $ArCH_2CH_2$), 2.52 t (2H, $ArCH_2$), 3.10 t [4H, $N(CH_2CH_2CH_3)_2$], 3.15 m (2H, $ArCH_2CH_2CH_2$), 5.00 s (1H, OH), 6.87 s (2H, H_{arom}). IR spectrum, $CHCl_3$, ν, cm^{-1}: 3640 (OH), 966 (NO).

Found, %: C 76.03, H 11.54, N 3.93.
$C_{23}H_{41}NO_2$.
Calculated, %: C 75.98, H 11.37, N 3.85.

We also examined the inhibiting activity of 2,6-di-*tert*-butyl-4-methylphenol (Ionol) and *N,N*-dimethyldodecylamine (Acros Organics). Oxidation of lard (Novosibirsk Meat-Canning Plant) was performed under the conditions of oxygen bubbling at 130°C in an oxidation cell similar to that described in [19]. The weight of the lard sample was 50 g, and AO concentration, 1.5 μmol per gram of lard. In the course of the oxidation, 1-g samples of the lard were taken, and the concentration of peroxy compounds was determined by iodometric titration [25]. The kinetic curves were plotted (see figure), and the induction period (time in which the lard was oxidized to a peroxide number of 0.1) was determined graphically. All the measurements were repeated 3–4 times; the mean results with the rms errors are listed in the table.

CONCLUSIONS

(1) *N,N*-Dialkyl-ω-[4-hydroxy(methoxy)aryl]alkylamines of various structures, forming structurally related series, and their *N*-oxides were prepared.

Kinetic curves of oxidation of lard. Inhibitor: (*1*) none, (*2*) amine **XX**, (*3*) Ionol, and (*4*) amine **IX**. (PN) Peroxide number and (*t*) time.

(2) The aminoalkylphenols synthesized, owing to the bifunctional mechanism of the antioxidative effect and the occurrence of intramolecular synergism, surpass in the inhibiting activity commercial antioxidants and show promise as inhibitors preventing oxidation of fat-containing products.

(3) The inhibiting activity of the aminoalkylphenols synthesized increases with an increase in the distance between the nitrogen atom and aromatic core, decrease in the length of *N*-alkyl substituents, and increase in the extent of steric shielding of the phenolic OH group; in going from aminoalkylphenols to the corresponding *N*-oxides, the antioxidative activity decreases.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Improvement of the Synthesis of 6-Bromo-5-methylimidazo[4,5-*b*]pyridine, a Stabilizer for Color Photography

Abstract—Procedures were suggested for preparing 6-bromo-5-methylimidazo[4,5-*b*]pyridine, a stabilizer for TsMF-2 color photographic moment, a component of developing pastes of the photographic kit.

Imidazo[4,5-*b*]pyridine derivatives exhibit unique antifogging properties among color photographic materials [1–8]. A particular mention should be made of 6-bromo-5-methylimidazo[4,5-*b*]pyridine **I**, which is simultaneously a stabilizer of a photographic layer and a component of developing pastes of the Polaroid color photographic kit; it provides high quality of a photographic image.

Data on the synthesis of **I** are available from two patent [1, 2]. The suggested four-step procedure involves bromination of 2-amino-6-methylpyridine **II**, nitration of the resulting 2-amino-5-bromo-6-methylpyridine **III**, reduction of 2-amino-3-nitro-6-methylpyridine **IV** to diamine **V**, and its subsequent cyclization into **I**. According to [1, 9], bromo derivative **III** is prepared by bromination of **II** with bromine in 20% sulfuric acid. An experimental check of the procedures from [1, 9] shows that the yield of **III** after purification is as low as 50–55%. It is known that amino and hydroxy derivatives of nitrogen heterocycles are smoothly halogenated in aqueous solutions or in glacial acetic acid [10, 11]:

Attempted bromination of **II** with an equivalent amount or small excess of bromine in aqueous solution at 20–70°C results in low yields of the reaction product. Bromination of **II** in glacial acetic acid at room temperature gives the product in almost quantitative yield. To bind HBr that is released in the reaction and may prevent the bromination of **II**, an equivalent amount of sodium acetate was added to the reaction mixture. The melting point of the resulting bromopyridine **III**, 73–74°C, somewhat differs from the value reported in the literature (70–71°C [1]).

A GLC analysis of this product revealed the presence of two impurities (10 wt %) along with the main substance **III**. The first impurity was unchanged substrate **II**, and the second, 2-amino-3,5-dibromo-6-methylpyridine **VI**, identified by comparison with an authentic smaple specially prepared by bromination of **II** under the conditions described in [9]. When the bromination of **II** was performed at 10–15°C, the content of unchanged **II** decreased to a minimum, but the content of dibromo derivative **VI** remained virtually the same, 7–8 wt %. By-product **VI** could be eliminated neither by decreasing the amount of bromine taken for the reaction, nor by repeated recrystallization of bromination product **III** from various organic solvents. We found that the concentration of **VI** in the reaction product depends on the rate of adding bromine: The lower the bromine concentration in the reaction mixture, the lower the probability of dehydrobromination. However, we failed to ensure formation of **III** as the only product. To separate **VI**, we took advantage of the fact that monobromo derivative **III** forms with acetic acid a salt readily soluble in water (30 g in 100 g of water at 23°C), whereas 3,5-dibromo derivative **VI** does not form such a salt and is virtual-

1070-4272/05/7805-0787 © 2005 Pleiades Publishing, Inc.

ly insoluble in water. After the bromination completion, the acetic acid was distilled off almost to dryness, and water was added to the residue. By-product **VI** remained in the insoluble residue, and it was filtered off. By alkalization of the filtrate, we isolated virtually pure **III**, without impurity of **VI**.

The nitration of amine **III** under the conditions described in [1, 2] often yielded, instead of the expected nitro compound **IV**, a black precipitate from which we failed to isolate the desired product by recrystallization from solvents in the presence of activated carbon or alumina, or by reprecipitation with alkalis from weakly acidic solutions. In nitration of 2-amino-5-bromopyridine **VII** under the same conditions, a significant amount of 3-nitro-5-bromo-2-pyridone **VIII** is formed along with the desired 3-nitro derivative of **VII** [13].

Nitration of **III** under the similar conditions is also accompanied by deamination. From dark tarry products, we isolated a compound identified as 3-nitro-5-bromo-6-methyl-2-pyridone **IX**.

To avoid formation of **IX** in nitration of **III**, we changed the order of mixing the reactants. Fuming nitric acid was added to a solution of **III** in sulfuric acid not at 55–60 but at 0–5°C, after which the temperature was gradually raised to 55–60°C. By so doing, we considerably reduced the yield of tars. However, after recrystallization of the products from methyl ethyl ketone, we detected **IX** in an amount comparable with that of the target product. By-product **IX** is insoluble in methyl ethyl ketone, alcohol, water, and the majority of aprotic solvents. At decreased nitration temperatures, the amount of **IX** decreased considerably (to 5–10 wt % relative to **IV**).

We examined the influence exerted by the conditions of nitration of **III** on the composition of the reaction products. It is advisable to perform nitration at 0–5°C in concentrated sulfuric acid with 60–63% nitric acid. In isolation of the desired nitro compound **IV**, to avoid formation of tarry impurities, the mixture should be neutralized to pH 2–3 with sodium acetate; in this case, the yield of **IV** is 80–85%. However, even with all these conditions observed, a certain amount of tar is formed; it decreases the melting point of **IV** by 10–20°C. Even a slight excess of nitric acid in nitration of amine **III** causes strong darkening of **IV**. For accurate dosage of nitric acid in nitration, we used instead of amine **IV** its nitrate **X** and added this salt with vigorous stirring at 15°C to concentrated sulfuric acid. Salt **X** is readily formed by mixing a melt of **III** with 60–63% nitric acid in water. Salt **X** can be obtained from crude **III** without its drying. To obtain pure nitro compound **IV** after the transformation of **X** in concentrated sulfuric acid, the acid solution after the nitration was neutralized with sodium acetate. After adding a half of the amount of sodium acetate required for complete neutralization of the reaction mixture, a bright yellow precipirtate of **IV** containing no by-products is formed. Neutralization of the filtrate after the isolation of **IV** to pH 6–7 allows isolation of the precipitate of dibromo derivative **VI**. If salt **X** taken for the nitration is free of amine **VI**, almost quantitative yield of **IV** can be attained, and its purity considerably increases. After recrystallization of **IV** from DMF, its melting point increases by 2–3°C (mp 213°C).

When in nitration of **III** HNO_3 is replaced by a less aggressive and more convenient in handling agent, e.g., KNO_3 in concentrated H_2SO_4, the reaction at 0–10°C yields no nitro compound **IV**, and heating to 40–50°C causes formation of pyridone **IX**. The nitration of **III** in glacial acetic acid also gives negative results.

According to [1, 2], nitro compound **IV** is reduced to diamine **V** with hydrogen in the presence of Raney nickel. Despite a fairly high yield of **V**, ~70%, this procedure is not quite feasible for industrial application, because the catalyst is pyrophoric and hydrogen is dangerously explosive. In the reduction of **IV** with $SnCl_2$ in concentrated HCl according to [12], the yield of **V** does not exceed 60%, and diamine **V** is contaminated with by-products and requires additional purification. Taking into account the fact that structurally related 2-amino-3-nitro-5-chloro(bromo)-6-methylpyridine is smoothly reduced with sodium sulfide in aqueous solution [10], we examined the applicability of this procedure to the reduction of **IV** at 60–100°C. At 60°C, no reduction occurs, and at 100°C the reaction is accompanied by extensive tarring. At 75–80°C, the yield of **V** does not exceed 40%. Experiments on reduction of **IV** with iron in aqueous solution containing a small amount of HCl showed that, when iron dust is added in small portions to a solution of **IV** at 80–90°C, the reduction occurred readily without self-heating and could be controlled. The yield of **V** reached 80% and did not decrease when the reaction time and amount of iron were decreased by half.

The most efficient is the reduction of **IV** with hydrazine hydrate. Refluxing of **IV** with a 15-fold excess of hydrazine hydrate for 5–6 h results in the formation of **V** in 68–70% yield. When the process is performed in a solvent, the consumption of hydrazine hydrate can be decreased by a factor of more than 3. 1-Butanol appeared to be the best solvent for this

purpose, because of high solubility of **IV** and **V** in it and sufficiently high boiling point providing the required reaction temperature. However, the reaction in 1-butanol requires longer time. To accelerate the reduction, we tested the following metals as catalysts: Raney nickel, iron of various brands, powdered aluminum, and zinc dust. The best results were obtained with zinc dust.

By varying the amounts of hydrazine hydrate, 1-butanol, and zinc dust, and also the temperature, we obtained highly pure diamine **V** in 87–90% yield.

When optimizing the synthesis of **I**, we started from the procedure [1, 12] involving heating of diamine **V** in 98–100% formic acid. Our experiments showed that the yield of **I** did not change at the consumption of formic acid decreased by a factor of 3 and the reaction time, by a factor of 2. The by-product was the *N*-formyl derivative of **V**. It seemed appropriate to use as a cyclizing agent pentyl formate suggested previously for the synthesis of a series of imidazo[4,5-*b*]- and -[4,5-*c*]pyridine derivatives [14]. This agent has significant advantages over formic acid: it is less toxic and does not cause scalds and damage mucous membranes of lungs and eyes. Furthermore, the consumption of pentyl formate for preparation of 1 kg of **I** is 5 l, whereas the required amount of formic acid is two times greater. The yield of **I** in refluxing of **V** in pentyl formate is 90–91%.

EXPERIMENTAL

The purity of volatile products was checked in an LKhM-72 analytical chromatograph (2000 × 4-mm column, stationary phase 15% Apiezon on Chromaton N-AW-DMC, carrier gas He, column temperature 220°C). Nonvolatile compounds were analyzed by TLC on Silufol UV-254 plates (eluent ethanol).

2-Amino-5-bromo-6-methylpyridine III. Amine **II** (16.1 g) and anhydrous sodium acetate (12.3 g) were dissolved in 126 ml of glacial acetic acid with stirring at 20–22°C. Then the mixture was cooled to 10–15°C, and a solution of 7.7 ml of bromine in 21 ml of glacial acetic acid was added dropwise at this temperature. After adding the whole amount of bromine, the mixture was stirred at 15°C for 1 h. The solvent was distilled off almost to dryness (~150 ml), and the residue was filtered off, washed with 10 ml of glacial acetic acid, and mixed at 20–25°C with 100 ml of water. The insoluble residue ot **VI** was filtered off, washed with 5 ml of water, and dried in air. Yield of by-product **VI** 2.1 g, mp 142–143°C [5]. The aqueous filtrate was alkalized with 6 ml of 30% NaOH to pH 8, and the colorless precipitate of bromo derivative **III** was filtered off. The product was washed with 5 ml of water, recrystallized from 20% acetic acid, and dried. Yield 25 g (90%), mp 80–82°C. According to [21], mp 71–72°C.

2-Amino-5-bromo-6-methylpyridinium nitrate X. To 16 ml of water heated to 80–85°C we added with stirring 7.6 g of molten 2-aminopyridine **III**. To the resulting emulsion, we added over a period of 5–10 min 3.4 ml of 60% HNO_3. In so doing, base **III** dissolved, and nitrate **X** started to precipitate on cooling the reaction mixture to 60–55°C. After cooling to 10–15°C, the precipitate was filtered off. Yield of **X** 9.7 g (95.5%), mp 170–172°C.

Found, %: C 28.59, H 3.16, N 16.61.
$C_6H_7BrN_2 \cdot HNO_3$.
Calculated, %: C 28.82, H 3.22, N 16.80.

2-Amino-3-nitro-5-bromo-6-methylpyridine IV. Nitrate **X** (21 g) was added in small portions to 45 ml of concentrated sulfuric acid cooled to 10–15°C. The mixture was stirred for 1 h and poured onto 160 g of ice, and 110 g of sodium acetate ($CH_3COONa \cdot 3H_2O$) was added. The light yellow precipitate was filtered off, washed with 10 ml of water and 5 ml of acetone, and dried; 19.5 g (~100%) of nitro compound **IV** was obtained, mp 211–213°C (from DMF); according to [12], mp 210–213°C.

2,3-Diamino-5-bromo-6-methylpyridine V. (*a*) To a mixture of 24 ml of 2-propanol, 6 ml of water, 5.6 g of aminonitropyridine **IV**, and 0.8 ml of concentrated HCl, we added with stirring at 70–75°C 5.6 g of iron carbonyl in portions over a period of 2 h, so that the mixture mildly boiled. Then the mixture was refluxed for 2 h and filtered while hot. The black precipitate on the filter was washed with hot 2-propanol, and the wash solution was combined with the filtrate. The resulting solution was alkalized with 25% aqueous ammonia to pH 8 and refluxed for 0.5 h. The precipitated iron oxides were filtered off, and 2-propanol and then water were distilled off in a water-jet-pump vacuum to ~1/4 of the initial volume. The residue was cooled to 15–20°C, and the precipitate of diamine **V** was filtered off. Yield 4.04 g (80%), mp 135–137°C (from H_2O). According to [12], mp 136–137°C.

(*b*) To a mixture of 5.8 g of **IV**, 50 ml of 1-butanol, and 7 ml of hydrazine hydrate, we added with stirring at 100°C 1.0 g of zinc dust in portions over a period of 2 h. The mixture was refluxed for 3–4 h until the gas evolution ceased. Then the mixture was cooled to 60–70°C and filtered. The gray precipitate

on the filter was washed with 20 ml of hot 1-butanol, and the wash solution was combined with the filtrate. Then 55–60 ml of 1-butanol was distilled off in a water-jet-pump vacuum. The residue was cooled to 15–20°C, and the precipitate of **V** was filtered off. Yield 4.55 g (90%), mp 135–137°C (H_2O).

6-Bromo-5-methylimidazo[4,5-*b*]pyridine I. A mixture of 5 g of **V** and 7 ml of pentyl formate was heated at 170–175°C for 2 h until 0.4–0.5 ml of water was released and then at 170–180°C for 2 h more. Pentyl formate and 1-pentanol were distilled off in a water-jet-pump vacuum (40–50°C, 25–30 mm Hg) to dryness, and the residue was crystallized from ethyl acetate or water–2-propanol (5 : 1). Yield 4.75 g (90.5%), mp 206–207°C. According to [12], mp 204–205°C.

CONCLUSION

Procedures were suggested for preparing 2-amino-5-bromo-6-methylpyridine by bromination of 2-amino-6-methylpyridine in glacial acetic acid in the presence of anhydrous sodium acetate in 90% yield, nitration of the resulting compound in the form of nitrate in concentrated sulfuric acid at 10–15°C (~100% yield), reduction of the product in an acidified alcohol with iron carbonyl (~80% yield) or with hydrazine hydrate and zinc (~87–90% yield), and cyclization of 2,3-diamino-6-methylpyridine in refluxing pentyl formate to 6-bromo-5-methylimidazo[4,5-*b*]pyridine (~90.5% yield), an antifogging compound for color photographic materials.

Abstract—The kinetics of acid hydrolysis of *N*-acetylglucosamine at different temperatures and reagent concentrations was studied. A mathematical model of the hydrolysis was proposed. The rate constant and activation energy of deacetylation were calculated.

Utilization of large volumes of chitin-containing waste of crustaceans involves usually chemical hydrolysis of chitin and chitosan. Under these conditions, chitin is hydrolyzed to its monomers: glucosamine (GA) and acetylglucosamine (AGA). Complete depolymerization of chitin and chitosan is usually performed in an acidic solution at elevated temperatures [1]. Under these conditions, the glucoside bonds in the polysaccharide are ruptured to form the monomers. Deacetylation occurs in parallel with depolymerization. The deacetylated monomer is usually isolated in the form of its salt of the acid used for hydrolysis. The study of the mechanisms of acid hydrolysis of chitin and chitosan as influenced by the degree of deacetylation and molecular weight of the initial polysaccharide and hydrolysis conditions (temperature and acid concentration) is of both practical and theoretical interest.

Acid hydrolysis of chitin and chitosan was extensively studied [1–5]. However, the kinetics of this process was not understood and the rate constants of its elementary steps were not determined. Previously we suggested a mathematical model of acid deacetylation of chitin [6, 7]. We found that the chitin deacetylation is described by the first-order kinetic equation and the dependence of the reaction rate passes through a maximum at the hydrochloric acid concentration w_{HCl} = 29.8%.

The aim of this study was to estimate the rate constant and activation energy of AGA deacetylation and to determine the hydrolysis rate of the acetamide bond as influenced by the degree of polymerization of the polysaccharide.

EXPERIMENTAL

We used *N*-acetylglucosamine (AGA) prepared by acetylation of *D*-glucosamine with acetic anhydride by the reaction [8]

$$C_6H_{11}NO_5 + (CH_3CO)_2O \rightarrow C_8H_{15}NO_6 + CH_3COOH. \quad (1)$$

Acetylation was performed as follows. A 900-ml portion of AV-17-8 anion exchanger converted into the CO_3 form by treatment with 10% aqueous solution of sodium carbonate was placed into a flask equipped with a stirrer. A 900-ml portion of 0.38 M aqueous solution of *D*-glucosamine hydrochloride [75 g (0.46 mol) GA·HCl] and 90 ml of ethanol (w = 96%) were added at 0–5°C. Acetic anhydride (45 ml, 0.64 mol, w = 99%) was added in small portions at 0–5°C. The reaction mixture was stirred for 3 h at 0–5°C. The resin was filtered off, washed with 500 ml of distilled water, and regenerated.

The filtrate and wash waters were evaporated under reduced pressure (10–20 mm Hg) at 50–60°C to a viscous syrup containing crystals. Ethanol (75 ml, w = 96%) was added, and the resulting mixture was left to crystallize at 0–5°C for 12–15 h.

The crystals were filtered off, washed with 300 ml of acetone (chemically pure grade) to remove water, and dried in a vacuum. The *N*-acetylglucosamine yield was 73.5% of the theoretical yield corresponding to Eq. (1).

N-Acetylglucosamine was hydrolyzed in hydrochloric acid with a concentration from 10 to 37.2% at 40, 60, and 80°C. The hydrolyzate was neutralized first with 2.7 M NaOH and then with 0.1 M NaOH to pH 7.0, filtered through a Schott filter (pore diameter no larger than 10 μm, POR 10), and analyzed for AGA and GA content (M).

The AGA content was determined by the procedure described in [9]; the total AGA + GA content, by the procedure from [10]. The GA amount was calculated

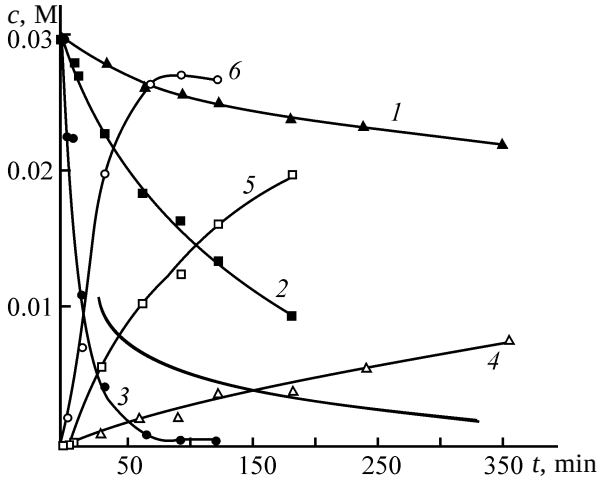

Fig. 1. Kinetic curves of AGA hydrolysis at (*1*) 313, (*2*) 333, and (*3*) 353 K and kinetic curves of GA formation at (*4*) 313, (*5*) 333, and (*6*) 353 K. c_{HCl} = 6.02 M (w_{HCl} = 20%). (*c*) concentration of AGA and GA and (*t*) hydrolysis time.

as the difference between the total AGA + GA amount and the AGA amount. The kinetic curves of AGA consumption and GA accumulation in 20% HCl at different temperatures are shown in Fig. 1. Hydrolysis of AGA is accelerated with increasing temperature. The major product of AGA hydrolysis is glucosamine:

$$C_8H_{15}NO_6 + H_2O \rightarrow C_6H_{11}NO_5 + CH_3COOH. \quad (2)$$

Analysis of the kinetic curves of AGA hydrolysis shows that the reaction can be described by a first-order kinetic equation. The rate constants of AGA deacetylation and GA formation at different temperatures were calculated by the first-order kinetic equation [11]

$$k = 1/t \ln(c_0/c), \quad (3)$$

where t is the reaction time (s^{-1}); c, current concentration of the reactant at time t (M); and c_0, initial concentration of the reactant (M).

The results of these calculations are presented in Table 1.

Table 1. Rate constants of AGA hydrolysis and GA formation. c_{HCl} = 6.02 M (w_{HCl} = 20%)

T, K	AGA		GA	
	k, s^{-1}	$\ln k$	k, s^{-1}	$\ln k$
313	0.00129	–6.653	0.00079	–7.143
333	0.00804	–4.824	0.00638	–5.055
353	0.0544	–2.912	0.0369	–3.301

Table 2. Rate constants of deacetylation of chitin and AGA at T = 353 K

Compound	w_{HCl}, %	c_{HCl}, M	k, s^{-1}
Chitin	35.8	11.57	0.0523
	29.8	9.38	0.0558
AGA	20	6.02	0.0544
	37.2	12.08	0.0428

The rate constants of AGA deacetylation were compared with the rate constant of acid deacetylation of chitin, determined in our previous study [6]. The rate constants of chitin deacetylation at 353 K, calculated by Eq. 3, are presented in Table 2.

As seen from Table 2, the rate constants of deacetylation of AGA and chitin at 353 K are of the same order. These results suggest that the rate constant of deacetylation of chitin and oligomeric and monomeric products of its acid hydrolysis is independent of the molecular weight.

The activation energy of hydrolysis of the acetamide bond was calculated from the temperature dependence of the rate constant by the Arrhenius equation [11]:

$$k = Ae^{-E_a/RT}. \quad (4)$$

The activation energy is 85.7 kJ mol^{-1}.

The calculations were performed on the assumption that the AGA deacetylation is described by the first-order kinetic equation and the true (second) reaction order is reduced owing to large excess of hydrochloric acid [11]. Since the rate of chitin deacetylation depends on the hydrochloric acid concentration [6], we studied the similar dependence for AGA.

The dependence of the rate constant of AGA deacetylation at T = 353 K on the hydrochloric acid concentration is shown in Fig. 3.

The dependence of the rate constant of chitin deacetylation on the hydrochloric acid concentration is similar [6]: it passes through a maximum at the hydrochloric acid concentration of 9 M (w = 29%) and then decreases with a further increase in c_{HCl}.

Since the acid is involved in the catalytic reaction, its concentration should enter into the pseudo-first-order rate constant $k = k'c_{HCl}$. However, the sharp ac-

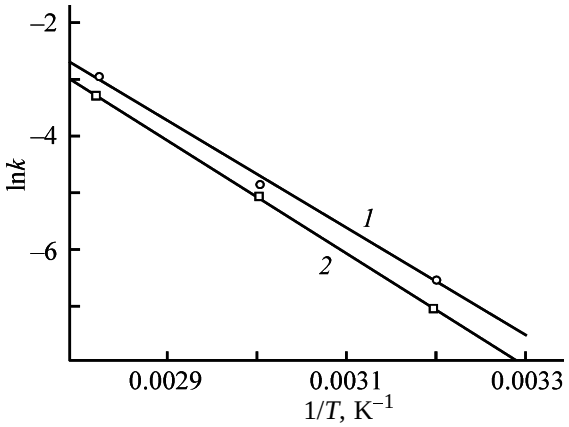

Fig. 2. Logarithms of rate constants ln*k* of (*1*) AGA hydrolysis and (*2*) GA formation as functions of 1/*T*.

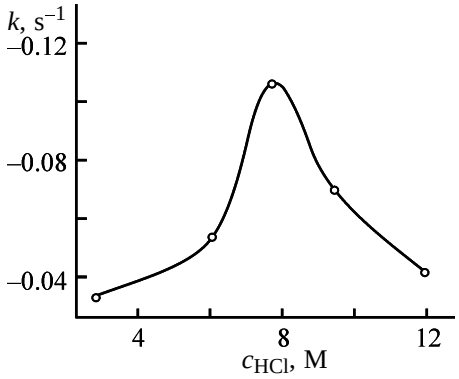

Fig. 3. Rate constant *k* of AGA deacetylation at 353 K as a function of the hydrochloric acid concentration c_{HCl}.

celeration of the reaction in 9 M HCl (Fig. 3) is difficult to explain.

The fact that the dependence for acid hydrolysis of chitin is similar additionally confirms that the mechanism of acid deacetylation of the monomeric and polymeric species is the same.

CONCLUSIONS

(1) The rate constant of acid hydrolysis of acetamide bonds in chitin is similar to that in its oligomers and *N*-acetylglucosamine.

(2) The dependence of the rate of *N*-acetylglucosamine deacetylation on the hydrochloric acid concentration passes through a maximum at $c_{HCl} \sim 8$ M ($w_{HCl} = 26\%$).

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Prospects for Using Polyacrylonitrile for Preparing Carbonized Polymeric Composites

Abstract—The thermochemical cyclization of different polyacrylonitrile samples prepared by radical and anionic polymerization was studied by thermal analysis, spectroscopy, and AM1 semiempirical calculations. The possibility of using polyacrylonitrile as a cocarbonizate for preparing mixed carbon composites with nitrogen-containing polysaccharides was examined.

Our previous studies were aimed to enhance the heat resistance of polymers by their compounding with polyimides [1–4]. Some of the carbonized residues showed fairly high coke numbers (CNs) and exhibited properties deserving a special study. Another heat-resistant polymer is polyacrylonitrile (PAN), with which, as with polyimides, mixed composites with enhanced heat resistance and strength were prepared [5].

In the context of development of various carbon materials based on polymers, it is interesting to examine the effect of PAN on the thermochemical carbonization of other polymers and hence on the properties of the resulting products. From the viewpoint of the PAN reactivity, the most promising is the step of thermal cyclization occurring in the range 200–300°C. Despite numerous papers concerning this process, its mechanism is not yet elucidated unambiguously. The scheme of formation of "ladder" polymers as infinite chains of cyclic sequences, postulated in early studies [6–9], was not confirmed and gave way to the concept [10–16] according to which cyclization of PAN yields chains with the number of cyclic sequences not exceeding 8–10. Attempts to consider the mechanism of PAN cyclization taking into account the conformation of macromolecules [17, 18] were not properly developed, as major attention was given to solution of materials-science and processing problems. A number of tentative schemes reflecting attempts to take into account the features of production of real items, mainly fibers, were suggested [19].

Our goal was to develop procedures for preparing cocarbonizates from PAN and cellulose derivatives. The first step was to find the most probable routes that could ensure incorporation of the PAN structure into other polymers by their thermochemical reaction. To this end, we modeled cyclization of PAN in the absence of chemical additives (catalysts, oxidants, accelerators). Solution of this problem is complicated by the difficulties associated with preparation of PAN samples free of oxygen-containing functional groups remaining in the polymer after its isolation and purification. Such polymers cannot be prepared by radical polymerization (r-PAN). Polymerization of acrylonitrile by the anionic mechanism under definite conditions yields samples whose thermal cyclization in an inert atmosphere [20, 21] gives products containing no impurities and volatile low-molecular-weight cyclization products. For such samples of anionic PAN (a-PAN), the exothermic effect appreciably shifted toward higher temperatures. Thus, the conditions of PAN activation can correspond to the conditions of thermochemical reactions with other polymers. The most suitable for this purpose are cellulose derivatives; their thermal degradation occurs most actively in the same temperature range (200–300°C) as the cyclization of PAN [22, 23].

EXPERIMENTAL

Returning to the modeling of suitable PAN structures, we chose samples prepared by the radical and anionic polymerization mechanism, with different ratio of the atactic, isotactic, and syndiotactic structures [15, 24].

* Thermal analysis was performed by DSC in air (numerator) and nitrogen (denominator). PAN structure: (s) syndiotactic, (a) atactic, and (i) isotactic; (CB) coefficient of stereoblock structure of the polymers [19]; (T_{max}) temperature of the exothermic maximum of PAN cyclization; (ΔT) temperature interval of the exothermic peak; (ΔH) heat of cyclization up to T_{max}; (Δm_1) PAN weight loss up to T_{max}; and (Δm_2) PAN weight loss in the whole interval of temperatures of the exo effect.

The table shows that the structure of r-PAN is less regular than that of a-PAN. To simplify the subsequent presentation, we denote the samples in accordance with the structures whose content in the given sample is maximal: r-PAN, atactic; a-PAN prepared in toluene, isotactic (a-PAN-i); and a-PAN prepared in DMF, syndiotactic (a-PAN-s). The temperature and energy characteristics of the cyclization show certain correlation with the features of the steric structure of each sample. However, actually each sample contains all the three types of structure, with a high content of atactic structures; therefore, for some of the parameters the structure–property correlation is not unambiguous.

It is interesting to compare the DSC (differential scanning calorimetry) data for PAN samples in air and nitrogen (see table). Both in nitrogen and in air, the a-PAN-i samples are characterized by the noticeably lower temperatures of the exothermic effects associated with PAN cyclization and by lower weight loss in the cyclization. The pyrolysis of a-PAN-s in air is characterized by high T_{max} and the narrowest temperature interval of the exothermic effect of cyclization, with the minimal weight loss. The r-PAN sample is characterized by the highest levels of heat release and weight loss and by a broad temperature interval of the exothermic effect. In an inert atmosphere, the thermal cyclization of all the samples occurs in a narrower interval with a considerably weaker exothermic effects and weight losses. When interpreting the results, we should take into account the qualitative composition of the polymers and procedures for their preparation and purification. In particular, the IR spectra of a-PAN contain absorption bands of carbonyl groups. These groups appear in the polymer in the course of its synthesis in a nonpolar medium owing to the reaction of organometallic initiators with cyano groups [12]. Weak "foreign" bands in the IR spectra of a-PAN-s suggest the presence of traces of the solvent (DMF) in which the synthesis was performed. A band at 775 cm^{-1}, sometimes termed the PAN ordering band, is noticeable in all the samples studied, and it grows in intensity in going from r-PAN to a-PAN-i and a-PAN-s.

To examine the influence exerted by the structural organization of PAN macromolecules on the energy characteristics of thermal cyclization, we performed AM1 semiempirical calculations. For a polymeric chain of nine monomeric units with various steric arrangements, we calculated the heats of formation of rings in the iso- and syndiotactic polymers. We found that the initial step of cyclization (formation of primary naphthyridine units) is accompanied by the release of 766.92 kJ mol^{-1} at the isotactic arrangement of the cyano groups and 756.41 kJ mol^{-1} at the syndiotactic arrangement. An increase in the length of the cyclic sequences in the course of further cyclization is accompanied by the invesion of this ratio. In particular, the cyclization energy in the step of formation of an eight-ring chain is 884.31 kJ mol^{-1} for a-PAN-i and 906.15 kJ mol^{-1} for a-PAN-s. Hence, to obtain longer cyclic macromolecules, it is energetically preferable to use a-PAN-s. In this case, the cyclized syndiotactic isomer acquires the shape of a double helix, which is more favorable for the subsequent formation of oriented carbonizates. As the length of the cyclic chain in a-PAN-i increases, the steric hindrance associated with the growing internal strain in the forming ladder structure becomes more pronounced [25]. Figures 1 and 2 illustrate the steric rearrangement of iso- and syndiotactic PAN in the course of stepwise cycli-

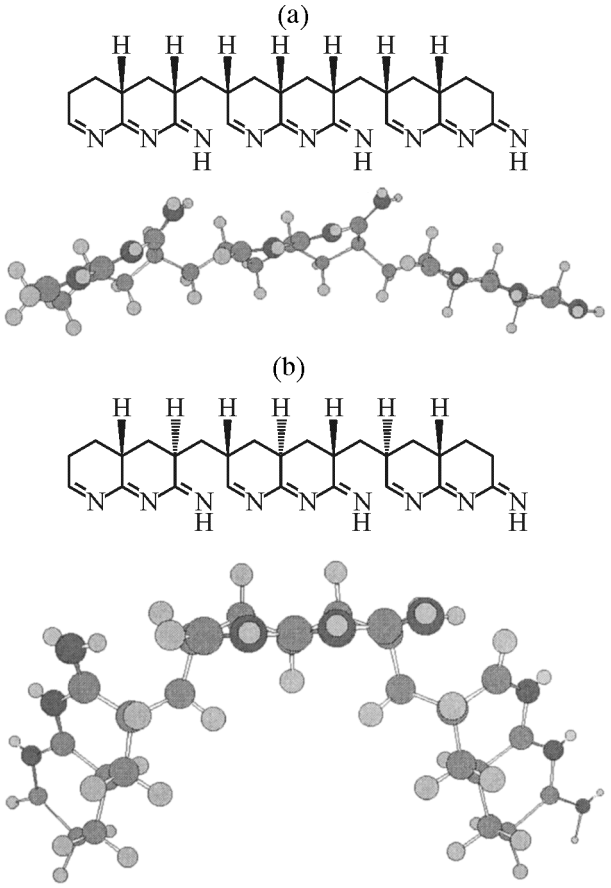

Fig. 1. Schematic and calculated structures of (a) isotactic and (b) syndiotactic PAN in the step of formation of naphthyridine rings.

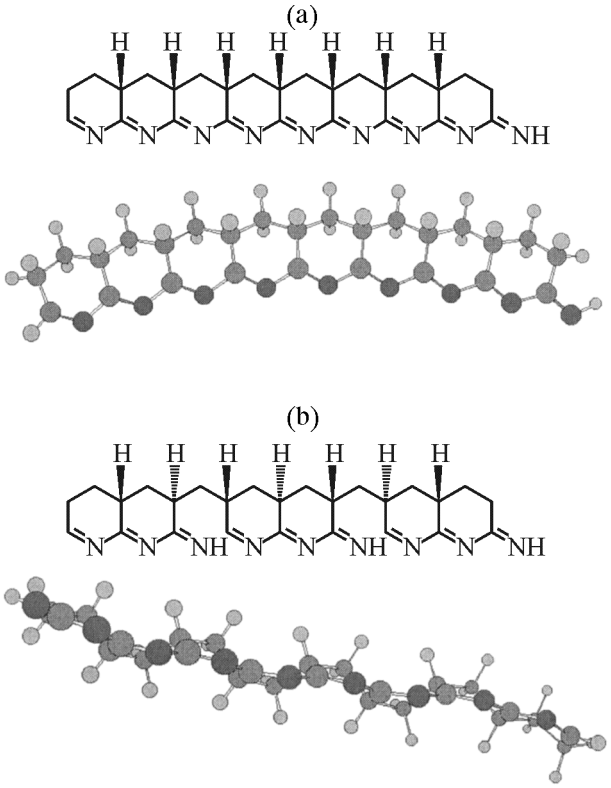

Fig. 2. Schematic and calculated structures of (a) isotactic and (b) syndiotactic PAN in the step of formation of a chain of eight cyclic units.

zation, from the closure of naphthyridine rings (Fig. 1) to formation of a chain of eight cyclic units (Fig. 2).

Our calculations reflect a trend that should be taken into account when choosing a procedure for preparing PAN so as to obtain structures with the required properties. Thus, the steric orientation of PAN macromolecules may be of decisive importance when the conditions of synthesis and isolation of the polymers and of their transformation into cyclic products are strictly observed. Our experiments showed that thermal cyclization of r-PAN in air is accompanied by degradation, which is confirmed by high thermal effects and significant weight loss. The heat release in the interval 250–350°C is a superposition of at least two exothermic processes: cyclization and oxidation with the release of low-molecular-weight products. Furthermore, r-PAN samples are characterized by high polydispersity and chain branchings. Therefore, the packing density of r-PAN macromolecules in precipitation from a solution is low, and powdered samples are subject to more intense thermal oxidation. In contrast to r-PAN, a-PAN polymers have narrow molecular-weight-distribution (MWD) and contain no low-molecular-weight fractions and branchings. These factors, along with the stereoblock structure (see table), are responsible for the high density of a-PAN [13]. In addition, the PAN packing density is appreciably affected by the presence of intermolecular bonds whose content depends on the steric ordering of macromolecules. In solution, a-PAN macromolecules have, to a certain extent, the double helix shape due to the interaction between the cyano groups and α-H atoms, between two cyano groups of adjacent PAN chains [26, 27], and, in some cases, between the adjacent cyclic structures [18]. These factors cause an appreciable shift of the exothermic cyclization toward higher temperatures and a decrease in the content of volatiles in the initial step of cyclization [21]. These structural features of a-PAN result in the prevalence of the cyclization over thermal degradation. As for the related reactions with r-PAN samples, the prevalence of heterostructures, presence of low-molecular-weight

fractions, broad MWD, significant branching, and presence of various functional (mainly oxygen-containing) groups make possible a wide spectrum of low-energy reactions yielding diverse reactive by-products. These factors, along with the fact that the temperature ranges of the highest reactivity of both components coincide (200–300°C), are necessary conditions for efficient cocarbonization with cellulose derivatives (ethers, esters, chitin, chitosan) releasing a number of reactive compounds in thermal degradation [22, 23]. It was also shown in [22, 23] that cyano derivatives of these carbohydrates are characterized by a high yield of the coke residue.

CONCLUSIONS

(1) The energetic, temperature, and gravimetric parameters of thermal cyclization of polyacrylonitrile prepared by radical and anionic polymerization were determined.

(2) The most suitable for cocarbonization with cellulose ethers and esters, chitin, and chitosan are samples of atactic polyacrylonitrile with a broad molecular-weight distribution, the presence of branchings, and a high content of low-molecular-weight fractions and thermoreactive groups.

Abstract—The kinetics of radiation-initiated copolymerization of *N*-vinylpyrrolidone with triethylene glycol dimethacrylate was studied. The variation of the composition of the 3D cross-linked copolymer and of the amount of *N*-vinylpyrrolidone homopolymer in the course of the process at various initial monomer ratios was monitored.

Polyvinylpyrrolidone and its copolymers are used in various branches of chemistry, medicine, and food and perfumery industries [1]. The use of triethylene glycol dimethacrylate (TGM-3) as a long-chain cross-linking agent in copolymerization with *N*-vinylpyrrolidone (*N*-VP) allows preparation of sorbents that efficiently recover polyphenols from food and perfumery liquids and are used for stabilization and clarification of juices, wine materials, and strong drinks [2–4]. The sorbent performance is largely determined by the composition and structure of the copolymer. The sorption properties of the sorbent are due to the presence of carbonyl oxygen atoms in *N*-VP units. However, as TGM-3 is more reactive than *N*-VP, it is difficult to prepare the product of the required structure in a high yield.

The goal of this study was to examine the kinetic relationships of radiation-initiated (^{60}Co γ-radiation) copolymerization of *N*-VP with TGM-3 and find the optimal conditions for preparing the sorbent. The reaction was monitored calorimetrically. A combination of the calorimetry with radiation initiation is very convenient for studying the block polymerization of a cross-linking system, as it allows the reaction rate to be measured directly during the process and the degree of conversion of double bonds in the monomers to be estimated up to high conversions.

EXPERIMENTAL

N-Vinylpyrrolidone was purified by double distillation in a vacuum, and TGM-3, by threefold filtration through a column packed with activated alumina. To perform the reaction, a monomer mixture of a definite composition was placed in glass calorimetric cells, deoxygenated, and sealed.

The radiation copolymerization was monitored calorimetrically [5]. A calorimeter with the reaction cell was placed in the chamber of a Gammatok-100 γ-ray installation, theromstated at the required temperature, and irradiated at a dose rate of 1.5 Gy s^{-1}. In the course of the experiment, we monitored how the rate of the heat release due to the polymerization varies in time. The degree of conversion and reaction rate were calculated using the following heats of polymerization (kJ mol^{-1}): 58.6 for *N*-VP [6] and 114.0 for TGM-3 [7].

After the reaction completion, the product was precipitated with diethyl ether and dried to constant weight in a vacuum, after which the total polymer yield was determined gravimetrically. To remove the soluble linear homopolymer of *N*-VP (PVP), the product was washed with distilled water, and the insoluble cross-linked copolymer was dried. The yield of PVP was calculated from the difference between the total yield of the polymer and the yield of the insoluble cross-linked copolymer.

The composition of the 3D copolymers were determined by elemental analysis for nitrogen.

To study the copolymerization of *N*-VP with TGM-3, we took samples of *N*-VP, TGM-3, and their mixtures with various initial molar ratios of the monomers. The calorimetric curves of the polymerization of *N*-VP and TGM-3 and of their copolymerization in the course of γ-irradiation at 295 K are shown in Fig. 1a, and the time dependences of the consumption of the

1070-4272/05/7805-0798© 2005 Pleiades Publishing, Inc.

double bonds during irradiation, calculated from these calorimetric curves, in Fig. 1b.

The calorimetric curves of *N*-VP polymerization show that, after the start of γ-irradiation, the reaction rate reaches a constant value and then sharply increases (gel effect, Fig. 1a, curve *1*). Then the rate of the *N*-VP polymerization decreases because of the consumption of the monomer. The autoacceleration of the process, observed in this case at approximately 40% conversion, is usually attributed to a decrease in the termination rate constant with an increase in the viscosity of the system, caused by accumulation of the polymer. The PVP yield reaches 100% at an irradiation dose of 10.8 kGy (Fig. 1b, curve *1*).

The polymerization of TGM-3 in a γ-ray field is considerably more efficient than that of *N*-VP (Fig. 1a, curve *2*). It is known that the 3D polymerization of TGM-3, a typical oligoether acrylate with two C=C bonds, occurs by the pronounced microheterogeneous mechanism [8–10]. After starting the irradiation, the reaction first develops autocatalytically, the reaction rate increases, and then it reaches a maximum followed by the reaction deceleration. The content of unchanged C=C bonds in the cured block of the TGM-3 polymer (gel fraction) is relatively high (~10–15% at a dose of 8.1 kGy; Fig. 1b, curve *2*).

A study of the copolymerization of the monomers shows that, on adding TGM-3 to *N*-VP, the initial polymerization rate increases relative to the *N*-VP homopolymerization to the greater extent, the higher the TGM-3 content in the initial system (Fig. 1a, curves *3*–*5*). The shape of the calorimetric curves changes also. It is interesting that, for the samples with the initial *N*-VP content exceeding 85 mol %, the reaction rate passes through two maxima (Fig. 1a, curves *3*, *4*). Comparison of these calorimetric curves with that of the *N*-VP homopolymerization (Fig. 1a, curve *1*) suggests that the second peak is due to the *N*-VP homopolymerization. Indeed, the corresponding products contain, along with the cross-linked *N*-VP–TGM-3 copolymer, also a water-soluble polymer. According to elemental analysis, this water-soluble product is the *N*-VP homopolymer. The yield of the *N*-VP homopolymer in the samples with the initial *N*-VP content of 86 and 95 mol % after the reaction completion (irradiation dose 10.8 kGy) is 3 and 35%, respectively. In the samples with the initial *N*-VP content less than 85 mol %, no *N*-VP homopolymer was detected after the reaction completion.

Thus, at least two processes can occur in the *N*-VP–TGM-3 system upon radiation initiation: copolymerization of the monomers to form a cross-

Fig. 1. Fig. 2. Yield of the forming homopolymer PVP γ_{PVP} as a function of the total polymer yield $\gamma_{CP} + \gamma_{PVP}$. Initial monomer ratio in the *N*-VP : TGM-3 mixture, mol %: (*1*) 95 : 5, (*2*) 86 : 14, and (*3*) 72 : 28; the same for Fig. 3.

linked product and polymerization of *N*-VP to form a soluble homopolymer.

In this connection, it is interesting to examine the behavior of the system in the course of the process at various conversions. Figures 2 and 3 show how the amount of the forming *N*-VP homopolymer (Fig. 2) and the content of *N*-VP units in the cross-linked copolymer (Fig. 3) vary in the course of the process at three different initial ratios of *N*-VP and TGM-3.

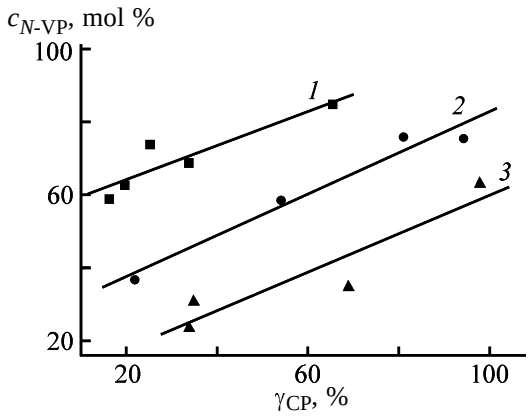

Fig. 3. Content of *N*-VP units $c_{N\text{-VP}}$ in the copolymer as a function of the yield of the cross-linked copolymer γ_{CP}.

These data show that the *N*-VP homopolymer is formed even at the beginning of the process (Fig. 2). The amount of the *N*-VP homopolymer increases in the course of the process, reaching a maximum at 70–80% conversions. Specifically these conversions correspond to the second maximum of the reaction rate for the samples containing 86 and 95 mol % *N*-VP. After passing through a maximum, the content of the homopolymer decreases. In the samples with the initial *N*-VP content of 95 mol %, the content of the homopolymer in the course of the process is considerably higher than in the samples with 86 mol % *N*-VP (Fig. 2, curves *1*, *2*).

The *N*-VP homopolymer is formed in the course of the process also at the initial *N*-VP content less than 85 mol % (Fig. 2, curve *3*). However, the final product in this case contains no homopolymer. A decrease in the amount of the homopolymer in the final steps of the process and its virtual disappearanece in the samples containing less than 85 mol % *N*-VP suggest that the PVP radicals generated by γ-radiation react with the unchanged C=C bonds of TGM-3, i.e., PVP is grafted to the copolymer.

It is known that the limiting conversion of the double bonds in radiation-initiated polymerization of TGM-3 is less than 100%. In particular, it follows from [11] that the content of the C=C bonds in the insoluble polymer (gel fraction) is not constant during the process and varies from 30% at the beginning of the process to 10% at its end. This fact indicates that, under γ-irradiation, the insoluble polymer phase undergoes further cross-linking involving the pendant C=C bonds.

Thus, in our case, along with the copolymerization of *N*-VP with TGM-3, grafting of PVP molecules to the three-dimensional framework is possible owing to the reactions between the PVP radicals generated by γ-irradiation and unchanged pendant double bonds. Note that the conversion of the double bonds increases with an increase in the *N*-VP content in the starting system (Fig. 1b, curves *1–5*).

The composition of the forming copolymer changes with the progress of the polymerization (Fig. 3). Irrespective of the initial comonomer ratio, the content of the *N*-VP units in the copolymer increases with an increase in the copolymer yield. The content of the *N*-VP units grows with an increase in the *N*-VP content in the initial mixture. In particular, the final copolymers prepared from mixtures containing 72, 86, and 95 mol % *N*-VP are characterized by the *N*-VP : TGM-3 molar ratio of ~65 : 35, 75 : 25, and 85 : 15, respectively.

The optimal monomer ratio for preparing the sorbent should be chosen so as to minimize the content of the *N*-VP homopolymer in the product (because the homopolymer should be separated) and, on the other hand, to provide the highest content of bound *N*-VP units in the copolymer (because these units are responsible for the sorption properties). Our results show that the initial *N*-VP : TGM-3 molar ratio of 86 : 14 is close to the optimum. Indeed, although the content of the *N*-VP units in the copolymer prepared at the initial *N*-VP : TGM-3 molar ratio of 95 : 5 is as high as ~85 mol %, the yield of the *N*-VP homopolymer is also relatively high (~35%). At the initial *N*-VP : TGM-3 molar ratio of 86 : 14, the content of the *N*-VP units in the copolymer is only slightly lower (~80 mol %), but the content of the *N*-VP homopolymer decreases considerably (to less than 3%). As the initial *N*-VP : TGM-3 molar ratio is decreased further, the content of the *N*-VP units in the copolymer becomes too low.

CONCLUSIONS

(1) Radiation-initiated copolymerization of triethylene glycol dimethacrylate with *N*-pyrrolidone yields the cross-linked 3D copolymer (major product) and the soluble *N*-vinylpyrrolidone homopolymer (by-product).

(2) With an increase in the *N*-vinylpyrrolidone concentration in the initial mixture, the content of the *N*-vinylpyrrolidone units in the copolymer increases, and a higher conversion of the double bonds in triethylene glycol dimethacrylate is attained.

(3) The optimal initial molar ratio of the comonomers for preparing the copolymers to be used as sorbents is 86 : 14.

Abstract—Lauryl peroxide initiated radical copolymerization of 1,1,3-trihydroperfluoropropyl methacrylate and 1,1,5-trihydroperfluoroamyl methacrylate with methyl methacrylate was studied. The kinetic parameters of copolymerization for these systems were determined at low degrees of conversion. Optically transparent copolymers with glass transition points within 50–80°C were synthesized.

Polymers based on fluorine-containing acrylates and methacrylates find application in various fields of industry owing to an advantageous combination of properties: transparency and weather, thermal, and chemical resistance, as well as other parameters. They are used for impregnation of leather, paper, and textiles for imparting water-, oil-, and mud-repelling properties to these materials [1]. Because of high oxygen permeability, polyfluoroalkyl (meth)acrylates were patented as gas-separation membranes [2]. Optical properties (low refractive indices, high light transmittance) make these materials suitable for optical and optoelectronic applications [3]. In this context, polymerization of fluoroalkyl (meth)acrylates has recently received much attention [4, 5].

It should also be noted that some properties of homopolymers (water repellency, cold fluidity, low glass transition points), as well as high costs of the initial monomers, limit their application. These drawbacks can be eliminated to a certain extent by copolymerization of fluorinated monomers with vinyl monomers, for example, alkyl methacrylates, styrene, and methacrylic and acrylic acids. For such systems, it is urgent to carry out regular kinetic studies and also to establish the structure–property relationships.

In this work, we studied radical copolymerization of 1,1,3-trihydroperfluoropropyl methacrylate (F_1) and 1,1,5-trihydroperfluoamyl methacrylate (F_2) with methyl methacrylate (MMA) and the physicochemical properties of the copolymers synthesized.

EXPERIMENTAL

Copolymerization of F_1 and F_2 with MMA was carried out at 65°C. The monomers were purified by vacuum distillation in a nitrogen atmosphere. Lauryl peroxide which served as initiator was purified by reprecipitation from chloroform into methanol. The concentration of the initiator was 5×10^{-4} mol mol^{-1} of the monomer mixture. The content of the fluorinated components in the monomer mixture was varied from 9.09 to 83.3 mol%. The kinetics of copolymerization to high conversions were studied gravimetrically. The copolymers were isolated by reprecipitation from acetone into methanol. The composition of the copolymers was determined by IR spectroscopy. As analytical band served that corresponding to vibrations of the $–CF_2–$ groups at 800 cm^{-1} [6]. The IR spectra of the copolymers were recorded on a Specord 75-IR spectrometer in an acetonitrile solution in KBr cells with a layer thickness of 0.4 cm. The viscosity of the monomer mixtures was measured in an Ubbelohde viscometer. The thermomechanical properties of the polymers were studied by the method described in [7]. The water wettability of the polymers at 20°C was determined by measuring the contact angle [8]. The time dependences of the conversion of the monomer (Fig. 1) show that, in the initial stages of copolymeri-

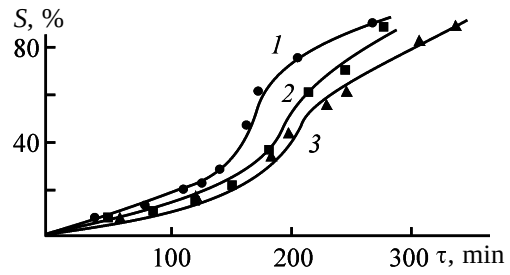

Fig. 1. Variation of the conversion of the monomer *S* with the time τ at *T* = 65°C. Mixture composition: (*1*) MMA, (*2*) F_1–MMA, and (*3*) F_2–MMA.

zation, the plots for these systems contain a linear portion, which is followed by autoacceleration at 25–30% conversions. The copolymerization rate in all the stages of synthesis is smaller than that of homopolymerization of MMA and tends to decrease with lengthening of the fluoroalkyl substituent, the gel effect being smoothened out. The length of the fluoroalkyl substituent affected the homopolymerization kinetics in studies of a number of fluoroalkyl acrylates as well [4].

It was found earlier [9] that the rate of homopolymerization of fluoroalkyl monomers in the initial stages (up to 10% conversion of the monomer) is 35–45% lower than the MMA homopolymerization rate. We estimated the ratio of the rate constants of addition of the "own" or "foreign" monomer to the propagating macroradical during copolymerization of the monomers by studying the composition of the copolymer formed in the initial stages of the reaction. From the IR data, we elucidated the compositions of the copolymers obtained by copolymerization of F_1 with MMA and F_2 with MMA, as well as their dependences on the composition of the initial monomer mixture (Fig. 2).

It is seen that the copolymers synthesized are enriched in fluorinated components. Table 1 presents the copolymerization constants r_1 and r_2 calculated by the Fineman–Ross method. For comparison, Table 1 also presents the copolymerization constants for these systems, calculated by the Alfrey–Price method using the published data on the Q–e parameters. The experimental and calculated copolymerization constants are close and suggest that the resulting macroradicals containing one of the monomers (fluoroalkyl methacrylate or MMA) as a terminal unit preferably add molecules of fluorinated monomers. Such a character of the chain propagation can be due to the known ability of fluoroalkyl methacrylates to form associates by hydrogen bonding between protons and $–CF_2–$ groups [10]. To estimate the degree of association of the mixtures of the monomers, we determined their viscosity at temperatures within 25–65°C and carried out calculations by the formula

$$g = \frac{2Nh}{\eta}\frac{\rho}{M}\exp\{1 + m[bT^m/(a + bT^m)]\}, \qquad (1)$$

where g is the degree of association; N, Avogadro number; h, Planck constant; a and b, constants from the equation $1/\eta = a + bT^m$; and m, varied parameter.

Figure 3 presents the dependence of the degree of association on the composition of the initial monomer

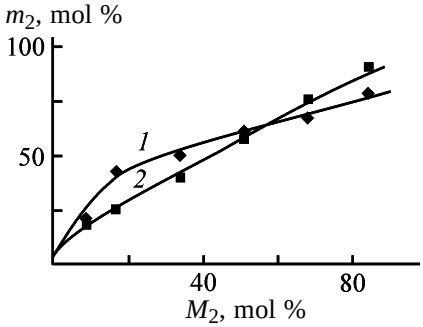

Fig. 2. Variation of the content of the F_1, F_2 units in copolymers (m_2) with the content of F_1, F_2 in the initial monomer mixture (M_2) for MMA copolymerization with (*1*) F_1 and (*2*) F_2.

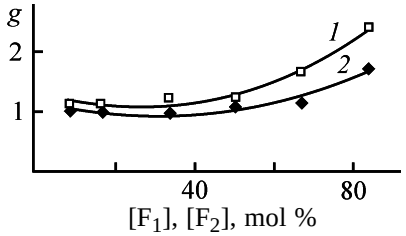

Fig. 3. Degree of association g of the MMA mixtures with (*1*) F_1 and (*2*) F_2 as a function of the content of fluoroalkyl methacrylates [F_1] and [F_2].

mixture. It is seen that the degree of association tends to increase with increasing proportion of the fluorinated component and length of the fluoroalkyl substituent. For example, for the F_2–MMA system, the degree of association is higher than for F_1–MMA. From the $\ln\eta$ vs. $1/T$ plot we determined the viscous flow activation energy E_a characterizing the energy of bonding between the molecules of the monomers (Table 2). It is seen that E_a tends to increase with increasing amount of the fluorinated component in the system. These data correlate with the degrees of association, calculated by formula (1).

It is known [11] that the structure of the associates in the liquid phase affects the polymerization kinetics, supramolecular structure of polymers, and their physical properties. This makes our data essential for interpreting the kinetic relationships in copolymerization in the systems of interest. For example, the relation-

ships for the rate of copolymerization of fluoroalkyl methacrylates with methyl methacrylate vs. the degree of association in the initial stages, which were established earlier [9] (Fig. 4), suggest that it affects the kinetics of the process: The higher the degree of association, the lower the rate. It is known that fluoroalkyl methacrylates form dimerized structures via cooperative interaction of the fluoroalkyl substituents of the neighboring molecules, and the energy of this interaction increases from 16.5 to 25.7 kJ mol^{-1} with increasing number of the $-CF_2-$ groups from 2 to 4 [12]. In this case, the most probable structure of the dimer being formed contains oxygen atoms and, correspondingly, the double bonds are at the maximal distance from one another. Probably, interaction of the propagating macroradical with such dimer does not result in its degradation. In this case, further propagation of the polymer chain is sterically hindered, which is responsible for deceleration of the process.

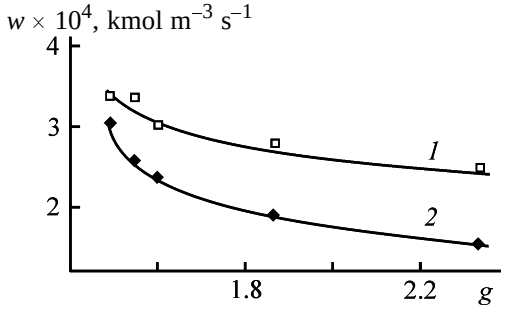

Fig. 4. Copolymerization rate w of MMA with (*1*) F_1 and (*2*) F_2 as a function of the degree of association g.

The copolymerization constants r_1 and r_2 that we determined show that, in the initial stages of copolymerization, the fluorinated monomer is consumed preferentially. With increasing extent of the reaction, the monomer mixture gets enriched in MMA, which favors formation of macromolecules with different compositions, though thermodynamically compatible, as suggested by the transparency of the copolymer throughout the composition range studied. For a number of the copolymers obtained, we determined the glass transition points, densities, and wettability with water. Thermomechanical measurements for the copolymers based on F_2–MMA showed that, with increasing proportion of the fluorinated component from 10 to 60 mol %, the glass transition point decreases from 80 to 50°C. The wetting contact angle varies from 65° to 80°, depending on the content of the fluoroalkyl methacrylate units in the copolymer.

We used the semiempirical method of group contributions proposed by Davies and Gottlieb [13], based on the principle of additivity, for establishing a relationship between the chemical composition and physical properties of the copolymers; Table 3 presents the calculated densities and refractive indices. These data suggest that the refractive index tends to markedly decrease with increasing amount of the fluoroalkyl methacrylate in the copolymer. Table 3 also presents the experimental densities of the copolymers based on fluoroalkyl acrylates and MMA, which slightly exceed the calculated data. Budovskaya *et al.* [14] showed that associates are formed not only between the fluoroalkyl acrylate molecules but also between the monomeric units of the homopolymer thereof, which is responsible for ordering of the structure and increase in the density of the copolymers. The discrepancy between the experimental densities and those calculated using the principle of additivity also suggests the possibility of formation of similar associative structures in these copolymers based on F_1 and MMA or F_2 and MMA.

CONCLUSIONS

(1) In the course of radical copolymerization of 1,1,3-trihydroperfluoropropyl methacrylate and 1,1,5-trihydroperfluoroamyl methacrylate with methyl methacrylate, the reaction rate decreases with increasing amount of the fluorinated monomer in the initial mixture. The compositions of the copolymers for these systems were determined, and the copolymerization constants were calculated.

(2) Transparent copolymers were synthesized from binary systems comprised of 1,1,3-trihydroperfluoropropyl methacrylate or 1,1,5-trihydroperfluoroamyl methacrylate and methyl methacrylate. These copolymers have glass transition points within 50–80°C and contact angles of wetting with water of 65°–80°, depending on the composition of the copolymer.

Received November 29, 2004

Abstract—Amphiphilic polymers of *N*-vinylpyrrolidone (M_n = 1100–11 000) and acrylamide (M_n = 2000–8000) with the terminal *n*-octadecyl group were prepared.

Nanosized carriers for biologically active substances and drugs (liposomes, nanoaggregates) attract much researchers' attention. They not only ensure controllable (prolonged) release of an active substance with a decreased probability of its side effects, but also make poorly soluble compounds lyophilic, allowing their administration in the form of disperse aqueous systems, e.g., by injection.

An efficient way to enhance the performance of nanosized carriers involves the use of water-soluble amphiphilic (diphilic) polymers for forming nanoaggregates and modifying liposomal membranes, thus increasing their stability. The most frequently used amphiphilic polymers are polyethylene oxides containing a terminal hydrophobic group [1–5].

Recently we suggested to use as such polymers amphiphilic derivatives of water-soluble carbon-chain polymers, primarily poly-*N*-vinylpyrrolidone (PVP), a component of many drug systems [6–10]. Modification of liposomes with amphiphilic *N*-vinylpyrrolidone polymers prolongs their circulation in the blood of laboratory animals and decreases their uptake by liver cells [6]. The interaction of aggregates of these polymers with proteins, including blood proteins, was considered [9, 10].

Here we consider the features of synthesis of amphiphilic *N*-vinylpyrrolidone and acrylamide polymers of various molecular weights with a single hydrophobic group of various structures.

EXPERIMENTAL

N-Vinylpyrrolidone was distilled in a vacuum at 363 K/14 mm Hg. Acrylamide was purified by recrystallization from benzene, mp 357–358 K. Azobis(isobutyronitrile) (AIBN) was purified by twofold recrystallization from ethanol, mp 378–379 K. Mercaptoacetic acid, 1,3-dicyclohexylcarbodiimide (DCC), and amines (*n*-octylamine, *n*-dodecylamine, *n*-hexadecylamine, *n*-octadecylamine, di-*n*-hexylamine, di-*n*-octylamine, di-*n*-octadecylamine) were used without additional purification. All the chemicals were purchased from Sigma.

Mercaptoethylamine was used as a solution in isopropyl alcohol; it was recovered from the hydrochloride (Sigma) by treatment with triethylamine. The reaction was performed in a round-bottomed flask equipped with a stirrer. The flask was charged with 11.35 g (0.1 mol) of mercaptoethylamine hydrochloride dissolved in 30 ml of dry isopropyl alcohol, and 10.1 g (0.1 mol) of triethylamine in 20 ml of dry isopropyl alcohol was added with cooling. The precipitate of triethylammonium chloride was filtered off, and the filtrate was stored at 275–278 K. The salt precipitate on the filter was washed with ether and dried to constant weight. Thus, a solution of 0.1 mol of mercaptoethylamine in 50 ml of isopropyl alcohol was obtained.

Stearoyl chloride was prepared by treatment of the acid with thionyl chloride. A flask for vacuum distillation, equipped with a tube for removal of HCl, was charged with 20 g (0.1 mol) of stearic acid. Thionyl chloride (29.28 g, 0.4 mol) was slowly added dropwise from a dropping funnel. A catalytic amount (0.8 ml) of dimethylformamide was added. The mixture was allowed to stand for 10 h, after which excess thionyl chloride was distilled off. The chloride was isolated by vacuum distillation (479 K/2 mm Hg). The

* Number-average molecular weight determined from the content of terminal groups.
** Number-average molecular weight determined by vapor osmometry.

product was stored in a refrigerator in sealed ampules filled with argon.

Solvents (dioxane, dimethylformamide, acetone, isopropyl alcohol, ethanol, chloroform, toluene, diethyl ether) were purified by common procedures.

N-Vinylpyrrolidone and acrylamide polymers containing a terminal amino or carboxy group were prepared as follows: 5.55 g (0.05 mol) of *N*-vinylpyrrolidone or 3.55 g (0.05 mol) of acrylamide and 0.05 g of AIBN initiator were dissolved in 10 ml of dioxane (35% or 25% solution of the monomer, respectively), and various amounts of mercaptoacetic acid or mercaptoethylamine were added. Ampules with the resulting solutions were purged with an inert gas, sealed, and kept at 343 K for 1 h. The polymers were isolated by precipitation into diethyl ether, purified by extraction with diethyl ether, and dried to constant weight in a vacuum. The yields of the polymers and amounts of the mercaptan added are given in the table. The content of terminal groups was determined by potentiometric titration.

N-Vinylpyrrolidone and acrylamide polymers containing terminal alkyl groups were prepared from the polymers with terminal carboxy or amino groups.

(1) A calculated amount of PVP or polyacrylamide (PAA) containing a terminal carboxy group (1CPVP–6CPVP; 1CPAA–5CPAA) was dissolved in dry isopropyl alcohol, and a solution of excess DCC (2.0 mol per mole of carboxy groups) in the same solvent was added with stirring. The mixture was stirred at 273 K for 1 h, after which a solution of appropriate aliphatic amine (*n*-octylamine, *n*-dodecylamine, *n*-hexadecylamine, *n*-octadecylamine, di-*n*-hexylamine, di-*n*-octylamine, di-*n*-octadecylamine; 1.5 mol per mole of carboxy groups) in dry isopropyl alcohol was added, and the mixture was heated for 2 h at 333 K. The precipitate that formed after cooling was filtered off, and the filtrate was evaporated to a volume of ~10 ml. The resulting polymer was precipitated into diethyl ether, extracted with diethyl ether, and dried in a vacuum to constant weight. The yield of the polymers was 75–80% in all the cases.

(2) A portion of PVP containing a terminal amino group (1APVP–5APVP) was dissolved in dry dioxane. To the resulting solution, the calculated amount of triethylamine in dioxane and then stearoyl chloride in dioxane were added with stirring at 273 K; the mixture was allowed to stand at room temperature for 2 h. The precipitate of triethylammonium chloride was filtered off, and the polymer was precipitated into diethyl ether, extracted with diethyl ether, and dried in a vacuum to constant weight.

The determinations of the number-average molecular weight by vapor osmometry were performed with a Knauer osmometer (Germany).

Amphiphilic derivatives of PVP and PAA containing terminal hydrophobic groups were prepared in two steps. The first step involved radical polymerization of the corresponding monomers in the presence of initiators generating primary radicals and radical-transfer agents which generate, under the action of primary radicals, new radicals initiating the chain propagation.

As such transfer agents we used mercaptans containing, along with the SH group, an additional functional group. The high reactivity of mercaptans in radical processes is well known [11–13]. With polystyrene and poly(methyl methacrylate) as examples, we demonstrated the feasibility of introducing terminal functional groups using mercaptans as chain-transfer agents [12].

Mercaproacetic acid and 2-mercaptoethylamine, used in this study, allowed introduction of a single terminal carboxy or amino group into the polymer.

The main reactions occurring in the system at a sufficient amount of a mercaptan can be described by the following scheme:

Generation of initiating radical

$$I \rightarrow [2R_1^{\bullet}],\ [2R_1^{\bullet}] \rightarrow R_1^{\bullet} + R_1^{\bullet}, \quad (1)$$

$$[2R_1^{\bullet}] \rightarrow R_1\text{–}R_1, \quad (2)$$

$$R_1^{\bullet} + H\text{–}S \rightarrow R_1\text{–}H + S^{\bullet}; \quad (3)$$

Initiation

$$S^{\bullet} + M \rightarrow S\text{–}M^{\bullet}, \quad (4)$$

$$R_1^{\bullet} + M \rightarrow R_1\text{–}M^{\bullet}; \quad (5)$$

Chain propagation

$$R_1^{\bullet}\text{–}M + M_n \rightarrow R_1\text{–}M_{n+1}^{\bullet}, \quad (6)$$

$$S\text{–}M^{\bullet} + M_n \rightarrow S\text{–}M_{n+1}^{\bullet}; \quad (7)$$

Chain termination

$$S\text{–}M_{n+1}^{\bullet} + H\text{–}S \rightarrow S\text{–}M_{n+1}\text{–}H + S^{\bullet}, \quad (8)$$

$$S\text{–}M_{n+1}^{\bullet} + {}^{\bullet}M_{n+1}\text{–}S \rightarrow S\text{–}M_{n+1}\text{–}M_{n+1}\text{–}S, \quad (9)$$

$$S\text{–}M_{n+1}^{\bullet} + S^{\bullet} \rightarrow S\text{–}M_{n+1}\text{–}S, \quad (10)$$

$$S\text{–}M_{n+1}^{\bullet} + R_1^{\bullet} \rightarrow S\text{–}M_{n+1}\text{–}R_1. \quad (11)$$

where I is the initiator; M, monomer; $R_1^{\bullet}$, primary radical formed by decomposition of the initiator; $S^{\bullet}$, radical formed from the mercaptan; $S\text{–}M^{\bullet}$, $R_1\text{–}M^{\bullet}$, $R_1\text{–}M_{n+1}^{\bullet}$, and $S\text{–}M_{n+1}^{\bullet}$, propagating polymeric radicals; $S\text{–}M_{n+1}\text{–}H$, $S\text{–}M_{n+1}\text{–}M_{n+1}\text{–}S$, $S\text{–}M_{n+1}\text{–}S$, and $S\text{–}M_{n+1}\text{–}R_1$, inert molecules; and H–S, molecule of the chain-transfer agent.

At a sufficient amount of a mercaptan, the chain propagation can be effected not by the primary radical formed by decomposition of the initiator but by the radical $S^{\bullet}$ formed by proton abstraction from the mercaptan, i.e., reaction (4) can prevail over reaction (5).

It is known that the rate of reaction of primary radicals with mercaptans exceeds the initiation rate by several orders of magnitude [14]. Therefore, presumably, the primary radical $R_1^{\bullet}$ is mainly consumed in reaction (3) rather than (5). Thus, under these conditions, the chain propagation is mainly initiated by the $S_1^{\bullet}$ radical, and the chain starts specifically from this group, which is confirmed by determinations of the number-average molecular weight of the polymers.

When studying polymerization of vinylpyrrolidone and acrylamide in the presence of a radical polymerization initiator (AIBN) and functional chain-transfer agents (mercaptoacetic acid, mercaptoethylamine), we examined how the amount of the mercaptan added affects the yield and molecular weight of the polymers formed.

In our case, the simplified reaction scheme is as follows:

$$AIBN \rightarrow 2CH_3\text{—}\overset{\displaystyle CH_3}{\overset{|}{\underset{|}{C^{\bullet}}}}\underset{\displaystyle CH_3}{} + N_2,$$

$$R_1^{\bullet} + HS\text{–}R' \rightarrow R_1\text{–}H + {}^{\bullet}S\text{–}R',$$

$$R_2^{\bullet} + nM \rightarrow R_2\text{–}(M)_{n-}^{\bullet}, \quad (R_3^{\bullet})$$

$$R_3^{\bullet} + HS\text{–}R \rightarrow R_3\text{–}H + R_2^{\bullet},$$

where M is a monomer molecule or monomeric unit; R' = $-CH_2COOH$ or $-CH_2CH_2NH_2$.

As seen from Figs. 1 and 2, the yield and molecular weight of the polymer decreased with an increase in the amount of the mercaptan added, which is apparently due to accelerated chain termination.

The polymers prepared contained a single terminal functional group, as confirmed by agreement of the molecular weights determined from the content of terminal groups and by vapor osmometry (see table).

Thus, this step yielded semitelechelic polymers with the molecular weights in the range suitable for

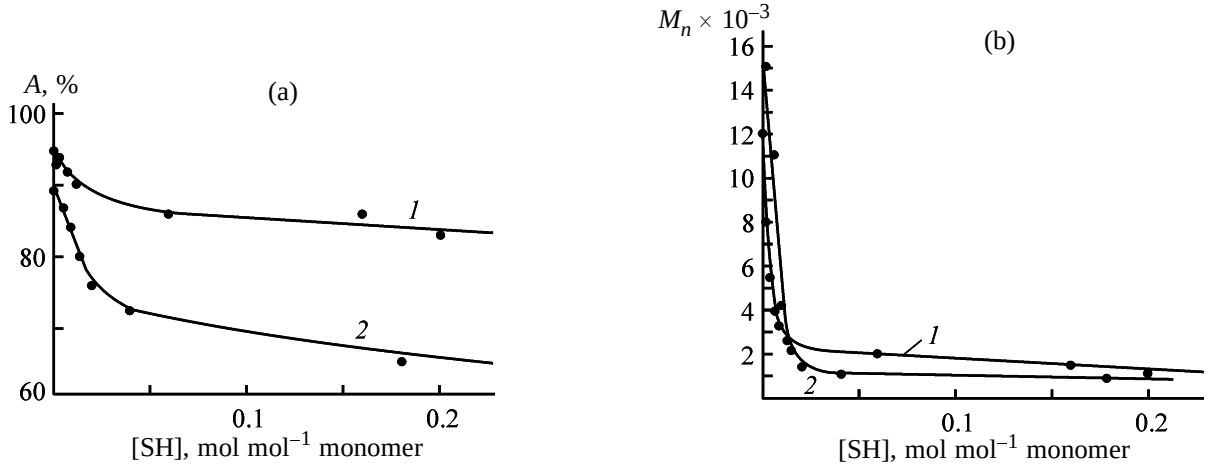

Fig. 1. Influence of mercaptan additions on the (a) yield *A* and (b) M_n of poly-*N*-vinylpyrrolidone. *N*-Vinylpyrrolidone and AIBN concentrations 35 and 1.5 wt %, respectively; 343 K; solvent dioxane. SH: (*1*) mercaptoacetic acid and (*2*) Mercaptoethylamine.

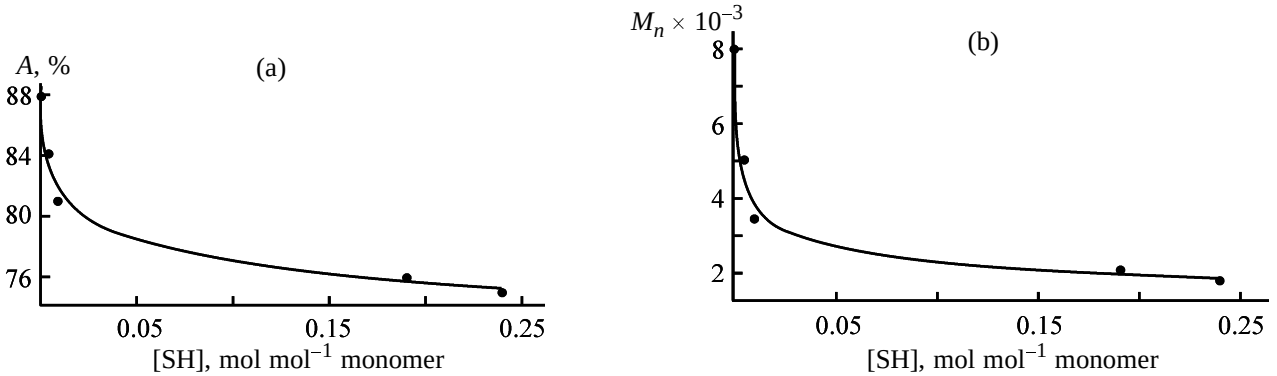

Fig. 2. Influence of mercaptoacetic acid additions on the (a) yield *A* and (b) M_n of polyacrylamide. Acrylamide and AIBN concentrations 25 and 1 wt %, respectively; 343 K; solvent dioxane.

preparing drug carriers. By varying the amount of the mercaptan added, it is possible to control the molecular weight of the products. We obtained in fairly high yield two series of polymers containing terminal amino and carboxy groups and having different molecular weights.

In the second step, into the semitelechelic polymers containing a terminal reactive group we introduced a long-chain alkyl group by the reaction with aliphatic amines containing various alkyl radicals (in the case of carboxy terminal group) or with an aliphatic acyl chloride (in the case of amino terminal group).

The modification of the carboxyl-containing polymer involved activation of the carboxy group with DCC followed by treatment with appropriate amine (*n*-octylamine, *n*-dodecylamine, *n*-hexadecylamine, *n*-octadecylamine, di-*n*-hexylamine, di-*n*-octylamine, di-*n*-octadecylamine), with *N*,*N*'-dicyclohexylurea (DCU) formed as by-product, and the modification of the amino-containing polymers, by treatment with stearoyl chloride, with the release of HCl.

This procedure allowed preparation of water-soluble amphiphilic polymers with the same hydrophobic terminal groups and different molecular weights of the polymeric fragment and with different hydrophobic terminal groups and the same molecular weight of the polymeric fragment. In the latter case, modification was performed with a PVP sample with M_n = 4000 and a terminal carboxy group.

Formation of amphiphilic polymers can be described by the following scheme:

$$\mathrm{H{-}[{-}M{-}]_n{-}SCH_2CH_2NH_2 + ClCO{-}C_{17}H_{35}}$$

$$\xrightarrow[-\mathrm{HCl}]{\mathrm{N(C_2H_5)_3}} \mathrm{H{-}[{-}M{-}]_n{-}SCH_2CH_2NHCO{-}C_{17}H_{35}},$$

$$\mathrm{H{-}[{-}M{-}]_n{-}SCH_2COOH + H_xNR_y}$$

$$\xrightarrow[-\mathrm{DCU}]{\mathrm{DCC}} \mathrm{H{-}[{-}M{-}]_n{-}SCH_2CONH_{x-1}R_y},$$

where M is a monomeric unit of *N*-vinylpyrrolidone

or acrylamide; H_xNR_y = $CH_3(CH_2)_{17}NH_2$, $[CH_3 \cdot (CH_2)_{17}]_2NH$, $CH_3(CH_2)_{15}NH_2$, $[CH_3(CH_2)_7]_2NH$, $CH_3(CH_2)_{11}NH_2$, $[CH_3(CH_2)_5]_2NH$, $CH_3(CH_2)_7NH_2$.

The degree of substitution of the reacting terminal groups was determined by potentiometric titration under the same conditions as in determination of these groups for evaluating the molecular weight. No residual terminal groups were detected, which suggests their virtually complete substitution. The elemental analysis is unsuitable for this purpose, because the difference in the C, H, N content due to substitution was insignificant in samples of higher molecular weights and did not exceed 1.5–2.5% in samples of lower molecular weights.

The IR spectra of the polymers (KBr pellets) in the range of carbonyl absorption exhibited, along with the major band corresponding to the fully substituted amide group in the pyrrolidone ring (~1650 cm^{-1}) and unsubstituted amide group in polyacrylamide (~1690 cm^{-1}), an additional band corresponding to a monosubstituted amine in the terminal group (~1680 and 1640 cm^{-1}). The relative intensity of this band increased with a decrease in the molecular weight of the polymer. Furthermore, the intensity of absorption of the methylene groups in the IR spectra of these polymers increased owing to introduction of long-chain terminal alkyl groups (633, 2850 cm^{-1}).

CONCLUSIONS

(1) Amphiphilic polymers containing a single terminal hydrophobic group were prepared.

(2) Reaction conditions were found for preparing amphiphilic *N*-vinylpyrrolidone and acrylamide polymers with the required molecular weight in the range M_n = 1500–11000; these polymers can be used for the development of new drug carriers.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Radiation-Induced Graft Polymerization of Glycidyl Methacrylate onto Nonwoven Polypropylene

Yu. V. Bondar', Hong Je Kim, and Yong Jin Lim

Institute of Environmental Geochemistry, Kiev, Ukraine

Received September 27, 2004; in final form, March 2005

Abstract—The influence of the major grafting parameters (irradiation dose, reaction time, and inhibitor concentration) on graft polymerization of glycidyl methacrylate from its 10% solution in methanol onto nonwoven polypropylene upon irradiation with an electron accelerator in air was studied.

Graft polymerization is an efficient method of modification of polymeric substrates. Economically efficient and environmentally clean radiation technologies, e.g., radiation-induced graft polymerizations, offer a number of undoubted advantages [1]. In particular, this method allows controlled introduction into an inert polymeric matrix of polymeric chains with functional groups and preparation of polymeric adsorbents (chemisorption fibers, fabrics, films) of the desired form and with varied concentration of ion-exchange groups. Functional groups can be introduced both by one-step radiation-induced graft polymerization of the appropriate monomers and by grafting of precursor monomers, followed by polymer-analogous reactions. In view of a limited number of accessible vinyl monomers with functional groups, the second option, in particular, grafting of glycidyl methacrylate (GMA), a vinyl monomer containing epoxy groups, showed much promise.

Radiation-induced (co)polymerization of GMA, as well as of other vinyl monomers, follows the chain radical mechanism, involving the double bonds, while epoxy rings remain fairly inert and contribute only slightly to formation of cross-links [2]. At the same time, the well-known [3] high reactivity of the epoxy rings of GMA in nucleophilic substitution reactions makes GMA a promising precursor monomer.

Radiation-induced graft polymerization and the subsequent modification of epoxy rings in GMA, aimed at preparation of adsorbents thereof, were actively studied by Saito, Kim, *et al.* [4–10]. Their technique included irradiation of the polymeric substrate with an electron accelerator in a nitrogen atmosphere up to a dose of 200 kGy, grafting of GMA chains in a 10% solution of GMA in methanol at 313 K, preparation of samples with the degree of grafting of 200% , and subsequent polymer-analogous reactions involving the epoxy rings.

More extensive information about the features of grafting GMA chains onto various polymeric substrates can be found in papers by Choi *et al.* [11–13]. They studied how the experimental parameters, namely, irradiation dose, monomer concentration (GMA–1,4-dioxane solution), temperature, and time of reaction affect the degree of graft polymerization of GMA upon irradiation of a polymeric substrate (^{60}Co source) in air. However, both research teams examined the influence of the experimental parameters only on the degree of graft polymerization of GMA chains (increase, in per cent, of the weight of the sample upon grafting). Therefore, we can only indirectly judge the efficiency of both grafting and conversion of the epoxy groups in GMA into functional groups during the subsequent polymer-analogous reactions.

In this study we examined how the major parameters of graft polymerization of GMA onto nonwoven polypropylene (PP) upon irradiation with an electron accelerator in air affect graft polymerization and represented the results as the plots of the density of grafted GMA chains vs. the degree of grafting.

EXPERIMENTAL

As a polymeric base for grafting GMA chains served nonwoven material from PP fibers, available from Saehan Filter Co Ltd, with an average thickness of 2 mm and density of 4.6×10^{-3} g cm^{-2}. Graft polymerization was performed by the pre-irradiation method [1]. Irradiation was carried out in an ELV-04 conveyor accelerator by a 1-MeV electron beam. After irradiation, the fabric was kept in a desiccator at room temperature, and polymerization was carried out with-

1070-4272/05/7805-0811 © 2005 Pleiades Publishing, Inc.

in 1–5 days after electron beam irradiation. In experiments we used GMA available from Aldrich. The irradiated sample was placed into a flask with an alcoholic solution of GMA; the resulting solution was purged with nitrogen, and the flask was closed tight and kept at the desired temperature, whereupon graft polymerization was carried out under continuous stirring and water cooling. The material was washed with tetrahydrofuran and then with methanol for 24 h to remove the homopolymer and unchanged monomer. The sample was dried to constant weight at 70°C.

The degree Q_{gr}, %, of grafting glycidyl methacrylate was estimated gravimetrically:

$$Q_{gr} = \frac{m_0 - m_1}{m_0} \times 100,$$

where m_0 and m_1 are the weights of the sample before and after grafting, respectively.

The density of the grafted GMA chains S_{GMA} (mmol g^{-1}) was calculated by the formula

$$S_{GMA} = \frac{(m_1 - m_0) \times 1000}{m_1 M_{GMA}},$$

where M_{GMA} is the molecular weight of GMA (142).

The presence of functional groups was judged from the IR spectra recorded on a Perkin–Elmer Golden Gate Single Reflection ATR System IR spectrophotometer.

The specific factor for graft polymerization by the pre-irradiation method is the absorbed irradiation dose, which governs the concentration of the active centers of grafting. However, by varying such parameters as temperature and time of reaction, the reaction medium, and the concentration of the sensitizing additives, it is possible to control the polymerization and prepare the product with the desired degree of grafting.

The specific features of radiation-induced graft polymerization of GMA onto various polymeric substrates (polyethylene, polypropylene, and polysulfone films, membranes, fibers) under irradiation with both γ-rays and accelerated electrons were considered in [4–13]. It was shown that efficient GMA grafting can be achieved in methanol, 1,4-dioxane, and water–methanol (1 : 1 by weight) system. Choi *et al.* [12, 13] noted a higher efficiency of grafting in the GMA–1,4-dioxane system, but their results did not differ essentially from those for the GMA–methanol system. In this study, we grafted the GMA chains onto nonwoven fabric made of polypropylene fibers in the GMA–methanol system, since methanol is relatively inexpensive and readily available.

As known, exposure of various polymers to radiation in the presence of atmospheric oxygen (pre-irradiation method) yields hydroperoxides as the main stable products [14], which are thermally stable at common temperatures and degrade upon heating above 60°C into macroradicals PPO$^{\bullet}$ and hydroxy radicals OH$^{\bullet}$. The macroradical provides the site for grafting, and the hydroxy radical can initiate homopolymerization of the monomers M. The scheme of this mechanism was discussed in numerous papers (e.g., in [15]) and can be represented as follows:

$$\text{PP–H} \xrightarrow{O_2} \text{PP–OOH} \xrightarrow{\Delta} \text{PPO}^{\bullet} + \text{OH}^{\bullet},$$

$$\text{PPO}^{\bullet} + n\text{M} \longrightarrow \text{PPO}^{\bullet}\text{–M}_n,$$

$$\text{M} + \text{OH}^{\bullet} \longrightarrow \text{M}^{\bullet}\text{–OH} \xrightarrow{n\text{M}} \text{M}^{\bullet}\text{–(M)}_n\text{–H},$$

$$\text{PPO}^{\bullet} + \text{M}^{\bullet}\text{–(M)}_n\text{–OH} \longrightarrow \text{PPO–M–(M)}_n\text{–OH}.$$

Homopolymerization of the monomers can be suppressed by addition of transition metal salts [16, 17], which increases the degree of grafting:

$$\text{OH}^{\bullet} + \text{Fe}^{2+} \longrightarrow \text{OH}^{-} + \text{Fe}^{3+}.$$

Transition metal salts favor efficient degradation of hydroperoxides at temperatures below 60°C:

$$\text{PP–OOH} + \text{Fe}^{2+} \longrightarrow \text{PPO}^{\bullet} + \text{OH}^{-} + \text{Fe}^{3+}.$$

Under excess of transition metal salts, active centers can be deactivated:

$$\text{PPO}^{\bullet} + \text{Fe}^{2+} \longrightarrow \text{PPO}^{-} + \text{Fe}^{3+}.$$

In [4–13], the influence of transition metal salts on the degree of graft polymerization of GMA was not discussed.

We studied how the absorbed dose affects graft polymerization of GMA from its 10% solution in methanol (Fig. 1). The reaction was run at 70°C, which favors degradation of hydroperoxides. However, for the samples irradiated at a dose under 40.2 kGy, grafting was not achieved even within 2 h of the reaction, and the degree of grafting of the samples irradiated at a dose of 70.5 kGy proved to be insignificant. This pattern may be due both to a low concentration of the macroradicals yielded by degradation of hydroperoxides and to the influence of

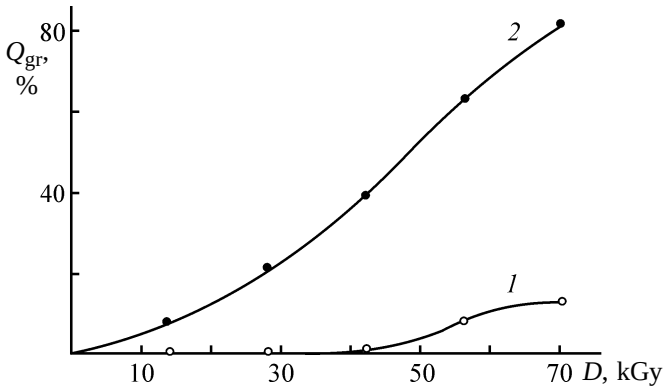

Fig. 1. Degree Q_{gr} of graft polymerization of GMA as a function of the absorbed dose D at the Mohr's salt content of (*1*) 10^{-2} and (*2*) 0 wt % (70°C, 2 h).

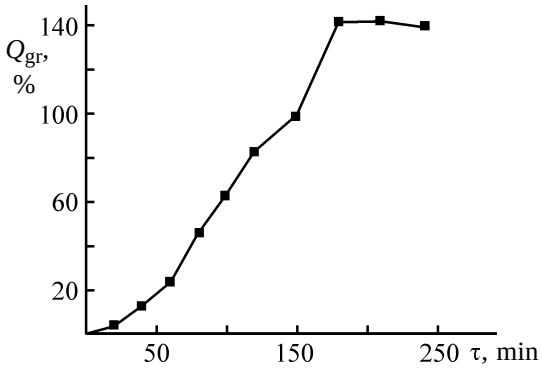

Fig. 3. Degree Q_{gr} of graft polymerization as a function of the reaction time τ. Irradiation dose 70.5 kGy, 70°C; Mohr's salt content 10^{-2} wt %.

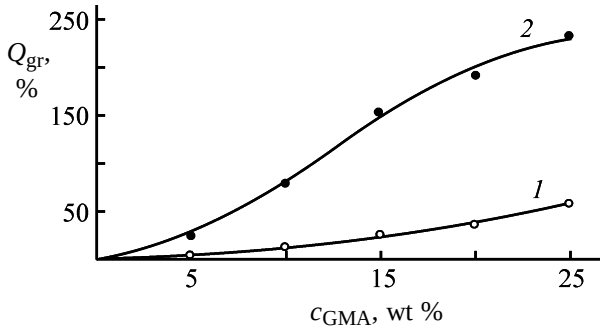

Fig. 2. Degree Q_{gr} of graft polymerization as a function of the monomer concentration c_{GMA} (*1*) upon addition of 10^{-2} wt % of Mohr's salt and (*2*) without Mohr's salt. Irradiation dose 70.5 kGy, 70°C, 2 h.

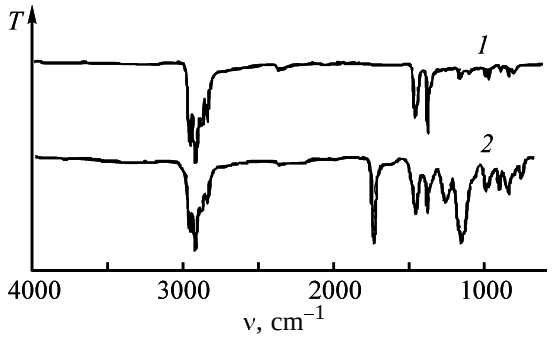

Fig. 4. IR spectra of polypropylene (*1*) before and (*2*) after GMA grafting. (*T*) Transmission and (ν) wave number.

homopolymerization. Grafting was intensified by addition of Mohr's salt (10^{-2} wt %) (Fig. 1, curve *1*). The degree of grafting GMA in this case increased with increasing absorbed dose from 14.1 to 70.5 kGy.

Also, we studied the sensitizing effect of the Mohr's salt on the degree of GMA grafting onto an nonwoven PP substrate from its 10% solution in methanol (irradiation dose 70.5 kGy, 70°C, 2 h). With increasing Mohr's salt concentration in solution from 0 to 0.03 wt % (0.5×10^{-5}, 10^{-4}, 5×10^{-3}, 10^{-2}, 2×10^{-2}, 3×10^{-2} wt %), the degree of grafting changed from 13.6 to 81.5% (13.6, 17.1, 51.0, 78.6, 81.5, 75.1, 74.8%, respectively). The maximal degree of grafting, 81.5%, was achieved upon addition of 10^{-2} wt % of Mohr's salt.

The dependence of the degree of GMA grafting on the monomer concentration was studied over the concentration range 0–25 wt % with and without Mohr's salt (Fig. 2). The degree of grafting of the GMA chains increases with increasing monomer concentration in both cases. However, addition of Mohr's salt (10^{-2} wt %) causes the degree of graft polymerization of GMA to increase 6–7-fold throughout the concentration range studied (Fig. 2, curve *1*). For example, the degree of grafting GMA from its 10% solution without Mohr's salt is 13.6%, and with Mohr's salt, 81.5%.

Also, we studied the kinetics of graft polymerizations of GMA onto a nonwoven PP substrate from its 10% solution in methanol. It is seen from Fig. 3 that the reaction goes fairly rapidly in the first 3 h, whereupon it is decelerated and attains saturation.

The presence of functional groups in the samples under study was judged from the IR spectra. Figure 4 shows the IR spectra of PP before and after GMA grafting. The IR spectrum of PP with grafted GMA chains contains absorption bands at 1730, 1300–1100 cm^{-1}, assigned to C=O and C–O–C vibrations, and also bands at 1260, 950–815, and 760 cm^{-1}, corresponding to vibrations of the epoxy groups.

Thus, by varying the experimental parameters [irradiation dose, time of reaction, inhibitor concentration in the course of graft polymerization at 70°C

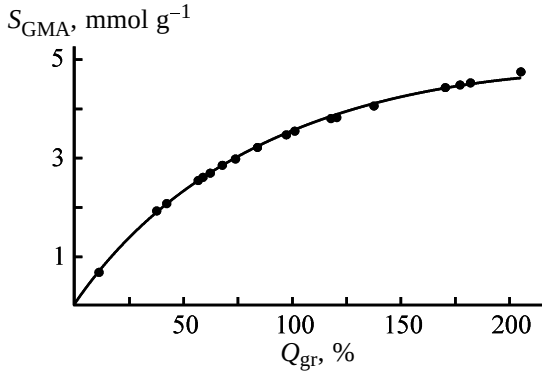

Fig. 5. Density of grafted GMA chains S_{GMA} as a function of the degree Q_{gr} of graft polymerization of GMA.

from 10% solutions of GMA in methanol (higher temperatures cause intensive evaporation of methanol under water cooling of the reactor)], we obtained samples with widely varying densities of epoxy groups, as seen in Fig. 5.

CONCLUSIONS

(1) Radiation-induced graft polymerization of glycidyl methacrylate chains onto nonwoven polypropylene fabric was studied. The influence of grafting parameters, namely, absorbed dose, concentration of the sensitizing additives (Mohr's salt), and time of reaction, on graft polymerization of glycidyl methacrylate from its 10% solution in methanol at 70°C was examined.

(2) Using pre-irradiation method, glycidyl methacrylate at 70°C can be grafted most effectively upon adding 10^{-2} wt % of Mohr's salt.

(3) The degree of grafting glycidyl methacrylate was studied as dependent on the density of its grafted chains on a nonwoven polypropylene substrate. This allows quantitative estimation of the efficiency of both grafting and conversion of the epoxy rings to functional groups in the subsequent polymer-analogous reactions.

Abstract—The radical polymerization of styrene in an emulsion stabilized with an ionic surfactant, with *C*-phenyl-*N*-*tert*-butylnitrone as chain-terminating agent and ammonium persulfate as initiator, was studied.

Pseudo-living radical polymerization is an actively developing field of synthetic chemistry of polymers [1–4]. Among chain-terminating agents used in these processes, stable nitroxyl radicals have been studied most comprehensively. With these radicals, the polymerization can be performed without gel effect, the molecular weight of macromolecular compounds can be linearly increased with conversion, and homo- and copolymers with relatively low polydispersity coefficients can be prepared. Furthermore, the polymers prepared in the presence of nitroxyls are macroinitiators themselves, which opens wide prospects for block copolymerization and design of macromolecules as a whole.

The most frequently used controlling agent in pseudo-living radical polymerization, both in the bulk [2–4] and in heterogeneous aqueous dispersions, including emulsions, suspensions, and miniemulsions [5–8], is 2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPO). An essential disadvantage of this compoumnd as a chain-terminating agent is that, with this compound, the controlled polymerization takes place only at relatively high temperatures (120–140°C) and only with styrene and its derivatives. However, even under these conditions the polymerization rate is extremely low (e.g., for styrene at 120°C the reduced rate w/[styrene] does not exceed $\sim 2 \times 10^{-5}$ s^{-1} [9]).

A search for new effective chain life regulators led to development of a procedure for *in situ* preparation of nitroxyl radicals. The sources of stable radicals in [10–16] were spin traps, nitroso compounds and nitrones, which react with propagating radicals to form sterically hindered macromolecular nitroxyls. These radicals effect bulk polymerization in the pseudo-living/controlled mode of not only styrene, but also methyl methacrylate, butyl methacrylate, vinyl chloride, and acrylonitrile; furthermore, the process occurs at lower temperatures (50–100°C). Data on the use of *in situ* formed nitroxyls with a macromolecular "tail" for controlling the propagation of a polymeric chain under the conditions of emulsion radical polymerization are virtually lacking.

In this study we examined the emulsion polymerization of styrene in the presence of *C*-phenyl-*N*-*tert*-butylnitrone (PBN) as a potential source of stable nitroxyl radicals.

EXPERIMENTAL

Styrene and organic solvents (chloroform, isopropyl alcohol) were purified by standard procedures [17, 18]. *C*-Phenyl-*N*-*tert*-butylnitrone was prepared according to [19]. The initiator [ammonium persulfate (AP), Ekros Joint-Stock Company, chemically pure grade] and emulsifier [S-10, TU (Technical Specifications) 2492-366-00208947–2002, general formula n-C_8H_{17}–C_6H_4–$(CH_2$–$CH_2O)_n$–$CH_2CH_2OSO_3NH_4$ (n = 10–12, 62 wt % dry residue) was used without additional purification. Water was double-distilled.

The kinetics of emulsion polymerization of styrene was studied gravimetrically [20]. A four-necked flask equipped with a reflux condenser with a gas seal, a bubbler, and a sampler was charged with 10 g of styrene containing the dissolved chain-terminating agent (PBN concentration 0.1, 0.2, 0.3 mol %), and 0.75 g of the emulsifier dissolved in 30 ml of water was added. The mixture was emulsified for 30 min at a constant stirring rate of 500 ± 1 rpm. The inert atmosphere was provided by argon bubbling. The synthesis temperature was kept constant (70, 80, 90°C, respectively). Then a solution of 0.25 g of AP in 9 ml of double-distilled water was added through the reflux condenser.

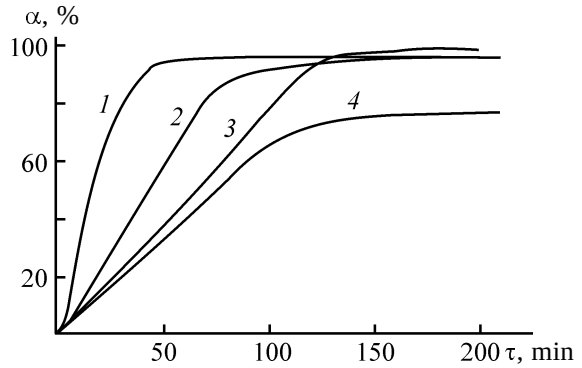

Fig. 1. Kinetic dependences of the emulsion polymerization of styrene at 70°C in the presence of 0.5 wt % PA and PBN. (α) Conversion and (τ) time. [PBN], mol %: (*1*) 0, (*2*) 0.1, (*3*) 0.2, and (*4*) 0.3.

Emulsion samples were taken at regular intervals, weighed on an analytical balance, dried to constant weight in a vacuum, and weighed again. The conversion α (%) was calculaed by the formula

$$\alpha = \frac{(m_3 - m_1) - a(m_2 - m_1)}{b(m_2 - m_1)} \times 100,$$

where m_1, m_2, and m_3 are the weights of the empty beaker, beaker with the latex, and beaker with the polymer, respectively; *a* is the correction for the emulsifier (0.015×0.62, i.e., the weight fraction of the emulsifier in the latex, multiplied by the dry residue of the emulsifier); and *b*, content of the monomeric fraction in the latex (20 wt %).

The molecular-weight characteristics of polymers were determined with a Knauer liquid chromatograph [21] equipped with a Phenomenex Phenogel 10u Linear (2) column (300×7.8 mm, 10 μm); the eluent was chloroform (flow rate 1 ml min^{-1}). The device was calibrated by polystyrene references with the molecular weight ranging from 900 to 1 049 000.

Polymer samples were ground in an agate mortar, washed with distilled water to remove water-soluble impurities (emulsifier and AP) and with isopropyl alcohol to remove impurities soluble in organic solvents (monomer, additives, etc.), and vacuum-dried to constant weight. Then the polymer samples were dissolved in chloroform, filtered through a glass frit (pore diameter 0.1 μm) to remove mechanical impurities, and analyzed by gel permeation chromatography.

The polymer isolated and purified to remove the initiator, monomer, and emulsifier (see above) was placed in an ampule (100 ± 0.2-mg portion, M_n = 7000 g mol^{-1}) and dissolved in 1 ml of styrene (macroinitiator concentration 1.57×10^{-2} M); then the solution was degassed by three freeze–pump–thaw cycles using liquid nitrogen. After that the ampule was sealed and placed in a thermostat to perform the postpolymerization at 90°C. The resulting polymer was analyzed as described above.

As already noted, PBN was successfully used previously in bulk polymerization of styrene [16]. Here we used this additive for the first time in polymerization of the same monomer in an emulsion stabilized with an ionic surfactant. As polymerization initiator we used AP, which is traditionally applied in industrial emulsion polymerization of vinyl monomers.

We found that PBN additions somewhat decelerate the emulsion polymerization of styrene (Fig. 1). However, even with excess nitrone the conversion in the first 30 min is as high as 60%. The decreased polymerization rate is undoubtedly due to the participation of the spin trap in the elementary steps of the process. In particular, the reaction of PBN with the propagating radicals (*in situ*) yields sterically hindered stable nitroxyl spin adducts [11]:

$$\sim P_n^{\bullet} + \underset{\underset{H}{|}}{\underset{\downarrow}{\underset{O}{|}}}{Ph–C=N–Bu^t} \rightarrow \sim P_n–\underset{Ph}{\underset{|}{CH}}–\underset{O^{\bullet}}{\underset{|}{N}}–Bu^t, \qquad (1)$$

where $\sim P_n$ is a macroradical containing *n* monomeric units.

Then the nitroxyl spin adducts react with the propagating radicals by the reversible inhibition scheme:

$$>N–O^{\bullet} + \sim P_n^{\bullet} \underset{k_d}{\overset{k_a}{\rightleftharpoons}} >N–O–P_n\sim, \qquad (2)$$

$$\sim P_n^{\bullet} \xrightarrow{+M,\ k_p} \sim P_n^{\bullet}$$

where $>N–O^{\bullet}$ is the nitroxyl radical; $\sim P_n^{\bullet}$, propagating radical; M, monomer, $>N–O–P_n$, alkoxyamine; and k_p, k_d, and k_a, rate constants of the propagation, dissociation, and accepting, respectively.

The molecular-weight characteristics of polystyrene are affected by the spin trap to a still greater extent. In particular, the molecular-weight distribution (MWD) curves of the samples synthesized in the presence of PBN (Figs. 2b, 2c) are shifted toward lower molecular weight compared to the polymers prepared without additions (Fig. 2a). With increasing concentration of nitrone, the general shape of the MWD curves changes. In particular, the samples prepared in the presence of 0.1 wt % PBN are essentially bimodal (Fig. 2b), which may be due to the realization of two mechanisms of chain propagation: common radical polymerization (high-molecular-weight shoulder) and polymerization in the reversible inhibition mode (2). As the PBN concentration is increased further, the

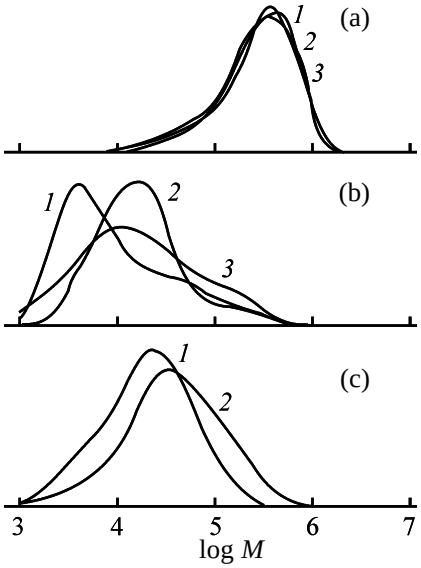

Fig. 2. MWD curves of polystyrene samples prepared at 70°C in the presence of AP (0.5 wt %) and PBN. (*M*) Molecular weight; the same for Figs. 3 and 5. [PBN], mol %: (a) 0, (b) 0.1, and (c) 0.2. Conversion, %: (a) (*1*) 27, (*2*) 55, and (*3*) 96; (b) (*1*) 8, (*2*) 58, and (*3*) 95; (c) (*1*) 53 and (*2*) 99.

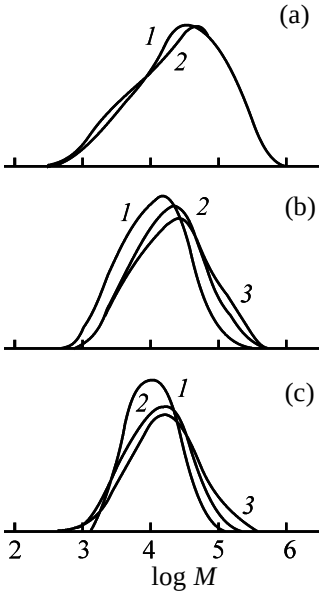

Fig. 3. MWD curves of polystyrene samples prepared in the presence of 0.5 wt % AP and 0.3 mol % PBN. Temperature, °C: (a) 70, (b) 80, and (c) 90. Conversion, %: (a) (*1*) 58 and (*2*) 79; (b) (*1*) 22, (*2*) 68, and (*3*) 92; (c) (*1*) 22, (*2*) 56, and (*3*) 98.

MWD curves become unimodal again, but are strongly broadened (Fig. 2c).

Thus, the experimental data show that the emulsion polymerization of styrene in the presence of PBN occurs by two mechanisms simultaneously: common radical and pseudo-living. It is known [22] that the equilibrium of reaction (2) shifts toward formation of radical products with increasing temperature. Hence, presumably, the contribution of the pseudo-living mechanism will also increase with temperature. Therefore, we studied the emulsion polymerization of styrene in the presence of 0.3 mol % PBN at 70, 80, and 90°C.

The MWD curves show that the polystyrene samples prepared at higher temperatures are less polydisperse (they have lower M_w/M_n, where M_w is the weight-average, and M_n, number-average molecular weight). This is manifested in narrowing of the MWD curves (Fig. 3). At higher synthesis temperatures, the MWD curves tend to shift toward higher molecular weights with increasing conversion. For the samples prepared at 90°C, *M* varies linearly with the conversion (Fig. 4). In contrast to the polymers prepared in the presence of low-molecular-weight nitroxyl radicals like TEMPO, for which the straight line reflecting this correlation passes through the origin [2–4], in our case $\lim_{\alpha\to 0} M_n \neq 0$.

According to the concept of classical pseudo-living radical processes [2], the radical initiating the polymerization directly adds to the stable nitroxyl radical to form alkoxyamine [similarly to scheme (2)]. After that, its length increases stepwise (in the controlled mode). Thus, the molecular weight of a polymer chain M_P will be $M_P = M_i + nM_M + M_N$, where M_i, M_M, and M_N are the molecular weights of the initiating radical, monomer, and nitroxyl radical, respectively; *n* is the number of elementary events of chain propagation. When the polymerization is performed in the presence of TEMPO, M_N is much lower than the molecular weight of the polymer (*nM*), and its contri-

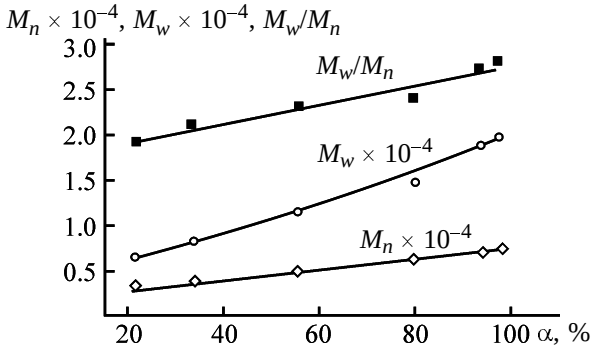

Fig. 4. Molecular-weight characteristics of polystyrene prepared at 90°C in the presence of 0.5 wt % AP and 0.3 mol % PBN as functions of conversion α: (M_n) Number-average and (M_w) weight-average molecular weights; (M_w/M_n) coefficient of polydispersity.

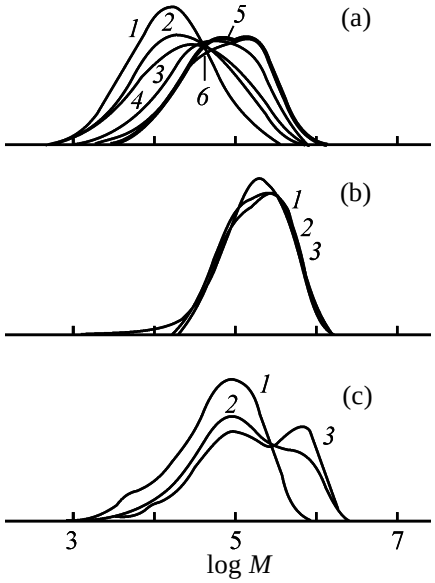

Fig. 5. MWD curves of polystyrene: (a) postpolymer, sample A; (b) thermal polymer, sample C; and (c) sample B. Conversion, %: (a) (*1*) initial polymer, (*2*) 8, (*3*) 14, (*4*) 24, (*5*) 26, and (*6*) 29; (b) (*1*) 7, (*2*) 20, and (*3*) 39; (c) (*1*) initial polymer, (*2*) 14, and (*3*) 23.

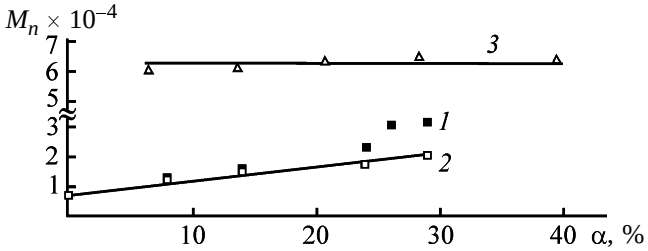

Fig. 6. Number-average molecular weight of polystyrene M_n as a function of conversion α: (*1*) postpolymer, (*2*) postpolymer without taking into account thermal polymer, and (*3*) thermal polymer.

bution to the total molecular weight of the macromolecules can be neglected; therefore, the linear dependence of *M* on the conversion passes virtually through the origin. In our case, on the contrary, the nitroxyl radical controlling the polymer chain propagation is formed *in situ* by the reaction of the spin trap with a polymeric radical [scheme (1)], and the contribution of *M* of such an adduct to the total molecular weight of the polymer is significant. It can be readily shown that in our system, on the average, M_N = 1800 g mol^{-1}. Thus, the polymeric radical bonded to PBN consists of 10–14 units. Therefore, in polymerization of styrene in the presence of PBN, the dependence of the molecular weight on conversion, though being linear, does not pass through the origin (Fig. 4).

One of the evidences of the living chain mechanism in radical processes is the postpolymerization in which the living polymeric chains, after removal of the initiator, residual monomer, and controlling additives can themselves act as initiators owing to the decomposition of active terminal groups [scheme (2)].

We found that the polystyrene isolated from the latex that was prepared in the presence of 0.3 mol % PBN at 90°C (sample A), after removal of residual initiator, monomer, and emulsifier, is indeed capable to initate the postpolymerization of a new portion of styrene. In particular, we prepared three series of samples under comparable conditions: sample A dissolved in styrene; solution of the polymer prepared under the same conditions as sample A but without PBN (sample B); and sample for thermal polymerization of styrene, containing the pure monomer only (sample C). The MVD curves for sample A (Fig. 5a) show that the curve maximum shifts toward higher molecular weights with increasing conversion. Correspondingly, in the region of $M \sim 1.5 \times 10^6$ ($\log M$ = 6.2), a shoulder appears, which is especially clearly seen in curve *5* (Fig. 5a). This high-molecular-weight shoulder is due to the occurrence of the polymerization by two mechanisms simultaneously: reversible inhibition and common radical mechanisms. In other words, both postpolymerization and common radical polymerization (due to thermal initiation) are observed in the system. It can be readily seen that the MWD maximum for the polymer (sample C) prepared by common (thermal) polymerization (Fig. 5b) coincides in the position with the high-molecular-weight shoulder in sample A (Fig. 5a). Sample B prepared without PBN shows no shift of the MWD curves toward higher molecular weights with the conversion (Fig. 5c). Thus, in this case no postpolymerization is observed. The polymer prepared by common radical polymerization (sample B), when added to the system, is inactive and remains dissolved as "dead ballast" in the monomer which, in turn, gradually polymerizes by the thermal mechanism. In this case, as in the case of the postpolymerization, a shoulder appears in the high-molecular-weight range, and its relative intensity grows with the conversion. The higher *M* of the thermal polymer is due to the initially higher viscosity of the monomer solution containing sample B.

The M_n of the postpolymer grows linearly with the conversion up to approximately 20% conversion (Fig. 6, curve *1*). The points corresponding to the samples with >20% conversion are shifted toward higher *M*. This is due to parallel formation in the system of the thermal polymer whose relative content increases in the course of the polymerization, introducing errors in the determination of M_n of the postpolymer.

To eliminate the disturbing effect of the thermal polymerization in the determination of *M* of the post-

polymer, we performed a mathematical treatment of the MWD curves. In so doing, we proceeded from the fact that the polymers formed in the system by thermal polymerization and pseudo-living mechanism have independent MWDs: for example, MWD of the thermal polymer is shown in Fig. 5b, and that of sample A, in Fig. 5a, curve *1*. Each of these distributions can be roughly approximated by a Gaussian curve. The superposition of the curves, taking into account the weight fraction of both kinds of the polymer, gives a bimodal curve, in particular, similar to that shown in Fig. 5a, curves *2–6*. Proceeding from these reasonings, we treated the experimental bimodal MWD curve as follows: first we took the logarithm $[\ln f(x)$, where $x = \log M]$ and then found its first derivative $\{\partial[\ln f(x)]/\partial x\}$.

By this sequence of operations, we brought the Gaussian function to the linear form: $\partial[\ln f(x)]/\partial x = y = x/\sigma^2 - m/\sigma$, where σ^2 is the variance and m is the mean value.

After the similar treatment of the experimental bimodal function, followed by singling out of linear portions, we decomposed this bimodal function into two unimodal functions. Taking into account the fractions of the postpolymer and thermal polymer in the mixture, we plotted the corresponding dependences of the number-average molecular weights of the samples on the conversion (Fig. 6). Thus, determination of the number-average molecular weight of the postpolymer proper (Fig. 6, curve *2*) showed that M of the postpolymer linearly increases with the conversion in the entire examined range of α.

CONCLUSION

Synthesis of polystyrene under the conditions of emulsion radical polymerization at 90°C in the presence of *C*-phenyl-*N*-*tert*-butylnitrone is characterized by the main features of the pseudo-living process: linear growth of the molecular weight of the polymer with the conversion, shift of the molecular-weight distribution toward higher molecular weights, and the possibility of block copolymerization.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Changes in Electret Characteristics of Polymeric Formulations in Their Processing into Articles

M. F. Galikhanov, A. N. Borisova, and R. Ya. Deberdeev

Kazan State Technological University, Kazan, Tatarstan, Russia

Received September 21, 2004

Abstract—The process of fabrication of an article with electret properties from a sheet composite corona-electret based on low-density polyethylene and titanium dioxide by vacuum forming was studied. The influence exerted by temperature and deformation on the preservation of electret properties of their formulations in their processing into articles was revealed.

Filling of polymers makes it possible to obtain material with novel working properties. Fillers can exert various kinds of influence on properties of polymers, including electret properties [1]. Fillers of varied nature with various characteristics can both improve and deteriorate the electret properties of polymers [1–8]. However, the lack of a rigorous theoretical substantiation of manifestations of the electret effect in polymeric composites and the insufficient amount of experimental data on processes of formation and relaxation of charges in these materials strongly hinder technical application of composite electrets.

It has been shown previously that prolonged keeping of composite electrets at elevated temperatures does not lead to complete charge relaxation, in contrast to unfilled polymers. This allowed a conclusion that articles can be fabricated from electret films and plates by the conventional techniques for processing of plastics [7, 8]. However, processing of formulations also leads to deformation of the polymer matrix, which, undoubtedly, must affect the charge retention by electrets. Unfortunately, data of this kind are virtually lacking. Therefore, the aim of this study was to find out how the electret properties of polymeric formulations depend on deformation at elevated temperatures.

EXPERIMENTAL

As objects of study we chose low-density polyethylene of 11503-070 brand [GOST (State Standard) 16337–77] and titanium dioxide of the R-01 brand (GOST 9808–65) with a particle size of 0.3 μm and a specific surface area of 15 $m^2 g^{-1}$.

The polymers were mixed with fillers and Irgonox 1010 stabilizer (0.2 wt %) on a laboratory micro roll mill at 135 ± 5°C and a mixing time of 3 min. Plates 0.6 mm thick were produced by compaction in accordance with GOST 12019–66 at 170 ± 5°C and a time of keeping under pressure equal to 5 min. The polymeric plates were polarized in the field of a corona discharge with an electrode comprising 196 pointed needles uniformly distributed over an area of 49 cm^2 in the form of a square. The distance between the plates and the electrode was 20 mm, and the voltage and time of polarization were 35 kV and 90 s. Prior to polarization, the plates were kept in a heating box at 100°C for 10 min.

The electret characteristics were measured once a day with an IPEP-1 instrument, whose operation principle is based on periodic shielding of the receiving electrode situated at a certain distance from the electret surface. The error in measuring the surface potential U_e, electric field strength E, and surface density σ_{eff} of electric charges did not exceed 3%.

Spectra of thermally stimulated currents were measured under linear heating of samples in a special measuring cell with blocking aluminum electrodes and a Teflon spacer [1].

The electret plates were processed into articles by the method of vacuum forming in an installation with one-side IR heater and a mold in the form of a vessel of irregular shape. The time of heating of the plates was 90 s. The degree n (%) of extension in forming was found using the formula

$$n = (\sigma_{in}/\sigma_{fin})^{1/2} \times 100,$$

where σ_{in} is the initial thickness of the sheet blank

1070-4272/05/7805-0820© 2005 Pleiades Publishing, Inc.

(mm), and σ_{fin}, thickness of an article upon forming (mm).

The wide availability of polyethylene makes it a very promising material for production of electrets. Having a low electrical conductivity, such a nonpolar polymer is well polarized in the field of a corona discharge, when charge carriers penetrate into the material to be captured there by traps. The role of traps can be played by impurities, phase boundaries, free volume of a polymer, etc. [9].

The advantages of polymer polarization in the field of a corona discharge, high rate and simple equipment, are manifested in charging of sheet- and film-type materials on a production line. At the same time, many areas of practical application of electrets, electronics, machine building, and medicine, require electret articles of various shapes and configurations [1], whose polarization presents some technological difficulties. Therefore, forming of articles from electret sheets (by punching or pneumatic and vacuum forming) may be markedly simpler and less expensive than the existing techniques for their manufacture. The problem of loss of the electret properties upon heating of polymers is solved by introducing powder-like fillers [7, 8].

Formulations composed of low-density polyethylene and 4 vol % titanium dioxide, considered in [7], exhibit high and stable electret characteristics: the surface potential U_e exceeds 1 kV after 3 years of storage. Keeping such electrets at 150°C for 30 min leads to a decrease in U_e to 0.6 kV.

A study of spectra of thermally stimulated depolarization (TSD) of the electrets based on polyethylene and filled formulations (Fig. 1) demonstrated that a TSD spectrum contains, in addition to the peaks characteristic of polyethylene (at 75–80 and 105–115°C), two new peaks at 165–170 and 195–205°C. The peaks of TSD currents appear in disintegration of some group of traps containing a trapped injected charge. The peak at 75–80°C corresponds to the Vicat softening point, at which the mobility of macromolecules in polyethylene increases dramatically. The peak at 105–115°C lies near the melting point of low-density polyethylene, at which ordered supramolecular formations constituting the crystalline phase of the polymer undergo thermal disintegration. The intensive motion of terminal groups, double bonds, and oxidized fragments of macromolecules releases charges from traps situated at the interface between the amorphous and crystalline phases of polyethylene (Fig. 1). The slight difference between the melting point of polyethylene and disintegration temperature of these

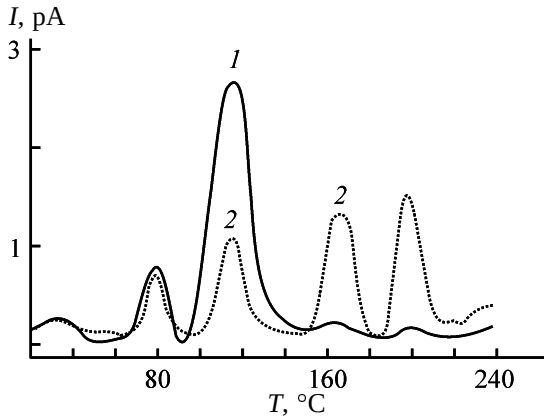

Fig. 1. Currents of thermally stimulated depolarization, *I–T*, of corona-electrets based on (*1*) low-density polyethylene and (*2*) polyethylene formulations with 4 vol % titanium dioxide.

category of traps is probably due to a too high rate of temperature variation in measuring the thermally stimulated currents, which is incomparable with the rate of relaxation of macromolecules of the polymer. The appearance of the peaks at 165–170 and 195–205°C (Fig. 1) is due to the Maxwell–Wagner polarization and to appearance of a new type of traps at the polymer–filler interface [7, 8]. Owing to the fact that these traps do not disintegrate at temperatures exceeding 150°C, the electret characteristics of the polyethylene formulations are not deteriorated down to zero at this temperature.

It is of interest that filling also changes the intensity and position of the TSD peaks characteristic of pure polyethylene. Presumably, this is due to the presence of a low-mobility adsorption layer of the polymer near the filler surface, which leads to a decrease in the mobility of various kinetic units of the polymer and to a broader range of relaxation times of its macromolecules.

In vacuum forming of a vessel of irregular shape from an electret composite plate, the material in different walls of the vessel is subjected to different extents of extension. This makes it possible to trace the effect of deformation at elevated temperatures on the retention of the electret effect in a polyethylene formulation. The data obtained revealed a rather interesting pattern. In deformation of composite plates, their electret characteristics (surface potential U_e, electric field strength E, and surface charge density σ_{eff}) decrease to a greater extent than do the parameters of undeformed plates, and this effect is less pronounced in the case of a 50% extension and more so at 25 and 75% extension (Fig. 2).

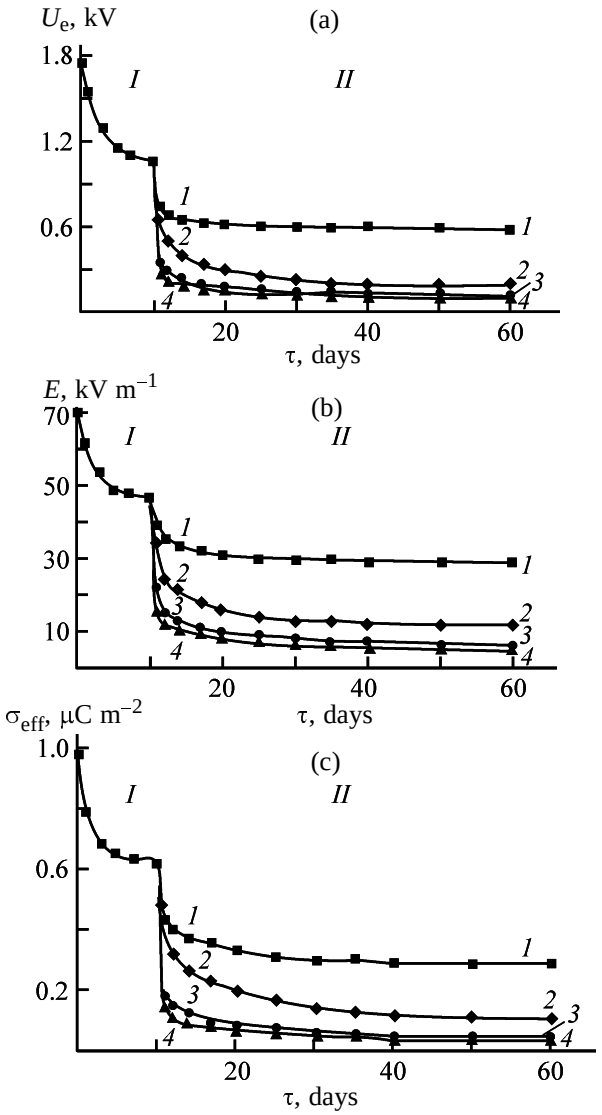

Fig. 2. (a) Surface potential U_e, (b) electric field strength E, and (c) surface charge density σ_{eff} of composite corona-electrets vs. storage time τ before (region *I*) and after (region *II*) vacuum forming. Degree of extension, %: (*1*) 0, (*2*) 50, (*3*) 25, and (*4*) 75.

The decrease in the electret characteristics of formulations under the action of temperatures exceeding the melting point of polyethylene (Fig. 2, curve *1*) is quite understandable. The depolarization resulting from disintegration of traps for injected carriers, which are characteristic of pure polyethylene, leads to partial relaxation of the charge. If account is taken of the fact that the area under the curve for the current is proportional to the charge of the electret [10], then disintegration of the first two trap levels in a polyethylene composite corona-electret (Fig. 1, curve *2*) must lead to a virtually 40% loss of electret properties, and this is the case in practice.

The deterioration of the electret characteristics of polyethylene corona-electrets in extension also would be expected. Borisova *et al.* [11] observed a similar phenomenon and identified two reasons why it occurred. First, a decrease in the film thickness and increase in the surface area at a fixed charge necessarily lead to a lower electret difference of potentials of the polyethylene films. Second, deformation of a polyethylene sample leads to disintegration of a part of structural traps because of the displacement of macromolecules of fragments of these, which releases injected charge carriers captured by these traps. Both these factors may also be responsible for the observed deterioration of the electret characteristics of polyethylene formulations in vacuum forming (Fig. 2, curves *2*–*4*).

At the same time, there is evidence that oriented polyethylene films considerably exceed unoriented films in their electret properties [12]. However, this is only observed in the cases of polarization of the already deformed polyethylene films.

In the context of the above considerations, it seems unreasonable that raising the degree of extension of an electret plate made of a polyethylene formulation containing 25 to 50% titanium dioxide leads to a slight improvement of electret characteristics (Fig. 2, curves *2*, *3*). Raising the degree of deformation of corona-electrets to 75% results in a decrease in U_e, E, and σ_{eff}, which would be expected (Fig. 2, curve *4*). However, such a dependence of the effective surface charge density in extension was observed in [13] in studying thermoelectrets based on polyethylene and its mixtures with silicon dioxide and powdered copper: under deformation, the charge first decreases, then starts to increase, and then again abruptly decreases. The rise in the charge at higher relative elongations in extension of unfilled and filled polyethylene films was attributed to formation and growth of microcracks, accompanied by charge formation on the surface of a film through emission of charge carriers and their capture by structural traps.

Indeed, the processes of carrier recapture in storage of electrets are markedly accelerated by elevated temperatures. Deformation of polymers leads to the following changes in their structure: the existing structural traps for charge carriers disintegrate and new traps, microcracks and radicals with a different trapping energy, are formed. It may be assumed that the recapture of carriers released from disintegrating traps into those newly formed at a 50% degree of extension occurs in a more optimal way than that at 25 and 75%. This may be also due to the possible partial recrys-

tallization of polyethylene, which occurs at >25% degrees of deformation and leads to changes in the area of the interface between the amorphous and crystalline phases.

Our results suggest that deformation of polymeric composite corona-electrets at elevated temperatures markedly impairs their electret characteristics, but does not lead to their fall to zero values in contrast to the case of unfilled polymeric electrets. This enables forming of articles with electret properties from sheet blanks, which markedly facilitates the technology of their manufacture, improves the productivity, and, consequently, makes lower the production cost. Undoubtedly, the charge distribution over the surface of a thus obtained article is nonuniform and depends on the degree of deformation of the material. However, this is not important in many cases of practical application of electrets.

CONCLUSIONS

(1) The electret characteristics of polyethylene formulations with titanium dioxide do not decrease in processing to zero values because of the presence in these formulations of high-energy levels of traps capturing charge carriers at the polymer–filler interface, which disintegrate at temperatures exceeding the flow point of polymers.

(2) Deformation of a sheet polyethylene composite corona-electret at elevated temperatures leads to a significant decrease in the surface potential, electric field strength, and surface density of electric charge. However, the residual level of the electret characteristics of the formulations makes it possible to produce articles with electret properties from sheet blanks. This can markedly facilitate the technology of their fabrication, raise the productivity, and, consequently, make lower the production cost.

(3) Raising the degree of extension of an electret plate made of a formulation composed of polyethylene and titanium dioxide from 25 to 50% leads to a slight improvement of their electret characteristics. This is accounted for by the more efficient recapture of carriers from disintegrating traps into those newly formed.

Received July 9, 2004; in final for, February 2005

Abstract—The regular trends in chemical degradation of rigid polyurethane foam under the action of oxypropylated hydroxy compounds were studied. The molecular-weight characteristics, functionality with respect to 4,4'-diphenylmethane diisocyanate and OH groups, viscosity, and the content of terminal OH groups of alcoholysis products at temperatures from 150 to 220°C were determined. A mechanism of degradation of the network structure of rigid polyurethane foam was suggested.

Owing to a unique combination of low thermal conductivity, low density, and high manufacturability rigid polyurethane foams (PUFs) are widely used in various branches of industry. An increase in their production volume estimated in 2003 at 2 000 000 tons results in accumulation of large amounts of wastes which are environmental pollutants. At the same time, a decrease in the natural resources and, as a result, rise of their price dictates the need of using secondary raw materials. The most promising solution of the above environmental and economic problem is chemical degradation of wastes from PUF production by alcoholysis.

The aim of this study was to reveal regular trends in the alcoholysis of rigid PUFs and to establish the mechanism of their chemical degradation.

EXPERIMENTAL

Experiments were performed with wastes from production of rigid PUF assigned for thermal insulation of refrigerating equipment. Foam plastic was prepared by the reaction of a hydroxy component with polyisocyanate (PIC) derived from 4,4'-diphenylmethane diisocyanate (MDI).

As a degradation agent (DA) we used oxypropylated hydroxy compound Laprol-564[1] (L-564), a polyether based on propylene oxide with a molecular weight M of approximately 500 and f_{OH} = 4. The weight ratio PUF : DA was 40 : 60 and was chosen experimentally based on evaluation of the maximum amount of wastes and minimum amount of DA.

Alcoholysis was carried out in the range 150–220°C. The instant of addition of PUF crumb was considered as the onset of degradation. Preliminary milled PUF was continuously added into DA at a stirring rate of 300 rpm. With increasing degradation temperature T_d, the monitored time interval decreased from 30 to 7 h. The alcoholysis products were analyzed starting from the instant of system homogenization.

The molecular-weight parameters were determined by gel permeation chromatography (GPC) with a chromatographic modular high-performance system designed from units produced by Waters-244. Chromatographing was carried out with Styrogel columns with the pore size of 10^4, 500, and 100 Å; the solvent was freshly distilled tetrahydrofuran (THF) prepurified to remove peroxy compounds; the concentration of sample solutions at the inlet of the chromatograph was 0.1–0.3 wt %. Detection was carried out with a refractometer and a photometer in parallel, which allowed determination of the polymer concentration at the outlet (refractometer) and the concentration of aromatic rings (photometer). The operating UV wavelength of the photometer was 255 nm.

The content of hydroxy groups c_{OH} in the alcoholysis products was determined by the acetylation method according to GOST (State Standard) 25 261-82.

The dynamic viscosity of the alcoholysis products η_{dyn} (Pa s) was determined on a Hoeppler rheovis-

[1] Produced by the Nizhnekamskneftekhim Joint-Stock Co.

1070-4272/05/7805-0824 © 2005 Pleiades Publishing, Inc.

cometer at 80±0.1°C [1]. The chemical structure of DA and alcoholysis products was studied by IR spectroscopy with a Specord 75-IR spectrophotometer. The samples for recording the spectra were prepared in the form of a drop pressed between NaCl plates.

A study of the parameters of molecular-weight distribution (MWD) of the alcoholysis products depending on the degradation conditions showed that, in the first hours of the process, the average M values decrease and then become constant (Table 1). For example, the weight-average molecular weight M_w, as the most sensitive to degradation processes, decreases from 8640 to 1370, and the number-average weight M_n, from 1100 to 660; the polydispersity coefficient M_w/M_n decreases from 7.85 to 2.09.

The decrease in the average M values is caused by development of the degradation processes, and their subsequent stabilization, by the attainment of the equilibrium state of the system. In this case, the higher is T_d, the lower is the equilibrium average M.

The progress of degradation can be judged from the differential MWD curves of alcoholysis products withdrawn in the course of degradation (Fig. 1). The content of fractions with high M decreases in the course of heating.

Data on distribution of alcoholysis products with respect to content of MDI fragments (Table 2) furnish more information on the mechanism of the polymer degradation. In the course of the process, the fraction of molecules containing six and more MDI fragments significantly decreases (functionality with respect to MDI fragments $f_{MDI} > 20$, from 15 to 0 wt %; $f_{MDI} > 10$, from 6 to 2 wt %; $f_{MDI} > 6$, from 16 to 2 wt %) with a simultaneous increase in the fraction of the compounds containing three aromatic fragments and less ($f_{MDI} = 3$, from 10 to 23 wt %; $f_{MDI} = 2$, from 3 to 17 wt %; $f_{MDI} = 1$, from 15 to 42 wt %).

In the course of alcoholysis, with increasing T_d f_{nMDI} decreases from 1.03 to 0.62, which confirms once again a decrease in the content of polymer molecules polyfunctional with respect to MDI fragments.

The most important parameter of alcoholysis products, allowing their use as polyol component in synthesis of polyurethane, is the nature and concentration of terminal functional groups, namely hydroxyls. As seen from Fig. 2, irrespective of the temperature and time of degradation, the concentration of OH groups remains constant and is equal to approximately 9.6 wt %, which corresponds to the amount of OH groups initially supplied by DA. The estimated number-average functionality with respect to OH groups f_{nOH} decreased from 6.1 to 4.72, which, as should be expected, exceeds the functionality of DA ($f_{nOH} = 4$).

respect to viscosity is shown in Fig. 3. In the course of degradation, the viscosity of alcoholysis products varies in agreement with the molecular weights. Initially the viscosity monotonically decreases owing to development of degradation processes and decrease in M_w of the alcoholysis products, which reach constant values at T_d 150, 165, and 180°C within 15, 12, and 8 h, respectively.

Qualitative analysis of the alcoholysis products was performed by IR spectroscopy. In the spectra of alcoholysis products (Fig. 4a) we found absorption bands characteristic of L-564 (Fig. 4b): strong bands of stretching vibrations of the ether group C–O–C at approximately 1080 cm^{-1}, stretching vibrations of associated OH group at approximately 3380 cm^{-1}, and in-plane bending vibrations of OH group at about 1400 cm^{-1}. In addition, new bands appeared: 1710 (C=O stretching vibrations of urethane group), 1600 (stretching vibrations of C=C bond in benzene ring), 1510 (N–H bending and C–N stretching vibrations of

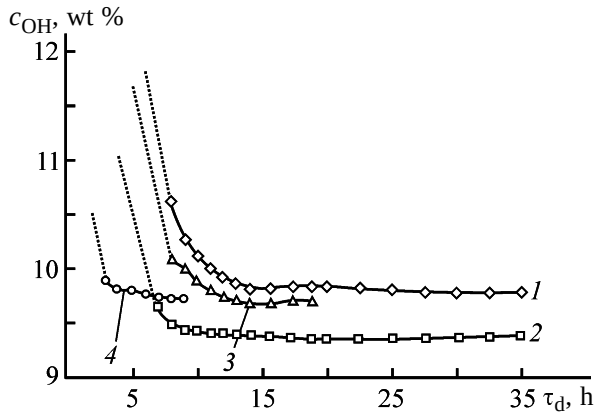

Fig. 2. Concentration of OH groups c_{OH} in alcoholysis products as a function of degradation duration τ_d. Process temperature, °C: (*1*) 150, (*2*) 165, (*3*) 180, and (*4*) 200.

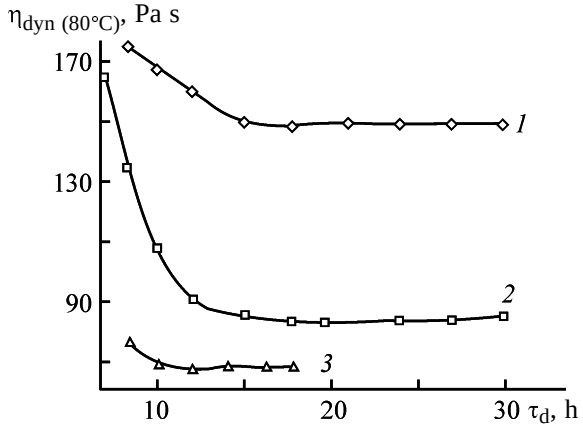

Fig. 3. Dynamic viscosity of alcoholysis products η_{dyn} as a function of process duration τ_d. Process temperature, °C: (*1*) 150, (*2*) 165, and (*3*) 180.

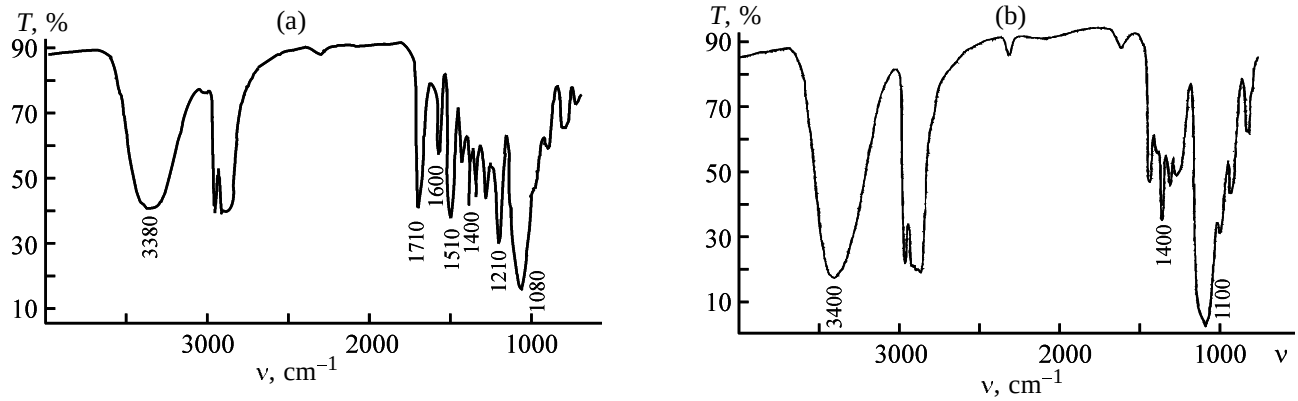

Fig. 4. IR spectra of alcoholysis products of (a) rigid PUF at T_d = 180°C and τ_d = 10 h and (b) L-564. (*T*) Transmission and (ν) wave number.

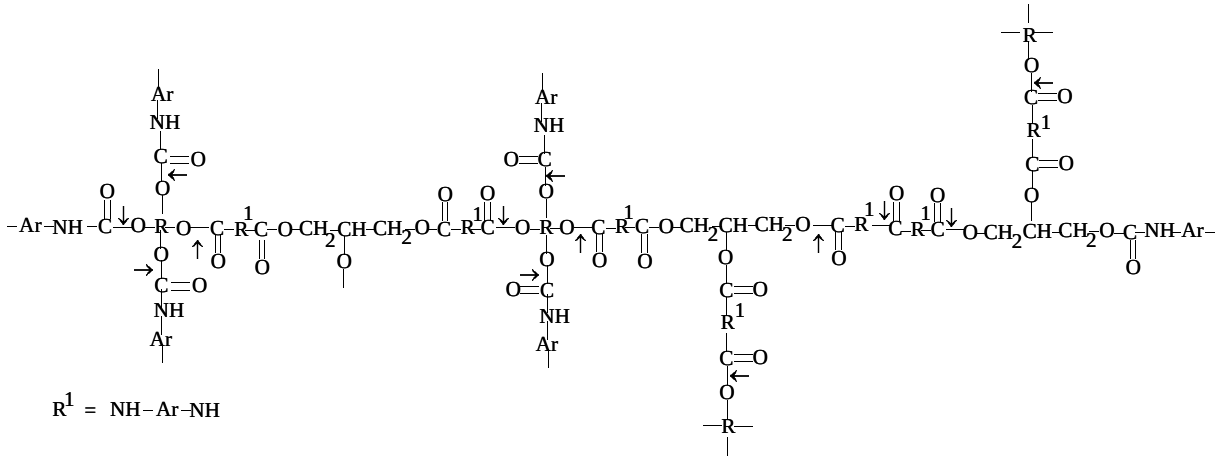
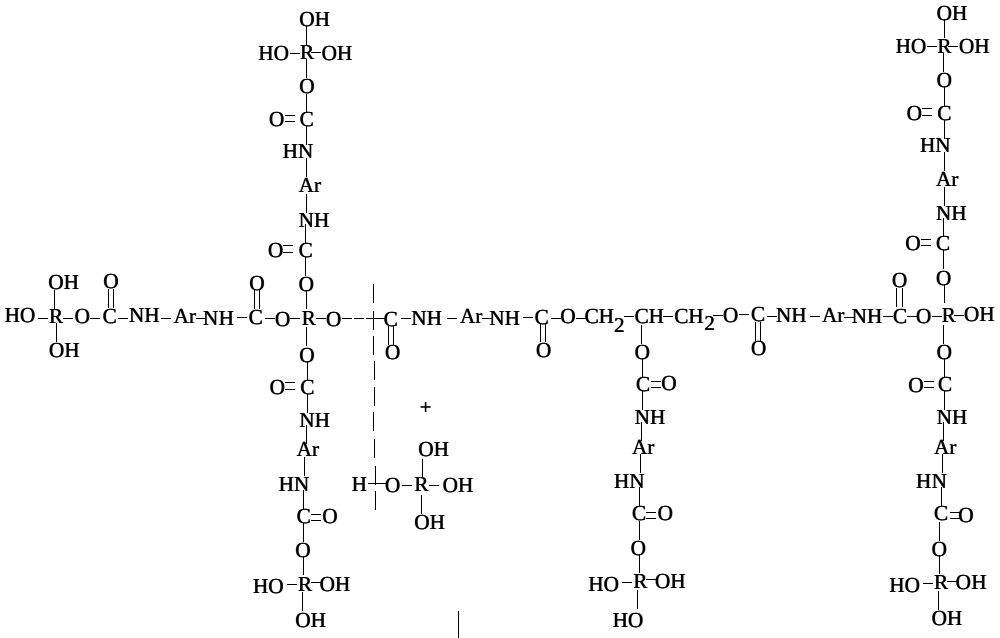


urethane group), and 1210 cm^{-1} (stretching vibrations of the C–N–H bond of the urethane group) [2–4]. Identification of the urea group is difficult since its characteristic absorption bands, such as N–H stretching vibrations at approximately 3300 cm^{-1} and C=O stretching vibrations in the range 1575–1660 cm^{-1}, overlap with stronger bands of hydroxy group and benzene ring.

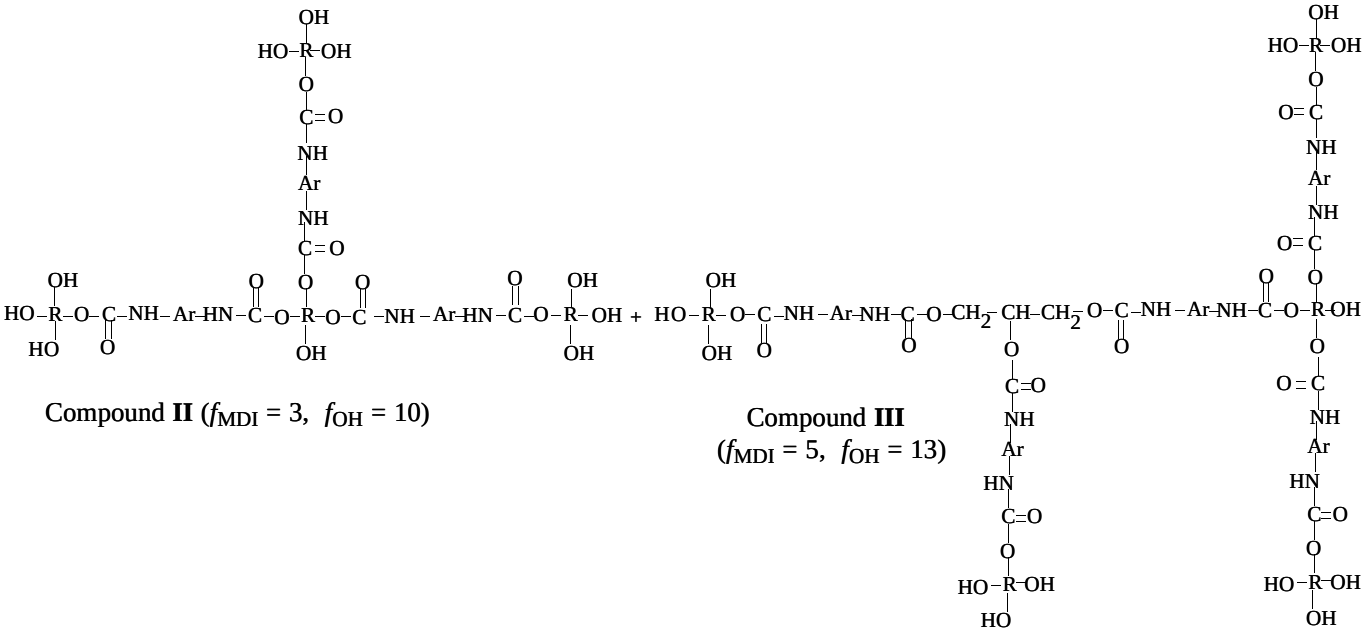
The IR data show that alcoholysis products are compounds containing ether, urethane, urea, aromatic, and hydroxy groups.

Thus, the study of alcoholysis products showed that, in the course of degradation, the physicochemical characteristics (M_n, M_w, M_w/M_n, $f_{n\mathrm{MDI}}$, $f_{n\mathrm{OH}}$, and viscosity) decrease with their subsequent stabilization. The higher T_d, the lower the values of these parameters. Irrespective of the degradation conditions, c_{OH} remains constant.

Based on the IR data and the revealed regular trends in variation of the physicochemical parameters, taking into account the structure of the rigid polymer to be destroyed, we suggested a mechanism of chemical degradation of the polymer.



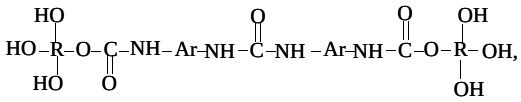
Polyurethane foam is a polymer with alternating laprolic, glycerol, and urea fragments linked through urethane bonds:



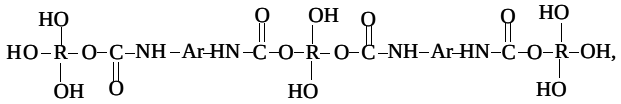
The mechanism of degradation of rigid PUF across urethane and urea bonds suggests their alcoholysis under the action of OH groups of L-584 by the ester interchange reaction. It is well known that alcoholysis of urethane groups is faster than that of urea groups; the most accessible are urethane bonds formed by OH groups of L-584 due to weaker steric hindrance.

In the initial period of degradation, large fragments of macromolecules are eliminated from the polymer matrix as a result of alcoholysis of less stable urethane bonds. Bulky branched molecules of compounds of type **I** with high functionality with respect to OH groups and aromatic fragments are formed. In these molecules, sterically hindered urethane and urea

groups as more resistant to hydrolysis are retained. This is confirmed by gel permeation chromatography. In particular, chromatograms of the samples withdrawn in the first hours after the start of degradation showed the presence of fractions with *M* of approximately 74000 and $f_{MDI} > 30$. Then, these macromolecular compounds undergo further alcoholysis to form smaller fragments. A longer polymer chain is subjected to degradation to a greater extent [5]:

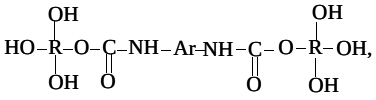


Compound **I** ($f_{MDI} = 8$, $f_{OH} = 19$)

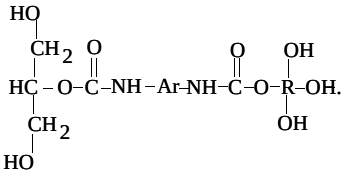


Compound **II** ($f_{MDI} = 3$, $f_{OH} = 10$)

Compound **III** ($f_{MDI} = 5$, $f_{OH} = 13$)

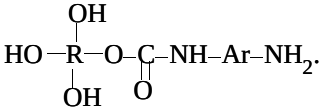


As the degradation develops further, compounds **II** and **III** degrade across the remaining urethane bonds to form compounds **IV**–**VII** containing 1–2 MDI fragments with $f_{OH} = 8–5$:



Compound **IV** (f_{MDI} = 2, f_{OH} = 6)

Compound **V** (f_{MDI} = 2, f_{OH} = 8)



Compound **VI** (f_{MDI} = 1, f_{OH} = 6)

Compound **VII** (f_{MDI} = 1, f_{OH} = 5)

The resulting low-molecular-weight compounds, in turn, can serve as degradative agents with respect to polyfunctional macromolecules and to PUF.

Under prolonged action of heating (above 180°C), urea group can be subject to alcoholysis to form amino polyol:

Compound **VIII** (f_{MDI} = 1, f_{OH} = 3)

However, we detected compounds of type **VIII** neither by IR spectroscopy nor by chemical analysis. It is evident that formation of products with amino groups is insignificant due to low concentration of urea groups in the system (there is only one urea group per 14 urethane groups in a PUF unit). Hence, the terminal functional groups of the degradation products are mainly hydroxy groups.

Thus, the mechanism of alcoholysis of rigid PUF involves degradation of the network polymer matrix across urethane bonds to form primarily large macromolecules with a high content of aromatic fragments and their subsequent degradation to smaller fragments. In this case, the alcoholysis products are hydroxyl-containing compounds such as polyols, urethane–polyols, and urethane–urea–polyols with various *M* and functionality with respect to aromatic and terminal OH groups.

CONCLUSIONS

(1) The following features of chemical degradation of rigid polyurethane foams were established: with an increase in the process duration and the average molecular weights, the coefficient of polydispersity and the functionality with respect to fragments of 4,4'-diphenylmethane diisocyanate and OH groups of alcoholysis products decrease and subsequently attain constant values; with an increase in the alcoholysis temperature, the time of attainment of the equilibrium state and the corresponding parameter levels decrease; the concentration of terminal functional groups in the alcoholysis products is constant and is independent of the degradation conditions.

(2) The mechanism of chemical degradation of rigid polyurethane foam was suggested. This mechanism is based on alcoholysis of urethane and urea groups with formation of long multinuclear macromolecules, followed by cleavage with formation of smaller fragments such as polyols, urethane–polyols, urethane–urea–polyols, and amino polyols.

Abstract—Formulations based on hollow glass spheres and polyurethane foams were obtained and studied. The positive influence exerted by an inorganic filler, which improves the strength and heat resistance of the formulations and makes lower the probability of process defects in their application in heat networks and in building, was examined.

At present, polyurethane foams (PUFs) are rather well studied materials, which are widely used in various areas of science and engineering for more than 50 years. Depending on a particular application field, PUFs successfully compete with metals, plastics, rubbers, or other materials [1–3].

Rigid PUFs are widely used in world's building industry owing to their good characteristics and convenience in manufacture and application. The main requirements to PUF as a construction material are its heat heat resistance, high softening point, minimum density combined with high compression and bending strength, light fastness, and convenience of deposition by pouring or spraying.

The last achievement in this field is a polyurethane heat insulation combined with a surface waterproofing layer [4], which has such advantages as low thermal conductivity and density and high reliability during a prolonged service life.

At the same time, PUFs have a number of disadvantages, such as combustibility, necessity for additional surface protection, poor adhesion to shell materials, comparatively low compression strength, etc., which cannot be eliminated within the existing technology.

At present, intensive studies are being carried out in order to improve the physicomechanical and working properties of PUF-based materials. The main ways to control the properties of both rigid and elastic PUFs are chemical modification of the raw material used to obtain PUF and production of various composites [5].

The strength properties of formulations are largely determined by the type of filler. The cellular structure of PUF enables its combination with powdered solid materials, which improves the physicomechanical characteristics, diminishes the production cost, and creates a predictable inhomogeneity in the bulk of an article.

On the whole, the filler is a powerful tool for controlling the service characteristics, which is frequently used in those cases when the construction resources of the polymeric matrix are already exhausted. For example, to impart enhanced strength properties to a PUF, inorganic fillers with a high strength, such as sand, concrete, and glass, are introduced into the material (mostly into a rigid heat-insulating PUF) [6]. This also improves the fire safety of the material. The physicomechanical properties of polyurethanes can be improved by their filling with a dispersed quartz filler, with the strongest effect achieved in use of quartz with organosilicon glaze deposited on its surface [7].

Table 1 lists data characterizing the basic parameters of PUFs and a number of other, most widely used materials, e.g., those insulating steel heat-transfer pipes.

All rigid PUFs used as heat-insulating materials have low thermal conductivity, the best among other materials serving for similar purposes [8]. Along with the advantages of use of filled PUF for heat insulation, there also exist disadvantages: highly filled systems have a PUF density higher by an order of magnitude, which leads to an increase in the mass of heat insulation and to a higher thermal conductivity.

This study is devoted to production and study of formulations based on polyurethanes and hollow

spheres used as fillers in order to eliminate some of the disadvantages mentioned above.

EXPERIMENTAL

Hollow glass spheres (GSs)[1] contain air and have a density of 140 kg m^{-3} and diameter of 140–160 μm, and, therefore, they must not lead to a significant increase in density.

The glass spheres were introduced into rigid PUF in amounts of 7, 11, 13, 15, and 28 wt %, relative to the block mass. Polyurethane foams were obtained using the spraying technique [1], with a binary Izolan 101 system used. Component A is A 1-17 N-1 manufactured by Izolan Open Joint-Stock Company (Vladimir), and component B is polyisocyanate of B brand. The components used in preparing the polyurethane foam system were taken in a 1 : 1 ratio.

In the case of concentrations in the range 0–15 wt %, GSs were introduced into component A, with the resulting mass thoroughly mixed so that the system remained stable for 4 h. The limiting content of GSs in component A corresponds to 15 wt % in the block, and, therefore, to raise their total content, GSs were introduced into both components: 15 and 13 wt % in components A and B, respectively.

[1] Supplied by NTS Ltd., St. Petersburg.

The kinetic parameters of foaming (times of onset, gelation, and foam rise) were monitored with a stopwatch. The samples were kept from the instant of fabrication to tests for no less than 24 h at 20°C.

The failure compression stress was determined in conformity with GOST (State Standard) 46 451–82 on a ZWICK-1445 tensile machine. In view of the construction features of the device, the test sample dimensions were 20 × 20 × 20 mm. The compression rate was 100 mm min^{-1}. The measurement error was ±0.03 MPa.

The apparent density was determined by the procedure prescribed by GOST 409–77. The error in determining the apparent density was ±0.5 kg m^{-3}.

The thermal conductivity λ (W m^{-1} K^{-1}) was determined by measuring the density of a stationary heat flux in a monotonic heating mode on an ITP-MG4 device in accordance with the operation manual. The measurement range was 0.04–0.8 W m^{-1} K^{-1}. The dimensions of the samples used were 100 × 100 × 20 mm. The thermal conductivity was found using the built-in calculating unit of the device with an error of ±0.002 W m^{-1} K^{-1}.

Table 2 illustrates the influence exerted by GSs on process parameters in spraying. It can be seen that, in mixing of filled components A and B in the presence of GSs, the onset and gelation times remain constant,

Table 2. Influence exerted by glass spheres on process parameters in spraying. Onset time 4–5 s, gelation time 15–20 s

GS content, wt %	Viscosity, mPa s, of indicated component		Curing time, min	PUF density, kg m^{-3}
	A	B		
0	440	600	25	51
7	4000	600	25	51.5
10.5	6000	600	25	52
13	8000	600	20	55
15	12 000	600	10	65
28	12 000	12 000	10	75

i.e., glass spheres act as an inert additive with respect to the macrokinetic parameters of foaming.

Viscosity measurements at different contents of GSs demonstrated that the rising curve follows the Chong–Christiansen dependence (Fig. 1), in which a characteristic point for monodisperse fillers is the filler content of 62 vol %. At a higher volume fraction, an asymptotic rise in viscosity is expected and motion in the system requires an extreme shear force.

As the content of hollow spheres becomes two times higher, the curing time of the system decreases

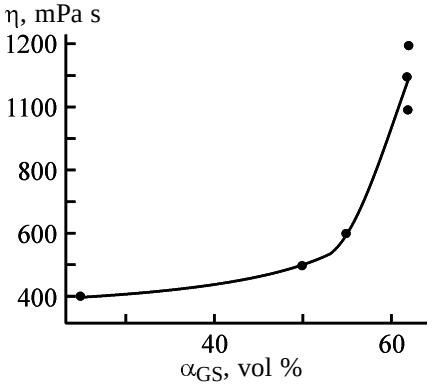

Fig. 1. Viscosity η of the formulation vs. the volume fraction α_{GS} of glass spheres.

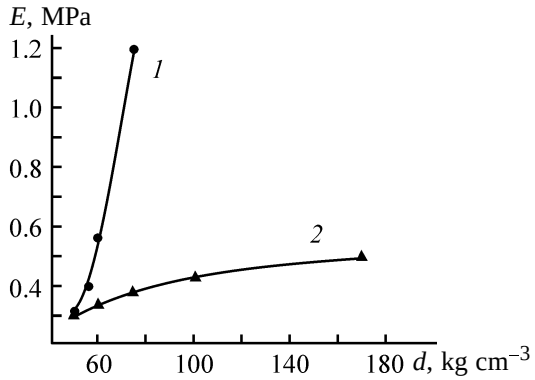

Fig. 2. Strength *E* vs. density *d* of PUF. PUF: (*1*) filled with glass spheres and (*2*) unfilled.

by a factor of 2.5, which indicates that the polymer cross-linking processes are accelerated.

Presumably, an increase in the area of contact with the material of glass spheres is important in the stage of formation of the final structure of polyurethane. It may be assumed in this case that the polyurethane structure in the surface adhesion–solvation layer differs from that in the bulk. The surface of glass spheres exerts an orienting influence on the structure of macromolecules:

$$V = V_{FVPU} + V_{ASLPU} + V_g,$$

where V is the total volume of the polymer binder; V_{FVPU}, free volume of polyurethane; V_{ASLPU}, volume of polyurethane in the adhesion–solvation layer; and V_g, gas volume.

As the content of glass spheres increases, the fraction of the polymer filler adsorbed on the surface grows.

It is known that use of fillers in foamed polymers yields articles that are nonuniform in density: the properties of the surface, crust layer differ from those in the bulk. The composite material based on PUF and hollow glass spheres, obtained in this study, is virtually isomorphic. It was found in determining the density of the casting sample with 12 wt % GS that samples taken at 10, 25, and 40 mm from the mold bottom have the same density of 60 kg m^{-3}.

The influence exerted by the density of unfilled and filled PUF on their strength varies (Fig. 2). As the density of a GS-filled PUF increases, the strength grows considerably faster and reaches markedly higher values. This fact can also be accounted for in terms of the theory of an adsorption–solvation interaction. Depending on the content of glass spheres, the structure of the formulations can be represented as follows (Fig. 3).

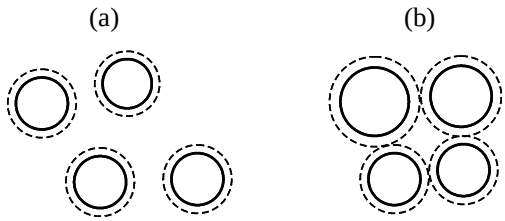

Fig. 3. Structure of a formulation based on PUF with glass spheres. Content of glass spheres (wt %): (a) <10 and (b) 10–30.

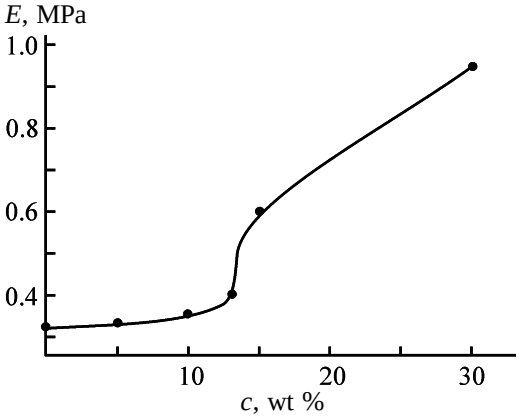

Fig. 4. Compression strength E of the formulation vs. filler content c.

Figure 4 shows how the compression strength of the polymers depends on the filler content. It can be seen that filling of PUF with hollows glass spheres leads to a significant increase in the compression strength of the polymer, especially at high contents. As the content of GS is raised from 5 to 13 wt %, the strength of the formulation under study steadily increases to 0.4 MPa; in the range 13–15 wt % filler, the strength steeply increases to 0.6 MPa; and in the range 15–20 wt % GS, the strength steadily grows to 0.95 MPa.

At a GS content lower than 5 wt %, the formulation properties are not modified to a sufficient extent, whereas in the case of GS present in amounts exceeding 30 wt %, spraying becomes impossible and the kinetics of casting significantly changes because of the high viscosity of the system.

It was shown that the thermal conductivity of an PUF-based composite material with 13 wt % GS is 0.06 W m^{-1} deg^{-1} at 20°C, and its bending strength, 2.5 MPa.

Thus, development of filled formulations based on PUF with an inorganic filler makes it possible to raise the strength and thermal resistance, diminish the probability and number of technological defects, ensure operation of heat-transfer networks at a temperature of the heat-carrying agent of up to 150°C, and make lower the moisture absorption, with the corrosion-protection properties of the coatings simultaneously improved.

CONCLUSIONS

(1) Hollow glass spheres are an inert additive with respect to the macrokinetic parameters of foaming of polyurethane foam, because the onset and gelation times remain unchanged.

(2) Raising the content of glass spheres in a polyurethane foam formulation accelerates formation of a network polymer.

(3) The composite based on polyurethane foam and glass spheres is virtually isomorphic and has a density of 60 kg m^{-3}, which expands the areas of its possible application.

(4) Filing of polyurethane foams with glass spheres leads to a considerable increase in the compression strength of the polymer from 0.32 to 0.95 MPa, and the bending strength is 2.5 MPa, which means that polyurethane foam materials with improved physicomechanical properties can be obtained.

Received January 19, 2005

Abstract—The source of raw materials for manufacturing softeners for rubber is extended through applying a nonwaste process of thermal dissolution of ordinary or enriched shale in crude producer-gas tar. The resulting products are less expensive than the conventional high-melting oil asphalts and oils.

Progress in the rubber industry is determined to a considerable extent by extension of the source of raw materials, i.e., by broadening of the spectrum of the products used. In production of elastomers, the weak point is a limited spectrum of softeners. Among the commonly used products of this type are asphaltic tar softeners, specialty bitumens, etc. Their introduction into rubber stocks allows control of the most important performance characteristics of rubber stocks and finished articles such as rubber-to-cord adhesion, ozone resistance, and abradability. These products serve also as dispersants for rubber stock components and as reinforcing agents.

Virtually the only source of softeners of this type is deep processing of oil. The rubber and tire industries are large-scale consumers of high-molecular-weight petroleum products such as PN-5 oil, black oils, tars, Rubraxes, and other asphaltic tar products. These softeners (plasticizers) demonstrate wide action spectrum: they reduce the shrinkage in calendering and extrusion molding of rubber stocks, improve the strength and heat resistance of rubber, and impart moisture resistance and solidity to finished articles [1, 2]. It was suggested that such products could be obtained from sapropelic coals, among them shales, whose reserves are huge.

In this study we examined the possibility of preparation of shale-oil bitumens by thermal dissolution of ordinary or enriched shales in shale-oil producer-gas tar and also of their use as softeners for rubber. Since bituminous softeners are used to improve performance characteristics of heavily extended elastomers and rubber stocks with a polymer body from rubber reclaim and SKD butadiene rubber, an associated task was to improve performance of the composites by introducing the indicated softeners, thus extending their application range.

Low branching of the macrochains and only slight temperature dependence of the viscosity of SKD cause its high cold flow in storage and transportation [3]. The processibility of SKD is characterized by its millability, estimated from the critical roll opening (mm). The millability of SKD ranges from 0.5 to 2 mm, depending on the molecular-weight distribution and polydispersity.

EXPERIMENTAL

Crude producer-gas tar and ordinary Baltic shale or enriched shale (Kerogen-70) (all the products from the Slantsy Works, Joint-Stock Company) were charged in 1 : 1 or 2 : 1 weight ratio into a three-necked flask equipped with a stirrer, electric heater, and outlet system for removal of liquid thermal dissolution products. The mixture was heated with continuous stirring for a fixed time (Table 1).

The effect of shale-oil bitumens A, B, and C (plasticizers) on properties of rubber stocks was studied in comparison with commercial plasticizers [bitumen BN-IV and bitumen G (Ukhta refinery)]. The characteristics of the plasticizers studied are summarized in Table 2.

The viscosity and tendency to scorching of the rubber stocks were determined with a Mooney viscometer according to GOST (State Standard) 10722–76. The tensile strength f_z, relative elongation (ε_z), and elongation set (θ) were determined on a tensile-testing machine (GOST 270–75).

* The rubber stock designations reflect the filler (Ch = chalk) and plasticizer.

The Shore hardness of the rubbers *A* was determined according to GOST 263–75. The thermal aging tests were performed according to GOST 9.024–74 and swelling tests, according to GOST 9.030–74. The softening points of the softeners were determined according to GOST 11506–73; penetration (needle penetration depth), according to GOST 11501–78; and ash content, according to GOST 11512–65.

SKD rubber is characterized by high elasticity, frost resistance, and durability. It is widely used in various rubber stocks, including those for tire production. However, its processing characteristics are extremely unsatisfactory, so that, to improve them, bitumen plasticizers are always added into composites.

Rubber stock preparation procedure using a laboratory roll mills included two steps. First, mother stock, containing rubber and all other ingredients except for a softener and a filler (chalk), was prepared. The mother stock content was as follows (wt %): SKD 100, sulfur 2, sulfenamide C 0.7, zinc oxide 5, and stearin 2. Secondly, chalk (50 wt % relative to SKD) and a softener (5 wt %) were introduced into the mother stock.

In preparing the rubber stocks, all the tested softeners demonstrated a positive effect on the performance characteristics of the SKD-based rubber stocks.

It was demonstrated in rolling the rubber stocks that the critical roll opening increased from 0.5 to 2 mm. Bitumen G only slightly affected the millability of the rubber stocks because of its nonuniform distribution. Bitumen BN-IV improved the millability, but to a lesser extent as compared to shale-oil softeners. Shale-oil bitumens A and B have relatively low softening points, and they soil the rollers. The preparation time of rubber stocks with the indicated softeners increases as compared to that with the use of the most manufacturable high-melting shale-oil bitumen C (it does not soil the rollers and decreases the process duration by 30–40% in the absence of a plasticizer).

All the bitumens under examination demonstrated high plasticizing effect, decreasing the minimal viscosity of the resulting rubber stock (Table 3). The highest effect was observed with BN-IV. The plasticizing effect of all the softeners tested was approximately the same. The examined plasticizers exert a decelerating effect in the initial vulcanization stage, i.e., on the inductive period t and the period of the initial process rate t_c. Evidently, the differences in t and t_c can be attributed to different content of functional polar groups in oxidized oil asphalts and less oxidized shale-oil bitumens.

The plasticizer effect on the tensile strength f_z,

relative elongation (ε_z), and elongation set (θ) of vulcanized rubbers is shown in Table 4. The best results were obtained with shale-oil bitumen C, which provided the highest relative elongation of the vulcanizate, the tensile strength being well comparable with other softeners. The use of bitumen softeners is often aimed at reducing the water absorption in vulcanizates. All the softeners studied reduced the swellability of the vulcanizate in water. In the rubbers prepared without plasticizers, after keeping in water, the weight increased by 2%, and in the rubbers with the indicated softeners, it decreased by up to 1% in 20 days. However, the weight of the rubber with plasticizer C remained practically unchanged even after long-time contact with water (weight loss 0.01–0.02%). Thus, plasticizer C imparts good performance characteristics to rubber stocks.

Addition of this plasticizer to the standard SKD-based rubber stock containing 50 wt % P-324 carbon black improved the performance characteristics of the product. After adding 5 wt % of the plasticizer, the critical roll opening was 2 mm, allowing ready manufacture of the rubber stock. Increase in the plasticizer content to 15 wt % did not deteriorate the performance of the rubber stock. At a 30 wt % content, we observed sticking of the rubber stock, which increased the time of its preparation. The effects of the content of bitumen C on the viscosity and initial vulcanization of rubber stocks were determined at 140°C by the standard method using a Mooney viscometer (Table 5).

As in the case of chalk-filled rubber stocks, introduction of bitumen C reduces the minimal viscosity of the product and decelerates the initial vulcanization step. With increasing plasticizer content, the induction period *t* regularly increases, the initial vulcanization rate decreases, and t_c grows. The observed abrupt decrease in the minimal viscosity of the rubber stock at a plasticizer content of 30 wt % is due to the fact that, at 140°C, the plasticizer is in the fluid state, and its amount is in excess relative to that sufficient to impregnate the solid components (note that the safety of rubber stock processing increases in parallel to the plasticizer content). However, these trends could result in a longer time required for vulcanization and attainment of the optimal mechanical characteristics of the vulcanizate by virtue of deceleration of the process in the major stage. Since the maximal decelerating effect was observed at a plasticizer content of 15 wt %, we prepared rubber stocks filled with carbon black without or with the indicated content of the plasticizer. Evolution of the mechanical characteristics of the rubber in the course of vulcanization of the indicated rubber stocks is shown in Fig. 1.

Introduction of the plasticizer only slightly affects the vulcanization rate. However, the softener effect on the performance of vulcanized rubbers is significant. Thus, the strength increases remarkably, regardless of the vulcanization mode, as well as the relative elongation and elongation set, as compared to unplasticized rubbers. The hardness index of plasticized rubbers depends on the vulcanization time, but it only slightly changes after reaching the optimal value (20 min). The plasticizer content influences the strength and hardness of rubber (Fig. 2, curves *1*, *2*) and relative elongation and elongation set (curves *3*, *4*). With increasing the plasticizer content to 30%, the strength and elasticity of vulcanizates increased. However, this is accompanied by an increase in the residual deformation, which is especially pronounced at high plasticizer content. The dependence of the hardness on the plasticizer content is represented by a curve with a maximum. The water absorption in plasticized products does not exceed that in the initial rubber stock.

Therefore, the recommended content of plasticizer C in vulcanizate is 10–15 wt %. The drawback of SKD-based rubbers is low vulcanization rate. Shale-oil bitumen C accelerates vulcanization, the effect being more clearly pronounced with the use of a

modified plasticizer. To the rubber stock containing 10 wt % shale-oil bitumen C, we introduced tetramethylthiuram disulfide (TMTD) as a rubber accelerator in amount of 0.5–1.3 wt %. The characteristics of the resulting products are given in Table 6.

Increase in the activity of a rubber accelerator reduces the elasticity and elongation set of vulcanizates and increases the hardness. The tensile strength increases at small accelerator contents, and decreases at high contents, which is probably due to too high density of the resulting 3D structure and decrease in the capability of the macrochains for spatial orientation, as demonstrated by the decrease in the relative elongation in the rubber.

CONCLUSIONS

(1) High-melting shale-oil bitumen obtained by thermal dissolution of enriched shale in crude producer-gas tar is an efficient softener for rubber stocks based on SKD rubber filled with chalk, improving their millability and uniformity of distribution. The elasticity of rubbers with such a softener is higher than that with standard softeners, petroleum bitumens G and BN-IV.

(2) At optimal content of shale-oil bitumen (10–15 wt %), SKD-based carbon-filled rubber stocks with the desired critical roll opening can be produced without technological problems. In this case, the strength of the products increases by 25–100%; the relative

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Water-Soluble Polymers of Acrylamide as Labeling Adhesives

L. P. Krul', T. A. Ivanova, L. B. Yakimtsova, and E. V. Grinyuk

Belarussian State University, Minsk, Belarus

Received January 19, 2005

Abstract—The adhesive and rheological properties of high- and low-molecular-weight polyacrylamides and the products of their partial hydrolysis were studied. The suitability of the hydrolyzates of high-molecular-weight polyacrylamide as labeling adhesives in the glass–paper system was elucidated.

A major proportion of the labeling adhesives used for gluing paper labels to glass containers is accounted for by aqueous polymeric adhesives [1]. An important place among them is occupied by water-soluble copolymers of acrylamide (AA) with sodium acrylate, prepared by base hydrolysis of waste from polyacrylonitrile fiber production [2, 3]. However, the molar ratio of the acrylamide to acrylate units in the macromolecule of such copolymers, capable of modifying their adhesive properties, can be varied within very narrow range only (from 0.25 : 0.75 to 0 : 1) [4–6]. The reason is that a solid fiber can pass into solution only at high concentrations of the hydrolyzing agent. At the same time, hydrolysis of water-soluble polyacrylamide (PAA) allows preparation of a copolymer with the desired ratio of the acrylamide to acrylate units [7]. This makes possible preparation of labeling adhesives on the basis of partially hydrolyzed PAA (HPAA) with easily controllable adhesive properties. Water-soluble polymers of AA, including HPAA along with PAA proper, are capable of gluing together polar substrates, in particular, paper and glass [7]. However, the properties making these polymers suitable as labeling adhesives were studied to a lesser extent than the properties of hydrolyzates of polyacrylonitrile fibers [8–10].

In this study, we examined the adhesive properties of PAA and HPAA with various molecular weights, hydrolyzed to various degrees, in the glass–paper system.

EXPERIMENTAL

For synthesis of PAA we used AA available from REANAL (Hungary) with 98.7% main substance. The synthesis was run in 7% aqueous solutions of the monomer using the ammonium peroxodisulfate–sodium sulfite redox initiating system. The molecular weight (MW) of PAA was controlled by varying the total concentration of the components of the redox system and the component ratio in it. Base hydrolysis of PAA was conducted in 7% aqueous solutions of the polymer at their boiling point for 3 h at various ratios of the amounts of the polymer and NaOH. For procedures of the PAA synthesis and base hydrolysis of the polymer synthesized, see [11].

The viscosity-average MW was determined viscometrically. The specific viscosity was measured in a suspended-level Ubbelohde capillary viscometer with a capillary diameter of 0.86 mm at 25°C.

The adhesive properties of the solutions in the glass–adhesive–paper system were determined by the known procedure [12, 13] on an RMU-0.05-1 tensile-testing machine. After the paper was glued to glass, the sample was maintained at room temperature, whereupon the shear strength of the glue joint was determined. The time of keeping of the sample after gluing was 1, 2, 3, 5, 10, and 20 min. Simultaneously with the strength of the glue joint we determined the character of its failure.

The dynamic viscosity of the solutions was determined at 20 ± 0.1 °C on a Rheotest 2 rotary viscometer with the cylinder–cylinder working unit.

The quality of polymeric adhesives for the glass–paper system is determined, above all, by the character of failure of the glue joint. It is known that conventional labeling adhesives finding wide commercial application should provide a paper–glass joint so strong that, at attempted break of the glue joint after drying of the adhesive, the failure occurs across the paper texture [7]. Also, it is necessary that, before drying of the adhesive, the label will not come off from the glass surface, which is achieved through

the use of high-viscosity adhesives exhibiting non-Newtonian flow. It was noted earlier [7] for adhesives based on copolymers of AA with sodium acrylate, prepared by base hydrolysis of polyacrylonitrile fibers, that, at brief times of keeping after gluing (up to 5 min), the glue joint fails by the cohesion mechanism across the liquid adhesive, and at longer time periods, across the paper texture, which makes these adhesives suitable for labeling.

The tabulated data suggest the cohesion mechanism of failure of the glue joint across the paper texture even 1 min after gluing, when a high-molecular-weight PAA (PAA HMW) is used as adhesive. When adhesives from PAA HMW hydrolyzates are used, the glue joint can fail across both the liquid adhesive and the paper, depending on the time of keeping of the sample since gluing till testing. The time of keeping of the glue joint, required for changing from the failure across the liquid adhesive to that across the paper, is much smaller (1–3 min) in the case of PAA HMW hydrolyzates compared to adhesives from hydrolyzates of polyacrylonitrile fibers [7].

Whatever the time of keeping of the glued sample, for low-molecular-weight PAA (PAA LMW) and hydrolyzates of PAA LMW (HPAA LMW) failure of the glue joint follows the adhesion mechanism at the glass–adhesive interface. Without the stage of failure of the glue joint across the liquid adhesive, the use of PAA LMW and HPAA LMW as labeling adhesives is problematic, as labels easily come off from glass containers, especially when high-speed automatic devices are used.

With HPAA HMW as labeling adhesives, the ratio of the acrylamide to acrylate units in the macromolecule affects, above all, the period from formation of the glue joint till application of the shear load, in which the mechanism of its failure changes. For unhydrolyzed PAA HMW, this period is less than 1 min (approximately 15 s), for HPAA HMW with the $CONH_2$: COONa ratio of 0.70 : 0.30 and 0.46 : 0.54, 1–2 min, and for HPAA HMW with the $-CONH_2$: –COONa– ratio of 0.31 : 0.69, 2–3 min. Thus, the time of setting of the adhesive increases with increasing degree of hydrolysis.

The strength of the paper–glass glue joint in all cases is enhanced with increasing period between formation of the glue joint and the shear tests and reaches a limiting value within 10–20 min, corresponding in the case of PAA HMW and HPAA HMW to the dry paper strength (Figs. 1a, 1b). For PAA LMW and HPAA LMW, the limiting strength is half that for the high-molecular-weight analogs. However, the strengths of different adhesives correspond to different kinds of failure mechanisms. In the case of the initial, unhydrolyzed PAA HMW, paper fails at shear even within 1 min after gluing. Low strengths are due to a high content of water in paper. With increasing period between applying paper to glass and beginning the tests, the water from the glue joint evaporates through the capillary-porous system of paper, and the strength of paper, responsible for the strength of the glue joint, increases. For PAA HMW hydrolyzates, the observed shear strengths correspond to the strength of the adhesive for the periods when the glue joint fails across the liquid adhesive by the cohesion mechanism. With increasing period from gluing paper to glass till beginning the tests, it is paper, first wet and then dry, that fails.

Of much interest are the shear strengths of adhesives failing across the liquid adhesive. As regards

the adhesives tested in this study, this holds for HPAA HMW only. The shear strengths of the glue joints for HPAA HMWs, differing in the ratio of the acrylamide to acrylate groups in the macromolecules, were estimated at 6.2, 5.6, and 2.9 kPa at the $CONH_2 : COONa$ molar ratios of 0.70 : 0.30, 0.46 : 0.54, and 0.31 : 0.69, respectively, 1 min after formation of the glue joint, when the failure occurs across the liquid adhesive. Therefore, the adhesive properties of HPAA HMWs tend to deteriorate with increasing degree of hydrolysis.

Deteriorated gluing performance of HPAA HMWs with increasing degree of hydrolysis is due to a decrease in the viscosity of the solution. Figure 2 shows how the dynamic viscosity of HPAA HMWs varies with the shear rate. It is seen that, at small shear rates comparable with those in shear tests of the glue joints, the dynamic viscosity tends to sharply decrease with increasing degree of hydrolysis. With increasing degree of hydrolysis, the content of the carboxylate groups in the macromolecules tends to increase, thereby enhancing their mutual repulsion and decreasing the effective concentration of the sites of the fluctuation network of intermolecular contacts. As a result, intermolecular interaction in the liquid adhesive weakens, and the strength of the glue joint failing across liquid adhesive decreases.

The adhesive properties of HPAA HMW with a high content of acrylate groups can be improved by increasing the concentration of the polymer solution. For example, for HPAA with $CONH_2 : COONa$ = 0.31 : 0.69 mol : mol, an increase in the solution concentration from 7 to 16% substantially increases the solution viscosity and enhances intermolecular interaction, thereby significantly increasing the strength of the glue joint in the initial stage of its formation from 2.9 to 6.3 kPa.

CONCLUSIONS

(1) The kind of failure of the glue joint in the glass–paper system with water-soluble polymers of acrylamide as adhesives is governed by the molecular weight of the polymer and the degree of hydrolysis. For low-molecular-weight polyacrylamide and its hydrolyzates, the failure of the glue joint follows the adhesion mechanism at the glass–adhesive interface even in the initial stages of formation of the glue joint. At the same time, for high-molecular-weight polyacrylamide and its hydrolyzates, the failure of the glue joint follows the cohesion mechanism and occurs across the paper texture or liquid adhesive.

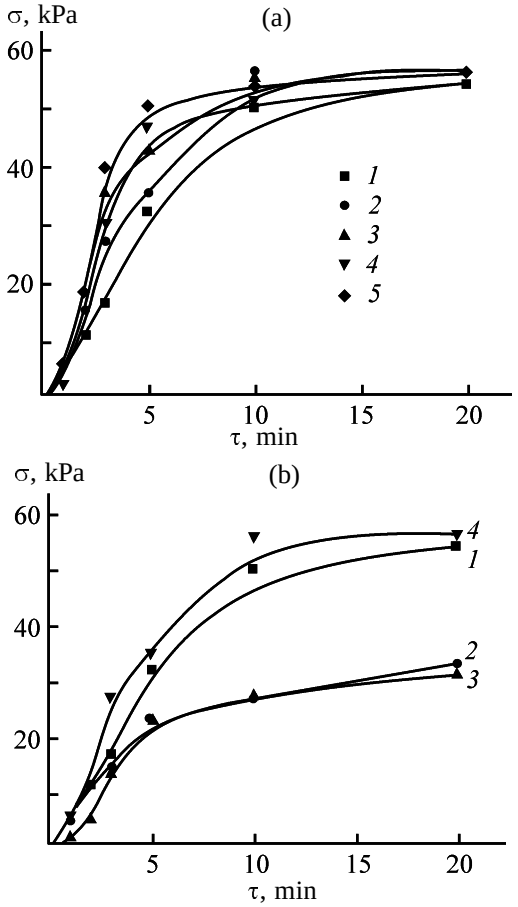

Fig. 1. Shear strength of the glue joint σ as a function of the time of keeping τ. (b) Polymer: (*1*) PAA HMW, (*2*) PAA LMW, (*3*) HPAA LMW, and (*4*) HPAA HMW. $–CONH_2 : –COONa$ molar ratio: (*3, 4*) 0.46 : 0.54. Solution concentration, %: (*1–4*) 7 and (*5*) 16.

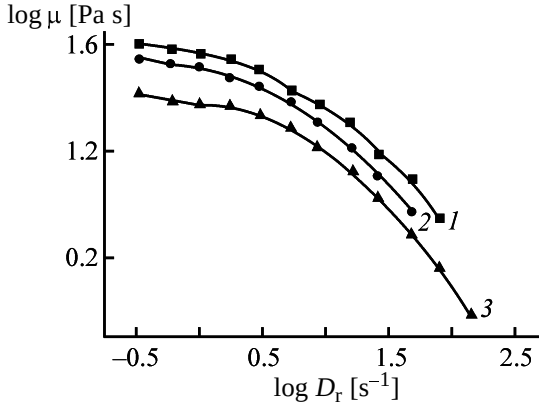

Fig. 2. Viscosity μ of 7% aqueous solutions of HPAA HMW as a function of the shear rate D_r. $–CONH_2 : –COONa$ molar ratio: (*1*) 0.70 : 0.30, (*2*) 0.46 : 0.54, and (*3*) 0.31 : 0.69.

(2) With increasing degree of hydrolysis of high-molecular-weight polyacrylamide, the period between formation of the glue joint and application of a shear load, within which the character of the glue joint failure changes from cohesion across the paper texture to cohesion across the liquid adhesive, increases. By contrast, the strength of the glue joint in the initial stage of its formation decreases, which correlates with a decrease in the dynamic viscosity of the adhesive.

(3) The adhesive properties of the high-molecular-weight polyacrylamide hydrolyzates are improved with increasing solution concentration.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis of Phosphate Epoxy Hardener–Flame Retardant and Rheokinetics of Curing of Epoxy Composites with Its Use

P. V. Nikolaev and E. P. Nikolaeva

Ivanovo State University of Chemical Engineering, Ivanovo, Russia

Received May 25, 2004; in final form, February 2005

Abstract—The effect of phosphate hardener obtained from phosphoric acid and acetic anhydride on the rheokinetics of extended epoxy composite is studied.

In reactions of epoxy oligomers (EOs) with phosphoric acid (PA), water contained in the acid contributes significantly to the formation and hydrolysis of di- and triesters [1, 2], responsible for the formation of linear and network structures in the system low-molecular-weight EO–PA in curing.

Data on reactions between phenyl glycidyl ether, as a model for a low-molecular-weight EO, with PA in solution [1], combined with those on the oligomeric block system [2], confirmed the adequacy of the suggested mechanism of curing and revealed specific features of the oligomeric system, associated with incompatibility and limited viability of the cured composite. It was demonstrated that the curing can proceed through both increase in the linear dimension of the molecules (formation of diesters) and branching (formation of triesters by the reaction with epoxide). In the latter case, a 3D polymeric network structure is formed, since the initial PA has a tetrahedral structure [3]. It is known that, for epoxy materials (EMs) cured without heating, the time of establishment of the critical viscosity (viability) is one of the most significant processing characteristics, since the polymer starts to form immediately after introduction of a hardener. Therefore, in developing novel phosphate hardeners (PHs), in addition to determination of the degree of curing of epoxy materials, we studied the kinetics of increase in the viscosity after their introduction into the composite as well as the effects of various factors on the rheokinetic properties of the systems.

EXPERIMENTAL

In this study we examined commercial alkylresorcinol epoxy oligomer AREM 2-20 [TU (Technical Specifications) 38.39.101–87] with an epoxy group content of 19.5 wt %; crushed quartz sand KP-3 [GOST (State Standard) 9077–82] as a filler; and polyethylenepolyamine (PEPA) A (TU 6-02-594–85) as a reference epoxy hardener. The reference composite contained EO and filler in 1 : 1 weight ratio and 14 wt % PEPA (relative to the oligomer). PA was introduced into the EO–filler system in the same amount.

The viability of the composites was determined by two methods. In the first method we determined the temperature of the maximum of the exothermic peak observed after introduction of the hardener into EO. This method was demonstrated to be more suitable in the case of the reference composite containing PEPA as a hardener. With addition of powdered quartz sand as a filler, the temperature of the exothermic peak as well as the time of establishment of this maximum decreased.

In the second method, the reaction rates in the system EO–hardener were characterized using the rheokinetic method based on measuring the viscosity of the composite in time starting from the instant of introduction of the hardener. The viscosity was determined with a V3-7 cone funnel which is commonly used in studying viscous extended thermosetting materials. The funnel was filled with 50 g of the compound (EO : filler = 1 : 1; 14 wt % hardener). The filler and EO were introduced first and thoroughly mixed to obtain a homogeneous composition. The estimated amount of PH was added to the resulting suspension with vigorous stirring, and the viscosity was measured. The first measurement was made 2 min after addition of the hardener and thorough mixing of the components. The compound was thorough mixed for 1–1.5 min before each measurement. The exhaust time was determined as the time corresponding to a break

1070-4272/05/7805-0843 © 2005 Pleiades Publishing, Inc.

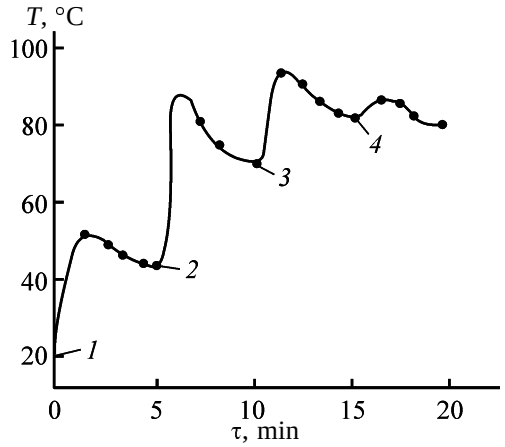

Fig. 1. Temperature T vs. time τ dependence for synthesis of the hardener based on aqueous PA and AcA. PA concentration 75.5 wt %. Total AcA content is equivalent to the water concentration in the acid. (*1–4*) Numbers of equal portions of the acid added to AcA.

of the flow of the compound at a distance of 40 mm from the funnel discharge. Simultaneously, the temperature of the composite was measured to characterize the exothermicity of the process. Each run involved 7–8 measurements of the viscosity. The experimental rheokinetic curve was compared with that obtained for the reference compound. For highly viscous systems we also used a semiquantitative method commonly applied in production of adhesives and compounds [4].

Our results showed that, thanks to high reactivity of the system, EO is cured with PA without heating even at large excess (up to twofold) of the epoxy groups relative to the hydroxy groups. However, the degree of cross-linking, being in direct proportion to the concentration and amount of the acid used, is low (maximal content of the gel fraction is 70 wt %). The presence of water in amounts up to tenfold molar excess relative to PA makes the components of the system incompatible, decreases the degree of curing, but increases the viability of the composite. These trends are caused by increasing volume of the aqueous phase and also by interaction of water with PA with formation of stable associates. We also observed the inhibiting effect of water in the reaction of α-oxo compounds with acids when studying the reaction kinetics in the model system containing phenyl glycidyl ether and *p*-dodecylbenzenesulfonic acid [5].

Keeping in mind the negative effect of water on curing and also the necessity in considerable improvement of the viability of composites based on low-molecular-weight EOs and PA, in developing PHs we used as modifiers such compounds that reacted with water contained in the acid with formation of nucleophilic compounds capable of reducing the activity of the acid in its reactions with epoxy groups of the oligomer. The use of carboxylic acid anhydrides appeared to be the simplest way to bind water. Comparison of acetic anhydride (AcA) with dicarboxylic acid anhydrides, phthalic and maleic, in reactions with aqueous phosphoric acid revealed considerable advantage of the former modifier [6]. The reactions of phthalic and maleic anhydrides with water produce the corresponding acids with high melting points (about 70°C above the melting points of the anhydrides). As a result of modification with these anhydrides, heterogeneous hardeners are formed, which are suitable only for organosoluble epoxy materials. Phosphate hardeners were prepared by stepwise addition of PA into AcA. Phosphate hardeners based on PA, AcA, and hexamethylenetetramine (HMTA) were prepared similarly. A part of water contained in the initial PA was bound with the equimolar amount of HMTA, estimated in accordance with the reaction

$$(CH_2)_6N_4 + 6H_2O \rightarrow 4NH_3 + 6CH_2O,$$

and the residual part, with the equimolar (relative to water) amount of AcA.

The synthesis of PHs based on aqueous PA and AA is spontaneous and autocatalytic, since acetic acid (HAc) formed by the reaction catalyzes the reaction of AcA with water [7]. The temperature–time relationship for the synthesis of PH based on aqueous PA (75.5 wt %) and AcA is shown in Fig. 1. As seen, the process is considerably exothermic, spontaneous, and autocatalytic. With excess of AcA relative to PA, it reacts with the acid with formation of acetic phosphoric anhydride (AcPA). Preparation of AcPA from anhydrous PA and AcA was described in [8]. AcPA demonstrates high activity in acetylation, suggesting high reactivity of the resulting PH with respect to both the initial secondary hydroxy groups of EO and hydroxy groups formed by opening of the epoxy ring of EO by the hardener.

The study of the rheokinetic characteristics of the system EO–filler–PH showed that the maximal viability of the composite is realized at the equimolar ratio of water contained in PA and AcA (Fig. 2). The viability of the composite depends also on the PH preparation procedure, increasing with increasing degree of completeness of the reactions occurring due to additional thermal cocondensation of the hardener components (Fig. 3). The use of EO to decrease the hardener activity, i.e., to convert it into an adduct,

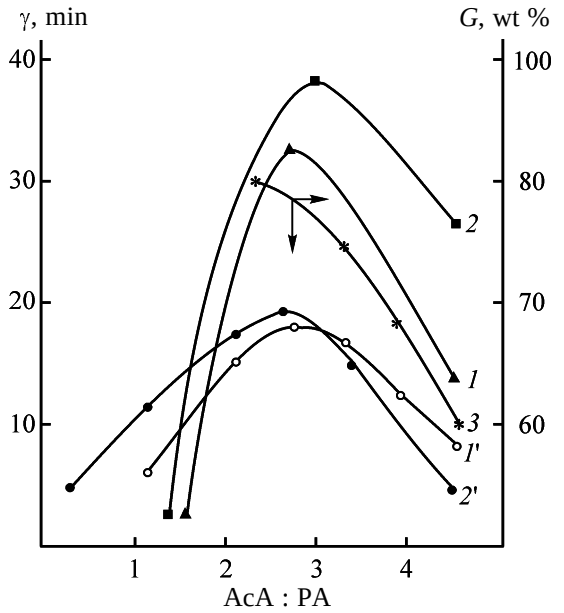

Fig. 2. (*1*, *1*', *2*, *2*') Viability and (*3*) gel fraction content in cured composite as functions of the PA concentration, AcA : PA weight ratio, and hardener preparation procedure. improves the viability of the composite. However, in this case, the viscosity of the curable systems considerably increases, thus deteriorating their processing characteristics (Fig. 3). This phenomenon is caused by considerable branching of the resulting acid adduct, and also by the fact that monophosphates formed by the reaction of PA with oxiranes are more reactive toward epoxy groups as compared to the initial PA [1].

Introduction of HMTA into the hardener also improves the viability of the system, but only at a fixed HMTA content in PH (Fig. 4) (viability of the composite may decrease as a result of interactions between HMTA decomposition products and EO).

Finally, our results obtained in studying the oligomeric systems confirmed the results of the kinetic studies in which we elucidated (with model systems) the mechanism of reaction of EO with acids, contribution of water to the formation of mono-, di- and triphenoxyhydroxypropyl phosphates and their derivatives [1]. These data were also used as a basis in developing novel phosphate hardeners and predicting their properties. In particular, higher reactivity of the monoesters formed by PA and EO causes abrupt

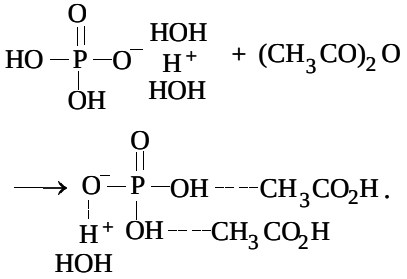
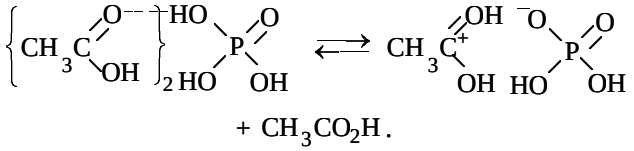
increase in the iniial viscosity of the composites cured with EO and PH adducts.



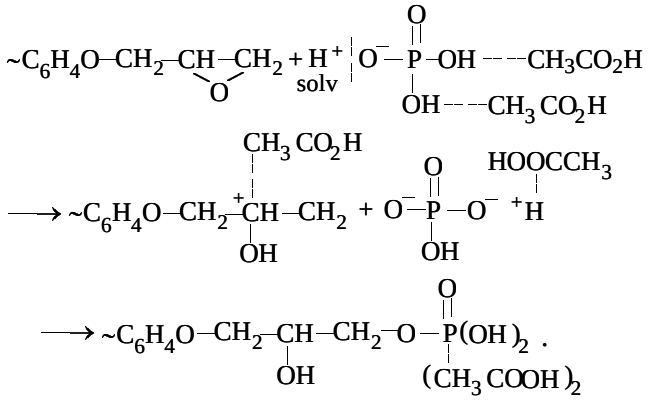
Evidently, acetic acid HAc, the product of the reaction of water contained in PA with AcA, like water, inhibits the reaction of the epoxy groups of PA with the acid hydroxy groups of PH. In this case, HAc acting as a nucleophile with respect to PA serves as

a solvating agent for the PA protons, reducing the reactivity of the EO–PH system. The interaction of PA with HAc involves protonation of the carbonyl oxygen of HAc. The hydroxy carbocation, an intermediate product of epoxy ring opening, also could be solvated by this mechanism [5]. It is not improbable that addition products of the mineral and organic acids are formed [3]. Here it should be taken into account that, in the reaction of 1 mol of water with 1 mol of AcA, 2 mol of HAc is formed, causing high degree of solvation of PA in PH.

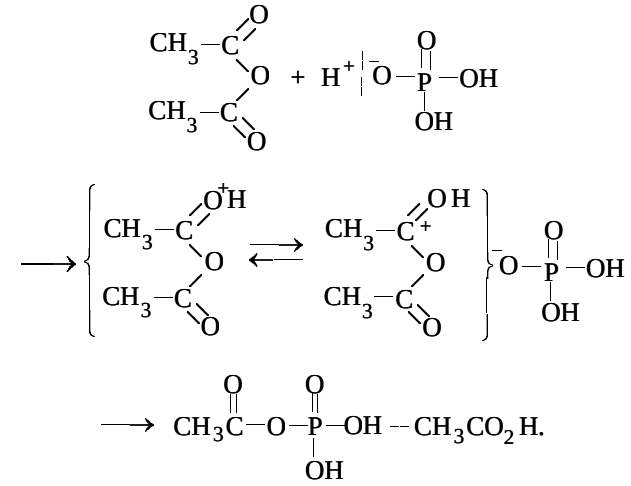


Taking into account the solvation effects, synthesis of PH and its reaction with EO can be described by the following scheme. Hydrous PA reacts with AcA with formation of solvated PA or of a mixture of hydrates and solvates, depending on the anhydride to water ratio:

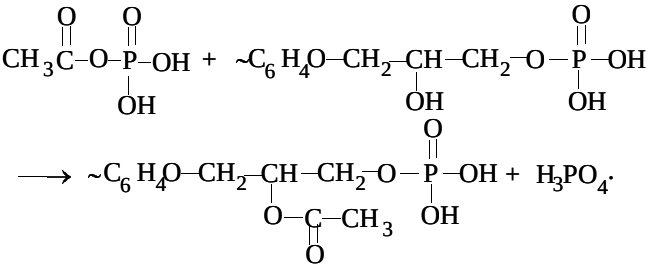
$$H_3PO_4(H_2O)_n + (CH_3CO)_2O \rightarrow H_3PO_4(CH_3CO_2H)_{2n}.$$



For example, at $n = 2$, since water is dimeric and the PA proton fluctuates between two water molecules [9], the interaction in the system aqueous PA–AcA produces PA solvatohydrate in which one proton is bound to the water molecule, and two other protons, to acetic acid molecules formed by the reaction of AcA with water:



It is known that HAc occurs as fairly stable dimers both in liquid and vapor phases. Phosphoric acid, as a stronger acid, can replace a weak acid from the associate, which is also taken into account in the suggested solvation–hydration mechanism. As a result of this interaction, low-activity adducts (associates) are formed. Acetic acid, forming homoassociates, in the adducts acts as a nucleophile with respect to PA, so that a 1 : 1 individual addition product can be formed:



The formation of not only adduct, but also addition products of PA and AcA was reported earlier [3]. In the reaction of PH with the epoxy groups of EO, intermediate hydroxy carbocation is formed, which then reacts with the solvated anion of PA:

It should be pointed out that, in synthesis of PH with excess AcA as a reagent with respect to water and PA, solvated acetyl phosphate (AcPA) can be formed:

In the resulting AcPA, the positive charge δ^+ on the carbon atom (reactive center) increases by virtue of the intramolecular hydrogen bond between the carbonyl oxygen and the proton, making it possible for AcPA to react with not only the epoxy groups of EO (see scheme above), but also with the hydroxy groups of phenoxyhydroxypropyl phosphates (epoxy ring opening products), and also with the initial hydroxy groups of EO:

It is well known that AcPA is a convenient acetylating agent, which provides better results than the Fritz–Schenk reagent [8].

The indicated reaction, producing free PA, causes the decrease in the viability of the composites. The modification of EO in the course of curing proceeds through acetylation of the secondary hydroxy groups.

Sufficiently high degree of curing in the systems studies suggests that the side reactions involving the epoxy groups of EO and PH components, particularly HAc as a chain-terminating agent, only slightly contribute to the process. Furthermore, the presence of PA and HAc in the hardener reduces the inflammability of the resulting epoxy polymers without adding special flame retardants [6].

CONCLUSION

The presence of acetic acid in the phosphate hardener reduces the curing rate, i.e., increases the viability of epoxy composites. The rate of the epoxy ring opening with the mineral acid is controlled by its solvation with the organic acid. The duration of the induction period of gelation in curing of epoxy oligomers is determined by interactions between phosphoric and acetic acids.

Abstract—The possibility of photostabilization of anthraquinone dyes with haloalkanols and haloalkanesulfonic acids was examined with model aminoanthraquinones.

Procedures for suppressing the photochemical degradation of optical brighteners and anthraquinone dyes with halide anions, complexones, arenes, arenesulfonic acids, haloarenes, and haloarenesulfonic acids [1–6] have certain drawbacks. In particular, bromide and iodide ions in a brightened or colored material are gradually oxidized with atmospheric oxygen to form free bromine and iodine, and arenes and their derivatives partially reabsorb the actinic light.

It is necessary to look for new ways of photostabilization, in particular, quenching the reactive excited states of the substrate with photochemically inactive additives that do not act on the substrate and material being brightened, do not reabsorb the excitation light, and are resistant to moisture and heat.

In this study we examined how haloalkanols (HAs) and sodium haloalkanesulfonates (HASs) affect the lightfastness of anthraquinone dyes (AQDs) using model anthraquinones (AQs) of a wide color range.

EXPERIMENTAL

Experiments with AQ + HA or AQ + HAS systems were performed in polyvinyl alcohol (PVAl) simulating the monomeric unit of cellulose and suitable for introduction of all the components (AQs, HAs, HASs) and for measuring the visible electronic absorption spectra (EASs) of AQs (analytical method; SF-46 spectrophotometer). The analytical wavelengths λ_a are listed in Table 1. They were chosen so that the optical density was less than 1 and could be reliably measured. The fluorescence of AQs was measured with a Neva-3 spectrofluorimeter.

The anthraquinones chosen (Central Laboratory, Rubezhnoe Chemical Combine, Ukraine) and their spectroscopic characteristics in PVAl are listed in Table 1. The compounds were purified by recrystallization from appropriate solvents followed by column chromatography on alumina or SiO_2. HAs and HASs were prepared as described in [6]; we chose 3-bromo-1-propanol **A**, 3-iodo-1-propanol **B**, sodium 3-bromo-1-propanesulfonate **C**, and sodium 3-iodo-1-propanesulfonate **D**, which appeared to be the most active with respect to optical brighteners [6]. Chemically pure grade PVAl was used without additional purification.

Films of pure PVAl (as reference samples in EAS measurements) and PVAl with additions of AQ, AQ + HA, and AQ + HAs were prepared by casting at a water : PVAl weight ratio of 1 : 1, so that the optical density at the excitation wavelength (366 nm) exceeded 2 (total absorption). The content of the additive (HA, HAS) was 20 wt % relative to AQ in all the cases. The film samples (5 cm in diameter) were ir-

radiated on a UIS-1 installation in air under temperature control (25°C); the wavelength of 366 nm was cut with a system of glass color filteres. The irradiation time (constant for each dye) was chosen so that the optical density at the analytical wavelength (*A*) did not exceed 20%. The degree of photochemical degradation *Q* of AQs was measured in the course of photolysis from a decrease in *A*: $Q = [(A_0 - A)/A] \times 100\%$, where A_0 and *A* are the optical densities of the nonirradiated sample and sample irradiated for a definite time, constant for each AQ, respectively (Table 2).

The electronic absorption and fluoresence spectra show that HAs and HASs do not form with AQs any associates or charge-transfer complexes in the ground state and excimers in the electronically excited state, as follows from the lack of the effect of HAs and HASs on the electronic absorption and luminescence spectra of AQs.

In the presence of HAs **A** and **B**, the rate of photochemical degradation of **I**–**X** decreases by a factor of 1.3–1.5 and 2.5–3.2, respectively. The effect of HASs **C** and **D** is still stronger: The deceleration factor is 1.8–1.9 and 3.2–3.4, respectively. Apparently, the lower inhibiting activity of HAs compared to HASs may be due to association of HA molecules by hydrogen bonding, with a decrease in the content of active species inhibiting the AQ degradation.

An increase in the HA and HAs performance in going from the bromides to the iodides confirms the acceleration of conversion of photochemically excited AQs to the ground state without transfer of the excitation energy from AQ to HA or HAS. Both mechanisms of AQ photochemical degradation (reductive, under the action of labile hydrogen atom at the carbinol carbon atom, and oxidative, under the action of singlet oxygen generated by AQ) are suppressed simultaneously [7].

We have not revealed any trends in the effect of substituents on the rate of photodecolorization of AQ and performance of AQ light stabilizers (HAs, HASs).

CONCLUSION

In the presence of haloalkanes and sodium haloalkanesulfonates (Hlg = Br, I; light stabilizer content 20 wt % relative to the dye), the lightfastness of model anthraquinone dyes in cellulose-like materials increases by a factor of 1.2–3. The performance of the iodine-containing stabilizers is 1.3–1.5 times higher than that of their bromine analogs.

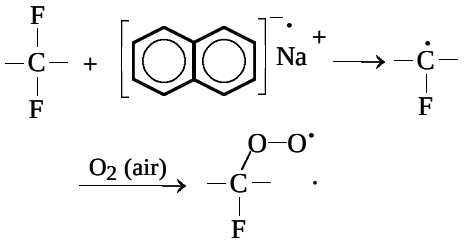
Abstract—The possibility of preparing modification solutions from sodium naphthalenide wastes and their effect on Teflon adhesion were studied.

Organometallic complexes of alkali metals (Li, Na, K) and aromatic hydrocarbons (diphenyl, naphthalene, anthracene, etc.) are widely used to enhance adhesion of inert polymers, including Teflon [1, 2]. Wastes remaining after modifying the Teflon surface with Na-naphthalene complex comprise more than 70% of the initial active solution. The spent inactive solution containing various toxic compounds after neutralization is discharged into industrial sewage and pollutes the environment.

Arene complexes of metals are unstable; they are prepared under the anaerobic conditions [1, 3]. Previously [4], we attempted to prepare arene complexes of metals at room temperature in air using ethers [tetrahydrofuran (THF), dimethyl ethylene glycol, dimethyl diethylene glycol, diethyl diethylene glycol] and obtained dark solutions whose color was determined by the kind of metal and aromatic hydrocarbon.

In this study we examined by ESR solutions of sodium and naphthalene in THF, prepared at room temperature. We also examined the possibility of reusing the spent inactive solution of sodium naphthalenide to enhance the Teflon adhesion.

EXPERIMENTAL



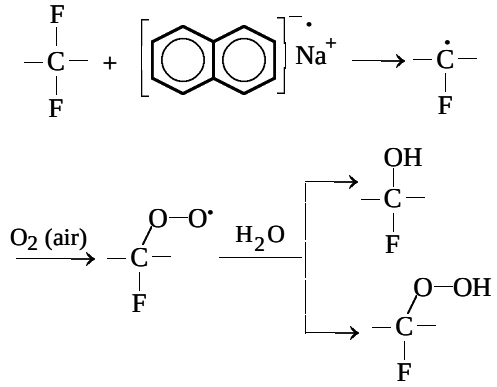
The ESR spectra were recorded on a Bruker ESR-300 spectrometer at T = 298 K. The g-factor in the ESR spectra of the solution in question agrees with that of the naphthalene radical anion [5].

We attempted to reuse the spent inactive solution. On adding sodium and naphthalene into the spent solution, its color changed from yellowish to dark brown; according to ESR data, this solution is diamagnetic.

The content of active sodium naphthalenide in the initial and regenerated solutions, determined on an LKhM-8MD chromatograph, was 12–13 and 18–20%, respectively.

The adhesion of Teflon films treated with solutions that had been prepared from the wastes is higher as compared to the films treated with solutions of the pure complexes. Probably, the Teflon surface is activated upon interaction with naphthalene radical anions and/or dianions, which can be formed under the experimental conditions studied [6].

As seen from the ESR spectra of the treated Teflon films, they contain paramagnetic centers probably belonging to the peroxy and carbon-centered radicals [7, 8]:



The IR spectra of the Teflon films treated with modifying solutions and washed with water exhibit bands in the 3600–3000 cm^{-1} range, belonging to hydroxy groups [9]:

Washing with water of untreated Teflon films does not result in appearance of such bands in the IR spectra.

Since the materials based on Teflon operate under various conditions, we studied the physicomechanical properties of activated glued Teflon films (Tables 1, 2).

The Teflon films were glued with metal support or with each other using adhesives BF-4 [GOST (State Standard) 12172–74] and K-300 (containing L-20 and SEDM-6 resins) at loads and drying modes corresponding to the GOST and TU (Technical Specifications) for the given adhesives. A plate (70 × 19.5 mm) of aluminum alloy (D 16T brand, GOST 21631–76) was used as a support. The mechanical strength of the resulting composites was evaluated from the breaking shear stress of the lapped glued samples (GOST 11262–80). The tests were performed on a ZM-40 tearing machine at a clamp velocity of 100 mm min^{-1}. The Teflon film thickness was 100 μm. The glued samples were tested in special temperature-controlled chambers at –12, –60, 20–22,

and 200°C. The strength parameters were recorded after storage for 1 day and 0.5, 1, 2, and 3 years (Table 1). Nine samples were used in each test. The results were treated using the procedures of mathematical statistics with 98% confidence probability. As seen from Table 1, the breaking shear stress for most of the glued samples changes insignificantly. However, certain trends in the strength properties can be revealed. The strength of the samples tested 1 day after gluing is lower than that of the samples stored for 0.5 year, and it slightly decreases (by 2–6%) upon storage for 2 and 3 years. At high temperature, changes in the sample strength are more pronounced. It is smaller by a factor of 1.5–2.0 than that of the samples stored at room and lower temperatures. Nevertheless, at 200°C the adhesion strength is fairly high, about 100 kN m^{-2}. With K-300 adhesive, the adhesion joint strength of the Teflon films is higher, and it only slightly changes in the temperature range studied. In the case of K-300 adhesive, the glue joint between the Teflon film and metal is stronger than that between two Teflon films, whereas with BF-4 adhesive the trend is opposite. The increase in the adhesion of the Teflon surface is confirmed by a decrease in the wetting angle of the samples treated with examined solutions (Table 2).

CONCLUSIONS

(1) According to the ESR data, sodium naphthalenide can be prepared in air in tetrahydrofuran (THF).

(2) The spent solution regenerated from the wastes by adding sodium and naphthalene increases the adhesion of the Teflon surface.

(3) Glued films of modified Teflon retain strength properties for a prolonged time in a wide temperature range.

Abstract—A procedure for preparing hydrobrominated peat humic acids with enhanced biological activity was developed.

Bromine is one of indispensible microelements of various human and animal tissues, ensuring normal development and activity of living bodies. In this connection, attempts were undertaken to prepare brominated humic acids (HA). Humic acids with a high bromine content (up to 18.6 wt %) were obtained by bromination of humic acids with bromine. It was found that bromination of humic acids is accompanied by their oxidation. Brominated humic acids are enriched in oxygen-containing functional groups, and their molecular weight decreases by a factor of 1.5–2.0 [1–4].

To prevent oxidative degradation of humic acids in the course of their bromination, we attempted to introduce bromine atoms into humic acid by hydrobromination.

EXPERIMENTAL

Table 1 shows how the time of hydrobromination of humic acids with 40% aqueous HBr at 20°C influences both their chemical characteristics (bromine and functional group content) and biological activity. It seen that, with increasing hydrobromination time from 0.5 to 2 h, the Br content in HA increases from 0.54 to 2.63 wt % and the content of the phenolic hydroxy groups increases from 3.86 to 5.95 mg-equiv g^{-1}. At the same time, under these conditions the content of the quinoid groups (QG) decreases from 2.34 to 0.61 mg-equiv g^{-1}, apparently due to formation of 5-bromohydroquinone groups. HBr can also add to alkene groups of HA and destroy the oxygen-containing heterocycles. As a result, after hydrobromination, the iodine number of HA and the oxygen content in heterocycles O_c decreases respectively, from 0.26 and 0.44 mg-equiv g^{-1} to zero.

In order to elucidate how atmospheric oxygen influences the hydrobromination of humic acids, this process was carried out both in air and under argon. Our experiments showed (Table 1) that, after hydrobromination for 2 h in air, the molecular weight of humic acids decreases by a factor of approximately 1.5. At the same time, after hydrobromination under argon, the decrease in the molecular weight was less pronounced (from 1400 to 1130). In going from air to argon, the effect exerted by hydrobromination on the content of functional groups noticeably changes. We suggest that, in hydrobromination in air, humic acid is partly oxidized with atmospheric oxygen. The hydrobromination of HA can be intensified by its treatment with concentrated aqueous HBr for 0.5–1.0 h. The biological activity of the initial and hydrobrominated humic acids was determined by a standard yeast technique with distilled water as a reference with zero biological activity. Our results showed that hydrobromination of humic acids, especially in the presence of air, enhances their biological activity.

Table 2 shows how treatment of HA with HBr of various concentrations for 0.5 h at 20°C influences the chemical characteristics (bromine and functional group content) and biological activity of humic acids. It seen that, in the presence of atmospheric oxygen, with increasing HBr concentration from 20 to 30 wt %, the bromine content in modified HA changed insig-

* The quantities in parentheses and without them refer to hydrobromination under argon and in air, respectively. The same for Tables 2 and 3.

Table 2. Influence of hydrogen bromide concentration on the chemical characteristics (bromine and functional group content) and biological activity of humic acids (τ = 0.5 h, T = 20°C)

c_{HBr}, wt %	Yield of modified HA, %	c_{Br}, wt %	M	PhG	QG	IN	O_c	BA
				mg-equiv g^{-1}				
Initial HA		0.00	1400	3.86	2.34	0.26	0.44	1.06
20	92 (98)	0.30 (0.32)	1400 (1450)	4.20 (4.35)	2.14 (1.73)	0.20 (0.23)	0.42 (0.44)	1.10 (1.12)
30	96 (98)	0.38 (0.56)	1400 (1430)	4.63 (4.67)	2.00 (1.50)	0.22 (0.20)	0.33 (0.37)	1.12 (1.13)
40	94 (94)	0.54 (0.80)	1360 (1400)	4.91 (5.30)	1.40 (1.25)	0.24 (0.18)	0.26 (0.30)	1.18 (1.25)

nificantly (from 0.30 to 0.38 wt %), and the iodine number remained approximately constant (0.20–0.22 mg-equiv g^{-1}). With increasing HBr concentration from 20 to 40 wt %, the amount of oxygen atoms contained in heterocycles O_c decreased from 0.42 to 0.26 mg-equiv g^{-1}. The initial humic acid contained 0.44 mg-equiv g^{-1} O_c. The hydrobromination of HA in air either did not influence or somewhat decreased its molecular weight. At the same time, in several cases the hydrobromination under argon slightly increased the molecular weight of HA.

After hydrobromination under argon, the iodine number of humic acids decreased to a larger extent than after hydrobromination in air. These results suggest that, in going from air to argon, the addition of HBr to alkene groups becomes more efficient. For example, after HA treatment with 40% HBr for 2 h under argon, its iodine number decreased to zero. Under these conditions, the content of the quinoid groups in humic acids decreased by a factor of more than three. It was found also that hydrobromination increased the content of the phenolic groups in humic acids, and this effect was more pronounced under argon than in air. We believe that this difference is caused by oxidizing effect of atmospheric oxygen.

The hydrobromination of HA was studied in relation to temperature at an HBr concentration of 40 wt % under argon and in the presence of air. In these experiments, the hydrobromination time was 0.5, and 2 h and the temperature, –5, +10, and +20°C (Table 3). Table 3 shows that hydrobromination for 0.5 h under argon and in air weakly affected the HA characteristics. Its molecular weight remained practically constant, i.e., under these conditions humic acids did not degrade. We found no significant cleavage of the heterocyclic fragments. For example, after hydrobromination at 10°C in air, the O_c content decreased from 0.44 mg-equiv g^{-1} in the initial HA to 0.38 mg-equiv g^{-1}. At 20°C, O_c decreased to 0.26 mg-equiv g^{-1}. In going to argon, the degradative effect of hydrobromination slightly decreased. The bromine incorporation into HA did not exceed 0.8%. At the same time, the QG content decreased by a factor of approximately two and PG content increased from 3.86 to 5.30 mg-equiv g^{-1}. With increasing hydrobromination time from 0.5 to 2 h, the influence of temperature on the content of bromine and functional groups in humic acids sharply increased. After 2-h hydrobromination at 20°C, the characteristics of humic acids changed as follows: bromine content increased to 2.63 wt % (under argon), alkene groups were

Table 3. Influence of hydrobromination temperature on chemical characteristics (bromine and functional group content) and biological activity of humic acids (c_{HBr} = 40 wt %)

		(79)	(2.63)	(1130)	(5.95)	(0.61)	(0.00)	(0.12)	(1.04)

completely saturated with HBr, molecular weight decreased by 35%, oxygen-containing heterocycles were completely cleaved, the QG content decreased by a factor of four (from 2.34 to 0.61 mg-equiv g^{-1}), PG content considerably increased (from 3.86 to 5.95 mg-equiv g^{-1}), and the biological activity increased by a factor of 1.5.

CONCLUSION

Treatment of humic acids with aqueous HBr (40 wt %) under argon for 1 h at 20°C ensures the optimal conditions for their bromination and enrichment with phenolic hydroxy groups, largely responsible for the biological activity.

HISTORY OF CHEMISTRY AND CHEMICAL TECHNOLOGY

François Marie Raoult (To 175th Anniversary of His Birthday)

A French physicist and chemist F. Raoult made an outstanding contribution to the investigation into the nature of solutions, established a relationship between the reduction of the saturated vapor pressure over a solution and the mole fraction of a solute (Raoult law), suggested methods for determining the molecular weight of a solute from a depression of the freezing point of the solvent (cryoscopy) and from an elevation of the boiling point of a solution (ebullioscopy), and carried out a number of other studies. Raoult's works largely favored the appearance of investigations in the field of solutions, performed by founders of the present-day physical chemistry: J. van't Hoff (1852–1911, 1901 Nobel Prize in Chemistry), W. Ostwald (1852–1932, 1909 Nobel Prize in Chemistry), S. Arrhenius (1859–1927, 1903 Nobel Prize in Chemistry), and W. Nernst (1864–1941, 1920 Nobel Prize in Chemistry). In the lecture devoted to Raoult's memory, van't Hoff named him one of the most outstanding scientists of his century [1, 2].

François Marie Raoult was born on May 10, 1830, in Fournes in northern France into the family of a tax official with a moderate income. Raoult started his working activities as an official at a patent bureau in his native town, but soon moved to Paris to continue his education. The young student had to earn his living and tuition payments himself. Unfortunately, evidence concerning this period of Raoult's life is insufficient and contradictory. After publishing the results of his first electrochemical study in *C. R. Acad. Sci. Paris*, 1853, vol. 36, p. 826, Raoult became, presumably without having finished the university, a lecturer at a lyceum in Rheims. Beginning in 1855, he taught physics at College St. Dié. In 1856, Raoult became an adjunct professor at the same college and later headed the course of physics. In 1862, Raoult moved to a small provincial town of Sens, where he was a teacher at the local lyceum and prepared, in difficult conditions, his dissertation in electrochemistry for the degree of a doctor of physics. In 1863, he successfully defended it at the university in Paris and the degree of a docteur és sciences physiques was conferred on him. In 1867, the already known scientist was invited to teach chemistry at the University of

Grenoble, and all his further pedagogical and scientific activities were associated, till the end of his life, with the University of Grenoble. In 1870, he became a professor, and for a number of years was dean of the faculty of sciences. In Grenoble, world fame came to Raoult.

The scientific works of François Marie Raoult were to a certain extent ahead of his time, but all his conclusions were based on a thorough analysis of a vast body of experimental data. Three periods can be distinguished in his scientific activities. The earliest includes electrochemical studies: measurements of the electromotive forces of voltaic cells and evaluation of the heat effects of chemical reactions occurring in these cells. Continuing the investigations of P. Favre (1813–1880), also a French chemist, Raoult measured the heats of the chemical reactions and the electric work for various voltaic cells of a design similar to that of the Daniel cell. In contrast to the conclusions made by Favre and to the commonly accepted opinion of that time, Raoult established that, in the general case, these quantities do not coincide. In the second part of his investigations in this area, Raoult evaluated, using an instrument specially designed by him, the heat effects accompanying the decomposition

1070-4272/05/7805-0856© 2005 Pleiades Publishing, Inc.

of aqueous solutions of salts under the action of electric current. Describing this series of works, Raoult wrote: "I was the first to give a method for measuring the heat released or absorbed in chemical transformations under the action of electric current" [2]. Raoult repeatedly reverted to the problem of distinction between the "electric heat" and "chemical heat" in his subsequent investigations. As noted by W. Ostwald [2], Raoult convincingly demonstrated that the chemical and electric kinds of energy are not simply converted into one another, but a certain role is played here by heat. The Daniel cell is almost the only one in which the work is equal to the heat effect of the current-forming reaction. For the overwhelming majority of voltaic cells, the heat effect exceeds the electric work obtained. Being highly important, Raoult's electrochemical studies still did not bring scientific recognition to the author.

Beginning in 1870, Raoult makes the scope of his research work wider and pays increasing attention to various purely chemical studies, even though attempting to consider physical aspects of each chemical problem. Raoult studied the composition of natural gas from a deposit near Grenoble, examined the sorption of ammonia by ammonium nitrate, established the effects of light on the rate of inversion of cane-sugar, and considered how the content of CO_2 in the atmosphere affect breathing. During the period from 1870 till 1882, Raoult published 14 papers devoted to chemical issues in the *C. R. Acad. Sci. Paris*. All of these were carefully performed, but less interesting than those belonging to the preceding series of studies in the field of thermochemistry of electrochemical processes [4, 5].

In the late 1870s, Raoult found a new area of research and developed it for many years to come. In 1878 appeared the first Raoult's publication reporting the results obtained in determining the freezing point of the solvent in a solution (*C. R. Acad. Sci. Paris, Ser. 2*, 1878, vol. 87, p. 167). Already at the very beginning of his studies, Raoult established proportionality between the depression of the freezing point, reduction of the vapor pressure, and elevation of the boiling point. Aqueous solutions of both organic and inorganic compounds served as objects of study. In a separate set of experiments, water was replaced with benzene and other organic solvents.

In 1886, Raoult commenced measurements of vapor pressure in nonaqueous solutions, because salts and saltlike substances exhibited an anomalous behavior in aqueous solutions. Numerous experiments allowed Raoult to establish the independence of the molecular reduction of the vapor pressure from the nature of a solute, with only the ratio of the number of solvent molecules to that of solute molecules being important.

Summarizing the aforesaid, it may be stated that the main Raoult's contribution to investigation of solutions consisted in that he established, based on a vast experimental material accumulated by his predecessors, a simple and direct relationship between the solution composition, on the one hand, and reduction of the vapor pressure over a solution, depression of the melting point, and elevation of the boiling point, on the other. As already mentioned, Raoult's works in the field of solutions favored the development of a number of areas of research in the incipient physical chemistry. It became possible to determine from the depression of the freezing point the molecular weights of numerous liquids and solids that do not vaporize without decomposition, especially among organic compounds. Cryoscopic measurements affected the development of the method for analysis of substances, named thermal analysis by G. Tammann (1861–1938). An important conclusion from Raoult's studies was made by S. Arrhenius. In 1887, a quantitative explanation of violations of Raoult's law in aqueous solutions of salts, acids, and alkalis served as evidence in proof of the theory of electrolytic dissociation.

Raoult's studies of properties of solutions became widely known, they are described in courses of physical chemistry of any level. In historical regard, these investigations were analyzed in detail in monographs by P.I. Walden [6], Yu.I. Solov'ev [7], and J. Partington [8]. The results of basic Raoult's results were presented in the already mentioned lecture by van't Hoff [1], included in the collection of his selected works [2]. Raoult's cryoscopic investigations are considered in [9], where a certain biographic evidence is also presented. Raoult's contribution to the development of chemistry was noted by B.N. Menshutkin [10], a known historian of chemistry. Raoult's law and all its violations are discussed in detail in terms of the present-day concepts in a monograph by T.N. Sumarokova [11] and in numerous publications by M.I. Usanovich [12].

By 1888, Raoult became one of the best known French chemists, his investigations are highly appreciated. In 1889, he was awarded an International prize in chemistry. The British Royal Society awarded to Raoult the Davy medal; in 1895, he became a recipient of the Award of the French Academy of Sciences; in 1900, Raoult was decorated with the highest State

Award of France, he became chevalier of the Legion d'Honneur.

In 1890, the scientist was elected a corresponding member of the French Academy of Sciences and an honorary (foreign) member of the Rotterdam Scientific Society. In 1892, Raoult was elected an honorary member of the Manchester Literary and Philosophical Society; in 1898, he became a member of the London Chemical Society; in 1899, he was elected a foreign corresponding member of the St. Petersburg Academy of Sciences.

In April 1900, Raoult reached the retirement age, but, by decision of the council of the University of Grenoble, he was left in his position (in supernumerary status). By that time this was the proof of the high appreciation of his activities. In 1900 and 1901, Raoult published two extensive papers in which he presented his modern views on measurements of the vapor pressure (*La tonométrie*, Paris, 1900) and on cryoscopy (*La cryoscopie*, Paris, 1901). The known bibliographic reference book by Poggendorf lists more than 100 Raoult's papers (1898, vol. III, p. 1089; 1904, vol. IV, p. 1212). A large number of references to the most important Raoult's studies can be found in [1, 2, 6, 7].

Van't Hoff was not personally acquainted with Raoult and only rarely exchanged letter with him. Nevertheless, when assessing Raoult's personal qualities, van't Hoff wrote: "Raoult's personality is seen from his works: activity, patience, immense persistence and purposefulness, fine keenness of observation, especially in minutest details, and total independence in opinions and conclusions. At the same time, his self-criticism and acceptance of others' opinions together with those of his own, calm analysis of these opinions with a solid confidence that the final word belongs to the experiment. These features of his personality can be found on any page of his works and this should be known by the entire chemical community" [2]. He continued, with reference to a letter from Mrs. Raoult: "All of those who knew him in his private life always highly appreciated his good nature, elegancy, intellectuality, exclusive kindness, and modesty in any circumstances."

The sudden death of François Marie Raoult on April 1, 1901, was a tremendous loss not only to his relatives and friends, but also to the entire university, whole Grenoble, and the French science in general. The most prominent scientific journals published obituaries devoted to Raoult and noted that he had been an outstanding physical chemist of world level [13, 14].

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Thermal Transformations of Titanium Oxochloride Nanostructures on Silica Surface

A. A. Malkov, E. A. Sosnov, and A. A. Malygin

St. Petersburg State Technological Institute (Technical University), St. Petersburg, Russia

Received March 2, 2005

Abstract—The nature of thermal transformations of titanium oxochloride surface groups on dispersed silica in the temperature range 25–600°C, both in the course of $TiCl_4$ chemisorption and in subsequent thermal treatments, is considered.

The problem of titanium(IV) chemisorption on silica has been studied extensively [1–10]. The available body of data indicates that the $TiCl_4$ chemisorption on silica in a wide temperature range mainly occurs by the reaction of electrophilic substitution of a proton in silanol groups to give titanium oxochloride groups $(\equiv Si–O–)_nTiCl_{4-n}$, where n = 1–3. The parameter n is used to evaluate the functionality of a surface group, i.e., the number of bonds between this group and the initial silica matrix. The functionality of titanium oxochloride surface structures formed in $TiCl_4$ chemisorption largely depends on the initial concentration of silanol groups, which is determined by the temperature T_0 of preliminary annealing of silica [2]. A review of the available experimental data on the influence exerted by T_0 on the nature of $TiCl_4$ chemisorption makes it possible to reveal the general pattern consisting in that the Cl/Ti ratio in surface groups increases from 1 to 3 as the concentration of ≡Si–OH decreases (with increasing T_0) [2, 6]. However, comparison of the results of syntheses performed at the same T_0 by different authors shows that the values of n widely vary. In the case of silicas thermally treated at moderate temperatures (180–300°C), the Cl/Ti ratio in the products synthesized varied between different studies from 0.5 to 2.6 [6]. Such strong discrepancies may occur for several reasons.

First, the concentration and topography of the reactive OH groups of silicas thermally treated at the same temperature, but obtained using different methods may widely differ [11].

Second, the accessibility of the OH groups to $TiCl_4$ molecules is determined both by the size of SiO_2 particles themselves and by the pore size [12]. In the case of nonporous pyrogenic silicas (aerosils), the nature of the interaction is affected by the curvature of the surface. For example, $TiCl_4$ chemisorption on an aerosil with $S_{sp} \geq 300$ $m^2 g^{-1}$ (particle diameter ≤8.5 nm) mainly yields $–OTiCl_3$ groups [9], each, in the authors' opinion, shielding two OH groups, which do not enter into the reaction because of the structural inaccessibility. The decrease in the radius of curvature of SiO_2 particles in aerosils with a smaller S_{sp} results in that chemisorption on these aerosils chemisorption occurs to give, in addition to $–OTiCl_3$ groups, also $(–O–)_2TiCl_2$ groups [9]. Presence of a porous structure in dispersed silicas (silica gels, silochromes), which have a negative radius of curvature of the pore surface, provides in $TiCl_4$ chemisorption not only a higher degree of hydroxylation of the pore surface as compared with pyrogenic forms of SiO_2, but also a firmer binding of titanium(IV) chloride molecules to give three bonds between titanium oxochloride structures and the surface, $(–O–)_3TiCl$ [1].

Third, the structure of titanium oxochloride groups is also affected by the experimental conditions (pressure, gaseous or liquid reaction medium, static or dynamic treatment modes, etc.). In $TiCl_4$ chemisorption from a solution of *n*-heptane or in a vacuum under static conditions, mostly $–OTiCl_3$ groups are formed on the surface of dehydrated silica [6]. Carrying out chemisorption under the same temperature conditions in a flow-through system with simultaneous removal of gaseous reaction products (HCl) makes it possible to shift the equilibrium toward a more complete course of the reaction [1]. In this case, the multiplicity of bonding between a titani-

um oxochloride group and the surface increases. Presence of trace amounts of moisture in the reaction medium (χ_{H_2O} > 16 mg m^{-3}) may distort the true value of the Cl/Ti ratio in surface groups on silica [13]. An additional important factor that affects the nature of chemisorption and the structure of the forming surface groups is the temperature at which the stage of $TiCl_4$ chemisorption is carried out (T_{CS}) or the products obtained are calcined (T_T) [14–16]. It may be assumed, on the basis of the results of [14, 15], that transformations caused by thermal instability of the titanium oxochloride groups synthesized may occur in the forming surface monolayer in the course of synthesis at temperatures higher than 200°C.

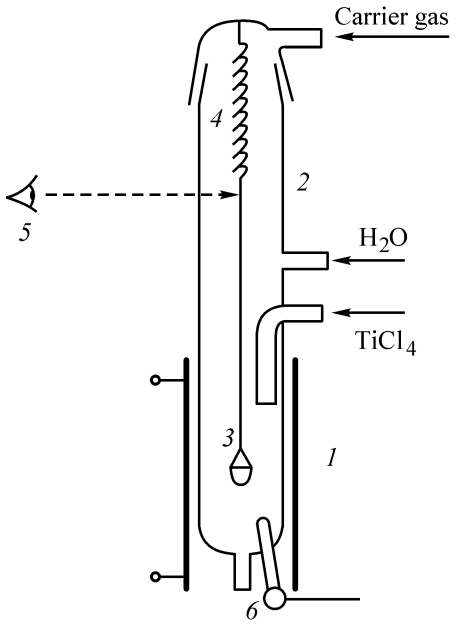

Fig. 1. Reactor with a quartz McBain balance. (*1*) Furnace for indirect heating, (*2*) flow-through quartz reactor, (*3*) vessel for silica, (*4*) quartz spring, (*5*) cathetometer, and (*6*) thermocouple.

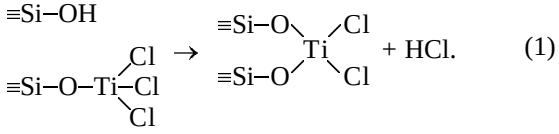

The aim of this study was to examine $TiCl_4$ chemisorption on silica and the subsequent thermal transformations of the reaction products in the temperature range 25–600°C.

The experiments were carried out with broad-porous silica of ShSKG brand (0.2–0.4-mm fraction), which was purified to remove iron ions by the procedure described in [17] and had a specific surface area (S_{sp}) of 235 $m^2 g^{-1}$, measured by the BET technique from low-temperature adsorption of air [18]. All silica samples were subjected to a preliminary thermal treatment at 600°C in air and then in a flow of dried argon for 6 h. After that the samples were treated with a $TiCl_4$ vapor at a fixed temperature T_{CS} in the range 25–600°C. The experiments were performed in flow-through conditions, which ensured continuous removal of gaseous reaction products from the reaction zone [13]. The thermal transformations of titanium oxochloride groups were studied in a flow-through reactor with a quartz-spring McBain balance (spring rate 3.3 mg mm^{-1}) (Fig. 1) on the basis of variation of the sample mass. In addition, the chemical composition of the initial samples and final solid and gaseous products of thermal transformations was monitored using the known techniques [19]. IR spectroscopic studies of products with surface titanium oxochloride groups were performed in the course of formation and subsequent thermal transformations on an IKS-29 instrument. The spectra were measured *in situ* in a flow-through reactor combined with a quartz cuvette with KBr windows [10]. The synthesis products were analyzed for the content of titanium(IV) [2, 20] and chloride ions [21]. To obtain the true stoichiometric ratios, the content of titanium(IV), chloride ions, and OH groups was recalculated to 1 g of anhydrous silica (to 1 g_0) [2].

Table 1 lists the chemical composition of products formed in interaction at various T_{CS} between $TiCl_4$ vapor and silica subjected to a preliminary thermal

treatment at 600°C. It can be seen that chemisorption of titanium(IV) chloride at 25°C yields mostly $-OTiCl_3$ surface groups (Cl/Ti ratio ~3.0). Raising T_{CS} to 100°C leads to a decrease in the Cl/Ti ratio in the synthesis products to 2.44, which indicates that polyfunctional titanium oxochloride structures are formed on the surface in this case. Together with the increase noted as T_{CS} is raised to 100–200°C, an increase in the content of titanium(IV) in the chemisorption products to 1.88–1.85 titanium atoms per 1 nm^2 is observed, compared with 1.68 titanium atoms per 1 nm^2 in samples obtained at 25°C (Fig. 2, curve *1*). Also significantly increases the consumption of OH groups in the reaction (from 41% at 25°C to 70–78% at 100–200°C, respectively). If T_{CS} is elevated further, the number of bonds between chemisorbed molecules and the surface increases, the total content of titanium(IV) and chloride ions decreases, and the number of OH groups involved in the reaction remains virtually unchanged.

To reveal the reasons for the above transformations, the possible ways in which temperature affects the system synthesized are now considered. It may be assumed that raising the chemisorption temperature from 25 to 100°C must lead to intensification of deformation vibrations of surface OH groups of the silica matrix and chemisorbed groups. Also possible is appearance at elevated temperatures of rotational degrees of freedom of surface OH groups about the bond between the oxygen atom of the OH group and silicon [22]. The whole set of the reasons mentioned above, as well as the known ability of surface silicon–oxygen tetrahedra in silicas to change without activation the Si–O–Si valence angle in the range 120–180°C [23], may lead to the following interactions of chemisorbed $-OTiCl_3$ groups with the unconsumed silanols by the scheme

(1)

The formation of titanium oxochloride groups bifunctionally bound to the silica surface, which occupy a significantly smaller surface area as compared with monofunctional groups ($S_{TiCl_3} \approx 0.37$ nm^2, $S_{TiCl_2} \approx 0.21$ nm^2)[1] leads to an increase in the consumption of the initial OH groups (Table 1). A calculation of the amount of OH groups consumed in chemisorption at T_{CS} = 100–600°C yields 1.17 ± 0.07 mmol g_0^{-1}, compared with 0.72 ± 0.03 mmol g_0^{-1}, the value characteristic of the samples obtained at T_{CS} = 25°C. Syntheses at $T_{CS} \geq 200$°C are accompanied by a decrease in the content of titanium(IV) and chloride ions in the surface groups synthesized, which is apparently due to their thermal instability [14, 15].

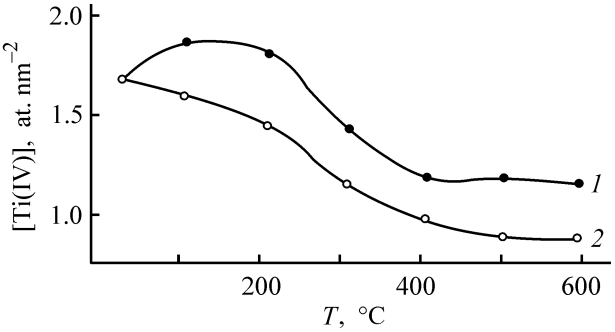

Fig. 2. (*1*) Concentration of Ti(IV) per unit surface area of Ti vs. the temperature T of $TiCl_4$ chemisorption and (*2*) variation of the same concentration in the course of thermal transformations of the product of chemisorption at T_{CS} = 25°C.

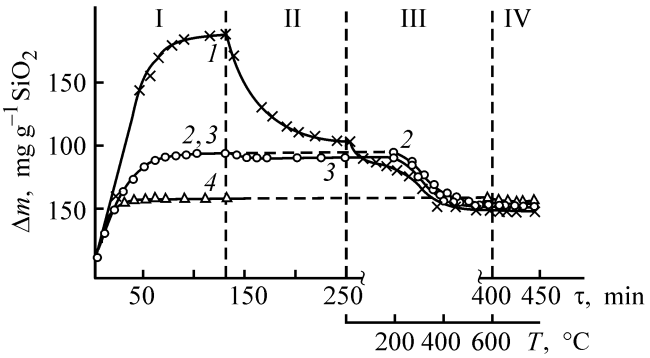

Fig. 3. Change in the sample mass, Δm, vs. time τ and temperature T of treatment of ShSKG silica gel with a $TiCl_4$ vapor and subsequent thermal treatment. T_0 = 600°C. T_{CS} (°C): (*1*) 25, (*2*, *3*) 200, and (*4*) 600. Stage: (I) $TiCl_4$ chemisorption, (II) $TiCl_4$ desorption in a flow of a carrier-gas at (*1*) 25 and (*3*) 200°C, (III) $TiCl_4$ desorption in thermal treatment of samples in a flow of the carrier-gas on raising T_T to 600°C, and (IV) $TiCl_4$ desorption in a flow of the carrier-gas at 600°C.

To verify the assumption made, the influence exerted by thermal treatment on the composition and structure of titanium oxochloride groups synthesized at 25°C was studied (Table 2; Fig. 3, curve *1*). For this purpose, a sample after chemisorption at T_{CS} = 25°C was subjected to a stepwise thermal annealing in a flow of an inert gas in the range 100–600°C, with the sample kept at each fixed temperature until

[1] The calculation was performed using the covalent radii of titanium, chlorine, and oxygen atoms, with account of the percentage of the ionic nature of bonding.

Table 2. Chemical composition of titanium oxochloride groups upon $TiCl_4$ chemisorption at 25°C by ShSKG silica gel and subsequent thermal treatment in the temperature range 100–600°C (T_0 = 600°C, content of OH groups 1.66 mmol g_0^{-1})

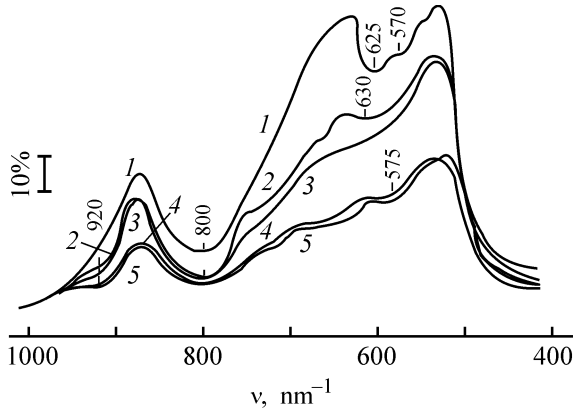
the evolution of chlorine-containing gaseous products ceased and a constant mass was reached. It can be seen from the data in Table 2 and curve *2* in Fig. 2 that calcination of a sample with titanium oxochloride groups obtained at 25°C leads to a decrease in the content of titanium(IV) and chloride ions, Cl/Ti ratio, and total mass. At the same time, calculation of the amount of OH groups involved in the formation of titanium oxochloride groups from the stoichiometric Cl/Ti ratio yields a virtually invariable value (0.72 ± 0.03 mmol g_0^{-1}) in the entire temperature range under consideration.

Analysis of the gaseous products at the reactor outlet in the course of stepwise heating demonstrates that titanium(IV) and chloride are present ions in a molar ratio close to 4 (4.06 ± 0.09). The results obtained indicate that the empirical formula of volatile compounds evolved in annealing is $TiCl_4$.

With account of the experimental data obtained, the possible course of interfunctional interactions of titanium oxochloride groups on the silica surface under thermal treatment can be represented as



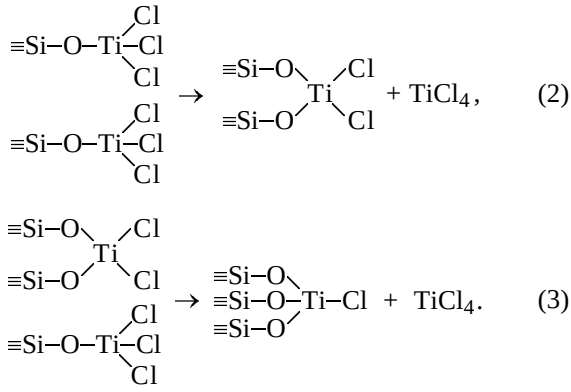


Fig. 4. IR transmission spectra of (*1*) initial silica gel with T_0 = 600°C, (*2*) that after $TiCl_4$ chemisorption at 25°C, and that after the subsequent thermal treatment at (*3*) 200, (*4*) 400, and (*5*) 600°C. (ν) Wave number.

The interfunctional interactions between $-OTiCl_3$ groups are the most pronounced in the T_T range 100–400°C, which points to a thermally activated nature of the rearrangement process. Its activation energy ΔE_a can be evaluated as

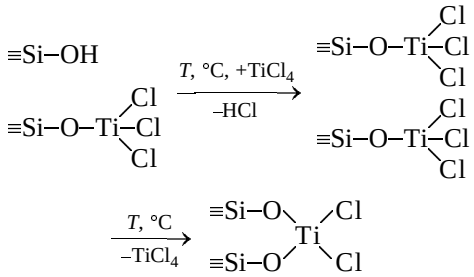
$$\Delta E_a = kN_A(T_T - T_{CS}), \quad (4)$$

where N_A is the Avogadro number and k is the Boltzmann constant. In the initial stage of the process (T_T = 25–100°C), the activation energy does not exceed 1 kJ mol^{-1}. At T_T > 400°C, the Cl/Ti ratio in the surface groups becomes less than 2.11, i.e., the remaining amount of closely spaced monofunctional titanium oxochloride groups is nearly zero, and, as a consequence, further decrease in the Cl/Ti ratio suggests that interfunctional transformations between $(-O-)_2TiCl_2$ and $-OTiCl_3$ groups in accordance with scheme (3) are possible. It should be noted here that, despite the removal of a part of titanium(IV) atoms from the surface in the form of $TiCl_4$, the amount of Si–O–Ti bonds between the silica substrate and surface titanium oxochloride groups remains virtually constant according to the results of a chemical analysis (Table 2). This is confirmed by IR spectroscopic studies of the products of thermal transformations (Fig. 4): the intensity of the ab-

sorption band at 920 cm^{-1}, which is associated with Si–O–Ti bonds, remains unchanged [7, 10]. The experimentally established pattern of structural-chemical transformations on the silica surface is in a good agreement with the results of a quantum-chemical simulation of structural transformations on the silica surface [24]. It was demonstrated in [24], based on the values obtained for the change in the Gibbs energy, that structural transformations of monofunctional, as well as mono- and bifunctional, titanium oxochloride groups with evolution of $TiCl_4$ into the gas phase proceed without any thermodynamic hindrance. The authors noted that an interaction between two structures bound to the surface by a single bond is more favorable than the reaction between the mono- and bifunctional groups.

The results obtained are in a good agreement with the previously made assumption that, depending on T_{CS}, interfunctional interactions may occur on the surface already directly in the course of synthesis, which results in that mostly $(–O–)_2TiCl_2$ and $(–O–)_3TiCl$ groups are formed at elevated temperatures [15]. Now, the experimentally determined content of chloride ions $[Cl_{exp}]$ in the products formed in interaction of $TiCl_4$ with silica at temperatures of 200–800°C [15] and the calculated Cl_{calc} in the samples obtained are compared on the assumption that mostly $TiCl_4$ is removed from the surface of silica containing titanium oxochloride groups on elevating the temperature from 200°C to T_{CS} at constant T_0:

$$(Cl_{calc})T_{CS} = (Cl_{exp})_{200} - 4[(Ti)_{200} - (Ti)_{T_{CS}}]. \quad (5)$$



The good agreement between the experimentally determined and calculated content of chloride ions in titanium oxochloride groups (Table 3) convincingly confirms that interfunctional rearrangements of surface groups can occur directly in synthesis by the suggested schemes (2) and (3). It should be noted that the excess of $TiCl_4$ in the gas phase can strongly affect the process of interfunctional rearrangements. As can be seen from schemes (2) and (3), the occurrence of interfunctional interactions does not change the amount of OH groups consumed in chemisorption. However, a rearrangement in an inert medium (Table 2) results in that a significantly smaller amount of OH groups is consumed in the reaction even at T_T = 400–600°C, compared with the case of chemisorption under the same temperature conditions (Table 1). In all probability, presence of an excess amount of $TiCl_4$ ensures, under the conditions of a thermal treatment, an additional interaction of

the $–OTiCl_3$ group with silanols, which can be represented as

(6)

Thus, the nature of thermal transformations of titanium oxochloride groups on the silica surface at 25–600°C depends on whether the initial reagent $TiCl_4$ is present or absent in the reaction space. In the presence of $TiCl_4$, the consumption of the initial OH groups grows from 40 to 70% as temperature increases from room temperature to 100°C and more, which is due to thermal activation of the chemisorption process. The dependence of the content of Ti(IV) is more complex: the Ti(IV) addition density per unit surface area grows as the chemisorption temperature increases from room temperature to 100–200°C and then decreases, approaching a constant value at T_{CS} of 400–600°C. The steady decrease in the Cl/Ti ratio in synthesis products from 3.0 to 1.65, observed in the entire temperature range under consideration, indicates that the amount of bonds between the groups synthesized and the silica surface increases.

In the absence of the initial reagent in thermal treatment in a flow of an inert gas, there occur structural-chemical transformations of monofunctionally bound titanium oxochloride groups, accompanied by evolution of $TiCl_4$ into the gas phase and formation of groups predominantly bifunctionally bound to the surface.

Abstract—An original technology for processing of a natural material, shungite-3 from the Zazhogino deposit (Karelia), was developed in order to obtain a new product, mixed nanocarbon material (MNS).

It is suggested to obtain a nanocarbon material (MNS) by using the available natural raw material, shungite rock widely occurring in the geologic profile of the world's largest Onega basin (Republic of Karelia) of Precambrian black-shale sedimentation. To the shungite rock is commonly related a large group of compositionally different carbon-containing Precambrian geologic formations. Commonly, rocks with 5–10% shungite substance are named shungitious, and those with 0.5–5%, shungite-containing. To high-carbon shungite rocks belong those in which the content of free shungite carbon exceeds 20%.

The total estimated resources of the shungite rock of the Onega basin according to Mikhailov [1] exceed one billion tons (1041 million), and the prospected resources (of classes B + C1 + C2) of the largest Zazhogino deposit (in Medvezh'egorskii district) are 148.8 million tons (reserves 321.8 million tons), with the average content of the shungite carbon, e.g., in the Maksovskaya bed, is about 31%.

Shungite (shungite rock) of the Zazhogino deposit is, on the average, composed of 30% carbon and 70% silicates [2]. It is by the content of carbon that it is referred [2] to the third variety of shungite rocks (shungite-3), or, according to the geological-genetic classification by Filippov, to maxovites, which are saprobitumolite rocks having the form of a fine homogeneous mixture of a shungite substance and a cryptocrystalline mineral substance. The conditions of the regional metamorphism of shungite rocks correspond to the chlorite and biotite zones of the greenshale facies. The microelements found in these rocks are Fe, Ti, V, Ni, Cu, and Zn, mainly in the sulfide (pyrite, pyrrhotine, sphalerite, etc.) and oxide (rutile etc.) mineral forms.

The conditions in which shungites are formed, as well as their chemical and phase composition, suggest that fullerenes and(or) fulleroid components of carbon fractions are present in natural shungites. Here and hereinafter by fullerenes are meant light fullerenes C_{60} and C_{70} and heavy fullerenes C_{76}, C_{78}, C_{84}, and C_{90}, as well as their mixtures; and by fulleroid materials are understood single- and multi-walled nabnotubes, nanobarrels, nano-onions, nanocones, and mixtures of these [4, 5].

The authors developed an original technique for mechanical and chemical processing of shungite-3 to obtain a heterogeneous catalyst. The technique includes the following processing stages: (a) decomposition of the rock in an alkaline (NaOH) melt at a temperature of 500–520°C to remove aluminosilicate and silicate components; (b) washing of carbon phases with water to remove trace amounts of the alkali, with the subsequent grinding and sieving to obtain a powder with a grain size of 80–100 μm; (c) acid treatment of carbon phases (HNO_3 65 wt %) at 60–65°C for 3–5 h to remove mixtures of metals, their oxides, and sparingly soluble salts and also to dissolve inactive amorphous carbon and graphite, which is present in carbon phases; (d) washing of carbon

phases with water to remove trace amounts of the acid and the forming salts and to oxidize the material with atmospheric oxygen at 650–700°C in the course of 10–15 h. Naturally, even if fullerenes or their derivatives were present in initial shungite samples, they would have irreversibly decomposed already in the first stage of treatment, in an alkali melt.

A natural, comparatively low-cost carbon nanomaterial was obtained for the first time by subjecting shungite-3 to a treatment of this kind. This material contained, depending on the extent of etching and quality of the starting shungite, 20 to 70 wt % fulleroid (mostly hollow) nanoparticles: multi- and single-walled nanotubes, nanobarrels, nano-onions, and nanocones. A typical electron micrograph (×500 000 magnification) of an as-modified shungite material (MNS) is shown in Fig. 1. A hollow, closed at both ends, multi-walled nanotube with a channel diameter of ~3 nm, outer diameter of ~20 nm, and length of ~0.2 μm is well seen, together with a set of fragments of singlewalled nanotubes, hollow nanobarrels, and nonhollow nano-onions. Also, rather exotic carbon nanoparticles and, in particular, hollow nanocones were found in shungite-3 (Fig. 2). Figure 3 shows for comparison a fragment image of an unmodified shungite material in which numerous fulleroid particles are embedded in silicate and aluminosilicate phases (naturally, the contrast in such an image is markedly lower than that in other images, and the fragment itself is rather untypical: fulleroid materials are rather nonuniformly distributed throughout the volume of shungite-3).

The authors estimate the total content of fulleroid particles in shungites-3 at 1 to 4 wt %, and the content of various nanotubes among other fulleroid particles may constitute 20 to 40 rel. % by mass. The total content of fulleroid particles in shungites with a high content of carbon phases may be a factor of 2 to 3 higher.

Up to 100 kg of the natural carbon nanomaterial MNS can be obtained from 1 ton of shungite-3 by the technique developed.

As the resources of oil are being exhausted all over the world, development of industrial technologies for synthesis of liquid hydrocarbons from other types of carbon-containing fossil fuels: coal, natural gas, peat, biomass of various types, etc., clearly becomes a matter of current interest.

It is suggested to use the new modified carbon material MNS, considered here, as a high-efficiency heterogeneous catalyst for processing of natural gas in a liquid, under normal conditions, mixture of hydro-

carbons (C_5-C_8). It was established in preliminary laboratory tests that MNS exhibits a rather well-pronounced sorption capacity for vapor of hydrocarbons (primarily methane) and oxygen- and nitrogen-containing compounds, hydrogen, and carbon(II) oxide, as well as for transition and heavy metals in sorption from solutions in a wide range of temperatures and pressures.

This made it possible to assume that MNS must have a high efficiency when used as a heterogeneous catalyst for processing of natural gas. Preliminary laboratory tests of MNS as a heterogeneous catalyst at temperatures of 200–450°C and pressures of up to 30 atm revealed that methane is effectively dehydrogenated to give a mixture of branched and normal saturated hydrocarbons (C_5-C_8) with a minor admixture of alkenes and aromatic compounds (up to several weight percent) at a sufficiently high completeness of methane conversion into the gasoline-ligroin fraction, of up to 30 wt %. The catalytic effect is strongly enhanced upon introduction of some elements (Ti, Zr, Al, Ru) in the form of metals and oxides into MNS in amounts not exceeding 1–2 wt %.

As analogous artificial carbon nanomaterials can be mentioned mixtures of single- or multi-walled carbon nanotubes open at both ends (SWNT and MWNT, respectively) [4] and mixtures of various fulleroid materials of unstable composition [5], the so-called astralenes (ASTR), fullerene black, or the so-called "washed" fullerene black (FB) [6]. The first two products (SWNT and MWNT) do exhibit a high heterogeneous-catalytic activity in processing of natural gas, which is comparable with that of the natural material, MNS. However, their manufacture is rather labor- and power-consuming. This is due to the use of the catalytic arc method for synthesis of SWNT, whose output capacity does not exceed 50 per 24 h per reactor, and to the necessity for subsequent multistage fine chemical purification. Similarly, the amount of SWNT and MWNT produced by CVD (chemical decomposition of carbon supports on a catalytically treated substrate) does not exceed several grams in 24 h [8], although the process of chemical purification is somewhat simpler in this case. These factors predetermine the very high cost of MWNT and SWNT. The prices for these materials are absolutely unacceptable for the chemical industry (they exceed the price of the developed material, MNS, by a factor of several hundreds). Two other types of materials are markedly less expensive; however, they have a smaller specific surface area and lower sorption capacity because the content of fulleroid carbon phases in these materials is significantly lower (up to 20–30 wt % in ASTR and not more than 1–2 wt % in FB). As a result, their heterogeneous-catalytic activity in reactions of chemicalization of natural gas is poorer than that of MNS.

The first report that fullerenes are contained in shungites appeared in 1992 [9]. Later, this issue was extensively studied, but the data obtained were contradictory. Some researchers found that the total content of fullerenes in natural shungites is about 1–3% relative to the mass of the shungite carbon [10–12], whereas others estimated it at 1–10 ppm [13]. First, we formulate what will be understood by the generalizing notion "fullerenes in shungites." These are light (C_{60} and C_{70}) and heavy (C_{76}, C_{78}, C_{84}, C_{90}, ...) fullerenes themselves, their oligomers [dimers, e.g., $(C_{60})_2$], and, possibly, some derivatives of fullerenes and their oligomers with undistorted or weakly distorted fullerene-type electronic structure: outer- and inner-sphere metal complexes; compounds with hydrogen, oxygen, sulfur, nitrogen, halogens, and hydroxy, carbonyl, and carboxyl groups with a moderate total number of substituents (≤6, best of all 1–2). We note several specific features of the analysis.

(1) When making an analysis, it is desirable to preliminarily remove from shungites silicate and, if possible, metal-containing phases, because fullerenes may be more or less strongly bound to components of these phases and, in any case, substantially blocked by these phases. This, undoubtedly, hinders their transfer into the liquid (e.g., in extraction) or vapor phase (e.g., in a mass-spectrometric determination).

(2) These phases should not be removed by strong oxidizing agents, e.g., molten alkalis, concentrated nitric or hydrochloric acid, because fullerenes are unstable in media of this kind and completely lose their fullerene structure upon oxidation.

(3) Direct determination of fullerenes in shungites (e.g., by mass-spectrometry in sublimation-ionization in a high vacuum) may lead to noticeable errors because of the possible direct synthesis of fullerenes from the carbon plasma generated directly in the course of a mass-spectrometric experiment.

In the experiments, the samples for analysis were prepared as follows:

(a) shungite-3 was ground in a ball mill;

(b) the fraction with a grain size of less than 40 μm was separated by sieving;

(c) the rock was decomposed in an acid (conc. HF) solution at 50–55°C in the course of 12–16 h to remove the aluminosilicate and silicate phases (as is known, fullerenes are quite stable against the action

of these hydrohalic acids in the comparatively mild conditions specified);

(d) a repeated acid treatment (HCl 36 wt %) at 50–55°C for 12–16 was performed to remove the mixture of metals, their oxides, and sparingly soluble salts;

(e) the carbon phases were washed with water to remove trace amounts of the acid and the forming salts;

(f) the material was dried in a vacuum oven at 100–110°C and a residual pressure of less than 0.1 mm Hg for 2 h (with carbon fractions that contain virtually zero amounts of other elements and can be used for direct chemical analysis obtained in an amount of up to 40 rel.% relative to the initial mass of the shungites);

(g) the carbon phases obtained were placed in a counterflow extractor of the type of a Soxhlet apparatus, and extraction with chemically pure *o*-dichlorobenzene, which is the most effective solvent for unmodified fullerenes [14], was carried out at 175–185°C under atmospheric pressure in the course of 240 h; (in the course of the extraction, the solvent acquired an increasingly intense yellow-brown coloration, which is rather characteristic of solutions of fullerene mixtures);

(h) the resulting solution was evaporated virtually to dryness in the vacuum oven at a pressure of 60–70 mm Hg;

(i) the residue was completely dried in the vacuum oven at 100–110°C and a residual pressure of less than 0.1 mm Hg for 8 h.

This procedure yielded a finely dispersed brown powder in an amount of 0.2–0.4 rel.% relative to the initial mass of shungites, and the sample preparation was complete.

Further, a sample was completely dissolved in chemically pure *o*-xylene and the absorption spectrum of the resulting solution was measured in the visible and near-UV spectral ranges in KU quartz cuvettes on an SF-46 instrument. The topological features of the spectrum obtained did not match the spectra of fullerenes and(or) their mixtures, dissolved in aromatic solvents [15]. For example, the band at 472 nm, characteristic of the C_{70} fullerene and heavier fullerenes is virtually absent; the UV part of the spectrum shows absorption steadily increasing as the wavelength becomes shorter; however, an exceedingly weakly pronounced, but reproducible shoulder is, nevertheless, observed at around 335.7 nm in the region characteristic of the absorption spectra of both light fullerenes. This shoulder can, in principle, be attributed to presence in the mixture of a certain, very small amount of fullerenes. A calculation performed using the absorption coefficients of light fullerenes at this wavelength [15] makes it possible to evaluate the possible content of fullerenes in shungites-3 at several hundredth of a weight percent (≤0.05 wt %). The concentrations of fullerenes were also measured by high-efficiency liquid chromatography with a UV detector (at 325 nm) upon a direct introduction of dilute samples dissolved in a mixture of *n*-hexane with toluene into the chromatographic column by the method described in [16]. As reference served solutions of individual light and heavy fullerenes and their mixtures of known composition.[1] Calculation by this method leads to virtually the same conclusion: the content of fullerenes in shungite-3 does not exceed 0.02 wt %.

CONCLUSION

The following fullerene materials were found in shungites in amounts of several weight percent: multi- and single-walled nanotubes, nanobarrels, nano-onions, nanocones (mostly hollow). Fullerenes themselves and their derivatives were virtually not detected at all by the measurement techniques employed.

Abstract—The kinetics of heat release in thermal decomposition of a mixture of ammonium nitrate and pyroxylin was studied. To elucidate the mechanism of this process, the kinetics of heat release in oxidation of ammonium nitrate with nitrogen dioxide and of cellulose with a nitric acid solution was examined. The kinetic equations of the processes and the temperature dependence of the constants in these equations were established. The influence exerted by addition of diphenylamine on the rate of heat release in the system constituted by ammonium nitrate and pyroxylin was analyzed.

Pyroxylin, which is incomplete cellulose nitrate with a nitrogen content of 12–13.5%, has a negative oxygen balance; introduction of oxidizing agents into pyroxylin improves its energetic characteristics. A possible way in this direction is to use NH_4NO_3, whose mixtures with TNT (ammatols) have long been employed as explosives for various purposes [1]. An essential obstacle to application of NH_4NO_3-based formulations as composite fuels and gas-generating compositions is that phase transitions occur in NH_4NO_3, which disrupts the continuity of a sample when the temperature of the mixture passes across the phase transition temperatures. However, ways to strongly decelerate or even rule out such transitions have been under development recently. To make an objective assessment of the possibility of practical application of NH_4NO_3 mixed with pyroxylin at elevated temperatures it is necessary to study the fundamental kinetic aspects of thermal decomposition of these mixtures. Taken separately, pyroxylin and NH_4NO_3 have a thermal stability sufficiently high for many practical purposes and they are industrially manufactured in considerable amounts. However, these components can interact in a mixture, which may hinder practical application of these mixtures.

Various aspects of the reaction of thermal decomposition of pyroxylin have already been studied for about 100 years; the basic features of this process have been established and described in numerous publications [2]. The initial rate of pyroxylin decomposition has been extensively studied and the results obtained are in a satisfactory agreement [3], the rate in question being determined by the rate of NO_2 detachment from the nitrocellulose link. The fundamental aspects of how the reaction is accelerated depend on the possibility of accumulation of the reaction products and their removal into the gas phase; here, only qualitative results are available for the most part, and quantitative data, in separate cases. The influence exerted on the rate of pyroxylin decomposition by the main decomposition products, primarily by nitrogen oxides, nitric acid, and water, which all accelerate the decomposition, with the main part played by the reaction of acid hydrolysis of the nitroester bond, has been studied. However, the kinetics of heat release in pyroxylin decomposition has been the subject of only a single study [4]. Under the experimental conditions used in this study (open system in air or continuous removal of products by pumping), the autocatalysis is relatively weak and, therefore, the process was studied at a temperature of 140–165°C exceeding that used in the present study, and the decomposition kinetics was described by a first-order autocatalysis equation.

Pure NH_4NO_3 is markedly more stable and decomposes at a noticeable rate only at temperatures higher than its melting point (169°C) [2]. At the temperatures considered in this study, its own thermal transformations are insignificant. Reverse equilibrium dissociation of NH_4NO_3 into NH_3 and HNO_3 always occurs in NH_4NO_3. Although the degree of this dissociation is low, just the presence of these products in

1070-4272/05/7806-0870 © 2005 Pleiades Publishing, Inc.

the salt predetermines many of its properties. In particular, the rate of thermal decomposition of NH_4NO_3 is determined by presence of molecules of nitric acid in this compound. As HNO_3 makes higher the rate of pyroxylin decomposition, it would be expected that introduction of NH_4NO_3 into pyroxylin should also raise this rate, but the heterogeneity of the mixture may strongly hinder this influence. No direct kinetic analysis of thermal transformations in this mixture has been made, and, therefore, the aim of this study was to analyze quantitatively the kinetics of heat release in a mixture of NH_4NO_3 and pyroxylin under conditions as close as possible to those of the probable practical application of these mixtures.

EXPERIMENTAL

Industrial pyroxylin releasing 208.9 ml of NO per 1 g of the product in a standard analysis for the degree of nitration, which corresponds to a nitrogen content of about 13.1%, was used in the study. Ammonium nitrate was taken from three different sources: sample no. 1, fresh reagent of analytically pure grade, conforming to GOST (State Standard) 22867–77; sample no. 2, granulated NH_4NO_3 manufactured as a fertilizer at Kirovo-Chepetsk chemical combine; and sample no. 3, granulated NH_4NO_3 manufactured in France (Toulouse). All the NH_4NO_3 samples were preliminarily ground in an agate mortar, in order to make larger the surface area of contact between the components, and manually mixed with pyroxylin. The kinetic aspects of the thermal transformations were studied by analyzing the rate of heat release, using a DAK-1-1 differential automated calorimeter [5].

The equilibrium vapor pressures of NH_3 and HNO_3 over NH_4NO_3 strongly differ: a larger amount of NH_3 passes into the gas phase at elevated temperatures, which leads to the corresponding increase in the HNO_3 content in solid or liquid NH_4NO_3. This circumstance predetermines the dependence of the decomposition rate of NH_4NO_3 and the rate of its interaction with the other components on the gas volume of the system, V_g^0, because the rates of these processes are determined by the content of HNO_3 in the solid or liquid phase. For this reason, the experiments should be performed at as small V_g^0 as possible, in which case the deviation from stoichiometry of the initial salt and, accordingly, the decomposition rate will be lower. It is desirable to have no free gas volume at all; in this case, however, the evolving gaseous products will rapidly destroy the working ampule because of the buildup of an internal pressure exceeding its limiting strength. The experiments were performed in sealed glass ampules with an internal volume of about 2 cm^3, placed fully within the working cell of the microcalorimeter. Such experimental conditions simulate rather well the storage conditions of gas-generating compositions. It was possible to carry out the decomposition virtually to completion without disintegration of the ampule when a 0.02–0.03-g portion of pyroxylin was used. When it was necessary to use larger masses, the experiments were terminated at earlier stages of the reaction. In thermal decomposition of pyroxylin, the dependence of its rate on the gas volume is also strong: as the volume decreases, the degree of self-acceleration increases.

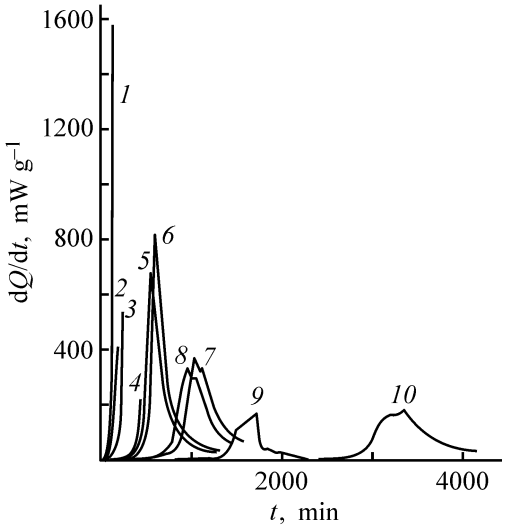

Fig. 1. Rate of heat release, dQ/dt vs. time t in thermal decomposition of a mixture of NH_4NO_3 with pyroxylin. Decomposition temperature (°C): (*1*) 121.6, (*2*) 117.1, (*3*) 112.8, (*4*) 106.3, (*5*) 104.3, (*6*) 104.3, (*7*) 99.0, (*8*) 98.9, (*9*) 96.8, and (*10*) 92.5.

First, the kinetics of heat release in thermal decomposition of the starting pyroxylin at a free gas volume V_g^0 = 65 cm^3 per 1 g of pyroxylin was studied in the temperature range 96.4–171.7°C, and that of a mixture of this pyroxylin with NH_4NO_3, under the same conditions at 92.5–121.6°C. The curves obtained for the mixture are shown in Fig. 1. The mixture contained about 30 wt % pyroxylin, which virtually corresponds to the oxygen balance, with the excess of oxygen equal to only 0.19 wt %. For all the three NH_4NO_3 samples studied, close results were obtained; sample no. 1 was used in further study. In all the experiments, the rate of heat release was calculated per 1 g of pyroxylin, which is convenient for analyzing the influence exerted by NH_4NO_3 on the heat and rate of the process; V_g^0 was also calculated per 1 g of pyroxylin.

The rate of intrinsic thermal decomposition of NH_4NO_3 at the temperatures studied is negligible, but

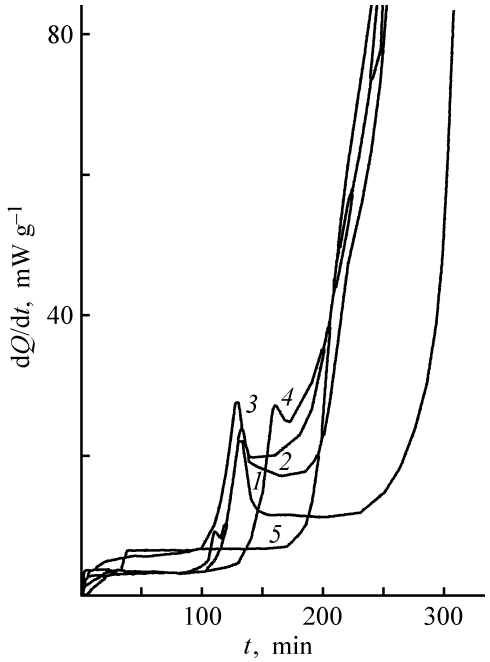

Fig. 2. Rate of heat release, d*Q*/d*t*, vs. time *t* in thermal decomposition of a mixture of NH_4NO_3 with pyroxylin at 113.3°C. NH_4NO_3 content in the mixture (wt %): (*1*) 25.05, (*2*) 39.20, (*3*) 57.46, (*4*) 77.12, and (*5*) 92.93.

it is involved in reactions with pyroxylin and products of its decomposition, which makes substantially higher the heat of the process in a mixture, compared with that in pure pyroxylin. The decomposition heat is about 3.1 kJ g^{-1} for pyroxylin and about 10.5 kJ g^{-1} for the mixtures with NH_4NO_3 under study. This points to a high extent of NH_4NO_3 involvement into the overall redox process, mainly in the reaction of NH_4NO_3 with the products formed in pyroxylin decomposition. The maximum possible heat of the process in this mixture can be calculated, provided that only liquid water and gaseous CO_2, N_2, and O_2 is formed, to be about 4.7 kJ per 1 g of the mixture or 15.8 kJ per 1 g of pyroxylin in the mixture. Comparison of the last value with that obtained in the experiment (10.5) shows that a larger part of the maximum possible heat of the process is released in thermal decomposition of the mixture.

Specific initial decomposition rates of pyroxylin and its mixture with NH_4NO_3

Pyroxylin		Pyroxylin–NH_4NO_3	
T, °C	$(d\eta/dt)_{t=0} \times 10^6$, s^{-1}	*T*, °C	$(d\eta/dt)_{t=0} \times 10^6$, s^{-1}
97	0.1	92.5	0.034
106.3	0.17	96.8	0.11
113.2	0.24	98.9	0.055
114	0.36	99	0.046
121.7	0.77	104.3	0.096
130.3	1.8	104.3	0.10
138.5	3.8	106.3	0.12
143.4	4.1	112.8	0.15
171.7	90	–	–

The initial rates of heat release in mixtures of pyroxylin with NH_4NO_3 are, on the average, 3.5 times those for pure pyroxylin, which virtually coincides with the increase in the total heat of the process. The initial specific rates for pyroxylin and mixtures $(d\eta/dt)_{t=0}$ (s^{-1}) nearly coincide and show the following temperature dependence:

$$(d\eta/dt)_{t=0} = 1.4 \times 10^{12} \exp(-138 \times 10^3/RT).$$

The rates are listed in the table.

The initial rates of heat release can be obtained from these values via multiplication by the corresponding heat of the process. Thus, introduction of NH_4NO_3 into pyroxylin has virtually no effect on the initial decomposition rate and only raises the total heat, which is apparently determined by the reaction of the products formed in pyroxylin decomposition with NH_4NO_3. The rate of this reaction must exceed the decomposition rate of pyroxylin. At the beginning of the process, HNO_3 and NH_4NO_3 have virtually no effect on the rate of pyroxylin decomposition, probably because of the heterogeneity of the mixture, and HNO_3 is in the NH_4NO_3 phase.

The values obtained for the initial rates of heat release from pyroxylin and its mixtures with NH_4NO_3 are close in magnitude to the values that can be calculated from the generalized temperature dependence of the initial decomposition rate of pyroxylin, obtained on the basis of a large number of experimental studies by different authors [3].

The influence exerted by the relative amount of the components in a mixture of NH_4NO_3 with pyroxylin on the kinetics of heat release in decomposition of the mixture was studied at 113.3°C (Fig. 2). In all the experiments, the mass of pyroxylin was the same, whereas the amount of NH_4NO_3 added was varied widely. It was found that, at the widely varying relative content of the components (40–90 wt % NH_4NO_3), the apparent rate of heat release is independent of the NH_4NO_3 content and starts to decrease only when it becomes lower than 40 wt %. The mixture under study is heterogeneous, the salt NH_4NO_3 and a macromolecular polymer pyroxylin can hardly dissolve in each other in noticeable amounts, and their interaction

is probably governed by reactions with gaseous products. The reasons for such a dependence of the rate on the mixture composition are discussed below.

Also, the influence exerted by V_g^0 on the kinetics of heat release in decomposition of a mixture of NH_4NO_3 with pyroxylin at 113.3°C was examined. The ampule volume is constant, and V_g^0 depends on the extent to which the mass of pyroxylin changes at the NH_4NO_3 content maintained within the limits ensuring a weak dependence of the kinetics on the NH_4NO_3 content. In accordance with published data on the effect of V_g^0 on the rate of pyroxylin decomposition, the extent to which the decomposition is accelerated decreases as V_g^0 becomes smaller, whereas the initial rate changes only slightly and in the opposite direction [2]. In a mixture of pyroxylin and NH_4NO_3, V_g^0 has a similar effect: as V_g^0 decreases, the initial rate of heat release becomes slightly slower, the maximum rate of heat release grows, and the time in which it is attained becomes shorter. In the range V_g^0 28.2–421 $cm^3\ g^{-1}$, the time in which the rate maximum is attained varies from 250 to 1170 min.

It was established by direct measurements of the rate of heat release that, both in pure pyroxylin and in its mixtures with NH_4NO_3, the rate of heat release grows slowly at the initial stage of decomposition, its value passes through a relatively weak maximum, and then the rate decreases equally slowly (Fig. 3). After the decomposition in a mixture of pyroxylin with NH_4NO_3 at temperatures lower than 115°C passes through the first maximum and about 80 $J\ g^{-1}$ of heat is released, the process rapidly accelerates following a second-order autocatalysis law until approximately 1000 $J\ g^{-1}$ is released. Then the parabolic dependence of the rate of heat release on the heat of the process changes for a weaker dependence and the rate continues to grow and reaches values exceeding those at the first maximum by a factor of several tens. After that, the rate slowly decreases because of the consumption of the components of the mixture (Fig. 1). The quadratic dependence of the rate on the degree of conversion has been repeatedly noted previously in studies of the thermal decomposition of various nitroesters [6, 7]. Because of such a nonlinear rise in the rate of heat release, critical jumps of the decomposition rate have been observed in mixtures of ammonium perchlorate and some nitroesters [8].

The rate constants of the catalytic stage, obtained from the dependence of the specific decomposition rate $(d\eta/dt)/(1 - \eta)$ on η^2 at running heats of the process in the range 80–1000 $J\ g^{-1}$ and V_g^0 = 65 cm^3 per 1 g of pyroxylin are listed below:

T, °C	92.5	96.8	98.9	99
$k_1 \times 10^3$, s^{-1}	0.86	1.9	2.1	1.4
T, °C	104.3	104.3	106.3	112.8
$k_1 \times 10^3$, s^{-1}	1.8	3.4	7.3	10

The temperature dependence of the rate constant k_1 (s^{-1}) has the form:

$$k_1 = 1.0 \times 10^{17} \exp(-154 \times 10^3/RT).$$

Within the measurement error, the temperature dependences of the rates of the decomposition reaction at the first $(d\eta/dt)_I$ (s^{-1}) and second $(d\eta/dt)_{II}$ (s^{-1}) maxima have the same activation energies and different pre-exponential factors:

$$(d\eta/dt)_I = 5.0 \times 10^{13} \exp(-154 \times 10^3/RT) \text{ and}$$

$$(d\eta/dt)_{II} = 2.0 \times 10^{15} \exp(-154 \times 10^3/RT).$$

In pure pyroxylin, the kinetic curve is qualitatively similar, the first maximum is also present, but shifted to higher conversions, and approaches the second maximum as temperature increases. The heat (and, accordingly, the extent) of the processes grows, on reaching the first maximum, from 20 to 110 $J\ g^{-1}$ as temperature increases in the range 96–130°C. At higher temperatures, this maximum merges with the second, stronger maximum. The first maximum has not been observed in previous studies concerned with

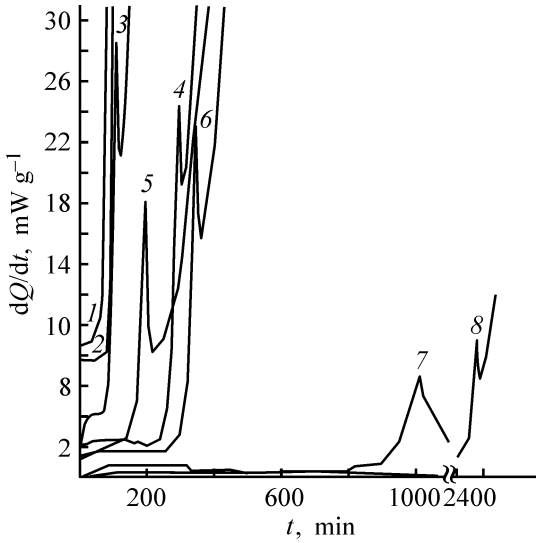

Fig. 3. Rate of heat release, dQ/dt vs. time t in thermal decomposition of a mixture of NH_4NO_3 with pyroxylin in the initial period of time. Decomposition temperature (°C): (*1*) 121.6, (*2*) 117.1, (*3*) 112.8, (*4*) 106.3, (*5*) 104.3, (*6*) 104.3, (*7*) 96.8, and (*8*) 92.5.

decomposition of nitroesters. Commonly, an initial period of slow growth is observed, which is probably due to difficulties encountered in revealing a weak maximum of the rate in the integral curve of accumulation of gaseous products. The rate of the process is measured directly on the dynamic calorimeter, and the measurement accuracy is sufficient for a reliable determination of this maximum. A similar maximum was observed in studying another batch of pyroxylin; it is probably due to a slow variation, in the course of decomposition, of the structure and molecular weight of pyroxylin, whose influence on the decomposition rate has been observed previously. It should be noted that, under the experimental conditions, the first maximum is observed at temperatures lower than 130°C in pure pyroxylin, and lower than 115°C in a mixture with NH_4NO_3; most of other published studies have been carried out at higher temperatures.

The curve for thermal decomposition of pyroxylin is described, in the range from the first maximum of the rate (on average, 2% degree of decomposition) to approximately 90% degree of decomposition, by the equation of a first-order autocatalytic reaction

$$d\eta/dt = (d\eta/dt)_{t=0}(1 - \eta) + k_2\eta(1 - \eta).$$

The rate constants of the noncatalytic stage are small and close in magnitude to the experimental initial specific rates of pyroxylin decomposition $(d\eta/dt)_{t=0}$. To a first approximation, the initial specific rate can be used in rate calculations instead of the constant of the noncatalytic stage. Below are given the resulting values of the rate constant of the catalytic stage, k_2

T, °C	96.4	106.3	114	121.7
$k_2 \times 10^4$, s^{-1}	1.6	5.0	5.1	6.1
T, °C	130.3	138.5	143.4	171.7
$k_2 \times 10^4$, s^{-1}	5.9	7.6	6.9	11

The temperature dependence of k_2 (s^{-1}) has the form

$$k_2 = 3\exp(-28 \times 10^3/RT)$$

The self-acceleration of the reaction of pyroxylin decomposition, which depends on temperature only very slightly, is considerably weaker than that in the system with NH_4NO_3 and begins later. Therefore, the temperatures studied for pure pyroxylin are, accordingly, higher. The lower activation energy of the rate constant in the catalytic stage of pyroxylin decomposition, compared with a similar value for decomposition of the mixed system, can probably be attributed to a more pronounced transfer of the catalytic agent into the gas phase at higher temperatures in the former case. In the mixed system, a considerable amount of NO_2 can be retained in the aqueous solution of NH_4NO_3, formed in the course of decomposition.

At temperatures exceeding 115°C, fundamental differences between the kinetic curves of heat release for thermal decomposition of a mixture of pyroxylin and NH_4NO_3 (Fig. 1) and pure pyroxylin are observed. In the mixed system at 117.1°C, the rate of heat release abruptly increases to values exceeding the measurement capabilities of the calorimeter already at the very beginning of decomposition, when approaching the first, relatively weak maximum of the heat release rate. This rate increases at 117.1°C very steeply, by about 0.2–0.35 W g^{-1} per minute. The true increase in the rate is probably even faster, because the dynamic characteristics of the calorimeter can markedly distort the kinetic curve at so fast changes in the rate of heat release. In an experiment of this kind, an explosive disintegration of the ampule was observed. At temperatures of 113.3°C and lower, only a monotonic, considerably slower variation of the rate of heat release was revealed in this part of the curve. In the stage of a developed self-acceleration of the process (at the second maximum), the rate of heat release considerably exceeds the level from which starts the steep increase in the rate at 117.1°C. Such a comparison demonstrates the nonthermal nature of the fast self-acceleration observed in the initial stage of the reaction, although a considerable warming-up of the mixture under study is observed in later stages of this process because high rates of heat release are reached. At a temperature of 115.3°C, which is a value intermediate between those considered above, a small plateau is observed at the first rate maximum; however, after that the rate starts, to grow rapidly to very high values instead of decreasing. The rise in this rate is somewhat slower than that at 117.1°C; a transition to a process with a fast acceleration is observed between 113.3 and 115.3°C. At a higher temperature of 121.6°C, the steep rise in the rate is even more pronounced and starts before the first maximum of the rate is reached. At still higher temperatures, the acceleration is even stronger, begins earlier, and has an explosive nature. However, no detailed studies of the rates of heat release were carried out in this range.

Here, a classical critical kinetic phenomenon is observed: a steplike change in the rate of the chemical process upon a small change in an external parameter, which is temperature in the case in question. Such a phenomenon may appear when equilibrium between formation and consumption of the intermediate reaction product, which is an active participant or a cata-

lyst of the process under study, is disturbed. In the given system, this is, most probably, NO_2. The main reactions leading to formation and consumption of NO_2 are presented below:

$$RONO_2 \rightarrow RO + NO_2, \quad (1)$$

$$RO + HNO_3(NO_2) \rightarrow \text{oxidation products}, \quad (2)$$

$$2NH_4NO_3 + 3NO_2 \rightarrow 2HNO_3 + 3NO + N_2 + 3H_2O, \quad (3)$$

$$4NH_4NO_3 + 3NO_2 \rightarrow 4HNO_3 + 3.5N_2 + 6H_2O, \quad (4)$$

$$RCH_2ONO_2 + H_2O(HNO_3) \rightarrow RCH_2OH + 2HNO_3, \quad (5)$$

$$RCH_2OH + 2HNO_3 \rightarrow RCHO + 2NO_2 + 2H_2O, \quad (6)$$

$$NO + 2HNO_3 \rightleftarrows H_2O + 3NO_2. \quad (7)$$

It is well known that the NO_2 molecule oxidizes most of organic substances at a considerably higher rate than does the HNO_3 molecule; the acceleration of the process in oxidation with nitric acid is commonly determined by accumulation of NO_2. However, water and HNO_3 can rather rapidly hydrolyze nitroesters. Nitrogen dioxide is incapable of reactions of this kind. At the same time, NO_2 is the primary product of monomolecular decomposition of pyroxylin and other nitroesters (1) and is partly consumed in the course of the process in various secondary oxidation reactions (2). In the presence of NH_4NO_3, nitrogen dioxide can be consumed at a high rate for oxidation of the ammonium into NH_4NO_3, with regeneration of nitric acid molecules by reactions (3) and (4). Reaction (4) has a higher heat, but leads to an irreversible consumption of nitrogen oxides. Water and HNO_3 formed in the process hydrolyze pyroxylin (5) with the subsequent oxidation of the alcohol and generation of NO_2 (6). Oxidation of NH_4NO_3 and organic compounds by the NO_2 molecule commonly yields NO, which can form in interaction with the accumulating HNO_3 three NO_2 molecules in accordance with equilibrium (7). This equilibrium is attained rather rapidly. Just this equilibrium leads to an increase in the content of NO_2 and to a strong self-acceleration of the reaction in which organic compounds are oxidized by nitric acid [9]. Possibly, just the turn-on of reaction (7), which occurs as nitric acid is accumulated, is the main reason for the critical jump of the rate.

To confirm the possibility of a fast reaction between NH_4NO_3 and NO_2, the kinetics of heat release in their mixture was measured. The required amount of gaseous NO_2 was refrozen into an ampule with a weighed portion of NH_4NO_3. Then the ampule was sealed and placed in a calorimeter, and the kinetics of heat release was studied in the temperature range 25–40.1°C. The rate of the reaction between NO_2 and NH_4NO_3 is high, and the process is rather fast even at room temperature. The heat effect of the oxidation reaction is about 3.3 kJ per 1 g of NO_2. The reaction occurs with a considerable self-acceleration, which is probably determined by accumulation of an HNO_3 solution in the ampule. Dissolution of NO_2 and NH_4NO_3 in this solution raises the rate of the reaction between these components, compared with that between gaseous NO_2 and solid NH_4NO_3. The resulting curves of heat release are described up to a 25% degree of decomposition by the kinetic equation of autocatalysis without burning-out

$$d\eta/dt = k_3 + k_4\eta.$$

The observed first order of the reaction with respect to the degree of conversion is determined by the proportional increase in the volume of the liquid phase. The subsequent decrease in the rate at higher degrees of conversion is due to consumption of NO_2. Below are given the resulting rate constants of the reaction in which NH_4NO_3 is oxidized by nitrogen dioxide:

T, °C	25	27.8	31.5	35.6	40.1
$k_3 \times 10^5$, s^{-1}	1.3	1.8	2.4	3.6	5.6
$k_4 \times 10^3$, s^{-1}	0.33	0.6	1.1	1.4	2.8

The temperature dependence of the rate constants k_3 and k_4 (s^{-1}) has the form

$$k_3 = 6.7 \times 10^7 \exp(-72\,000/RT),$$

$$k_4 = 3.2 \times 10^{14} \exp(-102\,000/RT).$$

The increase in the activation energy of the rate constant for the catalytic stage, k_4, as compared with that of k_3 may be due to a rise in the solubility of NH_4NO_3 in the forming aqueous solution with temperature. Also, the dependence of the rate of this reaction on the pressure of gaseous NO_2 in the ampule was studied and found to be directly proportional to this pressure. Calculation based on the kinetic data obtained shows that a 25% degree of NH_4NO_3 oxidation is achieved at 115°C already in 1 s, and this rate considerably exceeds the rate of pyroxylin decomposition.

Because of the high rate of the reaction between NH_4NO_3 and NO_2 in the case of the normal, smooth

course of the process, there is a competition between the formation and consumption of NO_2, and the quasi-stationary concentration of NO_2 in the system is low. Upon a critical increase in the rate, large amounts of NO_2 are formed. This means that a rise in the rate and an increase in the content of NO_2 are clearly related. The extent to which the overall reaction is accelerated is mostly determined by the slowest stage, reaction of NO_2 detachment from pyroxylin, and by other reactions of NO_2 formation. For this reason, the acceleration weakly depends on the content of NH_4NO_3, which is confirmed by the observed dependence of the process rate on the composition of the mixture (Fig. 2).

About 2 kJ per 1 g of NH_4NO_3 is released in reaction (3), which considerably exceeds the heat of its thermal decomposition, and about 3.5 kJ, in reaction (4). However, the latter reaction leads to chain termination, with NO_2 removed from the process. Together with reaction (6), these are the main processes leading to heat release. Reaction (7) is of equilibrium type and the equilibrium is attained rather rapidly; upon accumulation of HNO_3 in the system, this reaction may become the main reason for a rapid increase in the content of NO_2. Furthermore, an additional number of equilibria involving nitrogen oxides exist in the system; these equilibria have common products:

$$2NO_2 \rightleftarrows N_2O_4 \rightleftarrows NO^+ + NO_3^-,$$

$$2NO_2 + H_2O \rightleftarrows HNO_2 + HNO_3,$$

$$HNO_3(HNO_2) + H_2O \rightleftarrows H_3O^+ + NO_3^-(NO_2^-).$$

Owing to these equilibria, the concentrations of all the nitrogen-containing components in the system are interrelated, and, if the content of one of these is changed, the content of the others changes accordingly. NO_2 molecules formed in reaction (7) can again enter into the oxidation reaction to give NO; this process can be formally regarded as a chain reaction with continuous branching. In this case, the rate may grow very rapidly with a high oxidation rate constant; in the case in question, this is primarily the rate constant of the reaction between NO_2 and NH_4NO_3. Together with branching, chain termination reactions also occur in the system; the role of these reactions can be played both by reactions of oxidation by NO_2 molecules, with these molecules reduced to NO or N_2O, and by any reactions of NO reduction, yielding the same products. As in the case of an ordinary chain reaction, two modes of the process can be observed in the given case. In the first of these, quasi-stationary concentrations of NO and NO_2 are rapidly attained at virtually equal rates of their formation and consumption. This concentration gradually varies with time because of changes in the concentrations of the other components in the course of the reaction. All these changes determine the run of the corresponding kinetic curve with a comparatively slowly changing reaction rate. In the second mode, the content of NO_2 starts to grow rapidly if changes in the composition of the system or in the constants of formation and consumption of nitrogen oxides result in that the equilibrium between their formation and consumption is disturbed in favor of formation. Accordingly, the rate of the process increases virtually stepwise, and just this change is the critical phenomenon.

The excess of formation over consumption occurs because of the difference between the dependences of the corresponding rates on process parameters, primarily on temperature and component concentrations. For a critical phenomenon to occur, the dependences of the rates of formation and consumption of the leading component of the reaction on the other components must have different orders, and those on temperature, different activation energies, and the formation rate of the components whose accumulation gives rise to a critical phenomenon must grow faster. The most probable way to satisfy such a condition is a quadratic dependence of the rate of nitroester decomposition on the accumulation of decomposition products, with NO_2 formed and the rate of NO_2 consumption virtually always determined by a first-order reaction. A detailed study and analysis of dependences of this kind are beyond the scope of the present study. However, the key issue of the above consideration, which is the occurrence of a sufficiently fast reaction between NO_2 and NH_4NO_3 to give HNO_3, was tested and confirmed experimentally.

In a closed volume, pure pyroxylin always decomposes with a significant acceleration, which is predetermined by accumulation of nitrogen oxides and nitric acid. In view of this circumstance, stabilizers that can bind these products and thereby strongly diminish and, in the limit, eliminate the self-acceleration of the process are introduced into pyroxylin powders at the end of their shelf life. The historically first and the most frequently used stabilizer of pyroxylin is diphenylamine (DPA). It was appropriate to test the action of DPA also in the pyroxylin–NH_4NO_3 mixture, because the mechanism suggested for describing the acceleration of decomposition in this mixture is rather close to that for pure pyroxylin; anyway, binding of nitrogen oxides must diminish the acceleration of decomposition of the mixture.

A number of other experiments aimed to measure the rate of heat release in the ternary mixture pyroxylin–NH_4NO_3–DPA were performed. Some of the curves obtained are shown in Fig. 4. Introduction of DPA into the mixture changes the initial rate of heat release in the decomposition of the mixture only slightly, and even somewhat raises it, as it occurs in pure pyroxylin. Probably, this rise is determined by an increase in the total heat of the process through a turn-on of the reaction between nitrogen oxides and DPA.

Introduction of DPA into a mixture of pyroxylin and DPA strongly diminishes the main self-acceleration of the process and postpones its onset. However, the self-acceleration is not eliminated at all and the kinetic curve becomes more complex. For example, the first maximum is observed at 113.3°C in a mixture without DPA after 108 min and its magnitude is 0.03 W g^{-1}; the main acceleration reaches its maximum extent in 285 min, and the magnitude of this maximum is 2.2 W g^{-1}. Upon introduction of 4.2 wt % DPA, the first maximum is reached in 140 min and its magnitude decreases to 0.01 W g^{-1}. Then the second maximum with a magnitude of 0.033 W g^{-1} appears in 850 min, and after 4190 min comes the main acceleration with the maximum rate of 1.5 W g^{-1}. Upon introduction of 11 wt % DPA, the first maximum with 0.014 W g^{-1} occurs after 350 min, the second with 0.06 W g^{-1} appears in 990 min, and the development of the main acceleration is even slower, with the third rate maximum (0.5 W g^{-1}) reached in 6870 min. Upon introduction of 12.4 wt % DPA, the first maximum with a decreased magnitude of 0.011 W g^{-1} occurs in 350 min, and the second maximum (~0.06 W g^{-1}), in 1200 min; the maximum acceleration was not reached in this experiment. On the whole, raising the DPA content results in that the first maximum decreases in magnitude and occurs later and considerably later appears the second, also comparatively weak maximum, whose magnitude increases as the DPA content becomes higher; this is probably due to formation of products of DPA oxidation, which are oxidized easily or with a higher heat. The strongest stabilizing effect is observed in the development of the main acceleration process: introduction of 11.0 wt % DPA raises the time in which the maximum rate is reached by a factor of 27 and the rate itself decreases by a factor of 4.2. However, even addition of 11.0 wt % DPA does not fully eliminate the main acceleration of the process: after DPA is consumed in reactions with nitric acid and nitrogen oxides the acceleration develops as in a DPA-free mixture. The lower maximum rate of

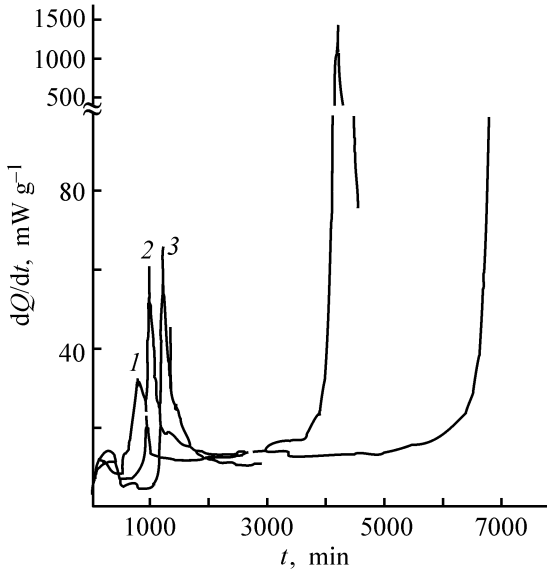

Fig. 4. Rate of heat release, dQ/dt vs. time t in thermal decomposition of a mixture of NH_4NO_3 with pyroxylin at 113.3°C. DPA content in the mixture (wt %): (*1*) 4.2, (*2*) 11.0, and (*3*) 12.4.

the process in this case is determined by the consumption of a considerable part of the components during the time before the beginning of a fast rise in the rate: at 11.0 wt % DPA, the degree of conversion during this time is 50–55%.

At temperatures exceeding the temperature of the critical rise in the decomposition rate, the influence of DPA is also important: the onset time of this acceleration strongly increases, but the acceleration itself still occurs. For example, at 121.3°C introduction of 8.9 wt % DPA results in that the time before the onset of an abrupt acceleration increases by a factor of 23, from 122 to 2850 min. The onset of acceleration is apparently determined by consumption of DPA in the course of decomposition: only after DPA is completely consumed, considerable amounts of nitrogen oxides can be accumulated.

To assess separately the contribution of nitrogen oxides to the acceleration of decomposition of the mixture, the following experiment was carried out. Carbamide was introduced into the reaction ampule with a mixture of NH_4NO_3 and pyroxylin in amount of 50% relative to the mass of the mixture in a separate glass vessel situated within the ampule over the mixture, so that carbamide could only interact with gaseous products. Carbamide rather rapidly reacts with nitrogen oxides and is used for preparative purposes to remove these oxides from HNO_3. If a mixture of pyroxylin with NH_4NO_3 is decomposed under these conditions at 116.2°C, the initial rate changes only

slightly, two weak peaks with a magnitude of about 0.03 W g^{-1} are observed in the kinetic curve after 450 and 1060 min, and no strong acceleration is obtained. This experiment shows that nitrogen oxides are a necessary factor in the development of a fast acceleration of the reaction in a mixture of pyroxylin and NH_4NO_3, and only an exceedingly small amount of HNO_3 passes into the gas phase at the temperature of the experiment. A similar curve is obtained under these conditions for pure pyroxylin, too: two weak peaks of the rate of heat release are observed and there is no strong acceleration at least during 4000 min; without introduction of carbamide into the upper position, the maximum rate of 0.4 W g^{-1} is reached already in 580 min. The heat released in the ampule under these conditions is close to 8.4 kJ g^{-1} and markedly exceeds the decomposition heat of pure pyroxylin (3.1 kJ g^{-1}), which results from oxidation of carbamide by nitrogen oxides in the upper vessel within the ampule.

At the same time, if decomposition of both the starting pyroxylin and its mixture with NH_4NO_3 is carried out at 113.2°C without additives, but in an open ampule, the initial rate of heat release is somewhat lower and the acceleration of decomposition is nearly completely eliminated. Under these conditions, all impurities in the starting components of the mixture and reaction products that have a noticeable vapor pressure at the temperature of the experiment, including water and nitrogen oxides, leave the reaction zone and are removed into the external atmosphere. In a hermetically sealed ampule, most part of water is in the liquid state, whereas in an open ampule, it passes into the gaseous state and is removed from the reaction zone, which strongly diminishes the role of hydrolytic reactions and the total heat of the process because of the consumption of the evaporation heat. At higher temperatures, the decomposition products probably have enough time, under these conditions, to partly enter into secondary reactions before passing into the gas phase and, as a result, a certain, but weaker acceleration of the process is observed [4].

In contrast to the case of full nitrates, an additional reaction is possible in a mixture of pyroxylin with NH_4NO_3: oxidation of free OH groups in nitrocellulose by HNO_3 molecules and nitrogen oxides. Such a reaction can lead to an increase in the reactivity of the neighboring nitrate groups of nitrocellulose and to formation of an additional amount of NO_2, which raises the rate of the overall interaction between the components of the system. This reaction was disregarded in the case of decomposition of pure pyroxylin, but the total content of HNO_3 is higher in the presence of NH_4NO_3, and, accordingly, the contribution of reactions involving the acid may become more important.

To assess the possible contribution from the reaction of oxidation of OH groups by molecules of nitric acid to the overall process, and primarily to the initial rate, the kinetics of heat release in a reaction between cellulose RB and a 45.1 wt % aqueous solution of HNO_3 was studied in the temperature range 65.1–133°C. Aqueous HNO_3 was used instead of NH_4NO_3 because it is difficult to bring cellulose RB in good contact with the NH_4NO_3 salt, and HNO_3 well impregnates cellulose. The concentration of HNO_3 molecules in the aqueous solution and in NH_4NO_3 can be evaluated by published data [10, 11]. The rate of the reaction is at a maximum at the beginning of the process and decreases as OH groups of cellulose are consumed. This rate for the most part obeys the kinetic law of a first-order reaction. The heat effect of the oxidation reaction is about 8.3 kJ per 1 g of cellulose. As HNO_3 is taken in a large excess, 120–210 mol per 1 mol of cellulose, its concentration remains virtually unchanged in the course of the process. Below are given the resulting values of the rate constant of the oxidation reaction:

T, °C	65.1	70.0	75.1	79.5	85.5	90.5
$k_5 \times 10^5$, s^{-1}	0.30	0.54	0.85	1.5	2.1	3.1

T, °C	96.5	116.8	121.0	126.8	133
$k_5 \times 10^5$, s^{-1}	4.5	17	25	41	61

The temperature dependence of the rate constant k_5 has the form

$$k_5 = 6.6 \times 10^7 \exp(-85.8 \times 10^3/RT).$$

The oxidation rate is rather high. An analysis of the rates obtained, which was made taking into account the difference in the content of HNO_3 molecules in an aqueous solution of HNO_3 and in NH_4NO_3 and the relatively low content of free OH groups in pyroxylin, demonstrated the following. In thermal decomposition of a mixture of NH_4NO_3 and pyroxylin, the possible contribution from the reaction of oxidation of OH groups of cellulose by nitric acid from NH_4NO_3 is rather important and accounts for up to 20–30% of the whole initial rate of heat release. It would be hardly expected for a mixture of two solid components that HNO_3 from an NH_4NO_3 crystal will be evenly distributed among NH_4NO_3 and pyroxylin. Therefore, the real contribution from oxidation of OH groups by nitric acid in pyroxylin will probably be considerably lower. It is quite possible that there is enough time for a certain amount of NO_2 to be formed

while the mixture is heated in the calorimeter. Then the contribution from the reaction with HNO_3 will be even smaller, and the rate of oxidation by nitrogen dioxide, lower than that with nitric acid [9]. The small contribution from the oxidation reaction to the initial rate of heat release in the mixture is also confirmed by the fact that the initial rates of heat release, related to the total heat of the process, virtually coincide. However, if the contact between NH_4NO_3 and pyroxylin is substantially improved, e.g., by compaction of their mixture, the initial rate of heat release may somewhat increase. In the case of a developed process, when a sufficiently large amount of HNO_3 is accumulated in the system through oxidation of NH_4NO_3, the contribution from the reaction of oxidation of OH groups will probably become important owing to, among other things, formation of a large amount of these groups in acid hydrolysis of pyroxylin.

CONCLUSIONS

(1) The specific initial rates of heat release in decomposition of pure pyroxylin and its mixture with NH_4NO_3 show the same temperature dependence. The observed difference between the initial rates of hear release in a mixture of NH_4NO_3 and pyroxylin and in a pure pyroxylin is due to the difference between the total heats of the processes.

(2) The degree of self-acceleration of the decomposition of a mixture exceeds that in decomposition of pure pyroxylin. Nitrogen dioxide is the active agent in the stage of acceleration of decomposition which produces in a fast reaction with NH_4NO_3 an equimolar amount of HNO_3. The acid, in turn, accelerates the decomposition of pyroxylin. In the temperature range 113.3–115.3°C, the degree of acceleration significantly changes upon a minor variation of temperature because of the different dependences of the rates of NO_2 formation and consumption on temperature and degree of conversion.

(3) Introduction of diphenylamine into a mixture of pyroxylin and ammonium nitrate diminishes the degree of acceleration in proportion to the added mass of NH_4NO_3 in all stages of the process, this effect being the most pronounced when the main acceleration process develops.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption Characteristics of Pillared Ferruginous Montmorillonite Modified with Cetylpyridinium Bromide

Abstract—The sorption capacity of pillared ferruginous montmorillonite modified with cetylpyridinium bromide for iodine, methylene blue, and phenol was studied. Procedures for preparing a modified sorbent with the optimal sorption power for phenol were developed.

Industrial processes yield large volumes of wastewater. Among pollutants contained in wastewater, organic compounds are the most hazardous since they are poorly removed by common techniques of water treatment. Wastewater can be purified to remove organic pollutants by deep oxidation, membrane filtration, adsorption, and also by treatment with aerobic and anaerobic microflora [1–3].

As a rule, wastewater is purified to remove volatile organic pollutants, pesticides, surfactants and chlorine by its treatment with granulated activated carbon [4]. However, the sorption capacity of activated carbon and its service life noticeably decrease in decontamination of natural water containing humic acids [5]. Along with activated carbon, contaminated water can be purified to remove pollutants by its treatment with modified clay materials having high exchange capacity. The fixation of toxic chemicals and patogenic microflora by clay minerals has been extensively studied [6–8].

To improve the sorption selectivity of clays for organic pollutants, their surface should be made hydrophobic. One of methods for hydrophobization of the hydrophilic surface of clay minerals is based on substitution of its exchangeable inorganic cations by organic cations containing hydrophobic long-chain alkyl groups. Upon such a treatment, the clay surface is covered with hydrophobic groups. After hydrophobization by this procedure, clays become efficient sorbents for aromatic hydrocarbons, chlorophenols, and toxic metals [9, 10]. Another approach to modification of clay minerals to improve their sorption characteristics involves formation of metal oxide columns between structural layers of a lamellar clay mineral and filling of the interlayer space with bulky hydrophobic organic cations. The thus modified clay is calcined to obtain a pillared ferruginous clay material which can be repeatedly saturated with appropriate organic modifying agent to obtain an improved sorbent [10].

Phenol is one of organic pollutants which is hazardous for human health and environment even in the minor amounts. Ingress of phenol and its derivatives into air, water and soil, can lead to gene mutation in living bodies and, at high phenol concentrations, to deterioration of the range of species. The aim of this study was to prepare a pillared ferruginous montmorillonite modified with cetylpyridinium bromide and test its sorption power for iodine, methylene blue, and phenol.

EXPERIMENTAL

In our experiments, we used montmorillonite taken from the Askan deposit, Georgia. Its composition was as follows, wt %: SiO_2 53.5, Al_2O_3 18.1, Fe_2O_3 0.84, MgO 4.9, CaO 1.65, Na_2O 1.1, K_2O 0.32, and H_2O 7.98 [11]. Iron(III) polyhydroxo complex (PHC) and ferruginous montmorillonite (Fe-FM) were prepared by the procedures described in [12]. In our sorption experiments, we used Fe-FM prepared by treatment of 3% aqueous clay suspension with Fe(III) PHC (10 mg-equiv Fe^{3+} per gram of clay) at the molar ratio OH^-/Fe^{3+} = 2.0. The specific surface area of

6	10	26	180	52	100	2.2	425	10.4

the initial Fe-Fm sample S_{sp} was 124 $m^2\ g^{-1}$. The initial Fe-Fm was washed with water and then, without drying, was treated with aqueous cetylpyridinium bromide (1, 3, 5, 8, and 10 mmol per gram of clay). The resulting suspension of organomodified clay (R · Fe-Fm) was settled for 1 day, separated from the liquid phase, washed with water, and dried first in air for 2 days and then at 120°C for 3 h.

A thermogravimetric analysis of R · Fe-Fm samples (500 mg) was carried out in air within the temperature range 20–800°C at a heating rate of 10 deg min^{-1}.

The specific surface area S_{sp} of R · Fe-Fm samples was determined by the BET technique based on measuring the low-temperature sorption of nitrogen with a Micromeritics 2200 express analyzer. The crystallographic parameter d_{001} was determined on a Siemens 500 diffractometer. The sorption capacity of R · Fe-Fm for methylene blue (MB) and iodine was measured under static conditions. In these experiments, 20 ml of aqueous MB (0.15 g l^{-1}) or 20 ml of aqueous iodine (10 g l^{-1}) was added to 100 mg of modified clay. The resulting suspension was kept with intermittent shaking at 20°C for 6 h. According to the data reported in [13], this time of phase contact is sufficient for the sorption equilibrium to be attained.

The sorption of phenol was studied under identical conditions from aqueous solutions containing from 5 to 400 mg l^{-1} of phenol. The equilibrium liquid phase was centrifuged and the phenol content in the resulting transparent centrifuged solution was determined by photometry of the colored complex of phenol with diazotized *p*-nitroaniline [14]. The MB and iodine content was determined photometrically and titrimetrically, respectively [15].

The table shows that, as the content of cetylpyridinium bromide in the modifying solution increases from 1 to 5 mmol per gram of Fe-Fm, the content of cetylpyridinium bromide in modified R · Fe-Fm grows from 5.8 to 10.4%. A further increase in cetylpyridinium bromide content in the modifying solution to 8 and 10 mmol per gram of Fe-FeM does not noticeably change the content of cetylpyridinium bromide in the modified material.

The DTA curves of R · Fe-Fm (Fig. 1) show a strong low-temperature endothermic peak accompanied by a weight loss assigned to the removal of adsorbed water [16]. As the content of cetylpyridinium bromide in R · Fe-Fm is raised to its maximum amount, the endothermic peak shifts toward lower temperatures and the weight loss decreases from 16.0 to 2.2%. We believe that this effect is caused by the fact that

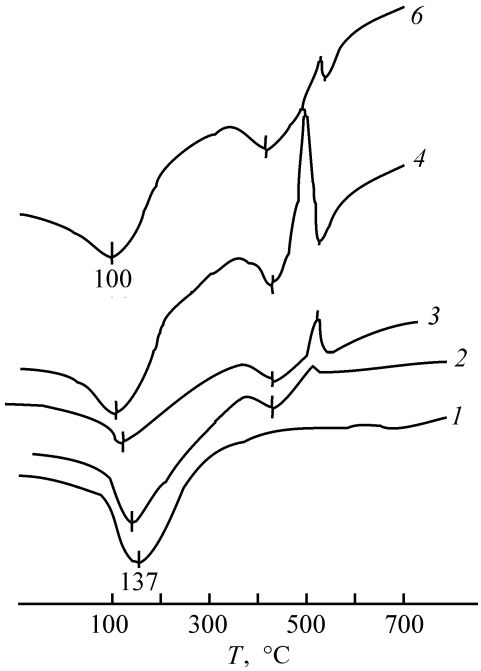

Fig. 1. DTA curves of the initial and modified Fe-FM. (*T*) Temperature. *Curve nos.* are sample nos. in the table; the same for Fig. 2.

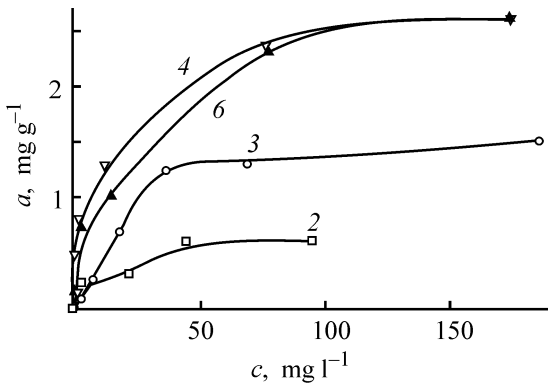

Fig. 2. Sorption isotherms of phenol on Fe-FM modified with cetylpyridinium bromide: (*a*) amount of sorbed phenol and (*c*) equilibrium phenol concentration in the aqueous phase.

the modification makes lower the hydrophilicity of R · Fe-Fm, and, as a result, facilitates the desorption of water at low temperature.

The DTA curves of R · Fe-Fm show one more weaker endothermic peak in the range 420–430 °C, associated with desorption of cetylpyridinium bromide, and an exothermic peak at 500°C, caused by oxidation of the modifying agent. The table shows that the content of the modifier in R · Fe-M does not affect the position of the endothermic peak, whereas the weight loss increases with the modifier content. It should be noted that the intensity of the endothermic peak for samples with an equal content of the modifier may noticeably differ (Fig. 1, curves *4*, *6*).

The table shows that the content of modifier in R · Fe-Fm correlates with its sorption capacity for iodine. In going from sample no. 1 to sample no. 4, the sorption capacity for iodine increases from 44 to 174 mg g^{-1} and does not appreciably change further, in going to samples nos. 5 and 6.

The sorption of MB is commonly used for evaluating the sorption power of sorbents. The table shows that the sorption capacity of the initial (nonmodified) Fe-M for MB exceeds that of the modified sorbent. After modification of Fe-M with a minimum addition of cetylpyridinium bromide, the sorption capacity for MB decreases by approximately a factor of two. However, a further increase in modifier content makes higher the sorption capacity of R · Fe-M for MB in spite of a decrease in S_{sp}. We believe that this phenomenon is caused by the fact that the sorption of alkylammonium cations on clay, as a rule, exceeds its cation-exchange capacity owing to association of alkylammonium cations with neutral amines and their salts [17]. The charged hydrophilic heads of these excess alkylamonium cations are oriended toward the aqueous phase. As a result, cationic groups sorbing MB appear in a certain amount on the hydrophobic surface of the modified clay. The content of these groups increases with the modifier content.

We found that phenol is not sorbed noticeably on the initial Fe-M. After modification of Fe-M with cetylpyridinium bromide, the sorption of phenol increases. The limiting sorption capacity of R · Fe-M for phenol is 2.5 mg g^{-1}. Similarly to iodine, the sorption of phenol does not change in going from sample no. 4 to sample nos. 5 and 6. We suggest that measurement of the sorption of iodine on R · Fe-Fm can be used for fast evaluation of the sorption capacity of this sorbent for phenol.

The sorption isotherms of phenol from aqueous solutions have a nonlinear shape (Fig. 2) typical of systems with prevalence of the physical sorption. At the content of phenol in the aqueous phase below 1 mg l^{-1}, the degree of phenol recovery is 80–95%.

CONCLUSION

Pillared ferruginous montmorillonite modified with cetylpyridinium bromide exhibits the best sorption properties for phenol at 5 mmol of cetylpyridinium bromide per gram of montmorillonite.

SORPTION AND ION-EXCHANGE PROCESSES

Determination of the Working Exchange Capacity of Weakly Basic Polyacrylic Anionites

A. V. Mamchenko and O. A. Savchenko

Institute of Colloid Chemistry and Chemistry of Water, National Academy of Sciences of the Ukraine, Kiev, Ukraine

Received June 3, 2004; in final form, January 2005

Abstract—The nonequilibrium dynamics of sorption of hydrochloric acid by weakly basic polyacrylic anionites was studied. An equation for calculating the working capacity of ion-exchange filters as a function of variable parameters (filtration rate, concentration of the starting solution, and height of the ionite bed in a filter) was derived using the theory of nonequilibrium dynamics of sorption.

In technological schemes intended for production of deeply desalinated water with exceedingly low electrical conductivity, weakly basic ionites are used in OH filters of the first stage to remove anions of strong acids from H-cationized water.

Matrices of weakly basic anionites can be obtained by copolymerization of styrene, esters of acrylic and metacrylic acids, and acrylonitrile with divinylbenzene, which is used as cross-linking agent. Polyacrylic anionites have a number of advantages over anionites synthesized on the basis of copolymers of styrene and divinylbenzene. Their matrix provides a reversible sorption of organic substances in a cycle of water treatment and ionite regeneration. They ensure a low specific consumption of an alkali per removal of a mole of anions of strong acids and specific expenditure of water for washing of the sorbent in the first-stage filter.

Under working conditions, the effectiveness and cost-efficiency of an ion-exchange resin is determined by its working capacity. It may constitute a larger or smaller fraction of the total exchange capacity, depending on a number of variable factors: concentration of ions to be sorbed, rate of water filtration, height of the resin bed, chemical composition, and concentration and amount of the regenerating solution.

Weakly basic polyacrylic anionites provide a complete regeneration at a nearly stoichiometric alkali expenditure. Therefore, the working capacity of ionites of this kind is determined by the stage of water desalination.

In industrial practice, all technological processes that employ ionites are carried out in the dynamic mode, because, in this case, the exchange capacity of the material is used the most completely [1]. In a dynamic system, equilibrium is not attained and the results obtained with ion-exchangers are affected by kinetic factors [2]. In view of this circumstance, the present study was concerned with the dynamics of sorption of hydrochloric acid by weakly basic polyacrylic anionites.

EXPERIMENTAL

As objects of study were chosen weakly basic polyacrylic anionites Amberlite IRA 67, Lewatit VP.OC.1072, Purolite A 845, Relite MG 1 , and MG 1/P. The first and second ionites contain only tertiary amino groups [3, 4]. Anionite Purolite A 845 contains, in addition to tertiary amino groups, a certain amount of strongly basic quaternary groups. This assumption can be made on the basis of an indirect information that this anionite can be used in cycles with regeneration with sodium hydroxide only at temperatures of 40°C and lower, because quaternary amino groups are decomposed at higher temperatures. Anionites Relite MG 1 and Relite MG 1/P both contain polyamines as exchange centers, but differ in matrix structure: the former is synthesized on a gel matrix,

Table 1. Main parameters of the weakly basic polyacrylic anionites under study

Ionite	Matrix structure	Type of functional groups	Total exchange capacity, M
Amberlite IRA 67	Gel-like	Tertiary	1.6 [3]
Lewatit VP.OC.1072	"	"	1.5 [4]
Purolite A 845	"	Tertiary and strongly basic	1.5 [5]
Relite MG 1	"	Polyamines	3.4 [6]
Relite MG 1/P	Porous	"	3.1 [6]

and the latter, on a porous matrix [6]. The main parameters of the ionites under study are listed in Table 1.

As a sorbate was chosen hydrochloric acid, because in water-treatment practice, first-stage OH filters are commonly cut-off, for regeneration to eliminate the breakthrough of chlorides [7, 8]. This is due to the following circumstances. First-stage OH filters in water desalination installations, which are charged with weakly basic anionites, are intended for absorption of sulfates and chlorides from solutions of the corresponding acids, formed in the stage of H-ionization of water [7–9]. In the case when a dissolved mixture of acids is passed through the anionites, anions of all strong acids are absorbed in the initial period of a filtering cycle. Then there occurs a breakthrough (in the form of acid) of the anion for which the sorption selectivity is the lowest, with the absorption of the other anions continued. As the initial solution is passed through the filter, the concentration of the anion for which the sorption selectivity is lower than that of other anions present in solution (chlorides in the case of first-stage OH filters) gradually increases and reaches a value equal to the total concentration (expressed in moles of equivalents of the substances) of all the anions in the initial solution. Passing the initial solution till the breakthrough of the sulfate ion into the filtrate is accompanied by a virtually complete displacement of previously absorbed chloride ions [9]. This circumstance makes it possible to simulate the operation of first-stage OH filters in water desalination installations by studying the sorption of only hydrochloric acid from its individual solution.

Experimental procedure. A sample of a commercial anionite, alternately treated with solutions of 1 M hydrochloric acid and sodium hydroxide and subjected to an intermediate washing with distilled water after measuring the sample volume in a graduated flask, was placed in a glass column in such a way that the bed height was approximately 1 m. A model solution of hydrochloric acid was pumped by a peristaltic pump across a bed of the anionite preliminarily regenerated with sodium hydroxide. The filtrate was collected in portions, the volume of the portions and the time during which each portion was collected were measured, and the acidity (alkalinity) of a solution of a portion was determined by titration with Methyl Red. The data obtained were used to calculate the linear velocity and volumetric rate of filtration of the liquid, as well as the amount of sorbed hydrochloric acid and the extent of acid breakthrough into the filtrate.

In a working cycle, weakly basic anionites in OH filters are in a dense bed. In this case, the theory of nonequilibrium dynamics of sorption is commonly used to describe the process.

Models constructed in terms of the theory of nonequilibrium dynamics of sorption can, in principle, describe the operation of ionite filters in any mode (of inner, outer, or mixed diffusion) [10–15]. However, it is necessary, in such a general case, to solve numerically systems of differential equations, which hinders application of the models to practical calculations. For particular cases, in which the sorption kinetics is limited only by outer or inner diffusion, the mass-transfer coefficient remains constant, and a parallel transfer of the sorption front occurs in the ionite bed, analytical solutions to a system of equations have been obtained, which makes it possible to prognosticate the working parameters of ionite filters [11, 14–20].

If the sorption kinetics is limited by outer mass transfer, then the following relation is valid [14, 15, 18]

$$t = a_0 h (v c_0)^{-1} - a_0 (c_0 \beta)^{-1} \times \{(B c_0)^{-1} \ln[(c_0/c) - 1] + \ln(c_0/c) - 1\}, \quad (1)$$

whereas in the case when the process is limited by inner-diffusion mass transfer, another equation is valid [14, 15, 19, 20]:

$$t = a_0 h (v c_0)^{-1} - \beta^{*-1} \times \{(B c_0)^{-1} \ln[(c_0/c) - 1] + \ln(1 - c/c_0) + 1\}. \quad (2)$$

Here, t is the time reckoned from the onset of the process; a_0, specific sorption of hydrochloric acid, calculated per unit volume of the bed under conditions of equilibrium between the ionite and the initial solu-

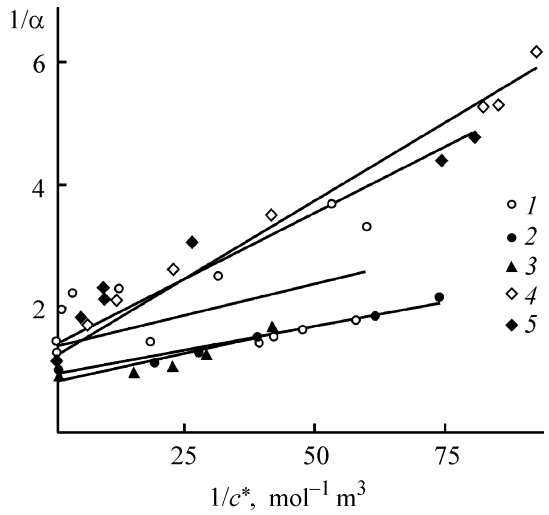

Fig. 2. Isotherms of equilibrium sorption of hydrochloric acid in the coordinates of the linear form of Eq. (4).

tion; h, height of the adsorbent bed; v, linear flow velocity of the liquid, calculated per total cross-section of the sorption column; c_0, concentration of the substance being sorbed in the initial solution; β and β^*, kinetic coefficients of inner and outer mass transfer, respectively; c, concentration of the substance being absorbed in the filtrate at instant of time t; and B, empirical coefficient of the sorption isotherm of the type of a Langmuir isotherm

$$a = f(c^*) = Ac^*/(1 + Bc^*). \quad (3)$$

Here, A is an empirical coefficient, and c^* is the concentration of the substance being sorbed (hydrochloric acid), which is in equilibrium with a.

Figure 1 shows isotherms of equilibrium sorption of hydrochloric acid by the anionites under study. It can be seen that these isotherms are strongly convex and can be identified as rectangular isotherms, for which formation of a stationary sorption front and its parallel transfer are characteristic [10, 11, 13, 21]. Equations (1) and (2) have been derived just for conditions of this kind [14, 15, 18–20].

To determine the coefficient B, Eq. (3) was brought to a linear form

$$1/\alpha = B/A^* + 1/(A^*c^*), \quad (4)$$

where α is the extent to which the anionite is converted to the salt form; $A^* = A/E_0$; and E_0, total exchange capacity of the anionite.

The average values of the total exchange capacity, obtained in a study of the equilibrium sorption, are listed in Table 2.

It follows from Fig. 2 that the dependence of $1/\alpha$ on $1/c^*$, plotted in the coordinates of the linear form of Eq. (4), satisfactorily describes the isotherm of sorption of hydrochloric acid by polyacrylic anionites. The values of parameter B, calculated by the least-squares method, are listed in Table 3.

Table 2. Total exchange capacity of weakly basic polyacrylic anionites with account of the specific volume, determined under static conditions

	m^3 mol^{-1}	
Amberlite IRA 67	81	39
Lewatit VP.OC.1072	77	14.5
Purolite A 845	90	30.7
Relite MG 1	37	1.8
Relite MG 1/P	37	3.5

Equations (1) and (2) make it possible to determine the limiting stage of the sorbate diffusion by processing of experimental data. The kinetic coefficient β^* in Eq. (2) is, by definition, independent of the hydrodynamic conditions of the process even if it depends on the composition of the resinates. By contrast, if the process is limited by outer diffusion, the kinetic coefficient β in Eq. (1) markedly increases with the linear velocity of filtration of the liquid phase [12–16, 18].

To analyze experimental data, it is appropriate to transform Eqs. (1) and (2) into expressions containing quantities directly determined from the experiment. Accordingly, Eqs. (1) and (2) take the form

$$Qc_0/W_0 = a_0 - [va_0/(\beta h)][(Bc_0)^{-1}\ln(c_0/c - 1) + \ln(c_0/c) - 1] = a_0 - (a_0/\beta)z. \quad (5)$$

Here, $z = v[(Bc_0)^{-1}\ln[(c_0/c) - 1] + \ln(c_0/c) - 1]/h$; Q, volume of filtrate passed across the ionite bed till breakthrough of the acid with concentration c; W_0, volume of the ionite charge in the filter; and

$$Qc_0/W_0 = a_0 - [vc_0/(h\beta^*)][(Bc_0)^{-1}\ln(c_0/c - 1) + \ln(1 - c/c_0) + 1] = a_0 - Z/\beta^*, \quad (6)$$

where

$$Z = (vc_0/h)\{(Bc_0)^{-1}\ln[(c_0/c) - 1] + \ln(1 - c/c_0) + 1\}.$$

According to Eq. (5), a linear dependence of Qc_0/W_0 on z must be observed in the case of the outer-diffusion sorption kinetics and any linear filtration velocity of the liquid phase. The plot must remain linear at different linear filtration velocities of water. However, the dependence of β on the hydrodynamic situation around ionite grains must lead to a decrease in the slope of the straight lines with increasing filtration velocity, because β grows owing to the decrease in the thickness of the immobile liquid film around an ionite grain.

When the process is controlled by inner-diffusion mass transfer, the dependences of Qc_0/W_0 on z must coincide in a wide range of linear filtration velocities of the liquid phase, although they may be nonlinear, because the theoretical model (5) is certainly inadequate to the real process.

Figure 3a shows, in the coordinates of the linear form of Eq. (5), the experimental data obtained in a study of the dynamics of sorption of hydrochloric acid by weakly basic polyacrylic anionites in a wide range of linear filtration velocities of the liquid.

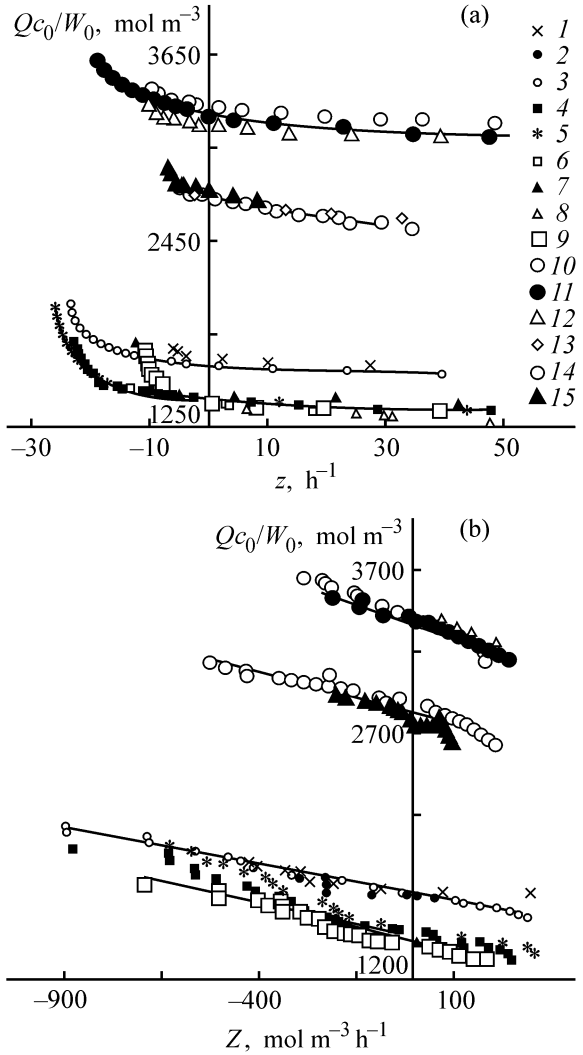

Fig. 3. Output sorption curves for hydrochloric acid, plotted in the coordinates of the linear form of equations (a) (*5*) and (b) (*6*) at various filtration velocities of the liquid through weakly basic polyacrylic anionites (*1–3*) Amberlite IRA 67, (*4–6*) Lewatit VP.OC.1072, (*7–9*) Purolite A 845, (*10–12*) Relite MG 1, and (*13–15*) Relite MG 1/P. (Qc_0/W_0) Total amount of counterions absorbed by the ionite bed. Filtration velocity v (m h^{-1}): (*1*) 8.4, (*2*) 17.3, (*3*) 23.2, (*4*) 4.5, (*5*) 20.2, (*6*) 22.9, (*7*) 7.3, (*8*) 11.8, (*9*) 13.0, (*10*) 15.0, (*11*) 20.0, (*12*) 22.0, (*13*) 8.0, (*14*) 14.0, and (*15*) 20.0.

As follows from Fig. 3, the experimental data are not described by the theoretical expression derived for the conditions in which the sorption kinetics is governed by outer diffusion. First, the experimental points fall on a clearly curved line, rather than on a straight line (is it would have been if Eq. (5) were adequate to the experimental data). Second, no dependence of the curves on the linear filtration velocity of the liquid phase is observed: irrespective of the flow rate of

water. This unambiguously shows that, at the flow rate in the range under study, the sorption kinetics of hydrochloric acid by weakly basic polyacrylic anionites is determined only by mass transfer within ionite grains. Consequently, relation (6) should be used for processing of experimental data.

Figure 3b shows dependences of Qc_0/W_0 on Z. It can be seen that, for all of the ionites studied, these dependences are linear and have the same slope rate. This corresponds to Eq. (6) and indicates that the kinetic coefficient of inner mass transfer of hydrochloric acid, β^*, is independent of the hydrodynamic conditions of the process. Consequently, the sorption of hydrochloric acid occurs in the inner-diffusion mode. Moreover, the chosen experimental conditions guarantee that a stationary sorption front is formed and the mechanism of its parallel transfer across the ionite bed is operative. Thereby, necessary and sufficient conditions are created for application of the theoretical model of the inner-diffusion sorption dynamics for an adequate description of the technological process.

Table 4 lists quantitative parameters characterizing the inner-diffusion kinetics of sorption of hydrochloric acid by weakly basic polyacrylic anionites at various linear filtration velocities of the initial solution. It can be seen that the values of the kinetic coefficient β^* coincide for all the ionites within the determination error [characterized by standard deviation $S(\beta^*)$ and confidence interval $\Delta(\beta^*)$ at a confidence probability of 0.95]. The values of parameter a_0, found by measuring the characteristics of the sorption dynamics, coincide for all the anionites. They are also in an agreement with the values of the total exchange capacity found in the case of sorption of hydrochloric acid by anionites under static conditions (with account of the specific volume) (Table 2) and those furnished

by the manufacturers (Table 1). Hence follows that parameter a_0 is the total exchange capacity of the anionites.

As can be seen from Table 4, the average values of the kinetic coefficients of inner mass transfer, β^*, coincide for anionites with the same amino groups. For example, $\beta^* \approx 2h^{-1}$ for ionites with tertiary amino groups: Amberlite IRA 67, Lewatit VP.OC.1072, and Parolite A 845.

For Relite MG 1 and Relite MG 1/P anionites, the value of the kinetic coefficient β^* is virtually independent of the presence or absence of porosity in grains of the ion-exchangers and is two times smaller (~1 h^{-1}) than that in the case of anionites with tertiary amino groups. This may be due to two factors: presence in the exchange centers of these anionites of groups with basic properties weaker than those in tertiary groups and smaller free volume in the gel phase of the anionites because of the presence of bulky polyamine chains.

As indicated by the data in Table 4, Relite MG 1 and Relite MG 1/P anionites show poorer kinetic characteristics than the anionites with tertiary amino groups, but have a considerably higher total exchange capacity.

However, the parameters found are insufficient for making a unique choice of an anionite for a technological process, because the operation cost of a filter is determined by the working capacity of the ionite used. The physical meaning of the working capacity of an ion-exchanger is the amount of acid anions that can be absorbed by unit volume of the bed until the concentration of the acid in the filtrate reaches the breakthrough value. The working capacity can be represented by the equation

$$E_w = \int_0^{Q_{br}} (c_0 - c)\, dQ/W_0, \qquad (7)$$

where Q_{br} is the volume of the initial solution that can be passed across the resin bed until the breakthrough concentration c of the acid is reached in the filtrate.

It is known from the experience of water treatment that the concentration of anions of strong acid in H-cationized water delivered to first-stage OH filters is 2–10 g-equiv m^{-3}. The breakthrough concentration of the acid, at which the filters are put out of operation and then are regenerated, is in the range 0.02–0.14 g-equiv m^{-3}. Because the breakthrough concentration is considerably lower than the concentration of the initial solution ($c << c_0$), it can be stated that, to a good approximation,

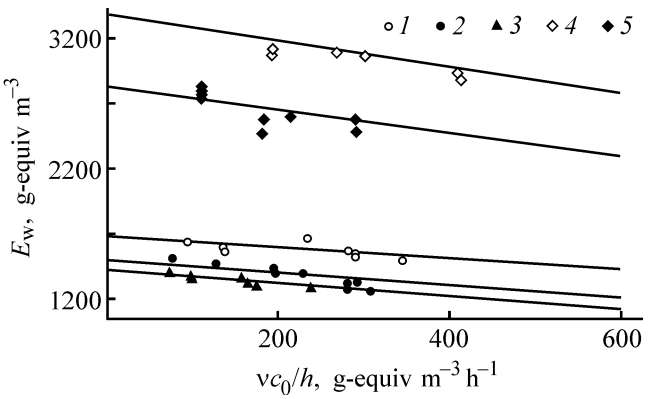

Fig. 4. Theoretical (*straight lines*) and experimental (*points*) dependences of the working capacity E_w on hydrodynamic conditions in the coordinates of the linear form of Eq. (9). (vc_0/h) Amount of counterions absorbed by the ionite bed in unit time.

$$E_w = Qc_0/W_0. \qquad (8)$$

Substitution of the value of Qc_0/W_0 from Eq. (6) into (8) yields the following equation for determining the working capacity of an ion-exchange filter:

$$E_w = E_0 - (vc_0/h)\beta^{*-1}\{(Bc_0)^{-1}\ln[(c_0/c) - 1] + \ln(1 - c/c_0) + 1\}. \qquad (9)$$

Equation (9) expresses the dependence of the working capacity E_w of an ionite on variable parameters of the process, such as linear filtration velocity v of the liquid phase, concentration c_0 of anions of strong acids in the initial water, and height h of the ionite bed in the filter. The parameters β^* and B are constant for each ionite. The c/c_0 ratio at the instant when the filter is put out of operation to be regenerated is also constant for a particular water composition. For the experimental conditions used (initial concentration of the model solution 10 ± 2 g-equiv m^{-3} and breakthrough concentration taken to be 0.1 g-equiv m^{-3}), the ratio is equal to 0.01.

Thus, it follows from Eq. (9) that the working capacity E_w of an ionite is a function of the linear filtration velocity of water, concentration of the initial solution, and height of the ionite bed in the filter.

Theoretical dependences of E_w on vc_0/h were calculated for weakly basic polyacrylic anionites with various types of amino groups in a wide range of linear filtration velocities of the liquid at certain values of the parameters β^*, B, h, and c_0 (Fig. 4). Figure 4

also shows the dependences of the working capacity on variable conditions, experimentally obtained in a study of the nonequilibrium dynamics of sorption of hydrochloric acid by these anionites. As can be seen in Fig. 4, the experimental values of the working capacity of the anionites fall on the theoretical curves with a satisfactory accuracy.

CONCLUSIONS

(1) It was established that the kinetics of sorption of hydrochloric acid by weakly basic polyacrylic anionites with amino groups of varied basicity is limited in water filtration modes characteristic of operation of first-stage OH filters in installations for desalination of water by diffusion within ionite grains.

(2) It was found that, irrespective of the porosity of anionites, the kinetic coefficient remains constant for ionites with identical groups and is determined by the chemical nature of ionogenic groups.

(3) An equation derived in terms of the theoretical model of inner-diffusion sorption dynamics was suggested for an *a priori* calculation of the working exchange capacity of ionite filters at any variable conditions of the process (linear filtration velocity of the initial solution, concentration of anions of strong acids in this solution, and bed height in the filter).

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Possibility of Depositing Electrolytic Manganese Dioxide onto Titanium Anodes from Manganese Chloride Solutions

Abstract—Fundamental aspects of the deposition of electrolytic manganese dioxide from chloride electrolytes were studied. The optimal parameters of the electrolysis on titanium anodes were determined.

In production of organochlorine compounds, a large amount of hydrochloric acid is formed as a waste gas (HCl_{wg}). Therefore, it is necessary to develop processes that would make it possible to utilize HCl_{wg} to give a new commercial product. One of the main ways to utilize HCl is its use for leaching-out of manganese ions from oxidized manganese ores (substandard manganese ores, floatation tails, and other manganese-containing wastes).

When oxidized manganese ores are decomposed with hydrochloric acid, chlorine and manganese chloride solutions are formed by the reaction:

$$MnO_2 + 4HCl_{conc} \rightleftarrows MnCl_2 + Cl_2\uparrow + 2H_2O. \quad (1)$$

Chlorine can be used in manufacture of organochlorine compounds and $MnCl_2$ solutions, electrolytic manganese dioxide (EMD), and electrolytic manganese metal (EMM).

Thus, two problems can be solved in the same technological process: utilization of HCl_{wg} and processing of substandard manganese ores and other manganese-containing wastes. The use of HCl_{wg} and manganese-containing wastes as raw materials will make it possible to develop a competitive process for manufacture of EMD and EMM [1].

It should also be noted that MnO_2 obtained from chloride electrolytes is a more electrochemically active and pure material [2].

In developing a process for obtaining electrolytic MnO_2, a considerable attention is paid to the choice of the anode material. As the anode material for electrolysis of $MnCl_2$ solutions were used iridium [3], platinum [4], lead coated with lead dioxide [4], graphite [5], ORTA, and titanium electrodes coated with titanium carbide or manganese dioxide [6–8]. Because platinum and iridium are very expensive metals, it is unreasonable to use them in industrial electrolysis. Lead anodes contaminate MnO_2 with lead dioxide through their dissolution in the course of electrolysis. Graphite anodes gradually burn away because of the partial evolution of hydrogen and should be replaced at regular intervals.

We suggested that less expensive metal anodes, widely used in electrolysis with evolution of chlorine, can be used to obtain EDM, because a manganese dioxide film formed on titanium at the beginning of electrolysis will increase its corrosion resistance.

In this study, we examined the possibility of application of titanium anodes for deposition of EMD from $MnCl_2$ solutions.

EXPERIMENTAL

Manganese(IV) oxide was synthesized in a Plexiglas electrolyzer with plane-parallel electrodes. VT-1-00 titanium plates ($150 \times 70 \times 2$ mm) were used as the anode, and Kh18N10T stainless steel, as the cathode. The separation between the opposite electrodes was 5 mm.

Prior to the electrolysis, the surface of the electrodes was trimmed with an M-40 emery paper, washed

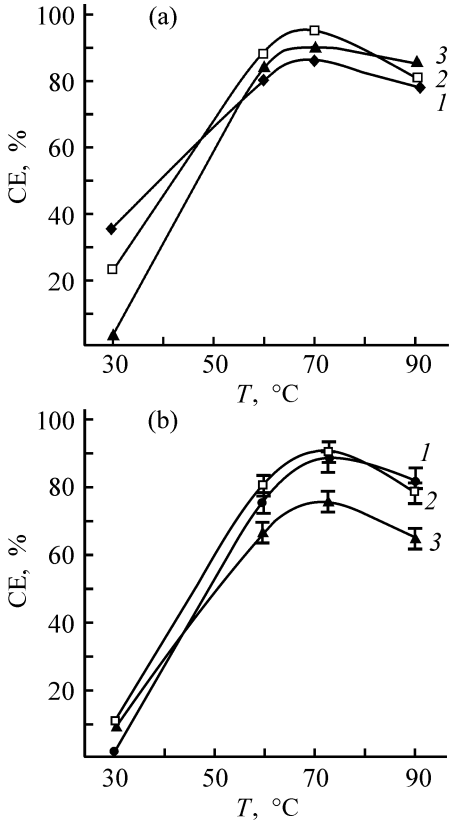

Fig. 1. Current efficiency CE by MnO_2 vs. temperature *T*. $MnCl_2$ concentration 1.0 M; the same for Figs. 2, 3. Current density (mA cm^{-2}): (a) 5.0 and (b) 10.0; the same for Fig. 2. HCl concentration (M): (*1*) 0, (*2*) 0.05, and (*3*) 0.25.

with distilled water and acetone, and dried in air for 1–2 min. The thus prepared electrodes were kept in a desiccator before the experiment.

The electrolyzer temperature was maintained constant with a U-8 water thermostat (Hungary). The anode and cathode potentials were measured relative to a silver chloride reference electrode.

The electrolyzer was polarized with a stabilized B5-47 dc power source. The voltage across the electrolyzer was measured with a V7-38 digital voltmeter. The electrode potentials and pH of the electrolytes were determined with an HI-9025 C portable microprocessor-controlled pH/mV/°C-meter (Portugal).

As electrolytes were used 1 M $MnCl_2$ solutions containing a varied amount of hydrochloric acid. The solutions were prepared from analytically pure $MnCl_2 \cdot 4H_2O$ and chemically pure HCl.

The manganese(II) content in the electrolytes was determined by back titration [9].

The experiments were performed as follows. First, the electrolyzer with the electrode system prepared was placed in the bath of the thermostat and kept there at a prescribed temperature for 1 h. The electrolysis time ensured deposition of 20–30% manganese from the electrolyte. The current efficiency (CE) was calculated from the loss of Mn(II) by the electrolyte solution after the electrolysis. The corrosion rate of the polarized and unpolarized (initial) titanium anodes was determined gravimetrically [10]. After the electrolysis, the electrodes were dried in air, and MnO_2 was carefully removed from their surface with a brush. Then, the electrodes were washed with 5% hydroxylamine hydrochloride and distilled water, and dried in air to constant mass. The accuracy in determining the corrosion rate was 7%.

The EDM deposited during the electrolysis was washed with distilled water to negative reaction for chloride ions. The MnO_2 deposit was dried to constant mass under an IR lamp at 105°C.

The temperature dependences of the current efficiency by MnO_2 at a current density of 5 and 10 mA cm^{-2} and different HCl concentrations are presented in Figs. 1a, 1b. It can be seen that the CE-vs.-temperature dependences are bell-shaped and pass through a maximum at 65–75°C. At a low temperature (30°C) and a current density of 5 mA cm^{-2} the current efficiency decreases with increasing HCl concentration (Fig. 1a). Raising the current density to 10 mA cm^{-2} makes the current efficiency significantly lower and changes the character of the dependence of CE on the HCl concentration (Fig. 1b). The lowest current efficiency is observed in the absence of the acid, and the highest, with 0.05 M of HCl.

As temperature increases, the current efficiency sharply grows. At temperatures close to the temperature of the maximum, the highest current efficiency is reached at an acid concentration of 0.05 M, irrespective of the current density (5 or 10 mA cm^{-2}). At 90°C, the current efficiency grows at j_a = 5 mA cm^{-2} as the HCl concentration becomes higher, and, reaches a the minimum at j_a = 10 mA cm^{-2}.

It should also be noted that titanium anodes rapidly disintegrate at low temperatures (30–40°C). The rate of this process increases as the density of polarizing current and the acid concentration become higher. In these conditions, the electrolyzer voltage reaches its maximum value of 10–12 V.

The dependences of the electrolyzer voltage on temperature and anode and cathode potentials at differ-

ent HCl concentrations are shown in Figs. 2a, 2b. It can be seen that the anode potential and the electrolyzer voltage decrease as the temperature becomes higher. The cathode potential is virtually temperature-independent. The electrolyzer voltage decreases with increasing HCl concentration in the electrolyte at a current density of 5 mA cm^{-2} and exhibits a complex dependence at 10 mA cm^{-2}. These results show that the electrolyzer voltage is mainly determined by the anode potential.

In the course of the electrolysis, a film consisting of the reaction products was formed on the anode. In the absence of the acid, the film was matte, uniform, black, and strongly adherent to the electrode surface. In the course of the electrolysis, the thickness of the product layer increased, but no flaking from the anode surface was observed. Addition of hydrochloric acid to the electrolyte changed the properties of the film. It acquired a metallic luster and became flaky, with flakes exfoliating from the electrode surface and going down to the bottom of the electrolyzer as their size increased. In the process, the initial film of the reaction products was retained on the anode surface. The surface film possessed a reasonably high corrosion resistance. According to a visual inspection and a gravimetric analysis, the film on the anode remained unchanged during several hundred hours after the current was switched off.

The variation of the electrolyzer voltage in the course of electrolysis is shown in Fig. 3. It can be seen that at 30°C the electrolyzer voltage first increases and then decreases. At temperatures of 60 to 90°C, the electrolyzer voltage somewhat decreases and then reaches a constant value or slightly increases.

The electrolytic deposition of EMD and EMM from $MnCl_2$ solutions was studied in [3, 5, 11]. In the course of electrolysis from manganese(II) chloride solutions, several electrochemical and chemical reactions proceed simultaneously at the anode and in the solution bulk, including the electrochemical oxidation of Mn^{2+} ions to the highest degrees of oxidation and the oxidation of chloride ions and water, which can be described by the following reaction equations:

$$Mn^{2+} + 2H_2O - 2e \rightarrow MnO_2\downarrow + 4H^+, \; E = +1.228 \text{ V}, \quad (2)$$

$$\text{pH} \sim 4\text{–}3,$$

$$Mn^{2+} - e \rightarrow Mn^{3+}, \; E = +1.510 \text{ V}, \quad (3)$$

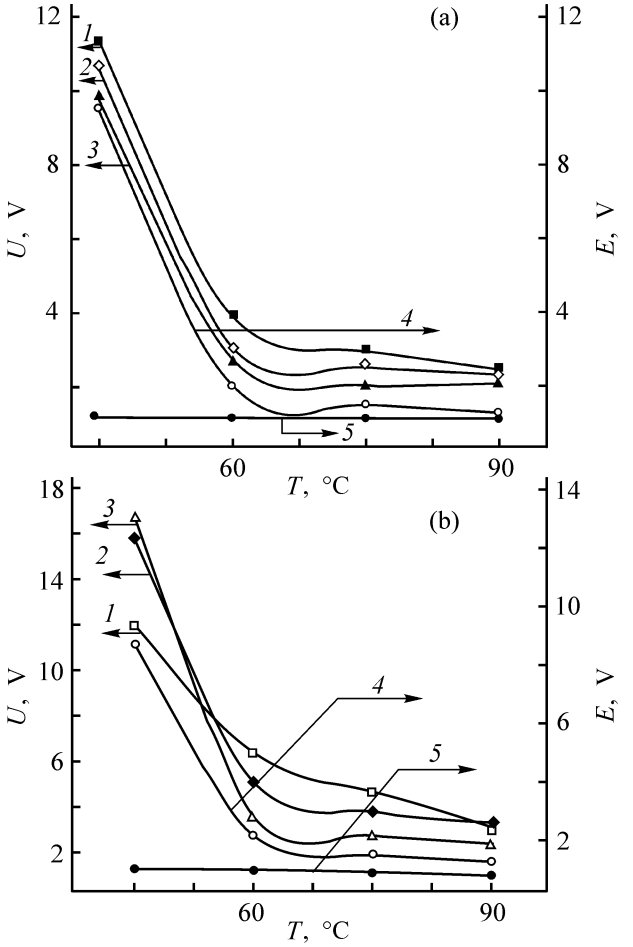

Fig. 2. Electrolyzer voltage U and the potential E of the (*4*) anode and (*5*) cathode vs. temperature T. HCl concentration (M): (*1*) 0, (*2*) 0.05, (*3*) 0.25, and (*4, 5*) 0.05.

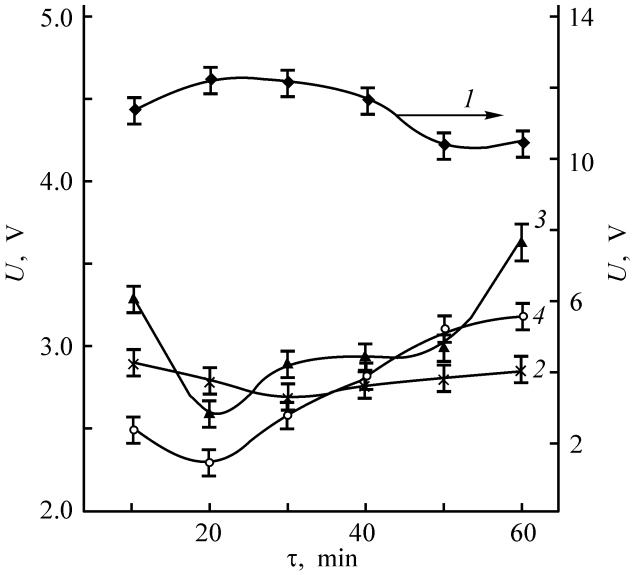

Fig. 3. Electrolyzer voltage U vs. time τ. Current density 5 mA cm^{-2}. Temperature (°C): (*1*) 30, (*2*) 60, (*3*) 75, and (*4*) 90.

$$Mn^{2+} - 2e \rightarrow Mn^{4+},\ E = +1.840\ V, \quad (4)$$

$$Mn^{2+} + 4H_2O - 5e \rightarrow MnO_4^- + 8H^+,\ E = +1.507\ V,\ pH \sim 2, \quad (5)$$

$$2Cl^- \rightarrow Cl_2 + 2e,\ E = +1.36\ V, \quad (6)$$

$$Cl_2 + H_2O \rightleftarrows HClO + HCl, \quad (7)$$

$$2HClO + ClO^- \rightleftarrows ClO_3^- + 2H^+ + 2Cl^-, \quad (8)$$

$$Mn^{2+} + x/2Cl_2 \rightleftarrows Mn^{(2+x)+} + xCl^-. \quad (9)$$

The resulting chlorine partly dissolves in the electrolyte to form hypochlorous and hydrochloric acids [reaction (7)], which results in a pronounced acidification of the electrolyte near the anode surface. In addition, the forming Cl_2 can oxidize Mn^{2+} to Mn^{4+} [reaction (9)]. The relative rates of the individual anodic reactions depend on the electrolysis conditions and are determined by the electrode potential and the temperature and acidity of the solution.

The rate of reaction (9) in the solution bulk is many times less than that of reactions (2) and (4) [3], which means that reactions (2) and (4) are the main source of manganese(IV).

In the course of the electrochemical oxidation of Mn^{2+}, the anode potential is the key parameter. Raising the anode potential favors successive oxidation of Mn^{2+} to Mn^{3+} and then to Mn^{4+}. At a potentials of approximately up to 1.5 V, Mn^{2+} is oxidized in solution to Mn^{3+} [equation (3)]. Another electrode reaction [equation (4)] takes place when the potential increases to 1.8 V.

Manganese(IV) can be also obtained by disproportionation of Mn^{3+} by the reaction

$$2Mn^{3+} \rightarrow Mn^{4+} + Mn^{2+}. \quad (10)$$

Manganese dioxide deposited from chloride solutions can be regarded as a product of hydrolysis [reaction (11)] of manganese(IV), which is formed by reactions (2), (4), (9), and (10):

$$MnCl_4 + 2H_2O \rightarrow MnO_2\downarrow + 4HCl. \quad (11)$$

Manganese tetrachloride may also decompose to yield $MnCl_2$ and Cl_2 via the inner-sphere redox reaction

$$MnCl_4 \rightarrow MnCl_2 + Cl_2\uparrow. \quad (12)$$

Apparently, the strong temperature dependence of CE is due to several factors: instability of higher manganese chlorides formed by electrolysis at high temperatures and by intense anodic dissolution of titanium at low temperatures, with both these factors being interrelated.

At low temperatures the hydrolysis rate of the Mn(IV) formed is low. Therefore, the reaction mainly proceeds in the bulk of the electrolyte rather than on the anode surface or in the near-anode space. Therefore, no MnO_2 film possessing high protective properties is formed on titanium. As a result, Ti undergoes at low temperatures a strong electrochemical dissolution to give a dense passivation film of titanium oxide. This is manifested in a fast increase in the anode potential, and, consequently, in the electrolyzer voltage. Owing to the intense passivation of titanium, the current is concentrated at those places where the passivation film is damaged, which results in a fast electroerosion disintegration of the anode.

Raising the temperature leads to an increase in the rate of $MnCl_4$ hydrolysis. Therefore, MnO_2 is formed on the surface of the titanium anode, rather than in the bulk of the electrolyte, to give a dense protective layer. This layer does not hinder reactions (2), (4), and (6) owing to its high electrical conductivity, but prevents the anodic dissolution of titanium.

It is known that the $MnCl_4$ dissociation at room temperature to form chlorine [reaction (12)] is extremely slow. The rate of this reaction sharply increases as temperature is raised [5]. As a result, the current efficiency starts to decrease above 60–70°C owing to the lowering of the Mn(IV) concentration.

As chloride ions compete with manganese(II) ions for the oxidation on the electrode, it may be suggested that an increase in the acidity would make lower the current efficiency by MnO_2. However, it can be seen from Figs. 1a, 1b that the dependence of CE on the concentration of hydrochloric acid is complex.

The decrease in CE upon an increase in the HCl concentration at low temperatures is probably due to a rise in the rate of anodic dissolution of titanium with increasing electrolyte acidity. The increase in CE from 80 to 95% as the HCl concentration is raised from 0 to 0.05 M may be due to a rise in the $MnCl_4$ concentration as a result of reaction (9).

The data obtained in studying the corrosion rate of unpolarized and polarized titanium anodes are listed

in Tables 1, 2 in relation to temperature and HCl concentration.

The results of the study show that titanium does not corrode in neutral $MnCl_2$ solutions. In the presence of HCl, titanium corrodes, but the corrosion rate is low. As the temperature and HCl concentration increase, the rate of titanium corrosion slightly grows. The results obtained are in a good agreement with reference data. For example, the corrosion rate of a titanium plate was zero after 200 h of electrolysis at 20°C in the presence of 5% HCl, 0.05 g m^{-2} h^{-1} after the same time of electrolysis at 60°C, and 4.23 g m^{-2} h^{-1} after as short a time as 25 h of electrolysis at 90°C [12].

Application of an anodic polarization makes the rate of titanium corrosion somewhat higher. As the temperature increases, the corrosion rate first grows, reaches a maximum at 75°C, and then falls, irrespective of the HCl concentration in the electrolyte. Raising the HCl concentration somewhat decreases the corrosion rate.

A visual inspection of the electrodes demonstrated that the MnO_2 deposit formed in electrolysis at 60°C is strongly adherent to the anode surface. Magnesium dioxide deposited at higher temperatures (75–90°C) has a weak adherence and exfoliates in the form of black flakes in the course of electrolysis, with the dense protective MnO_2 film retained on the surface of the titanium anode.

Several concurrent reactions, oxidation of titanium, evolution of Cl_2 and O_2, and formation of MnO_2, occur in the case of anodic polarization of the titanium electrode in HCl solutions [13]. A thin passivating TiO_2 film formed on the anode via oxidation at the beginning of the electrolysis hinders further ionization of titanium. As a result, the anode potential increases and reaches the potential of MnO_2 deposition. The thickness of the oxide film formed on the titanium electrode and, accordingly, its potential, depend on the current density, temperature, and electrolyte pH.

First, a primary passivating TiO_2 film exhibiting high protective properties is formed on the titanium surface at low current densities and relatively high temperatures. Then, the secondary passivating film, mostly composed of freshly deposited γ-MnO_2 is formed and reliably protects the titanium surface from disintegration. The protective properties of the MnO_2 film increase with temperature.

At low temperatures and high current densities, a titanium oxide layer with a high electrical resistance rapidly grows on the titanium surface. As a result, the anode potential increases to reach the potential of Cl_2 evolution. The distribution of the polarizing current along the anode surface is nonuniform. It is predominantly concentrated in the damaged areas of the passivating film, thus causing electroeroison of the anode.

Table 1. Chemical corrosion rate v_{ch} of VT-01-00 titanium at various temperatures and electrolyte compositions

c_{MnCl_2}, M	c_{HCl}, M	T, °C	τ, h	v_{ch}, g m^{-2} h^{-1}
1.0	–	60	6	0
1.0	–	75	15	0
1.0	–	90	15	0
1.0	0.05	60	6	0
1.0	0.05	75	10	2.4×10^{-4}
1.0	0.05	90	10	3.7×10^{-4}
1.0	0.25	60	6	1.1×10^{-4}
1.0	0.25	75	10	2.4×10^{-4}
1.0	0.25	90	10	6.7×10^{-4}
–	0.05	60	6	1.1×10^{-4}
–	0.05	75	10	2.6×10^{-4}
–	0.05	90	10	4.0×10^{-4}
–	0.25	60	6	8.0×10^{-4}
–	0.25	75	10	7.5×10^{-4}
–	0.25	90	10	9.3×10^{-4}

Table 2. Electrochemical corrosion rate v_{ech} of VT-01-00 titanium at various temperatures and HCl concentrations (Current density 5 mA cm^{-2}, $MnCl_2$ concentration 1 M)

c_{HCl}, M	T, °C	τ, h	U_{ini}, V	U_{fin}, V	v_{ech}, g m^{-2} h^{-1}
–	60	6	3.9	10.0	0
–	75	15	3.5	5.1	9.4×10^{-3}
–	90	15	2.6	5.1	7.2×10^{-3}
0.25	60	6	2.7	5.2	0
0.25	75	10	2.3	3.5	6.8×10^{-3}
0.25	90	10	2.9	3.2	2.8×10^{-3}

Calculations demonstrated that the rate at which the thickness of the titanium anodes decreases because of the chemical and electrochemical corrosion in the course of the electrolysis in manganese chloride electrolytes does not exceed 0.03 mm/year.

CONCLUSIONS

(1) VT-01-00 titanium can be used as anode in deposition of electrolytic manganese dioxide from chloride electrolytes.

(2) The optimal conditions for deposition of MnO_2 with a high current efficiency are as follows: temperature 70–75°C, current density 5 mA cm^{-2}, and HCl concentration 0.05 M. Under these conditions, the MnO_2 deposit has the form of coarsely crystalline aggregates that can be easily detached from the anode surface.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrochemical Synthesis of Complex Compounds of Transition Elements with Carboxyl- and Carbonyl-containing Ligands

V. Yu. Frolov, S. N. Bolotin, and V. T. Panyshkin

Kuban State University, Krasnodar, Russia

Received February 25, 2004

Abstract—Complex compounds of *d*- and *f*-elements with carboxyl- and carbonyl-containing ligands were synthesized by the electrochemical method. The influence exerted by a number of factors on the process course was studied. The dependence of the electrosynthesis parameters on the composition of the forming compounds was established. The composition of these compounds was determined. A new method for anodic synthesis of these compounds was developed.

The electrochemical method simplifies synthesis of known compounds [1–5] and makes it possible to synthesize compounds that cannot be obtained otherwise [6]. Moreover, the advantage of the anodic synthesis is in that the process can be controlled and performed in mild conditions with a high yield and purity of the final products [7].

Despite that the electrosynthesis is one of the oldest methods for synthesis of coordination compounds [8], the analysis of the anodic synthesis methods in [1–7, 9–13] shows that many problems concerning the theory and practical application of the method have not been studied.

Transition-metal carboxylates of composition $M(O_2CR)_n$ (M = Cr; R = C_2H_5 or C_6H_5; n = 3; M = Mn, Fe, or Ni; R = CH_3, C_2H_5, C_6H_5, or n-C_7H_{15}; n = 2) have been prepared [14] by electrochemical oxidation of the corresponding metals in solutions of carboxylic acids RCOOH in acetonitrile. In [15–17], monocarboxylic acids containing one to four atoms in the carbon chain were successfully used to synthesize $M(O_2CR)_2$ salts. Oxalate complexes of iron and copper were synthesized by the electrochemical method in [18]. On the whole, publications devoted to carboxylate complexes are scarce and analyze a rather small number of the ligands.

The goal of this study was to develop new original methods that would enable application of the electrochemical synthesis in a wider range and to a larger number of objects and make it possible to perform directed syntheses in which the composition of the forming products is controlled by varying the process conditions (ligand concentration, temperature, solvent, and electrode potential), and also to compare the properties of compounds synthesized by electrochemical methods with those produced by chemical methods. Acetylacetonates of rare-earth elements (REE) were synthesized to confirm the suggestion that substances exhibiting a tendency toward sublimation, which could not be synthesized previously by other methods [19, 20], can be obtained by electrochemical synthesis.

EXPERIMENTAL

The installation for anodic synthesis (Fig. 1) comprised a three-electrode cell, PI-50-1 potentiostat,

PR-8 programmer, copper coulometer, instruments for external monitoring of the current and voltage (potential), magnetic or mechanic stirrer, and thermostat.

The working electrode was made of the metal subjected to anodic dissolution. Auxiliary electrodes were made of inert materials or of the same materials as working electrodes, depending on the objective. A standard silver chloride electrode served as a reference. In nonaqueous solvents, an electrolytic bridge was also used to prevent contamination of the solvent with water.

The cell includes a thermostated jacket for performing syntheses at elevated temperatures. In addition, the cathodic and the anodic compartments of the cell are separated with a porous glass separator. The electrochemical measurements can be performed

using a magnetic stirrer. The PR-8 programmer makes it possible to apply to the potentiostat a potential that can be varied by an arbitrary program, including linear or stepwise parts. The circuit includes a copper coulometer for determining the current efficiency.

The table lists the conditions in which complex compounds of zinc, copper, nickel, and a number of REEs (Nd, Tb, Pr, Gd, Er) with lactic (HLac), malic (H_2Mal), citric (H_3Cit), succinic (H_2Suc), and γ-oxybutyric (HButOH) acids, arginine (HArg), valine (HVal), methionine (HMet), and acetylacetone (HAcac) were synthesized. The presence of the compounds as individual phase was confirmed by elemental and thermogravimetric (TG) analyses and by IR spectroscopy.

The content of metals was determined by complexometric titration [21] and that of carbon, hydrogen, and nitrogen, by elemental gas-volumetric analysis.

The IR spectra were measured on a Perkin–Elmer 180 spectrophotometer in the range 4000 – 400 cm^{-1} in a Vaseline oil suspension. The IR spectra of the carboxylic acid compounds synthesized were mainly analyzed for the position of the absorption bands associated with the carboxylic group and carboxylate ion, which is consistent for the compounds studied with published data [20, 22–25] for compounds with similar structure and composition.

The thermogravimetric curves were measured at 20–1000°C on an MOM derivatograph (Hungary). We used platinum crucibles, a platinum–platinum-rhodium thermocouple, and aluminum oxide as reference. The weighed portions were 50 mg, and the heating rate, 10 deg min^{-1}. As objects of analysis of the thermogravimetric data served DTA, DTG, and TG curves. In those cases when the composition of the final phase formed by the thermolysis can be predicted rather reliably (e.g., formation of CuO as the final product for complex copper compounds), we performed a quantitative analysis for the content of the ligand. The results of such an analysis were always in an agreement with the data obtained by chemical analysis.

The synthesis was performed in water and in nonaqueous solvents: acetonitrile (Acn) and dimethylformamide (DMF). In aqueous solutions, the synthesis was carried out without a supporting electrolyte, with the electric conduction provided by ions formed upon the dissociation of the ligands (H^+, L^{n-}). The decrease in the electrical conductivity, which is due to the fact that these substances are weak electrolytes, is compensated for by the absence of foreign ions in the solution, and, consequently, by the formation of simpler complex compounds. The ions formed upon dissociation migrate toward the electrodes and enter into the electrode reactions [4, 12].

$$\text{C: } 2H^+ + 2e \rightarrow H_2 \quad (H_nL + ne \rightarrow L^{n-} + n/2H_2),$$

$$\text{A: } mL^{n-} + nM - (nm)e \rightarrow M_nL_m.$$

In the electrochemical systems Cu/HLac, Cu/H_2Mal, and Cu/H_3Cit, the synthesis was performed using a liquid (molten) ligand as a solvent. The working temperature of the synthesis (see table) was higher than the melting point of the ligand and lower than its decomposition point. Inorganic chlorides were added to the molten ligand, and the supporting electrolyte was formed directly by the reaction

$$n\text{LiCl} + H_nL \rightleftarrows Li_nL + n\text{HCl}\uparrow.$$

The synthesis in a liquid ligand was performed with a preliminary dehydration of the ligands to a water content of 1–10 mmol l^{-1}. The compounds obtained contained a large amount of water, but their degree of hydration was considerably lower than that for compounds obtained from solution and subjected to dehydration. Therefore, the synthesis in a melt can be recommended for obtaining substances with the minimum content of water or compounds hardly hydrated by the conventional methods. However, the process rate is low in this case.

To choose the optimal range of ligand concentrations for the anodic synthesis, we studied how the potential of the metal electrodes varies with the ligand concentration in the solution at a constant ionic strength (1 M LiCl).

The dependences of the electrode potentials on the ligand concentration in solution are shown in Fig. 2 for three typical systems. For the system constituted by copper and amino acid (curves *1*), extrema are observed in the ligand concentration range studied (0.005 M). In those cases when a complex compound has a low stability constant, the equilibrium potential of the electrode is mainly determined by the concentration of the metal aqua complexes. If the complex compound forms a sparingly soluble phase on the electrode surface and(or) a very stable complex compound is formed, then the electrode potential is also dependent on the concentration of the anionic form of the ligand in solution. This predetermines the complicated character of the dependences presented.

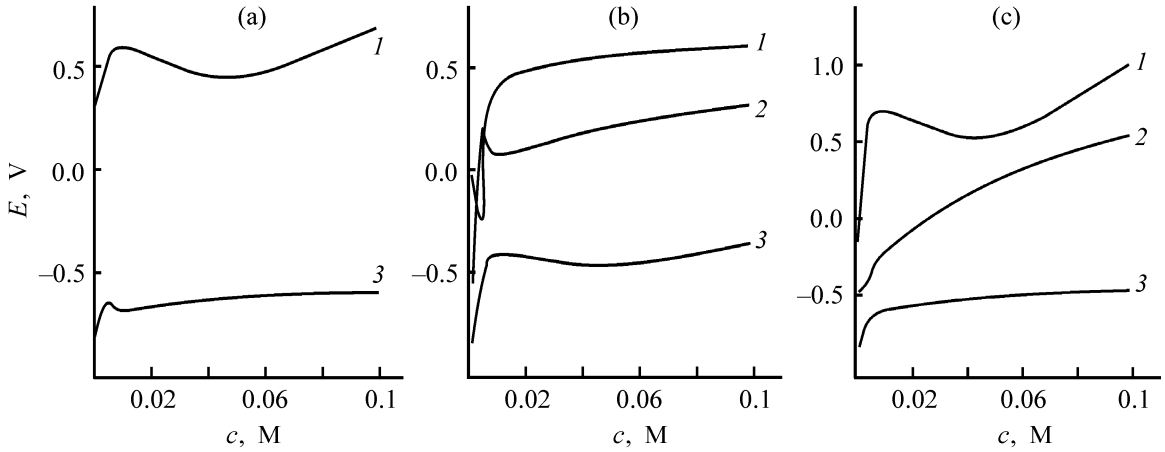

Fig. 2. Potential *E* of (*1*) copper, (*2*) nickel, and (*3*) zinc vs. the concentration *c* of (a) malic acid, (b) valine, and (c) arginine.

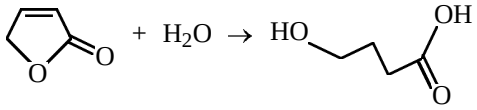

At low concentrations of the ligand (0.005 M and less), the electrode is frequently passivated. In the absence of a supporting electrolyte, such concentrations also lead to a low electrical conductivity of the solution. In these cases, it is suggested to perform electrolysis at high ligand concentrations by gradually raising the content of a ligand to the maximum possible value at a given temperature. For the amino acid systems, this means that the concentration can be raised from 0.005 M to the point of saturation (Fig. 2). It was found that such a procedure frequently makes it possible to avoid passivation of copper and zinc electrodes.

Copper easily dissolves in all the systems studied, with a high current efficiency at small shifts of the potential from the equilibrium value and high dissolution current densities.

Zinc dissolves well in the system with a stronger polarization, at higher anode potentials and lower current densities. Hydrogen is evolved at the cathode at the beginning of the process. Then, as metal ions are accumulated in the electrolyte, a parallel process of zinc separation commences, which decreases the current efficiency of the anodic process. The metal ions are discharged at the cathode to form dendrites, which are accumulated on the cell bottom because of the poor adherence to the electrode, thus creating additional difficulties in isolation of the final product. This difficulty is eliminated if a cell with separated electrode compartments is used. In all probability, the high current efficiencies by the zinc compounds are due to the simultaneous spontaneous dissolution of the zinc electrodes:

$$Zn + 2HL \rightarrow ZnL_2 + H_2\uparrow.$$

The electrosynthesis of the complex nickel compounds with hydroxy acids (except γ-hydroxy butyric acid) poses certain difficulties. When the electrode potentials are low (1–2 V), the electrode in the system chosen is passivated, the electrolysis proceeds very slowly, and the anodic products cannot be identified by analysis as individual compounds. At high anode potentials (up to 3 V), oxygen evolution from water proceeds at the anode, which makes the nickel electrode completely inert. The successful synthesis of the nickel(II) complex with γ-hydroxy butyric acid is probably favored by the fact that it is synthesized from the preligand (2-butenolide), the true concentration of the ligand near the anode surface is very low, and its loss is continuously compensated for by hydrolysis of 2-butenolide directly at the anode surface:

It was established for copper in an analogous system that copper compounds with different states degrees oxidation are formed by electrochemical synthesis at different temperatures: a pale green copper(II) complex insoluble in water (compound **VI**) is formed at 25°C, and a copper(I) complex insoluble in water (compound **VII**), at 65°C.

Comparison of the IR spectra of the compounds obtained in the REE(Nd, Tb)/HAcac system, which have, according to the results of an analysis, the composition $LnAcac_3$, with the spectrum of the pure ligand (shift of the carbonyl vibrational band at around 1650 cm^{-1} by 50–60 cm^{-1}) shows that a chemical carbonyl bond is formed [22]. The thermogravimetric

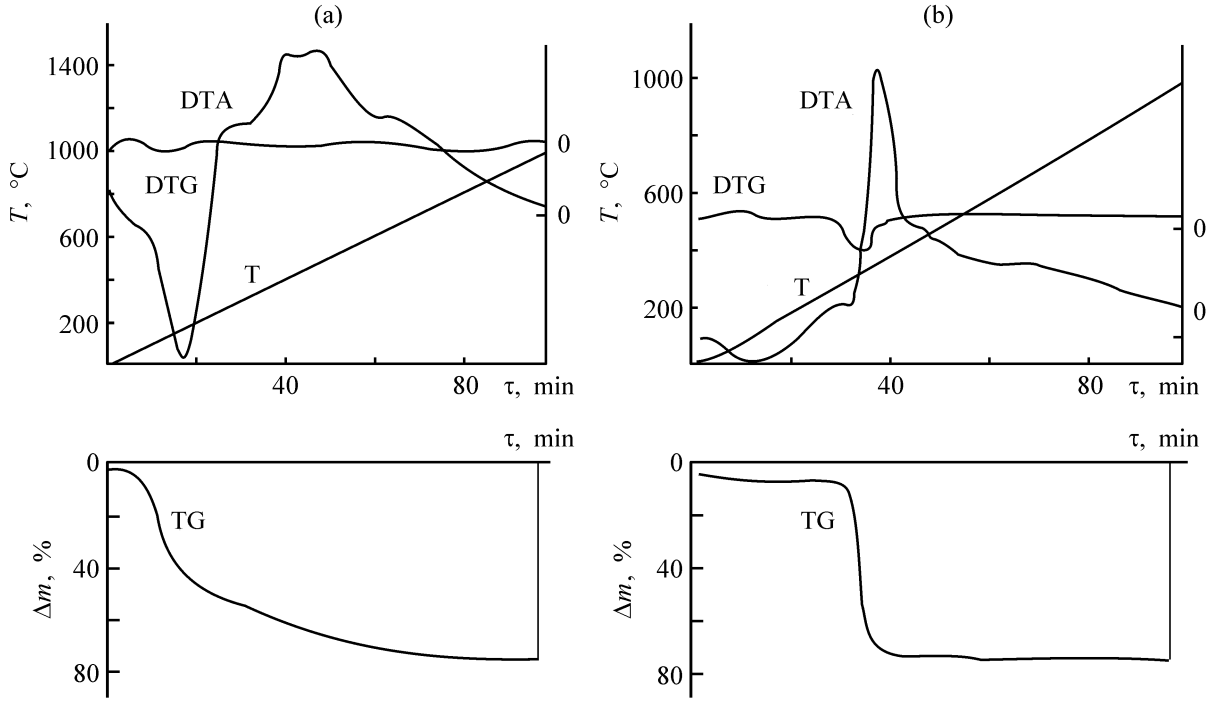

Fig. 3. Thermograms of (a) neodymium and (b) terbium trisacetylacetonates. (T) Temperature, (Δm) relative loss of mass, and (τ) time.

data in Fig. 3 suggest that the substances synthesized are volatile: a drastic mass loss (96%) observed at T = 310°C for compound (**XXXIX**) corresponds to a strong exothermic effect, which may be due to sublimation of a sample and its simultaneous combustion in the vapor state; for compound (**XL**), a 75%-loss of mass, accompanied by a pronounced endothermic effect, is observed at T = 220°C. Thus, the electrochemical synthesis of acetylacetonates of rare-earth elements is a simpler and less expensive method, and, which is the most important, it gives anhydrous compounds with a molecular crystal lattice [26].

In the course of synthesis in a system containing copper electrodes and an aqueous solution of lactic acid at high anode potentials (2–3 V), a finely dispersed colorless water-insoluble solid substance is formed at the anode alongside with a compound $CuLac_2 \cdot 5H_2O$, which is obtained in a very low yield (5–10%). An analysis of the compound obtained revealed neutral anhydrous copper carbonate $CuCO_3$. Therefore, it was suggested that the electrochemical anodic reaction of decarboxylation of lactic acid (Kolbe reaction) occurs in such a synthesis as a side process unknown previously for α-substituted hydroxy carboxylic acids and their salts. The process can be used to introduce into the anodic Kolbe synthesis new classes of organic substances, which is important for practice.

Various nonaqueous solvents also differently affect the composition of the products obtained and the process efficiency. Use of aqueous-alcoholic media in synthesis of *d*-element succinates was ineffective. It was found for aprotic solvents that there is a relationship between the solvent chosen and formation of solvated complexes. The formation of solvates (solvation) depends on the relative donor strength of the solvent and the ligand used and on the temperature mode of electrolysis. For example, solvated complexes are always formed in dimethylformamide, whereas in acetonitrile, this occurred only in several cases. It may be concluded that acetonitrile is the most suitable solvent for synthesis of unsolvated compounds.

The electrochemical synthesis has a high efficiency: the yield of substance and the current efficiency (>50%) are considerably higher than those in the conventional chemical syntheses. In addition, the electrochemical synthesis is a single-stage process, which also makes higher the yield of the product. In the general case, the yield of substance and the current efficiency may be different or may coincide.

The effect of the process temperature on the composition of the products obtained was especially strong in interaction of copper with 2-butenolide, when at a comparatively small temperature difference, two products of different compositions were formed, with

copper in different oxidation states. In other cases, differently solvated compounds were formed.

CONCLUSIONS

(1) The optimal concentration ranges of the ligand for electrochemical synthesis of complex compounds, temperature, solvent, and gaseous medium of synthesis were determined on the basis of potenstiostatic data.

(2) Anodes made of rare-earth metals were used in electrochemical synthesis for the first time. Thermogravimetric data demonstrated that the physical properties (high volatility) and structure of acetylacetonates of rare-earth elements synthesized by this method in anhydrous acetonitrile differ from the properties of the previously synthesized analogues.

(3) It was shown that the anodic dissolution of the metal facilitates decarboxylation of hydroxy acid.

Abstract—Processes of electrolytic dispersion of ferromagnetic metals (nickel and cobalt) to give oxides or metal powders were studied. The influence of an external magnetic field and current reversal on the processes of anodic dissolution was analyzed.

The known method for production of nickel(II) hydroxide (green) by electrochemical dissolution of rough nickel [1] cannot process lump or granulated metals. This problem was partly solved by the technique [2] that makes it possible to treat subquality powders. The electrochemical technology is the most suitable for this purpose, as it requires no chemicals and does not pollute the environment.

Also known is the intensification of certain diffusion-limited electrode processes by an external magnetic field [3]. This effect is due to a decrease in the thickness of near-electrode diffusion layers, which results from strong electrolyte flows tangential to the electrode surface, initiated by a one-dimensional magnetic field [4] and by that of a three-dimensional topography [5]. The anodic dissolution of nickel and cobalt in neutral solutions proceeds to give solid hydroxides, which are deposited onto the electrodes to form layers partially screening the electrode surface. Probably, this process can be prevented both by the action of an external magnetic field and by current reversal.

The known filled electrodes for anodic dissolution of nickel and cobalt, placed in perforated pockets made of a chemically resistant material (e.g., titanium), have the following drawbacks. First, the pockets screen no less than 50% of the surface area of a metal to be dissolved and, second, they are cluttered in the course of the electrolysis with hydroxides hardly removable through the perforation.

The aim of this study was to examine the effect of an external magnetic field and current reversal on the electrochemical dispersion of nickel and cobalt without screening of their surface and to assess the possibility of using ammonium chloride as an electrolyte, instead of sodium chloride.

To study the anodic dissolution of the metals, we used a 120-mm-high electrolyzer with a 160×280-mm cross-section and a standard electrochemical cell for recording of polarization curves. Solutions (2 M) of analytically pure sodium or ammonium chloride were used as electrolytes. A twofold decrease in the concentration of sodium chloride diminishes the conductivity of the solution by 80%, and an increase in this concentration results in an undesirable crystallization of salt on the electrolyzer walls above the electrolyte mirror.

To make a qualitative observation of the process, we first used a simplified electric circuit that allowed us to measure the current strength at a stepwise variation of the voltage across the electrolyzer. After that, the polarization of nickel and cobalt electrodes under potentiostatic conditions was studied with a PI-50-1.1 potentiostat. The efficiency of the anodic dissolution was estimated by the current efficiency, and the cost efficiency, by the expenditure of electricity per unit amount of the product.

The qualitative experiments were carried out in a 0.2-dm^3 cell. As the cathode served platinum, as the anode were used, in succession, nickel, cobalt, and titanium, as well as the nickel–titanium and cobalt–titanium combinations, with a working surface area of 4.0 ± 0.2 cm^2. Titanium was chosen as a metal for the current lead to lumpy nickel and cobalt owing to its chemical inertness. It was important to check its electrochemical stability in electrolysis in highly concentrated chloride solutions.

The experimental current-voltage dependences indicate that nickel and cobalt are anodically dissolved in a sodium chloride solution without any limitations (Fig. 1, curves *1* and *2*). Being a valve metal, titanium is anodically blocked: the current in the cell does not

exceed 0.12 mA up to a voltage of 6 V; in the voltage range 6–15 V, the current increases to 0.4 mA due to a rise in the oxide film thickness; and only beginning at 16 V, a breakdown occurs in the film and the current increases to 1.5 A. In this case, white flakes, products of titanium(IV) hydrolysis, are formed in the solution. Under real conditions, the electrolyzer voltage does not exceed 10 V and, therefore, titanium is electrochemically inert.

To obtain more complete information on the anodic dissolution of Ni and Co in NaCl solutions, we recorded potentiostatic curves (Fig. 1, curves *4* and *5*) which also indicate that the dissolution proceeds without any hidrance.

As the sodium ion is an undesirable admixture in the final product, we checked up the possibility of carrying out the electrolysis in a NH_4Cl solution. It would be expected *a priori* that it is hardly possible to obtain precipitates of hydroxides under these conditions owing to the formation of soluble nickel complexes with ammonia. In this case, the anodic dissolution of nickel involves the following reactions:

$$Ni - 2e \rightarrow Ni^{2+}, \quad (1)$$

$$H_2O + 2e \rightarrow 2OH^- + H_2, \quad (2)$$

$$Ni^{2+} + 2OH^- \rightarrow Ni(OH)_2, \quad (3)$$

$$Ni(OH)_2 + 2NH_4^+ \rightarrow Ni^{2+} + 2NH_4OH, \quad (4)$$

$$Ni(OH)_2 + nNH_4OH \rightarrow [Ni(NH_3)_n]^{2+} + nH_2O + 2OH^-. \quad (5)$$

It was appropriate to find out whether there are ranges of pH values and NH_4Cl concentrations in which nickel(II) hydroxide can be precipitated in the presence of ammonium salts.

Compared with nickel, cobalt forms with ammonia stronger complexes and its precipitation as $Co(OH)_2$ in the presence of ammonium ions is virtually impossible.

According to the distribution diagrams of polyamine complexes with nickel(II) and cobalt(II) in 2 N solutions of their salts in the presence of ammonia, uncoordinated ions can exist only at p[(NH_3)] exceeding 4.4 and 3.5 or at concentrations less than 4.0×10^{-5} and 3.2×10^{-4} M, respectively, which corresponds to pH values less than 9.42 and 9.87.

The dependence of the solution pH on the salt concentration is calculated by the formula:

$$[H^+] = cK_w/K_b. \quad (6)$$

Here c is the concentration of NH_4Cl (M); K_w, ionic product of water; and K_b, constant of NH_4OH dissociation.

The calculated data are presented in Fig. 2, which shows that the pH of formation of nickel hydroxides in the presence of NH_4Cl can be reached only at concentrations of this salt less than 0.5 M. It is known [6] that, at an NH_4Cl concentration of 0.16 M (8.56 g l^{-1}), nickel(II) hydroxide is formed even at pH 3.3.

We carried out an experiment on anodic dissolution of nickel in such a solution at a current density of 125 A m^{-2} and a temperature of $20 \pm 1°C$, and found out that nickel(II) hydroxide is formed. However, the electrolyzer voltage increased to 8 V because of the low electrical conductivity of the solution. Therefore, dispersion of nickel under these conditions will involve an increase in the electricity consumption. It is also known that addition of boric acid makes lower the pH of hydroxide formation, but its application would lead to an increase in the consumption of deionized water for washing of precipitates.

In view of the aforesaid, a solution of kitchen salt is the most suitable electrolyte.

To make an electric contact with fragments of ferromagnetic metals, we used a magnetic block (Fig. 3) with an *m*-metal plate on the back side, which served as a magnetic core and diminished the magnetic leakage.

The magnetic block was assembled from flat permanent magnets with alternating poles. The magnetic induction of a single element was 0.04–0.50 T. The block provides an electric contact, via the titanium plate, with all fragments of a metal to be dissolved. Furthermore, this block creates in the near-electrode region a three-dimensional magnetic field whose component orthogonal to the electric field vector generates tangential electrolyte flows, which enhances the mass exchange. Moreover, nickel(II) and cobalt(II) hydroxides precipitated in a magnetic field have a better filterability.

Nickel and cobalt hydroxides $M(OH)_2$ formed in anodic dissolution partially adhere to the surface to screen it. Current reversal with a period of 5–30 min makes it possible to avoid this phenomenon almost completely due to hydrogen bubbling during the cathodic period.

The effect of a magnetic field and current reversal on the technological process is reflected in the table. These data were obtained on the above-mentioned laboratory electrolyzer in a NaCl solution with a concentration of 120 g l^{-1}. The amount of $Ni(OH)_2$ obtained in 20.8 h at an electricity consumption of 93.7 A h was 165.3 g. This intermediate product was further thermally reduced in a hydrogen medium to give 104.7 g of a nickel powder. The bath voltage was 2.6 V. The quantity of electricity consumed in magnetoelectrolytic dispersion was 2.33 kW h per 1 kg of the nickel powder.

In the course of the electrolysis, the electrolyte is somewhat alkalified. In our experiment, pH increased from 6.20 to 9.55 pH units in 20.8 h owing to the formation of a new phase from poorly soluble nickel(II) hydroxide, whose solubility product in the freshly precipitated state is 2.0×10^{-15}. Based on this value, we estimate the concentration of OH^- ions at 10^{-5} M (with the presence of a concentrated sodium chloride solution disregarded), which corresponds to pH 9. This satisfactorily accounts for the increase in the electrolyte pH.

* *B* is the induction of a unit magnet; τ_r, reversal period, min; v_{md}, metal dissolution rate; *Q*, specific electricity consumption; and Φ, filterability.

Raising the electrolyte pH to 10 units has virtually no effect on the technological process and the product quality. Further increase in pH can be avoided by adjusting the electrolyte with hydrochloric acid.

An analysis of the reduced nickel powder for sodium demonstrated that its content does not exceed 0.03 wt %, which satisfies the requirements of GOST (All-Union Standard) 9722–97.

Similar experiments were carried out with an anode made of waste metallic cobalt. The technological process is similar to that of nickel dispersion.

In conclusion, it is necessary to note that dispersion of nickel at higher current densities yields black Ni(III) hydroxide, the same being true for cobalt.

COCNCLISIONS

(1) An external magnetic field intensifies the anodic dissolution of Ni and Co in NaCl solutions.

(2) Periodic current reversal prevents formation of hydroxide layers on the anode and intensifies the process, too.

(3) The calculated and experimental data obtained in this study demonstrate the possibility of precipitation of nickel(II) hydroxide by the electrochemical technique from NH_4Cl solutions with concentrations of 0.16 M and less.

Received July 14, 2004; in final form, March 2005

Abstract—The electrochemical behavior of cerium(III) in nitric acid solutions of rare-earth elements was studied. The activation energy and reaction order of cerium(III) oxidation were determined for various levels of anodic polarization.

Published data [1–6] on cerium(III) recovery from a mixture of rare-earth elements (REEs) and preparation of its pure compounds show that the method of preliminary electrochemical oxidation of Ce(III) to Ce(IV), followed by separation by precipitation or extraction, is the most promising. The comparative simplicity of separation is based on the substantial difference in the chemical properties of REE(III) and Ce(IV). The advantages of the electrochemical oxidation are the absence of chemical oxidants, possibility of preparation of stable Ce(IV) solutions, feasibility of a continuous process, higher equipment productivity, and smaller working area. However, this method has been insufficiently developed for industrial application [7]. The high yield of Ce(III) oxidation is achieved at a low current efficiency.

In this study, we examined how the electrochemical oxidation of Ce(III) in nitric acid solutions depends on the current density i, Ce(III) concentration, and electrolyte stirring intensity (characterized by the Reynolds number Re). The conditions ensuring complete Ce(III) oxidation with a current efficiency exceeding 92% were determined.

EXPERIMENTAL

Nitric acid solutions of REEs containing approximately 200 g l^{-1} Ce(III) (recalculated to CeO_2)[1], which amounts to 54% of the sum of REE, were electrolyzed.

In an electrolyzer with unseparated electrode spaces, a cylindrical platinum grid with a 0.1-dm^2 surface area was the anode, and a coaxial titanium rod with varied surface area, the cathode. The electrolyte volume was 0.1 dm^3. The solution was stirred with a blade stirrer (blade diameter 30 mm) at varied rate.

Polarization measurements were performed on a PI-50-11 potentiostat equipped with an electrochemical cell containing a platinum working electrode with a 0.25-cm^2 surface area. The Ce(IV) concentration (g l^{-1}) in the solution was determined by titration with Mohr's salt in the presence of a Na DAS indicator. From the data of the analysis, the degree of Ce(III) oxidation C (%), current efficiency η (%), and rate of Ce(IV) accumulation in the electrolyte per unit anode surface area Q (kg m^{-2} h^{-1}) were calculated by the common methods.

To examine the influence of the electrode current density on the efficiency of electrochemical oxidation of Ce(III), the ratio of the anode and cathode surface areas, $S_a : S_c$, was varied from 1 : 2 to 6 : 1. Under these conditions, the cathode current density varied from 5 to 60 A dm^{-2}.

The following reactions can proceed in a nitric acid electrolyte under the action of direct current: at the anode

$$H_2O - 2e \rightarrow 1/2O_2 + 2H^+, \quad (1)$$

$$Ce(III) - e \rightarrow Ce(IV); \quad (2)$$

[1] In papers devoted to technology and analytical chemistry of REEs, their concentrations are usually expressed in terms of oxides. Hereinafter, the cerium concentration for both cerium oxidation states was recalculated to the CeO_2 content.

at the cathode

$$H^+ + e \rightarrow 1/2H_2, \quad (3)$$

$$Ce(IV) + e \rightarrow Ce(III). \quad (4)$$

Reactions (2) and (3) are major reactions.

In the case of hydrogen ion deficiency (low acidity of the electrolyte), crystals of basic cerium nitrate of variable composition may precipitate:

$$Ce(IV) + xNO_3^- + yOH^- \rightarrow Ce(OH)_y(NO_3)_x\downarrow. \quad (5)$$

To avoid Ce(IV) redistribution between the liquid and solid phases, nitric acid should be introduced into the electrolyte in the amounts required for formation of $Ce(NO_3)_4$.

A study of the ratio of electrode surface areas during electrolysis showed that the Ce(IV) accumulation in the electrolyte is the most efficient when the cathode surface area is a factor of 5 and more smaller than the anode surface area, i.e., at cathode current densities higher than 50 A dm^{-2} (Table 1). For instance, as $S_a : S_c$ increases from 1 : 2 to 6 : 1, i.e., the cathode current density increases from 5 to 60 A dm^{-2}, the Ce(IV) current efficiency grows from 0.8 to 73.2%. In this case, the degree of Ce(III) oxidation increases from 0.09 to 8.18%, i.e., by more than a factor of 90. The effect observed can be attributed to the fact that the fraction of the current expended for hydrogen liberation substantially increases with the cathode polarization, and the Ce(IV) reduction is suppressed [reactions (3), (4)].

In studying the influence of the anode current density on the Ce(III) electrochemical oxidation, the current density was varied from 1 to 50 A dm^{-2} at the ratio of the electrode surface areas $S_a : S_c$ = 5 : 1.

Experiments without stirring (Re = 0) and with vigorous stirring (Re = 54000) of the electrolyte (Table 2) showed that the dependence of the rate of Ce(IV) accumulation, Q, on the anode current density shows a maximum, whereas the current efficiency η gradually decreases. The decrease in η can be caused by an increase in the overvoltage of Ce(III) discharge and a larger contribution of water electrolysis under these conditions [reaction (1)].

The above dependences show that Ce(III) oxidation is diffusion-controlled: stirring of the electrolyte favors delivery of cations to the anode surface and, under equal other conditions, makes higher the Ce(III) oxidation rate. Therefore, an increase in Re shifts the maximum efficiency to higher current densities. For instance, it is ~9.5 kg m^{-2} h^{-1} at the anode current density of 30 A dm^{-2} without stirring, and 23.3 kg m^{-2} h^{-1} at 40 dm^{-2} under conditions of a turbulent flow. It should be noted that stirring of the electrolyte substantially increases the process efficiency also at relatively low current densities, 1–30 A dm^{-2}. In this case, the current efficiency reaches 100–96.5%, being 76.4–47.9% without stirring.

The influence of the intensity of electrolyte agitation on the rate of Ce(III) oxidation was studied in detail in an electrochemical cell with a platinum elec-

trode with a surface area of 0.25 cm^2 at 20, 30, 40, and 50°C. The velocity of the electrolyte flow relative to anode surface was varied from 0 to 10 m s^{-1}, which corresponds to Re variation from 0 to 71000.

The typical polarization curves at 50°C are shown in Fig. 1. There are no well-defined limiting currents in all the polarization curves of Ce(III) oxidation. A smooth transition from the major reaction to the reaction occuring jointly with evolution of O_2 is observed. The electrolyte flow velocity strongly affects the current density at all polarizations. The effect increases with polarization. Comparison of the current densities at Re = 0 and Re = 71000 (developed turbulence) shows that, at a polarization of 0.025 V, the current density increases by a factor of 4, and at 0.4 V, by a factor of 12.8. Under the conditions of diffusion kinetics of Ce(III) oxidation on smooth electrodes, the rate of the process should increase by several orders of magnitude as the velocity is raised from 0 to 10 m s^{-1} (Re = 71000). The weaker effect of the flow velocity on the current density shows that electrolysis proceeds in the transition region (region of mixed kinetics) even at high polarizations.

To reveal the role of the chemical stage on the basis of the experimental polarization curves at 20–50°C and by analyzing the dependence $\log i = f(1/\tau)$ in term of the Arrhenius equation [from the shape of curves in Fig. 2 (Table 3)], we determined the equitransport activation energy of Ce(III) oxidation

$$\ln i = \ln A - E/RT, \qquad (6)$$

where i is the current density (A dm^{-2}); A, rate constant (A dm^{-2}); E, activation energy; R, gas constant; and T, temperature (K).

We found that the activation energy of Ce(III) oxidation under the conditions of both laminar and turbulent flows is virtually independent of the mass exchange intensity. Its deviation from the mean value

at a constant polarization, as a rule, does not exceed the maximum error in determining the activation energy by this method, which is 1.7 kJ mol^{-1}. The dependence of the mean activation energy on polarization is shown in Fig. 3. It is 29.3 kJ mol^{-1} at a polarization of 0.025 V, smoothly decreases to 10.0 kJ mol^{-1} at 0.15 V, and then remains virtually constant up to 0.5 V. The decrease in the activation energy with increasing polarization shows that the role of the chemical stage in the process decreases as the polarization becomes stronger, but does not completely unimportant, because the activation energy would become zero other wise.

We also studied the effect of Ce(III) concentration on the rate of Ce(IV) accumulation under the conditions of a constant Ce(IV) : Ce(III) ratio (1 : 10), concentration of free nitric acid (30 g l^{-1}), and solution temperature (50°C). The dependence of the current density on the Ce(III) concentration at stirring with Re = 71 000 is shown in Fig. 4. From the slope of straight lines obtained, we found that, within the polarization range from 0.025 to 0.5 V, the formal reaction order with respect to Ce(III) changes from 0.6 to 0.94, whereas a first order with respect to the reacting substance is typical of the exclusively concentration control.

At high polarizations (0.4–0.5 V), when n = 0.94, we can speak of the diffusion control of the Ce(III) oxidation.

The instant of transition from the predominant Ce(III) oxidation to combined Ce(III) oxidation and oxygen evolution at the electrode cannot be derived from the shape of the polarization curves. Therefore, we performed special experiments at various current densities, with the Ce(IV) current efficiency determined (Table 4).

A $Ce(NO_3)_3$ solution with a Ce(III) concentration of 98 g l^{-1} was electrolyzed at 40°C and a flow velocity of 7.8 m s^{-1} (Re = 54 000). The data obtained show that the Ce(III) current efficiency remains close to 100% up to a current density of 35 A dm^{-2}. The electrolyte stirring allows the process to be performed efficiently at higher current densities and hence at a higher rate. When the above-indicated current density is exceeded, the current efficiency sharply decreases, suggesting a concurrent evolution of oxygen at the electrode. The dependence of the main elec-

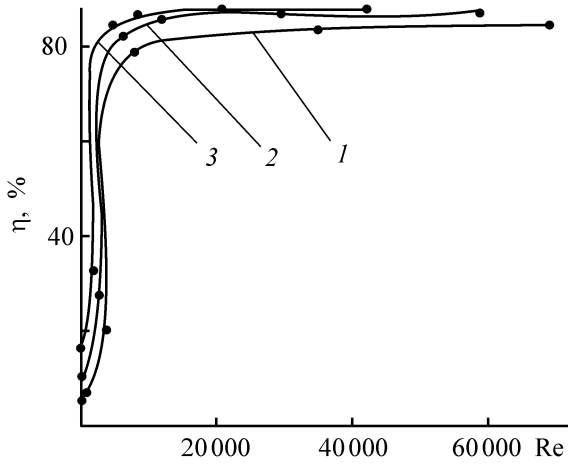

Fig. 6. Ce(IV) current efficiency η vs. the intensity of electrolyte stirring at various initial Ce(III) concentrations. Initial cerium(III) concentration (g l^{-1}): (*1*) 54, (*2*) 98, and (*3*) 210.

trolysis parameters *C* and η on the intensity of the electrolyte stirring is shown in Figs. 5 and 6. Transition from a laminar to a turbulent flow sharply increases the efficiency of Ce(III) oxidation.

Thus, an increase in the relative anode surface area (to $S_a : S_c \geq 5 : 1$), anode current density (to 30–40 A dm^{-2}), and turbulence of electrolyte flow (Re ≥ 10000) makes higher the efficiency of the Ce(III) electrochemical oxidation. The last two conditions are interconnected. The better the conditions of the mass exchange, the higher the current density at which the electrolysis can be performed.

CONCLUSIONS

(1) The activation energy of electrochemical oxidation of Ce(III) in a nitric acid solution of REEs is not higher than 32.2 kJ mol^{-1}; it decreases to 8.8 kJ mol^{-1} with increasing polarization, suggesting the transition to the diffusion control.

(2) The experimentally determined order of Ce(III) oxidation increases with polarization to $n = 0.94$, which also suggests the diffusion control of the Ce(III) oxidation.

(3) An increase in the anode polarization activates the side reaction of oxygen evolution, which decreases the current efficiency of Ce(III) oxidation.

(4) High parameters of Ce(III) electrochemical oxidation can be achieved at a relatively high cathode polarization ($i_c : i_a \geq 5 : 1$) and turbulent electrolyte flow (Re ≥ 10000).

CATALYSIS

Study of the Stability of Catalysts for Decomposition of Spent Sulfuric Acid

N. A. Dobrovinskaya, E. I. Dobkina, and S. M. Kuznetsova

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received November 15, 2004

Abstract—The influence of various factors on the stability of operation of heterogeneous catalysts for decomposition of spent sulfuric acid is analyzed.

The stability of operation of a catalyst [1] in decomposition of spent sulfuric acid (SSA) containing organic admixtures is strongly affected by several factors, including the mechanical action associated with the mode of the boiling bed and a long exposure to a high temperature. The first factor can promote destruction of the support and removal of active components. The second can diminish the catalytic activity through a transformation of the porous structure that leads to a decrease in the specific surface area. This study is devoted to examination and analysis of the effect of these factors on the catalyst.

EXPERIMENTAL

We used as real sulfuric acid waste to be subjected to decomposition the SSA formed in alkylation and in manufacture of methyl ethyl ketone. These two kinds of waste are representatives of concentrated and diluted SSA containing small amounts of organic admixtures (Table 1). The admixtures have a complex chemical composition including components of initial raw materials and products of target and side reactions. In view of the difficulties in determining such a composition, we estimated the amount of organic admixtures in SSA by a conventional method [2], by their sum in terms of carbon.

The abrasion resistance was estimated directly under conditions of SSA decomposition on an installation with a boiling-bed reactor (Fig. 1). The catalyst bed was poured on a porous quartz partition situated in the middle of a heated reactor *1* and brought into a fluidized state with air whose flow rate was measured with a rheometer *2*. Spent sulfuric acid was delivered by a mechanical batcher *3* into the catalyst bed through a side capillary built into a condenser *4* to prevent the catalyst coking. The loss of substance from the bed was judged from the increase in the mass of a trap *5* filled with fiberglass. To prevent condensation of sulfuric acid, the trap was placed in a furnace *6* which maintained its temperature at 300°C. To make a control measurement of the substance removal, the entire bed was additionally weighed every 10 h during the test.

The catalyst activity was estimated by the degree of SSA decomposition, β. It was studied on the same installation as the mechanical strength after dismantling the trap *5* and furnace *6*. A cooled gas mixture from the reactor *1* was analyzed by chromatography after removing SO_3 and water vapor.

The degree of SSA decomposition is the ratio between the amount of sulfur dioxide contained in the gas phase after the reactor and the total amount of sulfur dioxide in the SSA fed into the reactor.

The completeness of burning-out of organic admixtures was determined from the content of carbon oxide in gaseous decomposition products.

The wear resistance of the samples was studied *in situ* in the natural mode of the thermocatalytic decomposition of SSA. The samples were tested for 100 h

under conditions chosen on the basis of the experience gained in determining the optimal parameters of thermocatalytic decomposition of SSA in a boiling bed. Thee conditions were highly severe: T 850°C, load in terms of H_2SO_4 900 kg h^{-1} m^{-3}, and fluidization number 4. The results obtained in testing the supports are shown in Fig. 2. Comparison of curves *1* and *2*, corresponding to pure and silicated aluminum oxide [1], demonstrates not only the quantitative aspect of differences in abradability between these two supports, but also the fact that these dependences differ in their nature. For example, curve *2* of the time dependence of abradability of a silicated sample levels off after first 30 h of its operation, whereas the loss of pure γ-Al_2O_3 remains appreciable within the entire period of tests, although it becomes slower in the course of time. This can be explained as follows. In the course of the tests, unmodified γ-Al_2O_3 is subjected not only to a purely mechanical treatment, but also to a chemical action of the reaction medium, and undergoes polymorphic transformations under long-term influence of high temperatures. Probably, the action of the last two factors on silicated aluminum oxide is diminished due to a screening effect of the modifier. The abradability of such a support was about 0.2% per month.

An X-ray study of both samples (Fig. 3) demonstrated that they crystallize in 100 h of the tests (the intensity of discrete lines increases by 10–15%). The phase composition of silicated γ-Al_2O_3 remains virtually unchanged during the tests, whereas the initial Al_2O_3 is partially converted into the theta-form. Thus, the silication raises the stability of the phase composition and, accordingly, improves the performance of the support and, hence, of the catalyst itself.

Testing the wear resistance of finished iron-copper oxide catalysts based on the supports described above

[1] is of special interest. Experiments demonstrated that use of an unmodified support for preparing a catalyst for SSA decomposition is unacceptable at all. As can be seen in Fig. 4 (curve *1*), the abradability of such a sample within the first 20 h of operation was 7.5%. Then the destruction process presumably passed from the surface into the bulk of grains. As a result, it was necessary to stop the test ahead of schedule because of the catalyst transformation into a shapeless mass. As to a sample prepared on a silicated support (Fig. 4, curve *2*), the loss of substance from it within the running-in period somewhat increased in comparison with that from the support (Fig. 2, curve *2*), probably through loss of a certain amount of active components. However, the abradability determined after this period remained unchanged and constituted 0.2% per month.

One of the main factors impairing the activity of the catalysts operating in high-temperature processes is their caking. It can lead to a decrease in the total surface area of a support and(or) in the dispersity of deposited components.

The most important function of the support is to minimize the rate of growth or migration of crystallites of the active components. Nevertheless, these processes are inevitable if a catalyst is used at high temperatures, because the caking of the support gradually diminishes its role as a dispersant, which adversely affects the activity of the catalyst.

To study the thermal stability of the iron-copper oxide catalysts synthesized, we tested them in decomposition of real sulfuric-acid wastes from the alkylation process for 100 h under conditions considerably more severe than the optimum, which long-run tests more objective.

We determined the following optimal parameters of the process, which provide a nearly equilibrium degree of SSA decomposition to sulfur dioxide at a complete oxidation of organic admixtures: temperature 850°C, fluidization number 3, specific load by SSA 500 kg h^{-1} m^{-3}, and contact duration 1.4 s.

A test of the chosen catalyst under conditions of decomposition of SSA formed in alkylation demonstrated (Fig. 5) that the catalyst activity steeply falls within the first 15–20 h of operation. Apparently, the decrease in the activity of this sample is determined by recrystallization processes occurring in it.

Three stages are commonly distinguished in the mechanism of caking of oxide supports with a developed surface [3]. The area of contact between fine particles increases in the first of these, and new closed pores appear as a result of overlapping of the newly formed contacts in the second. Both these stages are accompanied by an essential decrease in the surface area accessible to reagents. In the third stage, closed pores disappear completely. In this stage, which is most prolonged, the specific surface area changes less considerably. The experimental data on changes in the S_{sp} of the sample under study in thermocatalytic decomposition of SSA after alkylation are given below:

S_{sp} (mg^2 g^{-1}) after operation for τ (h)		
Initial	20	100
98.0	32.2	25.6

To gain a better insight into the processes occurring in the samples under study during the tests, we studied them by means of X-ray photoelectron spectroscopy.

It follows from these data (Table 2) that silicon, iron, and copper are at the surface of the support in the initial samples, as can be seen from a comparison of their relative concentrations at the surface (in a 2–5-nm-thick layer), determined from the intensities of XPS lines, and in the bulk, from the data of quantitative elemental analysis. The relative concentrations of these elements in the surface layer under study in spent samples decrease. This may occur for two reasons. First is a "transfer" of a certain amount of active components from the surface of a support into its bulk, which can take place upon formation of closed pores in caking. The second is formation of enlarged "islands" of the active components, i.e. a decrease in their dispersity.

It is evident that both these factors contribute to in the decrease in the activity of the sample under study. The first of these is inevitable, because the catalyst is indeed transformed, and the occurrence of the second is confirmed by an electron-microscopic study of the catalyst. Electron micrographs of the initial and spent samples prepared for analysis by a microdispersion technique are shown in Fig. 6. The magnification of 200 000 allowed us to examine the growth of crystallites of the active components of the catalyst in the course of its operation. The largest crystallites in the initial sample have projection dimensions of about 5×25, whereas the corresponding average values for the spent sample are 10×75 nm (Fig. 6). Thus, according to the electron-microscopic data, the dispersity of phases of the active components in the catalyst decreases by approximately a factor of 2–3 upon 100 h of operation under conditions of SSA decomposition.

Table 2. Relative amounts of elements in a supported iron-copper oxide catalyst

Sample	Relative atomic concentrations of elements					
	surface, as given by XPS			bulk, as given by elemental analysis		
	Cu/Al	Fe/Al	Si/Al	Cu/Al	Fe/Al	Si/Al
Initial	1.19	0.258	0.397	0.21	0.08	0.18
Spent	0.94	0.197	0.321	0.20	0.08	0.18

At the same time, according to the X-ray data, these phases in the spent sample remain, on the whole, rather highly dispersed, which is seen from the small increase in the intensities of the discrete lines associated with the active components (Fig. 7).

In this context, it is probable that the contribution of the decrease in the surface area to the fall of the catalyst activity is more important than that of caking of the active components themselves. It is also seen from Fig. 7 that higher iron and copper oxides, as well as copper ferrite $CuFe_2O_4$, are present in the initial catalyst. All these compounds were detected in trace amounts, which is, in all probability, a consequence of their high dispersity. The absence of peaks corresponding to CuO and α-Fe_2O_3 with $2\theta = 58°$ and 64° in the X-ray diffraction pattern of the sample after the test and the decrease in the intensity of the peak of α-Fe_2O_3 with $2\theta = 38.9°$ suggest that these phases

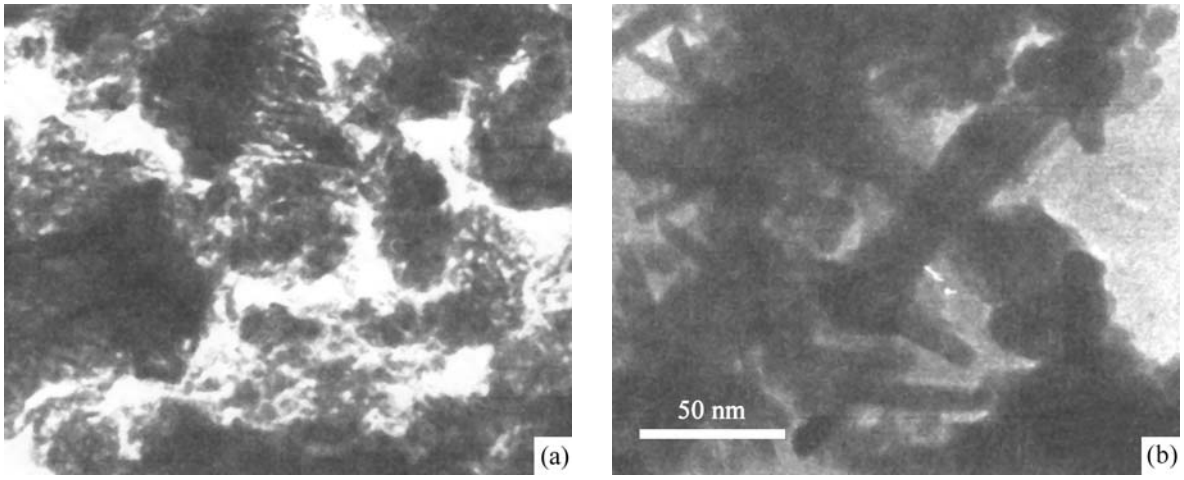

Fig. 6. Crystallization of active components under working conditions. Sample: (a) initial and (b) that after 100 h of operation.

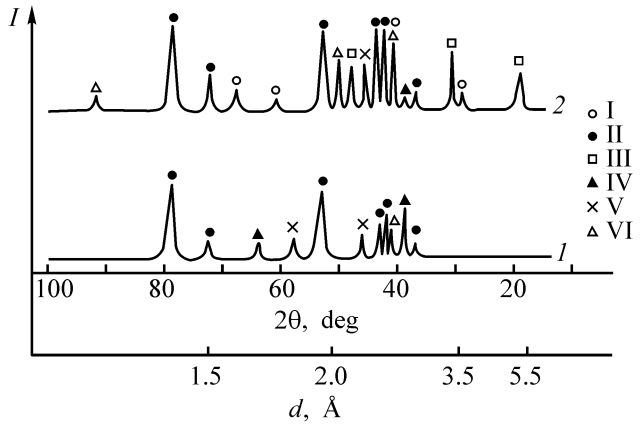

Fig. 7. X-ray diffraction patterns of (*1*) fresh and (*2*) spent catalysts. (*I*) Intensity, (2θ) Bragg angle, and (*d*) interplanar spacing. (I) α-Al_2O_3, (II) γ-Al_2O_3, (III) I-Al_2O_3, (IV) Fe_2O_3, (V) CuO, and (VI) $CuFe_2O_4$.

are consumed in catalyst operation. The increase in the intensity of $CuFe_2O_4$ (2θ = 41°), which is already present in the initial sample, and also the appearance of new peaks related to copper ferrite (2θ 50.6° and 92.4°) [4] suggest that iron and copper oxides react to give a ferrite. It is probable that the heat treatment of the catalyst during synthesis results in that only a part of iron and copper oxides enters into the reaction. The extent of ferrite formation increases further directly in the course of the sample operation during SSA decomposition. The formation of a more active phase of copper ferrite compensates for the decrease in the activity of the catalysts caused by a decrease in their specific surface area.

As to the support, it is represented in the initial sample by low-crystalline γ-Al_2O_3 (Fig. 7, curve *1*). During the test, it weakly crystallizes and undergoes insignificant polymorphic transformations. For example, a high-temperature phase *i*-Al_2O_3 and trace amounts of α-Al_2O_3 are observed in the spent catalyst (Fig. 7, curve *2*). The metastable phase of θ-Al_2O_3, formed in operation of non-silicated γ-Al_2O_3 (Fig. 3), is absent in this case.

CONCLUSIONS

(1) Comparative tests of the wear resistance of "pure" and silicated γ-Al_2O_3 and of catalysts prepared on their basis were carried out directly in decomposition of sulfuric acid.

(2) It was shown that silicating protects a support from the chemical action of the reaction medium, which prevents its destruction, and hinders the reaction of the support with the active components, thereby considerably improving the thermal stability of the catalyst.

(3) The abradability of iron-copper oxide catalysts was determined to be 0.2% per month.

(4) It was established that the decomposition of spent sulfuric acid is accompanied by caking, which results in a decrease in the surface area. Furthermore, active components are redistributed within catalyst grains.

(5) It was found that the highest stability of operation is exhibited by samples in which the CuO/Fe_2O_3 ratio is the closest to that in stoichiometric copper ferrite $CuFe_2O_4$.

CATALYSIS

Synthesis of Fine Carbon Nanotubes on Coprecipitated Metal Oxide Catalysts

A. V. Melezhik, Yu. I. Sementsov, and V. V. Yanchenko

TMSpetsmash Ltd., Kiev, Ukraine

Institute of Surface Chemistry, National Academy of Sciences of the Ukraine, Kiev, Ukraine

Received September 28, 2004; in final form, February 2005

Abstract—Catalysts for vapor-phase deposition of multi-walled carbon nanotubes are considered. A method for synthesis of iron-containing catalyst by coprecipitation of aluminum, magnesium, and iron(II) hydroxides is suggested.

Carbon nanotubes (CNT), which were only available in milligram amounts several years ago, are gradually becoming a product of large-tonnage synthesis. Simultaneously with the increase in the production scale, new application fields of CNT are being revealed. For example, Hyperion Catalysis International Co. (USA) manufactures CNT 10–15 nm in diameter and CNT-containing polymeric formulations. Introduction of 2–5% CNT into polymeric materials makes them electrically conducting and thereby hinders accumulation of static electricity [1]. Mechanical properties of CNT-filled polymeric materials have been studied [2–4]. CNT and CNT-based composites are under intensive scientific and technological development in China [5–10].

According to the results of [9], the most valuable are fine CNT less than 20 nm in diameter. In the best variants reported in numerous publications devoted to synthesis of multi-walled CNT by the chemical vapor deposition technique, the CNT diameter is 10–20 nm. The authors of the present study are not aware of any method for obtaining multi-walled CNT with an average diameter of less than 10 nm.

It is commonly believed, even though this issue remains insufficiently studied, that the diameter of a growing nanotube is determined by the size of the cluster of a catalytically active metal, e.g., iron, cobalt, or nickel. Presumably, the most efficient way to obtain and stabilize nanosize clusters of catalytically active metals is their immobilization on some highly dispersed or porous support, e.g., aluminum oxide, silicon, magnesium, or carbon. For this purpose, a dispersed support is impregnated with solutions of metal compounds (nitrates, acetylacetonates, salts of organic acids, etc.) On being introduced into a hot reactor, these compounds decompose to give, commonly, metal oxides, from which catalytically active metal clusters are formed in a reducing atmosphere (as a rule, a mixture of hydrogen and hydrocarbons). Such a procedure for fabrication of catalysts for synthesis of multi-walled CNT was described, e.g., in the patent [11]. Aluminum oxide with a particle size of about 10 nm was used as a highly dispersed support, and nitrates and acetylacetonates of iron, molybdenum, manganese, and chromium, and mixtures of these, as compounds of catalytically active metals. Ethylene mixed with hydrogen served as a source of carbon. The mass of the multi-walled CNT obtained was tens of times that of the catalytically active metals, and the diameter of the resulting CNT was in the range from 3.5 to 70 nm. The method described has the following disadvantage. As a result of impregnation and drying, particles of the material undergo aggregation and the size of metal oxide clusters formed in pyrolysis may markedly exceed the particle size of the highly dispersed support. Thus, the nanotubes obtained are nonuniform in diameter.

In another method, hydroxides of metals, e.g., of iron, cobalt, magnesium, or molybdenum, are coprecipitated, or mixed metal oxides are obtained by thermal decomposition of a mixture of appropriate compounds. Because oxides of catalytically active metals are uniformly distributed in the matrix of an inert oxide (of aluminum or magnesium), such an approach makes it possible to obtain more monodisperse catalytically active clusters and, consequently, finer carbon nanotubes that are more uniform in diameter.

For example, effective catalysts (or, more precisely, precursors of catalysts) for growth of multi-walled

1070-4272/05/7806-0917 © 2005 Pleiades Publishing, Inc.

CNT from acetylene, mixed oxides of magnesium and cobalt, were synthesized in [12, 13]. These catalysts were fabricated by drying an aqueous solution containing metal salts (nitrates, acetates) and citric acid, with the subsequent thermal treatment of the resulting xerogel at 700°C. A thermal treatment in the atmosphere of argon yielded a solid solution of oxides (homogeneous phase) of composition Co_xMg_{1-x} [12], whereas in thermal treatment in air, cobalt was partly oxidized to a trivalent metal to give a microheterogeneous mixture of phases Co_3O_4/MgO [13]. The average diameter of CNT fabricated using these catalysts could be varied within the range 16–70 nm by changing the composition of the gas mixture.

In the system under consideration, a homogeneous mixed oxide of magnesium and cobalt can be obtained owing to the fact that the ionic radii of bivalent cobalt and magnesium are nearly equal. One of the most effective catalytic systems for growth of multi-walled CNT from ethylene and propylene is a mixed oxide of iron, molybdenum, and aluminum. However, the ionic radii of these metals are different, and, therefore, special contrivances are necessary for obtaining a homogeneous mixed oxide or a nanosize microheterogeneous mixture. If these mixtures are obtained by coprecipitation of hydroxides from an aqueous solution of metal salts, the differences in pH values and rates of precipitation of different metals should also be taken into account. For example, the pH of the onset of precipitation of hydroxides from 1 M aqueous solutions of iron and aluminum salts is 1.5 for $Fe(OH)_3$ and 3.3 for $Al(OH)_3$ [14]. In addition, formation of soluble basic salts in the form of metastable solutions and gels is typical of aluminum, this being uncharacteristic of iron. Thus, precipitation of a considerable part of iron hydroxide in the form of a separate coarsely dispersed phase is probable upon addition of a precipitant to a mixture of aluminum and iron salts.

In [15], it was suggested to perform coprecipitation of iron, molybdenum, aluminum, and magnesium hydroxides in the presence of anions of carboxylic acids. Because it is known that carboxylic acids form rather stable complexes with Fe^{3+} ions, the role of these additives probably consists in that the precipitation rates of aluminum and iron hydroxides are equalized and(or) coagulation of iron hydroxide into a coarsely dispersed phase via adsorption of nanosize clusters of iron hydroxide is prevented.

Another approach to synthesis of homogeneous mixed metal oxides is also possible. It is known that, under certain conditions, hydroxides of bi- and trivalent metals form layered structures: anionic clays of composition $A_{1-x}B_x(OH)_2X_z \cdot mH_2O$, where A is a cation of a bivalent metal (e.g., Mg, Ni, Cu, Ca, Fe, Co, Sn, Mn, Cr, Cd, V, Zn); B, cation of a trivalent metal (e.g., Al, Fe, Ga, Co, Mn, Sc, Cr); and X, anion of an organic or inorganic acid [16]. Among the metal cations listed above are those exhibiting a catalytic activity in synthesis of carbon nanotubes. Thus, the given class of substances is of interest as regards the possibility of synthesis of oxide structures in which cations of catalytically active metals are uniformly distributed in an oxide matrix. In [17, 18], methods for synthesis of iron-containing hydrotalcites were suggested. In these syntheses, iron was introduced in the form of salts of bivalent iron. However, the catalytic activity of these substances in CNT growth has not been studied yet.

In [5], a nickel-containing hydrotalcite of composition $Ni_6Al_2(OH)_{16}Co_3 \cdot 4H_2O$ was deposited onto the surface of oxidized multi-walled CNT from a propylene–hydrogen gas mixture. Interestingly, the same nickel-hydrotalcite deposited in a pure form onto a substrate other than CNT yielded carbon nanofibers, instead of nanotubes. Thus, the nature of a substrate strongly affects the properties of the resulting catalyst.

The aim of this study was to examine the catalytic properties of hydrotalcite-like iron-containing substances in synthesis of carbon nanotubes.

EXPERIMENTAL

Iron-containing mixed metal hydroxides were synthesized by the conventional method of coprecipitation from aqueous solutions of metal (iron, aluminum, magnesium, ammonium molybdate) salts and a stoichiometric amount of aqueous ammonia. Iron was introduced into the reaction mixture in the form of a chloride of bivalent iron. The coprecipitated metal hydroxides were washed with water until the chlorine anion disappeared in the washing water, dried at 200°C, and ground in a vibration mill for 30–40 min. It should be noted that the bulk density of ground catalysts was rather high, 490–560 g dm^{-3}. With catalysts in this form, agglomeration of the forming carbon nanotubes into a loose solid mass was frequently observed, which is undesirable, especially in those cases when CNT are to be used in composites. The authors found that this adverse effect can be eliminated by mixing a ground catalyst with a highly dispersed pyrogenic silica (A-300 aerosil) in a mixer in the course of 5 min. In the process, the bulk density of the catalyst decreased by more than an order of

magnitude. In one of the experiments, preliminarily synthesized nanotubes were used as a loosener instead of aerosil.

Carbon nanotubes were synthesized in a 2.1-dm^3 cylindrical quartz reactor with a catalyst bed agitated by rotating the reactor by means of an electric drive at a rate of 60–90 rpm. The rotation axis of the reactor was inclined at an angle of 8° to the horizon. The gas mixture was fed into the reactor through an immobile quartz extension connected to the reactor neck by a ground joint lubricated with a mineral oil. The reactor was placed in an electric furnace with controllable temperature.

Prior to the beginning of an experiment, a catalyst was introduced into the reactor and the temperature was raised to 680°C in a flow of argon. After this working temperature was reached, a gas mixture was fed into the reactor. The mixture was composed of ethylene (400 $cm^3\ min^{-1}$) and hydrogen (200 $cm^3\ min^{-1}$; the volumetric flow rate of the gases was measured at room temperature. After that, the flow of argon was turned off and the gases discharged from the reactor through a quartz tube were burnt. The flame coloration could be used to judge qualitatively the degree of ethylene conversion into carbon and to determine in this way how the catalyst activity varies with time. At a low conversion of ethylene, a bright yellow flare was observed, the flame at a high conversion being small and virtually colorless or pale yellow.

To remove mineral impurities, the products were treated with an alkali solution (to dissolve aerosil) and then with hydrochloric acid to dissolve metal oxides. It should be noted that, even upon a thorough purification (many-hour heating in conc. hydrochloric acid), the samples were noticeably attracted by a magnet, which points to incorporation of a certain fraction of iron into the nanotubes. Indeed, electron micrographs (Figs. 1–4) show inclusions at some places in the inner channel of nanotubes (indicated by arrows). Figure 4 shows a chain of four inclusions in the same

4	Run no. 2, in another grinding mode: $FeAlMo_{0.07}$, in accordance with [15] (2 parts) + A-300 (1 part, grinding) + A-300 (6 parts), fluffing up; 12 g of the mixture in the reactor	Ocher-colored powder, 24 g dm^{-3}	120 min, C = 43.6 g (87%), C/Fe = 51	Nonpurified: black powder, 55.1 g, 1.8 dm^3, 31 g dm^{-3}, 220 m^2 g^{-1}
5	$FeAlMo_{0.105}$, grinding; 3.0 g in the reactor	Ocher-colored powder, 550 g dm^{-3}	120 min, C = 35.1 g (70%), C/Fe = 34	Nonpurified: black powder + lumps, 37.8 g, 0.7 dm^3, 54 g dm^{-3}, 200 m^2 g^{-1}
6	$FeAlMo_{0.105}$, grinding; 1 part of ground product + A-300 (1 part), fluffing-up; 6.5 g of the mixture in the reactor	Ocher-colored powder, 26 g dm^{-3}	120 min, C = 46.0 g (92%), C/Fe = 41	Nonpurified: black powder + exceedingly loose lumps, 51.8 g, 1.65 dm^3, 31 g dm^{-3}, 210 m^2 g^{-1}
7	$FeAlMo_{0.105}$, grinding; 1 part of ground product + A-300 (2 parts), fluffing-up; 8.5 g of the mixture in the reactor	Ocher-colored powder, 19 g dm^{-3}	120 min, C = 49.5 g (92%), C/Fe = 42	Nonpurified: black powder, 54.2 g, 1.95 dm^3, 28 g dm^{-3}, 190 m^2 g^{-1}
8	$FeAlMo_{0.105}$, grinding; 1 part of ground product + 1 part of A-300, fluffing-up; 5.6 g of the mixture in the reactor	Ocher-colored powder, 32 g dm^{-3}	120 min, C = 40.0 g (87%), C/Fe = 55	Nonpurified: black powder, 45.3 g, 1.9 dm^3, 24 g dm^{-3}, 235 m^2 g^{-1} Purified: electron micrograph in Fig. 3
9	$FeAlMo_{0.105}$, grinding; 1 part of ground product + 1.67 parts of preliminarily synthesized CNT, fluffing up; 6 g of the mixture in the reactor	Brown-black powder 33 g dm^{-3}	85 min, C = 27.6 g (78%), C/Fe = 48	Nonpurified: black powder, 33.6 g, 1.3 dm^3, 26 g dm^{-3}, 220 m^2 g^{-1}

* Grinding: a catalyst was ground (with or without addition of aerosil) in a vibration mill; fluffing up: a catalyst was mixed (fluffed-up with aerosil in a mixer; carbon yield is given in grams, in percent relative to the theoretical value (in terms of ethylene passed through the reactor), and as a mass ratio of deposited carbon to elementary iron in the catalyst.

Table (Contd.)

Run. no	Composition, catalyst fabrication procedure, mass in the reactor	Outward appearance, bulk density of the catalyst	Process duration, min; yield of carbon	Outward appearance of the product, mass, volume, bulk density, specific surface area
10	$FeAlMo_{0.2}$, grinding; 1 part of ground product + 1 part of A-300, fluffing-up; 6.4 g of the mixture in the reactor	Ocher-colored powder, 26 g dm^{-3}	120 min, C = 43.4 g (86%), C/Fe = 54	Nonpurified: black powder, 49.6 g, 1.4 dm^3, 35 g dm^{-3}, 297 m^2 g^{-1} Purified: electron micrograph in Fig. 4
11	$FeAlMo_{0.2}$, grinding; 1 part of ground product + 1 part of A-300, fluffing-up; 9.9 g of the mixture in the reactor	Ocher-colored powder, 22 g dm^{-3}	120 min, C = 37.4 g (78%), C/Fe = 40	Nonpurified: black powder, 46.6 g, 1.4 dm^3, 33 g dm^{-3}, Purified: black lumps, 394 m^2 g^{-1}, electron micrograph in Fig. 5

nanotube, with the nanotube markedly dilated around the two right-hand inclusions.

The electron micrographs were obtained on a JEM-100 CXII transmission electron microscope.

The table lists the compositions of the catalysts (the atomic ratios of metals are given with oxygen and hydroxy groups disregarded) and modes of their preparation, synthesis modes, and properties of the carbon nanotubes obtained. If there is no reference to [15] in the table, the catalysts are synthesized by coprecipitation, with iron introduced in the form of iron(II) chloride. In several runs, catalysts fabricated by a method similar to that described in [15], with a solution of iron(III) formate-acetate, were used for comparison purposes.

In an analysis of the data in the table, the following should be noted. A catalyst of composition $FeAlMo_{0.07}$, synthesized by coprecipitation of iron(III) in the presence of anions of carboxylic acids by a procedure similar to that described in [15], is moderately active (carbon yield 77%) when used as a powder ground in a mortar (run no. 1). In this case, the CNT being formed tend to agglomerate into lumps and the carbon product has a comparatively high bulk density (77 g dm^{-3}). On grinding this catalyst in a vibration mill, with the subsequent fluffing-up of the ground product in a mixture with aerosil in a mixer (run nos. 2–4), the bulk density of the catalyst itself falls dramatically, the carbon yield increases to 87–97%, and the bulk density of the carbon product decreases to 31–43 g dm^{-3}. In this case, the product (CNT) is obtained in the form of a powder, rather than as lumps. Raising the amount of aerosil introduced (run nos. 3, 4) leads to a decrease in the bulk density of the carbon product. Probably, aerosil hinders aggregation of particles of both the catalyst and CNT, acting as a kind of a pseudoliquid solvent.

Judging from the electron micrographs (Figs. 1, 2) and the values of the specific surface area (see table), the diameter of the forming carbon nanotubes is little dependent on the mode of catalyst preparation and amount of aerosil introduced, being about 10–20 nm for the given catalyst, with a minor inclusion of thicker nanotubes. The diameter of the inner channel is, on the average, approximately half of the outer diameter.

Further, the results obtained with coprecipitated catalysts upon introduction of iron in the form of iron(II) chloride, without addition of carboxylic acids or their salts, are considered.

A catalyst of composition $FeAlMo_{0.07}$ without addition of aerosil (run no. 5) behaves similarly to the catalyst of the same composition, synthesized by the method described in [15] (run no. 1). Addition of aerosil makes it possible to markedly raise the yield of carbon and to eliminate the agglomeration of product particles (run nos. 6, 7).

Run no. 8 was carried out with a hydrotalcite-like catalyst of composition $FeAlMgMo_{0.105}$. The yield of catalyst was high, 87%. According to electron micrographs, the carbon nanotubes synthesized in run no. 8 (Fig. 3) do not differ significantly from the CNT obtained on the $FeAlMo_{0.07}$ catalyst [15] (Fig. 2, run no. 3). Thus, these catalysts are similar in activity and diameter of the forming nanotubes. However, the bulk density of the carbon product in run no. 8 is lower than that of the catalyst fabricated by the method described in [15]. This may be important for application of the CNT obtained in composites.

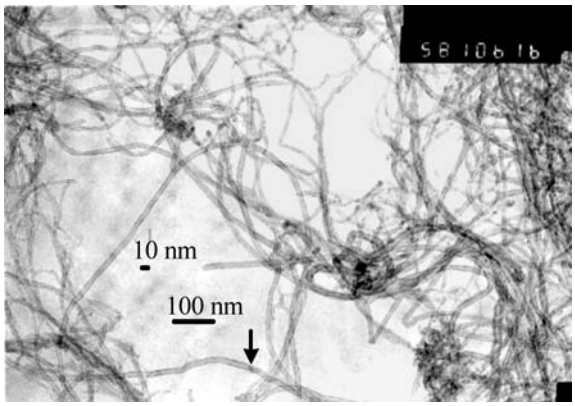

Fig. 5. Electron micrograph of carbon nanotubes grown on a $FeAl_3Mo_{0.2}$ catalyst with addition of aerosil (run no. 11).

In [5, 15], carbon nanotubes were studied as substrates for deposition of metal oxide catalysts, instead of mineral supports. Doing so makes it possible to diminish the content of mineral impurities in the final product and, in some applications, to skip the stage of its purification. However, treatment of carbon nanotubes in a solution is technologically inconvenient because CNT occupy a very large apparent volume (both in the dry state and as a suspension), and drying causes agglomeration, which gives rather dense lumps. The authors made an attempt to distribute a ground metal oxide catalyst of composition $FeAlMgMo_{0.105}$ on a CNT substrate by simple treatment of a dry mixture in a mixer and obtained good results for the carbon yield, bulk density, and specific surface area of the product (run no. 9).

As already noted, it is assumed that the diameter of the growing multi-walled CNT is determined by the size of clusters of the catalytically active metal. It would be expected that a decrease in the concentration of the oxide of a catalytically active metal in the oxide matrix of the type of hydrotalcite should yield finer CNT. For this purpose, catalysts with an increased content of magnesium, $FeAlMgMo_{0.105}$, were synthesized. It was found that doubling the content of magnesium in the catalyst leads to a decrease in the carbon yield to 34–42% and in the specific surface area of the carbon product to 160 $m^2 g^{-1}$, instead of the expected increase in the latter parameter.

However, dilution of iron oxide by raising the amount of aluminum oxide was successful (Figs. 4, 5; run nos. 10, 11). Although a minor decrease in the carbon yield was observed on raising the concentration of aluminum oxide, the specific surface area of the product increased substantially, from 200 to 297–394 $m^2 g^{-1}$. On certain assumptions, the specific surface area of multi-walled CNT can be regarded as being related to their diameter and number of carbon layers in a wall [19]. Consequently, the specific surface area and the average outer diameter of nanotubes can be used to roughly evaluate the number of carbon layers in the wall. For the product formed in run no. 10 ($FeAl_2Mo_{0.2}$ catalyst), the specific surface area is 297 $m^2 g^{-1}$, compared with 200–250 $m^2 g^{-1}$ in the preceding experiments. No differences can be revealed visually between the nanotubes in Fig. 4 and those in Figs. 2, 3. However, the nanotubes obtained in run no. 11 (Fig. 5, $FeAl_3Mo_{0.2}$ catalyst) were considerably thinner-walled than those in the preceding experiments. The average diameter of the nanotubes in Fig. 5 can be roughly estimated at 10–12 nm. Then, according to the data of [19], the number of carbon layers is 3–4.

Thus, dilution of iron oxide with aluminum oxide makes it possible to obtain thin-walled CNT with a small diameter and large specific surface area, which are promising as materials for electrochemical devices, adsorbents, and catalyst supports.

The output capacity of the above-described laboratory installation is (at the specified catalyst charges and ethylene flow rates) about 20–23 g of CNT per hour. On doubling the length and diameter of the reactor at the optimal catalyst charge, it is possible to raise the output capacity of the installation to 150–200 g of CNT per hour. It is unclear how the scaling factor will be manifested on making the reactor even larger. In [8], a reactor for continuous synthesis of CNT, in which the catalyst is supported in the suspended state by a gas flowing from below, was described. It is difficult to decide which design is more efficient. However, a supposedly higher degree of conversion of the gas serving as a source of carbon can be achieved in the rotating reactor. Because the gas medium within the reactor is mainly composed of hydrogen at a high degree of conversion, there is no need to add hydrogen to ethylene fed into the reactor, and this was experimentally confirmed in this study. For example, run no. 2 was repeated with hydrogen supply turned off 15 min after the beginning of the process (after the catalyst activation was complete), and it was found that the yield and properties of the resulting product remained virtually unchanged.

Mention should also be made of the different modes of CNT growth in a reactor with a fixed catalyst bed and in a rotating reactor, which affects the properties of the forming carbon products. For example, in the case of CNT grown from acetylene on the surface of thermally expanded graphite (TEG) promoted

with iron compounds in a horizontal tubular reactor with a fixed Fe/TEG bed, the specific surface area of the resulting (nonpurified) CNT/TEG composite was 110 $m^2 g^{-1}$ at a content of CNT equal to 35 wt % and decreased to 42 $m^2 g^{-1}$ at a CNT content of 85 wt % [20]. Carrying out the same process in a rotating reactor yielded carbon composites containing 20% TEG and 80% CNT, with a specific surface area of 304–387 $m^2 g^{-1}$, depending on the reactor charge. It may be assumed that CNT synthesis includes stages in which there occur addition of a molecule of an unsaturated hydrocarbon (acetylene, ethylene) to a catalytically active metal center and, further, several elementary events in which a hydrogen molecule is split off and the carbon nanostructure of a nanotube (nanofiber) is formed. If the tubular structure is formed more slowly than the preceding stages, carbon with an amorphous or imperfect structure may be obtained. If the substrate (catalyst) bed is agitated, a particle of the material is, at different instants of time, either in contact with the gas serving as a source of carbon or deep within the bed, where the gas diffusion is hindered. Thus, there is enough time for structuring of carbon clusters.

This mode reminds a "pulsed" supply of the gas serving as a source of carbon into the reactor, which was suggested in [21] and resulted in a higher yield of nanotubes and led to changes in their morphology.

CONCLUSIONS

(1) Iron-containing hydrotalcites are efficient catalysts for synthesis of carbon nanotubes by chemical vapor deposition.

(2) Dilution of the oxide of the catalytically active element (iron) in the hydrotalcite matrix with aluminum oxide leads to a decrease in the average diameter of the carbon nanotubes synthesized.

(3) Introduction of aerosil into a catalyst makes it possible to diminish the aggregation of the resulting carbon nanotubes and to prevent caking of the product.

(4) A rotating reactor is an efficient device for synthesis of carbon nanotubes by chemical vapor deposition.

CATALYSIS

Synthesis of Porous Carbon Nanofibers on Catalysts Fabricated by the Mechanochemical Method

A. V. Melezhik, Yu. I. Sementsov, and V. V. Yanchenko

Received September 28, 2004; in final form, February 2005

Abstract—A mechanochemical method for fabrication of catalysts for vapor-phase deposition of porous carbon nanofibers from acetylene is suggested.

Carbon nanotubes (CNT) and nanofibers (CNF) are the most promising materials for energy-storage devices: chemical power cells, supercapacitors, fuel cells, and hydrogen adsorbers [1–8]. The energy storage capacity is determined by the structure of the carbon materials. For example, the highest capacity for carbon has been observed for nanofibers in which the carbon layers are perpendicular to the fiber axis or have a "fir-tree" orientation. A reproducible capacity for hydrogen of about 15 wt % has been achieved [8].

Porous CNF with a developed surface have been synthesized. For example, chemical activation of CNT and CNF with molten potassium hydroxide makes it possible to raise manyfold the specific surface area through burning-out of a part of graphene layers and their unfolding [9, 10]. In [11], carbon nanofibers with porous walls in the form of honeycomb were obtained by chemical vapor deposition.

The main factors determining the structure of CNT and CNF in vapor-phase deposition are the composition and structure of the catalyst used. The conventional methods for fabrication of catalysts for the process in question (aerosol techniques are disregarded) are as follows: impregnation of porous or highly dispersed mineral substrates with solutions of compounds of catalytically active metals (most frequently, iron, cobalt, and nickel) [12], coprecipitation of a mixture of metal hydroxides [13], and thermal decomposition of a mixture of metal salts and organic acids [14]. The forming homogeneous or microheterogeneous mixtures of metal oxides give rise, under the conditions of vapor-phase deposition (temperature, reductive atmosphere), to clusters of catalytically active metals, on which CNT or CNF of certain structure grow. In the process, the structure is determined not only by the nature and size of clusters of the catalytically active metals, but also by the nature of a substrate. For example, it was shown in [15] that a mixed nickel-aluminum oxide deposited onto oxidized carbon nanotubes catalyzes growth of carbon nanotubes, and nanofibers grow on this mixed oxide without a carbon substrate. It was demonstrated in [16] that a thin layer of iron, deposited in a vacuum on a substrate made of a mixed indium-tin oxide, catalyzes growth of carbon nanocoils. At the same time, comparatively straight CNT or CNF are formed on other iron-containing catalysts.

A disadvantage of the impregnation or deposition from solution is that particles of the substrate or catalyst undergo aggregation upon drying. For example, highly dispersed pyrogenic oxides of aluminum and silicon, used as supports, lose fluffiness and turn into dense lumps of a xerogel upon impregnation with aqueous or methanol solutions and drying. In growth of CNT or CNF on catalysts of this kind, there appears a tendency toward agglomeration of the carbon product into more or less dense concretions, which is unfavorable for its use in composites.

The aim of this study was to analyze the possibility of obtaining catalysts for vapor-phase deposition of CNF by the mechanochemical method and to examine the properties of CNF formed on these catalysts.

EXPERIMENTAL

Technical-grade acetylene additionally purified by a procedure described in [17] was used in the study. Gas flow rates were measured with calibrated rheometers.

1070-4272/05/7806-0924 © 2005 Pleiades Publishing, Inc.

As highly dispersed materials-supports for the catalysts served aerosils manufactured by Kalusha pilot plant: A-300 aerosil (specific surface area 300 $m^2 g^{-1}$), GOST (State Standard) 14922–77; aluminoaerosil with a weight content of aluminum oxide equal to 3% and a specific surface area of 200 $m^2 g^{-1}$ (AA-200); and aluminoaerosil with a weight content of aluminum oxide equal to 4% and a specific surface area of 90 $m^2 g^{-1}$ (AA-90), TU (Technical Specification) U 88 251-02–84.

As precursors of the catalytically active metals were used metal stearates of composition $Fe_2^{III}(OH)_2St_4$, $CoSt_2$, and $Fe^{II}Sn^{IV}(OH)_2St_4$, synthesized by precipitation from an aqueous solution. The synthesis procedures were described in detail in [18].

X-ray diffraction patterns were recorded with a DRON-3 diffractometer; thermogravigrams, on a Q-1500D derivatograph; and electron micrographs, on JEM-100 CXII transmission electron microscope.

A vibration mill with steel balls was used for mechanochemical distribution of organic compounds of metals on aerosils. It was established in control experiments that, under the experimental conditions, the transfer of iron from the balls to a substance being treated is insignificant and has no effect on the catalytic activity.

After a mechanochemical distribution of metal stearates on aerosils, a thermal treatment was performed to remove organic groups. Upon a thermal treatment in air at 600°C, organic substances and the remainder of carbon completely burned out. However, it was found in a number of experiments that the catalytic activity in CNF formation markedly increases if the catalysts contain an admixture of carbon produced in carbonization of organic groups. For this purpose, the mixture subjected to a mechanochemical treatment in a vibration mill (MCT), was thermally treated at 250°C for several hours with a restricted access of air, and then a finishing thermal treatment at the working temperature of CNF synthesis (620°C) was carried out in a flow of argon. The thus treated catalysts had a black-brown coloration because of the formation of carbon. In the process, the oxidation catalyzed by iron or cobalt contained in the samples led to a partial burning-out of organic substances with a loss of mass equal to 30–70% relative to the mass of organic groups in the starting material.

The catalysts produced by the procedures described above had a bulk density of 120–200 g dm^{-3}. To obtain less dense catalysts, aerosil was added and the mixture was treated for several minutes in a mixer with a rotation frequency of the cross-shaped blade of 10000–15000 rpm. In this case, the bulk density decreased to 50–60 g dm^{-3}. The thus loosened catalysts provided fabrication of CNF in the form of a lightweight powder without agglomeration into lumps.

CNF were synthesized in a 2.1-dm^3 cylindrical quartz reactor in which the catalyst bed was agitated via rotation of the reactor at a rate of 60–90 rpm. The reactor design was described in detail in [18]. A gas mixture (hydrogen + argon + acetylene) was fed into the reactor. The working temperature was 620°C. The conversion of acetylene into carbon was qualitatively monitored by the coloration of the flame of burning waste gases. If the catalyst was sufficiently active, the flame was small and virtually colorless, because nearly pure hydrogen came out of the reactor. If, however, the conversion of acetylene was incomplete, the flame was large, bright yellow, and smoking. In this way, the activities of different catalysts could be qualitatively compared and the variation of their activity with time could be monitored. In most cases, the catalyst activity increased during the first 5–10 min of operation (probably, metal oxides were reduced by hydrogen) and then remained high (virtually 100% conversion of acetylene) for at least 3 h for good catalysts. In some cases, oligomerization of acetylene to give smoke at the reactor outlet was observed for low-activity catalysts.

The carbon products obtained were purified by their treatment with solutions of an alkali (to remove the aerosil) and hydrochloric acid (to dissolve metals and metal oxides). The purification procedure was described in detail in [18]. The weight content of ash in the purified samples did not exceed 1–2%.

Table 1 presents the composition, preparation procedure, and catalyst properties.

As can be seen from Table 1, the catalysts fabricated by the mechanochemical method are very lightweight powders with a bulk density of 120–200 g dm^{-3} without addition of a loosener, and 50–60 g dm^{-3} with a loosener. Thus, they have a large free volume for CNF growth. One more advantage of the mechanochemical method is that no organic solvents are used and a considerably wider variety of organic compounds of metals can be employed, including those nonvolatile and insoluble in water and organic solvents.

Table 2 illustrates the synthesis modes and properties of CNF obtained using the catalysts described above. The process was carried out at 620°C. If there is no indication of a loss of activity by a catalyst by

* ACO, autocatalytic oxidation at 250°C.

** Mass content of catalytically active metals is given with the mass of loosener disregarded.

the end of the process, its activity did not decrease during the chosen reaction time. If there is no indication of smoke formation, no smoke was observed at the reactor outlet.

A comparison of the results obtained in tests of catalyst nos. 1 and 2 (Table 2) shows that the catalytic activity markedly increases (with virtually 100% conversion of acetylene into carbon during the entire process) if autocatalytic oxidation (ACO) is followed by further thermal treatment in the mode of carbonization of organic substances (catalyst no. 2). Moreover, the specific surface area of the resulting carbon material markedly increases, from 116 $m^2 g^{-1}$ (catalyst no. 1) to 210 $m^2 g^{-1}$ (catalyst no. 2).

Catalyst nos. 3 and 4 are similar to catalyst nos. 1 and 2, but contain cobalt, instead of iron, as a catalytically active metal. In this case, too, thermal treatment after ACO in the mode of carbonization of organic substances (catalyst no. 3) leads to a certain increase in the yield of the carbon product and to a considerable rise in the specific surface area, compared with catalyst no. 4, in which organic substances were completely burned-out in air at 600°C.

It may be assumed that carbon clusters formed in carbonization of organic substances hinder coarsening of clusters of catalytically active metals and their oxides and thereby favor growth of finer CNF with a high specific surface area. Possibly, nuclei of carbon nanostructures are formed already in the course of thermal treatment of a catalyst in an oxygen-free medium.

Also, experiments devoted to comparison of the activities of the same catalysts in reactions of formation of CNF from acetylene and CNT from ethylene were carried out. The conditions in which CNT are obtained from ethylene have been described previously [19]. It was found that an admixture of carbon in the catalyst, which raises the catalytic activity and specific surface area of CNF in the system with acetylene, completely suppresses the catalytic activity in the reaction of CNT deposition from ethylene. Further, iron- and tin-containing catalysts were found to be virtually inactive in the system with ethylene. These data indicate that the mechanisms of these processes are markedly different.

Iron-containing catalyst nos. 5 and 6 were obtained in about the same thermal treatment modes, but with

different dispersed metal oxides as supports: aluminoaerosil AA-200 (catalyst no. 5) and aerosil A-300 (catalyst no. 6). Comparison of the results obtained in tests of these catalysts (Table 2) shows that use of aerosil A-300 as a support (catalyst no. 6) leads to a lower activity of the catalyst and incomplete conversion of acetylene, with the specific surface area of the carbon product decreasing. A comparison can also be made with catalyst no. 2, prepared using aluminoaerosil AA-90 at a somewhat lower content of iron.

To explain this phenomenon, it should be noted that aluminoaerosil contains on the surface of its particles rather strong acid centers, which are absent in the unmodified aerosil. These acid centers may be of both Brönsted (proton donors) and Lewis (acceptors of an electron pair) types. It is also known that Brönsted acid centers on the surface of mixed metal oxides eliminate water at high temperature to become Lewis centers. It can be assumed that presence of acid centers on the surface of support particles results in that clusters of a catalytically active metal (iron in the given case) interact with these centers with a partial transfer of the electron density to acceptor centers of the substrate. This stabilizes metal clusters and prevents their coarsening (and the ensuing decrease in their catalytic activity) through migration of metal atoms. It can also be assumed that, owing to the presence of Brönsted acid centers in the initial aluminoaerosil, organic compounds of iron interact with these centers in the course of MCT by the mechanism of ion exchange of a proton for a metal cation. This favors fixation of stearate clusters and, then, of the oxide of a catalytically active metal on the surface of aluminoaerosil particles.

Catalyst nos. 7 and 8, which contain tin and iron, differ in the mode of the ACO procedure. Comparison of the test results shows that ACO in a rotating reactor (catalyst no. 8, air passed through the reactor at a flow rate of 200 $cm^3\ min^{-1}$) yields a carbon product with a larger specific surface area (475 $m^2\ g^{-1}$) than that obtained upon ACO in a fixed bed (catalyst no. 7, 340 $m^2\ g^{-1}$). This is possibly due to the higher homogeneity of the product obtained with agitation of the catalyst in the course of ACO and to weaker aggregation of particles. In these systems, tin, which is not active by itself in the reaction of vapor-phase deposition of CNF, affects the structure of the forming CNF. Addition of tin makes it possible to obtain a carbon product with a large specific surface area and coil-like shape of fibers, as it is shown below in discussion of electron micrographs.

In fabrication of catalyst nos. 9 and 10, previously synthesized carbon fibers were used as a dispersed inorganic support. The catalytic activity of such a catalyst is very high, as can be seen from the results of tests. In this case, no mineral components are introduced into the system, with the exception of a minor amount of a catalytically active metal (iron), which markedly simplifies the purification of the carbon product or even makes it possible to do without purification if there are no stringent requirements to the content of mineral impurities. Introduction of a loosener (aerosil A-300, catalyst no. 10) prevents aggregation of particles of the carbon product in the course of synthesis and makes larger the specific surface area of the material.

Figure 1 shows TEM micrographs of a raw carbon material obtained using a tin-and-iron-containing catalyst no. 7. It can be seen that the material is mostly composed of nanofibers 50–200 nm in diameter, with a characteristic interweaving of the fibers into coils. It can be assumed that mobilization of nanofibers because of the agitation of the catalyst bed cor-

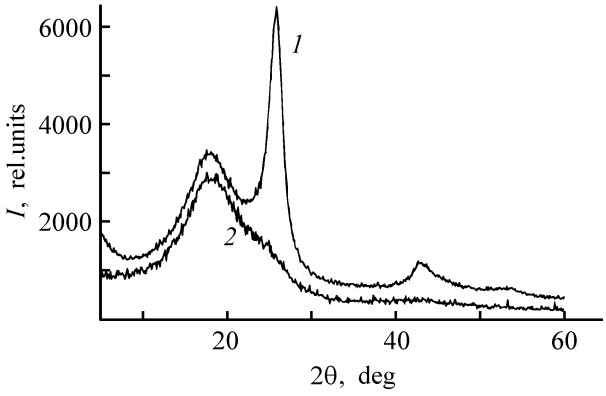

Fig. 5. X-ray diffraction patterns of purified nanofibers obtained on catalyst nos. (*1*) 5 and (*2*) 8. Cu_{K_α} radiation. (I) Intensity and (θ) Bragg angle.

responds to such an interweaving. The agitation results in that separate nanofibers collide in the course of growth and adhere to form a bundle under the action of intermolecular forces.

Figure 2 shows an electron micrograph of purified CNF obtained on catalyst no. 8 (with composition identical to that of catalyst no. 7, but a somewhat different ACO mode). It can be seen that nanofibers are composed of finer structural elements, which are poorly resolved by the available instrument. Possibly, these are bundles of thinner primary nanofibers or aggregates of bent graphene layers with pores in between.

The same fine structure is observed for nanofibers grown on the iron-containing catalyst no. 5 (Fig. 3).

Figure 4 shows thermogravigrams of purified carbon nanofibers obtained using catalyst nos. 5 and 8. It can be seen that these materials start to be oxidized in air at a noticeable rate at temperatures exceeding 500°C. As would be expected, the material with a larger specific surface area (catalyst no. 8) burns faster than catalyst no. 5. At the same time, it is known that amorphous carbon is rather rapidly oxidized in air even at 350–400°C. These data indicate that the admixture of amorphous carbon in the carbon materials obtained is insignificant. At the same time, the bends in the thermogravigrams indicate that carbon modifications with different types of structure are present in the samples.

Figure 5 shows X-ray diffraction patterns of purified carbon nanofibers obtained using catalyst nos. 5

and 8. It can be seen that the curve for sample no. 5 has two peaks at 2θ 17.9° and 25.9°, the second of which corresponds to an interplanar spacing of 3.44 Å in packets of turbostrate-disordered graphene layers. This peak is also characteristic of multi-walled carbon nanotubes. The structure of the phase corresponding to the first, broad peak (interplanar spacing of about 5.0 Å) is unclear. According to the X-ray pattern, sample no. 8 is entirely composed of this phase.

Thus, carbon fibers with different types of structure are obtained, depending on the catalyst composition, by chemical vapor deposition with the use of acetylene. The CNF obtained are promising for use in energy-storage devices. An activation of a carbon nanofiber synthesized from acetylene on a $Fe/C/SiO_2$ catalyst with molten potassium hydroxide yielded a carbon material with a specific surface area of 1700 $m^2 g^{-1}$ and a high electrical conductivity, which is promising for use in chemical power cells [20].

CONCLUSIONS

(1) The mechanochemical method makes it possible to obtain efficient catalysts for vapor-phase deposition of carbon nanofibers from acetylene.

(2) Thermal treatment a precursor of a catalyst in the mode of carbonization of organic groups markedly raises the catalytic activity and specific surface area of the forming carbon nanofibers.

(3) Introduction of tin into an iron-containing catalyst makes it possible to raise the specific surface area of carbon nanofibers to 475 $m^2 g^{-1}$. In this case, the peak at 3.44 Å, which corresponds to packets of graphene layers, disappears from the X-ray diffraction pattern of fibers.

CATALYSIS

Effect of Synthesis Conditions on Composition and Properties of Microspherical Catalyst for Polymerization of Propylene

V. P. Nekhoroshev, N. S. Ushakova, A. V. Nekhorosheva, and S. V. Ruban

Tomsk State University, Tomsk, Russia

Received January 31, 2005

Abstract—Experimental data on the influence exerted by the synthesis conditions on the composition and properties of a microspherical catalyst for polymerization of propylene are presented. The possibility of using this catalyst for synthesis of noncrystalline propylene polymers is demonstrated.

The problem of cost-efficiency and competitiveness of the product are commonly solved in manufacture of polypropylene in two ways, by using more efficient catalytic systems based on titanium-magnesium catalysts and by setting-up production of noncrystalline propylene polymers, which are in high demand on the market [1]. The first way requires a gross investment for reconstruction of a shop for synthesis of the catalyst and for licensing [2], and the second involves laboratory investigations. Despite that a single-stage synthesis of a microspherical catalyst (MSK-1) for propylene polymerization has been developed and brought to a commercial level [3], no scientific papers devoted to the influence exerted by the synthesis conditions on the composition and properties of MSK-1 have been published [4]. This is due to the fact that leading scientists and specialists in synthesis of catalysts for propylene polymerization have long believed that a single-stage synthesis of the catalyst is impossible, because low-temperature reduction of $TiCl_4$ with diethylaluminum chloride (DEAC) to $TiCl_3$, performed in three stages (MSK-3), is a more promising process for technological applications [5–7]. The idea of mixing all the reagents in the same reactor in a single stage in the course of 8–9 h was considered absurd and contradictory to the scientific concept of a prolonged multistage synthesis of MSK-3, controllable in many parameters [7]. As a scientific substantiation of the synthesis of MSK-3 can serve the general tendency toward a decrease in the reactivity of $TiCl_4$ and the reducing agent [DEAC or triethylaluminum (TEA)] via their preliminary binding into a donor–acceptor complex with an electron-donor compound (EDC). This idea proved to be fruitful and was confirmed virtually in the very first syntheses with dibutyl sulfide (DBS), dibutyl ether (DBE), diisoamyl ether (DIAE), and toluene as EDC. This made it possible to rule out use of low temperatures (down to –15°C), considerably shorten the time of synthesis, and simplify the technology of the process [8].

Synthesis of MSK-1, performed in a single stage in a hydrocarbon solvent, includes several steps. These are reduction of $TiCl_4$ with a DEAC complex in the presence of EDC, thermal treatment of the reduction products at an elevated temperature, settling with the subsequent decantation of the liquid phase and washing of the catalyst with a solvent, and discharging of the catalyst suspension with its simultaneous packaging.

In the course of synthesis, the most important parameters of the catalyst: activity, stereospecificity, and granulometric composition of its particles, are controlled. The reaction of $TiCl_4$ reduction in the presence of an aliphatic ether R_2O occurs by the scheme

$$TiCl_4 \cdot 0.2R_2O + 0.32(C_2H_5)_2AlCl \cdot 0.46R_2O$$

$$\rightarrow TiCl_3 \cdot 0.02AlCl_3 \cdot 0.05TiCl_4 \cdot 0.19R_2O \cdot Q,$$

where Q is the unidentified organic part of the catalyst, which constitutes 8.0–14.0 wt %; possibly, the main substance are oligomers of ethylene, formed in the course of the reaction.

The composition and properties of MSK-1 are affected by the synthesis conditions: relative content of the reagents, temperature mode of reduction and thermal treatment, and composition of the catalytic system

1070-4272/05/7806-0931 © 2005 Pleiades Publishing, Inc.

used in propylene polymerization. The primary role in synthesis of MSK-1 is played by processes of DIAE complexation with electron-acceptor compounds present in the reaction mixture, because the coloration of the reaction mass continuously changes in the course of synthesis: brown → green → brown → dark cherry. A characteristic feature of the synthesis is that the excess of the forming $AlCl_3$ passes in the form of ternary donor-acceptor complexes with an ether, of composition $TiCl_4 \cdot AlCl_3 \cdot 2(i\text{-}C_5H_{11})_2O$, into the solvent (heptane) and is removed together with the liquid phase in decantations and washing of the catalyst with the solvent. Commonly, such stable complexes have a large dipole moment and are strongly polar and insoluble in hydrocarbon media [8].

The goal of the present study was to examine the influence exerted by the synthesis conditions on the composition and properties of MSK-1 in order to determine the possibility of its use to obtain noncrystalline propylene polymers.

EXPERIMENTAL

MSK-1 was synthesized from $TiCl_4$ of special-purity grade, DIAE with the content of the main substance and isomers of no less than 99.9%, and DEAC with a content of butyl groups of no less than 2.0%. Compounds of DEAC and TEA were used in the form of 15% solutions in heptane; the chlorine-to-aluminum ratio was varied by adding a calculated amount of TEA to DEAC. As solvents in synthesis of the catalyst were used reference heptane, regenerated heptane, and cyclohexane, all dried over calcined zeolite of NaA and NaX brands. An inert atmosphere was created using dried argon with a purity of no less than 99.9%. The laboratory installation used to synthesize the catalyst comprises a four-necked flask with a stirrer and a thermostat filled with Vaseline oil. The flask is equipped with a pocket for a thermocouple, dropper for batching of the reducing agent, and connection pipes for input and discharge of the inert gas. After the batching of DEAC is complete, the dropper is replaced with a movable siphon through which the mother liquor and washing solution are discharged. The temperature is recorded with a KSP-4 instrument. Prior to the beginning of the synthesis, the reactor is purged with the inert gas for 30 min. The finished catalyst is discharged into ampules in the form of a suspension in a solvent, and the ampules are hermetically sealed. The catalyst has a dark violet color and contains spherical $TiCl_3$ particles 10–40 μm in size.

The general procedure for synthesis of MSK-1 consists in the following [9, 10]. A glass reactor is charged with 80 ml of a solvent, 64 ml of $TiCl_4$, and 22.5 ml of EDC. Another glass vessel is charged with 120 ml of the solvent, 20 ml of DEAC (in terms of the 100% concentration), and 58 ml of EDC. The $TiCl_4$ solution is heated in the reactor under stirring (240 rpm) to 25–50°C and a complex of DEAC with EDC is gradually added dropwise in the course of 4 h. The reaction mixture in the reactor is agitated for 1 h at 35°Cand then heated to 85–100°C in the course of 1.5 h and kept at this temperature for 2 h. The stirrer is switched off and, after 10 min of settling, the mother liquor is decanted from the reactor at 90°C with a retractable siphon. The catalyst obtained is thrice washed with the solvent (a 200-ml portion each time) at 65°C. To improve the granulometric composition of the catalyst, a employed batching of the DEAC : EDC complex is performed as follows. First, 20 ml of the complex is poured-in (about 10.0 vol %) in the course of 5 min, the reaction mixture is allowed to stand for 20 min for crystallization nuclei to be formed, and then the remaining part of the complex is measured out at a rate of 0.65 ml min^{-1}.

Propylene was polymerized in a 0.7-l stainless steel reactor with a stirrer and a heating jacket at 70°C and a pressure of 0.4 MPa, with the polymerization time equal to 5 h. The polymerization procedure was described in detail in [11]. The granulometric composition of the catalyst was determined by the known procedure [12] and that of the polypropylene powder, by sieving. The content of DIAE in MSK-1 was found by decomposition of the catalyst suspension with water, with the subsequent extraction of the ether released with heptane; the content of the ether in the extract was determined by gas–liquid chromatography. The stereoisomer composition of polypropylene was determined by extraction with, first, cold (25°C, 12 h) and then boiling heptane (98°C, 8 h). IR spectra of the polymers were measured on an Impact 410 Nicolet IR Fourier spectrometer, using the method of multiple frustrated total internal reflection on a zinc selenide crystal. The conditions under which the IR spectra were recorded were as follows: number of scans 36, resolution 4 cm^{-1}, amplification 4, scanning frequency 0.6329, aperture 35, detector DTGS KBr, scanning range 4000–650 cm^{-1}. The IR spectra were processed using the Omnic software. Polymer samples were identified using the computer database of IR spectra, with a special software employed to calculate the degree of coincidence of two spectra. The softening point of the polymers was determined by the ring-and-ball method, the dynamic viscosity was measured with a Brookfield programmable viscometer, and the penetration was found in accordance with TU

(Technical specification) 2211-056-05796653–98. The noncrystalline propylene polymers used to manufacture bituminous-polymeric binders at the Izofleks plant (Kirishi) were supplied by ALPHAMIN Co. (Belgium) (Table 1).

Polymer sample no. 1 (Table 1) is a mechanical mixture of isotactic and atactic polypropylene in approximately equal amounts. The degree of coincidence of the IR spectrum of this polymer with the spectra of isotactic and atactic polypropylene from the database is 88.4 and 87.3%, respectively (see Fig. 1a). A specific feature of the spectrum of sample no. 1 is the presence of a broad low-intensity band peaked at 1649 cm^{-1}, associated with stretching vibrations of olefin double bonds. This indicates that the polymer was preliminarily subjected to a prolonged thermal destruction at 300°C [13]. The polymer is supplied as 6-mm-thick plates. The whole set of the above data indicates that the noncrystalline propylene polymer of S-10 brand is manufactured at a plant employing the first-generation technology with a low-stereospecific catalytic system.

Polymer sample nos. 2 and 3 have an anomalously high melt viscosity and rather high softening points and penetrations, which is characteristic of noncrystalline copolymers of propylene and ethylene. They are exceedingly well mixed with molten bitumen at 180°C. The polymer of RSC brand corresponds to a block-copolymer of propylene and ethylene (degree of coincidence of the spectra 89.5%), and that of AAC brand, to a noncrystalline propylene copolymer containing 54 mol % ethylene units in the chain (degree of coincidence of the spectra 90.4%). The IR spectra of these polymers (see Figs. 1b, 1c) show an increase in the relative intensity of the bands peaked at 721 and 723 cm^{-1} [pendulum vibrations of the C-H bond in the methylene groups $(CH_2)_{n \geq 3}$]. This fact, combined with the increase in the relative intensity of the absorption band at 1376 cm^{-1} (deformation vibrations of methyl groups), indicates that methylene side chains C_4–C_8 are present in the form of alkyl branchings [14] formed in the course of polymerization in the presence of a third comonomer, α-olefin C_4–C_8. The branching of the ternary copolymer accounts for the anomalous properties of sample nos. 2, 3 (Table 1), i.e., the exceedingly high viscosity of the melts at an increased penetration, which imparts caoutchouc-like highly elastic properties to the copolymers.

The effect of the reagent ratio on the composition and properties of MSK-1 is illustrated in Table 2. The composition of MSK-1, having the general formula $TiCl_3 \cdot n_1AlCl_3 \cdot n_2TiCl_4 \cdot n_3R_2O \cdot Q$, varies

tion of the catalyst (compared with DBE). Probably, the key role is played by the 3*D* branching and length of the aliphatic chains in the ether, which creates an additional steric hindrance in orientation of the monomer on a catalytic center. An increased yield of the atactic polypropylene is observed at a small $TiCl_4$: DEAC ratio (Table 2, run no. 1). The overall molar ratio of the reagents is maintained within $TiCl_4$: DEAC : ether = (3.4–3.7) : 1.0 : (2.1–2.5). $TiCl_4$ is reduced with DEAC containing up to 11.0 mol % ethylaluminum dichloride (EADC) or up to 20.0 mol % TEA.

An specific feature of the MSK-1 formulation consists in the increased content of the organic part (the content of the ether and ethylene oligomers combined is as high as 30.0 wt %) and of an admixture of cocrystallized $TiCl_4$. This provides its increased (by a factor of 6–7) poison resistance to impurities in the solvents used in the stages of synthesis and polymerization of propylene (alcohols, water, aromatic hydrocarbons, unsaturated and sulfurous compounds. The MSK-1 catalyst has a virtually uniform granulometric composition (96% of catalyst particles are 10–40 μm in size), which makes it possible to obtain an isotactic polypropylene powder with a high bulk density (420–500 g dm^{-3}) and a narrow granulometric distribution (92–100% of catalyst particles 250–710 nm in size). The technology of synthesis is simpler because there is no need to use low temperatures, the process is single-stage, and the regenerated heptane fraction of oil, which is widely used in polymerization of propylene, serves as a solvent in synthesizing the catalyst. If DEAC containing an admixture of TEA (up to 20 mol %) is used as a reducing agent, the yield of MSK-1 increases by 40%, which lowers its production cost by 25% [10]. In addition, MSK-1 has a 1.5 times higher thermal stability (compared with MSK-3), which allows propylene polymerization at higher temperatures, up to 90°C [15].

The temperature mode of reduction and thermal treatment strongly affects the streospecificity of MSK-1, and this can be used in synthesis of noncrystalline propylene polymers (Table 3).

Raising the reduction temperature from 25 to 50°C and that of thermal treatment to 100°C makes lower the yield of the catalyst in synthesis and diminishes its activity in polymerization of propylene (run no. 7). The catalyst synthesized without thermal treatment at an elevated temperature (run no. 8) has a low stereosopecificity and a sufficiently high activity in polymerization. The increased yield of the catalyst in this synthesis is due to the presence of a considerable amount of $AlCl_3$ in its composition.

The composition of the catalytic system used in propylene polymerization strongly affects its stereospecificity [16]. At a mass ratio DEAC : MSK-1 = 3 : 1 and less in the polymerization reactor, the yield of atactic polypropylene increases to 9 wt %.

Thus, the catalytic system for propylene polymerization and for synthesis of noncrystalline copolymers of propylene with ethylene and α-olefins, based on MSK-1 and having a low stereospecificity, should prepared with a mass ratio DEAC : MSK-1 = 2.5 : 1. The low-stereospecific MSK-1 is synthesized under the following conditions: molar ratio $TiCl_4$: DEAC : DIAE = 3.1 : 1.0 : 2.1, reduction temperature 25–35°C, no thermal treatment in synthesis. A propylene homopolymer obtained on MSK-1 under the conditions specified is subjected to initiated thermal destruction at 250°C in the presence of 0.1 wt % dicumyl peroxide for 4 h by the procedure described in [13]. The polymer obtained contains 32 wt % atactic fraction soluble in cold heptane, 55% fraction soluble in boiling heptane, and 45% isotactic fraction. The IR spectra and properties of the resulting noncrystalline propylene homopolymer correspond to those of S-10 brand (Table 1), which confirms the possibility of industrial synthesis of noncrystalline propylene polymers. With account of the high cost of noncrystalline propylene polymers ($1000 per ton) and posssibilty of their export in large amounts, the technique suggested for their synthesis on MSK-1 is economically sound.

CONCLUSIONS

(1) The influence exerted by the synthesis conditions on the composition and properties of the MSK-1 catalyst for propylene polymerization was experimentally studied. It was shown that a catalyst for propylene polymerization, having a low stereospecificity, can be obtained on the basis of MSK-1.

(2) Noncrystalline propylene homopolymer, having the necessary set of service characteristics, was synthesized.

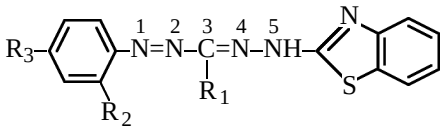
Abstract—New copper(II) benzothiazolylformazane complexes were synthesized and immobilized on AN-18 anion exchanger. The influence of the composition of the coordination core of copper(II) benzthiazolylformazanates and temperature on their catalytic properties in decomposition of H_2O_2 and oxidation of Na_2S in aqueous solution was studied.



Development of heterogenized catalysts with a high concentration of active centers of known composition is an efficient way to obtain stable catalysts with a good reproducibility and high activity. The composition of active centers of such catalysts is similar to that of active centers of homogeneous catalysts; however, the active centers themselves are chemically bound with one or more ligands fixed on an insoluble support. Such complex catalysts combine properties of both homogeneous complexes (possibility of varying the type of the central atom and its ligand environment) and heterogeneous systems (formation of coordination-saturated structures on the support surface [1]). Ion exchangers of various types are widely used as solid supports. Their modification with functional complexing groups allows synthesis of new catalysts [2].

Anion exchangers with hetarylformazane groups have been prepared previously [3, 4], and it was shown that the formazan structure and the synthesis procedure substantially affect the catalytic activity of metal–formazan complexes in decomposition of H_2O_2 in aqueous solutions and liquid-phase oxidation of Na_2S.

In this study, we prepared certain copper(II) benzothiazolylformazanates and examined their composition and catalytic properties at various temperatures in the same reactions.

EXPERIMENTAL

To synthesize copper(II) complexes to be immobilized on the polymeric support, we used 1-aryl-3-alkyl-5-benzothiazolylformazans **I**–**III**:

where R_1, R_2, R_3 are CH_3, H, 4-SO_3H (**I**); CH_2Br, H, H (**II**); and CH_2Br, OH, 4-NO_2 (**III**), respectively.

It is known [5] that hetarylformazans are rather labile polydentate ligands and can form metal complexes of various compositions and structures depending on the substituent in 1-, 3-, and 5-positions.

First, the complexation of compounds **I**–**III** with copper(II) acetate in solution was studied by spectrophotometric titration. This method allows direct monitoring of the complexation process and calculation of the stoichiometry of the complexes formed [6, 7].

The clearest spectral pattern is observed with formazan **I**. In the course of titration of the ethanolic solution of this compound ($c_{\mathbf{I}} = 3 \times 10^{-5}$ M) with a copper(II) acetate aqueous solution ($c_{CuAc_2} = 10^{-3}$ M), the intensity of the absorption band of the initial formazan (λ_{max} = 430 nm) gradually decreases, and

1070-4272/05/7806-0936 © 2005 Pleiades Publishing, Inc.

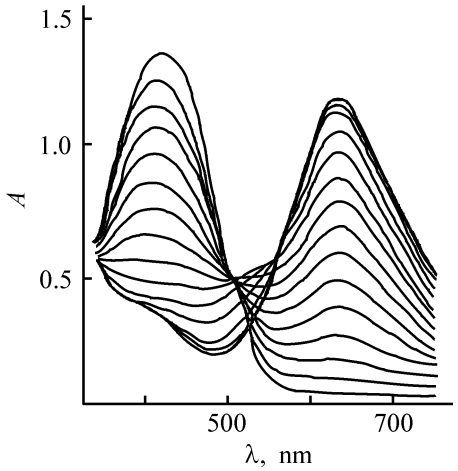
that of the band at λ_{max} = 640 nm grows (Fig. 1). The spectral curves intersect at two isobestic points of titration, which indicates formation of two complexes. The complex with L : M = 2 : 1, showing a broadened band at 470–500 nm, and 1 : 1 complex with λ_{max} = 640 nm are formed when the copper(II) salt is in deficiency and excess, respectively.

Titration of formazan **II** with copper(II) acetate solution is also accompanied by a decrease in the intensity of the band of the initial compound (λ_{max} = 370 nm) and by appearance of a weak band at 610 nm. Only one isobestic point is observed in the titration curves, which corresponds to formation of the CuL complex. In the case of formazan **III**, the spectral pattern for titration with the copper(II) salt is more complex and cannot be interpreted unambiguously.

Based on the spectrophotometric titration data, we synthesized crystalline complexes of copper(II) with formazan **I** at L : M ratio of 1 : 1 and 2 : 1 complexes **IV** and **V**, with formazan **II**, at L : M = 1 : 1 complex **VI**, and with formazan **III**, at L : M = 1 : 1 and 2 : 1 complexes **VII** and **VIII** (Table 1).

Copper(II) formazanates **IV**–**VIII** were prepared by the following general procedure. To a solution of 0.15 mmol (or 0.30 mmol) of formazan in a minimal amount of ethanol (or aqueous ethanol for formazane **I**), a solution of 0.15 mmol of copper(II) sulfate in the minimal amount of water was added at 40°C with stirring, and the mixture was left for 1 h. The precipitate thus formed was filtered off, washed with water, and dried.

It follows from the elemental analysis that complexes **IV**, **VI**, and **VII** have the composition CuL, and **V** and **VIII**, CuL_2 (Table 1). All the compounds are crystal solvates with ethanol. The electronic absorption spectra of complexes **IV**–**VIII** in ethanol are similar to the spectra of Cu(II) formazanates obtained in titration of formazans **I**–**III**.



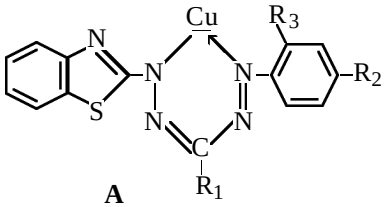


Fig. 1. Electronic absorption spectra of formazan **I** in ethanol in titration with aqueous solution of copper(II) acetate. $c_{\mathbf{I}} = 3 \times 10^{-5}$ M, $c_{CuAc_2} = 10^{-3}$ M, (λ) Wavelength; (*A*) transmittance.

The ESR spectra of copper(II) formazanates in toluene [8] suggest formation of a $Cu|4N|$ distorted tetrahedron for **V**, $Cu|4N|$ square-planar structure for **VIII**, and mixed nitrogen–oxygen $Cu|3N,O|$ structure for **VII**.

Our and published (for similar ligands [5]) data suggest structure **A** for copper(II) formazanates **V** and **VIII**:

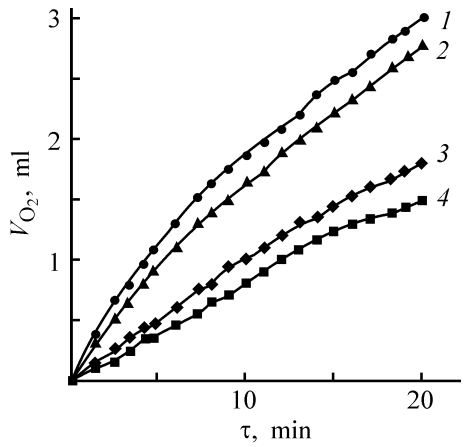

Fig. 2. Kinetic curves of decomposition of 1% H_2O_2 aqueous solution in the presence of copper(II) formazanates. T = 20°C, V_Σ = 27 ml, and c_{Cu} = 0.01 M. (V_{O_2}) oxygen volume and (τ) reaction time. Compound: (*1*) **VIII**, (*2*) **VII**, (*3*) **VIIIp**, and (*4*) **VIIp**; the same for Fig. 3.

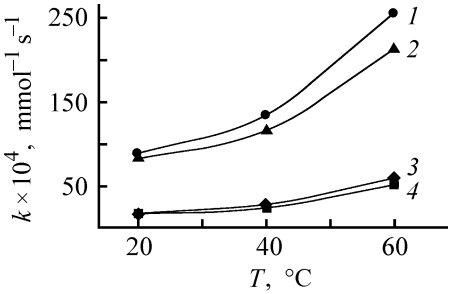

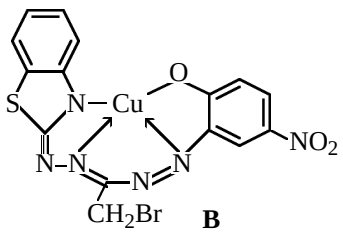

Fig. 3. Temperature (T) dependence of the rate constant of H_2O_2 decomposition (1% aqueous solution) in the presence of copper(II) formazanates.

The structure of complexes **IV** and **VI**, corresponding to the composition L : M = 1 : 1, is probably formed by additional coordination of $CuSO_4$ to nitrogen atoms of the benzothiazole fragment.

For complex **VII**, the structure **B** is the most probable:

B

To obtain metal complexes suitable for heterogeneous catalysis, we immobilized formazanates **IV**–**VIII** on AN-18 styrene-divinybenzene anion exchanger. The presence in its structure of primary and secondary amino groups allowed immobilization of formazanates **IV** and **V** containing sulfonate group in the ligand by ion exchange and of complexes **VI**–**VIII** containing labile bromine by covalent bonding.

Immobilization of Cu(II) formazanates was performed as follows. To a solution of **IV** in ethanol, a sample of AN-18 anion exchanger was added so that the copper ion concentration in the polymer was 0.01 mmol g^{-1}, and the mixture was stirred to complete decolorization of the solution. The modified anion exchanger was filtered off, washed with ethanol, and dried in air. In such a way, formazanate **IVp** was prepared. Similarly, formazanates **V**–**VIII** were immobilized to obtain catalysts **Vp**–**VIIIp**, which exhibit a high activity and can be easily separated from the reaction products.

The ESR data show the square-planar structure of the coordination core Cu|4N| for formazanate **VIIIp** and Cu|3N, O| for **VIIp**, similarly to the initial complexes **VIII** and **VII** [8, 9]. Presumably, immobilization of formazanates **IV**–**VI** on the polymeric support does not change the structure of the coordination core.

The catalytic properties of copper(II) formazanates **IV**–**VIII** and **IVp**–**VIIIp** were studied in the model reaction of H_2O_2 decomposition (1% aqueous solution). It is known [4] that complexes containing no more than 0.01 mmol of Cu(II) per gram of the polymeric matrix have the highest catalytic activity. Therefore, we studied the catalytic activity of **IV**–**VIII** and **IVp**–**VIIIp** under the similar conditions as follows. A sample of copper(II) formazanate [([0.1 g for **IVp**–**VIIIp** and 0.0028–0.0061 g for **IV**–**VIII**) was added to 27 ml of 1% H_2O_2 aqueous solution. The reaction curse was monitored by the volume of liberated oxygen at 20, 40, and 60°C.

The kinetic curves of H_2O_2 decomposition at 20°C for **VII**, **VIIp**, **VIII**, and **VIIIp** are shown in Fig. 2. Formazanates **VII** and **VIII** exhibit a high catalytic activity in H_2O_2 decomposition, which is probably caused by the square-planar structure of the metal chelate core. Copper(II) formazanates immobilized on the anion exchanger (**VIIp** and **VIIIp**) behave similarly. It should be noted that the related metal complex systems studied in [3, 4] show lower rate constants of H_2O_2 decomposition under the same conditions (0.12–11.78 × 10^{-4} mmol^{-1} s^{-1}).

Proceeding with the previous studies [3, 4], we examined the H_2O_2 decomposition in the presence of copper(II) formazanates at 40 and 60°C. The kinetic data obtained were used to calculate the rate constants of H_2O_2 decomposition [10] (Table 2).

The temperature dependences of the rate constants of H_2O_2 decomposition for complexes **VII**, **VIIp**, **VIII**, and **VIIIp**, as examples, are shown in Fig. 3.

Table 2. Catalytic activity of copper(II) formazanates in decomposition of 1% H_2O_2 aqueous solution and liquid-phase oxidation of 0.03% Na_2S solution at various temperatures

Compound no.	$k \times 10^4$, $mmol^{-1}\ s^{-1}$ at indicated temperature, °C			Degree of conversion S^{2-}, % at indicated temperature, °C		
	20	40	60	20	40	60
IV	46.8	89.9	203.6	–	–	–
IVp	0.7	2.6	11.2	31.2	64.0	71.3
V	57.5	95.1	219.0	–	–	–
Vp	1.2	5.6	17.3	34.1	64.9	74.1
VI	42.4	71.3	162.4	–	–	–
VIp	2.9	8.3	20.4	59.9	62.8	67.1
VII	82.3	114.8	212.0	–	–	–
VIIp	16.1	23.7	51.3	32.7	54.3	74.7
VIII	86.5	133.6	254.6	–	–	–
VIIIp	17.8	27.1	58.5	38.3	58.3	73.5

As can be seen from Fig. 3 and Table 2, the decomposition rate increases with temperature. For copper(II) formazanates **IVp**–**VIIIp**, the rate constants are lower than those for **IV**–**VIII**. Probably, this is caused by partial solubility of the "free" complexes, which increases with the temperature of the reaction mixture, thereby making the reaction conditions similar those in homogeneous catalysis.

In spite of the relatively low catalytic activity of **IVp**–**VIIIp** as compared to their crystalline analogues **IV**–**VIII**, they can be successfully used in heterogeneous catalysis, since their composition and the structure of the coordination core, and hence the catalytic properties, do not change in repeated use [11].

The liquid-phase Na_2S oxidation with molecular oxygen and calculation of the degree of catalytic conversion $S^{2-} \rightarrow SO_4^{2-}$ were performed by the method described in [11]. The use of **IV**–**VIII** as oxidation catalysts was unsuccessful because of their solubility in the reaction mixture. The catalytic activity of formazanates **IVp**–**VIIIp** in liquid-phase Na_2S oxidation is virtually independent of the composition and structure of the complexes (this is characteristic of the previously studied benzothiazolylformazanates [3, 4]) and slightly changes with the reaction temperature (Table 2).

CONCLUSIONS

(1) Complexation of 1-aryl-5-benzothiazolylformazans with copper(II) was studied by spectrophotometric titration, and the stoichiometry of complexes formed was calculated.

(2) It was found that the coordination core has the $Cu|4N|$ or $Cu|3N,O|$ structure. The crystalline copper(II) complexes synthesized were immobilized on a AN-18 solid support.

(3) The catalytic activity of immobilized copper(II) formazanates was studied in comparison with the initial analogues. The complexes with the square-planar copper environment show the highest activity.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis and Antioxidative Properties of Conjugates of Dextran with 4-(4-Hydroxy-3,5-di-*tert*-butylbenzylidene)-2-phenyl-4,5-dihydrooxazol-5-one

O. Yu. Sergeeva, D. V. Aref'ev, N. S. Domnina, and E. A. Komarova

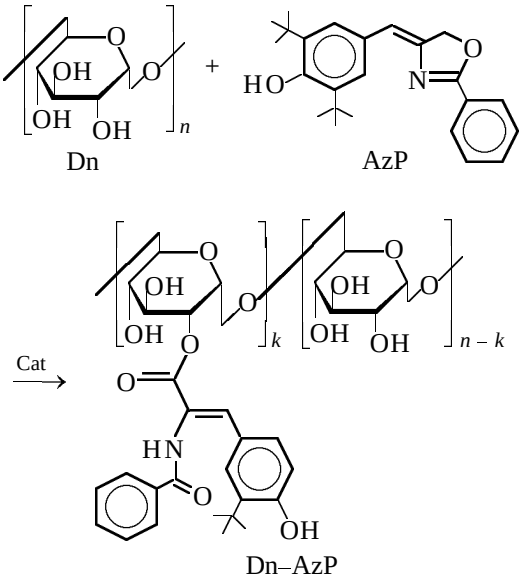
Received January 20, 2005



Abstract—The possibility of synthesis of conjugates differing in molecular weight, degree of substitution of the dextran glycoside units, and, accordingly, in the solubility in water from a hydrophilic polymer (dextran) and an azlactone derivative of a sterically hindered phenol, 4-(4-hydroxy-3,5-di-*tert*-butylbenzylidene)-2-phenyl-4,5-dihydrooxazol-5-one, was analyzed, and their antiradical and antioxidative activity was studied.

Search for, and study of biologically active substances with antioxidative properties become increasingly topical because of the important role of antioxidant-controlled free-radical processes in biological systems [1]. Among compounds exhibiting pronounced antioxidative properties and high biological activity, particular mention should be made of sterically hindered phenols (SHPs) [2]. Owing to their high antioxidative acvitivy (AOA) and nontoxicity of SHPs (Ionol, Probucol, Phenoxan, etc.), they are widely used in medicine and food industry [3, 4]. The recently developed polymeric SHP derivatives (conjugates) with hydrophilic polymers not only exhibit properties of the related macromolecular systems (prolonged effect, solubility in water, susceptibility to pH-dependent hydrolysis, etc.) [5, 6], but also show an enhanced antiradical activity (ARA), compared to the low-molecular-weight analogs. As shown in [7, 8], the high ARA of the conjugates is determined not only by the polymeric structure, but also by the structure of the spacer linking SHP to the polymer.

In this study, we suggested a procedure for preparing conjugates from dextran (Dn) and an azlactone derivative of SHP and examined the antioxidative properties of these compounds.

Dextran is a convenient polymeric carrier for immobilization of active substances, including antioxidants, owing to the presence of hydroxy groups and capacity for biodegradation in a living body.

The procedure for preparing Dn–SHP conjugates was based on acylation of alcohols with azlactones [9]. As azlactone we chose 4-(4-hydroxy-3,5-di-*tert*-butylbenzylidene)-2-phenyl-4,5-dihydrooxazol-5-one (AzP):

The most convenient solvent for modification of Dn with water-insoluble compounds is dimethyl sulfoxide

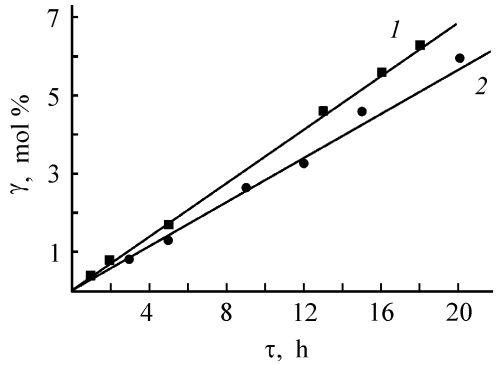
(DMSO) [10], and we used it to perform the reaction. As catalysts we chose tertiary amines: triethylamine (TEA), pyridine (Py), and *p*-dimethylaminopyridine (DMAP). Conjugates with different degree of substitution of the Dn glycoside units were prepared by varying the reactant ratio and the reaction temperature and time (Table 1). DMAP was found to be the best catalyst, and the optimal temperature was 60°C. The extent of modification of the glycoside units is virtually independent of the molecular weight (MW) of dextran (see figure). All the conjugates obtained are soluble in DMSO and in 1 : 1 (by volume) mixed solvents (water–dioxane, water–ethanol). The limiting degree of substitution of glycoside units in Dn, above which the conjugate becomes insoluble in water, is 6, 8, and 10 mol % at MW 200000, 40000, and 18000, respectively.



Thus, we found conditions in which conjugates differing in the content of SHP fragments and, accordingly, in the solubility in water can be prepared.

Sterically hindered phenols are highly reactive toward free oxygen-containing radicals, which determines their antiradical properties [2]. As shown in [11, 12], the reaction of SHPs and conjugates based on them with a water-soluble free radical, sodium salt of sulfonic acid derived from 2,2-diphenyl-1-picrylhydrazyl (DPPH–SO_3Na), can be a test for quantitative evaluation both antiradical and antioxidative properties of SHPs:

We found that the ARA in the reactions of our antioxidants with free radicals depends on the solvent polarity and, in the case of the conjugates, is also determined by the structure of the spacer between the polymer and SHP [11, 12]. As a solvent we chose aqueous dioxane (1 : 1 by volume) in which DPPH–SO_3Na,

Degree γ of substitution of glycoside units in dextran vs. reaction time τ (*T* = 60°C). Conjugates with MW (*1*) 40000 and (*2*) 200000.

the conjugates, and their low-molecular-weight analogs are soluble.

The rate constants obtained for the reaction with DPPH–SO_3Na indicate that the low-molecular-weight model (k = 1500 ± 100 l mol^{-1} s^{-1}) and, especially, the conjugates (k = 7500 ± 500 l mol^{-1} s^{-1}) exhibit high ARA. Under the same conditions, we determined the rate constans of the reaction of DPPH–SO_3Na with another conjugate, Dn–CP, containing an ester spacer (Table 2). Comparison of the constants obtained shows that just the spacer of a complex structure, with a system of conjugated bonds considerably enhances the ARA. On passing to a polar medium (water), the difference between the rate constants of the reactions of DPPH–SO_3Na with the conjugate containing an ester spacer and its low-molecular-weight analog dramatically increases. With our conjugates, we could not evaluate the ARA in water in the reaction with DPPH–SO_3Na, because this reaction occurred instantaneously when mixing the solutions.

We have shown previously that, in aqueous solutions of the conjugates, the SHP molecules covalently bound to dextran occur in the solvation shell of the polymer and react with a free radical within this shell [8]. Water forming the solvation shell of dextran exhibits a higher ionizing power [13], which, in our opinion, results in a stronger stabilization of the radical cation transition state in the conjugates, compared to the low-molecular-weight analogs. Apparently, this is the major factor responsible for the very high ARA of the conjugates.

The antioxidative activity of the conjugates was evaluated in simulating the toxic response of human cells in the presence of methyl methacrylate (MMA) toxicant [14] by the integral activity of mitochondrial respiratory enzymes. Since the activity of respiratory enzymes largely depends on the integrity of the internal mitochondrial membrane, the test results provide an indirect estimate of the extent of peroxide oxidation of lipids in cells.

Table 3 shows that MMA exerts a significant toxic effect on the total activity of the enzymes. α-Tocopherol, a well-known antioxidant, only slightly protects the enzymes from inactivation. In the presence of Phenoxan (synergistic water-soluble antioxidant), the enzymatic activity increases, and in the presence of the conjugate, it is fully preserved, which confirms the high antioxidative activity of the conjugates prepared and suggests their wider cytoprotective properties.

EXPERIMENTAL

We used dextran of linear structure (MW 18 000, 40 000, 200 000), purchased from Fluka. The sodium salt of sulfonic acid derived from 2,2-diphenyl-1-picrylhydrazyl was prepared as described in [15]. 4-(4-Hyroxy-3,5-di-*tert*-butylbenzylidene)-2-phenyl-4,5-dihydrooxazol-5-one was synthesized according to [16]. The conjugate with an ester spacer (Dn–CP) was prepared as described in [8]. Dioxane and DMSO were purified by standard procedures [17].

Dn–AzP conjugates were prepared in DMSO in the presence of a catalyst at 20, 40, 50, and 60°C. The mixture was precipitated into 2-propanol and then reprecipitated from aqueous DMSO into 2-propanol to remove low-molecular-weight impurities.

The amount of the added SHP fragments in the conjugate was determined with an SF-56 spectrophotometer (Leningrad Optical and Mechanical Association) in aqueous ethanol (1 : 1 by volume) at λ = 320 nm [18]. As a low-molecular-weight model of the conjugate, we used the related acid, β-(4-hydroxy-3,5-di-*tert*-butylphenyl)-2-benzoylaminoacrylic acid, prepared according to [16].

The ARA of the low-molecular-weight model and conjugates toward DPPH–SO_3Na was evaluated by comparing the rate constants of their reaction in aqueous dioxane (1 : 1 by volume) and in water at 20°C [19, 20]. The reaction was performed to 20% conversion of the radical at the initial antioxidant concentration of 2×10^{-5} M. The DPPH–SO_3Na concentration was determined spectrophotometrically at λ = 520 nm. The rate constants of the reactions of the conjugates and the model were calculated by the equation

$$k\tau = (y_0 - x_0)^{-1} \ln\left(\frac{x_0 y_\tau}{y_0 x_\tau}\right),$$

where k is the rate constant of the reaction of the antioxidant with the radical ($l\,mol^{-1}\,s^{-1}$); τ, reaction time (s); x_0, initial ($\tau = 0$) concentration of the antioxidant (M); y_0, initial ($\tau = 0$) concentration of the radical (M); x_τ, concentration of the antioxidant at time τ (M); and y_τ, concentration of the radical at time τ (M).

CONCLUSIONS

(1) Conjugates were prepared from 4-(4-hydroxy-3,5-di-*tert*-butylbenzylidene)-2-phenyl-4,5-dihydrooxazol-5-one and dextran of molecular weights 18000, 40000, and 200000.

(2) The conjugates show a high antioxidative and antiradical activity, compared to the known antioxidants, Phenoxan and α-tocopherol, and efficiently inhibit free-radical processes in model systems. The major role in the process is played by the spacer containing a conjugated bond chain.

ACKNOWLEDGMENTS

The authors are grateful to E.M. Eropkina (Vreden Institute of Traumatology and Orthopedics) for testing the conjugates in biological systems.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Sorbitol-Based Demulsifying Agents and Their Surfactant Properties

Abstract—Sorbitol-based block copolymers of ethylene and propylene oxides were synthesized and characterized as surfactants and demulsifiers.

The great diversity of oil production and treatment processes, as well as of the properties of produced oil, which vary not only on passing from one oil field to another, but also with time within the same oil field, make necessary a search for new high-performance demulsifiers.

An analysis of the available published data revealed that, at present time, the most efficient demulsifiers are nonionic surfactants, such as alkylene oxide block copolymers [1–3]. Nonionic surfactants are mostly synthesized from glycols, amines, synthetic fatty acids, and phenols.

Alkylene oxide block copolymers based on polyhydric alcohols have not been adequately explored as demulsifying surfactants [1–3].

Therefore, we prepared in this study sorbitol-based high-molecular-weight compounds and characterized their surfactant and demulsifying properties.

EXPERIMENTAL

In the syntheses, we used the conventional alkylene oxide addition route. First, we synthesized a prepolymer by adding 1 mol of propylene oxide (PO) per hydroxy group of the initial compound, and then PO and ethylene oxide (EO) were successively added.

Hydroxyalkylation was carried out at 120–160°C and 1.5–1.8 atm in the presence of a base catalyst.

As a result, we prepared a series of block copolymers with various hydrophobic to hydrophilic group ratios (Table 1).

The characteristic of the block copolymers that reflects the addition of ethylene oxide is the cloud point of their aqueous solutions.

When dissolved in water, nonionic substances form hydrates through hydrogen bonding between water molecules and ether oxygen atoms of the polyethylene glycol residue. With increasing temperature of the aqueous solution in which a nonionic substance is dissolved, these hydrogen bonds are broken, and the solution becomes turbid (the solute separates out as suspended droplets). After cooling, the solution becomes clear again. The cloud points of the samples obtained are listed in Table 1.

Table 1 shows that the cloud point increases with the number of the hydroxyethyl units, i.e., the number of hydrogen bonds between the EO units and water molecules.

Sample SPE80 : 20 is insoluble in water because of the high hydrophobicity, and, therefore, its cloud point has not been determined.

To determine the molecular weight, we measured the hydroxyl number by the procedure involving esterification of the hydroxy groups with acid chlorides or anhydrides. The theoretical and experimental hydroxyl numbers are also listed in Table 1.

As seen, the experimental hydroxyl numbers differ from the theoretical values, which can be attributed to formation of polyethylene glycols and also to the broad molecular-weight distribution in the resulting products. As the number of the hydroxyethyl groups added increases, the main reactions are accompanied by side reactions. On passing from step to step, both further hydroxyethylation of the polyethylene glycols present in the system and formation of new polyethylene glycols proceed. This makes more pronounced the difference between the experimental and theoretical data. However, this difference remains within the experimental error.

Among the significant characteristics of surfactants is their ability to reduce the surface tension at the interface between the solution and a gas or another liquid.

The surface tension of aqueous solution of nonionic surfactants at the interface with air, and the interfacial tension at the toluene/water interface, were measured by the ring detachment (Du Nouj) method using a LAUDA tensiometer. In this method, the force acting on an immersed body is measured electronically.

Figures 1a and 1b show the surface tension isotherms of aqueous solutions of the nonionic surfactants investigated at the air/water and toluene/water interfaces.

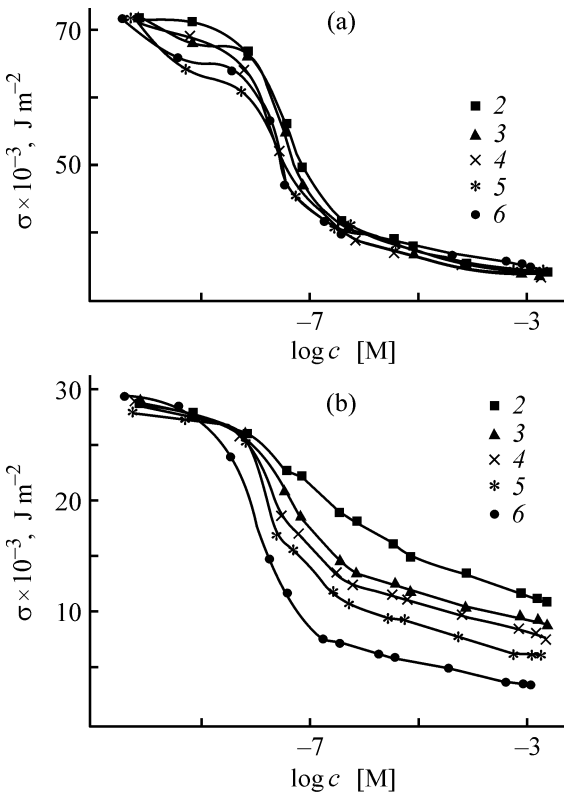

Fig. 1. Surface tension isotherms of the samples at (a) air/water and (b) toluene/water interfaces. (σ) Surface tension and (*c*) concentration. *The curve numbers* correspond to the sample numbers in Table 1.

The results show that the differences between the samples are more pronounced at the toluene/water interface, which is, most likely, due to a stronger influence exerted by toluene on the hydrophobic blocks, making less important the contribution of the steric factor.

We did obtain the isotherm for SPE80 : 20, since we failed to prepare its aqueous solution. However, we prepared a toluene solution of this sample and characterized its surfactant properties at the toluene/water interface.

There are two portions in the surface tension isotherms on passing from infinitesimal concentrations to the critical micelle concentrations (CMC). The samples demonstrate different variation ranges of the surface tension (Figs. 1a, 1b).

Petrov *et al.* [4] have shown that, in mixtures of ethers with different numbers of glycol residues, compounds with shorter polyglycol chains form micelles at a lower concentration, whereas longer-chain compounds have higher critical micelle concentrations [4]. Therefore, the surface tension isotherms level out

smoothly in our case, and the critical micelle concentration range is extended.

From the surface tension using the procedures described in [5–7] the following parameters: isotherms we estimated adsorption Γ; limiting adsorption Γ_m; work of adsorption, W_a; landing area of the molecule, S_m; and CMC.

The adsorption Γ (g-mol m^{-2}) was determined from the slope of the tangent to the initial portion of the isotherm. The slope $d\sigma/d\log c$ was then substituted in the Gibbs equation [6]:

$$\Gamma = -\frac{1}{2.3RT}\frac{d\sigma}{d\log c},$$

The limiting adsorption Γ_m (g-mol m^{-2}) was determined from the slope of the second portion of the isotherm, in which the limiting adsorption is attained. Again the slope $d\sigma/d\log c$ was substituted in the Gibbs equation [6]:

$$\Gamma_m = -\frac{1}{2.3RT}\frac{d\sigma}{d\log c}.$$

The landing area of the molecule, S_m (m^2), was estimated from the limiting adsorption [6]:

$$S_m = \frac{1}{\Gamma_m N}.$$

where N is the Avogadro number (6.02205 × 10^{23} mol^{-1}).

The work of adsorption, W_a (kJ mol^{-1}), is among the most significant characteristics of surfactants. It is the energy gain in transfer of a mole of the surfactant from the bulk to the interface [6]:

$$W_a = RT\ln\left(\frac{\Gamma}{\delta c}\right),$$

where δ is the adsorption layer thickness determined with account of the range of intermolecular forces at the interface and equal to 9×10^{-10} and 12×10^{-10} m for the air/water and toluene/water interfaces, respectively [5, 8].

The work of adsorption of the surfactants under study was estimated at the maximum dilution and extrapolated to zero concentration, i.e., for the case of ideal solution.

The CMC values were also determined from the surface tension isotherms (Tables 2, 3).

Using these data, we plotted vs. the degree of oxyethylation the limiting adsorption Γ_m; landing area of

the molecule, S_m; and work of adsorption, W_a. For the air/water and toluene/water interfaces, these plots are shown in Figs. 2, 3 and 4, 5, respectively. The resulting dependences are well consistent with the data from [5, 6, 9, 10].

As can be seen from Table 2, CMC grows, which is due to the increasing number of the oxyethyl chains in the samples (solubility increases, thus making higher the CMC).

The range of variation of the surface tension at the air/water interface with the experimental degree of oxyethylation is insignificant (Table 2), since the bulkier hydrophilic part of the molecule is retracted into the aqueous phase more strongly [5] and thereby adsorbed at the interface more weakely. We observed no decrease in the surface tension throughout the homologous series of the samples, and its insignificant increase is within the experimental error.

The dependence in Fig. 2 shows a gradual rise in the landing area of the molecule arranged in parallel to the interface. A further insignificant decrease can be attributed to stronger steric effects arising from twisting of the oxyethyl chains [9, 10]. At a low degree of oxyethylation, the hydrophilic chains are straightened in the aqueous phase, having the minimum landing area. With increasing number of the hydrophilic blocks, the oxyethyl units are twisted to form globular structures. In this case, a rise in the landing area is associated with an increase in the globule diameter. However, further growth of the oxyethyl part results in retraction of the globule into the aqueous phase, and the landing area of the molecule gradually decreases. The same factors are responsible for the changes in the limiting adsorption (Fig. 2).

The curve with a maximum, obtained for the work of adsorption (Fig. 3), may be interpreted in terms of self-association of the oxyethyl units with formation of globules [5, 10]. The resulting decreased hydration of the molecule makes lower the energy gain originating from the occurrence of the molecule in the aqueous phase, which leads to an increase in the contribution of the hydrophobic part and, accordingly, in the work of adsorption. With a further increase in the degree of oxyethylation, the solubility in water grows. The energy of globular oxyethyl chains prevails over the energy of the hydrophobic part. Evidently, this is responsible for the observed decrease in the work of adsorption.

In the case of the toluene/water interface, the indicated dependences are somewhat different.

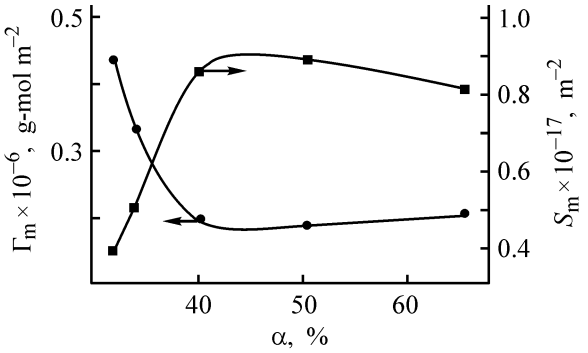

Fig. 2. Limiting adsorption Γ_m and landing area of the molecule, S_m, at the air/water interface vs. the degree of oxyethylation, α. (α) Percentage of EO in Table 1; the same for Figs. 3–5.

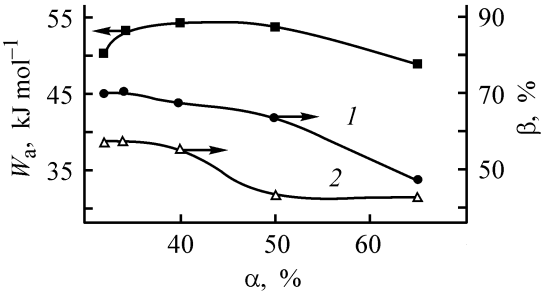

Fig. 3. Work of adsorption, W_a, and demulsifying efficiency β vs. the degree of oxyethylation, α (air/water interface). Oil field: (*1*) Elabuga and (*2*) Kaliningrad; the same for Fig. 5.

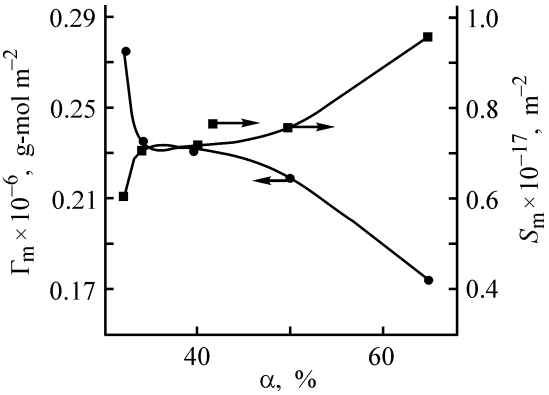

Fig. 4. Limiting adsorption Γ_m and landing area of the molecule, S_m, vs. the degree of oxyethylation α (toluene/water interface).

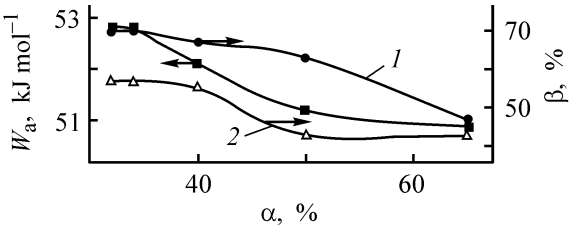

Fig. 5. Work of adsorption, W_a, and demulsifying efficiency β vs. the degree of oxyethylation, α (toluene/water interface).

Table 3 shows that, with increasing hydrophilicity of the molecule, the surface tension decreases throughout the homologous series, and CMC, by contrast, grows with the number of the oxyethyl groups added, which is associated with the enhanced hydrophilicity. The decrease in the surface tension at the toluene/water interface is more clearly pronounced, as a result of the effect of the organic solvent on both hydrophobic and hydrophilic blocks.

Figure 4 shows that the landing area of the molecule steadily increases with the amount of ethylene oxide added. This phenomenon is probably due to a different arrangement of the blocks in the molecule as compared to the case of the air/water interface. Here the hydrophobic parts of the molecules are regularly arranged at the interface, which is caused by intermolecular interaction of the surfactant molecules with water and toluene. The retraction into toluene of the hydrophilic part, in addition to the hydrophobic part, also straightens the molecular chains (in the case of the air/water interface, the chains take the shape of globules, which hinders their optimal arrangement at the interface).

The observed insignificant decrease in the work of adsorption (Fig. 5) is caused by the effect of the contacting phases on the hydrophilic and hydrophobic parts [6]. As the oxyethyl chain grows, occurrence of the molecule in the aqueous phase becomes more energetically favorable, and the fraction of the oxypropyl chains immersed in toluene decreases with respect to the total length of the molecule. As a result, the work done by the molecule on passing from the bulk to the interface decreases. The interaction of functional groups of the surfactant with the solvent hinders this transfer [11].

It was interesting to find a correlation between the demulsifying efficiency and the work of adsorption as the most relevant characteristic of the surface activity of a substance.

The demulsifying efficiency was studied using the conventional "bottle sampling" method with artificial emulsions. The emulsions (30% watering) were prepared from anhydrous coal-bearing oils from the Novo-Serebryanskoe oil field (Kaliningradneft' Joint-Stock Company) and from the Novo-Suksinskoe oil field (Tatneft' Joint-Stock Company, NGDU Prikamneft'), using a model stratal water.

The data obtained in testing the samples for the demulsifying efficiency are listed in Table 1. As seen, all the block copolymers investigated break the water/oil emulsions.

Comparison of the dependences of the demulsifying efficiency and work of adsorption on the degree of oxyethylation of the samples studied (Figs. 3, 5) shows that the most efficient are the samples with an oxyethyl group content of 32–40%. A decrease in the demulsifying efficiency correlates with the decreasing work of adsorption in the case of the toluene/water interface (Fig. 5).

In the case of the air/water interface (Fig. 3), no clear correlation is observed between the work of adsorption and the demulsifying efficiency, which is due to the lacking effect of the hydrophobic phase (toluene) on the nonionic surfactant molecules.

CONCLUSIONS

(1) Sorbitol-based block copolymers of ethylene and propylene oxides with various hydrophobic to hydrophilic part ratios demonstrate a surface activity and demulsifying action.

(2) The critical micelle concentration, surface tension, limiting adsorption, landing area of the molecule, work of adsorption, and demulsifying efficiency were determined as functions of the degree of oxyethylation of the samples. The highest demulsifying efficiency was shown by the compounds with a content of oxyethyl group equal to 32–40 wt %.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis of Esters of Dioxane Alcohols and Their Performance as Plasticizers for Polyvinyl Chloride Compounds

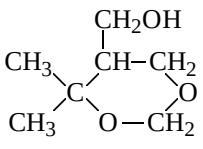
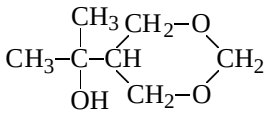
Abstract—A procedure was developed for preparing a plasticizer for polyvinyl chloride compounds from the fraction of dioxane alcohols. The main physicochemical properties of the new plasticizer were determined. Items prepared from formulations containing the new plasticizer were fabricated and tested in laboratory.

Since the discovery of the dioxane method for preparing isoprene, the utilization or reprocessing of dioxane alcohols has been topical problem.



The world's annual production of isoprene reaches now 1000–1100 thousand tons, of which 250 thousand tons (23–25% of the total amount) is produced by the dioxane method. In Russia, the annual production of isoprene is 700–800 thousand tons, of which 190 thousand tons (24–27% of the total amount) is produced by the dioxane method. In this method, the amount of dioxane alcohols (by-products) reaches 100–110 kg per ton of isoprene. Thus, formation of large amounts of dioxane alcohols is inevitable [1].

The fraction of dioxane alcohols from the production of isoprene rubber is a colorless or light yellow mobile liquid containing 50–70 wt % dioxane alcohols; the boiling onset temperature is no less than 225°C, and the flash point, no less than 120°C. The fraction belongs to hazard class 3, recommended value of MPC (with respect to dioxane alcohol) 10 mg m^{-3}, LD_{50} for mice 2700 mg kg^{-1} [2].



The fraction of dioxane alcohols contains three isomeric alcohols:

4-Methyl-4-hydroxyethyl-1,3-dioxane (**I**)

4,4-Dimethyl-5-hydroxymethyl-1,3-dioxane (**II**)

5-(1-Methyl-1-hydroxyethyl)-1,3-dioxane (**III**)

The major component (60–70% of the sum of the isomers) is 4-methyl-4-(2-hydroxyethyl)-1,3-dioxane **I**.

A number of possible applications of dioxane alcohols have been outlined in the literature: as an efficient solvent for nitrocellulose, nitrocellulose lacquers, rosin, lac, for bakelite, epoxy, and polyvinyl chloride resins, and for insulating lacquer; as a component of epoxy hardener [3–8]. One of promising ways of processing of the fraction of dioxane alcohols is preparation of plasticizers for polyvinyl chloride resins and rubbers [9–13].

However, proper utilization of this large-tonnage waste remains a matter of current interest.

We believe that the presence of hydroxy and acetal groups in molecules of dioxane alcohols, their low toxicity, absence of odor and color, and high boiling and flash points make these compounds interesting both as objects for theoretical studies (reactivity) and as potential raw materials for chemical industry.

Our goal was to examine the possibility of preparing esters from dioxane alcohols and carboxylic acids, as potential plasticizers.

EXPERIMENTAL

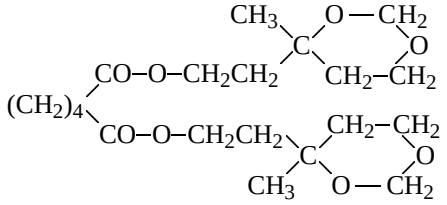
Esters of dioxane alcohols were prepared by two procedures.

(1) Carboxylic acids (acetic, adipic, phthalic, butyric, oxalic) were esterified with dioxane alcohols in the presence of acid catalysts (sulfuric, phosphoric, benzenesulfonic acids; KU-23 cation exchanger). The reactions were performed at 140–165°C for 4–6 h in an excess of dioxane alcohols (molar ratio 4 : 1). The acid conversion did not exceed 30%; the reaction mixture was dark.

(2) It was suggested to prepare esters of dioxane alcohols by ester interchange catalyzed by both acid and base catalysts, and also by transition metal salts [14].

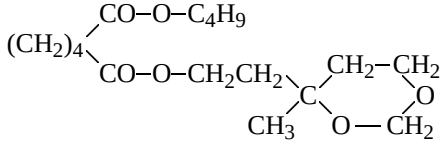
The latter procedure involved two steps: esterification of adipic acid with butanol to obtain dibutyl adipate and ester interchange of dibutyl adipate with dioxane alcohols.

Esterification of adipic acid was performed with an excess butanol; concentrated sulfuric acid was used as a catalyst. The temperature was maintained within 90–117°C, which enabled distillation of the azeotrope. The concentration of adipic acid in the reaction mixture was monitored titrimetrically [15].



The reaction was stopped at a 98% conversion of adipic acid. Then the mixture was cooled and washed to neutral reaction. Water and excess alcohol were removed from the resulting crude ester by distillation at atmospheric pressure. The ester was distilled at 15 mm Hg; the fraction boiling at 210–213°C was collected. The dibutyl adipate obtained was analyzed for the acid number by the standard procedure [18]. The acid number of dibutyl adipate should not exceed 0.05 (mg KOH) g^{-1}. A higher acid number results in darkening of the reaction mixture in the step of ester interchange of dibutyl adipate with dioxane alcohols.

The ester interchange of dibutyl adipate was performed in an excess of dioxane alcohols in the temperature range 215–250°C, so as to ensure continuous distillation of the released butanol at a vapor temperature of 117–120°C. The released butanol can be returned to the step of esterification of adipic acid. As catalyst we used zinc stearate.



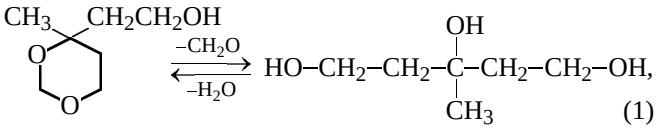
The completeness of the ester interchange was judged from the amount of the butanol released. The reaction was stopped at a 85–90% conversion of dibutyl adipate.

From the reaction mixture, we distilled off low-boiling components; the remaining target product (light yellow mass) was a mixture of esters of adipic acid and dioxane alcohols, with an admixture of dibutyl adipate and zinc stearate. The product yield was 97% of the theoretical value; the content of the mixture of the esters was no less than 98%.

The qualitative analysis of the product was performed by GC/MS on a Finnigan Trace DSQ device in the chemical ionization (isobutane) mode (in the electron impact mode, the molecular ions were not recorded). For the major components, we obtained *m*/*z* 331 and 403 ($[M + H]^+$), which corresponds to the molar weights of the following compounds:

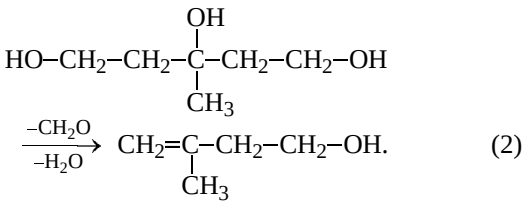
M = 402 g mol^{-1}

M = 330 g mol^{-1}



Thus, ester interchange of dibutyl adipate with dioxane alcohols yields a mixture of isomeric mono- and disubstituted esters.

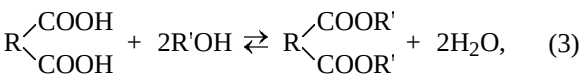
To evaluate the plasticizing power of the product, we prepared samples of the middle PVC layer of calender-rolled linoleum. The samples had the following composition (%): PVC 51, chalk 21, dioctyl phthalate 13, test plasticizer 13, and calcium stearate 2.



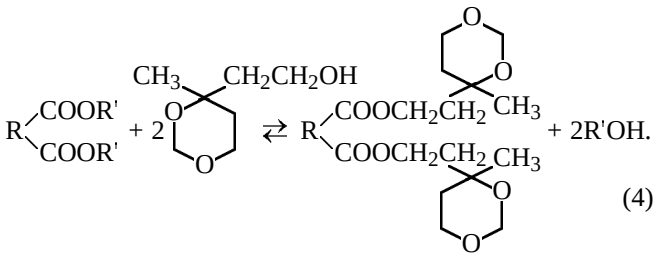
As the lower layer we used cotton underwarp (Netkol). A PVC film with a printed pattern is applied onto the upper layer; all the three layers are doubled on a Bersdorf continuous press.

The plastic compound was prepared from a suspension PVC, special stabilizers and pigments, and the test plasticizer (35–40 wt % of the total).

Our experiments showed that esters of dioxane alcohols could not be prepared in reasonable yields and with acceptable quality by esterification with carboxylic acid. Even weak acid catalysts, such as cation exchangers, caused dehydration of dioxane alcohols with ring opening and formation of triols and unsaturated compounds:



(1)



(2)

Analysis of the reaction mixture shows that dehydration occurs much faster than esterification. Water released in reaction (2) shifts the equilibrium of the target reaction (4), thereby decreasing the yield of the esters. The unsaturated compounds formed in the process undergo condensation, yielding tarry products which impair the quality of the esters.

The two-step procedure we suggested involves the following reactions:

(3)

(4)

In the first step (3), adipic acid is esterified with a primary aliphatic alcohol. The second step (4) is ester interchange of the adipic acid ester with dioxane alcohol. To esterify adipic acid, we used aliphatic alcohols that form heteroazeotropes, so as to continuously remove the released water and thus to reach a high conversion of adipic acid (98–99%).

For the product obtained, we determined the main physicochemical parameters [GOST (State Standard) 8728–77] and compared them with those of commercial analogs (Table 1).

Table 1 shows that the plasticizer prepared from dioxane alcohols is similar in physicochemical properties to high-quality commercial plasticizers, such as dioctyl adipate and dioctyl phthalate, and surpasses EDOS plasticizer, widely used today.

To confirm the plasticizing properties of the product we developed, we tested it in linoleum specimens (Table 2). The analysis showed that polyvinyl chloride (PVC-E, PVC-EP) swells in the suggested plasticizer to form fluid easy-to-apply pastes, thickening with time. We prepared specimens of linoleum and PVC RE-0.4 film (PVC-S : PVC-E = 5 : 1) and benzine-resistant plastic compound PB-BK, using the plasticizer developed.

As can be seen, replacement of EDOS plasticizer in the linoleum formulation with the new plasticizer enhances the strength of binding of the face layer and underwarp with the PVC layer. The ready linoleum exhibits higher tensile strength and higher elasticity.

With dioctyl phthalate replaced in the formulation of PB-BK benzine-resistant plastic compound with the new plasticizer, the compounding is quite feasible and the hardness and strength are enhanced relative to the commercial specimens; the benzine resistance remains high (see Table 3).

Table 1. Comparison of the physicochemical properties of the polyester plasticizer prepared in this study with those of commercially used plasticizers

Parameter	Dioctyl adipate	Dioctyl phthalate	EDOS, grade I	Plasticizer prepared
Flash point in open crucible, °C, no less than	190	205	150	216

Table 3. Comparison of the properties of PB-BK plastic compound prepared with the plasticizer developed and with dioctyl phthalate

Parameter	Prescribed value	With plasticizer developed	With dioctyl phthalate	Testing procedure
Shore hardness, units	80 ± 0.5	80	79	TU 2246-022-00282323–01 (plastic compound for PVC tubes)
Benzine resistance, %, no more than	1.6	0.1	–	TU 2246-022-00282323–01 (plastic compound for PVC tubes)
Tensile strength, MPa, no less than	18.6	19.3	18.9	TU 2246-022-00282323–01 (plastic compound for PVC tubes)

CONCLUSIONS

(1) Previously unknown esters of adipic acid and dioxane alcohols were prepared.

(2) A catalyst for ester interchange of dibutyl adipate with the dioxane alcohol fraction was suggested, and the main process parameters were determined.

(3) The physicochemical properties of the mixture of dioxane alcohol adipates are comparable with those of commercial PVC plasticizers. The new plasticizer can be used for fabricating items with enhanced strength, elasticity, and benzine resistance.

Abstract—The behavior of 1,3,3-trimethylspiro[indoline-2,3'-2*H*-naphtho[2,1-*b*][1,4]oxazine under plastic deformation was studied on high-pressure Bridgman anvil-type apparatus at 0.5–4 GPa and room temperature.

High pressures strongly modify various solids, e.g., cause an insulator–conductor transition, unusual chemical processes, changes in phase diagrams, etc. Substances subjected to high pressures are often exposed to shear stresses responsible for plastic deformations substantially affecting their behavior. A combined effect of high pressures and shear deformations on substances is strongly manifested in the case of high-pressure Bridgman anvil-type apparatus. In particular, various chemical reactions were revealed in the absence of initiators and catalysts for many classes of organic compounds. This suggests an electronic excitation of substances under such impacts. The rate of chemical processes under plastic deformations at high pressures is very weakly dependent on temperature, which supports the athermal mechanism of excitation of chemical transformations.

In the context of studying the excitation mechanisms of the electronic subsystem of solids under mechanical impacts, of much interest are organic reactions that can be photochemically initiated under ordinary conditions. For such systems, the positions of the ground and excited levels of the reacting molecules, the transition energies, and transformation pathways of the excited states are well understood. We have applied such an approach to a study of the behavior of linear annelated aromatic compounds [1]. It was shown that, under plastic deformation at high pressures, only 20% of the energy required for a chemical reaction to occur in the substances under study is due to high pressures, and the remainder comes from plastic deformation. In [2], we analyzed the baric dependences of a purely mechanical characteristic of solids (flow stress) for a wide variety of organic compounds and found that such dependences can be correlated with the processes occurring in the electronic subsystem of organic substances.

Another class of organic compounds whose photochemical transformations in solutions and polymer films are well understood are photochromes and, in particular, spiropyrans and spirooxazines [3–6]. Under photoirradiation in solution, they acquire a predominantly dark blue color (λ_{max} ~600 nm and over) owing to a transition of the molecule from a colorless initial state **A** with opening of the spiro bond into a colored merocyanine form **B**:

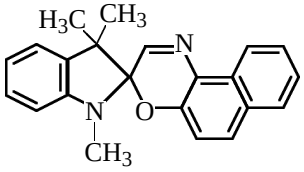
A **B**

where X = CH, N.

Under ordinary conditions, the equilibrium between the colored and colorless forms depends on the sol-

vent: the greater the solvent polarity, the stronger the shift of the equilibrium toward the colored form. Acid medium shifts the color of the spiro compound to the red spectral range, which has been attributed to formation of the protonated form [7].

The appearance of the red form of a spiro compound in an acid medium without UV irradiation has also been revealed by Kol'tsova *et al.* [8] who noted that this form is not decolorized, which was attributed to formation of a salt structure. Kozlovskaya *et al*. [9] studied transformations of selected spironaphthooxazines in various solvents in the presence of $LiClO_4$ when exposed to electric field with a strength of 5–100 V cm^{-1}. In this case, solutions turned red without UV irradiation, under electric field exposure only. It was suggested that the appearance of the red form is due to ionization of the molecules.



Certain spiro compounds exhibit photochromic properties in the solid phase as well. For example, Sychev *et al*. [10] showed that amorphous spirophenanthrooxazine films prepared by vacuum sputtering get colored under UV radiation and decolorize with time, which was attributed to crystallization.

Thus, the available experimental data suggest that transitions of spirooxazines to a colored form are extremely sensitive to the charge state of their surrounding molecules. This allows the changes induced in various solids by high pressure and shear deformation to be examined using molecules of photochromic spiro compounds as specific markers responding to changes in the environment.

Maksimychev *et al*. [11] and Zhorin *et al*. [12] found that, in the case of organic compounds having no conjugated bond system, compression to 4 GPa increases the average dielectric constant by a factor of 2–3.5. Under plastic deformation, this parameter can increase by 30% from the value achieved under pressure only. Also, under compression of organic compounds, a potential difference of several tens of volts appeared between the upper and lower surfaces of the samples placed between the metallic anvils. Thus, under plastic deformations at high pressures, organic molecules get polarized, which increases their reactivity. Also, Enikolopyan *et al*. [13–15] showed that high pressures intensify injection of electrons from the anvil metal into insulators being treated under pressure. Thus, the electrophysical state of organic substances subjected to plastic deformation at high pressures substantially differs from that under normal conditions.

EXPERIMENTAL

We examined 1',3'3'-trimethylspiro[indoline-2,2'-2*H*-naphtho[2,1-*b*][1,4]oxazine, mp 124–125°C, R_f = 0.93 (benzene : ether, 7 : 3, Silufol); λ_{max} 300 and 320 nm (dioxane, $\varepsilon = 9.75 \times 10^{-5}$ l mol^{-1} cm^{-1}); 1H NMR spectra ($C_6D_5CD_3$), δ, ppm; 1.08 and 1.2 (CMe_2), 2.45 (NMe), 7.58 (H^3). 8.93 (H^5), 7.43 (H^6), 7.20 (H^7), 7.48 (H^8), 7.29 (H^9), 6.73 (H^{10}), 6.90 ($H^{4'}$), 6.82 ($H^{5'}$). 7.00 ($H^{6'}$), and 6.30 ($H^{7'}$):

SPO

As matrices we used various chemically pure low-molecular-weight crystalline organic compounds (with physicochemical constants agreeing with reference data) and various commercial polymers, which were used without further purification.

Mixtures of 5 and 10% SPO with the substances chosen were prepared by mixing the initial powdered components in a mortar, which was followed by combined action of pressure in the range 0.5–4 GPa and shear deformations (the anvil rotation angles were varied from 10° to 400°). Pressures from 0.5 to 2 GPa were created on KhVG hardened steel anvils, and higher pressures, on VK6 hard alloy anvils. The changes in the color of the samples after plastic deformation at the chosen pressure were examined visually. Calorimetric studies were carried out on an MAS DSM-2M microcalorimeter at a heating rate of 8 deg min^{-1}; the sample weight was 20 mg. The deformation currents were measured with an M-95 indicator microammeter.

The results of the studies of the coloration of SPO under plastic deformation at 0.5–4 GPa suggest that, after treatment under pressure, the samples acquire a dark blue color whose intensity grows with increasing degree of deformation (anvil rotation angle). In this case, the most intensely colored samples lost their color at room temperature within ca. 1 h. All samples are completely dissolved in acetone, rapidly getting colorless in it, and such solutions, when exposed to UV radiation, acquire a dark blue color. Our data suggest that, during deformation, the initial SPO is not irreversibly changed, and all the arising colored states of the samples are metastable. The fact that

the times of decolorization of the dark blue samples treated within different pressure ranges are close suggests a similarity of the mechanisms and conditions of the relaxation processes.

An X-ray diffraction analysis showed that, after deformation at 1 and 4 GPa, the SPO samples are X-ray-amorphous; the time from termination of the treatment under pressure till the beginning of an X-ray diffraction analysis is sufficient for the samples to get completely colorless. Thus, the appearance of the dark blue form (DBF) in the SPO samples due to plastic deformation at different pressures is most likely not associated with degradation of the crystalline structure.

The DSC data in Fig. 1 suggest that, in the initial SPO, there are two crystalline phases with different melting points. The peak with mp 116°C is characterized by an enthalpy of 60 J g^{-1}, and that with mp 130°C, of 10 J g^{-1}. After treatment at 1 GPa, the low-temperature peak shifts to lower temperatures by 8°C, and its enthalpy decreases to 20 J g^{-1}; the position of the high-temperature peak on the temperature scale remains unchanged, and its enthalpy increases to 50 J g^{-1}. The thermograms of the samples treated at 4 GPa are identical to those of the samples treated at 1 GPa. It should be noted that, by the time of beginning of the calorimetric experiments, the samples treated under pressure were virtually colorless. Thus, the occurrence of endothermic peaks on thermograms of the colorless X-ray-amorphous samples of SPO suggests that, in the course of heating in the calorimeter, the substance undergoes recrystallization, yielding a structure different from that of the initial substance.

The effect of cathodochromism, consisting in coloration of various inorganic compounds under electron beam exposure, has been known since 1895 [16]. It could be assumed that a possible mechanism of coloration of SPO subjected to plastic deformation under pressure involves interaction of electrons injected from the anvil metal with SPO molecules. Measurements of thermostimulated currents in various polymers subjected to plastic deformations at high pressures showed that the injected electrons can penetrate the polymer samples to a depth of up to 40–50 μm. This situation with electron capture by the structural defects and their retention in the samples after removing the pressure can be compared to that arising after irradiation of the polymers with a 100-keV electron beam [17]. The electrons localized on the structural defects were liberated by heating the samples, when various kinds of molecular mobility of electrons in polymers existed. In this context, it can be

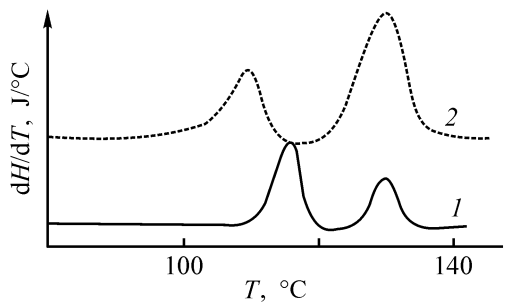


Fig. 1. Thermograms of SPO. Sample: (*1*) initial and (*2*) after treatment under 1 GPa. (*dH*/*dT*) Heat capacity change and (*T*) temperature.

assumed that decolorization of colored SPO is due to liberation of captured electrons from the structural traps.

We attempted to affect the liberation of electrons from the samples subjected to high pressure treatment and, thereby, to change the rate of their decolorization and the number of captured electrons in colored samples. In the case of the conventional experimental procedure, when, after removing the pressure, the anvils were taken out of the press and mounted on a dielectric support ("insulated"), the decolorization time was ca. 1 h. When the anvils remained in the press after removing the pressure (were "grounded"), the samples virtually lost their color within 10–15 min. To accelerate the charge leakage in the samples, we added 5–10 wt % powdered aluminum or copper to the initial SPO. After treatment under pressure, such samples were colorless. Thus, a facilitated charge leakage from the samples intensified their decolorization.

There are two processes occurring in samples treated under pressure: formation of structural defects at which charges can be localized and injection of electrons from the metal of an anvil into the material of the sample. As shown previously [18], the former process is virtually pressure-independent at pressures within 1–6 GPa and is determined by the magnitude of deformation (rotation angle of the anvils). The latter process is enhanced as the pressure at which the samples are subjected to deformation increases. It should be noted that, during plastic deformation, a part of the structural defects with captured electrons leaves the sample, but new defects are formed, which ensures dynamic equilibrium of the system.

The number of electrons remaining in the sample after removing the pressure can be controlled. To this end, the samples should be subjected first to a plastic deformation under pressure, when intense coloration is observed. Then, without terminating the de-

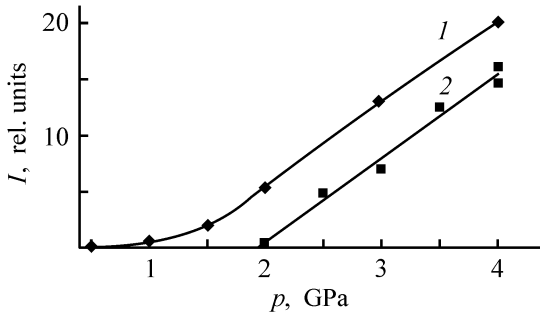

Fig. 2. Baric dependences of the deformation currents. (*I*) Current intensity and (*p*) treatment pressure. (*1*) SPO and (*2*) SPO in a mixture with succinic acid, 30 wt %.

formation, i.e., with the number of structural defects maintained constant, the pressure should be lowered. This will decrease the number of electrons injected and, consequently, captured by the structural defects. This procedure will remove from the sample the structural defects, together with the electrons localized on them. The number of charges retained in the samples will be much smaller than that in the case of a simple removal of the pressure after terminating the deformation.

Indeed, after treatment of the SPO samples preliminarily deformed at 2 GPa by the "deformation under pressure lowering" scheme, the samples are colorless. Our results suggest that the dark blue form of SPO, arising under plastic deformation at a high pressure, is at least partially due to the presence of injected electrons in the samples.

The presence of mobile charges in the SPO samples during treatment under pressure is evidenced by the deformation current. We reported in [19] that deformation currents flow through metal and metal-polymer composite samples subjected to plastic deformation under pressure. These currents are due to migration of charged structural defects. Figure 2 shows the baric dependence of the deformation current in SPO samples. At pressures under 1 GPa, the deformation current is manifested as individual pulses. During deformation at pressures of 2 GPa and over, the current monotonically increases with the degree of deformation to a limiting value achieved at the anvil rotation angles of 80°–100°. After terminating the rotation of the anvils, the current decreases to zero within several seconds. Under repeated deformation at the same pressure, the current exhibits identical dynamics.

Extensive experimental data suggest that, with increasing pressure, the substances under study begin to exhibit to ever growing degree the properties that evidence ionization and dissociation of molecules under plastic deformation. For example, deformation of maleic acid at 4 GPa yields a polyester, which suggests migration of the proton from the carboxy group to the double bond of the neighboring molecule [20]. Zhorin *et al*. [21] showed that, under plastic deformation of mixtures of organic acids with aromatic and aliphatic amines, a proton is transferred even in those acid–base pairs in which no salt is formed in liquid media. The proton transfer intensity increases with pressure; ion pairs were recorded by IR spectroscopy in samples subjected to treatment under pressure. Studies of the electrical conductivity of oxalic acid under pressure [22] showed that, at pressures above 2 GPa, a noticeable contribution to the conductivity comes from the ionic component. Formation of metal complexes of porphyrins from mixtures of metal-free porphyrins with metal salts and oxides under plastic deformation suggests dissociation of the metal salts and oxides under such conditions [23].

Thus, under plastic flow at high pressures, the electronic structure of bonds in organic molecules is substantially modified to the point of ionization and dissociation; the electronic excitation energy of ions of organic molecules is more than 2 times lower than that for molecules in the neutral state [24]. Also, a system of charged structural defects is formed in the material of the samples; local gradients of electric fields must exist in this system.

To further study the processes occurring in organic compounds under plastic deformation at high pressures and yielding, in the case of SPO, a colored form, we treated with pressure mixtures of SPO with various organic compounds, both low-molecular-weight and polymeric.

It turned out that all low-molecular-weight substances chosen as matrices can be divided into three groups: substances in which SPO turns blue; substances in which SPO turns red; and substances in which no coloration of SPO can be recorded.

Out of the totality of the organic matrices in which SPO is intensely colored, the amide and organic acid series can be singled out. The amide series includes acrylamide, methacrylamide, *N*,*N*'-methylenebisacrylamide, and propionamide. The first three members are unsaturated compounds arranged in order of decreasing tendency to polymerize under plastic flow at high pressure. In these matrices, SPO turns red. The intensity of SPO coloration varies in parallel with the activity of these unsaturated amides in polymerization. At the same time, a mixture of SPO with a saturated

analog of arcylamide, propionamide, acquires only a slightly blue color, rapidly disappearing under ambient conditions. We found that, when red samples of SPO mixed with unsaturated amides are dissolved, a part of the reaction mixture dissolves neither in acetone, nor in water; it dissolves only in dimethyl sulfoxide, yielding a red solution. Thus, red forms (RFs) appear only in mixtures with unsaturated amides. Evidently, coloration is due to chemical reactions of SPO with unsaturated amides.

With SPO–acrylamide mixtures as an example, we monitored the changes in the color of the samples with increasing degree of deformation (anvil rotation angle). We found that treatment at a pressure of 0.7 GPa and an anvil rotation angle of 50° yields a two-color sample, with a bright red peripheral zone and a dark blue center. Between these two extreme colors, there is a transition zone, in which both colors are present. The dark blue color disappears more rapidly, and the bright red color in the peripheral zone gets less intense in going to the center of the sample, and the center is virtually colorless. With increasing degree of deformation, the red zone tends to widen, and at the anvil rotation angles above 150° the whole sample is red. Thus, while the blue dark color in the samples treated under pressure is spread uniformly over the entire sample, the red color appears first in the peripheral zone of the sample; with increasing degree of deformation, the ring red zone tends to widen toward the center of the sample. Similar changes in the color of the samples have been observed previously, when substances subjected to plastic deformation at high pressures underwent chemical transformations into colored products (notably, the maximal deformation of the sample is observed in the peripheral ring zone).

The conclusion that formation of the red zone of SPO is due to the presence in the matrix molecules of active C=C bonds is confirmed by the results of treatment under pressure of the SPO mixtures with acenaphthylene and its saturated analogue, acenaphthene. We found that the SPO–acenaphthylene mixtures turn red, and the mixtures with acenaphthene are not colored.

As noted above, the color intensity of unsaturated amides depends on the reactivity of the double bond. It was of interest to study this effect for other compounds as well. To this end, we chose vinylcarbazole and tetraphenylethylene. In vinylcarbazole, the chemical activity of the double bonds is extremely low because of the strong steric hindrance. Therefore, for mixed samples based on vinylcarbazole we could record only a weak pink color in a narrow ring zone at the periphery of the samples. Even more hindered is the double bond in tetraphenylethylene, which is completely shielded by four phenyl rings. For this matrix, we could not record any coloration at all.

Thus, in mixtures with unsaturated amides, both the DBF and RF are manifested in SPO samples. Our results suggest that the DBF is formed in earlier stages of deformation, compared to the RF. The latter results in mixtures with amides from chemical reactions between the SPO molecules and unsaturated amide molecules.

To elucidate the influence exerted by organic acids on the coloration of SPO, we chose mono- and dibasic aromatic acids, as well as dibasic aliphatic acids; all these acids differed in strength.

In the case of mixtures of SPO with unsaturated dibasic acids, maleic and fumaric, we found that the RF was formed even under treatment at 1 GPa. To test the assumption concerning reactions between the SPO molecule and the double bonds of the matrix molecule, samples of the SPO–maleic acid mixtures were dissolved in various solvents after deformation under pressure. The samples are rapidly and completely soluble in acetone, the solution retaining a red color. About 50% of the substance is dissolved in water; the undissolved fraction has a dark brown, and the solution, a yellowish green color. Such a behavior of the samples in dissolution suggests chemical reactions between the mixture components during plastic deformation under pressure.

Mixtures of SPO with a saturated analogue of maleic and fimaric acids, succinic acid, were treated under pressures of 1–1.5 GPa. The samples with succinic acid have a dark blue-red color after treatment. Upon heating to 80–90°C, the dark blue color disappears, and the sample acquires an intense red color disappearing upon dissolution of the samples in acetone. The fact that the RF appears both in unsaturated acids and in their saturated analogue suggests that, in the acids, SPO can be colored not only due to reactions of the SPO molecules with the C=C bond, but also via protonation of the open form. Similarly to the case of SPO, deformation currents flow through the samples of the mixtures of SPO with succinic acid (the corresponding baric dependence is shown in Fig. 2).

Mixtures of SPO with a number of organic acids of different strengths were treated at 1–1.5 GPa. For comparison, we chose the series of acidity in water

Coloration of mixtures of SPO with organic acids after plastic deformation at 1.5 GPa, depending on the strength of the acid

Acid	pK_α	Color
Sebacic	4.55	Dark blue
Adipic	4.41	"
Glutaric	4.34	"
Succinic	4.21	Red
Benzoic	4.19	Dark blue
Cinnamic	3.89	"
Itaconic	3.85	"
Naphthylacetic	3.70	"
Isophthalic	3.62	"
o-Fluorobenzoic	3.27	"
Citric	3.13	Red
Fumaric	3.02	"
Phthalic	2.95	"
Malonic	2.86	"
Maleic	1.92	"
Pyromellitic	1.40	"
Oxalic	1.27	"

(see table). The tabulated data suggest that, within a certain pK_a range, organic acids favor appearance in the mixed samples of the red form of SPO, coexisting with the DBF. The monotonicity of the series established is violated by succinic acid: The dark blue and red forms are metastable, with the DBF being decolorized even during heating, and the RF, during dissolution in acetone. The most probable reason for the appearance of the RF is protonation of the SPO molecules with acids weak under ordinary conditions.

Protonation of SPO with weak organic acids formally means the enhancement of their acid properties. To estimate the possible magnitude of such an effect, we prepared solutions of trichloroacetic (pK_a = 0.66) and monochloroacetic (pK_a = 0.74) acids in acetone. Upon introduction of SPO into these solutions, they turn red. It should be noted that, when colored under pressure, the mixtures of SPO even with the strongest of the acids chosen, oxalic, are completely decolorized in acetone. Our data suggest that, for coloration of SPO in an acidic solution, the strength of the acid should be no lower than that of monochloroacetic acid; at the same time, coloration of SPO under pressure begins with citric acid. Thus, the degree of dissociation of citric acid under plastic flow at high pressures should formally increase by almost a factor of 300 to get equal to that of monochloroacetic acid.

The third group of the substances used to study the properties of SPO include propionamide, acenaphthene, anthracene, adamantane, pentaerythritol, pentaerythritol diformal, camphor, fluorene, carbazole, *N*-methylcarbazole, 9-propylcarbazole, 9-(2,3-dihydroxypropyl)carbazole, tetraphenylethylene, and triethylenediamine. For mixtures of SPO with these substances, we could not record after treatment at 2 GPa any color at all or it was very weak, bluish, and the mixture rapidly lost its color. This suggests that, in the substances discussed, SPO acquires a dark blue color, but in this case the decolorization rate is high. The substances in the third group are nonpolar and contain no functional groups that could stabilize the colored form of the SPO molecule, thereby decelerating decolorization.

Along with low-molecular-weight organic substances, we used the following polymers as matrices: high- and low-density polyethylene, polypropylene, polystyrene, cellulose, polyvinyl alcohol, polyvinyl chloride, and polycarbonate.

A characteristic feature of the mixtures of SPO with the polymers chosen is that, after treatment at 1–2 GPa, all the samples acquire either a dark blue-red or a pink-blue color. Within a period from 10 min to 1.5 h, the samples virtually lose the blue color and get pink-red or bordeaux. This color is retained for at least a month.

In samples of SPO mixtures with polymers (high-density polyethylene, polycarbonate, polyvinyl chloride), we recorded deformation currents. They belong to the same range as in the baric dependences shown in Fig. 2; after treatment under pressure, the samples were strongly electrified.

For the SPO mixtures with high-density polyethylene, we found that, under deformation at 2 GPa at small anvil rotation angles (50°), we can observe a blue color only. With increasing anvil rotation angle to 100°–150°, the samples acquire a pink tint. It intensifies with increasing degree of deformation, and the sample gets bright red at anvil rotation angles of 500°–700°.

The appearance of the red form of SPO in the polyethylene matrix is hardly attributable to chemical reactions or protonation, in contrast to the case of low-molecular-weight matrices. Here, it is appropriate to mention that coloration of SPO can be achieved by exposing the solution to an electric field.

Treatment under pressure of samples of SPO mixed with polyethylene yielded films easily detachable from the working surface of the anvils. This allowed measurement of the thermostimulated currents for such samples. The thermostimulated curent was

ca. 10^{-9} A in the polyethylene samples and 10^{-6} A in samples of the 30% SPO–polyethylene mixtures. Thus, the number of charges in the mixed samples is much greater than in individual polyethylene. Probably, this means that a large proportion of the SPO molecules occurs within the range of action of local electric fields.

CONCLUSIONS

(1) Under plastic deformation, spirooxazine can transform both to the dark blue and red forms. Early stages of deformation yield a dark blue form, and a more profound deformation, a red product.

(2) The dark blue form is an open merocyanine structure into which spiropyran is transformed. This process is strongly influenced by electrons injected from the anvil metal.

(3) The red form is the product of protonation of the open form, yielded by the reactions of the spirooxazine molecules with the matrix molecules. The appearance of the red form is favored by the action of electric fields arising in polymer matrices during treatment under pressure.

Abstract—Graft copolymers of acrylonitrile with chitosan were prepared by radical polymerization of acrylonitrile in aqueous acetic acid solution of chitosan.

The interest of applied chemists in natural polymers and, in particular, in polysaccharides, steadily grows. Among these polymers is chitosan, CTS [poly-β-(1,4)-2-amino-2-deoxy-*D*-glucosamine], the product of deacetylation of natural polymer chitin, which is a structural analogue of cellulose. The presence of an amino group in the monomeric unit of chitosan imparts to it solubility in dilute solutions of organic and some inorganic acids, and also a set of unique physicochemical and biological characteristics [1]. One of the promising applications of chitosan is preparation of membranes and fiber-forming materials based on it [2]. However, the widespread use of chitosan as a composite material is limited by its inadequate physicochemical parameters characteristic of all polysaccharides. Therefore, modification of chitosan and development of new materials based on chitosan with synthetic polymers are metters of current interest. It is of particular interest to use a fiber-forming synthetic polymer, polyacrylonitrile, for modification of chitosan. Combination of chitosan with this polymer can, on the one hand, improve the physicochemical characteristics of chitosan and, on the other hand, yield hygienic characteristics of polyacrylonitrile fiber dependent on the ratio of the components. In addition, the fairly high solubility of acrylonitrile (AN) in water (7.3 g per 100 ml H_2O at 20°C) is of significant importance, allowing modification of chitosan under homogeneous conditions.

The aim of this study was to examine the grafted polymerization of AN on chitosan and to analyze the properties of the products obtained.

EXPERIMENTAL

We used chitosan produced by Sonat Co. (Moscow) with molecular weight (MW) equal to 2.5×10^5 and degree of deacetylation of 82%. Before use, acrylonitrile was dried with NaOH for 4 h and distilled under atmospheric pressure on a setup equipped with a total-reflux head. The fraction with bp 78.5°C was collected. A 1.5% aqueous CH_3COOH served as a solvent; isopropanol of chemically pure grade was used as a precipitant.

Precipitation was performed in a three-necked flask equipped with a reflux condenser. The flask was charged with 100 g of a 3% solution of chitosan in 1.5% aqueous CH_3COOH, and then a weighed portion of monomer with dissolved initiator, azobis(isobutironitrile) (AIBN), was added. The process was carried out at 60°C.

The degree of conversion of AN in polymerization was monitored by three methods: chromatographic analysis, potentiometric titration of unchanged AN, and gravimetric analysis (by variation of the weight of the resulting product). For this purpose, samples of a certain weight were taken during the process, and the reaction product was precipitated, washed several times with isopropanol on a filter, and dried in a vacuum to constant weight. The filtrate was transferred into a measuring flask and analyzed for the AN content by chromatographic and potentiometric methods. The chromatographic analysis was performed on a Tsvet-500 chromatograph, 2000×4 mm column, sorbent SE, carrier gas argon, column temperature 75°C, detector temperature 103°C, and vaporizer temperature 130°C. The AN concentration in the samples was determined using n-butanol as internal reference. The unchanged AN was determined by potentiometric titration according to [3].

Films of the initial chitosan and products of its reaction with AN were prepared by casting from a solution in 1.5% aqueous CH_3COOH. One set of films

1070-4272/05/7806-0962 © 2005 Pleiades Publishing, Inc.

was dried in air for 40–48 h and then in a vacuum to constant weight. Another set was washed with 3% aqueous NaOH to remove CH_3COOH and then with distilled water to pH 7 and dried in a vacuum to constant weight. The tensile strength and relative elongation at break were determined on an RMI-5 tensile-testing machine at an extension rate of 50 mm min^{-1}.

IR Fourier spectra of the films were recorded on a Paragon 500 Perkin–Elmer Fourier spectrophotometer.

X-ray diffraction patterns were recorded on a DRON-4 diffractometer (Cu_{K_α} radiation, graphite monochromator, reflected beam).

The particle size of the graft product dispersion was determined by the turbidimetric method based on measurements of the intensity of scattered light passed through a disperse system, using a KFK-2-UKhL 4.2 device [4]. The electrokinetic potential of the dispersion particles was measured from the rate of electrophoresis by the method of a moving boundary [4].

The moisture absorption by films prepared from the graft copolymer of AN with chitosan was studied gravimetrically at 25°C. For this purpose, films of a certain weight were fixed on hooks and placed in a hermetically sealed beaker filled with distilled water. At certain intervals of time, the films were removed from the beaker, excess moisture was removed with a filter paper, and the films were weighed on an analytical balance. The percentage of swelling was evaluated by the formula

$$\omega = (m - m_0)/m_0 \times 100,$$

where m_0 and m are the weights of the initial and swollen films, respectively.

We studied how the polymerization conditions, such as initiator concentration, reactant ratio (chitosan : AN), and pH of the medium, affect the degree of AN conversion and the efficiency of grafting.

It should be noted that, in the course of polymerization, we used in all the runs an AN concentration lower than its limiting solubility in water (7.3 g per 100 ml H_2O at 20°C). At in the beginning of polymerization, the system was a homogeneous solution. The influence of chitosan concentration on the degree of AN conversion is illustrated by Fig. 1. It is seen that, at chitosan concentrations of 0.5 to 1.5 wt %, the maximum of AN conversion in the synthesis is as low as 25%, irrespective of the process duration. The AN conversion increases with the chitosan concentration and reaches 97.5% at a chitosan concentration of 3 wt %. Further increase in the chitosan concentration does not affect the limitingof AN conversion; therefore, all runs were performed at a chitosan concentration of 3 wt %. Since chitosan is a polyelectrolyte, we can suggest that the pH of the medium should noticeably affect the process. Actually, the limiting yield of AN is 93% at pH 3.9 and 97.5% at pH 5.5 (Fig. 2). In this case, the initial rate of the process increases by a factor of 1.3. The resulting product is an aggregatively stable dispersion with a particle size of 8.2×10^{-7} to 3×10^{-5} cm, remaining constant for no less than 8 months. This high aggregative stability of the dispersion of the graft copolymer in water is apparently caused by two factors: electrostatic

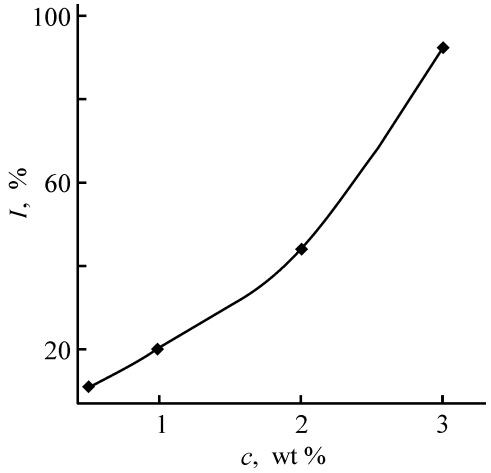

Fig. 1. Limiting degree of AN conversion, *I*, vs. chitosan concentration *c* in polymerization in a solution of chitosan. [AN] = 1.0 M, pH = 3.9, 60°C.

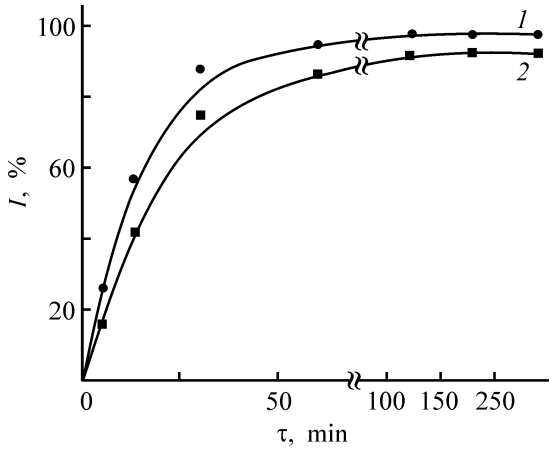

Fig. 2. Variation of the degree of AN conversion, *I*, with time τ in polymerization in a solution of chitosan at various pH of the reaction mixture. [AN] = 1.0 M, [CTS] = 0.187 M, $(\nu_{AN}/\nu_{CTS}) = 3.0$, ν_{AN} and ν_{CTS} are the number of AN moles and base-moles of chitosan, respectively, 60°C. pH: (*1*) 5.5 and (*2*) 3.9.

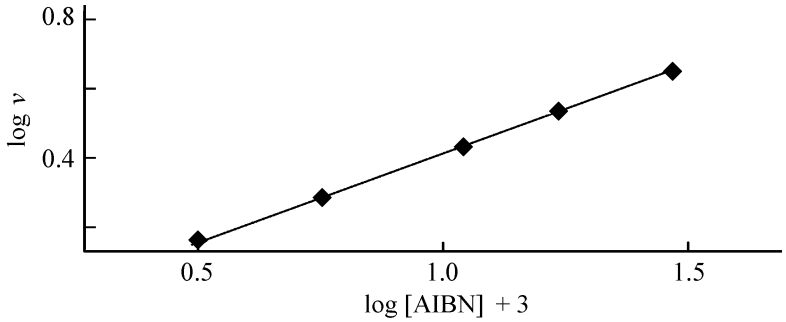

Fig. 3. A plot of log*v* vs. (log[AIBN] + 3). [AN] = 1.0 M, [CTS] = 0.187 M, 60°C, pH 3.9. (*v*) Initial polymerization rate.

repulsion of particles due to appearance of an electrical double layer at their surface caused by protonation of amino groups of chitosan (the electrokinetic potential of the dispersion particles determined by electrophoresis is approximately 56 mV; this significantly exceeds the critical value of 30 mV which, as a rule, corresponds to loss of stability by colloidal solutions) and structural mechanical factor [5].

As the concentration of the initiator increases from 2.8×10^{-3} to 2.8×10^{-2} M, the initial reaction rate grows by a factor of 1.5. The dependence of the initial reaction rate on the initiator concentration is linear. The reaction order with respect to the initiator was determined to be 0.65 (Fig. 3).

It is not improbable that the polymerization yields, in addition to the graft copolymer, also a PAN homopolymer. Therefore, to determine the degree and efficiency of grafting, the graft product and PAN were separated by extraction of the latter with dimethylformamide in a Soxhlet apparatus. Preliminary experiments on separation of a mixture of chitosan with PAN under the same conditions showed that the time required for complete removal of PAN from the mixture is approximately 40 h. It was found that the reaction product is mainly the graft copolymer. The content of the homopolymer does not exceed 3%. Formation of graft copolymers was proved by IR spectroscopy. After extraction in a Soxhlet apparatus, the sample of the copolymer was dissolved in 1.5% aqueous CH_3COOH and then films were prepared. The IR Fourier spectrum contains an absorption band at 2243.7 cm^{-1} corresponding to stretching vibrations of the –C≡N bond (Fig. 4).

For the optimum conditions of the process (pH 5.5, [AN] 1.0 M, [AIBN] 2.8×10^{-2} M), we calculated the degree of grafting (DG, weight of grafted AN/chitosan weight, %) and the efficiency of grafting (EG, weight of grafted AN/weight of polymerized AN, %). The degree and efficiency of grafting were 182 and 97%, respectively.

For the samples prepared under these conditions, the molecular weight of the grafted chains of PAN was determined. These chains were separated from chitosan chains by hydrolysis in the presence of a 3% NaOH solution for 30 min according to the procedure described in [6]; the precipitate was washed with water and methanol. Then, PAN was extracted with dimethylformamide and precipitated with methanol. The molecular weight of PAN (M_η) was calculated from viscometric data (DMF, 30°C) by the equation [7]

$$\log[\eta] = \log 2.3 \times 10^{-4} + 0.75 \log M_\eta,$$

where M_η of grafted chains was 2.2×10^4.

From the concentrations of chitosan and AN in synthesis, we calculated taking into account the efficiency of grafting, MW of chitosan (2.5×10^5), and MW of grafted PAN chains (2.2×10^4), the average number of grafted PAN chains per chitosan molecule. It was 20, i.e., one branching per 70 units of the chitosan chain.

The X-ray diffraction data (Fig. 5) for films of chitosan (curve *2*) and graft copolymer of chitosan with AN (curve *1*) indicate that their structures are strongly different. A high degree of structural ordering is characteristic of the initial sample of chitosan. The degree of crystallinity, evaluated by the procedure described in [8], was 41.8% for this sample. The positions of the main diffraction peaks correspond to the angles $2\theta_1 = 11.7°$, $2\theta_2 = 18.8°$, and $2\theta_3 = 21.6°$ (the respective interplanar spacings are $d_1 = 0.754$, $d_2 = 0.472$, and $d_3 = 0.411$ nm). Comparison of curves *1* and *2* shows that the diffraction respective characteristic of chitosan are absent in the X-ray diffraction pattern of the graft copolymer. Presumably, the grafted chains of PAN prevent ordered packing of chitosan chains, and its supramolecular structure becomes less ordered. At the same time, a sharp diffraction peak appears at $2\theta_4 = 17.2°$ against the background of the amorphous halo of chitosan; this peak corresponds to crystalline formations in the PAN structure [8]. In this case, the degree of crystallinity of the graft copolymer is as low as 16.1%. The improved physicomechanical characteristics of the graft copolymer in comparison with chitosan can be attributed to the decrease in the degree of crystallinity. The table shows that the ultimate tensile strength of graft copolymers of AN with chitosan increases to 600 MN m^{-2}, against the value of 290 MN m^{-2} for pure chitosan, and the degree of limiting deformation is approximately 30%, against 8% for pure chitosan. The moisture absorption of films prepared from the graft copolymer reaches 26%.

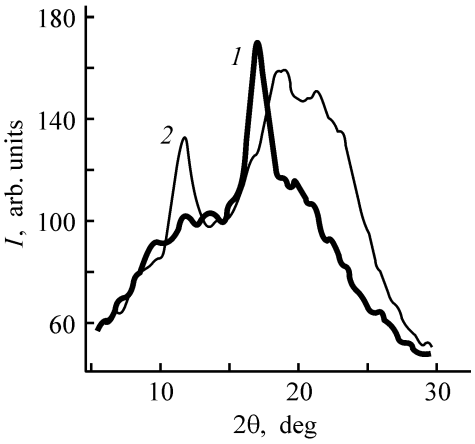

Fig. 5. X-ray diffraction patterns of the samples of (*1*) graft copolymer of chitosan with AN and (*2*) initial chitosan. (*I*) Intensity and (2θ) Bragg angle.

A comparison of the strength and relative elongation of the resulting graft copolymer with those of PAN fiber shows that these values are comparable: for PAN fiber, the tensile strength is 600 MN m^{-2} and the relative elongation is in the range 10–35% [9].

CONCLUSIONS

(1) Graft copolymer of acrylonitrile with chitosan with a high degree and efficiency of grafting was prepared in the form of a highly stable aqueous dispersion.

(2) Graft copolymers compare well with the polyacrylonitrile fiber in physicomechanical character-

Ultimate tensile strength σ and limiting strain ε of films prepared from graft copolymer chitosan–AN in relation to the AN content

Abstract—The viscosity of melts of a blend of a ternary copolyamide 6/66/610 and polysaccharide (chitosan) used as biodegradable additive was determined by capillary viscometry at 150–170°C.

Properties of blends of synthetic and natural polymers are studied to develop new environmentally clean materials temporarily used in homes, agriculture, and cosmetic and medical industry. The natural polymers contained in these blends promote degradation of the composite under the action of H^+ and OH^- ions, soil moisture, microorganisms, fungi, worms, and other biological and chemical agents causing degradation of polymers with subsequent decomposition of the disposed articles. Starch is most frequently used as a biodegradable component of polymer composites. Starch is a plant polysaccharide which readily degrades under the physiochemical and biological action of the environment [1, 2]. Another natural polysaccharide, chitin, produced by *Crustacea*, insects, and other living things, can also be used for this purpose. Chitin is a renewable natural polymer accumulated in large amounts. However, it is used to a lesser extent than starch [3, 4]. The acetamide group of chitin can be readily hydrolyzed to form chitosan, which is a copolymer of (2-amino-2-deoxy)- and (2-acetamido-2-deoxy)-β-1,4-*D*-glucans. Chitosan and chitin are biodegradable polymers [5]. The solubility of chitosan and its miscibility with other polymers are higher than those of chitin owing to formation of inermolecular hydrogen bonds between the components or of ion-polymer complexes with polyelectrolytes [6]. Therefore, blends of synthetic polymers with chitosan should be of practical interest.

Here we studied the rheological properties of chitosan blends with synthetic copolyamide (SPA) used in production of films and hot-melt adhesives. The miscibility of these polymers should be promoted by formation of hydrogen bonds between the amide groups –NH–CO– of the SPA macromolecule and chitosan. Previously, we have shown [7] that SPA forms homogeneous blends with starch in the presence of plasticizers (glycerol and water) providing the compatibility of the polymers (so-called compatibilizers). The similarity between the rheological properties of these blends and those of common synthetic polymers makes these mixtures promising for practical applications. A specific feature of the SPA–chitosan blend is that only relatively reactive compounds like acetic or formic acids are suitable as compatibilizers for these components. In this study, we used polymer blends free of these additives. The copolyamide served as a matrix, and chitosan, as a filler providing biodegradation of the composite. We used ternary copolyamide 6/66/610. Since the melting point of the copolyamide was lower by approximately 100°C than the temperature of thermal degradation of chitosan, the blends were prepared by direct addition of chitosan to an SPA melt.

Since the processing conditions of a polymer blend are determined by its rheological properties (viscosity), we studied the temperature dependence of the viscosity of chitosan–copolyamide melts as influenced by the chitosan content of the blend.

EXPERIMENTAL

We studied blends of ternary copolyamide 6/66/610 with chitosan. The copolyamide was prepared by cocondensation of caprolactam, and AG and SG salts taken in a 45/10/45 weight ratio. The molecular weigh and the degree of substitution of chitosan, determined by the procedure described in [8], were 1.2×10^5 and 89%, respectively. We used polymer powders with a particle size of about 7×10^{-5} m. Chitosan was X-ray-amorphous, and the degree of crystallinity of SPA

* Solutions in formic acid.
** Solutions in acetate buffer [8].

6/66/610 was $n \approx 10\%$. The properties of these polymers are summarized in the table.

Prior to mixing, SPA was stabilized by addition of 1.0% Irganox antioxidant. Weighed portions of the powdered components were thoroughly mixed and pelletized. The pellets corresponded in the shape and size to the viscometer channel. The blends were pressed at 180°C under a pressure of 15 MPa.

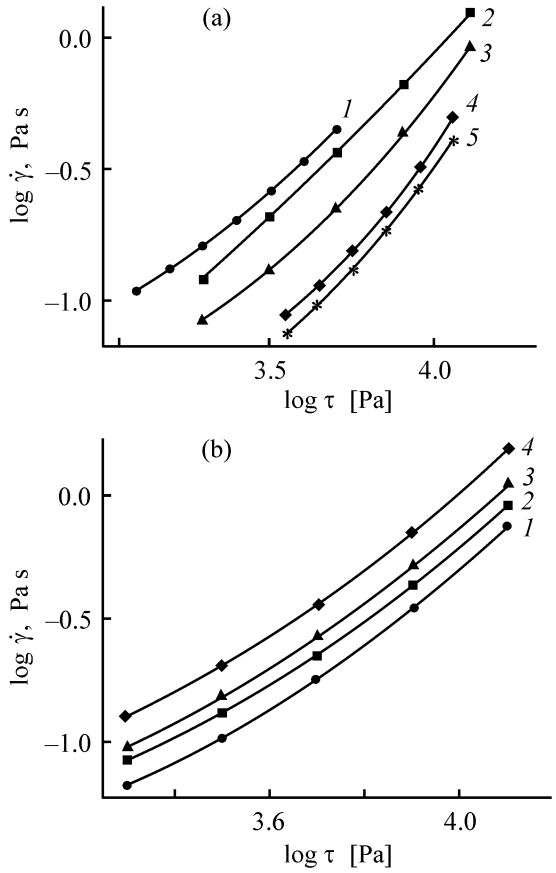

Fig. 1. Flow curves of SPA–chitosan blends. ($\dot{\gamma}$) Shear rate and (τ) shear stress. (a) 160°C; weight fraction of chitosan: (*1*) 0.0, (*2*) 0.05, (*3*) 0.1, (*4*) 0.12, (*5*) 0.15. (b) Weight fraction of chitosan 0.1; temperature (°C): (*1*) 150, (*2*) 155, (*3*) 160, and (*4*) 170.

The viscosity of SPA–chitosan melts η was measured at 150–170°C on an MV-2 microviscometer at a shear rate $\dot{\gamma} = 1 \times 10^{-2}$–$5 \times 10^{-1}$ s^{-1} and shear stress τ = 1.2–2.1 kPa. Since the ratio of the capillary length to its radius was 25, the viscosity was calculated without correction for the entrance effect [9]. The true flow curve (shear rate vs. shear stress) was constructed by the procedure described in [10] using the conventional Excel software.

The flow curves of SPA and its blends with chitosan at 160°C are shown in Fig. 1a. The shape of these curves is typical of pseudoplastic structured systems [11], in which the shear rate nonlinearly increases with the shear stress. As can be seen from Fig. 1a, deviation from linearity are more appreciable at increased chitosan content in the system. Similar rheological curves were obtained for all the examined systems at 150, 155, and 170°C.

The flow curves of a SPA–chitosan melt of one of the four compositions examined, measured at four temperatures, are shown in Fig. 1b. The viscosities of the melt are typical of melts of common synthetic polymers. As can be seen from Fig. 1, the shear rate, i.e., the flowability of the melt increases with temperature at a given shear stress. This trend is typical of polymer melts. Similar dependences were obtained for all the compositions examined.

The dependences of the viscosity of SPA–chitosan melts on the polysaccharide concentration are shown in Fig. 2. At all the temperatures examined, the viscosities of the melts increase with the chitosan content.

The activation enthalpy of viscous flow of SPA–chitosan melts was estimated by the Frenkel–Eyring equation [12]

$$\eta = A\exp[\Delta H/(RT)]. \quad (1)$$

The results are shown in Fig. 3 in the form of a dependence of ΔH on the polysaccharide concentration c in the melt at a constant shear stress. The activa-

tion enthalpy increases with the chitosan content. In the examined range of mole fractions of chitosan, the dependence can be approximated by a linear equation

$$\Delta H = 43.1 + 157.5c. \quad (2)$$

The rise in η and ΔH with increasing chitosan concentration is due to the introduction of a rigid-chain polymer with a higher molecular weight. This polymer can form $NH_2\ldots O{=}C<$ intermolecular bonds with the copolyamide. This assumption is confirmed by the IR spectra of films of chitosan blends with polycaprolactam and polyamide 66, whose units are similar in chemical stricture to those of SPA [13]. The concentration dependences of the viscosity and activation energy are similar and show a decrease in the viscosity of an SPA–chitosan melt (Figs. 2, 3) with increasing polysaccharide concentration.

The concentration dependence of the viscosity of a SPA–chitosan melt cannot be described by the Einstein equation for dispersions [14] since the components form intermolecular hydrogen bonds. To describe the rheological properties of the melts, we used the invariance principle applicable to different polymers and their blends [15, 16]. The maximum Newtonian viscosity of the melt η_0 was determined by extrapolation of the viscosity (Fig. 1a and 1b) to zero shear stress ($\tau \to 0$). These values were used to construct the dependence of the rheological properties of the system in the "invariance" coordinates: reduced viscosity η/η_0 vs. specific shear rate $\dot{\gamma}\eta_0$. The results are shown in Fig. 4. The points fall into a narrow band, which is typical of polymers [16]. A similar dependence was observed for various polymers and their blends, including a blend of synthetic ethylene–vinyl acetate copolymer (SEVA-15) with starch. In this case, the natural polymer was also used as the biodegradable filler [17]. The viscosity of SPA–chitosan blends can be calculated within the band shown in Fig. 4 at known shear rate and η_0.

Thus, we measured the viscosity of SPA–chitosan blends, determined the temperature dependence of the viscosity, and found that these systems follow the principle of invariance of rheological properties. Based on these results, the rheological properties of environmentally clean SPA–chitosan blend, required for their processing, can be predicted.

CONCLUSIONS

(1) Introduction of chitosan into synthetic copolyamide 6/66/610 leads to an increase in the viscosity

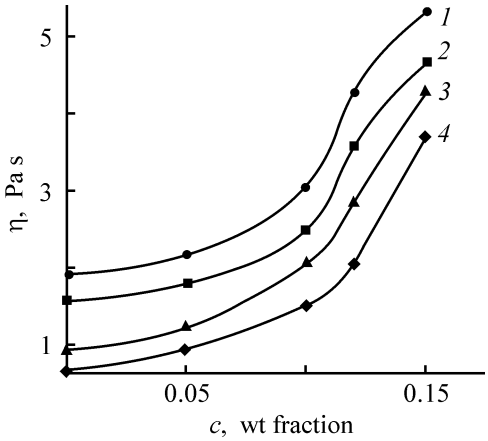

Fig. 2. Viscosity η of SPA–chitosan melts vs. the weight fraction of chitosan, *c*. Shear stress 5 kPa ($\log \tau = 3.7$); the same for Fig. 3. Temperature (°C): (*1*) 150, (*2*) 155, (*3*) 160, and (*4*) 170.

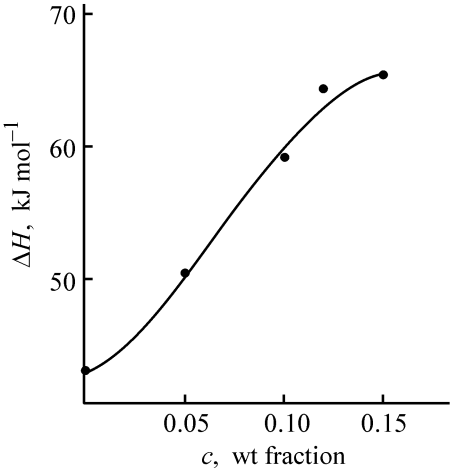

Fig. 3. Activation enthalpy of ΔH of viscous flow of SPA–chitosan melts vs. the weight fraction of chitosan, *c*.

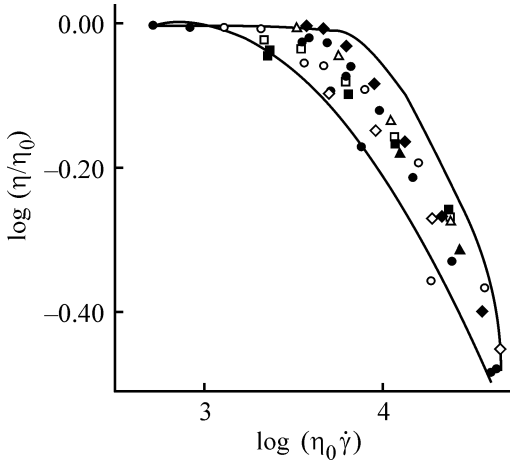

Fig. 4. Temperature-invariant characteristic of the viscosity of SPA–chitosan melts. (η/η_0) Reduced viscosity and ($\eta_0\dot{\gamma}$) specific shear rate. Filled and hollow symbols refer to 150 and 170°C, respectively.

of its melt and in the activation enthalpy of viscous flow of the blends.

(2) The dependences of the viscosity of SPA–chitosan blend on temperature and composition follow the principle of invariance of rheological properties, known for polymer systems, which can be used to predict the rheological properties of these blends in development of new biodegradable polymer materials.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Structural and Hydrodynamic Characteristics of Dextrans in Liquid-Phase Media

O. V. Alekseeva, O. V. Rozhkova, O. V. Eliseeva, and A. N. Prusov

Institute of Chemistry of Solutions, Russian Academy of Sciences, Ivanovo, Russia

Received February 9, 2005

Abstract—Viscous and volume properties of solutions of dextran with various molecular weights in water and dimethyl sulfoxide were studied.

In recent years, the researchers' attention has been attracted by natural polymer systems based on polysaccharides, which are not only biologically active compounds, but also an adequate model of amorphous regions of cellulose for studying solvation interactions in solution. Of particular interest are bacterial polymers, dextrans. Owing to their unique physicochemical properties, they are widely used in medicine and pharmacology. The practical use of these polysaccharides as effective blood substitutes makes a study of their behavior in dilute solutions a matter of current interest. Unfortunately, publications devoted to this issue are scarce [1].

In the present study, viscous and volume properties of solutions in water and dimethyl sulfoxide (DMSO) of dextrans with various molecular weights were subjected to a systematic analysis.

EXPERIMENTAL

Dextrans of Fluka AG Buchs brand, with molecular weights of 70×10^3–500×10^3, served as objects of study. The dextrans were dried in a vacuum at 330 K for 24 h. Water (twice distilled) and DMSO purified and dehydrated by the procedure described in [2] were used as solvents. The content of water in the solvent was determined by amperometric titration by the Fisher method to be ±0.002%. Polymer solutions were prepared gravimetrically using a VLR-200 balance with an accuracy of $\pm 5 \times 10^{-5}$ g. The viscosity of polymer solutions with concentrations of 3–16 kg^{-3} was measured with a capillary Ubbelohde viscometer at 293–303 K. The root-mean-square error in viscosity measurements was ±0.5%.

The dependences of the reduced viscosity of dilute solutions of dextrans, η_{sp}/c, on the polymer concentration c were linear for all the systems studied ($r = 0.98$). The viscometric Huggins constant was found using the equation from [3]:

$$\eta_{sp}/c = [\eta] + K_H c[\eta]^2, \quad (1)$$

where K_H is the Huggins constant, which describes the interaction of segment of polymer macromolecules with the solvent, and $[\eta]$ is the characteristic viscosity.

The solvent was characterized by K_H, $[\eta]$, and average statistical dimensions of macromolecular coils. The volume V_m of a polymer macromolecule and the root-mean-square distance $(\bar{h}^2)^{1/2}$ between the chain ends of polymer macromolecules were calculated by the formulas [4, 5]:

$$[\eta] = \Phi(\bar{h}^2)^{1/2}/M, \quad (2)$$

$$[\eta] = 2.5 N_A V_m/M, \quad (3)$$

were Φ is the Flory coefficient, which accounts for the deviation of the actual volume of the macromolecules from the spherical volume and for the partial permeability of the coil to the solvent; M, molecular weight of dextran; 2,5, form factor of a spherical particle; N_A, Avogadro number.

The density of dextran solutions was studied with a vibrational densitometer. The design of the densitometer and the experimental procedure were described in [6]. The error in density measurements was $\pm 2 \times 10^{-6}$ g cm^{-3}, which made it possible to calculate the volume characteristics of dextran with a sufficient reliability. The volume parameters were evaluated by an efficient procedure based on the experimentally measured solution density as the input value.

To diminish the calculation error, partial molar volumes were calculated directly from experimental data on density by the equation [7]

$$V_2 = M_2/\rho - \frac{(1000 + mM_2)}{\rho^2}\frac{\partial\rho}{\partial m}, \quad (4)$$

where V_2 is the partial molar volume of the solute; M_2, molecular weight of the solute; ρ, solution density; and m, molal concentration of the solution (mol kg^{-1}).

The apparent molar volume V_Φ of the solute was calculated using the equation [8]:

$$V_\Phi = 1000(\rho_0 - \rho)/m\rho\rho_0 + M_2/\rho, \quad (5)$$

where ρ_0 is the density of the pure solvent.

The data in Table 1 demonstrate that solutions of dextrans with different molecular weights in water and DMSO have comparatively viscosities. The highest values of [η], V_m, and $(\bar{h}^2)^{1/2}$ are observed in DMSO, and the lowest, in water. At the same time, K_H has the minimum value in DMSO. Such a behavior of K_H is due to different mechanisms of solvation of polymer macrochains by molecules of water and DMSO. Water has a tetrahedral structure owing to the formation of strong hydrogen bonds between its molecules. Dimethyl sulfoxide is an associated liquid composed of clusters [9]. Having an unshared electron pair, the DMSO molecule can interact with both polar (ionic compounds) and nonpolar molecules and, therefore, dextran molecules are easily incorporated into the DMSO structure (because of the lower energy expenditure as compared with water) to form stable compounds with DMSO clusters. In this case, the macromolecular coil increases in size and a developed three-dimensional (3D) system of intermolecular bonds is formed. The strong intermolecular interaction between polysaccharide molecules and DMSO is confirmed by the negative enthalpy of dextran transfer from water into DMSO [1]. The increase in [η] and in average statistical dimensions of dextran macromolecules may be due in the given case both to a decrease in the thermodynamic lability of the molecular coil and to conformational changes (transition to a more unfolded state) through formation of new intermolecular complexes polymer–DMSO. In this case, the conformational lability of dextran is, as follows from NMR data, higher in water, compared with DMSO [10], which is in a good agreement with experimental data on viscosity.

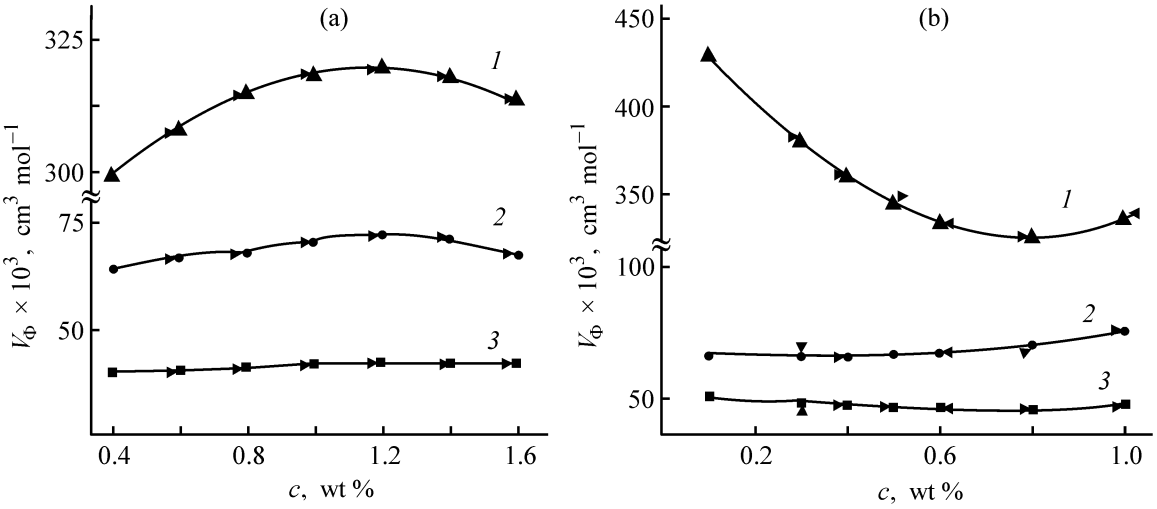
Lowering the molecular weight of the polymer from 500×10^3 to 70×10^3 in the liquid-phase systems studied leads to an increase in K_H and decrease in [η] and in hydrodynamic dimensions of dextran macromolecules and is accompanied by their transition to a more folded conformation.

As temperature is raised from 293 to 313 K, the characteristic viscosity, dimensions of the macromolecular coil, and the intensity of intermolecular polymer–solvent interactions for dextrans with different molecular weights in water and DMSO decrease (Table 1). Presumably, this is due to structuring processes occurring in solutions because of the weakening of intermolecular interactions upon enhancement of the thermal motion.

To determine the structural changes in the systems under study, the enthalpies of activation of the viscous flow of polymers in solutions in the temperature

range 293–313 K were calculated. The enthalpies of activation of the viscous flow for samples of dextrans with molecular weights of 70×10^3–110×10^3 in water (9.2–10.3 kJ mol^{-1}) and DMSO (8.1–7.0 kJ mol^{-1}) differ only slightly. Another pattern is observed for samples of a dextran with a molecular weight of 500×10^3 in the solvents studied. As noted above, aqueous solutions of a dextran with $M = 500 \times 10^3$ have a lower viscosity than solutions in DMSO. However, the enthalpy of dextran activation in DMSO (3.7 kJ mol^{-1}) is lower than that in water (14.7 kJ mol^{-1}). The lower enthalpies of activation of the viscous flow of the polymer in DMSO are due to the following: a developed 3D system of intermolecular bonds is formed in DMSO, but it is not as stable as that in water, because dextran macromolecules are bound together by DMSO clusters. In this case, differences between the entropies of the viscous flow of solutions in water and DMSO must be observed. Indeed, the manner in which the entropy of activation changes in the systems under study indicates that orientation effects are predominant in a flow of dextran solutions in DMSO ($T\Delta S$ = –6.5 kJ mol^{-1}), compared with aqueous solutions ($T\Delta S$ = 5.6 kJ mol^{-1}), in which destruction of order dominates.

To confirm the previously advanced hypotheses, the volume properties of the polymers were studied. The figure and Table 2 show the concentration dependences of the density and the apparent and partial molar volumes of dextrans with different molecular weights in the solvents studied. It can be seen that the densities and volumes in equally concentrated solutions grow as the molecular weight of the polymer increases (Table 2). The types of behavior of the partial and apparent molar volumes of dextrans in water and DMSO with the polymer concentration were found to be different. As the polymer concentration in aqueous solutions is raised, the partial and apparent molar volumes grow and pass through a maximum, with the maximum becoming stronger at higher molecular weights of the polymer. In DMSO, a similar dependence passes through a minimum, and this minimum becomes more pronounced for dextrans with a molecular weight of 500×10^3. These differences may be due to different mechanisms of solvation of the polymer by molecules of water and DMSO.



Thus, the results obtained in a study of the volume properties of dextran solutions are in a good agreement with their viscous characteristics. The data obtained are of interest for a deeper insight into the dextran structuring in liquid-phase media.

Received October 14, 2004; in final form, February 17, 2005

Abstract—Calculated and experimentally measured characteristic viscosities [η] of polystyrene in some binary solvents used as eluents in chromatographic experiments in a wide range of mixture compositions were compared. The values of [η] were measured in solvents of varied thermodynamic quality, including the theta solvent and mixtures of solvents of the following compositions: two good solvents; good solvent and theta solvent; good solvent and precipitant; poor solvent and theta solvent. An equation that relates the anomalies observed in the dependences of [η] on the composition of a solvent mixture to parameters of the Flory–Huggins thermodynamic interaction was suggested.

Ternary polymeric systems (a polymer in a binary solvent) have long attracted researchers' attention. Binary mixtures have been frequently used as theta solvents. Specific features in the behavior of these solutions, which cannot be understood in terms of the existing theories of polymer–solvent systems, have been revealed. Mixtures of solvents are widely used in practice of polymer processing. The recent interest in systems of this kind is due to their application in chromatography, and specifically in adsorption chromatography under critical conditions.

In the 1960–1970s, there appeared a large number of publications reporting on experimental and theoretical studies of polymer solutions in mixed solvents. In many systems, the dependences of the characteristic viscosity [η], second virial coefficient, sorption selectivity coefficient, and unperturbed size of macromolecular coils on the solvent composition were nonlinear [1]. This phenomenon has been mainly related by researchers to the balance of forces of intermolecular interactions in systems constituted by a polymer and solvent (1), polymer and solvent (2), solvent (1) and solvent (2), and two polymers. Numerous attempts have been made to introduce additional parameters, to take into account ternary interactions, into the equations used to calculate the size of macromolecular coils in binary solvents [1]. However, many of these parameters can be neither calculated nor measured [2]. Until now, the questions concerning the conformation of macromolecular chains, selective sorption of solvents, and effect of temperature in ternary systems constituted by a polymer in a binary solvent remain unanswered. It is known that the absolute viscosities of low-molecular nonelectrolyte liquids (binary and ternary) differ from the additive values by 10–18% [3], and the existence of dipole–dipole interactions in binary systems substantially enhances the deviations of their viscosity from linearity. In some cases, the dependences of the absolute viscosity on the mixture composition have an extremal nature [4].

It has been shown previously [5, 6] that the thermodynamic quality of the mobile phase is, under conditions of adsorption chromatography, a factor that affects the adsorption behavior of macromolecules and determines the degree of unfolding of the polymer chain in a single sorption–desorption event. To attain the same retaining factor of macromolecules, the polarity index of the mobile phase should be the higher, the better its thermodynamic quality. Therefore, the problem of the thermodynamic quality of a solvent used in chromatographic experiments is a matter of current interest.

Because the simplest way to compare the quality of solvents is to determine the characteristic viscosity [η], it seemed advisable to perform special-purpose experiments aimed to compare the calculated and measured values of [η] in some binary solvents used in chromatographic experiments, in a wide range of mixture compositions. In doing so, we made an at-

1070-4272/05/7806-0975 © 2005 Pleiades Publishing, Inc.

tempt to express the effects we observed in terms of the readily determinable parameter of the thermodynamic interaction, χ (Flory–Huggins parameter).

EXPERIMENTAL

It is known that the characteristic viscosity $[\eta]$ is proportional to the volume of macromolecules in solution and is related to the root-mean-square size of a thermodynamically unfolded coil by the following expressions:

$$[\eta]_\theta = \Phi_\theta (h_\theta^2)^{3/2}/M \text{ (in a theta solvent)}, \quad (1)$$

$$[\eta] = [\Phi_\theta (h_\theta^2)^{3/2}/M]\alpha^3 \text{ (in a good solvent)}, \quad (2)$$

where M is the molecular weight of the polymer; Φ_0, universal (under theta conditions) Flory constant; $(h_0^2)^{1/2}$, linear size of a chain molecule under theta conditions; and α, degree of swelling of the macromolecular coil [7, 8].

In good solvents, coils swell to a greater extent than in poor solvents, i.e., the better the thermodynamic quality of a solvent, the higher $[\eta]$:

$$[\eta] = [\eta]_\theta \alpha^3. \quad (3)$$

It is possible to determine $[\eta]$ for well-studied polymers, such as polystyrene and polymethyl methacrylate, in individual solvents by calculation, because the constants in the Mark–Kuhn–Houwink equation ($[\eta] = K_\eta M^a$) have been experimentally determined for most of solvents and can be found in the reference literature [9]. However, solvent mixtures are, as a rule, used as eluents in chromatographic experiments, and calculation of $[\eta]$ for these mixtures is, as shown above, a more complicated procedure. For example, a calculation of $[\eta]$ in a mixed solvent as a sum of products of $[\eta]$ in an individual solvent by the volume fraction of the solvent in the mixture, x_i, is only possible in the absence of specific polymer–solvent and(or) polymer–polymer intermolecular interactions [8]. In this case, the dependence of the additive viscosity $[\eta]_{ad}$ on the composition of the binary mixture is expressed by the equation

$$[\eta]_{ad} = [\eta]_1 x_1 + [\eta]_2 x_2, \quad (4)$$

where x_i is the volume fraction of a component, with $x_1 + x_2 = 1$.

The deviations $\Delta[\eta]$ of the experimental values of $[\eta]$ (or, accordingly, α^3) from their calculated additive values are occasionally related to the excess free energy of solvent mixing, ΔG. In particular, it follows from the equation suggested by Dondos and Patterson [10] that $\Delta[\eta]$ must be positive at $\Delta G > 0$ and negative at $\Delta G < 0$.

To relate the effects observed to the known constant χ_{ik} of the thermodynamic Flory–Huggins interaction, which characterizes intermolecular interactions in the system, we can use the following simple expression [8, 11]:

$$\varepsilon_i = 2\chi_{i3} - 1. \quad (5)$$

Here, the Flory–Huggins constant χ_{ik} is expressed in terms of the reduced excluded volume $-\varepsilon_i$, which also characterizes the interaction of the polymer with the mixture components:

$\varepsilon \approx -0.2\ldots0$ for good solvents, $\varepsilon \approx 0-0.1$ for bad solvents, and $\varepsilon > 0.3$ for precipitants.

Then we have for the mixture constituted by solvent (1), solvent (2), and polymer (3):

$$\varepsilon_m = x_1\varepsilon_1(1 - x_2\chi_{12}) + x_2\varepsilon_2(1 - x_1\chi_{12}) + x_1x_2[\Delta\chi^2 - \chi_{12}(2 - \chi_{12})], \quad (6)$$

where x_1 and x_2 are the volume fractions of the solvents ($x_1 + x_2 = 1$); χ_{12}, the solvent–solvent interaction parameter for easily mixed solvents, equal to 0.1–0.6; $\Delta\chi = \chi_{13} - \chi_{23}$; and χ_{13} and χ_{23}, interaction parameters for the polymer–solvent (1) and polymer–solvent (2) systems, respectively. Relation (6) can be represented as

$$\varepsilon_m = \varepsilon_{ad} + \Delta\varepsilon, \quad (7)$$

where

$$\varepsilon_{ad} = x_1\varepsilon_1 + x_2\varepsilon_2, \quad (8a)$$

$$\Delta\varepsilon = x_1x_2[\Delta\chi^2 - \chi_{12}(\chi_{12} - 2\chi_{13} - 2\chi_{23})]. \quad (8b)$$

It can be seen from relations (6), (7), (8a), and (8b) that a strong deviation from additivity is associated with the values of χ_{12} and $\Delta\chi^2$. An increase in $\Delta\chi^2$ always leads to a rise in $\Delta\varepsilon$, whereas the contribution from χ_{12} depends on the quality of a solvent used. It is known that, in some cases, the thermodynamic quality of a mixture of poor solvents is better than that of the initial components [1]. Simple calculations show that the strongest deviation from additivity must be observed at $x_1 = x_2 = 0.5$, i.e., at a 1 : 1 ratio of solvents in the mixture.

Flory–Huggins constants, second virial coefficients, reduced excluded volumes, C constants, and $\Delta[\eta]/x_1x_2$ [Eq. (14)] for polystyrene in individual solutions and mixtures of these

MEK	0.491	1.00	0.015	MEK/Cyclohexane	19.5	1.75
Cyclohexane (35°C)	0.5	0.93	0.0	–	–	–

It is known that the solvent quality also affects the Huggins constant K', which characterizes intermolecular and hydrodynamic interactions in a shear flow. Its values depend on the polymer–solvent interactions. For linear flexible-chain polymers, K' varies from 0.2 (good solvents) to 0.5 (bad solvents) [7, 8]. An expression describing K' in a wide range of α has been derived [8]:

$$K' = 0.25 + 0.3/\alpha^6. \quad (9)$$

The validity of expression (9) was confirmed for many polymer–solvent systems; however, this expression has not been extended to ternary polymeric systems until now. We found it appropriate to determine the dependence of K' on α [Eq. (9)] for polymers in binary solutions.

We chose for our experiments polystyrene with a weight-average molecular weight $M_w = 460 \times 10^3$ and a molecular-weight distribution $M_w/M_n < 1.1$. The values of $[\eta]$ were measured in good solvents: toluene, carbon tetrachloride CCl_4, and terahydrofuran (THF); in methyl ethyl ketone (MEK), a solvent with a poorer thermodynamic quality; in cyclohexane, a theta solvent; and solvent mixtures of the following compositions: two good solvents (1), good solvent and theta solvent (2), good solvent and precipitant (3), and poor solvent and theta solvent (4). The solvents were of analytically pure grade. All the solvents are indefinitely soluble in one another, with the exception of the MEK/cyclohexane pair, whose poor compatibility is indicated by the thermodynamic nature of the process of their mixing.

The thermodynamic quality of individual solutions with respect to polystyrene was well studied long ago. The relevant data are available in numerous publications and in the reference literature [9, 12]. This property of the solvents used was characterized by the second virial coefficient A_2 (see table).

The characteristic viscosities were measured in capillary viscometers of the Ubbelohde type with a suspended level. The time of solvent outflow was ~100 s, with the measurement error not exceeding 2%. The experiments were performed at 25°C, and those with cyclohexane-containing solutions, at 25 and 35°C.

We obtained an experimental dependence of $[\eta]$ of polystyrene on the composition of a binary solvent constituted by a pair of good solvents (toluene/CCl_4). As can be seen from Fig. 1 (curve *1*), the experimental values of $[\eta]$ coincide with the additive values [Eq. (4)]. The hydrodynamic volume of macromolecules is virtually independent of the solvent composition. The maximum deviation from the additive values of $[\eta]$, $\Delta[\eta]$, was 2.6%. The scatter of K' is also insignificant: 0.35–0.42.

The dependences of $[\eta]$ on the composition of mixtures constituted by a theta solvent and a good solvent, to which belong the mixtures cyclohexane/toluene (Fig. 1, curve *2*), cyclohexane/THF (Fig. 1, curve *3*), and cyclohexane/MEK (Fig. 2, curves *2* and *3*), exhibit deviations from linearity. As the fraction of cyclohexane increases from zero to 0.6 in a cyclohexane/THF mixture and to 0.4 in a cyclohexane/toluene mixture, the values of $[\eta]$ for polystyrene change only

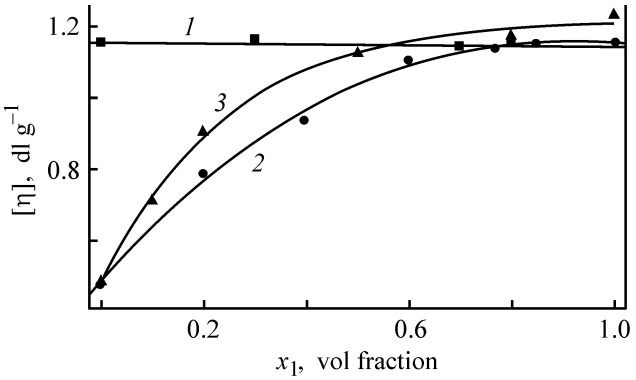

Fig. 1. Characteristic viscosity $[\eta]$ for polystyrene with $M_w = 460 \times 10^3$ in the mixtures (*1*) toluene/CCl_4, (*2*) toluene/cyclohexane, and (*3*) tetrahydrofuran/cyclohexane. (x_1) Volume fraction of toluene or tetrahydrofuran.

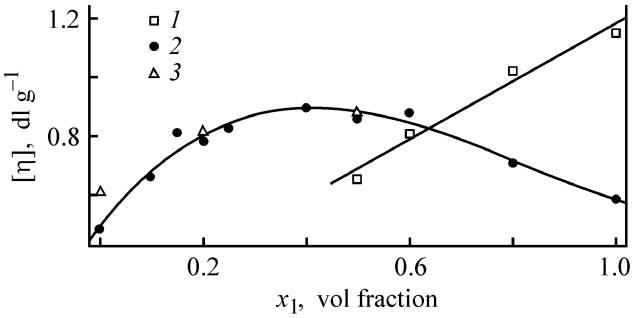

Fig. 2. Characteristic viscosity [η] of polystyrene with $M_w = 460 \times 10^3$ in the mixtures (*1*) toluene/hexane, (*2*) methyl ethyl ketone/cyclohexane at 25°C, and (*3*) the same mixture at 35°C. (x_1) Volume fraction of toluene or methyl ethyl ketone.

slightly: by 9 and 5%, respectively. Further addition of cyclohexane leads to their dramatic decrease, although the values of K' emain close to those for good solvents. This fact can be accounted for by selective sorption of the solvent by polystyrene molecules, which leads to an increase in the concentration of the good solvent in the solvation shell of a macromolecule, compared with its concentration in the surrounding solution. The degree of macromolecule swelling will be higher in this case.

An interesting pattern is observed for a mixture of two poor solvents: cyclohexane/MEK. Pure MEK is not a good solvent for polystyrene. This is also indicated by low [η] and K' close to 0.5. In addition, this is, as already noted, the only pair of solvents, of those used in the experiments, for which the mixing process is endothermic. A dependence of [η] on the solvent composition with a maximum was obtained for this mixture (Fig. 2). At the maximum, at a 1 : 1 component ratio, the value of [η] exceeds by 53% that for pure MEK, and by 87% that for pure cyclohexane.

The experiments were performed at two temperatures: 25 and (because the theta temperature for polystyrene in cyclohexane is 34°C) and 35°C. At all compositions of mixtures of these solvents, the values of [η] virtually coincide for these two temperatures. Differences are only observed in pure cyclohexane: [η] grows from 0.48 dl g^{-1} at 25°C to 0.607 dl g^{-1} at 35°C, in a good agreement with published data [13]. Similar nonlinear viscosity–composition dependences have been obtained previously for polystyrene in acetone/methyl cyclohexane and dioxan/chloroform mixtures [1].

As the values of [η] in MEK and cyclohexane are close, it may be considered that ε_1 and ε_2 are also close. Then, we have for the symmetric case ($\varepsilon_1 = \varepsilon_2$) from relation (6) that

$$\varepsilon_m = \varepsilon_1 - x_1 x_2 \chi_{12}(\varepsilon_1 + 2 - \chi_{12}). \qquad (10)$$

It can be seen that, for a mixture of solvents, the second term is always negative, i.e., the thermodynamic quality of the system is improved upon addition of the second component. The second term is at a maximum at $x_1 = x_2 = 0.5$, and just this is the case in the experiment.

In mixtures constituted by a solvent and a precipitant (toluene/hexane), the value of [η] steadily decreases as the fraction of the precipitant in the mixture increases till the onset of polymer precipitation (Fig. 2). At a 1 : 1 solvent/precipitant ratio, [η] decreases from 1.16 to 0.66 dl g^{-1} ($\Delta[\eta] = 43\%$), which means that the hydrodynamic volume of macromolecules considerably decreases. However, the values of [η] (and, accordingly, the volume of macromolecules) are somewhat higher than the additive values, which is also confirmed by chromatographic experiments. The run of these experimental curves is accounted for by the same selective polymer–solvent interactions as in the case of a system constituted by a good solvent as a theta solvent.

For the sake of convenience and simplicity of interpretation of the data obtained, let us revert to Eq. (3). According to Fixman's equation

$$\alpha^3 = 1 + 2z, \qquad (11)$$

where z is the known excluded volume parameter, which can be expressed in terms of the parameters ε_m, ε_{ad}, and $\Delta\varepsilon$, we introduced, as

$$\alpha^3 = 1 + C\varepsilon_m = 1 + C(\varepsilon_{ad} + \Delta\varepsilon), \qquad (12)$$

where C is a constant (negative, because ε_m is negative for good solvents), and ε_{ad} is the excluded-volume parameter calculated by the additive scheme [Eq. (8a)].

The values of ε_i, which can be readily found using relation (5) from the known Flory–Huggins parameters, are listed in the table. The same table presents values of C for the systems mentioned. The average value of C is –19.1.

Let us denote the deviations of $[\eta]_m$ from the additive value by

$$\Delta[\eta] = [\eta]_m - [\eta]_{ad}. \qquad (13)$$

Then, taking into account relations (3) and (12), we obtain

$$\Delta[\eta]/x_1x_2 = [\eta]_\theta |C| [\chi_{12}(2\chi_{23} + 2\chi_{13} - \chi_{12}) - \Delta\chi^2]. \quad (14)$$

It follows from Eq. (14) that an increase in the first term $\chi_{12}(2\chi_{23} + 2\chi_{13} - \chi_{12})$ virtually always leads to a rise in $\Delta[\eta]$, i.e., to a larger coil size. At the same time, an increase in the second term $\Delta\chi^2$ always leads to a decrease in $\Delta[\eta]$, i.e., to contraction of macromolecules.

Based on the experimental data, we obtained dependences of $\Delta[\eta]$ on the product x_1x_2 (Fig. 3). For all the systems constituted by a good solvent and a theta solvent, which we studied, these dependences are linear, in agreement with the theoretical predictions [Eq. (14)]. However, the slopes of these straight lines vary between different pairs of solvents and have the following values: 0.88 for toluene/cyclohexane, 1.11 for THF/cyclohexane, and 1.75 for MEK/cyclohexane. This means that the experimentally strongest effect is observed for a mixture constituted by a poor solvent and a theta solvent.

Figure 4 shows dependences of K' on α^3 for all the binary solution mixtures studied. It can be seen that all these dependences can be described by the same expression:

$$K' = 0.3 + 0.3/\alpha^6. \quad (15)$$

Thus, it was shown that the experimental dependences for ternary systems (a polymer in a binary solvent) are close to the dependences previously obtained for solutions of polymers in individual solvents, and Eq. (15) virtually coincides with relation (9), suggested in [8].

It is demonstrated that, in principle, values of $[\eta]$ in mixed solvents can be calculated. However, this calculation requires a knowledge of such thermodynamic characteristics as the interaction parameter for systems constituted by a polymer and solvent (1) or (2) or by solvent (1) and solvent (2) (χ_{12}, χ_{13}, and χ_{23}), which are not always available.

CONCLUSIONS

(1) It was shown that the values of $[\eta]$ measured for polystyrene in mixtures of two good solvents of various compositions are equal to the calculated additive values. The values of $[\eta]$, measured in solvent/precipitant mixtures, somewhat exceed the additive values. In mixtures constituted by a solvent and a theta solvent, nonlinear (and extremal for the MEK/cyclohexane mixture) dependences of $[\eta]$ of polystyrene on the solvent composition were obtained.

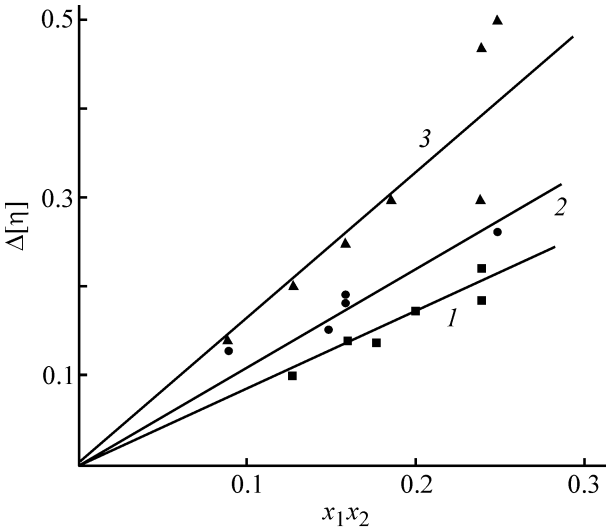

Fig. 3. Dependences of $\Delta[\eta]$ on x_1x_2 for different pairs of a solvent and a theta solvent. (*1*) toluene/cyclohexane, (*2*) THF/cyclohexane, and (*3*) MEK/cyclohexane.

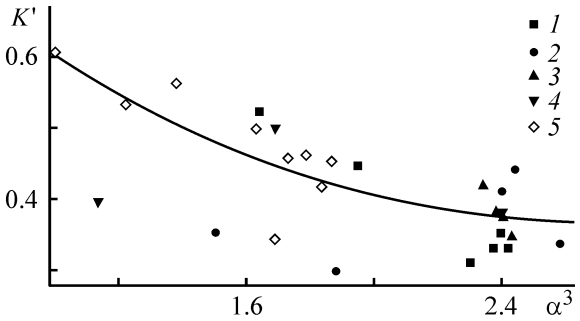

Fig. 4. Dependence of the Huggins constant K' on the degree of swelling, α^3, for polystyrene in mixtures (*1*) toluene/cyclohexane, (*2*) THF/cyclohexane, (*3*) toluene/CCl_4, (*4*) toluene/hexane, and (*5*) MEK/cyclohexane.

(2) The deviations of $[\eta]$ from the additive values, observed for polystyrene in mixed solvents, were attributed to selective solvation of macromolecules in ternary solutions, and this was confirmed by calculations of $\Delta[\eta]$ with account of the Flory–Huggins parameters of the thermodynamic interaction between the polymer and the solvent.

(3) It was shown that the experimental dependences of the Huggins constants on the degree of swelling of macromolecular coils for ternary systems (a polymer in a binary solvent) are close to the dependences previously obtained for solutions of polymers in individual solvents.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Specific Features of Glucoamylase Immobilization by Adsorption on Fibrous Polyelectrolytes

I. V. Shkutina, O. F. Stoyanova, and V. F. Selemenev

Voronezh State University, Voronezh, Russia

Received March 2, 2005

Abstract—Some fundamental aspects of the immobilization of a hydrolytic enzyme glucoamylase via adsorption on aminocarboxylic ion-exchangers with fibrous structure were considered. The sorption capacity of amphoteric supports for the enzyme was studied in relation to the time of immobilization, concentration of hydrogen ions and the protein, and the ionic form of a polyelectrolyte. The catalytic properties of free and immobilized enzymes were compared.

Recently, the importance of reactions used to obtain products from renewable vegetable raw materials has been steadily increasing. A stage in production of glucose syrups widely used in food industry is saccharification of dextrinized starch, involving glucoamylase (α-1,4-glucanhydrolase, KF 3.2.1.3). The presently arising increased interest in immobilization of enzymes by supports of various kinds is due to the large potentialities in use of bound enzymes as specific and stable heterogeneous biocatalysts. A study of the immobilization of enzymes is primarily aimed to obtain data related to optimization of the process, which presumes an effective combination of the choice of a support with various conditions and parameters of the system and provides that the activity of the heterogeneous catalyst is preserved to the maximum possible extent.

Among the existing immobilization methods, the adsorption technique is distinguished by simplicity, requires no preliminary modification of a support, uses easily regenerated sorbents, and changes the structure of the enzyme to a lesser extent, compared with the case of covalent binding. In addition, of no less importance is the economic expediency and ecological safety of the method [2].

Despite that a large number of studies concerned with glucoamylase immobilization have been reported, the enzymatic process of hydrolytic amylolysis with a hereterogeneous catalyst has not been implemented [3, 4].

Previously, glucoamylase has been immobilized on a nonionogenic sorbent Stirosorb and granulated amphoteric ion-exchangers [5–7]. The present communication reports the results obtained in glucoamylase immobilization via adsorption on aminocarboxylic fibrous ion-exchangers of the Fiban type. The choice of sorbents as supports for enzyme immobilization is due to the similarity of the structural components of protein molecules and functional groups of polyelectrolytes. Use of fibers as supports is preferable in some cases to application of sorbents in other forms. Fiban fibers have a three-dimensional structure, highly developed surface, good mechanical strength, and chemical and osmotic resistance [8]. The physical form and properties of the biocatalyst obtained enable its use in continuous processes, e.g., in column reactors. The enzymes incorporated into its structure are protected from the inactivating influence of microorganisms.

EXPERIMENTAL

A hydrolytic enzyme glucoamylase from *Aspergillus awatori* was studied. As supports for glucoamylase immobilization served fibrous aminocarboxylic polyelectrolytes K-3, K-5, and AK-22-1, which contain $–NH_2$, =NH, ≡N, and –COOH as functional groups [9]. The ion-exchangers were prepared for immobilization by selecting a fraction with a required grain size, conditioning, and converting the ion-exchangers into the necessary ionic form [10].

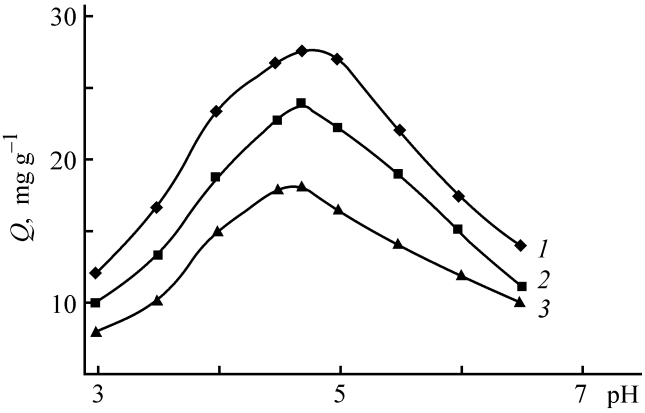

Fig. 2. Amount of sorbed glucoamylase, *Q*, vs. the pH value of the equilibrium solution.

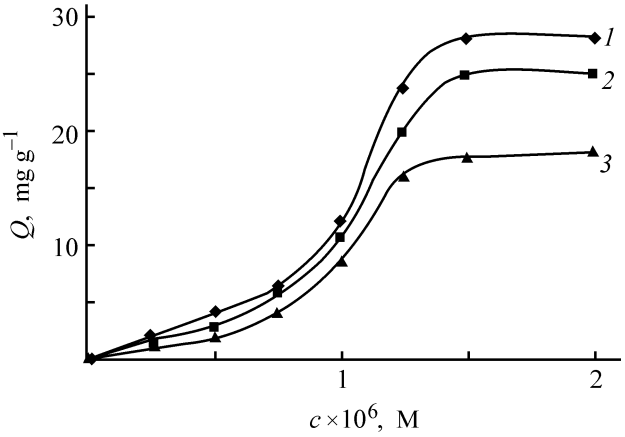

Fig. 3. Kinetic curves of glucoamylase sorption at pH 4.7. (*Q*) Amount of sorbed glucoamylase and (*c*) initial concentration of the protein in solution.

The immobilization was performed by the adsorption method under static conditions with periodic agitation at a temperature of 20°C. The desorption of the protein into buffer solutions did not exceed 5%. The total amount of the protein in native enzymatic preparations was determined by the Lowry method, and that in immobilized enzymes, by the modified Lowry method [11]. The catalytic activity of glucoamylase was measured by the glucose oxidase method [12]. As the activity unit of glucoamylase was taken such an amount of the enzyme, which catalyzes hydrolysis of starch at 25°C and pH 4.7 in 1 min to give 1 μmol of glucose. The mass of water in the sorbent was determined after phase separation by centrifugation at 3000 rpm for 5 min. The standard deviation of the results obtained did not exceed 0.05.

To determine the conditions in which glucoamylase can be immobilized the most effectively, the influence exerted by the time of immobilization and by the concentration of hydrogen ions on the amount of bound protein was studied. Figure 1 shows kinetic curves for immobilization of glucoamylase on fibrous supports. The shape of the curves obtained demonstrates that the sorption process occurs in about the same way on the ion-exchangers under study. Beginning at the very first minutes of phase interaction, the enzyme is sorbed at a rather high rate, so that the amount of adsorption in the first 2 h is 65–75% of the total amount of the bound protein. In all the cases under consideration, the amount of immobilized glucoamylase decreases in the final stages of the process and equilibrium is attained, on average, in 4 h.

The range of pH values in which an enzyme is selectively bound to supports depends on the electrochemical characteristics of the protein. The maximum sorption of glucoamylase is observed at pH 4.5–5.0, when most part of the enzyme is in the form of zwitter ions (Fig. 2).

The sorption curves shown in Fig. 3 point to a layer-by-layer nature of glucoamylase adsorption on fibrous supports. In an adsorption interaction of proteins with aminocarboxylic ion-exchangers, supramolecular complexes may be formed via interaction with, simultaneously, cationic, anionic, and neutral binding centers. Apparently, adsorption may occur via ion exchange at low enzyme concentrations in solution. Further, the interaction between sorbate molecules is more effective than the sorbent–sorbate interaction, and the subsequent distribution of the protein in the sorbent phase occurs mostly via non-ion-exchange binding.

The largest amount of glucoamylase is sorbed on a K-3 polyelectrolyte, in which acid groups predominate over basic groups. In this study, the acid-chloride form of ion-exchangers was used because it

free	5.51	9.20	K-5	6.55	7.45
K-3	6.06	8.28	AK-22-1	6.72	7.18

was found in preliminary experiments that a 1.3–1.8 times greater amount of the protein is sorbed on the H–Cl form, compared with the H–OH and Na–OH forms of the same polyelectrolytes. It is known from the literature that, similarly to amino acids, polypeptides are better sorbed on hydrogen forms of ion-exchangers than on sodium forms [13]. This fact is probably due to recharging of ions in adsorption, with the result that the electrostatic repulsion between the sorbate and sorbent disappears.

An important role is played in immobilization by the effect of the medium as a result of interaction of solvent molecules with a support and the enzyme, as well as with one another. The adsorption of glucoamylase on fibers is accompanied by a considerable dehydration of the sorbents (Fig. 4), which indicates that the binding of the protein to the support surface becomes stronger.

In immobilization, the catalytic activity of the biocatalyst, which is dependent on the secondary and tertiary structure of the protein macromolecule, may decrease significantly. As a result of binding of the enzyme to the support, its structural-functional properties may change because the protein finds itself in a medium of a polymeric sorbent with other values of the local dielectric constant, electric potential, and concentration of hydrogen ions, compared with the solution. Immobilization may also lead to spatial hindrance to the action of factors controlling the rate of the enzymatic catalysis and to formation of a thermodynamically unfavorable conformation of the enzyme-substrate complex. As demonstrated by the experiments (see table), immobilization of glucoamylase on the ion-exchangers under consideration leads to an insignificant increase in K_m and a decrease in V_{max}, compared with the free enzyme, which indicates that the native structure of the protein is preserved.

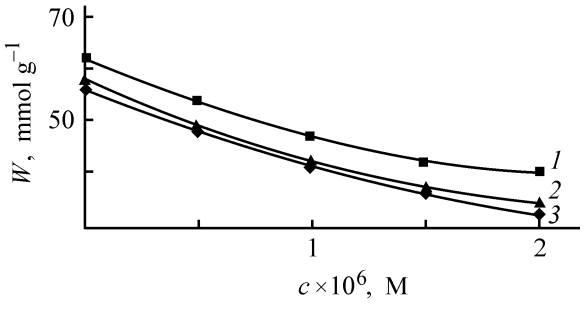

Fig. 4. Variation of the content of water in ion-exchangers in sorption of glucoamylase. (*W*) Amount of water in the sorbent and (*c*) initial concentration of the protein in solution.

Thus, the data obtained indicate that aminocarboxylic ion-exchangers are promising for immobilization of glucoamylase.

CONCLUSIONS

(1) The optimal conditions of adsorption immobilization of glucoamylase on aminocarboxylic polyelectrolytes with a fibrous structure were determined to be as follows: immobilization time 4 h, pH 4.5–4.7, sorbate concentration $(1.5–2.0) \times 10^{-6}$ M.

(2) It was established that the kinetic parameters of the reaction of starch hydrolysis for glucoamylase immobilized on K-3 ion-exchanger change to a lesser extent, compared with the native enzyme.

(3) It was shown that it is advisable to use the sorbents under consideration as supports for immobilization of glucoamylase.

Abstract—NMR and the sorption method were used to study the structure of composites based on ultrahigh-molecular-weight polyethylene and peat (filler).

Composite materials (CM) are widely used in various fields of technology (building and construction materials, supported catalysts, porous polymeric materials, sorption-active composites, etc.). The porous structure of composites plays a primary role in their application and determines their physicomechanical characteristics. In both cases, an important role is played by the interaction of components of the composite and the extent to which their surfaces overlap. In [1], the notions "host" and "guest" were introduced to characterize the interaction between the components of composites. The scheme of the host–guest interaction, suggested for catalysts [1], is to be extended for polymeric formulations, especially for those cases in which the guest is a fibrous ionexchange sorption-active or a fibrous material that is responsible for the large internal surface area of a composite and, simultaneously, is its physicomechanical skeleton. The possible schemes of the host–guest interaction are shown in Fig. 1. In position *a*, the guest is totally blocked by the polymeric matrix; in position *b*, part of the guest is in position *a*, and the other part may be in contact with the third phase or another part of the host. In position *c*, one side of the guest adheres t o the host surface. Scheme *d* is a superposition of states *a* and *b*. Most of polymers swell in some media. If a medium is inert for the host, but causes swelling of the guest, the polymeric matrix may be ruptured to give cracks (pores) (position *e*).

The structure of composites is analyzed by adsorption methods, and the state of the surface and the sorbate, by spectral techniques [1]. Here, the polymeric formulations also have specific features, because a noninert sorbate is absorbed by the bulk of the polymer and causes a sorption deformation of the polymer [2, 3], rather than remaining at the phase boundary. In the present study, composites based on a porous ultrahigh-molecular-weight polyethylene (UHMWP, molecular weight 1.5×10^6), which is the host, and a filler, guest, which is peat, were examined. Peat was introduced into the composite in amounts of 10 (CM-1 sample) and 30 wt % (CM-2 sample). A water vapor served as sorbate. The methods used to measure the amount of sorption and ^{1}H NMR spectra and to form the composites have been described previously [4, 5]. The most important characteristic of porous bodies is their specific surface area, which is commonly found [1] from the sorption capacity of a monolayer, a_m (mol g^{-1}), in the equation

$$\frac{h}{a(1-h)} = \frac{1}{a_m C} + \frac{C-1}{C a_m} h. \qquad (1)$$

Here a is the amount of sorption (mol g^{-1}); $h = p/p_0$, where p is the equilibrium pressure, and p_0, the saturated vapor pressure of the sorbate; and C is an energy constant.

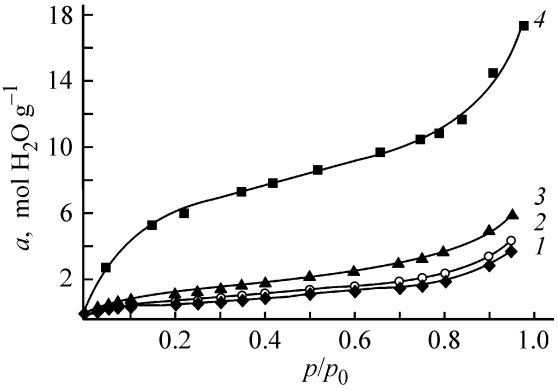

Fig. 2. Sorption isotherms (20°C) of water vapor. (*a*) Amount of sorption and (p/p_0) relative pressure of the sorbate. (*1*) UHMWP-1, (*2*) CM-1, (*3*) CM-2, and (*4*) peat; the same for Figs. 3, 4.

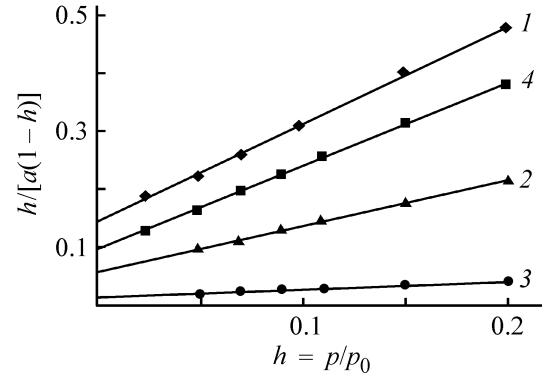

Fig. 3. Sorption isotherms of water vapor in the coordinates of Eq. (1).

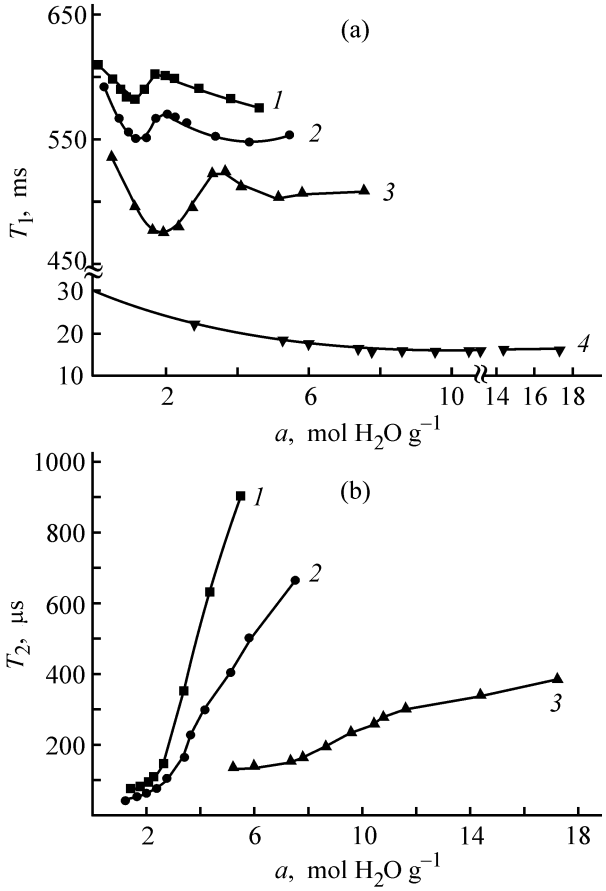

Fig. 4. Times of (a) spin–lattice (T_1) and (b) spin–spin (T_2) relaxation vs. the equilibrium water content *a*.

Figures 2 and 3 show sorption isotherms of water vapor in the ordinary coordinates and linear coordinates of Eq. (1). It can be seen from Fig. 3 that the initial portions of the isotherms satisfactorily obey Eq. (1). This made it possible to calculate the constants a_m (mmol g^{-1}): 0.53 (UHMWP), 0.66 (CM-1), 1.16 (CM-2), and 6.35 (peat); C: 13.4 (UHMWP), 15.2 (CM-1), 15.6 (CM-2), and 15.6 (peat).

For UHMWP, water is an inert sorbate and the data obtained make it possible to calculate the specific surface area by the equation

$$S_{sp} = a_m N_A \sigma, \quad (2)$$

where *A* is the Avogadro number; σ, the landing site area for a water molecule, which depends on the nature of the surface (with its common value of 0.105 nm^2, S_{sp} = 33.5 m^2).

The authors of [6] suggested a comparative method for determining the specific surface area of hydrophobic sorbents from water sorption isotherms. According to this method, 1.7, on average, adsorption layers are formed on hydrophobic surfaces at pressures close to the saturated vapor pressure. Then, $S_{sp} = 1.7a_m(26^{-1} \times 10^3)$ (a_m, mmol g^{-1}; $26^{-1} \times 10^3$, slope rate of the comparative plot); in the case in question, calculations yield S_{sp} = 34.6 m^2 g^{-1}), which is in a satisfactory agreement with the data obtained using Eq. (1). Interestingly, measurements in [7] demonstrated that, in the case of water adsorption on polyethylene films, approximately two monolayers are also formed at $h \to 1$. However, an analysis of this kind for the composite and peat is incorrect in the given case, because the constants obtained for Eq. (1) do not reflect the mechanism of water absorption by peat [8].

The state of UHMWP, composite, and water along the sorption isotherm was analyzed by ^{1}H NMR spectroscopy. Figure 4 shows how the time of spin–lattice relaxation, T_1 depends on the equilibrium water content.

A sample of pure UHMWP shows a longer time of spin–lattice relaxation along the entire sorption isotherm, compared with the composite. This is due to the chemically homogeneous regular structure of polyethylene (–CH_2–CH_2–), which contains no relaxation-active functional groups, on which the energy of the spin system is largely dissipated. Therefore, the process in which equilibrium is established between the spin system and the "lattice" at a slower rate. The minimum observed in the time of spin–lattice relaxation (Fig. 4a, curve *1*) indicates that the samples studied contain hydrophilic impurities and(or) a certain amount of oxidized groups acting as primary active sorption centers. The position of the minimum corresponds to a water content at which these centers are completely filled (the minimum is rather sharp, which points to a narrow distribution of the correlation times of different types of molecular motion, or, in other words, the sorption centers are rather uniform chemically and energetically).

Introduction of a filler into UHMWP leads to a pronounced shortening of the time of spin–lattice relaxation. Being a hydrophilic chemically inhomogeneous substance, peat contains a large number of polar groups of varied nature, which act as both sorption and relaxation centers (Fig. 4a, curve *4*). The irregular structure and the chemical inhomogeneity are the reason for very short times of spin–lattice relaxation of the filler in a wide range of water contents. Therefore, raising the content of the filler leads not only to a decrease in the time of spin–lattice relaxation, T_1, but also to an increase in the water content at its minimum and to broadening of this minimum. This indicates that the number of accessible sorption centers in the composites becomes larger and the chemical nonuniformity of these centers is enhanced. The general shape of the dependence of the time of spin–lattice relaxation on the water content for composite is, in the authors' opinion, a superposition of similar dependences for pure UHMWP and filler, because there is no exchange of protonic magnetization between them (Fig. 4a, curves *2*–*4*). Figure 4b also shows the dependences of the spin–spin relaxation of sorbed water (T_2) on the equilibrium water content of the samples, which can be used to judge the mobility of the sorbate. The highest sorption capacity and lowest mobility of sorbed water is observed for peat. This indicates a high hydrophilicity and amorphism of the filler.

Reverting to the method for analysis of composites, based on the balance between the surfaces of the guest, host, and composite [1], it should be noted that it is advisable, for complex systems constituted by an adsorbent and absorbent, to replace the balance of surfaces by the balance of amounts of sorption along the sorption isotherm. In the case of additivity of the contributions of the host and guest to the amount of sorption, a_{ad} (Figs. 1*b* and 1*c*), this quantity can be calculated by the equation

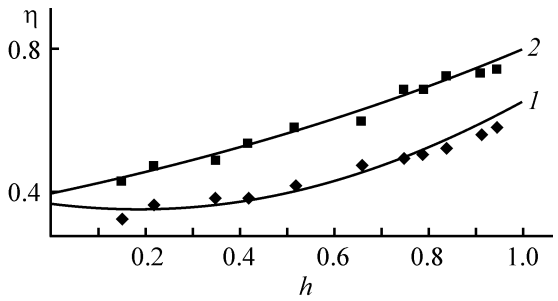

Fig. 5. Variation of the sorption activity coefficient η of the guest along the sorption isotherm, *h*.

$$a_{ad}(h) = a^0_{PE}(h)(1 - x) + a^0_P(h)x, \quad (3)$$

where a_{ad}, $a^0_{PE}(h)$, and $a^0_P(h)$ are the amounts of water sorption: additive and (by the initial UHMWP and peat) along the isotherm; x is the mass fraction of the guest.

On the assumption that the properties of the host are not changed in the presence of a guest, the amount of sorption along the isotherm, $a(h)$, is described by the expression

$$a(h) = a^0_{PE}(h)(1 - x) + a_P(h), \quad (4)$$

where $a_P(h)$ is the contribution of the guest to the total amount of sorption.

Then the dimensionless sorption activity of the guest, η, along the isotherm can be represented as (Fig. 5)

$$\eta = \frac{a_P(h)}{a^0_P x} = \frac{a(h) - a^0_{PE}(h)(1 - x)}{a^0_P x}. \quad (5)$$

Along most part of the isotherm, the sorption activity of the guest $\eta < 1$, i.e., a part of the filler is blocked by the host matrix in positions *a* and *d* (Fig. 1). At vapor pressures close to the saturated vapor pressure, swelling (increasing volume) of the guest may rupture the host (Fig. 1*e*), which is manifested in that $\eta \to 1$ at $h \to 1$. In approximately the same range of amounts of sorption, the curves of spin–lattice relaxation show a bend (Fig. 4). A similar, less pronounced, bend in the curve for UHMWP is possibly associated with capillary phenomena and with a disruption of the surface structure of polyethylene at $h \to 1$, suggested in [7].

CONCLUSIONS

(1) Adequate results were obtained in measuring the specific surface area in adsorption of water by porous polyethylene by the method of polymolecular adsorption and by the comparative method for analysis of water adsorption on hydrophobic surfaces.

(2) A scheme of interaction between the polymer and filler in a composite and a method for analysis of the state of the matrix of the composite in the case when the filler swels in a sorbate vapor were suggested.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Mathematical Description of the Kinetics of the Heterophase Macromolecular Reaction of Hydrazidation of Grafted Polyglycidyl Methacrylate

T. V. Druzhinina, G. I. Efremov, and M. A. Struganova

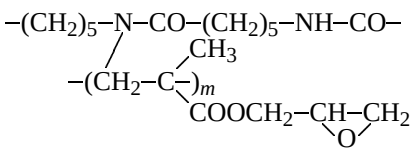
Kosygin State University of Textile, Moscow, Russia

Received April 23, 2004; in final form, November 2004

Abstract—Hydrazidation of a grafted copolymer of polycaproamide and polyglycidyl methacrylate was mathematically modeled by solving the diffusion equation with a boundary condition in the form of a flow.

At present, an important role in the environment protection is played by sorption-active polymeric materials, including those in the fibrous form [1, 2]. However, only two kinds of chemisorption fibers are manufactured industrially (TsM-A2 and Mtilon-1) and the VION-KN fiber is produced at a pilot plant. Other types of fibrous chemisorbents are manufactured as one-time pilot batches. Of fundamental importance for the functioning of modern industrial processes used to manufacture chemisorption fibers is mathematical modeling, which makes it possible to create reliable systems for the control techniques being developed. In this context, the aim of this study was to construct a mathematical model of the heterophase macromolecular reaction in which a special class of branched polymers—grafted copolymers of polycaproamide (PCA) and polyglycidyl methacrylate (PGMA), undergoes hydrazidation, in order to solve the problem of optimization of the process for production of fibrous chemisorption materials with predictable sorption properties.

Among the known ways to obtain chemisorption fibers, the method based on the graft polymerization and chemical transformation in the polymer chains is the most promising [3]. This is because modification of a finished fiber is a simpler technological process, compared with that in which fibrous chemisorbents are obtained by synthesis of copolymers with functionally active groups and then fibers are formed. Owing to the distribution of sorption-active groups in the surface layers of the fiber, the sorbent has good mechanical properties and the highly developed specific surface area provides high rates of mass-exchange processes. The wide diversity of forms of fibrous sorption materials enables their efficient technological implementation in sorption processes [4].



Previously, the modified quasi-stationary method (MQM) has been used for mathematical analysis of the occurring processes in studying the fundamental aspects of the kinetics of polymer-analogous transformations of grafted PGMA under the action of sulfur-containing compounds (thiourea and potassium thiocyanate) [5] and diamines (ethylenediamine and hexamethyldiamine) [6]. As this method is based on a simple summation of the kinetic and diffusion resistances, it can only be regarded as a simplified mathematical model, whose disagreement with the experiment may be as wide as 15% [7]. Therefore, a more precise mathematical kinetic model derived by analytical solution of the equation of isotropic diffusion [8] was adopted in the present study.

The interaction between the oxirane groups of a grafted PCA–PGMA copolymer and hydrazine hydrate underlies the method for production of the POLAN-OG chemisorption fiber having a high sorption capacity and good sorption kinetics [9]. The macrokinetics of this interaction was described by solving the equation of isotropic diffusion with a boundary condition in the form of a flow. Compared with the case of MQM, mathematical calculations of the kinetics of the macromolecular reaction by this method are somewhat more complicated, but provide a better precision of simulation. The method in which the diffusion equation is solved with a boundary condition in the form of a flow has been tested in analysis of some stages of the chemical technology of fibrous materials (dyeing, impregnation, washing, and drying) [7, 10].

As a polymeric matrix containing reactive oxirane groups providing a high rate of chemical transformations, with sorption-active groups introduced into the polymer, served grafted PCA–PGMA copolymer

1070-4272/05/7806-0989 © 2005 Pleiades Publishing, Inc.

with a fibrous structure, a 47 : 53 composition, and the following general structure:

Hydrazine hydrate was used as a modifying agent. To find the type of a solvent ensuring the greatest extent of polymer-analogous transformations, the process was performed in different media: water and aprotic bipolar solvents that cause swelling of the grafted polymer [11].

As applied to the polymer system under study, which is constituted by a grafted PCA–PGMA copolymer and a solution of hydrazine hydrate, the mathematical model of the kinetics of the reaction studied, based on solution of the diffusion equation with a boundary condition in the form of a flow, assumes that the first stage of hydrazidation of the grafted PGMA occurs at the initial instant of time ($\tau = 0$) on the surface of the fiber, with hydrazine hydrate distributed in the adjacent reaction solution. As shown by experimental data, the rate of the macromolecular reaction between polymeric oxirane and hydrazine depends on the concentration c_{HH} of the nucleophilic reagent at the phase boundary (fiber-reaction solution).

In this case, the equation of the isotropic molecular diffusion in the direction of the x axis has the form

$$\frac{\partial c}{\partial \tau} = D\frac{\partial^2 c}{\partial x^2}, \qquad (1)$$

and the boundary condition for the flow of the hydrazine hydrate solution at the phase boundary can be represented as

$$J = -D\frac{\partial c}{\partial x}\bigg|_{x=0} = k(c^* - c), \qquad (2)$$

where D is the diffusion coefficient; k, kinetic coefficient having the dimension of the reaction rate; c^* and c, content of the amine nitrogen in the reaction products upon completion of the reaction and its running concentration, respectively (%).

Using the Laplace operator method to solve the diffusion equation (1) with a boundary condition (2) yields, upon certain rearrangements, an equation for the process kinetics in the form of an error formula [8]:

$$\frac{c}{c^*}\operatorname{erfc}\left(\frac{x}{2\sqrt{D\tau}}\right) - e^{\frac{kx}{D}+\frac{k^2\tau}{D}}\operatorname{erfc}\left(k\sqrt{\frac{\tau}{D}} + \frac{x}{2\sqrt{D\tau}}\right), \qquad (3)$$

where $\operatorname{erfc}(a)$ is an error unction of argument a [7].

Expression (3) for the dimensionless concentration of the amine nitrogen, introduced into the grafted copolymer by the reaction of hydrazidation, at the fiber surface (at $x = 90$) is simplified:

$$\frac{c}{c^*} = 1 - e^{\frac{k^2\tau}{D}}\operatorname{erfc}\left(k\sqrt{\frac{\tau}{D}}\right), \qquad (4)$$

For simplicity of calculations, it is convenient to introduce into the algorithm for solving the diffusion equation with a boundary condition in the form of a flow a modified Fourier number:

$$\mathrm{Fo} = \frac{D}{k^2\tau}. \qquad (5)$$

Then Eq. (4) is transformed into the following expression:

$$\frac{c}{c^*} = 1 - e^{\frac{1}{\mathrm{Fo}}}\operatorname{erfc}\left(\frac{1}{\sqrt{\mathrm{Fo}}}\right), \qquad (6)$$

To account for the convective flows in the reaction medium, it is necessary to introduce an exponent n. In this case, Eq. (4) takes the form

$$\frac{c}{c^*} = 1 - e^{\frac{1}{\pi}\left(\frac{\tau}{\sigma}\right)^n}\operatorname{erfc}\left[\sqrt{\frac{1}{\pi}\left(\frac{\tau}{\sigma}\right)^n}\right], \qquad (7)$$

where σ is the characteristic time of the process (parameter with dimension of time),

$$\sigma = \frac{D}{\pi k^2}. \qquad (8)$$

A rearrangement of Eqs. (5) and (8) with account of the exponent n changes the expression for the modified Fourier criterion:

$$\mathrm{Fo} = \pi\left(\frac{\sigma}{\tau}\right)^n. \qquad (9)$$

A specific feature of Eq. (7) is that its solution has a discontinuity at $1/\mathrm{Fo} > 35$, and, therefore, it is inapplicable at large 1/Fo. To find a solution in this range, it is necessary to use in Eq. (7) an expansion of the error function $\operatorname{erfc}(a)$ into an asymptotic series [7]:

$$\operatorname{erfc}(a) \approx \frac{e^{-a^2}}{\pi}\left(\frac{1}{a} - \frac{1}{2a^3} + \frac{3}{4a^5} - \ldots\right). \qquad (10)$$

For two terms of the asymptotic series expansion of function, (7) leads to the expression

$$\frac{c}{c^*} = \left\{1 - \left[1 - \frac{\pi}{2}\left(\frac{\sigma}{\tau}\right)^n\right]\left[\sqrt{\left(\frac{\sigma}{\tau}\right)^n}\right]\right\}. \qquad (11)$$

An asymptotic solution of Eq. (11) for the interval $1/\mathrm{Fo} > 35$ with the use of expression (7) makes it possible to perform calculations in the entire range of variation of the modified Fourier criterion, with

the solutions overlapping at $13 < 1/Fo < 35$. As a consequence, it is recommended to use expression (11) for $1/Fo > 20$ and Eq. (7) for $1/Fo < 20$.

The above-described algorithm for solving the diffusion equation with a boundary condition in the form of a flow was used to process experimental data obtained in a study of the kinetic dependences $N_a = f(\tau)$ for polymer-analogous transformations of a grafted PCA–PMGA copolymer under the action of hydrazine. The macromolecular reaction of hydrazidation was performed at 80°C in various solvents: water, dimethyl sulfoxide (DMSO), dimethyl acetamide (DMAA), and dimethyl formamide (DMFA). The concentration of hydrazine hydrate in the reaction mixture was varied from 6.2 to 28.1 M. The experimental values of the content of the amine nitrogen in the reaction products and the corresponding parameters of the interaction involving the oxirane groups of grafted PGMA were mathematically processed using the Mathcad software. The exponents n were determined for all the experimental sets by the least-squares method. As a result, the following equations were obtained for the equilibrium content c^* of the amine nitrogen in the reaction products and the characteristic time σ as functions of the content of hydrazine hydrate in the reaction solution in various media:

Solvent of hydrazine hydrate	n	Expression for the parameters of Eqs. (7) and (11)	
DMSO	4.55	$c^* = 2.144 + 0.033c_{HH}$	(12)
		$\sigma = 5.331 - 0.108c_{HH}$	(13)
DMAA	5.97	$c^* = 1.816 + 0.046c_{HH}$	(14)
		$\sigma = 6.532 - 0.044c_{HH}$	(15)
DMFA	6.06	$c^* = 1.759 + 0.045c_{HH}$	(16)
		$\sigma = 8.006 - 0.147c_{HH}$	(17)
Water	5.13	$c^* = 1.431 + 0.028c_{HH}$	(18)
		$\sigma = 10.047 - 0.174c_{HH}$	(19)

A general analysis of Eqs. (12)–(19) points to an ambiguous influence exerted by the concentration of hydrazine hydrate and reaction duration on the rate and extent of hydrazidation of the oxirane groups of grafted PGMA: common terms and proportionality coefficients of the linear equations obtained are different. Their values well correlate with the dielectric constants ($\varepsilon_{DMSO} = 46.7$, $\varepsilon_{DMAA} = 37.8$, $\varepsilon_{DMFA} = 36.7$ [12]) and donor numbers ($DN_{DMSO} = 29.8$, $DN_{DMAA} = 27.8$, $DN_{DMFA} = 26.6$ [13]) of the solvents used, which lead to an increase in the nucleophilicity of hydrazine hydrate. The data obtained [Eqs. (12), (14), (16), (18)] indicate that, in accordance with the content of the amine nitrogen, the highest degree of conversion of polymeric oxirane is achieved when the reaction of hydrazidation is performed in DMSO, which will yield, in the end, a chemisorption fiber with better sorption characteristics.

mer-analogous transformations (Table 1) corresponding to $1/Fo_1 = 35$. The instability of the solution is also seen in the plot of Eq. (11) for processes in various media (Fig. 1, curves *2*) at τ in the range from 9.6 to 11.3 min (Table 1) and $1/Fo_2 = 9$. At the same time, both the curves plotted using the solutions to Eqs. (7) and (11) lie at the critical value $1/Fo_{cr}$ ($1/Fo_{cr} = 20$). Therefore, the τ values corresponding to $1/Fo_{cr} = 20$ should be used in further calculations.

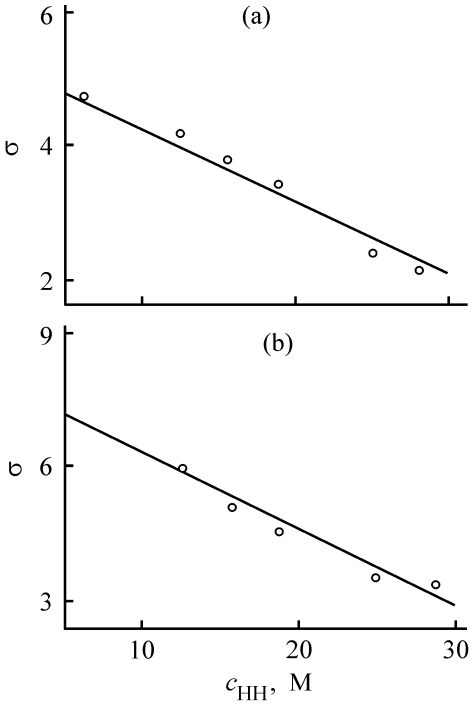

Fig. 2. Characteristic time σ of polymer-analogous transformations of grafted copolymers vs. the content c_{HH} of hydrazine hydrate in the reaction medium. Solvent: (a) DMSO and (b) DMFA.

To reveal the influence exerted by the duration of the process under study on the conversion of oxirane groups at various concentrations of hydrazine hydrate in the modifying solution and varied nature of the reaction medium, the values of the dimensionless time factor $(\sigma/\tau)^n$ were calculated using Eq. (11), which describes the dependence of c/c^* on the simplex $(\sigma/\tau)^n$ being varied. As can be seen from Table 2, the kinetic effect becomes less pronounced as the concentration of hydrazine hydrate in the reaction medium increases. Such a dependence is observed when polymer-analogous transformations are performed in any of the solvents used.

Analysis of the calculated values of $(\sigma/\tau)^n$ for different concentrations of the hydraziding reagent in order to compare the influence exerted by various media reveals the following efficiency series of hydrazine hydrate solvents in solutions of various concentrations: 6.2–18.7 M: DMSO < DMAA < water < DMFA; 25.0 M: DMSO < DMAA < DMFA < water; 28.1 M: DMSO < DMFA < water < DMAA.

As for the characteristic time, a linear dependence of the σ values on the concentrations of hydrazine hydrate in all of the solvents studied was obtained by the least-squares method (Fig. 2).

A mathematical simulation of the process of polymer-analogous transformations of the grafted PCA–PGMA copolymer under the action of hydrazine hydrate, by solving the diffusion equation with a boundary condition in the form of a flow, yielded two equa-

tions. One of these describes the interaction of polymeric oxirane with a hydraziding reagent up to τ values corresponding to $1/Fo_{cr} = 20$, and the other, the reaction at $1/Fo_{cr} > 20$.

Below are presented the corresponding equations derived for hydrazidation in various media with account of the empirical relationships found for dimethyl sulfoxide

$$\frac{c}{2.144 + 0.033c_{HH}} = 1 - e^{\frac{1}{\pi}\left(\frac{\tau}{5.331 - 0.108c_{HH}}\right)^{4.55}} \operatorname{erfc}\left[\sqrt{\frac{1}{\pi}\left(\frac{\tau}{5.33 - 0.108c_{HH}}\right)^{4.55}}\right], \quad (20)$$

$$\frac{c}{2.144 + 0.033c_{HH}} = \left\{1 - \left[1 - \frac{\pi}{2}\left(\frac{5.331 - 0.108c_{HH}}{\tau}\right)\right]^{4.55}\left[\sqrt{\left(\frac{5.331 - 0.108c_{HH}}{\tau}\right)^{4.55}}\right]\right\}; \quad (21)$$

for dimethyl acetamide

$$\frac{c}{1.816 + 0.046c_{HH}} = 1 - e^{\frac{1}{\pi}\left(\frac{\tau}{6.532 - 0.044c_{HH}}\right)^{5.97}} \operatorname{erfc}\left[\sqrt{\frac{1}{\pi}\left(\frac{\tau}{6.532 - 0.044c_{HH}}\right)^{5.97}}\right], \quad (22)$$

$$\frac{c}{1.816 + 0.046c_{HH}} = \left\{1 - \left[1 - \frac{\pi}{2}\left(\frac{6.532 - 0.044c_{HH}}{\tau}\right)\right]^{5.97}\left[\sqrt{\left(\frac{6.532 - 0.044c_{HH}}{\tau}\right)^{5.97}}\right]\right\}; \quad (23)$$

for dimethyl formamide

$$\frac{c}{1.759 + 0.046c_{HH}} = 1 - e^{\frac{1}{\pi}\left(\frac{\tau}{8.006 - 0.147c_{HH}}\right)^{6.06}} \operatorname{erfc}\left[\sqrt{\frac{1}{\pi}\left(\frac{\tau}{8.006 - 0.147c_{HH}}\right)^{6.06}}\right], \quad (24)$$

$$\frac{c}{1.759 + 0.045c_{HH}} = \left\{1 - \left[1 - \frac{\pi}{2}\left(\frac{8.006 - 0.147c_{HH}}{\tau}\right)\right]^{6.06}\left[\sqrt{\left(\frac{8.006 - 0.147c_{HH}}{\tau}\right)^{6.06}}\right]\right\}; \quad (25)$$

and for water

$$\frac{c}{1.431 + 0.028c_{HH}} = 1 - e^{\frac{1}{\pi}\left(\frac{\tau}{10.047 - 0.174c_{HH}}\right)^{5.13}} \operatorname{erfc}\left[\sqrt{\frac{1}{\pi}\left(\frac{\tau}{10.047 - 0.174c_{HH}}\right)^{5.13}}\right], \quad (26)$$

$$\frac{c}{1.431 + 0.028c_{HH}} = \left\{1 - \left[1 - \frac{\pi}{2}\left(\frac{10.047 - 0.174c_{HH}}{\tau}\right)\right]^{5.13}\left[\sqrt{\left(\frac{10.047 - 0.174c_{HH}}{\tau}\right)^{5.13}}\right]\right\}; \quad (27)$$

Equations (20), (22), (24), and (26) should be used to describe the interaction of the grafted PGMA with hydrazine hydrate in the initial stage of the process [by Eq. (7) in the algorithm of solution of the diffusion equation]. For further calculation of the hydrazidation reaction under study, it is necessary to use Eqs. (21), (23), (25), and (27), derived using the theoretical expression (11) and experimental kinetic coefficients.

The calculated values of the dimensionless content of the amine nitrogen in the reaction products are in a good agreement with the experimental data, which indicates that the given mathematical model is applicable to the polymeric system under study (Fig. 3). This mathematical model makes it possible to diminish the scatter of the experimental and calculated values of c/c^* to ±6%.

CONCLUSIONS

(1) The diffusion equation was solved with a boundary condition in the form of a flow for describing the kinetics of hydrazidation of a grafted copolymer of polycaproamide and polyglycidyl methacrylate with account of the influence exerted by the medium on the reaction course. This method was used to find the optimal parameters of the process under study

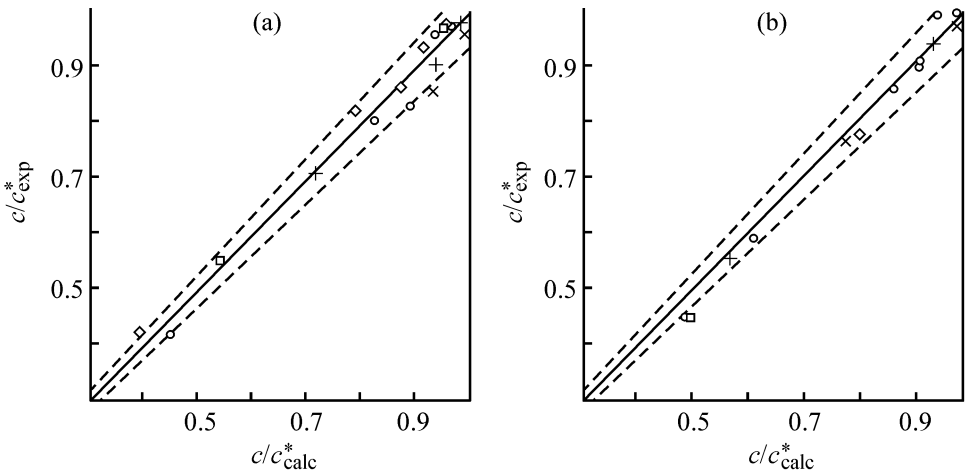

Fig. 3. Relationship between the experimental and calculated c/c^* in (a) DMSO and (b) DMFA.

(duration, reagent concentration), which ensured introduction of a prescribed amount of sorption-active groups into the polymer.

(2) The mathematical expressions derived in theoretical and experimental studies of the kinetics of a macromolecular interaction between grafted polyglycidyl methacrylate with hydrazine hydrate make it possible to control chemical transformations of polymeric oxiranes, which are used to produce chemisorption fibers and to obtain information about the extent of the reaction at a current instant of time.

Abstract—The kinetics of thermal degradation of commercial samples of copolymers of acrylamide with sodium acrylate of various molecular characteristics in water and 1.5% NaCl aqueous solutions at 40–80°C was studied viscometrically.

Water-soluble polymers and, in particular, copolymers of acrylamide (AA) with sodium acrylate (Na-A) are used as accelerators in well-boring, thickening agents for water injected into oil strata to displace oil, structure-forming agents for preparing protective shields for an aquifer, agents lovering the water content in the extracted oil, etc. The efficiency of their use is determined by molecular properties of copolymers and their resistance to thermal degradation. The thermal degradation of polyacrylamide (PAA) in aqueous solutions at 75°C was studied in [1]. Previously, we have studied the degradation of partially hydrolyzed PAA in aqueous solutions at 40–70°C [2] and in aqueous salt solutions at 50°C in the presence of a degradation agent (potassium persulfate) [3] and some other additives [4]. An analysis of some features and of the mechanism of thermal degradation of AA copolymers with Na-A with a low content of ionic units (commercial Praestols) at 40–80°C showed that the polymer degrades under the effect of radicals formed by breakdown of the residual initiator in the commercial copolymers. As the temperature is elevated from 40 to 60°C, the molecular weight of the copolymers decreases owing to degradation, whereas on subsequent heating to 80°C, it increases due to possible intermolecular imidization of amide groups of the polymer. However, the possibility of imidization has not been confirmed experimentally.

In this study, we examined the thermal degradation of AA copolymers with Na-A of various compositions in water and 1.5% NaCl aqueous solution at 40–80°C and determined the content of imide units in the products of copolymer degradation.

EXPERIMENTAL

We studied samples of AA copolymers with Na-A (AA–Na-A), produced by Stockhausen GmbH (Krefeld, Germany); their properties are listed in the table. The experimental samples were prepared using distilled water and chemically pure grade chemicals.

The content of the ionic units, α, in AA–Na-A copolymers was determined by potentiometric titration [5]. The intrinsic viscosity $[\eta]$ of copolymer solutions was measured in a 0.5 M NaCl solution at 30°C on a VPZh-3 viscometer (d_c = 0.56 mm). The $[\eta]$ values were determined from the experimental linear depen-

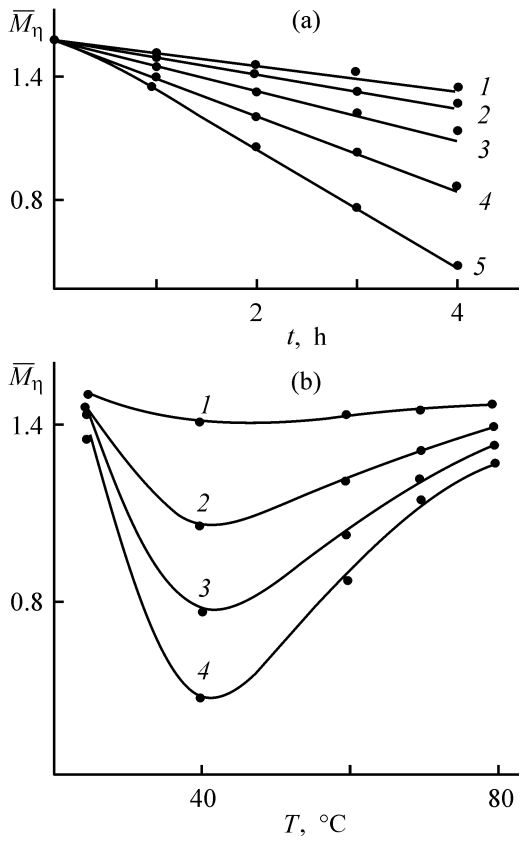

Fig. 1. $\bar{M}_\eta$ vs. (a) time *t* and (b) temperature *T* of degradation of an AA–Na-A copolymer (sample no. 5) in 1.5% NaCl solution. (a) Temperature, °C: (*1*) 26, (*2*) 80, (*3*) 70, (*4*) 60, and (*5*) 40. (b) Time, min; (*1*) 1, (*2*) 2, (*3*) 3, and (*4*) 4.

dence of the reduced viscosity $\eta_{sp}/c_p = f(c_p)$, where c_p is the copolymer concentration.

$$[\eta] = \lim(\eta_{sp}/c_p) \text{ at } c_p \to 0.$$

The viscosity-average molecular weight $\bar{M}_\eta$ of AA–Na-A copolymer was calculated using the Mark–Houwink equation

$$[\eta] = K\bar{M}_\eta^a,$$

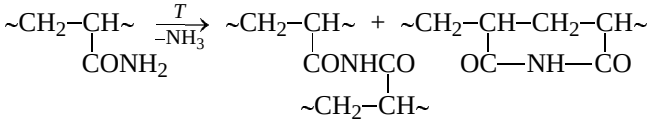
where the factors *K* and *a* vary with the concentration of the ionic units in the copolymer; the numerical values of *K* and *a* were taken from [6].

The degradation was performed in 0.1% solutions of AA–Na-A copolymers at 60°C in the course of 4 h. The solvents were pure water and a 1.5% NaCl solution (model medium), because these copolymers are often used in aqueous salt systems.

The reactions were carried out in a glass vessel equipped with a thermostating jacket, magnetic stirrer (MM-5), outlet through which the samples were taken to determine [η], and VPZh-3 capillary viscometer (d_c = 0.56 mm) to monitor the viscosity of the reaction mixture in the course of degradation.

The degradation kinetics was monitored by viscometry [7]. For this purpose, we measured at certain intervals the times of outflow of the reaction mixture t_1 and calculated the reduced viscosities $\eta_{sp}/c_p = f(t)$, where $t = t_2 + t_1/2$ and t_2 is the period of time from the start of degradation to the start of viscosity measurements.

The total content of carboxy and imide groups in the degradation products of AA–Na-A copolymers was determined by the procedure described elsewhere [8]. In this case, a weighed sample of the copolymer was dissolved in 0.1 M NaOH and kept at room temperature for 20 h (during this time the imide groups are hydrolyzed [8], whereas the amide groups remain unchanged), and back titration was carried out according to the procedure reported in [5].



The solution acidity was measured with a pH-121 pH-millivoltmeter equipped with an ESL-63-07 working glass electrode and an EVL 1M-3 silver chloride reference electrode.

To evaluate the effect of temperature on the degradation of AA–Na-A copolymers (sample no. 6), the experiments were performed at 40–80°C, other experimental conditions being the same. The dependence of $\bar{M}_\eta$ on the reaction time is shown in Fig. 1a. As can be seen, $\bar{M}_\eta$ decreases in the course of degradation in the entire temperature range studied. This is due to rupture of the carbon–carbon bonds in the primary polymer chains under the effect of radicals R$^\bullet$ formed in thermal degradation of the residual initiator in the samples of the commercial copolymer.

The experimental data obtained at *t* = const show that $\bar{M}_\eta$ varies with temperature nonmonotonically (Fig. 1b). In the course of degradation, $\bar{M}_\eta$ first decreases as temperature increases from 26 to 40°C. This is obviously due to a rise in the rate of initiator decomposition, which makes higher the concentration of free radicals in the reaction mixture and, thus, promotes the copolymer degradation. In the second stage of degradation (40–80°C), $\bar{M}_\eta$ increases. These changes in $\bar{M}_\eta$ with temperature become more pronounced in the course of degradation (Fig. 1b, passing from curve *1* to curve *4*). For sample no. 2, temperature-related changes in $\bar{M}_\eta$ were similar.

The observed increase in $\bar{M}_\eta$ with temperature in the second step of degradation (Fig. 1b) is probably

due to acceleration of the cross-linking of macromolecules owing to intermolecular imidization of the amide groups of copolymer by the following reaction:

To confirm the possibility of imidization under the conditions of degradation of an AA–Na-A copolymer (sample no. 6), we experimentally determined the content of imide groups in the degradation products (Fig. 2). It can be seen that the content of these groups in the degradation products increases with temperature (in the range from 60 to 80°C) and time of degradation. Similar trends in variation of the content of imide groups in the course of degradation were found for sample no. 2. Thus, the intermolecular imidization during degradation of AA–Na-A copolymers at 60–80°C leads to an increase in $\bar{M}_\eta$, which exceeds the decrease in $\bar{M}_\eta$ caused by degradation of the copolymer backbones.

Let us compare the behavior of AA–Na-A copolymers of various compositions in the course of thermal degradation. The experiments were carried out in 1.5% NaCl solution at 60°C, other experimental conditions being the same. As can be seen from Fig. 3, $\bar{M}_\eta$ decreases in the course of degradation for all the samples studied. Moreover, despite the difference in the copolymer composition (see table), which can affect the process, the degradation rate increases with the initial $\bar{M}_\eta$ of copolymers. This trend agrees with the acceleration of PAA degradation in aqueous solutions as the initial $\bar{M}_\eta$ increases [9] and with data on degradation of some other copolymers [10]. Apparently, at equal number of breaks per macromolecule, a more pronounced decrease in $\bar{M}_\eta$ should be observed for heavier copolymers.

The data on degradation of an AA–Na-A copolymer (sample no. 6) in water and 1.5% NaCl are given for comparison in Fig. 4. As can be seen from the comparison of the experimental data at t = const, the reduced viscosities η_{sp}/c_p of the reaction mixtures and $\bar{M}_\eta$ both decrease on passing from water to a 1.5% NaCl aqueous solution (Figs. 4a and 4b, respectively). This is probably due to changes in the ionic strength of solution μ: with its increase, the electrostatic repulsion between similarly charged acrylate anions along the chain decreases. As a result, the effective size of copolymer aggregates and η_{cp}/c_p decrease. Therefore, the diffusion of the reagents (both degrading agent and macromolecules) becomes more intense with de-

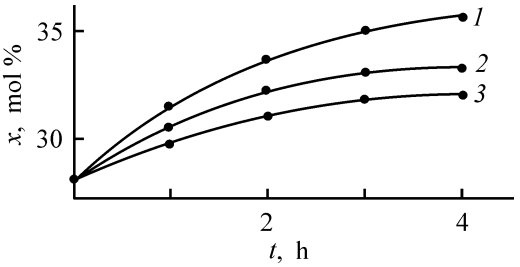


Fig. 2. Content x of imide groups in macromolecules vs. the time t of degradation of AA–Na-A copolymer (sample no. 5) in a 1.5% NaCl solution at various temperatures. Temperature, °C: (*1*) 60, (*2*) 70, and (*3*) 80.

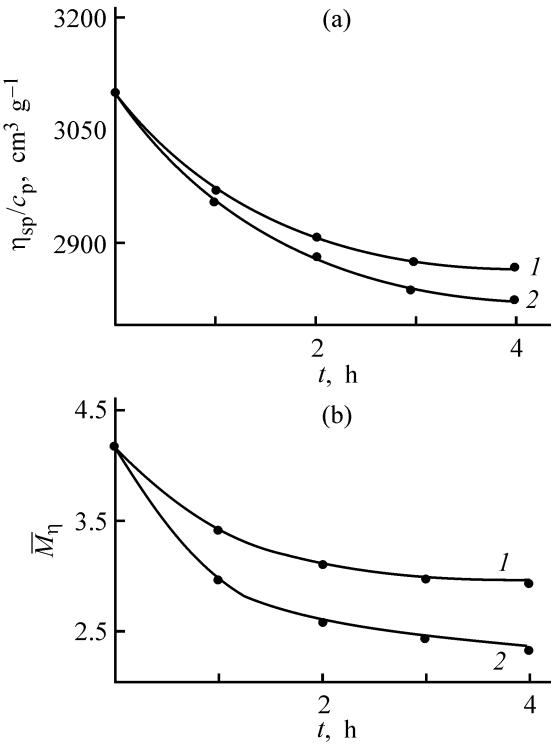

Fig. 5. (a) Reduced viscosity η_{sp}/c_p and (b) $\bar{M}_\eta$ vs. the time t of degradation of an AA–Na-A copolymer (sample no. 5) in a 1.5% NaCl aqueous solution at pH (*1*) 5.3 and (*2*) 9.

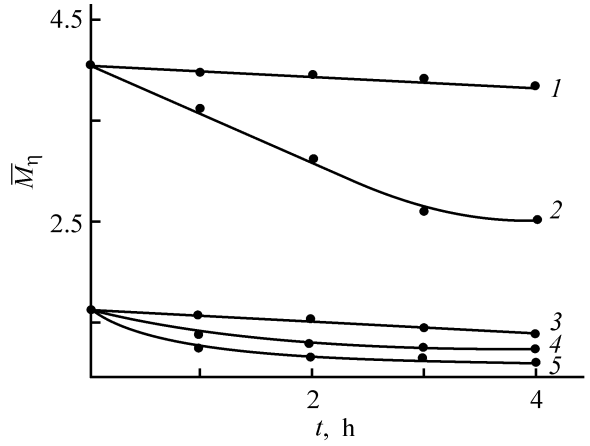

Fig. 6. $\bar{M}_\eta$ vs. time t of degradation of various AA–Na-A copolymers in a 1.5% NaCl solution (*2*–*5*) in the absence of additions and in the presence of (*1*) 0.1 KI, (*3*) 1.0 Na_2SO_3, and (*4*) 2.3% formaldehyde. Sample no.: (*1*, *2*) 3 and (*3*–*5*) 6.

creasing viscosity of the reaction mixtures, which enhances the copolymer degradation.

The dependences $\eta_{sp}/c_p = f(t)$ and $\bar{M}_\eta = f(t)$, recorded in the course of an AA–Na-A copolymer (sample no. 5) degradation in a 1.5% NaCl solution at pH 5.3 and 9, are shown in Fig. 5. It can be seen that with increasing pH, the reduced viscosities and $\bar{M}_\eta$ both decrease (t = const). These results are probably due to changes in μ, whose effect on the degradation was analyzed above.

To evaluate the possibility stabilization of 0.1%, solutions of an AA–Na-A copolymers in 1.5% NaCl aqueous solution at 60°C, we studied the effect of KI, Na_2SO_3, and formaldehyde on the degradation. As can be seen from Fig. 6, $\bar{M}_\eta$ of copolymer at t = const in the presence of KI (curve *1*), Na_2SO_3 (curve *3*), and formaldehyde (curve *4*) changes less strongly (especially in the presence of KI) than in the absence of the additives (curves *2*, *5*). This suggests that these additives deactivate the residual initiator in the commercial copolymer samples and thus suppress its promoting effect on the thermal degradation. Thus, these additives (KI, Na_2SO_3, and formaldehyde) can be used to suppress the thermal degradation of AA–Na-A copolymers.

CONCLUSIONS

(1) Data on the kinetics of thermal degradation of commercial samples of acrylamide copolymers with sodium acrylate of various compositions in 0.1% aqueous and 1.5% NaCl solutions at 40–80°C showed that $\bar{M}_\eta$ of the copolymers decreases as temperature increases from 26 to 40°C, pH grows from 5.3 to 9.0, time of degradation becomes longer, and water is chahged for a 1.5% NaCl solution; however, on heating from 40 to 80°C, it increases owing to intermolecular imidization of amide groups of the copolymer.

(2) Copolymer solutions can be stabilized using KI, Na_2SO_3, and formaldehyde additives.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis of an Unsaturated β-Alanine Derivative

G. N. Khimich, M. Yu. Slabospitskaya, V. A. Korzhikov, and T. B. Tennikova

Abstract—A procedure was developed for preparing an acrylic derivative of β-alanine. A terpolymer of this compound with glycidyl methacrylate and ethylene glycol dimethacrylate was prepared.

Preparation of novel supports and sorbents for the analysis and isolation of biologically active substances is an actively developing field of polymer science.

The surface of supports used in affinity chromatography can be modified with ligands specific to target products [1]. An ideal case is direct synthesis of a peptide ligand on an appropriate matrix and its subsequent use for analytical or preparative separation [2, 3]. In so doing, the matrix should meet the requirements both to solid phases for peptide synthesis and to sorbents for chromatography.

Synthesis of acrylic derivatives of amino acids, capable of terpolymerization with glycidyl methacrylate (GMA) and ethylene glycol dimethacrylate (EDMA), is important in view of their use for preparation of monolithic porous sorbents [2] ready for analysis and use in solid-phase peptide synthesis. The capacity of the monolith, as determined by the amino group content, can be controlled by varying the monomer ratio.

Previously, we have demonstrated the possibility of preliminary covalent binding of a peptide with glycidyl methacrylate, followed by copolymerization of the resulting conjugate with GMA and EDMA [3]. A direct peptide synthesis was made on the GMA–EDMA monolithic sorbent modified with β-alanine, a stable and convenient anchor amino acid [4].

In this context, our goal was to prepare an acrylic derivative of β-alanine and to examine the possibility of preparing a terpolymer of this monomer with GMA and EDMA in the presence of a porogenic solvent.

EXPERIMENTAL

We used the following chemicals: glycidyl methacrylate (Fluka Chemie AG, Switzerland), 2,2-dimethyl-2-hydroxyacetophenone (Merck–Schuchard, Germany), ethylene glycol dimethacrylate, di-*tert*-butyl pyrocarbonate, β-alanine, cyclohexanol (all Sigma–Aldrich, Germany), 2,2'-azobis(isobutyronitrile) (Merck–Schuchard), dodecanol, ethylenediamine, 2-propanol, and acryloyl chloride (all Reakhim, Russia).

The ^{1}H NMR spectra were recorded on a Bruker AC 300 spectrometer (300 MHz) in acetone-d_6 or dimethylformamide-d_7.

The IR spectra were taken on a Bruker IFS 88 spectrophotometer.

UV irradiation was performed with a 125-W mercury lamp with a broad radiation spectrum and constant intensity.

Methyl 3-*tert*-butyloxycarbonylaminopropionate III. β-Alanine methyl ester hydrochloride (3.03 g, 21.6 mmol) was dissolved in 7 ml of MeOH. To the resulting solution, we added 60 ml of a 10% solution of triethylamine in methanol and then, in small portions, a 1.57 g (7.2 mmol) of di-*tert*-butyl pyrocarbonate. The mixture was heated to 50°C and kept at this temperature for 30 min. After that, it was left overnight at room temperature. Then the mixture was evaporated, diluted with 50 ml of ethyl acetate, and acidified with 2% $KHSO_4$. The resulting mixture was washed with water. The organic layer was dried over Na_2SO_4. The product was obtained as a colorless oil; yield 3.48 g (80%).

Amine IV. Methyl 3-*tert*-butyloxycarbonylaminopropionate **III** (3.48 g, 17 mmol) was dissolved in 30 ml of methanol, and a solution of 30 ml of ethylenediamine in 60 ml of methanol was slowly added dropwise with stirring. The reaction was performed at room temperature in the dark for 5 days. Then the mixture was evaporated. The product was purified by column adsorption chromatography on silica gel (40–60 μm), with methylene chloride as eluent. The product was obtained as an oil; yield 2.94 g (75%).

^{1}H NMR spectrum (300 MHz, acetone-d_6), δ, ppm: 1.41 s (9H, *t*-C_4H_9), 2.31–2.46 m (2H), 3.24–3.33 m (4H), 3.34–3.45 m (2H).

Found, %: C 52.12, H 9.26, N 18.05.

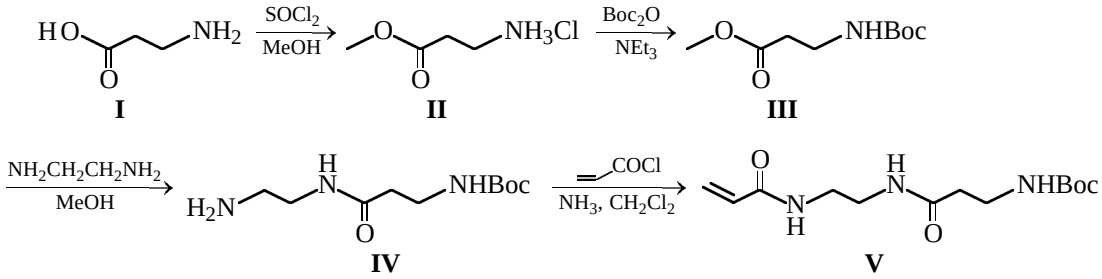
$C_{10}H_{21}N_3O_3$.

Calculated, %: C 51.93, H 9.15, N 18.17.

Monomer V. To a solution of 1.43 g (6.2 mmol) of **IV** in 20 ml of methylene chloride, cooled with a mixture of ice and NaCl, we added with stirring 1.1 ml of triethylamine. Then we added dropwise a solution of 0.6 ml of acryloyl chloride in 5 ml of methylene chloride. The mixture was kept in a refrigerator for 7 days. After that, the mixture was diluted with 30 ml of methylene chloride and washed with water. The organic layer was dried over Na_2SO_4 and concentrated. The product was obtained as a white crystalline substance; yield 1.54 g (87%).

IR spectrum, ν, cm^{-1}: 3300, 3085, 1689, 1668 (C=O, amide I), 1540 (C=O, amide II). ^{1}H NMR spectrum (300 MHz, acetone-d_6), δ, ppm: 1.4 s (9H), 3.25–3.44 m (6H), 3.8 m (2H), 5.58 d.d (1H), 6.2 m (2H).

Found, %: C 54.87, H 8.21, N 14.83.

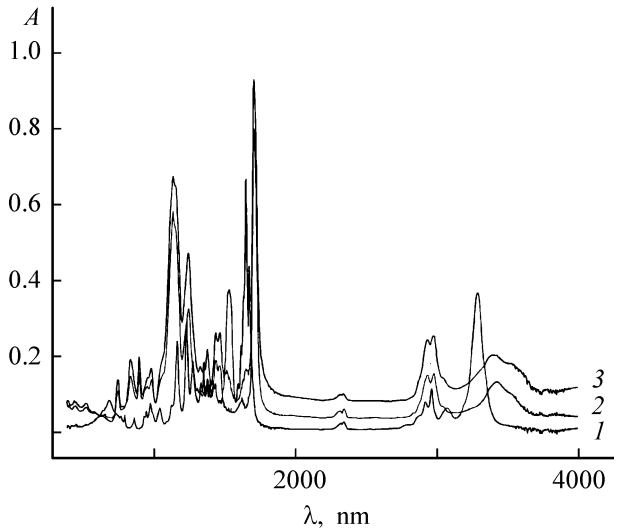


$C_{13}H_{23}N_3O_4$.

Calculated, %: C 54.72, H 8.12, N 14.73.

Free-radical copolymerization of GMA, EDMA, and the acrylic monomer (molar ratio 5.4 : 4 : 0.6) was performed under the photoinitiation conditions in cyclohexanol–dodecanol (7 : 3) in the presence of 2% Darocure 1173. The reaction time was 1 h. After the reaction was complete, the products were washed with ethanol and dried at 100°C.

Thermal copolymerization of GMA, EDMA, and the acrylic monomer (molar ratio 5.4 : 4 : 0.6) was performed in 2-propanol at 60°C, with 1% 2,2'-azobis(isobutyronitrile) as initiator, following the procedure described in [5]. The reaction time was 3 h. After the reaction was complete, the polymers were washed with ethanol and dried at 100°C.



The synthesis of the acrylic derivative of β-alanine with a protected amino group involved several steps:

In the first step, the carboxy group of amino acid **I** was protected by conversion into methyl ester **II**. The reaction was performed in methanol in the presence of thionyl chloride [6].

The amino group of β-alanine methyl ester hydrochloride was protected with di-*tert*-butyl pyrocarbonate (Boc_2O). This reaction can be performed in aqueous–organic or organic media [6]. We found that the attempted protection in aqueous dioxane in the presence of NaOH is accompanied by saponification of the ester. Therefore, the Boc protection of the amino group in **II** was performed in the presence of a milder base, triethylamine [7]. The reaction was performed in methanol for 0.5 h at 50°C.

Boc-protected β-alanine ester **III** was converted to ethylenediamine derivative **IV** by the reaction with

IR spectra of (*1*) acrylic monomer, (*2*) GMA–EDMA copolymer, and (*3*) terpolymer of GMA, EDMA, and acrylic monomer. (*A*) Absorption and (λ) wavelength.

excess ethylenediamine. Acrylic monomer **V** was prepared by the reaction of the free amino group in **IV** with acryloyl chloride in dry methylene chloride at a low temperature (–5°C). A procedure was developed for isolation and purification of this monomer. The structures of the new compounds prepared in this study were confirmed by ^{1}H NMR spectroscopy and elemental analysis.

We examined the possibility of preparing a monolithic porous material by copolymerization of glycidyl methacrylate, ethylene glycol dimethacrylate, and monomer **V** containing an anchor amino acid, β-alanine. We found that, under the conditions of photoinitiated polymerization in the presence of 2,2-dimethyl-2-hydroxyacetophenone (Darocure 1173), with a 7 : 3 mixture of cyclohexanol and dodecanol as a porogenic solvent, monomer **V** is not involved in the copolymerization, as follows from the IR and analytical data. This may be due to the low solubility of **V** in the solvent chosen.

The terpolymer containing units with the anchor amino acid was successfully prepared by thermal copolymerization of GMA, EDMA, and monomer **V** in 2-propanol at 60°C for 3 h, with 2,2'-azobis(isobutyronitrile) as initiator.

The involvement of the acrylic monomer in the copolymerization was confirmed by elemental analysis and IR spectroscopy. The figure shows the IR spectra of monomer **V**, GMA–EDMA copolymer, and the terpolymer. The IR spectrum of the acrylic monomer contains the bands of stretching (3085 cm^{-1}) and bending (700 – 650 cm^{-1}) vibrations of the =C–H bond, the C=C stretching band (1620 cm^{-1}), and the amide C=O vibration bands (1689 and 1668 cm^{-1}, amide **I**; 1540 cm^{-1}, amide II), and also a strong N–H band (3300 cm^{-1}). The presence in the spectrum of the terpolymer of the amide bands (1678 cm^{-1}, amide **I**; 1546 cm^{-1}, amide II) confirms the involvement of acrylic monomer **V** in the copolymerization.

CONCLUSION

A monomer in which the acrylic residue is linked through a spacer with Boc-protected β-alanine was synthesized. A ternary copolymer was prepared by radical thermal copolymerization of glycidyl methacrylate, ethylene glycol dimethacrylate, and acrylic derivative of β-alanine.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis of a Methacrylic Monomer Containing an *L*-Lysine-Based Dendron

G. N. Khimich and T. B. Tennikova

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received July 26, 2004; in final form, January 2005

Abstract—Procedures were developed for preparing a polylysine dendron of second generation, containing terminal Boc-protected amino groups and a free focal amino group; from this substance, a previously unknown methacrylic monomer linked to the *L*-lysine-based dendron was prepared.

Much attention is given today to development of hybrid materials combining dendritic and linear structural fragments [1]. The use of dendritic monomers as building blocks along with linear monomers substantially extends the possibilities of macromolecular design; it has led to preparation of polymers of unusual architecture [2]. By using various structural elements forming a polymeric framework, it is possible not only to modify the physical properties of polymers, but also to impart additional functions to the polymer skeleton, such as complexing power, response to certain physical actions, and possibilities of further transformations. Introduction of dendrimers combining a high functionality with a compact molecular structure opens wide prospects for application of such materials in biology, medicine, and medical diagnostics [3–7].

Dendrimers prepared from natural amino acids by peptide synthesis [8–10] contain on the periphery a controllable amount of reactive functional groups.

The interest in polymers containing branched polylysine [11, 12] is due to the possibility of preparing new amphiphilic materials to be used in molecular biology. Dendrimers derived from *L*-lysine and block copolymers containing dendritic poly-*L*-lysine exhibit a high compacting power toward DNA [13, 14].

Two types of denritic-linear polymers containing poly-*L*-lysine fragments are known: dumbbell-like compounds prepared by reactions of bifunctional linear compounds (low-molecular-weight or polymeric) with dendritic fragments [12] and compounds in which one end of a polymer chain is linked to the focal point of a dendron [11, 12].

Published data on synthesis of dendritic polymers and copolymers containing monomeric units with dendritic poly-*L*-lysine fragments are lacking. There are three fundamentally different routes to such substances: (1) synthesis of a linear polymer, followed by addition of separately prepared dendrons to the chain (convergent route); (2) synthesis of a polymer with active substituents, followed by stepwise build-up of a dendron at the polymer chain (divergent route); and (3) synthesis of macromonomers, i.e., dendrons containing a polymerizable functional group at the focal point, followed by polymerization [1, 15]. Use of such macromonomers containing terminal functional groups capable of further chemical transformations under relatively mild conditions may be promising for preparation of new polymeric materials and macroporous polymeric sorbents [16].

The goal of this study was to develop a procedure for preparing a methacrylic monomer containing a fragment of a poly-*L*-lysine dendron of second generation.

EXPERIMENTAL

We used the following chemicals: *L*-lysine hydrochloride (Reanal, Hungary), di-*tert*-butyl pyrocarbonate, dicyclohexylcarbodiimide (DCC), *N*-hydroxybenzotriazole (HOBT) (all Sigma–Aldrich, Germany), methacryloyl chloride, and thionyl chloride (both Reakhim, Russia).

Methylene chloride, ethyl acetate, and chloroform were dried over P_2O_5 and then distilled (bp 40, 77, and 62°C, respectively). Tetrahydrofuran and diethyl ether were refluxed over alkali and then distilled (bp 65 and 35°C, respectively). Acetone was refluxed

1070-4272/05/7806-1003 © 2005 Pleiades Publishing, Inc.

over anhydrous K_2CO_3, distilled (bp 56°C), and stored over molecular sieves. Thionyl chloride was distilled (bp 79°C). Other solvents and solid chemicals were used without additional purification.

The ^1H and ^{13}C NMR spectra were recorded on Bruker AC 300 (300 MHz) and Bruker DRX 500 (500 MHz) spectrometers in DMSO-d_6 or acetone-d_6.

MALDI-TOF mass spectra were taken on a Bruker IV device. Samples were ionized with an N_2 laser from a matrix of 2,4-dihydroxybenzoic acid.

The IR spectra were recorded on a Bruker IFS 88 spectrophotometer.

***L*-Lysine methyl ester dihydrochloride I.** Thionyl chloride (8 ml) was added dropwise with stirring to 60 ml of methanol cooled to –5°C with an ice–salt mixture, after which *L*-lysine hydrochloride (9.13 g, 0.005 mol) was added in portions with cooling. The mixture was stirred for 40 min at room temperature and then refluxed for 80 min. After cooling, the mixture was left overnight. The precipitate was filtered off and washed with diethyl ether (1 : 1). The precipitate was dried in air and then in a desiccator over NaOH. Yield 10.17 g (87.2%); white crystals.

^1H NMR spectrum (DMSO-d_6), δ, ppm: 1.39 m (2H, CH_2), 1.59 m (2H, CH_2), 1.83 m (2H, CH_2), 2.74 m (2H, CH_2), 3.75 s (3H, OCH_3), 3.96 t (1H, CH), 8.16 br.s (NH_3^+), 8.72 (NH_3^+).

Di(*tert*-butoxycarbonylamino)-*L*-lysine II. To a solution of 3.2 g (0.08 mol) of NaOH in 30 ml of H_2O, we added with stirring *L*-lysine hydrochloride (7.306 g, 0.04 mol) and then sodium hydrocarbonate (1.68 g, 0.02 mol). A solution of 18.2 g (0.088 mol) of *tert*-butyl pyrocarbonate in 40 ml of ethanol was added dropwise with stirring to the solution of the amino acid, cooled with ice and water. The mixture was stirred for a day at room temperature, after which 50 ml of H_2O was added to dissolve the precipitate. Excess *tert*-butyl pyrocarbonate was extracted with petroleum ether. The aqueous phase was acidified with 1 M $NaHSO_4$. The product was extracted with ethyl acetate. The organic layer was washed with a saturated NaCl solution, dried over anhydrous Na_2SO_4, and evaporated; the residue was dried in a vacuum. Yield 10.98 g (85.4%); white crystals.

^1H NMR spectrum (DMSO-d_6), δ, ppm: 1.2–1.4 m (20H, *t*-C_4H_9, CH_2), 1.53 m (2H, CH_2), 1.61 m (2H, CH_2), 2.88 m (2H, CH_2NHBoc), 3.82 m (1H, OCCH), 6.72 t (1H, NH), 6.96 t (1H, NH), 12.35 s (1H, COOH).

CH_3OLys(LysBoc$_2$)$_2$ III. To a solution of 3.244 g (0.014 mol) of *L*-lysine methyl ester dihydrochloride in 20 ml of DMF, we added 4.6 ml (0.033 mol) of triethylamine to obtain mixture A. To a solution of 10.5 g (0.042 mol) of di(*tert*-butoxycarbonylamino)-*L*-lysine in 40 ml of DMF, we added 3.97 g (0.033 mol) of HOBT and 6.84 g (0.033 mol) of DCC. After standing for 40 min, the solution of the activated ester was filtered through a glass frit and added to mixture A. The mixture was stirred for a day, and the precipitate was separated. The filtrate was evaporated in a vacuum to 1/3 of the initial volume. The resulting solution was diluted with 100 ml of ethyl acetate and washed successively with saturated NaCl solution (40 ml), 2% $NaHSO_4$ solution (2 × 20 ml), 5% $NaHCO_3$ solution (2 × 20 ml), and H_2O (2 × 20 ml). The organic layer was dried over Na_2SO_4 and evaporated; the yellow oily residue was purified by preparative adsorption chromatography on a column packed with silica gel (40–60 μm). The major fraction was additionally purified by repeated chromatography on a similar column. A mixture of chloroform with methanol (ratio from 10 : 1 to 5 : 1) was used as eluent. A white crystalline substance was obtained; yield 9.84 g (86%).

^1H NMR spectrum (DMSO-d_6), δ, ppm: 1.10–1.75 m (54H; *t*-$C_4\underline{H}_9$, CH_2), 2.88 m (4H, $C\underline{H}_2$), 2.95–3.1 m (2H), 3.61 m (3H, $OC\underline{H}_3$), 3.80 m (1H, CH), 3.91 m (1H, CH), 4.20 m (1H, CH), 6.66 d (1H, NH), 6.71 m (3H, NH), 7.71 t (1H, NH), 8.05 t (1H, NH).

^{13}C NMR spectrum (DMSO-d_6), δ, ppm: 22.51, 22.72, 22.83, 24.48, 25.37, 28.22, 28.31, 28.61, 29.24, 29.26, 30.58, 31.64, 31.83, 33.38, 38.15, 39.72, 40.83, 47.55, 51.75, 54.03, 54.37, 77.34, 77.94, 155.28 (CO), 156.59 (CO), 171.95 (CO), 172.41 (CO), 172.53 (CO).

Found, %: C 57.41, H 8.95, N 10.40.

$C_{39}H_{72}N_6O_{12}$.

Calculated, %: C 57.33, H 8.88, N 10.29.

MALDI, *m*/*z*: 818.1 $[M + H]^+$, 840.1 $[M + Na]^+$, 856.1 $[M + K]^+$. IR spectrum, *ν*, cm^{-1}: 3150–3500 (NH), 2978 (*t*-C_4H_9), 1693 (C=O, amide **I**), 1525 (amide **II**), 1170 (CO).

$NH_2CH_2CH_2NH$Lys(LysBoc$_2$)$_2$ IV. A solution of 1.58 g (1.93 mmol) of dendron **III** in 15 ml of absolute methanol was added dropwise with stirring to 15 ml of ethylenediamine, cooled with ice. The mixture was purged with nitrogen and left in the dark at room temperature for 3 days. After that, the solvent and excess ethylenediamine were distilled off in a vacuum. The product was purified by preparative adsorption chromatography on a column packed with

silica gel (40–60 μm), with chloroform–methanol (5 : 1) as eluent. A white crystalline product was obtained; yield 1.38 g (83.8%).

^{1}H NMR spectrum (DMSO-d_6), δ, ppm: 1.10–1.75 m (56H), 2.54 m (2H, –CH_2–NH_2), 2.87 m (4H, CH_2), 2.95–3.08 m (4H, CH_2), 3.81 m (1H, CH), 3.85 m (1H, CH), 4.17 m (1H, CH), 6.66 d (1H, NH), 7.62 m (2H, NH), 6.86 d (1H, NH), 7.68 m (2H, NH), 7.79 t (1H, NH).

^{13}C NMR spectrum (DMSO-d_6), δ, ppm: 22.52, 22.83, 28.22, 28.32, 28.79, 29.24, 31.44, 31.89, 31.96, 38.41, 39.69, 41.25, 42.29, 52.38, 54.33, 54.54, 77.34, 77.93, 78.15, 155.29 (CO), 155.46 (CO), 155.61 (CO), 171.46 (CO), 171.90 (CO), 171.96 (CO).

Found, %: C 56.93, H 9.35, N 13.21.

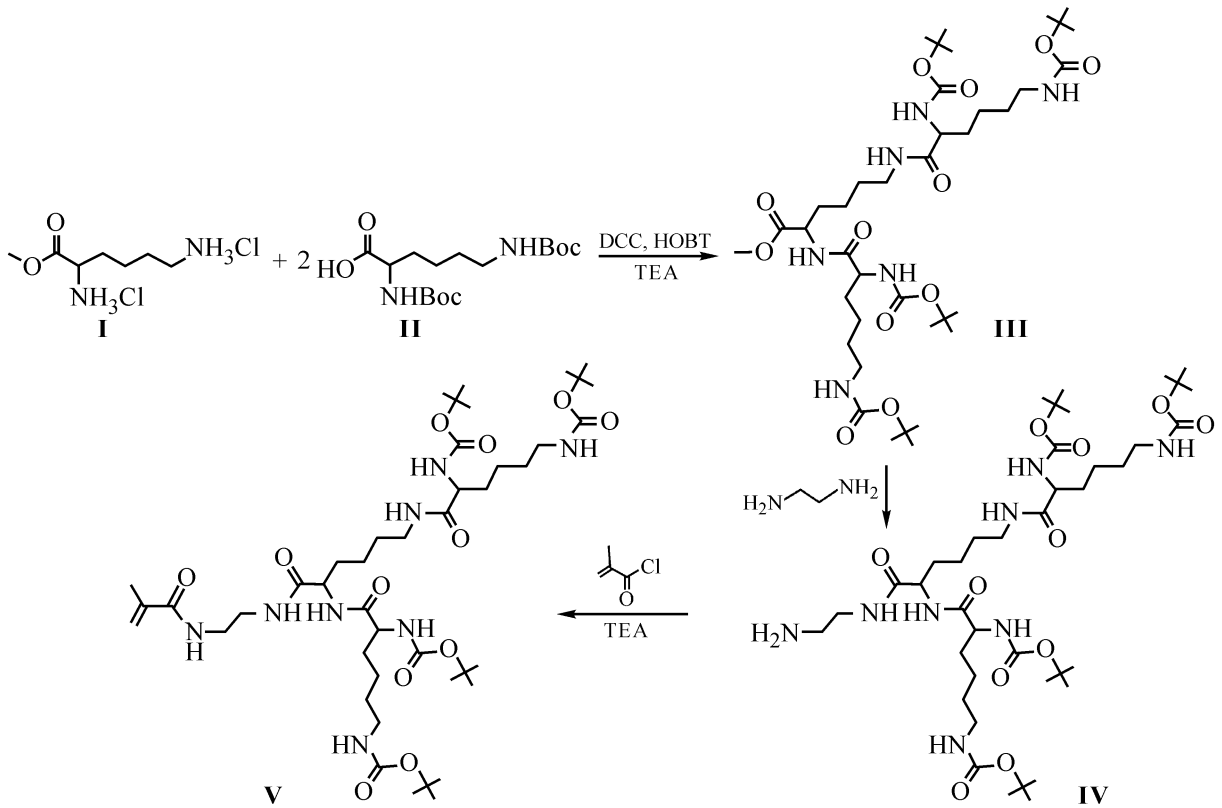
Calculated, %: C 56.85, H 9.06, N 13.26.

MALDI, *m*/*z*: 846 $[M + H]^+$, 868 $[M + Na]^+$, 884 $[M + K]^+$. IR spectrum, ν, cm^{-1}: 3150–3500 (NH), 2978 (*t*-C_4H_9), 1695 (C=O, amide **I**), 1525 (amide **II**), 1169 (CO).



Methacrylic monomer V. To a solution of 0.97 g (1.45 mmol) of dendron **IV** in 12 ml of dry THF, cooled to –5°C, we added 0.223 ml (1.60 mmol) of triethylamine. Then we slowly added a solution of 1.167 g (1.6 mmol) of methacryloyl chloride in 2 ml of THF. The mixture was stirred for 3 h and left overnight. On the next day, the solvent was distilled off in a vacuum. The residue was dissolved in dichloromethane and washed with water, dilute Na_2CO_3, and again water. The organic layer was dried over Na_2SO_4 and concentrated. A white crystalline substance was obtained; yield 1.1 g (83.3%).

^{1}H NMR spectrum (DMSO-d_6), δ, ppm: 1.1–1.75 m (52H), 1.98 s (3H, C=CCH_3), 2.87 m (4H, CH_2NHCO), 3.03 m (2H), 3.15 m (4H), 3.82 m (2H), 4.18 m (1H, CH), 5.28 (1H), 5.62 (1H), 5.95–6.9 (a series of broad NH signals).

			–	935.7	951.7

* Found.

** Calculated.

First, we prepared by known procedures *L*-lysine methyl ester dihydrochloride and di-Boc-*L*-lysine. The carboxy group was protected by esterification with methanol in the presence of $SOCl_2$. The Boc protection of the amino groups of *L*-lysine was performed by a standard procedure with *tert*-butyl pyrocarbonate (Boc_2O) [17].

From *L*-lysine methyl ester hydrochloride **I** and di(*tert*-butyloxycarbonyl)-*L*-lysine **II**, we prepared a dendron of second generation, $CH_3OLys(LysBoc_2)_2$ **III**, containing four Boc-protected amino groups. For this reaction to be successful, the carboxy group should be activated. Various activating agents are used in the synthesis of dendritic poly-*L*-lysines. Choi *et al*. [12] used, when preparing a hybrid copolymer of poly(ethylene glycol) and polylysine dendron by a divergent procedure, *N*-α-*N*-ε-di-Fmoc-*L*-lysine (Fmoc = 9-fluorenylmethoxycarbonyl) and HOBT in the presence of diisopropylamine. Chapman et al. [11] used as reagent pentafluorophenyl ester of *N*-α-*N*-ε-di-Boc-*L*-lysine in the presence of diisopropylethylamine (DPEA).

In the synthesis of *L*-lysine dendron **III**, we activated the carboxy group with dicyclohexylcarbodiimide and *N*-hydroxybenzotriazole (DCC/HOBT). The reaction occurs within 3 days at room temperature. The product was purified by column chromatography on silica gel, with chloroform–methanol as eluent; yield 86%.

Compound **III** contains two types of protecting groups: Boc groups on the periphery and methyl group in the focal point. By saponification of the carboxy group, the dendron with the reactive carboxy group can be obtained; it can be used for preparing dendrons of further generations.

Schlüter *et al*. reported on preparation of dendron-containing monomers by a procedure involving addition of a spacer to an acrylic or methacrylic monomer, followed by its modification with a dendron containing an appropriate functional group [1, 18]. In this study, we modified dendron **III** with ethylenediamine to obtain $NH_2CH_2CH_2NHLys(LysBoc_2)_2$ **IV**. This compound contains a focal amino group. In the subsequent step, it is brought into condensation with methacryloyl chloride, i.e., the spacer is added directly to the dendritic fragment.

The structures of dendrons **III** and **IV** and of macromonomer **V** were confirmed by IR and ^1H and ^{13}C NMR spectroscopy, and also by MALDI-TOF spectrometry (see table).

CONCLUSIONS

(1) A poly-*L*-lysine dendron of second generation, containing a focal amino group and terminal Boc-protected amino groups, was prepared.

(2) A procedure was developed for preparing a methacrylic monomer linked to the poly-*L*-lysine dendron of second generation through a spacer.

Abstract—Emulsion polymerization of styrene in the presence of an anionic surfactant, sodium dodecyl sulfate, in a concentration close to the critical micellization concentration, was studied, as influenced by the pH of the initial reaction mixture and the content of the carboxyl-containing azoinitiator.

Monodisperse polystyrene (PS) particles have long been used as calibration standard for electron microscopy. These particles are widely used for electron microscopic determination of the concentration of various components of natural water and, in particular, viruses, whose size is determined with the aid of an internal latex reference. To estimate quantitatively the virus population and the quality of drinking water, 50–150 nm latex monodispersions with similar polymeric structure are required. These references can also be used to estimate the retentivity of various antiviral filters and nutrient media and sera in production of vaccines and biologicals. Modification of the surface of latex particles with functional groups (e.g. carboxy groups) allows covalent binding of bioligands to the surface. The modified particles can be used to simulate virus particles not only in size but also in bioselective surface markers.

Submicrometer monodisperse microspheres of PS and poly(methyl methacrylate) (PMMA), containing surface carboxy groups, were prepared by emulsifier-free emulsion polymerization initiated by 4,4'-azobis(4-cyanoisovaleric acid) (CIVA) [1–3]. The stability of these particles against aggregation is provided by the surface charge produced in ionization of the terminal carboxy groups of the polymeric chains [4]. The degree of ionization of the initiator and polymerization products and, hence, the surface concentration of carboxy groups and the particle size depend on the pH of the reaction mixture. These particles can be used in biotechnology, since their carboxylated surface interacts with small biologically active compounds. The constancy of the polymeric structure of the particle surface makes it possible to provide the optimal conditions of immumochemical reactions with the surface change controlled by varying the pH of the reaction mixture.

To prepare 100-nm particles of this type, an emulsifier should be introduced into the reaction mixture to stabilize additionally the developed interface [5–7]. However, particles formed on the surface can migrate into the dispersion medium to promote there nucleation of new particles, thus broadening the particle size distribution of the latex.

To prepare 50–150-nm latex dispersions and to determine the factors affecting the dispersity of latex particles and the surface concentration of carboxy groups, we studied emulsion polymerization of styrene as influenced by the concentrations of emulsifier, sodium dodecyl sulfate (SDS), initiator (CIVA), and protons in the reaction mixture.

EXPERIMENTAL

Styrene was distilled under a reduced pressure. The procedures for treating CIVA are described in [4]. Sodium dodecyl sulfate (Serva) and standard solutions of HCl and NaOH were used as received. The polymerization was performed in double-distilled water. The procedure for preparing latexes has been described elsewhere [4]. The styrene to aqueous phase weight ra-

SDS concentration in the reaction mixture (M): (*1*) 4×10^{-3}, (*2*) 6×10^{-3}, (*3*) 8×10^{-3}, and (*4*) 10^{-2}.

tio was 5%. The CIVA concentration in the aqueous phase was $(3.57–17.9) \times 10^{-3}$ M. Polymerization was performed at 363 K in the presence of $(4.08–10.20) \times 10^{-3}$ M SDS and pH of the initial emulsion 9.5–11.5.

The diameter of the latex particles was determined by electron microscopy (JEM 100 S microscope, JEOL, Japan). The root-mean-square variance σ and polydispersion coefficient *k* were calculated from diameters of more than 400 particles by the equation

$$k = D_m/D_n,$$

where D_m and D_n are the weight-average and number-average diameters, respectively.

Water-soluble impurities were removed from the latexes by dialysis for 7 days against double distilled water, which was replaced at regular intervals. The content of the surface carboxy groups was determined by conductometric titration [8].

To prepare monodisperse particles, their nucleation was performed under homogeneous conditions. For this purpose, SDS was introduced in an amount close to the critical micellization concentration (CMC) equal to 8.16×10^{-3} M at 25°C [10]. The maximal SDS concentration was 25% higher than the CMC.

The diameter of latex particles regularly decreased with increasing emulsifier concentration at all the examined initial pH values of the emulsion (Figs. 1a, 2a). This dependence was the most pronounced in strongly alkaline solutions. By contrast, the SDS concentration of 4.05×10^{-3} M is insufficient to decrease the par-

Influence of the initial concentration c_{CIVA} of the initiator, emulsifier concentration c_{SDS}, and initial pH (pH_0) on the properties of polystyrene latex particles

* S_{COOH} is the concentration of COOH groups on the surface of PS particles.

ticle size to 108 nm at pH 9.5, and a further increase in its concentration has virtually no effect on the particle size. These distinctions can be due to the fact that SDS and surfactant oligomers containing terminal COOH groups formed in the first polymerization steps are involved in the nucleation. Deprotonation of the carboxy groups with increasing pH affects the particle size in two ways. On the one hand, the ionization increases the surface charge of primary nuclei and gives rise to stable polymer-monomer particles (PMP) of smaller size. On the other hand, negatively charged carboxy groups of the oligomer and sulfo groups of the emulsifier compete for sorption on the particle surface, which is confirmed by a decrease in the surface concentration of carboxy groups with increasing SDS concentration (Fig. 1c) and pH (Fig. 2c, curves *2*–*4*). The degree of carboxylation of the particle surface is almost independent of pH (Fig. 2c, curve *1*) at the lowest concentration of SDS (4.08×10^{-3} M) in the reaction mixture, which indicates that the surface concentration of the emulsifier is low.

The latex particles growin size with as the initial concentration of the initiator increases at the SDS concentration of 4.08×10^{-3} M and pH 9.5–9.6 (see table, Fig. 3). The particle size distribution of the latex is substantially broadened at the maximal CIVA concentration (sample no. 4). A similar dependence has been observed for emulsifier-free polymerization of styrene initiated by potassium persulfate [6, 7].

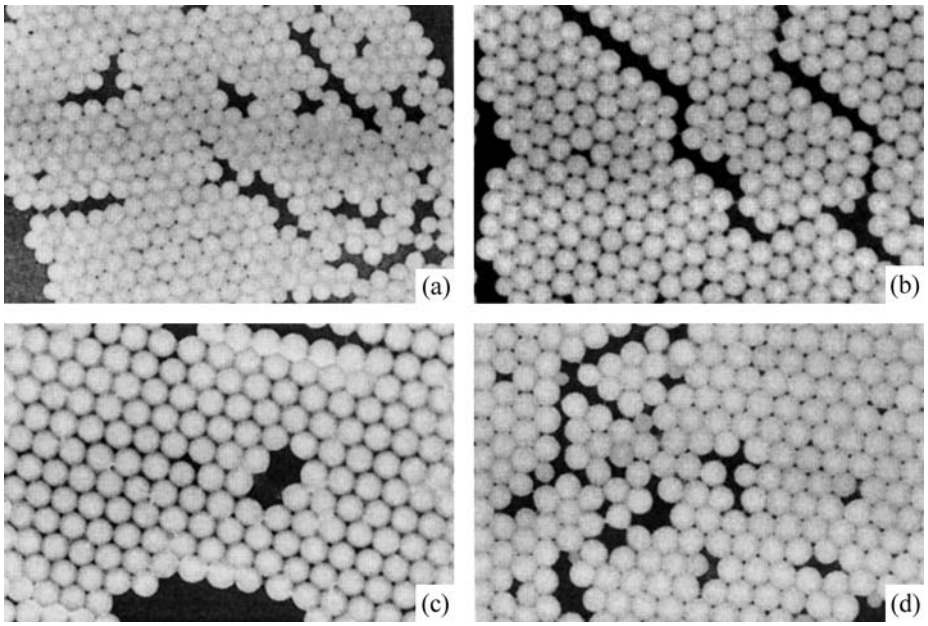

Fig. 3. Electron micrographs of latex nos. (a) 1, (b) 2, (c) 3, and (d) 4 (sample numbers are indicated in the table).

The negative concentration effect of high concentrations of water-soluble ionic initiators is due to an increase in the ionic strength of the reaction mixture and in the concentration of surfactant oligomers, which can form new PMPs in the course of polymerization, thereby making the latexes polydisperse. At pH 10.4–10.5 and the SDS concentration of 8.16×10^{-3} M, the dependence of the particle size on the CIVA concentration was inverse. The average particle diameter decreased and k and σ substantially increased owing to the above effects. The surface concentration of the terminal COOH groups also decreased. Therefore, most of the subsequent experiments were performed at the lowest CIVA concentration of (3.57×10^{-3} M).

The pH dependence of the particle diameter has a shallow minimum at pH 9.5 and SDS concentrations lower than CMC (Fig. 2a, curves *1*, *2*). This behavior is typical of an emulsifier-free polymerization of styrene, initiated by CIVA, and is caused by the fact that the degree of ionization of COOH groups on the surface of latex particles is at a maximum. In more alkaline solutions, $-COO^-Na^+$ ion pairs are formed owing to an increase in the ionic strength of the reaction mixture [1, 2]. By contrast, when the SDS concentration is equal to, or higher than CMC (Fig. 2a, curves *3*, *4*), this minimum is not observed and the diameter of particles formed in strongly alkaline solutions noticeably decreases. Clearly, both homogeneous and micellar nucleation mechanism are possible at SDS concentrations close to CMC. The average particle diameter decreases, the concentration of the surface COOH groups decreases, and the variance σ of the diameter of the latex particles substantially increases (Fig. 1b, curve *4*; Fig. 2b, curves *3*, *4*) as the SDS concentration decreases within the CMC range. However, monodisperse latexes with σ lower than 5–6% can be prepared in less alkaline solutions at this SDS concentration.

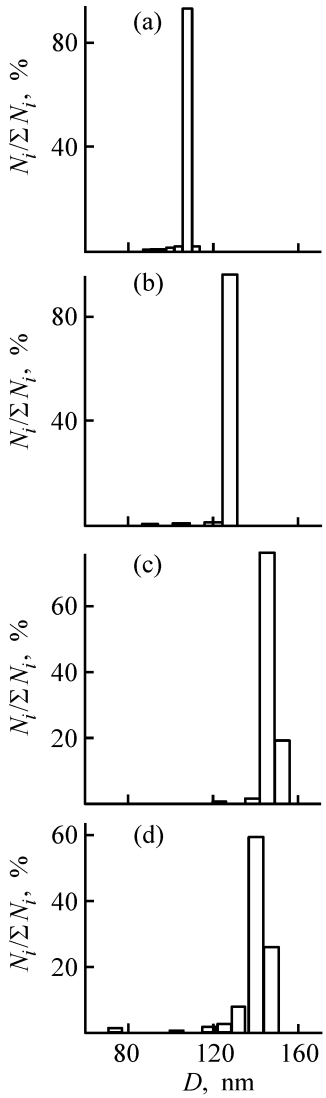

Fig. 4. Particle size distribution of latex nos. (a) 1, (b) 2, (c) 3, and (d) 4 (sample numbers are indicated in the table). ($N_i/\Sigma N_i$) Fraction of particles with a certain diameter and (D) particle diameter.

CONCLUSIONS

(1) Monodisperse 80–140-nm latex particles with a 0.50–1.35-μg-equiv m^{-2} surface concentration of carboxy groups were prepared by emulsion polymerization of styrene, induced by 4,4'-azobis(4-cyanoisovaleric acid) in the presence of sodium dodecyl sulfate in a concentration close to the critical micellization concentration.

(2) The particle diameter and the surface concentration of carboxy groups can be controlled in the indicated range by varying the pH of the initial reaction mixture and the azo initiator concentration in it. A dispersion characterized by a room-mean-square deviation from the average particle diameter lower than 5% can be prepared.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

A Study of the Affinity of Dyes for Cellulose Fiber within the Framework of a Fragment Approach in QSPR

N. I. Zhokhova, I. I. Baskin, V. A. Palyulin, A. N. Zefirov, and N. S. Zefirov

Lomonosov State University, Moscow, Russia

Received October 20, 2004; in final form, March 2005

Abstract—The affinity of azo and anthraquinone dyes for the cellulose fiber was first studied by the fragment approach in terms of the QSPR method. Linear-regression models that can prognosticate this parameter on the basis of descriptors taking into account the fragment composition of a molecule were suggested.

The interaction of various dyes with a cotton fiber is a complex physicochemical process governed by specific features of the structure of the textile polymer and by the nature of a dye molecule. This interaction is affected by various factors (electrostatic fields, Van der Waals forces, formation of hydrogen bonds, hydrophobicity, etc.), and the available experimental data are rather diverse. That is why theoretical methods for calculation of quantitative structure–property/activity relationships (QSPR/QSAR and 3D-QSAR) are widely used to study these interactions [1].

One of the main parameters characterizing the interaction of a dye with a fiber is the chemical affinity $-\Delta\mu^0$ (kJ mol^{-1}). It has been shown that, in the fixation of a dye molecule on a cellulose fiber, the key influence on the affinity of anionic and neutral azo [2, 3], heterocyclic monoazo [4], symmetric diazo [5], and anthraquinone [6] dyes for the cellulose fiber is exerted by electrostatic interactions. At the same time, it is commonly assumed thatthe binding of dye molecules may occur with specific binding centers involved, and the existence of these centers is due to the supramolecular structure of cellulose [7]. When studying dye–fiber intermolecular interactions, the authors of [8] concluded that steric factors are less important in this case than for the classical ligand–receptor interactions. As for the spatial structure of a dye molecule and presence of various kinds of substructures, they should be regarded as additional factors that affect the distribution of electrostatic potentials around a molecule, which are of primary importance for the dye–fiber interaction, too. In this context, it seems to be of interest to study how the affinity of dye molecules for cellulose depends on their fragment composition, which remains virtually unstudied. In the study, the affinity of a number of azo and anthraquinone dyes for cellulose was examined using the fragment approach the framework of the QSPR methodology.

Previously, descriptors characterizing the fragment composition of a molecule have been successfully used for QSPR-prognostication of physicochemical properties of organic compounds of various classes, including the chromatographic retention indices [9], boiling point [9], flash point [10], sublimation enthalpy [11], polarizability [12], and magnetic susceptibility [13].

The study was performed using the NASAWIN QSAR/QSPR software package [14, 15] and the integrated FRAGMENT software. Databases were compiled using MEOW and BASTET software specially developed for creating and refining structural databases [12]. Three samples of compounds, containing 30 anionic sulfur-containing azo dyes [3] were studied (Database 1). The affinity of a dye for the fabric was chosen as the property to be modeled. It was calculated as the difference of the standard chemical potentials of a dye molecule fixed on the fabric surface and that in an aqueous solution. These thermodynamic data were experimentally obtained in aqueous solutions at three temperatures and were described in detail in [16]. Further, data for 49 anthraquinone dyes [8] were collected (Database 2). Finally, a combined sample was obtained, which contained both sets of structures (Database 3). Based on a preliminary verification of all the databases by the BASTED software, the following corrections were introduced, by agree-

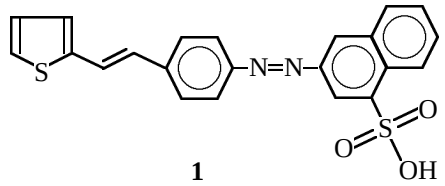
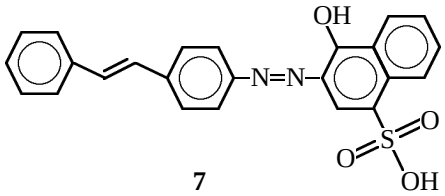
** Control sample includes every fifth compound of a database.



*** Number of fragment descriptors/Maximum number of atoms in a fragment.

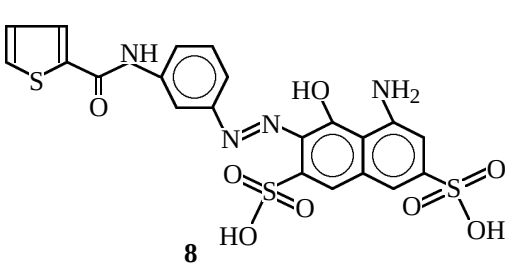
ment with the authors of [8], into Database 2: substituent 1-$NHCOCH_3$ in structure no. 12 changed ws changed to 1-$NHCOCH_2Cl$, and the place of addition of the substituent –[4-$OCH_3C_6H_4CONH$–] in structure no. 41, from position 5 to position 4.



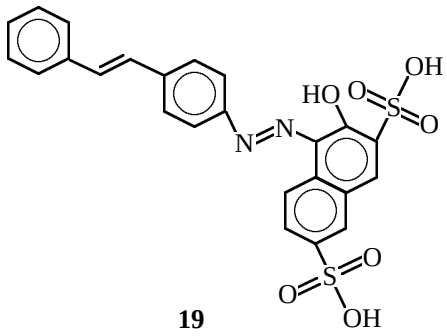
In the first stage of the study, linear-regression models based on descriptors characterizing fragments with the maximum chain lengths of 6, 10, and 15 atoms and an external control sample including every fifth compound of a database were constructed for the samples under study using the NASAWIN software package. These models (see table, model nos. 1–12) have good descriptive and prognosticating properties. The best prognosis quality was achieved with fragments having chains up to 15 atoms long included in the model.

The quality of fragment-based and published models obtained for the same samples by means of a comparative molecular field analysis and a multiple linear regression with the use of quantum-chemical descriptors (azo compounds) [3], and by the method of a comparative molecular surface analysis (CoMSA, azo and anthraquinone compounds) [8] was compared by constructing a number of models using a sliding control with exclusion of a single compound. The models obtained are comparable in their properties with those cited in the literature, and in some case, even surpass them. For example, the regression model constructed for Database 1 with four fragment descriptors (chain in a fragment up to 15 atoms long) has parameters (R^2_{learn} = 0.967; standard deviation s = 0.66; F = 181.6; squared correlation coefficient with a sliding control, Q^2 = 0.949; root-mean-square error RMS_{sl} = 0.74; standard deviation with a sliding control, s_{sl} = 0.80) exceeding those of the best regression model constructed for the same sample with the energies of the upper occupied and lower unoccupied molecular orbitals E_{HOMO}, E^2_{HOMO}, and E_{LUMO}, calculated by the AM1 method, used as descriptors (three descriptors, R^2_{learn} = 0.92, s = 1.02, F = 94.9, Q^2 = 0.89, standard deviation with a sliding control 1.19) [3]. For the PLS CoMFA [3] and CoMSA [8] models obtained for the given samples

the values of Q^2 fall within the ranges 0.63 – 0.75 and 0.829 – 0.970, respectively. The model constructed includes descriptors that describe the following fragments of azo compound molecules: =RC–C, RC_{Ar}÷C_{Ar}–NH_2, ·=·–·÷·÷·÷· (· is an arbitrary atom) and C–C–C÷(C÷)$_2$C–N=N–C÷ ÷(C÷)$_4$C–N. These fragment chains are more important for characterizing the affinity of the azo dyes. The largest difference between the calculated and experimental affinities is observed for structure **1** (1.3 kJ mol^{-1}) and **7** (1.2 kJ mol^{-1}):



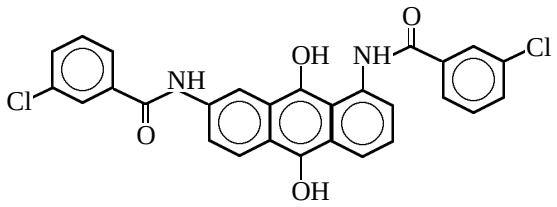
1



7

Combination of fragment descriptors with quantum-chemical descriptors of the energy of molecular orbitals, E_{HOMO} and E_{ILUMO} (data of [3] are used), fails to improve the quality of the models. Possibly, these descriptors are approximated by fragment descriptors.

The fragment models constructed for a sample of anthraquinone dyes (Database 2) also compare well in their prognosticating properties with published models [8]. Squared correlation coefficient with a sliding control for a model including eight descriptors (chains of 15 atoms; R^2_{learn} = 0.942, s = 0.46, F = 81.5, Q^2 = 0.915, RMS_{sl} = 0.50, s_{sl} = 0.55) exceeds the maximum value of Q^2 (0.88) for the Co MSA model [8]. The largest contribution to the model RC_{Ar}, and comes from the following components: C_{Ar}–N_{sp^3}–C, HC_{Ar}÷C_{Ar}–NHR, and C_{sp^3}–O–(C_{Ar}÷)$_7$ C_{Ar}–N_{sp^3}. The maximum deviation from the correlation is observed for structure **8** (0.98 kcal mol^{-1}) and **19** (0.94 kcal mol^{-1}):



8

19

The most important fragments included in the models for azo and anthraquinone compounds are distinguished by the existence of long chains of conjugated systems, which reflects their importance for the characterization of the property being modeled.

An attempt was made to construct a more versatile model for describing the dye–cellulose affinity by merging narrow samples of azo and anthraquinone dyes (Database 3). The prognosticating ability of this model was assessed by using the sliding control method. To make Database 2 uniform, the affinities from this database (kcal mol^{-1}) were expressed in kJ mol^{-1}. The model obtained includes 10 fragment descriptors (chains of 15 atoms) and has the following parameters: R^2_{learn} = 0.933, s = 1.72, F = 94.7, Q^2 = 0.901, s_{sl} = 2.09, RMS_{sl} = 1.94. The largest deviation from the correlation is observed for compound no. 68 (5.5 kJ mol^{-1}):

Below, the model obtained with this structure excluded from the learning sample is presented:

$$-\Delta\mu^0 = -4.36 + 1.87Fr1 - 2.63Fr2 - 1.31Fr3 - 1.38Fr4 + 0.67Fr5 + 1.56Fr6 + 1.14Fr7 + 1.78Fr8 - 0.82Fr9 + 1.38Fr10, \quad (1)$$

where R^2_{learn} = 0.947, s = 1.47, F = 119.4, Q^2 = 0.909, s_m = 1.93, RMS_m = 1.79; Fr1/C=, Fr2/–OH, Fr3/C_{sp^3}–N_{sp^3}–C, Fr4/C_{Ar}–(C=)–C, Fr5/RC_{Ar}÷C_{Ar}÷C_{Ar}, Fr6/N–C÷C–N, Fr7/·–·–·–·=·–·; Fr8/C_{Ar}–(C=)–NR–(C_{Ar}÷)$_7$$C_{Ar}$–OH, Fr9/C–N–(C÷)7C–N–C=O, Fr10/Cl–C_{Ar}(÷C_{Ar}H)$_2$.

In contrast to the case of models constructed for narrow samples (Databases 1 and 2), the largest con-

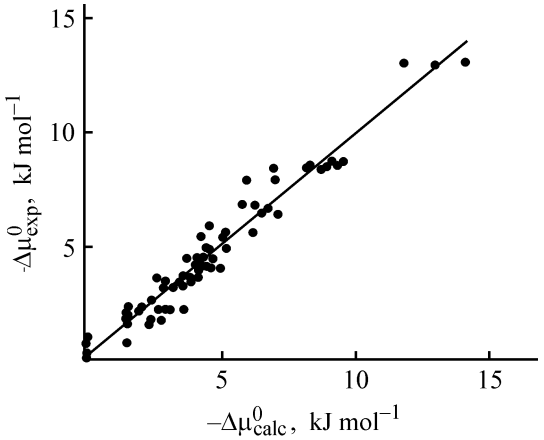


Diagram of scatter of the calculated and experimental values of the affinity of dyes for cellulose, $-\Delta\mu^0$, for a learning sample of Database 3, obtained in terms of the linear-regression model [Eq. (1)].

tribution to the combined model comes from descriptors of rather simple fragments: Fr1/C= and Fr2/–OH. The correlation plot for the calculated and experimental values of $-\Delta\mu^0$ for the combined model is shown in the figure.

Of interest is assessment of the prognosticating capacity of combined fragment models for the azo and anthraquinone dye samples under study. For this purpose, models were obtained using the combined Database 3 and the sliding control and were tested on two independent external samples including, respectively, every fifth compound from Databases 1 and 2. With these samples excluded from Database 3, the number of azo compounds and anthraquinones in the combined learning sample was 24 and 40, respectively. It was found that the prognosticating capacity of such a model (10 fragment descriptors, chains up to 15 atoms long) for an independent control sample of azo compounds considerably exceeds that for a sample of anthraquinones. For example, squared correlation coefficients between the experimental and predicted values, R^2_{prog}, for the appropriate control samples are 0.941 and 0.573, respectively. These data are in an agreement with the results of the study [8], in which the CoMSA models obtained for a sample of azo compounds surpass in prognosticating properties the models for a sample of anthraquinones. This confirms the efficiency of application of the fragment approach to modeling of the properties under study.

To improve the quality of the models, it seemed appropriate to include, in addition to the fragment descriptors, those characterizing the geometry (shape and size) of a molecule and making it possible to evaluate the degree of its compactness, i.e., topological indices. Descriptors of this kind were used to model the affinity of anthraquinone dyes for cellulose in [17]. More than 30 topological indices calculated using the EMMA software package [18, 19] were analyzed. However, the desired improvement of the quality of the models could not be achieved. This means that the set of fragment descriptors used in the present study enables a rather complete description of the relationship between the structural features of molecules of the dye groups studied and their affinity for cellulose.

CONCLUSION

Linear-regression QSPR models making it possible to prognosticate the affinity of azo and anthraquinone dyes for the cellulose fiber on the basis of descriptors that take into account the fragment composition of a dye molecule were suggested for the first time.

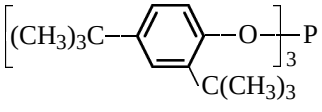
Received October 22, 2004; in final form, January 2005

Abstract—Wariation of the concentration of fullerenes C_{60} and C_{70} in poly(methyl methacrylate) films under UV exposure in atmospheric oxygen was studied. The mechanism of the influence exerted by addition of some photostabilizing polymers and xanthene dyes on the photooxidative degradation of fullerene in the polymer matrix was analyzed.

Poly(methyl methacrylate) (PMMA) and methyl methacrylate copolymers (MMACs) find practical application as organic glasses owing to their transparency, shock resistance, and stability against external factors.

Troitskii *et al.* [1, 3–6] and Shibaev *et al.* [2] have found recently that fullerenes C_{60} and C_{70}, thermally stable inorganic compounds, inhibit radical-chain reactions of thermal degradation of PMMA, MMACs, and branched chain reactions of thermooxidative degradation (TOD) of these polymers. An important feature of fullerenes as antioxidants is the deceleration of TOD of polymers at high temperatures of up to 340°C [7].

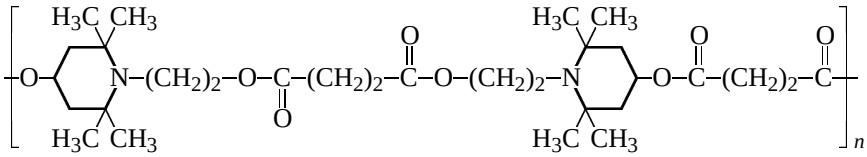
However, when exploited under natural conditions, organic glasses are subjected, above all, to solar radiation whose UV component exerts the strongest degrading action on the polymer and various additives introduced therein.



In this study, we examined (a) the influence of exposure to UV radiation in the presence of atmospheric oxygen on the concentrations of C_{60} and C_{70} dissolved in PMMA; (b) role of additives (selected photostabilizers and dyes) on this process; (c) mechanism of photooxidative degradation of fullerene in the polymer matrix; and (d) influence of a UV pretreatment on the TOD of PMMA with C_{60} and C_{70}.

EXPERIMENTAL

PMMA films of thickness 100 ± 20 μm, containing C_{60}, C_{70}, or a crude mixture of fullerenes, were prepared by the procedure described in [1].



The films were irradiated in air with a 230-W DRT-230 (λ_{max} = 254 nm) low-pressure mercury lamp. The lamp was cooled with a quartz cooler through which distilled water was passed. The distance between the center of the lamp and the sample with an area of 2×4 cm^2 was 20 cm. The films were irradiated on both sides for the same time. The changes in the concentration of C_{60} and C_{70} in PMMA were monitored by the intensities of the absorption bands at 331 (C_{60}) and 331 and 375 nm (C_{70}). The spectra of the films in the UV and visible spectral ranges were recorded on a Perkin–Elmer Lambda 25 UV/VIS Spectrometer.

Polymer photostabilizers Irgafos 168, Tinuvin 622, Tinuvin 770, and Chimassorb 944 were available from Ciba Specialty Chemicals and used without further purification. Given below are the chemical formulas of the stabilizers: Irgafos 168, tri(2,4-di-*tert*-butylphenyl) phosphite

Tinuvin 622, oligomer, a sterically hindered amine

Tinuvin 770, a sterically hindered amine

Chimassorb 944, a sterically hindered amine, oligomeric product

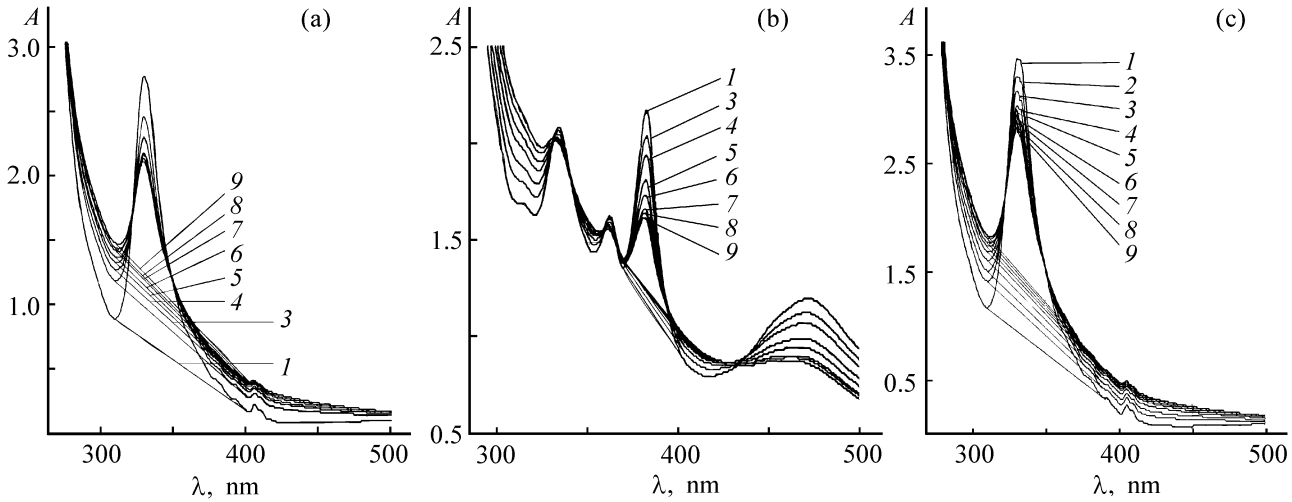
As dyes served chemically pure rhodamine C and rhodamine G.

Thermooxidative degradation of the PMMA films with additives was studied by TGA at 277°C and an oxygen pressure of 200 mm Hg.

Figures 1a and 1b show that, as the time of UV irradiation of the PMMA films with fullerene additives increases, the fullerene concentration tends to regularly decrease, as can be seen from a decrease in the intensities of the absorption bands at 331 (Fig. 1a) and 375 (Fig. 1b) nm. Simultaneously, the absorption at 400–500 nm tends to increase.

It should be noted that the photophysical properties of thin films consisting of C_{60} and C_{70} molecules only are well understood [7, 8]. When exposed to UV radiation in a vacuum or in an inert gas atmosphere, fullerene molecules pass from the ground state S_0 to an excited S_1 singlet state. The $S_0 \rightarrow S_1$ transition energy E_S is 221.5 for C_{60} and 192.3 kJ mol^{-1} for C_{70}. From the S_1 state fullerene passes to an excited triplet state with a yield of nearly 100%. Arbogast *et al.* estimated the triplet state energy E_T for C_{60} as 156.8 ± 18.8 kJ mol^{-1} [7].

In the triplet state T_1, fullerene C_{60} reacts with the double bond of the neighboring unexcited molecule by the 2 + 2 cycloaddition mechanism, to give a dimer [8]. By analogous mechanism, dimers can be converted into trimers, etc., which are insoluble in solvents. This makes thin C_{60} films suitable for photolithographic application [8]. The activation energy of



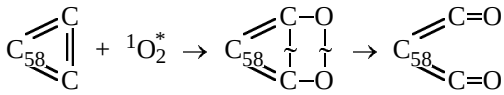


Fig. 1. Absorption spectra of UV-irradiated PMMA samples with various additives. (*A*) Absorption, and (λ) wavelength. Additive, mol kg^{-1}: (a) 3.3×10^{-3} C_{60}, (b) 4.1×10^{-3} C_{70}, and (c) 6×10^{-3} C_{60} + 0.3 wt % Tinuvin 622, (*1*) Nonirradiated sample; irradiation time, min: (*2*) 2×15, (*3*) 2×30, (*4*) 2×60, (*5*) 2×90, (*6*) 2×120, (*7*) 2×150, (*8*) 2×180, and (*9*) 2×210.

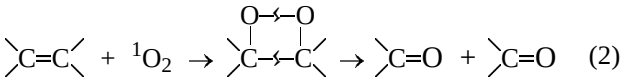
thermal degradation of the dimer was estimated as 120.4 kJ mol^{-1}. Above 100°C, the dimer degrades into the initial C_{60} [8]. Photodimerization and photopolymerization are much less pronounced in the case of C_{70}, compared to C_{60} [8].

When thin films of C_{60} or C_{70} are irradiated in the presence of oxygen, photodimerization and photopolymerization are completely suppressed, since oxygen quenches, with a huge rate constant $K_q(O_2) = 1.9 \times 10^9$ mol^{-1} s^{-1}, the triplet state of fullerene, passing to the excited singlet state [7, 8]. In the active singlet state, oxygen oxidizes fullerenes to give >C–O–, >C–O–C<, and >C=O [8].

The aforesaid suggests that UV irradiation of the PMMA films with fullerene additives involves photooxidation of fullerene by singlet oxygen by the scheme

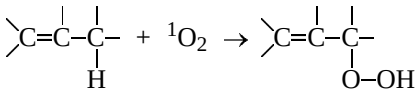
(1)



Formation of conjugated >C=C–C=O bonds is, evidently, responsible for the "broadening" of the absorption bands of fullerene and enhancement of absorption at 400–450 nm for C_{60} (Fig. 1a) and 430–500 nm for C_{70} (Fig. 1b).

Interestingly, reaction (1) results in degradation of the integral geometric structure of the fullerene (C_{60} is a sphere, and C_{70}, an ellipsoid) and formation of a "hole" at the site of rupture of the carbon–carbon double bond. Evidently, one molecule of fullerene C_{60} or C_{70} can add several molecules of singlet oxygen, with even more significant degradation of the geometric structure of the initial compound and formation of several holes on the surface of the sphere or ellipsoid.

In view of the fact that a fullerene molecule in the PMMA matrix is surrounded by fragments of macromolecules, it was reasonable to elucidate whether fullerene is a photosensitizer of photooxidation of the polymer. In other words, what is the probability of the reaction of the fullerene-activated singlet oxygen with fragments of macromolecules, rather than with fullerene, to yield active particles, with photooxidation of the polymer by the radical-chain mechanism.



To this end, we carried out photooxidation of PMMA films with C_{60} and C_{70} in the presence of the known effective inhibitors of photooxidative degradation of polymers, Tinuvin 622, Tinuvin 770, and Chimassorb 944. Figure 1c shows how the intensity of the absorption band of fullerene C_{60} in the PMMA film with a Tinuvin 622 additive varies with the UV irradiation time. Similar spectra were obtained for other photooxidation inhibitors as well. Figure 1c shows that photooxidation of C_{60} and C_{70} fullerenes is unaffected by inhibitors of photooxidative degradation.

Evidently, photooxidation of films of PMMA with C_{60} and C_{70} leads, above all, to oxidation of the fullerene proper, without sensitizing the oxidation of the polymer. De Rosa and Crutchley [9] showed that singlet oxygen actively reacts with compounds containing carbon–carbon double bonds to give thermally unstable cyclic peroxide, degrading into carbonyl compounds:

(2)

Singlet oxygen, probably, reacts with the activated bond in the allyl position, to give hydroperoxide

(3)

Fullerene C_{60} contains 30 carbon–carbon double bonds, and fullerene C_{70}, 35 double bonds. At the same time PMMA macromolecules contain virtually no carbon–carbon double bonds and allyl groups (the concentration of the terminal double bonds in the macromolecules is very low, no more than 0.1 mol %). Therefore, oxidation of fullerene by singlet oxygen is more probable than oxidation of the surrounding fragments of macromolecules.

We studied how xanthene dyes affect the photooxidation in the PMMA–C_{60} system. Table shows that addition of rhodamine G and rhodamine C decelerates oxidation of C_{60}. Fullerene C_{60}, in turn, decelerates photooxidation of these dyes. Evidently, this is due to the shielding effect, since both the fullerene and dyes intensively absorb UV radiation.

The TGA studies of the thermooxidative degradation revealed that preirradiation of the PMMA films containing C_{60} (Fig. 2a), C_{70} (Fig. 2b), or a C_{60} (80%) + C_{70} (20%) mixture (Fig. 2c) deteriorates the antioxidative performance of the fullerenes in TOD of the polymer. The induction period of TOD of unirradiated polymer with addition of C_{60} is 40 min (Fig. 2a, curve *1*), decreases to 15 min after 60-min UV irradiation (curve *2*), and disappears after 120-min UV irradiation (curve *3*). Nevertheless, even after a 300-min UV irradiation, the initial rate of TOD for

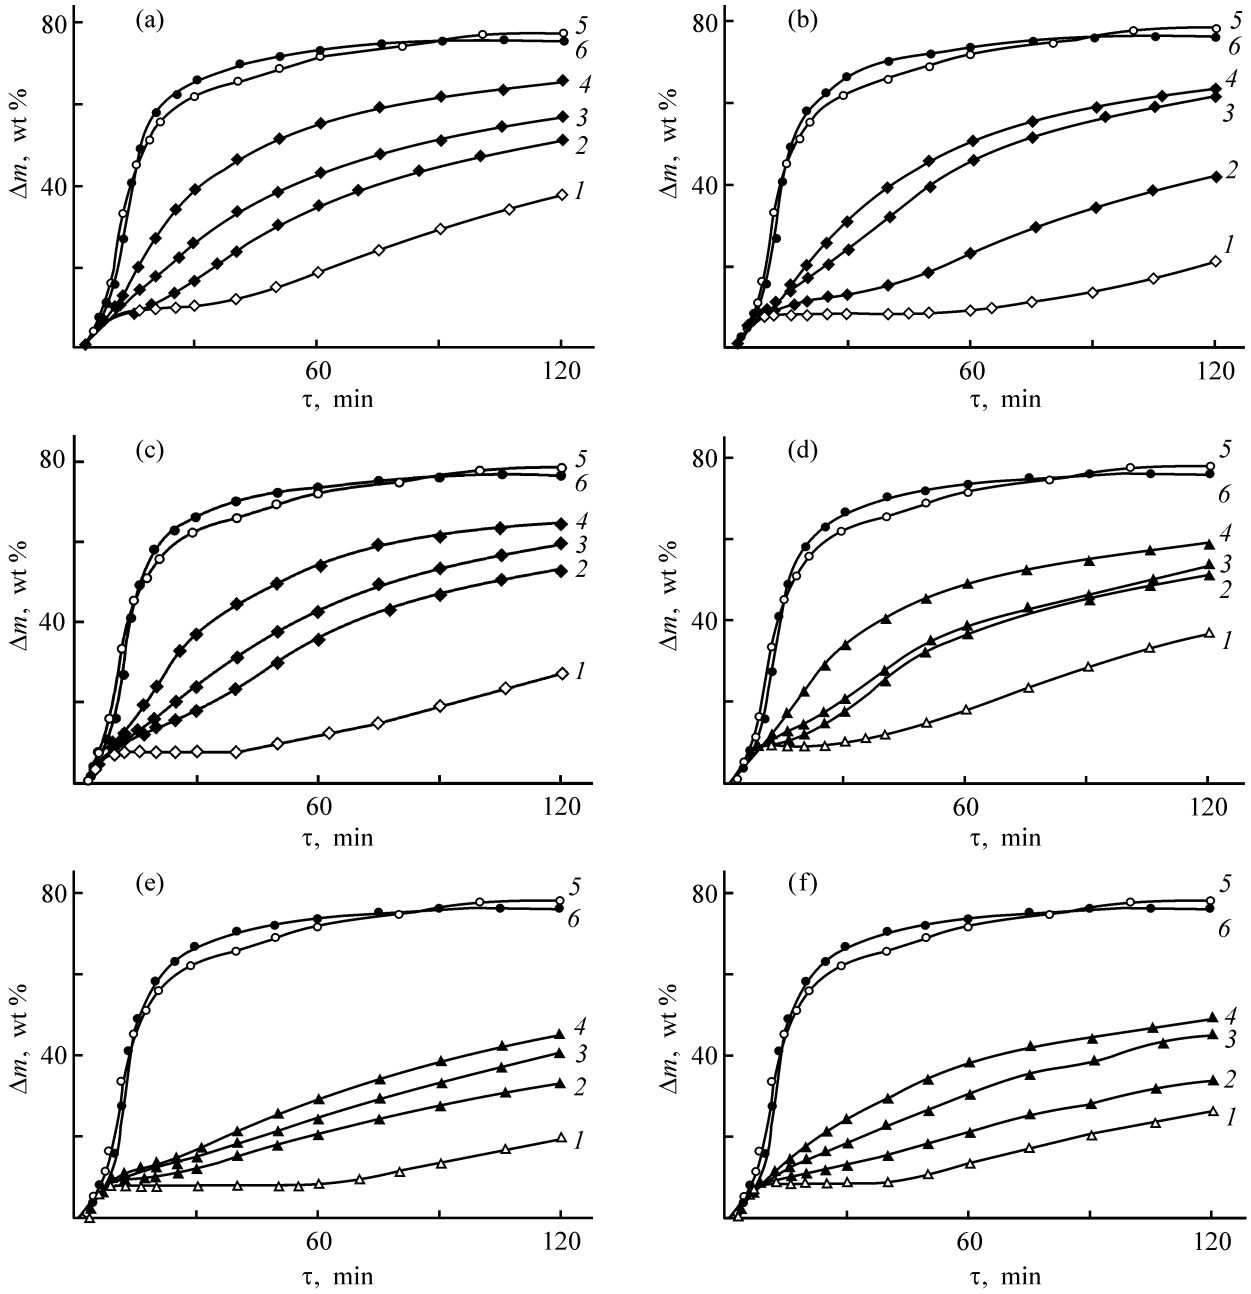


Fig. 2. TG (Δm) curves for thermooxidative degradation of PMMA (*1, 5*) before and (*2–4, 6*) after irradiation (*5, 6*) without and (*1–4*) with various additives. Irradiation time, min: (*2*) 60, (*3*) 120, (*6*) 180, and (*4*) 300. Addition, mol kg^{-1}: (a) 6×10^{-3} C_{60}, (b) 5.9×10^{-3} C_{70}, (c) 5.9×10^{-3} C_{60} + C_{70}, (d) 6×10^{-3} C_{60} + 0.29 wt % Irgafos 168, (e) 6×10^{-3} C_{60} + 0.294 wt % Chimassorb 944, and (f) 6×10^{-3} C_{60} + 0.3 wt % Tinuvin 622. T = 277°C; p_{O_2} = 200 mm Hg. (τ) Time.

PMAA with C_{60} is half that of PMMA without fullerene (Fig. 2a, curves *1* and *4*). After UV pretreatment, a fullerene mixture exhibits a stabilizing activity in TOD of PMMA (Fig. 2c), which is identical to that in the case of C_{60} (Fig. 2a). Fullerene C_{70} (Fig. 2b) is a more effective antioxidant than C_{60}, since the induction period in TOD of PMMA with C_{70} is 70 min, and that for PMMA with C_{60}, equals 40 min (Fig. 2a, curve *1*). However, the induction period disappears after a 120-min UV irradiation of PMMA with C_{70} (Fig. 2b, curve *3*). After 300-min irradiation of the PMMA film with C_{70} the initial rate of TOD of the polymer is three times lower (Fig. 2b, curve *4*), compared to PMMA without fullerene (Fig. 2b, curve *6*).

Decay of intensity *I* of the absorption band associated with the dye additive in PMMA during UV irradiation

Addition in PMMA	*I*, %, at indicated irradiation time, min					Addition in PMMA	*I*, %, at indicated irradiation time, min				
	0	60	120	240	360		0	60	120	240	360
	Band at 331 nm (C_{60})						Band at 535 nm (Rhodamine G)				
C_{60}	100	46	34	31	19	Rhodamine G	100	49	40	13	7
Rhodamine G + C_{60}	100	58	38	17	21	Rhodamine G + C_{60}	100	59	48	27	27
						Band at 556 nm (Rhodamine C)					
Rhodamine C + C_{60}	100	65	47	37	22	Rhodamine C	100	36	21	8	5
						Rhodamine C + C_{60}	100	49	30	17	7

The experimental data show that photochemical reactions of fullerene in PMMA films are responsible for the poorer performance of C_{60}, C_{70}, or a $C_{60} + C_{70}$ mixture as antioxidants in TOD of the polymer.

We found (Fig. 1c) that effective antioxidants of polymers Irgafos 168, Tinuvin 622, Tinuvin 770, and Chimassorb 944 virtually do not affect the decrease in the concentration of fullerenes C_{60}, C_{70}, or a $C_{60} + C_{70}$ mixture in PMMA films under UV irradiation at λ = 254 nm in the presence of atmospheric oxygen. Figure 2d shows that Irgafos does not affect TOD of PMMA with C_{60}. However, sterically hindered amines Tinuvin 622 and especially Chimassorb 944 (Fig. 2e, curve *3*, and Fig. 2f) significantly decelerate TOD of PMMA with C_{60}. This suggests that, at 277°C, these photostabilzers act as antioxidants in TOD of PMMA.

CONCLUSIONS

(1) UV irradiation of poly(methyl methacrylate) films containing fullerene C_{60} or C_{70} at 254 nm results in a regular decrease in the fullerene concentration with increasing irradiation time.

(2) Effective photostabilizers of polymers, Tinuvin 622, Tinuvin 770, and Chimassorb 944, do not affect the photooxidation of fullerenes. This suggests that oxidation follows the molecular, rather than the radical-chain, mechanism.

(3) Addition of Rhodamine G and Rhodamine C decelerates photooxidation of fullerenes C_{60} and C_{70} in the poly(methyl methacrylate) matrix, which is due to the shielding effect.

(4) Photochemical reactions of fullerenes in poly(methyl methacrylate) deteriorate the performance of fullerenes as antioxidants in thermooxidative degradation of the polymer.

(5) Sterically hindered amines Tinuvin 622, Tinuvin 770, and Chimassorb 944 at 277°C act as antioxidants in thermooxidative degradation of poly(methyl methacrylate) with addition of fullerenes and exhibit additional stabilizing effect in this process.

Abstract—The possibility of using fluoroplastic with various fillers to obtain thin protective coatings on heat-exchange surfaces for systems of technical water supply was examined.

The operation of the heat-exchange equipment inevitably poses the problem of decreasing efficiency of the heat-exchange surface, caused by formation of various contaminations (scale). The low heat conductivity of these deposits (0.3–1.2 $W\,m^{-1}\,K^{-1}$) and the short time before the beginning of their strong influence on the heat exchange (200–300 h of operation) make it necessary to envisage a reserve heat-exchange surface area of 30–40% relative to the calculated value, thereby increasing the steel intensity of the apparatus.

The rate at which the deposits are formed and the energy of their binding to the heat-exchange surface are strongly affected by electric and electrostatic phenomena. To diminish the electrostatic forces and improve the corrosion resistance of the heat-exchange surface, it is coated with thin polymeric coatings (PC) [1]. Being insulators, they, on the one hand, make markedly slower the rate of deposit formation, and on the other, reduce the total heat-transfer coefficient of the apparatus. The contribution of PC to the decrease in the heat-transfer coefficient can be found from

$$\alpha = \frac{K_{ht} - K_c}{K_{ht}} = \frac{1}{1 + \lambda_c/(K_{ht}\delta_t)^{-1}}, \quad (1)$$

where K_{ht}, K_c is the running heat-transfer coefficient without and with PC; λ_c, heat conductivity with a coating; and σ_t, PC thickness.

The quantity K_{ht} is variable and decreases with time following the dependence established in [2]:

$$K_{ht} = \frac{K_0}{1 + D[1 - \exp(-3 \times 10^{-10} H_0)]},$$

where H_0 is the homochronicity factor and D is a parameter dependent on technological (specific heat flux, flow mode R_e), design (material of the heat-exchange surface and its position, vertical or horizontal), and chemical factors (total content and concentration of suspended particles and $CaCO_3$ in water).

The experience of work with heat-exchange apparatus with coated tubes [2] shows that, in the course of time, the heat-transfer coefficient remains unchanged or decreases only slightly (within 5%), i.e., there comes a time when K_{ht} becomes equal to K_c.

Polyethylene, epoxy mixtures, etc. are commonly used as protective PC in heat-exchange apparatus [3]. However, these PC fail to provide the necessary thermal and physical properties: heat conductivity, viscosity, and elasticity. At a heat conductivity on the same order of magnitude, fluoroplastic can be deposited onto a surface as a 10–20 times thinner controllable layer, which results in the accordingly lower thermal resistance of the PC layer.

The aim of this study was to examine the thermal properties of thin protective PC formed from a fluoroplastic-based composite and the possibility of their use for protecting a heat-exchange apparatus from scaling.

Polymeric coatings were deposited on the surface of 08KP steel samples with or without a phosphate layer by auto- and electrophoresis. The phosphating was performed using the standard procedure [4].

A bath for PC deposition was fabricated from polymethyl methacrylate. The deposition was performed at 18–25°C. Prior to deposition of PC, a sample was attached with a special device to a mechanical stirrer and submerged in a polymeric dispersion, with the rotation frequency of the stirrer equal to 60 rpm. Electrodeposition was carried out on an installation com-

prising a rectifier, voltmeter, ammeter, and an electrophoretic bath in the constant-voltage mode (25 V s^{-1}). The heat conductivity was determined by the method of a dynamic calorimeter on an IT-λ-400 installation.

The coating thickness and the volume content of inclusions were determined by measuring and weighing the samples with a micrometric ruler, VLA-200 analytical balance, and MBS-10 microscope. The thickness of the PC was determined at six points of a sample, with six or seven measurements at each point, after which the values obtained were averaged. Using the geometric and weight characteristics of the samples, the volume content *V* of the filler was determined by the formula

$$V = \frac{m_{PC}(V_{PC})^{-1} - \rho_{PC}}{\rho_{inc} - \rho_{fl}}, \quad (2)$$

where m_{PC} is the mass of PC; V_{PC}, volume of PC; and ρ_{inc} and ρ_{fl}, the densities of the dispersed phase and the fluoroplastic, respectively.

The particle size distribution of the polydisperse inclusions was determined by means of a sedimentation analysis [5].

The pH value of the formulation was measured with a pH-340 laboratory pH-meter.

A polymeric coating was obtained from a composite containing as its main component a fluoroplastic of 4D and 4MD brands, introduced into the formulation in the form of an aqueous suspension stabilized with a surfactant.

As fillers served highly heat-conducting copper, bronze, and colloid carbon black (or graphite). For a better compatibility and wettability by the polymeric phase, the fillers were dressed with modifying agents, including heterocyclic compounds from the vinylpyrrolidone group, and hydroxyethylated alkyl phenol.

The dry residue of the initial composition was 55%, viscosity 15 St (by VZ-246), pH 6.5. In the case of the autophoretic method of PC deposition, the pH value of the initial composition was adjusted to 3 with orthophosphoric acid ($\rho = 1.3 \times 10^3$ kg m^{-3}).

The study demonstrated that, in contrast to the previously published dependences obtained in tests of an epoxy compound [1], the heat conductivity coefficient of a fluoroplastic with finely dispersed inclusions varies with the volume content of these additives in accordance with the Bruggeman dependence, rather than by the Odolevskii model. The deviation of the experimental data does not exceed 30% (Fig. 1).

The size distribution of the polydisperse inclusions is shown in Fig. 2. It can be seen that the size of certain inclusions exceeds the PC thickness (which was 2.5 to 20 μm), i.e., there appears a local possibility of heat transfer in accordance with the combined parallel-consecutive model. In this case, it is difficult to describe theoretically the mechanism of heat conduction in the initial stage, and it can be empirically represented as an expression similar to the Bruggeman formula [1]:

$$\lambda_0 = \frac{\lambda_1}{(1 - V)^n}, \quad n = 3. \quad (3)$$

The necessary slope of the curve describing the experimental data can be reached by making larger the exponent *n*. It can be described as a function of the particle size d_p, volume content V_p of particles, and PC layer thickness δ_l:

$$n = \frac{a d_p}{\delta_l V_p}, \quad (4)$$

where *a* is a coefficient that accounts for the material of inclusions: $a = 1/35$ for dispersed copper particles and 1/50 for bronze particles.

Effect of the volume content of inclusions in a formulation on the heat conductivity of coatings obtained by the autophoresis method

The suggested exponent *n* in the Bruggeman formula makes it possible to extend its applicability limits, because it can take a value of 3 for finely dispersed inclusions of certain size. With the exponent used in experimental data processing, more reliable heat conductivity data could be obtained (Fig. 1).

The data calculated using formula (1) are in a good agreement with the experimental values if $\rho_{inc} > \rho_{fl}$. The results of experimental studies are presented in the table and Fig. 3.

It can be seen from Fig. 3 that the heat conductivity of fluoroplastic-based multicomponent formulations decreases as the volume content of inclusions increases. This can be attributed to the fibrous structure of interwoven macromolecules. Introduction of various inclusions into a structure of this kind disrupts the arrangement of fibers and leads to destructuring of the PC layer. A noticeable effect of the destructuring is already observed at a low content of inclusions. For example, this threshold is 10% for copper and 5% for bronze. The difference in the threshold values is due to the fact that copper inclusions have a smaller size of dispersed particles than bronze inclusions. Thus, the larger dispersed particles of the filler in the fluoroplastic, the more pronounced, all other conditions being the same, the destructuring and the stronger their influence on the heat conductivity. As the volume content of inclusions of the same size exceeds a certain value, the heat conductivity starts to grow. This value varies between 30 and 40% for copper and

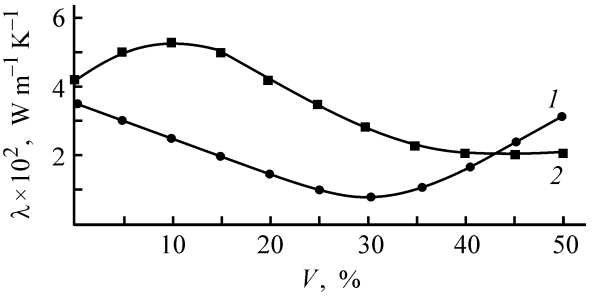

Fig. 3. Heat conductivity λ vs. volume content *V* of inclusions. Formulation: (*1*) with bronze and (*2*) with copper.

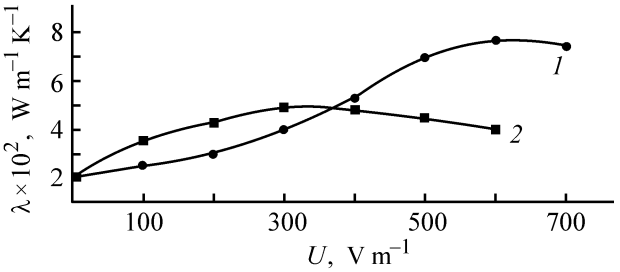

Fig. 4. Heat conductivity λ vs. the electric field strength *U* at a carbon black content of (*1*) 7 and (*2*) 3 wt %.

is 30% for bronze. In this case, copper and bronze inclusions cease to be dispersed and become a continuous phase diluted by the fluoroplastic.

Thus, filling of the fluoroplastic with high-heat-conductivity dispersed inclusions of copper or bronze fails to lead to the expected result and cannot make higher the heat conductivity of PC. In all probability, these inclusions loosen the polymer structure and do not favor formation of stronger polarized bonds between polymer molecules. In this connection, it was suggested to enhance the polarization of molecules in deposition by using electrophoresis and thereby to obtain denser structures having a higher heat conductivity.

The assumption is confirmed by an analysis of coatings deposited by electrophoresis at different electric field strengths. The heat conductivity of PC is 0.1 $W m^{-1} K^{-1}$ in this case.

Under similar conditions, a composite filled with a colloid carbon black (or graphite) was studied at a content of the colloid carbon black (or graphite) in the formulation equal to 3–7 wt %. If the density of inclusions is lower than that of the fluoroplastic (in the case of filling with a carbon black with ρ = 165 $kg m^{-3}$ and λ = 0.07–0.12 $W m^{-1} K^{-1}$), the heat conductivity grows to the value characteristic of the dispersed phase as the content of the filler increases to 7% (Fig. 4). Polymeric coatings deposited by electrophoresis at a varied voltage across the electrodes show a gradual rise in heat conductivity at a low content of inclusions. The curves show a bend at low voltages, which suggests that the voltage across the electrodes affects the amount of filler codeposited with the fluoroplastic. As the voltage decreases, the content of carbon black in the coatings becomes lower. This leads to formation of a looser structure with a low ?conductivity, which gives rise to peaks.

CONCLUSIONS

(1) Raising the electric field strength leads to a more significant increase in the heat conductivity of polymeric coatings than making higher the concentration of the filler, colloid carbon black (graphite).

(2) The heat conductivity increases only until the electric field strength reaches a certain value corresponding to a bath voltage of 70 V. As the field strength is raised further, the heat conductivity decreases to 0.1–0.15 $W m^{-1} K^{-1}$.

(3) The dependence of the coating density on the electric field strength exhibits a similar behavior, i.e., as the field strength increases to 2300 $V m^{-1}$, the density first grows to 80–90 and then decreases by 20%.

(4) The thermal resistance of the polymeric coatings is $(5–8) \times 10^{-4}$ $K m^2 W^{-1}$ and they can be rather effectively used at heat-transfer coefficients of 1200–200 $W m^{-2} K^{-1}$.

(5) Use of the fluoroplastic for obtaining thin protective coatings on heat-exchange surfaces for technical water supply systems can be regarded as promising in the case of deposition of coatings with a controllable thickness of 15–20 μm. As a filler of the fluoroplastic can be used, at the given thickness, finely dispersed particles of size not exceeding 1–2 μm: colloid carbon black or graphite.

Abstract—Toluene solutions of fullerene C_{60} with concentrations of 0.001, 0.01, and 0.2 wt % were studied by small-angle X-ray diffraction analysis. The radii of gyration of scattering elements were determined from the small-angle diffraction patterns plotted in the Guinier coordinates.

Toluene is a solvent widely used for recovering fullerenes from fullerene soot and for studying various fullerene-containing systems. Mass spectrometric data [1] showed that a certain fraction of toluene present in a fullerene C_{60} film is strongly retained when the film is heated in a vacuum to the point of its breakdown upon C_{60} sublimation. Such a behavior of toluene suggests that toluene strongly interacts with fullerene and thus fullerene dissolved in it can strongly change the structure of the solvent itself. In this paper, solutions of fullerene C_{60} in toluene were studied by small-angle X-ray scattering. Previously, similar studies have been performed with fullerenes C_{60} and C_{70} dissolved in *o*-xylene [2, 3]. In these studies, nonuniform areas were found in the entire concentration range examined. From the authors' viewpoint, the number of fullerene molecules in the associate is no more than four. No free single fullerene molecules were observed.

EXPERIMENTAL

The measurements were carried out on a KRM-1 device (Cu_{K_α}, Ni filter) with a slit collimation of the primary X-ray beam; the width of the intensity distribution in the primary beam was 5′ near the profile bottom of the corresponding curve. The scattering range was from 15′ to 2°. The error of the intensity measurements did not exceed ±2 pulse s^{-1} in the entire scattering range studied, i.e., it was as low as 2–4%.

Rectangular cells were prepared from a 7.5–10-μm polymeric film. Empty cells showed no noticeable scattering in the angle range studied. Then, the cells were filled with a sample to be analyzed, sealed, and placed in an evacuated chamber of the diffractometer.

The transmission measurements were carried out at 25–30°C. The cell with a solvent was placed at the center of a goniometer perpendicularly to the primary beam, and diffraction pattern 1 was recorded. Then, the sample was placed before the first slit and the contour of the primary beam after passing through the cell was recorded (diffraction pattern 2), and curve 2 was subtracted from diffraction pattern 1. These resulting difference patterns are given as the experimental curves $I(s)$, where $s = 4\pi\sin(\varphi/2)\lambda$, φ is the scattering angle, and λ is the wavelength of the X-ray radiation. Since the scattering angles are small, we consider that $s = 2\pi\varphi/\lambda$.

It should be noted that the scattering intensity in curves 2 at 15′ angle (scattering start) was similar within the measurement error for both solvent and C_{60} solutions in the entire concentration range; as a result, normalization of the curves to the same intensity of the primary beam was unnecessary. Fullerene C_{60} (99.7%) obtained by the Huffman-Kraetschmer method, was used to prepare solutions of fullerene C_{60} in toluene with the following concentrations: 0 (pure solvent), 0.001, 0.01, 0.1, and 0.2 wt %.

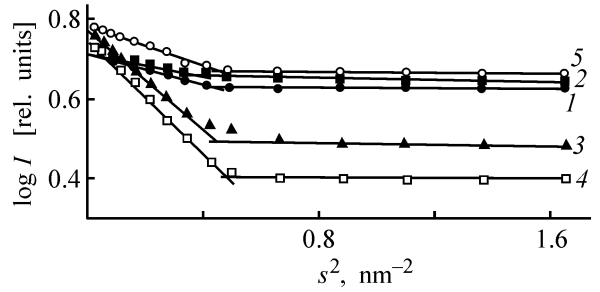

Fig. 3. Small-angle scattering patterns log I–s^2 of fullerene C_{60} solutions in toluene (Cu_{K_α} radiation) in the Guinier coordinates.

The resulting diffraction patterns are shown in Fig. 1. All the curves monotonically descend with increasing scattering angle (range 1) and then asymptotically reach constant I_c (range 2) at scattering angles of about 70′. Flattening-out of the curves is typical of homogeneous liquids and glasses [4], and, in this case, scattering can be accounted for by thermal fluctuations of the density. As temperature becomes lower, I_c decreases.

However, the dependence of I_c on the fullerene C_{60} concentration is rather unusual. At a 0.001% concentration, the shape of the scattering curve is close to that of the pure solvent, but with slightly higher intensities. This fact is probably due to an increase in the density of fluctuations involving fullerene molecules, because the electron density of fullerene molecules is higher than that of the solvent.

Sharp changes are observed at concentrations of 0.01 and 0.1% (Fig. 1, curves *3* and *4*); in this case, nearly the entire scattering curve runs below that of the solvent. These changes in I_c are probably due to the solvent structuring, when the thermal density fluctuations (with dimensions of about 35 Å and smaller, down to 6 Å, typical of short-range order) are suppressed by fullerene.

The wide-angle X-ray diffraction patterns of the solutions under study showed no changes in the amorphous halo (within the measurement error), i.e., the intermolecular spacing remains unchanged. However, the width of the halo slightly decreases, probably owing to an increase in the coherent scattering areas (Fig. 2), which agrees with the assumption that the solvent gets structured. The solvent structuring causes appearance of a negative entropy decrement in dissolution of fullerene in toluene (calorimetry data [5]).

Simultaneously with the decrease in I_c, the curve slope in range 1 increases on passing to small angles. At a concentration of 0.2%, I_c increases, whereas the curve slope at small angles decreases.

Figure 3 shows the same small-angle diffraction patterns plotted in the Guinier coordinates $\log I = f(s^2)$, which enables evaluation of the radius of gyration R_g of the scattering structural elements [6]. The values of I_c and R_g are listed in the table. As can be seen, the concentration dependences of I_c and R_g are opposite. To determine the number of molecules of structured solvent per fullerene molecule, we consider that the whole amount of the solvent is structured when I_c is at a minimum, i.e., at concentration of 0.1%. In this case, there are about 8000 toluene molecules per fullerene molecule.

Let us compare the radii of gyration with the size of C_{60} molecule. This molecule can be well approximated by a spherical shell with inner (R_i) and outer (R_e) radii of 200 and 357 nm, respectively [7]. The radius of gyration for a spherical shell with a uniform density distribution can be represented as

$$R_g = (3/5)^{1/2} R_e [(1 - C^5)/(1 - C^3)]^{1/2}, \qquad (1)$$

where $C = R_i/R_e$.

Thus, on the assumption of an equilibrium distribution of the electron density in a C_{60} molecule, its radius of gyration is 0.30 nm, which is smaller than our experimental results.

As can be seen from published data [8], the concentration dependence of the toluene solution density on the concentration of C_{60} passes through a maximum at a fullerene concentration of 0.05%. This fact indicates a compaction of the solution, probably due to its structuring. However, the electron density of fullerene exceeds that of liquid toluene by almost a factor of 2. As a result, the effect of ordered solvent on the fullerene molecules or aggregates can be neglected in our estimations of smallangle scattering.

Since the calculated and experimental radii of gyration are quite different, the model involving separate molecules C_{60} (even with a solvation shell) should be abandoned.

More adequate is a model based on fullerene aggregates. The size of the corresponding aggregates, calculated for a model sphere with uniform density from the experimental radii of gyration, and the number of C_{60} molecules accommodated in this sphere with hexagonal close packing are listed in the table. As can be seen, the number of fullerene molecules in this sphere is 80–90; in real aggregates, this value will be smaller, because the packing density should be lower than that in crystals.

The reasons for an increase in I_c and R_g at a fullerene concentration of 0.2% are still unknown. Probably, this is due to the approach to the solution saturation (2.15 mg ml^{-1} or 0.24% [9]). It is obvious that the model of supramolecular structure of solutions cannot be developed without additional independent data [2, 3]. We prefer the model of two-dimensional clusters, because the experimental data [9] suggest the fractal structures in fullerene solutions with a dimension close to 2. From our viewpoint, both the formation of fractal clusters and the long-range effect of fullerene on the solution structure probably suppress thermal density fluctuations.

Dimensions of nonuniform areas in the samples studied*

Sample	Range 1			Range 2
	R_g, nm	R_e, nm	$N_{C_{60}}$	$\log I_c$, arb. units
Toluene	–	–	–	0.63
Toluene + C_{60}, %:				
0.001	1.0	1.3	10	0.66
0.01	2.1	2.7	80	0.49
0.1	2.2	2.8	90	0.40
0.2	1.3	1.7	–	0.67

* R_c is the uniform sphere radius, and $N_{C_{60}}$ is the number of C_{60} molecules in this sphere.

** Range 1 corresponds to the small-angle section of the broken line in Fig. 3, and range 2, to the section parallel to the abscissa.

CONCLUSIONS

Solutions of fullerene C_{60} in toluene in the concentration range from 0.001 to 0.2% were studied by small- and wide-angle X-ray diffraction analysis. In all the small-angle diffraction patterns, the intensity decreases to some constant value I_c with increasing scattering angle. As the fullerene concentration becomes higher I_c first slightly increases, then sharply decreases, and finnaly increases again. The sharp decrease in I_c can be attributed to suppression of thermal fluctuations of the solution density. The radii of gyration were determined from the small-angle diffraction patterns plotted in the Guinier coordinates, which suggest that fullerene clusters consisting of 80–90 molecules are formed in the toluene solution.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Electron-Beam-Cured Adhesives Based on Low-Molecular-Weight Carboxylated Butadiene-Nitrile Rubber

Yu. A. Smirnova, I. V. Vasil'eva, and A. A. Persinen

St. Petersburg State Technological Institute, St. Petersburg, Russia

Radiant Technology Center, Limited Liability Company, St. Petersburg, Russia

Abstract—Effects of a series of additives on the initial sticking and autohesion dynamics of electron-beam-cured adhesives for adhesive tapes, based on low-molecular-weight carboxylated butadiene-acrylonitrile rubber, were examined.

Modification of pressure-sensitive adhesives (PSAs) with telechelic butadiene-acrylonitrile rubbers was reported in [1]. It is also known that liquid butadiene-acrylonitrile rubber with terminal carboxy groups is rapidly cured by electron beam at room temperature in air to give a rubber-like material (oligomer MW 1700; carboxy group content 3%).

In this study, we examined the possibility of synthesis of electron beam-cured PSA based on domestic carboxylated low-molecular-weight butadiene-nitrile rubbers SKN-10-1 and SKN-10-KTR [mean MW 1500; functional groups (3%) are arranged in the backbone or as terminal groups; acrylonitrile units are arranged in microblocks, each consisting of several units; butadiene units are connected essentially at the 1,4-positions.

To optimize the formulations, we studied the effects of a series of organic and mineral components on the radiation stability of the investigated formulation, autohesion of electron beam-cured PSAs, and sticking dynamics.

EXPERIMENTAL

The formulations were prepared by mixing the components at room temperature. As a support material we used a tape made of carbon-black-extended PVC. The electron-beam curing of the composites applied onto the PVC tape surface was carried out in air, using an RTE-1V experimental setup [2] (electron energy 500 keV; beam current 1 mA). The target material was passed under the accelerator scan-horn at a speed of 1 m min^{-1}.

The criteria for determination of the absorbed dose optimal for polymer conversion were the lack of a contact pattern of the tested layer on glass and of traces of low-molecular-weight fractions. The absorbed dose was determined by film dosimetry, using standard polycarbonate detectors with a phenazine dye [PD(F)-150/500 dosimetric films]. The optical density of the irradiated detectors was measured on an SF-46 spectrophotometer at 512 nm.

The adhesiveness of the resulting samples was determined according to GOSTs (State Standards) [3, 4]. As a measure of the adhesiveness we used the time in which the sample was separated under a fixed stress. The quality of the materials tested was evaluated by comparison of their adhesiveness with that of similar domestic commercial products meeting the requirements of GOST [5], using the procedure employed in this study (the thus obtained adhesiveness of the commercial products was 8 s).

By electron-beam treatment in air of PVC-supported straight SKN-10-1 elastomer, we obtained a constant-adhesiveness pressure-sensitive adhesive (absorbed dose 400 kGy; autohesion 11 s). On the surface of PSA obtained by electron-beam curing of SKN-10-KTR, we observed, even at an absorbed dose of 600 kGy, a layer of the low-molecular-weight fraction, which can be attributed to exudation of stabilizers. Therefore, the subsequent experiments were performed with SKN-10-1 rubber.

Mineral additives were introduced into low-molecular-weight rubber for the following reasons. It is known that extenders are sensitizers for the overwhelming majority of rubbers. They reduce the mac-

1070-4272/05/7806-1031 © 2005 Pleiades Publishing, Inc.

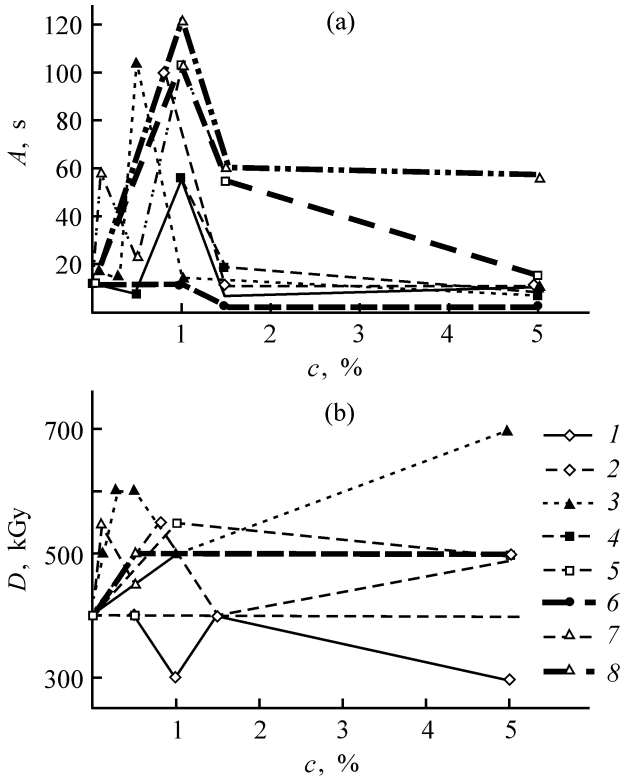

Fig. 1. (*1*) Initial adhesiveness of SKN-10-1-based PSA *A* and absorbed dose *D* vs. the additive concentrations. Additives: (*1*) TMPTA, (*2*) EHA, (*3*) MBT, (*4*) EAS-16, (*5*) EAS-20, (*6*) DEP-331, (*7*) Aerosil, and (*8*) alumina.

roscopic viscosity of the system, promote egress of the chain ends from the globules, and increase the probability of polymer branching [6]. Thus, the maximal initial adhesiveness of PSA was obtained by introducing inorganic additives in an amount of about 1 wt % (Fig. 1a), but, in this case, the absorbed dose increased (Fig. 1b).

Introduction into SKN-10-1 of monomers, such as trimethylolpropane triacrylate (TMPTA) and 2-ethylhexyl acrylate (EHA), was expected to decrease the macroscopic viscosity of the system, to promote egress of the chain ends from the globules, and to increase the probability of polymer branching. Indeed, over the experimental concentration range, the adhesiveness of PSA was at a maximum, and the absorbed dose changed noticeably as compared to that observed for the reference rubber (Fig. 1). The maximal adhesiveness of PSA was observed at a TMPTA concentration of 1 wt %. In this case, the dose required for preparation of a pressure-sensitive layer decreased as compared to the polymer without additive. For EHA, the absorbed dose increased at a concentration of 0.8 wt % corresponding to the maximal adhesiveness.

It is well known that sulfur-containing compounds, various acrylates, and polyfunctional oligoether acrylates demonstrate a high sensitizing power. For example, introduction of mercaptobenzothiazole (MBT) into rubber noticeably affects the parameters investigated (Fig. 1): the absorbed dose increases nonlinearly, and the maximal initial adhesiveness is observed at a concentration of 0.5 wt %. Introduction of epoxy-acrylate resins (EASs) has an effect on the homogeneity of the composite. Because of the low compatibility with the polymer, EAS can be regarded as an interstack plasticizer: the resin is primarily introduced between the coarsest supramolecular structures, breaking them and thus providing more favorable conditions for an adhesion contact. Therefore, we expected a considerable increase in the adhesion strength [9]. Introduction of epoxy-acrylate resins EAS-16 and EAS-20 did not decrease the absorbed dose, and the adhesion strength of PSA showed the maximum at an additive concentration of about 1 wt %. With epoxy-acrylate acrylated to 50% (DEP-331), we observed no noticeable change in the parameters investigated (Fig. 1).

Introduction into the elastomer of polypropylene glycol (PPE) or low-molecular-weight polysiloxanes (SKTN) increases the absorbed dose required for elastomer conversion, except for the formulation with 1 wt % SKTN. Polysiloxane strongly affects the initial adhesiveness of PSA. The optimal combination of performance characteristics was obtained with 1 wt % SKTN: initial adhesiveness 18 s at absorbed dose of 400 kGy. With 1 wt % PPG, the initial adhesiveness of 11 s was obtained at a dose of 500 kGy.

The ability of electron-donor and electron-acceptor additives to sensitize or inhibit the cross-linking suggests that charged species formed under the action of ionizing radiation are involved in the formation of the 3*D* network structure. For thermochemical PSAs, the curve of the adhesion strength passes through a maximum at an additive concentration of 0–2% [6]. Our results show that the radiation-chemical PSAs behave similarly.

The trends in the adhesion strength evolution with time are shown in Fig. 2. Two major features can be distinguished: exponentially decreasing initial maximum and fluctuating initial values. In the first case, the initial adhesiveness of PSA is an order of magnitude higher than that of the additive-free elastomer.

The observed differences in the adhesiveness dynamics can be attributed both to transient processes, such as after-effect upon completion of the formation of the adhesion layer and to conformational and re-

laxation processes prolonged by development of side and secondary reactions (for example, polymer-analogous transformations or cross-linking) and by aging in storage [7, 8].

CONCLUSIONS

(1) It was shown that organic and mineral additives affect the radiation sensitivity of low-molecular-weight carboxylated butadiene-acrylonitrile rubber and also the adhesiveness of pressure-sensitive adhesives prepared on its basis.

(2) The sensitizing effect was initiated by the addition of trimethylolpropane triacrylate (1 wt %).

(3) A high initial adhesiveness of pressure-sensitive adhesives was obtained by adding the additives investigated in an amount of about 1 wt %. However, the effect was short-term, and the initial adhesiveness decreased to below acceptable values in a month. Nevertheless, the results obtained demonstrate the possibility of preparing a pressure-sensitive adhesive on the basis of low-molecular-weight carboxylated butadiene-acrylonitrile rubber.

Abstract—Hydration and dehydration (on calcination) of $SrCl_2$, YOCl, and HoOCl powders were studied.

Single-crystal chloride materials are of interest for photonics owing to their transparence in the IR range and a "soft" photon spectrum. The main problem in both growing the crystals and working with them is their hydration. In particular, chlorides of rare-earth elements are very hygroscopic; hydrated rare-earth chlorides are readily hydrolyzed on heating [1–6]. This substantially complicates the use of such materials, though the spectroscopic characteristics, e.g., of $LaCl_3 : R^{3+}$ single crystals are highly promising [7]. Among matrices resistant to moisture are $PbCl_2$ and KPb_2Cl_5 [8–10].

In this study we examined the hydration of $SrCl_2$ powders and also of oxychlorides of rare-earth elements. Strontium chloride crystallizing in a cubic lattice of the fluorite type has a high isomorphous capacity with respect to chlorides of rare-earth elements [11]. Properties of $SrCl_2$ single crystals and of $Sr_{1-x}R_xCl_{2+x}$ solid solutions have been studied repeatedly [12–14]. Oxychlorides of rare-earth elements are more resistant to moisture than the chlorides [15]. Therefore they could be a convenient form for introducing dopants.

We used ultrapure 7–4 grade $SrCO_3$, chemically pure grade ammonium chloride NH_4Cl, and chemically pure grade hydrates of rare-earth elements $RCl_3 \cdot 6H_2O$ as starting substances. The initial chemicals were characterized by X-ray diffraction. The X-ray phase analysis was carried out on a DRON-2 diffractometer (CuK_α radiation, focusing monochromator from pyrolytic graphite). We recorded variations in sample weights on an Acculab V-200 electron balance. The humidity was measured with a psychrometer. The hydration was carried out at 19 ± 2°C and the relative humidity of 38 ± 5%.

We prepared strontium chloride by the reaction

$$SrCO_3 + 2NH_4Cl = SrCl_2 + H_2O\uparrow + CO_2\uparrow + 2NH_3\uparrow. \quad (1)$$

We used a fourfold excess of NH_4Cl. The reaction was carried out in an alundum crucible at 150–350°C for 6 h. The yield of $SrCl_2$ was 99%. The resulting $SrCl_2$ had a cubic fluorite-type lattice with a = 6.977 Å, which agrees with the published data (PDF card no. 38-0496). On exposure to air, the sample weight continuously increased; the process gradually decelerated with time (Fig. 1). The increase in the substance weight in the first hour was 7%. The increase in the sample weight was accompanied by changes in its X-ray pattern. Along with the $SrCl_2$ lines, an additional set of reflections appeared, and their intensities rapidly increased, whereas the lines of $SrCl_2$ weakened (Fig. 2). Analysis of the pattern using the PDF database revealed mixture of mono-, di-, and hexahydrates of $SrCl_2$. The final hydration product was $SrCl_2 \cdot 6H_2O$. On calcination of strontium chloride hexahydrate at 350°C for 2 h, the weight loss corresponded to complete dehydration. The subsequent

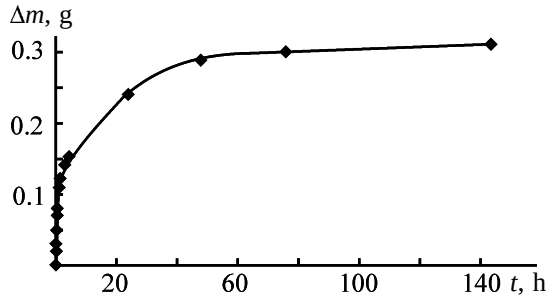

Fig. 1. Kinetics of $SrCl_2$ hydration. (Δm) Change in the weight of the sample and (t) time.

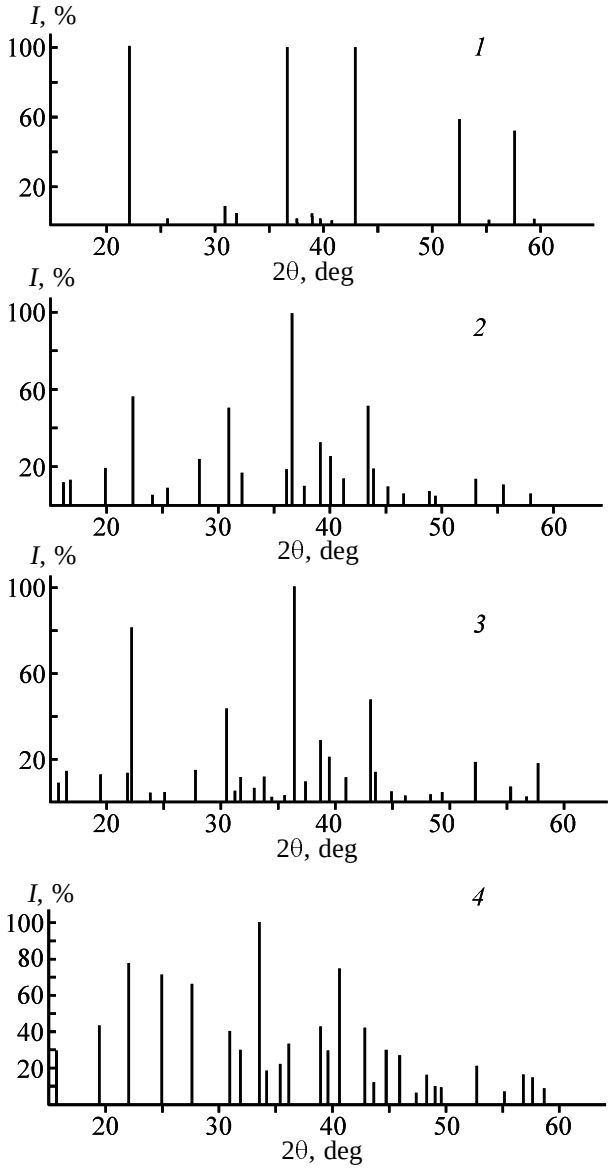

Fig. 2. X-ray patterns of $SrCl_2$ samples depending on the time of exposure to air. (*I*) Intensity and (2θ) Bragg's angle. Time, h: (*1*) 0.5, (*2*) 2, (*3*) 3, and (*4*) 24.

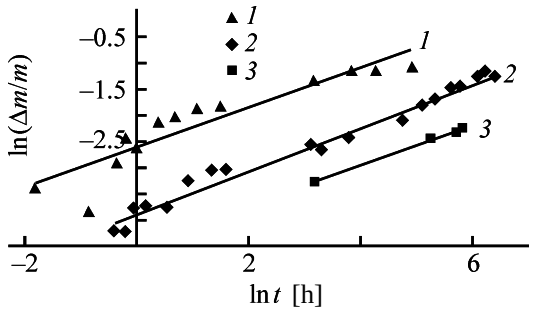

Fig. 3. Hydration of (*1*) $SrCl_2$, (*2*) HoOCl, and (*3*) YOCl samples. (Δ*m*/*m*) Relative weight gain of a sample and (*t*) time.

exposure to air resulted in repeated hydration. However, in this case only the lines of di- and hexahydrates of $SrCl_2$ were observed in the X-ray patterns.

We prepared yttrium and holmium oxychlorides by thermal decomposition of the crystal hydrates by the equation

$$RCl_3 \cdot 6H_2O \rightarrow ROCl + 5H_2O\uparrow + 2HCl\uparrow. \quad (2)$$

The reaction was performed in porcelain crucibles at 350°C for 2 h to obtain YOCl and for 5 h to obtain HoOCl. Tetragonal modifications of oxychlorides were obtained; their X-ray patterns corresponded to the published data (PDF nos. 85-0951 and 85-0897). On exposure of the oxychloride samples to air, their weight increased in a similar manner as with $SrCl_2$, but more slowly. An increase in the weight of YOCl was 0.2%. and that of HoOCl, 2.3% in the first hour of the exposure. No lines of any new phases were observed in the X-ray patterns, but only the intensities of the main peaks of oxychlorides decreased. On calcination, the starting weight of the samples and the X-ray pattern were restored. In the case of incomplete reaction (2), the hydration occurred more actively.

We found that the curves of the weight gain of the substances can be satisfactorily fitted in all cases by equations of the type

$$\Delta m/m = at^n,$$

where m and Δm are the weight of a sample and its gain, respectively (g); t is the time (h) (Fig. 3).

The exponent n in the equation is almost the same ($n = 0.380 \pm 0.015$) for the substances under study.

On the whole, moderate rates of hydration in air and the possibility of reversible removal of water by heating to 350°C indicate that the compounds under study may be promising for obtaining single crystals.

CONCLUSIONS

(1) The final product of hydration of $SrCl_2$ in air is the hexahydrate $SrCl_2 \cdot 6H_2O$. In the initial step of the process, mono- and dihydrates are formed as intermediates.

(2) The absorption of atmospheric moisture by Y(III) and Ho(III) oxychlorides is not accompanied by formation of new phases of hydrated compounds.

(3) Heating the products of $SrCl_2$, YOCl, and HoOCl hydration yields the starting anhydrous compounds.

ACKNOWLEDGMENTS

This study was financially supported in part by EOARD–ISTC (grant no. 2022TO).

The authors are grateful to A.G. Papashvili for submitting samples of hexahydrates of rare-earth elements.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Hydrated Zinc Ammine Diphosphate Isolated from Water–Ammonia Solutions and Its Thermal Properties

V. A. Kopilevich, L. V. Voitenko, and I. D. Zhilyak

National Agricultural University, Kiev, Ukraine

Received November 29, 2004; in final form, April 2005

Abstract—A synthesis of amorphous hydrated zinc ammine diphosphate was described. Thermal properties of this compound were studied and schemes of thermal transformations were suggested.

Compounds of transition metal phosphates obtained from ammonia solutions and containing ammonia coordinated to a metal ion are of interest due to their possible catalytic activity [1, 2]. This especially concerns amorphous phosphate compounds exhibiting a high reactivity owing to their thermodynamic instability [3]. Published data on the synthesis and thermal behavior of zinc ammine diphosphate are extremely scarce [4].

The goal of this study was to prepare hydrated zinc ammine diphosphate and to examine its thermal properties.

EXPERIMENTAL

Hydrated zinc ammine diphosphate was prepared by its salting-out with an organic solvent from an ammonia solution [5]. The starting zinc diphosphate $Zn_2P_2O_7 \cdot 5H_2O$ (41.2% ZnO) synthesized according to [6] in an amount of 6 g was dissolved in 62 ml of a 23% ammonia solution. The resulting solution was poured into tetrahydrofuran (70 ml). The precipitate thus formed was separated from the mother solution and kept at 15–25°C up to complete hardening in air (to constant weight). For zinc ammine diphosphate of the composition $Zn_2P_2O_7 \cdot 3.0NH_3 \cdot 1.5H_2O$ (**I**):

Found, %: ZnO 42.40, P_2O_5 37.11, NH_3 13.20, H_2O 7.20.
Calculated, %: ZnO 42.51, P_2O_5 37.08, NH_3 13.34, H_2O 7.06.

The anionic composition of the compound synthesized was determined by quantitative paper chromatography [7]; relative to total P_2O_5, it is as follows (%): $P_2O_7^{4-}$ 92.40 and PO_4^{3-} 7.60. The starting zinc diphosphate contained 6.00 rel. % of P_2O_5 in the form of PO_4^{3-}.

The content of zinc(II) was determined by EDTA titration [8], that of phosphorus, by gravimetric analysis [9], that of ammonia, by its distillation on a Seren'ev apparatus [10], and the total content of water and ammonia, by the weight loss at 750°C in 2 h. The X-ray diffraction analysis was carried out on a DRON-UM1 diffractometer (CuK_α radiation). A graphite single crystal arranged in the diffracted beam was used as a monochromator. The diffraction patterns were taken by step scanning in the range of angles $2\theta = 4°–80°$. The scanning step was 0.05°, and the exposure time in a point, 3–9 s. The measured diffraction maxima were approximated by a pseudo-Voigt function with selecting the K_{α_1} component. The IR spectra were recorded on a Specord 75-IR spectrophotometer. Samples for the measurements were prepared as 0.2–0.3 wt % KBr pellets.

Transformations of $Zn_2P_2O_7 \cdot 3.0NH_3 \cdot 1.5H_2O$ on heating were studied by thermal analysis with a Q-1500D derivatograph. Samples were heated in air in the range 15–900°C up to termination of the weight loss. Dynamic experiments were carried out using capped cylindrical platinum crucibles; weighed samples of compound **I** were 0.400–0.500 g. Final and all intermediate decomposition products were obtained at a heating rate of 2.5 deg min^{-1}. In quasi-isothermal experiments, 0.500-g samples were placed in a platinum labyrinthine crucible and heated under controlled conditions.

Anionic compositions of the intermediate decomposition products were determined by paper chromatography [7].

An X-ray phase analysis showed that the starting $Zn_2P_2O_7 \cdot 5H_2O$ was crystalline. We found that the zinc ammine diphosphate synthesized on its basis was X-ray amorphous. A reflection maximum for com-

1070-4272/05/7807-1038 © 2005 Pleiades Publishing, Inc.

pound **I** is observed at 2θ = 28°, which can correspond to a proportional distance in the compounds at the subsequent formation of the crystal structure (Fig. 1). The thermolysis products are also X-ray amorphous except for the sample obtained at 900°C, which corresponds to anhydrous $Zn_2P_2O_7$ [11].

A strong broad band corresponding to stretching vibrations of NH and OH groups is observed in the range 3400–3000 cm^{-1} in the IR spectrum of **I**; the absorption bands corresponding to bending vibrations of water and asymmetric bending vibrations of ammonia in ammines are present in the range 1650–1545 cm^{-1}. The absorption in the range 1485–1420 cm^{-1} in the spectrum of **I** is indicative of hydrogen bonding between an ammonia molecule coordinated to a Zn(II) ion and a $P_2O_7^{4-}$ anion, which is accompanied by averaging of the electron density over the entire chain of atoms forming the hydrogen bond [12]. The absorption related to symmetric bending vibrations of coordinated ammonia molecules is observed at about 1260 cm^{-1} [13]. Antisymmetric and symmetric stretching vibrations of the $P_2O_7^{4-}$ group are observed in the range 1120–900 cm^{-1} as strong absorption bands. Weak absorption bands at 720–540 cm^{-1} correspond to vibrations of the P–O–P and O–P–O groups. The bands of stretching vibrations of the Zn–N and Zn–O bonds in **I** are observed in the range 510–465 cm^{-1} [14, 15].

Thus, the IR spectrum suggests that at least a part of coordinated ammonia molecules in **I** participates in the hydrogen bonding with oxygen atoms of water molecules and $P_2O_7^{4-}$ anions.

According to the thermal analysis (Fig. 2), the thermolysis of **I** occurs in a wide temperature range (approximately from 75 to 460°C) and, as follows from the DTA curve, is accompanied by three endothermic effects with minima at 125, 272, and 295°C. At 460°C, a exothermic peak is observed, which is superimposed by an endothermic effect, as demonstrated, in particular, by abrupt weight loss of the sample in the DTG and TG curves.

According to the TG curve, the sample undergoes weight loss in the range 75–460°C. Chemical analysis of the decomposition products of **I** (Fig. 2, curves *3*, *4*) shows that in the range 75–150°C $Zn_2P_2O_7 \cdot 3.0NH_3 \cdot 1.5H_2O$ loses 0.64 mol of H_2O and 0.30 mol of NH_3. According to the chromatographic data (Table 1), the sample taken at 150°C contains 29.5% of P_2O_5 in the form of PO_4^{3-} and 70.5%, in the form of $P_2O_7^{4-}$. The chemical analysis of the thermolysis

products shows that the first step involves mainly removal of water:

$$[Zn_4(NH_3)_6(H_2O)_2(P_2O_7)_2] \cdot H_2O$$

$$\xrightarrow{75\text{–}150^\circ C} 1.3H_2O + 0.6NH_3$$

$$+ Zn_4(NH_3)_{5.4}(H_2O)_{1.7}(P_2O_7)_2.$$

The quantitative chromatography (Table 1) shows that the thermolysis of **I** at temperatures of up to

Table 1. Changes in elemental and chemical compositions of zinc ammine diphosphate during thermolysis in the dynamic mode

T, °C	Composition according to chemical analysis	Distribution of P_2O_5, rel. %			Removed from starting compound, mol	
		PO_4^{3-}	$P_2O_7^{4-}$	$P_3O_{10}^{5-}$	NH_3	H_2O
Starting	$2.0ZnO \cdot P_2O_5 \cdot 3.0NH_3 \cdot 1.50H_2O$	7.6	92.3	–	0	0
150	$2.0ZnO \cdot P_2O_5 \cdot 2.7NH_3 \cdot 0.86H_2O$	29.5	70.5	–	0.30	0.64
230	$2.0ZnO \cdot P_2O_5 \cdot 1.8NH_3 \cdot 0.75H_2O$	44.7	55.3	Traces	1.16	0.75
320	$2.0ZnO \cdot P_2O_5 \cdot 0.9NH_3 \cdot 0.60H_2O$	39.0	56.0	5.0	2.10	0.90
375	$2.0ZnO \cdot P_2O_5 \cdot 0.7NH_3 \cdot 0.18H_2O$	22.8	66.7	10.5	2.34	1.32
900	$2.0ZnO \cdot P_2O_5$	Traces	100	–	3.00	1.50

230°C involves partial (approximately 50%) transformation of diphosphate anions according to the scheme

$$[Zn_4(NH_3)_6(H_2O)_2(P_2O_7)_2] \cdot H_2O$$

$$\xrightarrow{75–230°C} Zn_4(NH_3)_{3.6}(H_2O)_{1.5}(PO_4)_2(P_2O_7)_1.$$

A further increase in temperature in the range 230–375°C results in the condensation of monophosphate and diphosphate ions into tripolyphosphate ions, which is accompanied by the additional removal of 2.34 mol of ammonia and 1.32 mol of water. In this case, according to the chromatographic data, the product of thermolysis at 375°C contains 22.8% of P_2O_5 in the form of PO_4^{3-}, 66.7% in the form of $P_2O_7^{4-}$, and 10.5% in the form of $P_3O_{10}^{5-}$. Such a distribution of P_2O_5 over oligomeric species can be presented by the following scheme of this thermolysis step, taking into account the available data on thermal transformations of hydrated phosphates [16]:

$$Zn_4(NH_3)_{3.6}(H_2O)_{1.5}(PO_4)_2(P_2O_7)_1$$

$$\xrightarrow{230–375°C} 2.2NH_3 + 1.1H_2O$$

$$+ Zn_4(NH_3)_{1.4}(H_2O)_{0.4}(PO_4)_{0.44}(P_2O_7)_{1.28}(P_3O_{10})_{0.33}.$$

At 460°C, a new phase crystallizes from X-ray amorphous thermolysis products. Its structure remains unchanged on further heating up to 900°C. This process is accompanied by a powerful exothermic effect and by simplification of the anionic composition of samples due to a decrease in the content of tri- and monophosphate ions. The X-ray pattern of the final thermolysis product of **I** corresponds, as a whole, to the X-ray pattern of $Zn_2P_2O_7$ [11]. The scheme of this transformation step is as follows:

$$Zn_4(NH_3)_{1.4}(H_2O)_{0.4}(PO_4)_{0.44}(P_2O_7)_{1.28}(P_3O_{10})_{0.33}$$

$$\xrightarrow{460°C} 1.4NH_3 + 0.4H_2O + 2Zn_2P_2O_7.$$

Also, the dehydration of **I** was studied under near-equilibrium conditions, i.e., in the quasi-isothermal heating mode at a partial pressure of water vapor over the sample of about 0.8 atm. The thermolysis in this mode occurs in the temperature range 95–448°C (Fig. 2, curve *2*), and the sequence of the transformations on heating is similar to that in the schemes considered above.

The sequence of water and ammonia removal from the substance, with appreciable differences in temperature ranges of particular thermolysis steps, taking into account the specific features of variation of the composition of phosphate anions in the calcination products, is accounted for by different nature of binding of H_2O and NH_3 molecules in the structure and by their contribution to the formation of the averaged electron density within the chain [Zn–NH_3–H_2O–P_2O_7] [16, 17].

When the temperature is increased to 375°C, the maximum of the strong broad absorption band of ν(NH) vibrations in the IR spectra of the thermolysis products of **I** is shifted from 3450 to 3180 cm^{-1} (Table 2). The IR spectra of the starting compound **I** and its thermolysis products contain absorption bands characteristic of diphosphate ions (520–1195 cm^{-1}). The band ν_{as}(POP) [P_2O_7] (700–730 cm^{-1}) observed in the spectra of all the decomposition products suggests the presence of a nonlinear POP bridge in the diphosphate ion. The ν(OH) and ν(NH) vibrations of ammonia and water molecules are mainfested in the range 2800–3500 cm^{-1} as a very broad band, suggesting formation of strong hydrogen bonds. The spectrum of the product obtained at 900°C corresponds to anhydrous zinc diphosphate $Zn_2P_2O_7$ [11].

CONCLUSION

Solid X-ray amorphous hydrated ammonia zinc diphosphate of the composition $Zn_2P_2O_7 \cdot 3.0NH_3 \cdot 1.5H_2O$ was isolated in the individual form from a water–ammonia solution. Its thermal behavior in the range 20–900°C was studied. It was found that the final thermolysis product is anhydrous crystalline zinc diphosphate and that the process occurs stepwise.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Properties of a Fireproofing Formulation Based on Liquid Glass and Mechanically Activated Aluminum Oxide

Abstract—Moistening of filler particles with binder, curing, and high-temperature synthesis were studied in a liquid-glass formulation based on aluminum oxide. Selected kinetic parameters of these processes were determined. The influence exerted by the phase composition and mechanical activation on the adhesion, yield of the synthesis product, and basic properties of the formulation were analyzed.

Liquid-glass formulations (LGFs)containig mineral fillers and some functional additives creating a combustion-inert atmosphere are used as fireproofing materials [1–3]. The most important properties of LGFs: long working life, good adhesion, and high fireproofing efficiency, are determined by processes that involve the binder and filler, including synthesis of phases in the high-temperature zone at the seat of fire. One of the main ways to affect the properties of an LGF is to change the chemical activity of fillers [4]. However, the expected result may vary between different properties. Raising the activity of a filler improves the fire-proofing efficiency, but, as a result of coagulation, impairs the adhesion and service life of an LGF. Mechanical activation (MA) is commonly used as an effective method for enhancing the reactivity of powdered media, but it virtually has not been studied at all as applied to LGF [5].

The aim of this study was to examine the adhesion properties of a liquid-glass formulation containing mechanically activated Al_2O_3 in stages of moistening and curing. The products formed in its thermal treatment in the range 200–1000°C were determined.

The choice of Al_2O_3 was governed by the strong variation of the chemical activity of this oxide with its phase composition. Alumina of G-00 brand [75 wt % γ-phase and α-phase, GOST (State Standard) 13078], was taken for MA. The powder was activated in a planetary-centrifugal mill with rubberized drums and corundum balls, at a material : balls ratio of 1 : 3 and a rotary acceleration of 18*g*. Alumina of GK brand, containing 100 wt % α-phase (GOST 30559), served as a chemically inert filler; and $Al(OH)_3$ (GOST 11841), as the most active filler passivated by annealing at 500, 700, 900, and 1000°C, which was accompanied by formation of transient Al_2O_3 phases of γ-, χ, æ-, and θ-types [6]. According to the results of an X-ray phase analysis, the phase composition of the annealing products varied as follows: 500°C, aluminum hydroxide and trace amounts of the γ-phase; 700°C, γ-phase and trace amounts of the χ-phase; 900°C, χ-phase and trace amounts of the æ- and θ-phases; and 1000°C, æ- and θ-phases. To eliminate any influence of the dispersity of a filler in LGF, the powder fraction obtained by sedimentation in water was used. According to the results of a granulometric analysis on a Sedigraf 5000 ET instrument, the fraction contained the following types of particles: 3–5 μm, up to 15 wt %; 5–10 μm, up to 73 wt %; and 10–15 μm, the rest.

A sodium liquid glass with a silica ratio of 2.8 and density of 1.34 g cm^{-3} was taken as a binder. The choice of the chemical composition of the binder was governed by the possibility of maximal accumulation of water in the hydration environment of the cation. It has been established that the fraction of crystallization-bound water for Na^+ considerably exceeds that for K^+ [5]. Intensive dehydration in the temperature range 150–450°C must markedly raise the porosity of LGF in the initial stages of a fire, which improves the fireproofing efficiency of a coating.

The formulation based on liquid glass contained 48 vol % binder and 52 vol % filler. The composition was chosen empirically, as providing the highest

adhesion of the formulation to a wood substrate. The requirements to the substrate material were in conformity with GOST 16363 for tests of the fireproofing efficiency of coatings. LGF was modified with a urea additive in an amount of 3.5 wt % (GOST 6691). X-ray diffraction patterns were measured on a DRON 3M diffractometer with Cu*K* radiation, and IR spectra, on a Specord 75-IR instrument in KBr pellets. The adhesion was measured using the method of film detachment from a wood substrate [1].

After a filler is introduced into the LGF, its particles are moistened by the binder. The components come close to within the range of action of intermolecular forces, which markedly enhances the adhesion [7]. In an LGF with Al_2O_3 as a filler, the adhesion increases in the stage of moistening by a factor of 3–5 at a process duration of 6–7 days (Fig. 1). Mechanical activation of Al_2O_3 makes moistening faster and, consequently, enhances the adhesion. The disintegration of a film with $Al(OH)_3$ filler is accounted for by chemical interaction between the components, to give sparingly soluble alkaline aluminosilicates of the composition $Na_4Al_3Si_3O_{12}(OH)$ and $1.08Na_2O \cdot Al_2O_3 \cdot 1.68SiO_2 \cdot 1.8H_2O$ (Fig. 2a). After annealing of $Al(OH)_3$ at 700°C, neither synthesis of the abovemention compounds nor disintegration of the formulation were observed. Further increase in the annealing temperature impaired the adhesion.

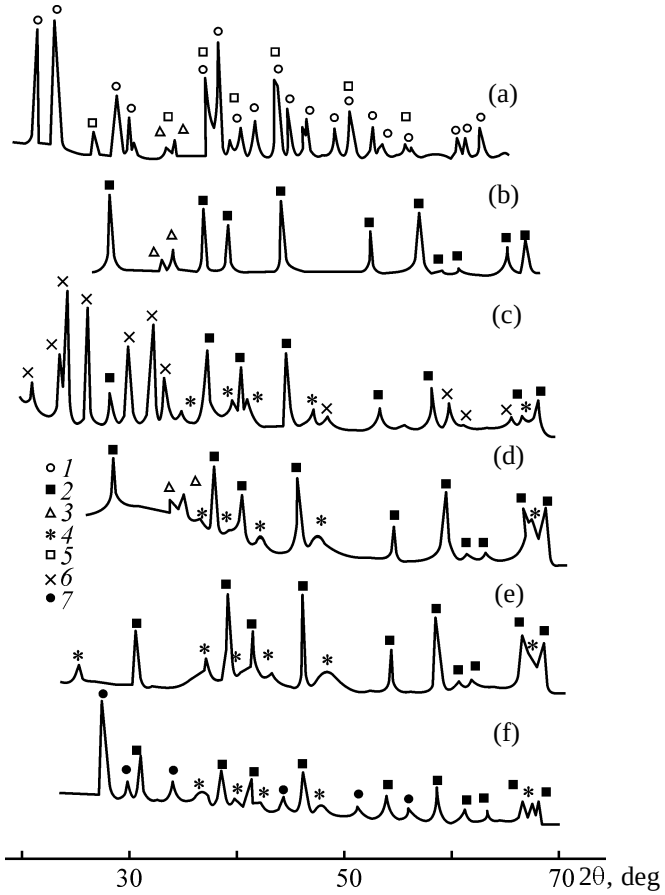

Fig. 2. X-ray diffraction patterns of samples of fireproofing formulations. (2θ) Bragg angle. Phase composition: (a) LGF + $Al(OH)_3$, (b) LGF + α-Al_2O_3, (c) LGF + G-00 (annealing at 1000°C), (d) LGF + G-00, (e) nonactivated G-00, and (f) LGF + G-00 (MA in air) + urea. (*1*) $Al(OH)_3$, (*2*) α-Al_2O_3, (*3*) $Na_2SiO_3 \cdot xH_2O$, (*4*) γ-Al_2O_3, (*5*) $Na_4Al_3 \cdot Si_3O_{12}(OH)$ or $1.08Na_2O \cdot Al_2O_3 \cdot 1.68SiO_2 \cdot 1.8H_2O$, (*6*) $Na_2O \cdot Al_2O_3 \cdot 2SiO_2$, and (*7*) $(NH_2)_2CO$.

In the X-ray diffraction patterns of LGF with G-00 alumina, the intensity of a γ-phase-related reflection from the plane with d = 0.456 nm and I_{rel} = 12% decreases to the background level (Fig. 2d). The same reflection is absent in powdered G-00 alumina mechanically activated in water or in air. For planes of the short-range order of the crystal structure, the decrease in the intensity of the diffraction profile is mostly due to appearance of static displacements [8]. These displacements arise under the action of external factors and are temperature-independent. The magnitude of the displacements was 0.03 nm under the given conditions of X-ray pattern recording, at a decrease in the profile intensity at the point of maximum by 5–7% to the background level.

The appearance of static displacements in a plane poorly populated by atoms with relatively weak intra-

crystalline bonds indicates that formation of chemisorption bonds is possible. In this case, the interatomic distance between the species involved must decrease, which is manifested experimentally in a decrease in the intensity of reflections in the X-ray diffraction pattern. With account of the occurrence of chemical reactions between the binder and Al^{3+} contained in $Al(OH)_3$, oxygen ions O^{2-} from siloxane links may form the chemisorption bond on the binder side, and Al^{3+} cations from γ-Al_2O_3, on the side of alumina particles. The phase composition of LGF with GK alumina corresponds to that of the starting components (Fig. 2b), which characterizes corundum as an inert filler interacting with the silicate binder by the mechanism of physical adsorption [7].

The observed increase in adhesion in the stage of moistening was used to study the process kinetics. The temperatures of isothermal keeping were 9, 22, and 40°C. Further lowering of the temperature terminated moistening because of a considerable increase in the viscosity of LGF, whereas heating to higher temperatures stopped the process because of the rapidly increasing loss of water. The maximum duration of keeping of the formulation corresponded to the actual length of the moistening period equal to 7 days, and that of coating curing in adhesion measurements, to 6 h. The apparent activation energy of the process was calculated using the Arrhenius equation. The rate constant was determined by differentiating the approximating equation with respect to time. The best fit was obtained for a power equation of the form $P = c\tau^n$, where P is the adhesion of a film; τ, moistening duration; and c and n, constants. The apparent activation energies E_m of moistening are listed in the table.

According to the data obtained, E_m decreases for an LGF containing a mechanically activated powder and reaches a minimum in the case of activation in air. As indicated above, a possible reason for the decrease in E_m is the static displacement of atoms in the plane with d = 0.456 nm of the γ-phase of Al_2O_3 in the course of MA. In the case of a nonactivated powder, such a displacement occurs in LGF after mixing of the powder with a binder. The lower E_m in formulations with a mechanically activated filler makes it possible to perform moistening at a lower temperature, which makes less stringent the requirements to the temperature conditions of LGF deposition onto a surface.

Urea has been conventionally used as a modifier of the properties of liquid glass [4]. Its introduction into a formulation in an amount of up to 3.5 wt % raised the adhesion by 18–20% and accelerated curing of LGF at a lowered temperature. The effectiveness of the additive increased in formulations based on a mechanically activated filler (Fig. 1). No effect of urea on the duration of the moistening process was observed. In the course of curing, urea crystallized into its own phase. X-ray diffraction patterns of LGF contained additive-related reflections from planes with d 0.4, 0.362, 0.305, 0.283, 0.253, 0.242, 0.223, 0.199, 0.187, and 0.167 nm. In formulations with mechanically activated fillers, the intensity of reflections increased to 30%, especially for a powder activated in air.

Apparent activation energies of moistening (E_m) and curing (E_c)

Composition	E_m, kJ mol^{-1}	E_c, kJ mol^{-1}, for indicated formulation	
		with urea	without urea
LGF with G-00 alumina:			
MA in water	35	32	63
MA in air	25	38	72
nonactivated	45	72	73
Liquid glass		67	65

The sorption of urea molecules on the surface of filler particles and the influence exerted on this process by mechanical activation of Al_2O_3 are confirmed by the IR data (Fig. 3). The most abundant in the spectrum are various kinds of vibrations of NH_2 and CN groups of urea [9]. The absorption by the oxide is observed at 1057 cm^{-1}. The absorption band of the carbonyl group CO is superimposed on NH_2 bending

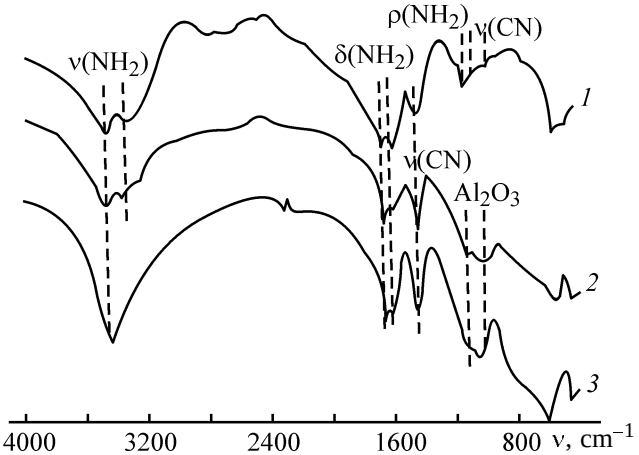

Fig. 3. IR spectra of fireproofing formulations. (ν) Wave number. (*1*) Urea, (*2*) LGF + G-00 (MA in water) + urea, and (*3*) LGF + G-00 (MA in air) + urea.

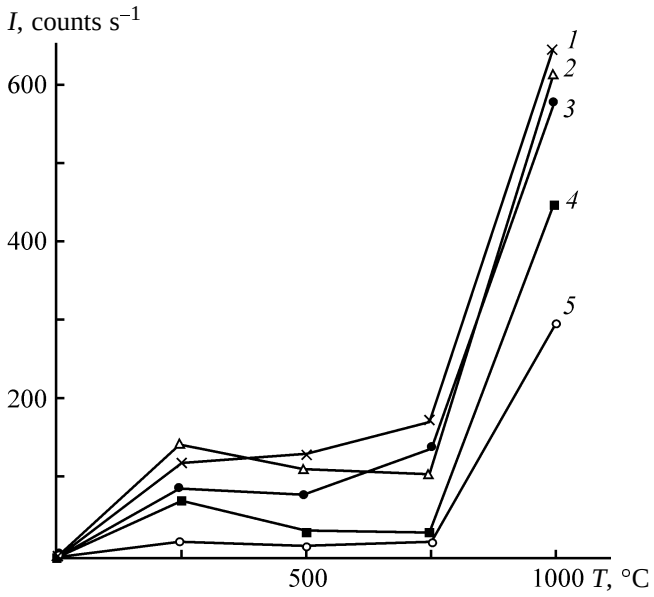

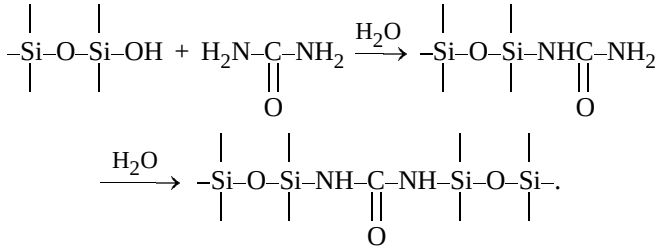

Fig. 4. Synthesis of nepheline from LGF. (*T*) Temperature and (*I*) absolute intensity. (*1*) G-00 (MA in air for 120 min, with subsequent disaggregation), (*2*) G-00 (MA in water for 30 min), (*3*) G-00 (MA in air for 30 min), (*4*) nonactivated G-00, and (*5*) G-00 (MA in air for 120 min).

(δ) vibrations. In contrast to that of pure urea, the spectrum of the formulation contains no stretching (ν) vibrations of the CN group or second overtones of NH_2 ν-vibrations. With a filler activated in air, the symmetric band of the NH_2 ν-vibrations becomes extinct. A similar behavior has been observed upon an increase in the coordination number of nitrogen atoms from 3 for the NH_3 molecule to 4 for the NH_4^+ cation [10]. An additional chemisorption bond between N^{3-} of the amide group and Al^{3+} cations of the γ-Al_2O_3 phase of alumina, disordered in the plane with d = 0.456 nm, may appear in an LGF with urea. The formation of this new bond can account for sorption of urea molecules at the interface between the solution and filler particles. This makes larger the fraction of the crystalline phase in curing and thereby leads to an increase in the experimentally observed intensity of reflections in the diffraction profile.

The kinetics of LGF curing after the moistening stage was studied in the isothermal mode. For this purpose, freshly prepared formulations were kept at 25°C for 7 days. The curing duration of the films was 0.5 to 6 h at 9, 22, and 40°C. The apparent activation energies E_c found for formulations without a urea additive are virtually the same and independent of the formulation composition and MA conditions (see table). E_c decreased by a factor of more than 2 upon introduction of urea into an LGF with an activated powder. The additive had no effect on E_c if other fillers were used.

In an LGF with an activated filler, the sorption activity of the amide group NH_2 of urea may increase via formation of a chemisorption bond. A local increase in the concentration of polymeric anions of the binder in the surface region may result in that the solubility limit will be exceeded and a precipitate will be formed. The weakening of the N–H bond in N^{3-} chemisorbed on the surface of Al_2O_3 particles makes probable the involvement of the urea additive in the reaction

Further, particles of this kind serve as growth centers of the solid phase.

Phase transformations that occur in high-temperature annealing of LGF are illustrated in Fig. 4. Heating to 200°C leads to appearance of the nepheline phase ($Na_2O \cdot Al_2O_3 \cdot 2SiO_2$). Reflections from the $Na_2SiO_3 \cdot xH_2O$ phase become extinct at the same temperature because of the transition to a readily fusible glassy state and dehydration. An increase in the rate of nepheline synthesis is observed at about 800°C. The yield of nepheline is primarily affected by the surface area of filler particles, which is characteristic of processes occurring at a phase boundary. The amount of the product synthesized decreases dramatically as the phase boundary area becomes smaller through aggregation of particles upon activation of the powder in air for 120 min. After disaggregation of the same powder (mechanical activation in an aqueous solution of liquid glass), the yield of $Na_2O \cdot Al_2O_3 \cdot 2SiO_2$ increases. The involvement of the γ- and α-phases of mechanically activated Al_2O_3 in synthesis is not the same. γ-Al_2O_3 is consumed from G-00 alumina to a greater extent. The consumption of the oxide phases in an LGF with a nonactivated filler is virtually the same.

Nepheline has a melting point of 1526°C. It forms with aluminum oxide, which is present in the formulations under study in a large excess, a eutectic that contains 7 wt % Al_2O_3 and melts at 1475 ± 10°C [11]. It would be expected that the material compares well in its fireproofing properties with the conventional refractories of mullite composition.

The formation of nepheline must lead to an increase in the heterodiffusion porosity of the coating. The volume of its unit cell exceeds that of γ-Al_2O_3 by a factor of 2. In the case of liquid-phase sintering of LGF at high temperatures, this hinders the rise in heat conductivity and provides a high fireproofing efficiency. Use of mechanically activated Al_2O_3 will improve the fireproofing efficiency of the coating, because it makes synthesis of nepheline faster.

CONCLUSIONS

(1) The processes occurring in liquid-glass formulations at the interface between the binder and filler are governed by the chemical activity of the filler. In a formulation with $Al(OH)_3$, there occurs a chemical interaction to give sparingly soluble alkaline silicates. The moistening of α-Al_2O_3 particles, which are chemically inert in liquid glass, occurs under the conditions of physical adsorption, whereas that of γ-Al_2O_3 particles yields a chemisorption bond that involves Al^{3+} and siloxane links.

(2) Mechanical activation of Al_2O_3 makes lower the apparent activation energy of particle moistening. Urea introduced into the composition is sorbed on the Al_2O_3 surface. In a formulation with a mechanically activated γ-Al_2O_3, a chemisorption bond is formed between Al^{3+} and N^{3-} of the amide group and the activation energy of curing decreases.

(3) The nepheline phase is synthesized at high temperatures. This phase forms, in a mixture with Al_2O_3, a high-temperature eutectic (mp 1475 ± 10°C). The synthesis occurs at the interface between the binder and filler. It becomes faster when mechanically activated Al_2O_3 is used.

(4) Use of mechanically activated Al_2O_3 makes it possible to perform a fireproofing treatment at lowered temperature and improves the adhesion and the fireproofing efficiency of a coating.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Reaction of Corundum with a Molten Mixture of Potassium and Sodium Tetrafluoroborates

O. G. Zarubitskii and B. F. Dmitruk

Vernadsky Institute of General and Inorganic Chemistry, National Academy of Sciences of the Ukraine, Kiev, Ukraine

Received December 22, 2004; in final form, April 2005

Abstract—Dissolution of synthetic corundum in KBF_4–$NaBF_4$ melts was studied as influenced by the composition of the salt mixture and temperature. The optimal parameters of the process for removal of synthetic corundum rods from internal channels of castings were determined.

A severe difficulty encountered in fabrication of gas-turbine engines is removal of ceramic rods composed of the chemically inert aluminum oxide from internal cavities in blades, which are important elements of these devices [1].

At present, industry uses for this purpose the method of dissolution of these rods in molten KHF_2 [2], which has a number of disadvantages: The process is performed at a temperature at which KHF_2 rapidly decomposes, the melt aggressively acts upon the alloy of castings, the quality of cleaning of channels in precision castings does not conform to the requirements imposed, and the expenditure of KHF_2 is too high (0.5–0.7 kg for removal of a rod with a mass of 12–15 g).

EXPERIMENTAL

Molten alkali metal tetrafluoroborates (MBF_4) were used in the process under consideration. It was found in experiments on removal of ceramic rods from internal cavities in turbine blades that the rod dissolution rate in this method is comparable with that in the existing technique [2]. Therefore, it was necessary to find an additive to KBF_4 that would raise the etching rate of the ceramic by a factor of no less than 2–3. In addition, the advantageous effect of the additive might consist in that it would raise the flowability of the molten mixture and make higher the limiting solubility of aluminum oxide, i.e., improve the reactivity of the fluoroborate melt or diminish the specific expenditure of salts for blade cleaning and simplify removal of the residue of the fluoroborate fusion cake by washing from the internal cavities in castings.

The experiments were performed using the procedure described in [3, 4]. The reactivity of the melts was studied on planar rectangular samples of a virtually pore-free synthetic corundum. After being treated in the melts, the samples were washed to remove reaction products by prolonged boiling in distilled water with a short-time intermediate treatment with a 10% HCl solution. The samples were dried to complete removal of moisture and then weighed. The change in the sample mass was used to calculate the specific reaction rate. The dissolution experiments were carried out using corundum rods taken from internal cavities in turbine blades quantity-produced at an aviation plant. The porosity of the rods was 15–18% at a grain size of 10–14 μm. KBF_4 and $NaBF_4$ of chemically pure grade were used. Thermogravimetric, X-ray phase, chemical, and microscopic analyses were made.

As possible additives for improving the removal of rods in a melt based on KHF_2 were tested KF and NaF, KCl, KNO_3, KHF_2, CaF_2 and BaF_2, and Na_2SiF_6 and NaB_4O_7. The experiments were performed at 600–700°C.

It was found that the most promising among the compositions studied, as regards their reactivity and other properties, are molten mixtures of KBF_4 and $NaBF_4$. For example, the dissolution time τ (h) of a synthetic corundum ceramics (rod) from a blade in KBF_4–$NaBF_4$ mixtures with a 1 : 1 mass ratio of the components is approximately three times that in pure molten KBF_4 (Table 1). It was found that the dissolution rate of synthetic corundum in KBF_4–$NaBF_4$ mixtures increases with the $NaBF_4$ content up to 65 wt %, and then falls abruptly (see figure). Other

1070-4272/05/7807-1048 © 2005 Pleiades Publishing, Inc.

advantages of the KBF_4–$NaBF_4$ melt were also revealed: It has an enhanced reactivity, i.e., provides dissolution of greater amounts of the ceramics, compared to the case when individual salts KBF_4 and $NaBF_4$ are used; after dissolution of a certain amount of Al_2O_3 (about 1%), the melt is covered with a crust which hinders volatility of the salts; and the viscosity of the mixtures is lower than those of individual KBF_4 and $NaBF_4$.

Attempts were made to find why the rate of reaction between aluminum oxide and molten KBF_4–$NaBF_4$ mixtures at a given temperature shows an abnormal dependence on the mixture composition (see figure). The peculiar shape of the dependence at $NaBF_4$ content below and above 65 wt % is due to the change of the reaction mechanism in the system. Below this $NaBF_4$ content, the process rate is limited by the chemical stage, with the main reaction product, potassium–sodium cryolite K_2NaAlF_6, being liquid at the temperature of the experiments. As the $NaBF_4$ content of the melt increases further, the process rate falls dramatically because of the formation on the Al_2O_3 surface of a layer (film) of a solid product, which is mostly a sparingly soluble glassy phase $MOBF_2$. It should be noted that reactions with Al_2O_3 in individual melts of KBF_4 and $NaBF_4$ proceed via different intermediates. Potassium tetrafluoroaluminate $KAlF_4$, which is in the liquid state at the temperature of the experiment (mp 574°C), is formed in a KBF_4–Al_2O_3 mixture, and a solid chiolite $Na_5Al_3F_{14}$ (mp 737°C), in a $NaBF_4$–Al_2O_3 mixture.

The following problems were solved in order to optimize the technology: the optimal process temperature was chosen; the duration of rod removal as a function of the amount of the ceramics introduced into the tetrafluoroborate melt and its limiting reactivity were determined; an efficient procedure was developed for washing of castings to remove the residue of the tetrafluoroborate fusion cake; the corrosion of the material of the castings was studied and its nature was determined; and the composition of the crust formed on the surface of the working melt was found by X-ray phase analysis.

The corrosion of samples of a heat-resistant alloy ZhS32 (material of castings) in the KBF_4–$NaBF_4$ melt of an equimass composition was determined at 600–750°C. It was found that the corrosion rate of the alloy, which is insignificant at 600–700°C, increases dramatically at 750°C. A microscopic study of the metal surface demonstrated that the corrosion is mostly uniform. Thickening of the melt with aluminum oxide leads to a considerable decrease in the corrosion rate. In particular, it decreases twofold at 700°C upon dissolution of 5 wt % Al_2O_3 in the KBF_4–$NaBF_4$ melt.

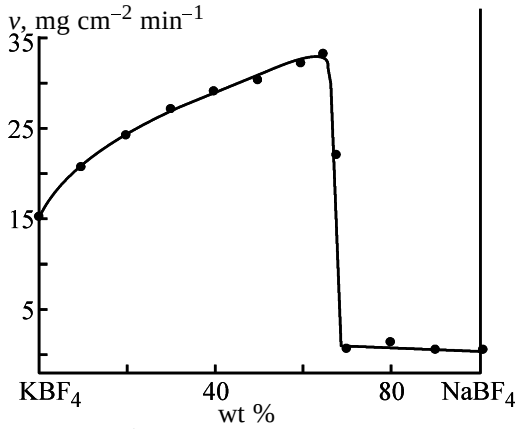

Table 1. Cleaning of castings of gas-turbine engines to remove the synthetic corundum ceramics in KBF_4 and KBF_4–$NaBF_4$ melts

Melt composition, wt %		*T*, °C	τ, h
KBF_4	$NaBF_4$		
100	–	600	4.0

50	50	600	1.4
80	20	650	1.5
35	65	650	0.8
50	50	650	1.0
50	50	680	0.8

The optimal temperature of rod removal in the KBF_4–$NaBF_4$ melt was chosen taking into account the corrosion behavior of the material of the castings and the intensity of rod dissolution. The rate of rod removal was determined on castings produced by oriented crystallization (rod length 86 mm). Below is given the duration of rod dissolution as influenced by temperature. In each experiment, 650 g of a freshly prepared molten KBF_4–$NaBF_4$ mixture was used; the rod mass was about 15 g. Thus, thickening of the melt with the ceramics was about 2% by the end of the experiment:

T, °C	600±5	630±5	655±5	695±5
τ, min	≥150	90±10	60±5	50±5

It follows from the data obtained that the temperature of 600–630°C cannot be recommended for use

Etching rate *v* of aluminum oxide in molten KBF_4–$NaBF_4$ mixtures at 650°C.

Table 2. Melting points and crystallization temperatures of KBF_4–$NaBF_4$ salt mixtures

Mixture composition, wt %		mp, °C	Crystallization onset temperature, °C

10	90	372	340
–	100	406	–

in the process because of the insufficient intensity of rod etching. In the course of casting treatment, the melt is continuously thickened by dissolution products and its reactivity decreases. Consequently, the working temperature should not be lower than 650°C. The upper limit to the working temperature was chosen taking into account the fact that, above 700°C, the volatility of the melt and its corrosivity toward the material of the castings substantially increase.

To choose the optimal composition and working mode of the fluoroborate melt, it is important to know the melting point and crystallization temperature of KBF_4–$NaBF_4$ mixtures. The parameters of the phase diagram of the KF–NaF–BF_3 system were reported in [5]. With account of the specific features of the behavior of fluoroborates (e.g., their decomposition can change the initial composition) and the conditions of the process being developed, the fusibility diagram of the system KBF_4–$NaBF_4$ was studied again by integrated thermal and X-ray phase analyses. The data obtained somewhat differ from those reported in [2]. Table 2 lists only the liquidus and solidus temperatures for a number of compositions. The temperature corresponding to the endothermic minimum in the DTA curve was taken as the melting point in heating the mixture, and that corresponding to the onset of the exothermic effect of crystallization, as the crystallization temperature in cooling the sample. It was found that the melting point of the KBF_4–$NaBF_4$ mixtures recommended as the optical composition is 400–410°C.

The reactivity of the KBF_4–$NaBF_4$ melt is largely determined by the composition of the interaction products and their solubility in a borofluoride mixture. It was found by X-ray phase analysis that mostly mixed cryolite is formed under the process conditions:

$$4KBF_4 + 2NaBF_4 + Al_2O_3 = 2K_2NaAlF_6 + 3BF_3 + (BOF)_3.$$

Simultaneously occur some other reactions to give potassium and sodium cryolites K_3AlF_6 and Na_3AlF_6, oxofluoroborates $NaBOF_2$ and $KBOF_2$, and sodium chiolite $Na_5Al_3F_{14}$. It is noteworthy that the solubility of cryolites in the KBF_4–$NaBF_4$ mixture markedly exceeds that in KBF_4, with the reactivity of the melt being, accordingly, higher, too.

The intensity of rod removal in the working melt depends on both the temperature and the thickening of the melt by interaction products. It was established that the rate of rod dissolution markedly decreases until approximately 3 wt % Al_2O_3 is accumulated in the melt at 650°C, and until 4–5 wt % Al_2O_3 is accumulated at 700°C. These values are apparently close to the solubility of Al_2O_3 in the form of the above-mentioned compounds. When these limits are reached, the rate of Al_2O_3 dissolution virtually stabilizes. The duration of rod removal strongly depends on the mass ratio between the molten KBF_4–$NaBF_4$ mixture and Al_2O_3, as well as on the amount of a ceramics introduced into the melt. Table 3 lists the results obtained in an experiment in which the minimum expenditure of the KBF_4–$NaBF_4$ melt is reached at a virtually

Table 3. Dissolution of a corundum rod in a KBF_4–$NaBF_4$ melt at 650°C

Casting mass, g		Mass of removed ceramics, g	Thickening of melt by ceramics, wt %	Rod removal
before experiment	after experiment			
253.7	240.4	13.3	1.9	Complete
254.5	241.2	13.3	3.8	Residue present
251.5	237.2	14.3	5.8	Complete
251.4	237.3	14.1	7.9	〃
257.5	242.5	15.0	10.0	〃

constant treatment duration of 1 h. Initial mass of the melt 700 g, treatment temperature 650°C.

In this experiment, the expenditure of the melt per blade was 140 g. Then, 15 more blades were processed and it was found that the minimum expenditure of the melt for cleaning of one casting (with a rod of mass 14 ± 1 g) is 115 g.

The most important among the secondary procedures of the process is their washing to remove the residue of the tetrafluoroborate melt. The difficulties encountered in washing are mostly due to the low solubility of KBF_4 and products formed in interaction between the ceramics and the melt (cryolites etc.). KBF_4 and $NaBF_4$ strongly differ in the solubility in water. For example, the solubilities of these salts in 100 g of water at different temperatures are as follows (g):

T, °C	20	25	30	40	100
KBF_4	0.45	0.55	0.98	1.4	6.3
$NaBF_4$	–	107.4	–	–	210.0

Consequently, the solubility of the KBF_4–$NaBF_4$ mixture in water is sufficiently high owing to the dissolution of $NaBF_4$. As shown by the experiments, the residue of the fusion cake of the fluoroborate mixture can be completely removed both from the surface and from the internal channels of the casting by washing with warm flowing water and by boiling in distilled water. If, however, the amount of the ceramics dissolved in the melt is considerable, cleaning to remove the fusion cake of KBF_4–$NaBF_4$ is hindered: in some cases, high-quality washing cannot be achieved even on repeating the procedures many times.

In view of the fact that the given procedure, which uses only water, is not efficient enough, other methods for removing the reaction products from internal cavities in a casting were sought for. As a dissolving medium were used acid and alkaline solutions (of sulfuric and oxalic acids) and low-melting substances (KOH–NaOH, KHF_2, NH_4KF_2, KOH, NaOH). It was found that complete removal of the residue of the fusion cake from the channels of castings is only guaranteed in melts of potassium hydroxide or hydrofluoride.

The reaction of tetrafluoroborate with an alkali is strongly exothermic, and, therefore, it is recommended to process castings at a temperature only slightly exceeding the melting point of KOH (400–450°C) in the course of 10–15 min. After the rods are removed in the KBF_4–$NaBF_4$ melt, the castings are cooled to the crystallization temperature of the tetrafluoroborate melt in order to preclude any interaction between the liquid melt of the salts and the alkali.

CONCLUSIONS

(1) The rate of the reaction between molten KBF_4–$NaBF_4$ mixtures and corundum at 600–700°C grows as the content of $NaBF_4$ in the melt increases to 65 wt %, and then strongly decreases at still higher concentrations of this salt.

(2) A method for removing synthetic corundum rods from internal channels of high-precision castings in melts was developed. The method includes treatment in a molten mixture of KBF_4 (50–55 wt %) and $NaBF_4$ (45–50 wt %) at 650–700°C for 1–2 h as the main process, as well as some additional procedures.

(3) The advantages of the new process are as follows: the intensity of rod removal increases by a factor of 2–3, the expenditure of the melt for removal of a rod is three times lower, the molten mixture of tetrafluoroborates is less corrosive toward the material of castings, and the contamination of the atmosphere and environment by noxious waste is diminished.

Abstract—Integral molar excess Gibbs energy, enthalpy of mixing of liquid alloys of the ternary system iron–copper–cobalt, and component activities at 1600°C were calculated by various methods from data on boundary binary systems.

Previously, thermodynamic properties of liquid alloys in the ternary systems nickel–copper–iron, nickel–copper–cobalt, and iron–nickel–cobalt were calculated from the available data on boundary binary systems [1–4]. Various geometric models and analytical Redlich–Kister polynomials were used in calculation. The fact that the results of calculation by six to eight geometric models, differing in the description of the surface of a thermodynamic property, and those obtained in calculation by geometric models and polynomials are in good agreement shows that the calculation methods are suitable for describing rather reliably the dependence of thermodynamic functions on the composition in the above systems.

Unfortunately, experimental data on liquid ternary alloys formed by copper and iron-group metals are virtually lacking. For a large number of more fusible systems and for the extensively studied ternary metallic systems, a possibility of describing thermodynamic properties by a particular model was repeatedly demonstrated by comparison of experimental and calculated values.

The thermodynamic properties of liquid alloys in the system Fe–Cu were repeatedly studied by various methods. The results presented in [5–7] were used in the calculations. In the Fe–Cu system at 1600°C, the isotherms of the component activities exhibit considerable positive deviation from the ideal behavior; the integral excess molar Gibbs energy ΔG^{exc} and the enthalpy of mixing ΔH are positive over the entire composition range. The thermodynamic functions of liquid alloys in the Fe–Cu system are close [8–11].

The thermodynamic properties of liquid alloys in the Cu–Co system, unlike those in the Fe–Cu system, have been examined in a few studies. A more detailed study was performed by Taskinen [12] who used the emf method with a $ZrO_2 + MgO$ solid oxygen-conducting electrolyte in the temperature range 1097–1457°C for compositions within $0.03 \le x_{Co} \le 0.70$ (x_{Co} is the mole fraction of cobalt in the alloy). The liquidus line in the same region of the compositions was determined in [12]. Previously, Timberg *et al.* [13] used the mass-spectrometric method to study the thermodynamic properties of liquid alloys formed by copper and cobalt ($0.060 \le x_{Co} \le 0.949$, 1422–1597°C). The component activities were calculated from data on their ion currents at 1550°C. Also, liquid alloys in the Cu–Co system were studied by the

calorimetric method [7, 14]. The system exhibits positive deviation from the ideal behavior. The results of the main studies of the system [12, 13] are in good agreement.

The thermodynamic properties of liquid alloys of the Co–Fe systems reported until 1980 are analyzed in [6]. Relatively complete set of the thermodynamic data devoted to this subject is presented in [15]. The isotherms of component activity in liquid alloys of the Co–Fe system show small deviation from the ideality, but the character of this deviation is controversial. Results of [16, 17] are the most reliable from the viewpoint of the research methods.

Table 1 presents the integral excess molar Gibbs energies and enthalpies of mixing of liquid binary systems used for calculating the corresponding integral characteristics of the ternary system Fe–Cu–Co. The calculation is based on the geometric models, which are described in detail in [18] and were used in our previous studies [1–4]. The four geometric models known as the Toop's (I), Kohler's (II), Muggiani's (III), and Colinet's (IV) models were used. The geometric schemes of the calculation are presented in Fig. 1 and the algorithms corresponding to them are reported in [1]. The ΔG^{exc} values in the ternary system calculated from the above models are in reasonable agreement (Table 2). This is largely due to the fact that the deviation from ideality in all the three boundary systems is similar, i.e., $\Delta G^{exc} > 0$. Because the ΔH values in the boundary binary system Co–Fe are negative, the surface of the enthalpy of mixing in the ternary system has the more complex shape. This is especially revealed in estimation of ΔH of the ternary system at low concentrations of copper (Table 3).

As noted previously [1, 5, 18], ΔG^{exc} and ΔH of the ternary systems can be calculated from the Redlich–Kister polynomials. For binary systems, the dependences of ΔG^{exc} and ΔH on the composition can be expressed in the following polynomial form:

$$\Delta G^{exc} = x_1(1 - x_1)[b + c(2x_1 - 1) + d(2x_1 - 1)^2], \quad (1)$$

$$\Delta H = x_1(1 - x_1)[b' + c'(2x_1 - 1) + d'(2x_1 - 1)^2]. \quad (2)$$

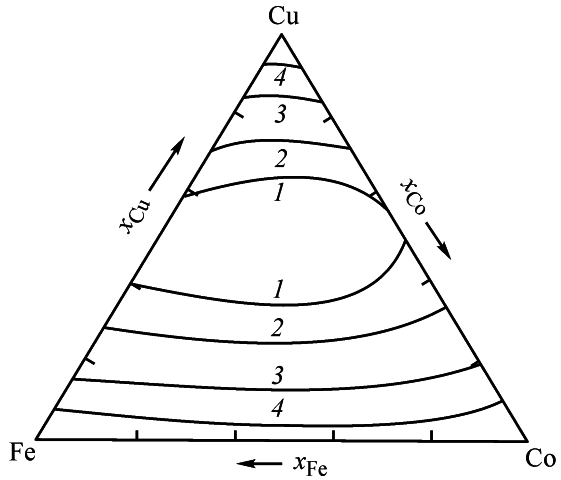

Fig. 2. Lines of equal integral molar excess Gibbs energies of liquid alloys of the Fe–Cu–Co system at 1600°C. (x_{Cu}, x_{Co}, x_{Fe}) Mole fractions of the component in the alloy; the same for Figs. 3 and 5. ΔG^{exc}, kJ mol^{-1}: (*1*) 7, (*2*) 6, (*3*) 4, and (*4*) 2.

To describe the concentration dependence of the integral thermodynamic functions in liquid binary metallic systems, it is not necessary to use polynomials of a higher degree [19].

For the binary systems considered, the following coefficients [ΔG^{exc} and ΔH (kJ mol^{-1})] were obtained:

Coefficient	Fe–Cu	Cu–Co	Co–Fe
b	29.6447	28.2676	5.2978
c	–0.3889	3.2043	3.4429
d	6.8478	3.5208	–1.9655
b'	34.9418	34.4250	–6.1419
c'	22.7298	–2.7500	–1.6528
d'	26.5721	9.0240	1.5121

For all the three binary systems, x_1 in Eqs. (1) and (2) corresponds to the components indicated first. The ΔG^{exc} can be calculated from the equation

$$\Delta G^{exc} = x_1x_2[b_{12} + c_{12}(x_1 - x_2) + d_{12}(x_1 - x_2)^2] + x_2x_3[b_{23} + c_{23}(x_2 - x_3) + d_{23}(x_2 - x_3)^2] + x_3x_1[b_{31} + c_{31}(x_3 - x_1) + d_{31}(x_3 - x_1)^2], \quad (3)$$

where x_1–x_3 characterize the composition of the ternary system and the subscripts in the polynomial coefficients denote the binary systems Fe–Cu (1–2), Cu–Co (2–3), and Co–Fe (3–1).

The similar equation with coefficients b', c', and d' can be written for the enthalpy of mixing in the ternary system.

Tables 2–4 show that ΔG^{exc} and ΔH calculated for the ternary system from different geometric models are in good agreement with those calculated using polynomials. The lines of the equal values of ΔG^{exc} and ΔH for liquid alloys in the Fe–Cu–Co system are plotted in Fig. 2.

As noted previously [3, 4], the partial molar thermodynamic characteristics of all the three components of the system can be estimated from the known relation connecting partial and integral molar quantities. For example, for component 2 at the composition along the secant with a constant ratio of two other components (x_2, x_1/x_3), we can write

$$\Delta G_2^{exc}(x_2, x_1/x_3) = \Delta G^{exc}(x_2, x_1/x_3) + (1 - x_2)(\partial \Delta G^{exc}/\partial x_2)_{x_1/x_3}. \quad (4)$$

Combining Eq. (4) and the Toop's expression for ΔG^{exc}, we obtain the following dependence [20, 21]:

$$\Delta G_2^{exc}(x_2, x_1/x_3) = [x_1 \Delta G_{2(1)}^{exc}/(1 - x_2) + x_{31} \Delta G_{2(3)}^{exc}/(1 - x_2)]_{x_2} - (1 - x_2)^2(\Delta G_{13}^{exc})_{x_1/x_3,\, x_2 = 0}. \quad (5)$$

In Eqs. (4) and (5). $\Delta G_2^{exc}(x_2, x_1/x_3)$ is the excess partial molar Gibbs energy of component 2 at the composition determined by the mole fraction of component 2 (x_2) and by the ratio of the mole fractions of the other two components (x_1/x_3); ΔG^{exc} is the integral molar Gibbs energy of the ternary system at the same composition; $\Delta G_{2(1)}^{exc}$ and $\Delta G_{2(3)}^{exc}$ are the partial molar Gibbs energies of component 2 in the boundary binary systems 1–2 and 2–3; ΔG_{13}^{exc} is the integral molar excess Gibbs energy of the boundary system 1–3 at the composition determined by the x_1/x_3 ratio.

The similar equations can be written for components 1 and 3. In total, the activity coefficients and component activities at 1600°C were calculated for 81 compositions of the ternary system. The data obtained were used to construct the lines of equal activity of the components (Fig. 3). The results of the calculation are also presented in Table 5 for a number of compositions.

Only positive deviation from the ideal behavior was observed for all the compositions of the ternary system. It was of interest to estimate the mutual consistency of the results obtained by the different calculation methods. To do this, the calculated values of the molar excess Gibbs energy of all the three components were used to calculate ΔG^{exc} by the equation

$$\Delta G^{exc} = x_1\Delta G_1^{exc} + x_2\Delta G_2^{exc} + x_3\Delta G_3^{exc} \qquad (6)$$

and the results obtained were compared with the ΔG^{exc} calculations based on geometric models (Table 2) and polynomials (Table 4). The agreement was quite satisfactory. The dependence of ΔG^{exc}, as calculated by different methods, on the composition along the secant with a constant ratio of the mole fractions of iron and cobalt equal to 3 : 1 is shown in Fig. 4.

A number of studies summarized in [18] has demonstrated the applicability of the Zdanovskii's rule to the description of liquid metallic systems. As known, this rule formulated nearly 70 years ago states that electrolyte solutions having similar water vapor pressures and not entering into chemical reactions with each other form a solution with the same pressure of water vapor (i.e., they form an isopiestic ideal solution). It is reasonable to represent the composition of a ternary system in the orthogonal coordinates (first Roozeboom's method [22]). The composition of the isopiestic ideal solutions in mixing changes along

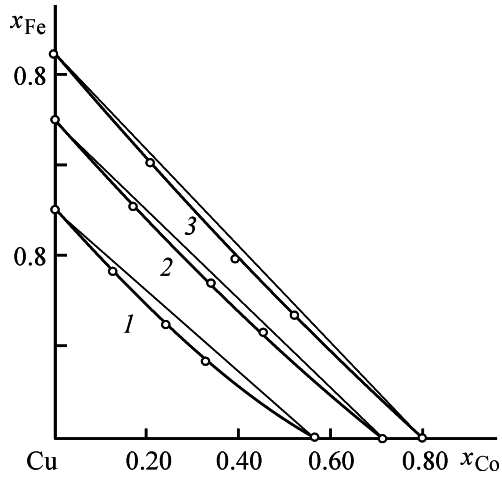

Fig. 5. Lines of equal activity of copper in liquid alloys of the Fe–Cu–Co system at 1600°C in the orthogonal coordinates. a_{Cu}: (*1*) 0.80, (*2*) 0.70, and (*3*) 0.60.

a straight line between the compositions of the binary mixtures. The analogous simple dependences were also observed for liquid metallic systems [18]. In the ternary Fe–Cu–Co system discussed here, lines of copper activity, if copper is solvent, only slightly differ from the straight lines (Fig. 5), which shows that deviation from the Zdanovskii's rule is minimal.

CONCLUSIONS

(1) The calculations of the integral thermodynamic characteristics of mixing of liquid alloys of the iron–copper–cobalt system based on geometric models (Toop, Kohler, Muggiani, and Colinet's models) and Redlich–Kister polynomials yield fairly consistent results. At 1600°C, the system exhibits positive deviation from the ideal behavior.

(2) The calculated activities of all the three components of the Fe–Cu–Co ternary system in the liquid state agree well with the integral thermodynamic characteristics of the system obtained by the independent methods.

(3) With copper as solvent, the Fe–Cu–Co system (at 1600°C) exhibits only minimal deviation from the Zdanovskii's rule.

Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Resources, Kola Scientific Center, Russian Academy of Sciences, Apatity, Murmansk oblast, Russia

Received January 26, 2005

Abstract—The dependence of the solubility of $NaLa(SO_4)_2 \cdot H_2O$, $NaCe(SO_4)_2 \cdot H_2O$, $KLa(SO_4)_2 \cdot H_2O$, and $KCe(SO_4)_2 \cdot H_2O$ on the concentration of acids in sulfuric, phosphoric, and sulfuric–phosphoric acid solutions containing up to 36 wt % H_2SO_4 and 33.12 g l^{-1} H_3PO_4 was studied at 20°C.

The most promising method of the recovery of lanthanides from phosphogypsum and phosphosemihydrate, which are formed in the manufacture of phosphoric acid by the processing of apatite concentrate with sulfuric acid, is the sulfuric acid leaching [1, 2]. Because these products contain sodium and potassium hexafluorosilicates, sparingly soluble double sulfates of lanthanides with sodium and (or) potassium can be formed in the leaching solutions. In addition, the sulfuric acid leaching solutions contain residual phosphoric acid from phosphogypsum. $NaLa(SO_4)_2 \cdot H_2O$ and $KLa(SO_4)_2 \cdot H_2O$ are poorly soluble in water [3, 4]. Data on the solubility of double sulfates $MLn(SO_4)_2 \cdot H_2O$ in sulfuric and sulfuric–phosphoric acid solutions are lacking. The concentration of lanthanum and cerium oxides in the sum of lanthanide oxides in the apatite concentrate exceeds 70 wt % [5]. Therefore, data on the solubility of lanthanum and cerium compounds are especially important for understanding processes that occur in sulfuric acid leaching of lanthanides. The goal of this study was to determine the solubility of double sulfates $M'M''(SO_4)_2 \cdot H_2O$ (M' = Na, K; M'' = La, Ce) in sulfuric and sulfuric–phosphoric acid solutions of low and medium concentrations.

EXPERIMENTAL

We used analytically pure grade chemicals. The double sulfates were synthesized by the standard procedure [4, 6], i.e., by evaporation of an aqueous solution containing lanthanide and alkali metal sulfates, with alkali metal sulfates taken in a 20% excess above stoichiometry. The precipitates were filtered off, the residual mother liquor was pressed out by filter centrifugation, excess alkali metal sulfates were removed from the mother liquor by washing with 3% H_2SO_4, the residue of the washing solution was pressed out by filter centrifugation, and the precipitate was dried at 125–150°C. The chemical analysis of the products synthesized (Table 1) was consistent (taking into account 3% error of the atomic absorption method used), and the X-ray phase analysis revealed no impurity phases. According to the thermogravimetric (TG) analysis, the products synthesized are monohydrates.

The sulfuric–phosphoric acid solutions were prepared by adding small amounts of 85 wt % H_3PO_4 into sulfuric acid solution of prescribed concentration $c_{H_2SO_4}$; the corresponding change in $c_{H_2SO_4}$ was neglected. The H_3PO_4 concentration $c_{H_3PO_4}$ in the solutions was in the range typical of process solutions obtained from leaching of phosphosemihydrate waste with sulfuric acid.

The content of lanthanides in the solutions was determined by oxalate gravimetric method [7] and by atomic-emission spectrometry with an inductively coupled plasma source on a Plasma 400 spectrophotometer (Perkin–Elmer). The low concentrations were analyzed spectrophotometrically with Arsenazo III [8]. The concentration of the sodium or potassium ions was determined by the atomic absorption method in acetylene–air flame on an AAS-30 spectrophotometer (Carl Zeiss, Jena) [9].

The solubility was studied by the isothermal method. Excess double sulfate was added to initial solutions of prescribed concentration. The mixtures were kept at agitation in hermetically sealed vessels at 20 ± 0.5°C until the equilibrium was attained (≥720 h).

The equilibrium was considered to be attained when the results of the analysis of the liquid-phase samples ceased to change. The experimental data are presented in Tables 2–5.

Tables 2–5 show that potassium and sodium were virtually the only ions that passed into dilute phosphoric acid solutions ($c_{H_2SO_4} = 0$), which may be due to secondary formation of hydrated lanthanum and cerium phosphates sparingly soluble under these conditions.

In sulfuric and sulfuric–phosphoric acid solutions of double sulfates, the molar ratio of lanthanide and

alkali metal oxides commonly ranged from 0.91 to 1.09 (Table 6), i.e., was close to unity within the error of the analytical method (≤4.5 rel. % for single determination). At the same time, only double sulfates as individual phases were revealed by the X-ray and crystal-optical analyses of the solid phases separated after the reaction of the double sulfates with both sulfuric acid and sulfuric–phosphoric acid solutions. Consequently, the deviation of the molar ratio from unity is due to the fact that the mother liquor of alkali metal sulfates could not always be washed out completely in the synthesis of the double sulfates. The dissolution of alkali metal sulfates in sulfuric acid can result in the salting-out of sparingly soluble double sulfates. As a result, the solubilities could be underestimated. This effect will be especially pronounced at increased concentrations of sulfuric acid $c_{H_2SO_4}$, when the solubility of the double sulfates is considerably lower.

In estimating the true solubility of the double sulfates, we assumed that their dissolution in water and sulfuric acid proceeds by the scheme

$$M^IM^{III}(SO_4)_2 \cdot H_2O \rightleftarrows M^I + M^{III} + 2SO_4^{2-}. \quad (1)$$

Then, the solubility product

$$SP = [M^I][M^{III}](SO_4^{2-})^2. \quad (2)$$

In the case of the dissolution in water, $[M^I] = [M^{III}] = x$, and $[SO_4^{2-}] = 2x$. Then, $SP = 4x^4$.

In the presence of a small excess of an alkali metal sulfate, the following relationships are valid for the experimentally found concentrations of alkali metal $[M^{I}]_{exp}$ and lanthanide $[M^{III}]_{exp}$:

$$[M^{I}]_{exp} = x_{exp}, \quad [M^{III}]_{exp} = y_{exp},$$

$$[SO_4^{2-}]_{exp} = 0.5(x_{exp} + 3y_{exp}), \text{ and}$$

$$SP_{exp} = 0.25x_{exp}y_{exp}(x_{exp} + 3y_{exp})^2.$$

Since $SP = SP_{exp}$, then

$$x = 0.5[x_{exp}y_{exp}(x_{exp} + 3y_{exp})^2]^{1/4}. \quad (3)$$

In estimation of solubility in sulfuric acid, a slight change in $c_{H_2SO_4}$ due to the dissolution of the double sulfates was neglected. In the dissolution of a double sulfate, the concentrations of alkali metal and lanthanide cations in the equilibrium solution are equal, i.e., $[M^{I}] = [M^{III}]$. Then,

$$SP = [M^{III}]^2[SO_4^{2-}]^2 = [M^{I}]_{exp}[M^{III}]_{exp}[SO_4^{2-}]^2, \quad (4)$$

where $[M^{III}]_{exp}$ and $[M^{I}]_{exp}$ are the experimentally determined concentrations of lanthanide and alkali metal ions, respectively. Hence,

$$[M^{III}] = [M^{I}]^{0.5}_{exp}[M^{III}]^{0.5}_{exp}. \quad (5)$$

In concentrated sulfuric acid solutions ($c_{H_2SO_4} \geq 15$ g-equiv l^{-1}), lanthanides exist in the form of acid sulfate anionic complexes [3, 5]. Since at a constant concentration of H_2SO_4 in a solution slight changes in the concentration of alkali metal cations should not affect the composition of these complexes, Eq. (5) is also applicable to this case.

The solubility of the double sulfates studied, calculated by Eqs. (2) and (4), is presented in Table 7. As seen, the solubility of double cerium sulfates in water and sulfuric acid solutions of similar composition is lower than that of lanthanum sulfates, and that of double sodium sulfates is markedly lower than that of potassium sulfates. With increasing $c_{H_2SO_4}$, the solubility of the double sulfates, like that of lanthanide sulfates [10], first increases, reaches a maximum, and then decreases. The maximum concentration of the lanthanide ions in the solution is observed at $c_{H_2SO_4}$ equal to 0.418 g-equiv l^{-1} for $NaLa(SO_4)_2 \cdot H_2O$ and $NaCe(SO_4)_2 \cdot H_2O$. For $KLa(SO_4)_2 \cdot H_2O$, it is observed at $c_{H_2SO_4}$ equal to 1.32 g-equiv l^{-1}, and for $KCe(SO_4)_2 \cdot H_2O$, at 0.858–1.32 g-equiv l^{-1}.

An increase in the solubility with an increase in $c_{H_2SO_4}$ at relatively low concentrations is probably due to replacement of alkali metal cations by H^+ ions, which becomes more intense at higher $c_{H_2SO_4}$, and its subsequent decrease is due to the salting-out effect, which is also observed with lanthanide sulfates [6].

No salting-out effect was exerted by the SO_4^{2-} ion at low concentrations of sulfuric acid, which suggests that, in sulfuric acid solutions, the lanthanide anionic complexes are formed not only at $c_{H_2SO_4} \geq 15$ g-equiv l^{-1}, but also at lower concentrations.

The calculated solubility products in water at 20°C are 1.48×10^{-7}, 0.426×10^{-8}, 1.62×10^{-6}, and $1.05 \times$

Table 7. Solubility of double alkali metal (Na, K) rare-earth (La, Ce) sulfates in sulfuric acid solutions at 20°C

10^{-6} for $NaLa(SO_4)_2 \cdot H_2O$, $NaCe(SO_4)_2 \cdot H_2O$, $KLa(SO_4)_2 \cdot H_2O$, and $KCe(SO_4)_2 \cdot H_2O$, respectively.

According to the data of [3, 4, 11], the solubility products of $NaLa(SO_4)_2 \cdot H_2O$, $KLa(SO_4)_2 \cdot H_2O$, and $KCe(SO_4)_2 \cdot H_2O$ at 25°C are 2.12×10^{-6}, $(1.45–8.01) \times 10^{-6}$, and 1.37×10^{-5}, respectively. This fact shows that the solubility of the double sulfates in water slightly increases with temperature.

Addition of H_3PO_4 in the examined concentration range to sulfuric acid solutions usually did not affect the solubility of all the double sulfates studied [the exception was $KCe(SO_4)_2 \cdot H_2O$, whose solubility in 4% H_2SO_4 decreased by 27 rel. % after 27.6 g l^{-1} of H_3PO_4 was added].

The data obtained suggest that the low solubility of the double sodium rare-earth (La, Ce) sulfates is one of the most important factors that restrict accumulation of lanthanides in the solutions in leaching of phosphogypsum and phosphosemihydrate with sulfuric acid.

CONCLUSIONS

(1) The solubilities of $NaLa(SO_4)_2 \cdot H_2O$, $NaCe(SO_4)_2 \cdot H_2O$, $KLa(SO_4)_2 \cdot H_2O$, and $KCe(SO_4)_2 \cdot H_2O$ at 20°C in water, sulfuric acid, and sulfuric–phosphoric acid solutions containing 0–36 wt % H_2SO_4 and 0–33.12 g l^{-1} H_3PO_4 was determined.

(2) The solubility of double cerium sulfates in water and sulfuric acid solutions of the same composition is lower than that of the related lanthanum compounds, and that of the double sodium sulfates is markedly lower than that of the potassium sulfates. As the H_2SO_4 concentration increases, the solubility of the double sulfates first increases, reaches a maximum, and then decreases. The maximum solubility is observed at the H_2SO_4 concentration of 0.418 g-equiv l^{-1} for $NaLa(SO_4)_2 \cdot H_2O$ and $NaCe(SO_4)_2 \cdot H_2O$, at 1.32 g-equiv l^{-1} for $KLa(SO_4)_2 \cdot H_2O$, and at 0.858–1.32 g-equiv l^{-1} for $KCe(SO_4)_2 \cdot H_2O$.

(3) Increasing the phosphoric acid concentration within the examined concentration range at a constant concentration of H_2SO_4 only slightly affects the solubility of $KLa(SO_4)_2 \cdot H_2O$ and $KCe(SO_4)_2 \cdot H_2O$. An exception is $KCe(SO_4)_2 \cdot H_2O$, whose solubility at $c_{H_2SO_4} \leq 4$ wt % markedly decreases as the H_3PO_4 concentration in the solution increases.

(4) In sulfuric acid solutions, the lanthanide anionic complexes are apparently formed not only at $c_{H_2SO_4} \geq 15$ g-equiv l^{-1}, but also at lower concentrations.

(5) The low solubility of the double sodium rare-earth (La, Ce) sulfates is one of the most important factors that restrict accumulation of lanthanides in sulfuric–phosphoric acid solutions in leaching of phosphogypsum and phosphosemihydrate with sulfuric acid.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Dissolution of Calcium Carbonate in Aqueous Solutions of Acetic Acid

E. V. Blinkova and E. I. Eliseev

Ural State Technical University, Yekaterinburg, Russia

Received July 14, 2004; in final form, February 2005

Abstract—A kinetic equation for the calcium carbonate dissolution, fitting the experimental data to within 8.1%, was obtained. The additional diffusion hindrance caused by the CO_2 evolution in the course of the dissolution was considered.

To extract zinc from slimes obtained in blast furnace gas treatment, a process based on the acetate leaching with acetic acid solutions was suggested [1]. The blast furnace slime contains about 6% calcium, mainly in the form of carbonate [2], which is formed by the reaction of CaO and CO_2 in the gas-conduit channel of a blast furnace.

Since the slurry from the treatment of blast furnace gases to remove dust contains calcium oxide and dissolved carbon dioxide, calcium carbonate is also formed in the course of its transportation by the pipe system. Calcium carbonate in the form of thin crystals is deposited on the walls of the pipes and causes their overgrowing. Therefore, the pipelines, which are relatively long, get out of order from time to time. One of the methods for overcoming this negative phenomenon is the dissolution of salt crystals in a solution of acetic acid.

To choose proper conditions for this process, it is necessary to study the calcium carbonate dissolution in acetic acid solutions. This reaction was not comprehensively studied previously.

The acetate method of the calcium carbonate dissolution is described by the reaction

$$CaCO_3 + 2C_2H_4O_2 = Ca(CH_3CO_2)_2 + H_2O + CO_2\uparrow. \quad (1)$$

EXPERIMENTAL

We used a 1 : 3 aqueous solution of analytically pure acetic acid. The concentration of the CH_3COOH (HAc) solution was determined by potentiometric titration with NaOH.

The $CaCO_3$ dissolution was studied by the rotating disc method. The discs were made of white marble, which, according to the data of the potentiometric titration, contained 98.9% $CaCO_3$. Samples in the form of a cylinder (diameter 29 mm) were cut out from a bulk mineral with a tubular cutter. The discs were attached to an ebonite cartridge with a silicone acryl sealant. Prior to each experiment, the disc was trimmed with an emery paper (fineness 0.2) and flush-mounted to the cartridge.

The dissolution conditions were varied in the following ranges: temperature, from 283 to 343 K, CH_3COOH concentration in the initial solution, from 0.3 to 3.1 g dm^{-3}, and the disc rotation frequency, from 3.6 to 18.5 Hz. The process was performed in a beaker (inner diameter 14 cm).

The content of the dissolved substance was judged from the content of Ca(II) in the solution. The solutions were analyzed for the Ca(II) content by the volumetric (complexometric) titration with Acid Chrome Dark Blue indicator [3], using a plunger microburet. The analytical error in determining the Ca(II) concentration did not exceed 1.5%. The experimental time was 3 h.

During the experiment, the rate of the $CaCO_3$ dissolution remained virtually constant and increased with the CH_3COOH concentration. The reaction order with respect to HAc was 0.5.

The dissolution rate was a linear function of the square root of the rotation frequency n in the frequency range 3.6–18.5 Hz (Fig. 1), which is one of the essential evidences of a diffusion-controlled process.

One of the reasons why dissolution is diffusion-controlled is formation of new (gas) phase [4]. The diffusion limitations due to CO_2 evolution should be

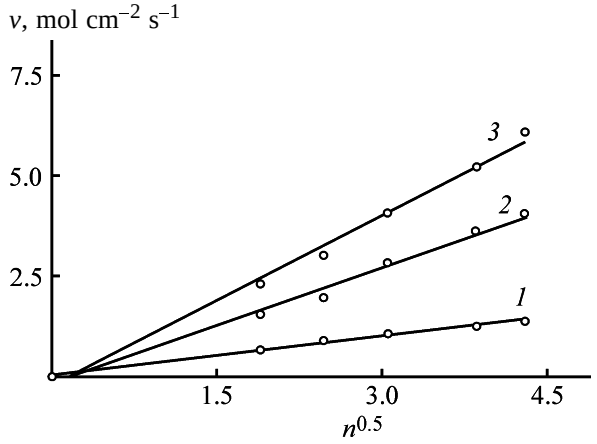

Fig. 1. Rate of $CaCO_3$ dissolution v vs. rotation frequency $n^{0.5}$. Temperature, K: (*1*) 283, (*2*) 323, and (*3*) 343.

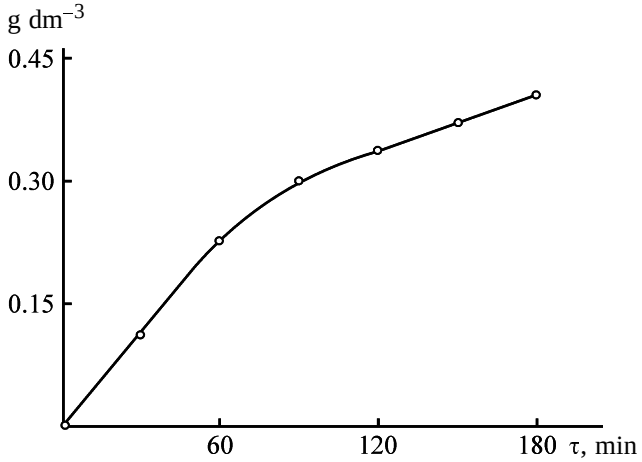

Fig. 2. Kinetic curve of $CaCO_3$ dissolution at 343 K and a disc rotation frequency of 14.9 Hz. (*c*) Calcium concentration and (τ) time; the same for Fig. 4.

less pronounced at low temperature, since the gas solubility in an aqueous solution is higher under these conditions [5]. At a higher temperature (343 K), additional factors affected the rate of the marble dissolution (especially at $n > 14.9$ Hz) after 60 min elapsed from the start of the experiment (Fig. 2). In this case, the initial linear portion of the kinetic curve was used for calculating the dissolution rate.

Increasing temperature within 283–343 K increases the dissolution rate over the entire range of the rotation frequences, i.e., the $CaCO_3$ dissolution is diffusion-controlled (Fig. 3). The temperature dependence of the dissolution rate of $CaCO_3$ was used to calculate the apparent activation energy of the process by the Arrhenius law.

The apparent activation energies calculated at different rotation frequencies were also typical of a diffusion-controlled process over the entire frequency range.

The discs subjected to the experiment at 343 K had a convex surface owing to evolution of CO_2 in the course of the dissolution. In the central part of the disc surface, where the centrifugal force developed in the rotation is minimal, the most stable CO_2 layer preventing dissolution was accumulated. The part of the blocked surface increased with the growth of this layer. Therefore, the dissolution mainly proceeded in the peripheral zone of the disc.

The effect exerted by the forming gas phase on the dissolution was eliminated in the presence of a surfactant. For this purpose we used a detergent, which, being a hydrophilizing agent, made the gaseous film less adhesive to the sample and facilitated its removal by the centrifugal force. Unlike the experiment performed without surfactant under the similar initial conditions, the plot of the Ca(II) concentration vs. dissolution time was linear (Fig. 4a). This was due to accessibility of the whole working surface area of the disc, which ensured the constant process rate. The rate of the $CaCO_3$ dissolution in the presence of surfactant was, however, lower, i.e., the surfactant concentrating at the interface created an additional diffusion hindrance.

The same result was obtained by lifting from time to time the disc over the solution to remove the accumulating CO_2. Under the conditions of vigorous evolution of CO_2 (at 343 K), the dissolution rate was constant only during the first 60 min and then markedly decreased. At this moment (90 min after the start of the experiment), the disc was removed from the solution for a short time. As a result, the gas phase was completely removed, and the initial dissolution rate was restored (Fig. 4b).

Thus, we obtained a kinetic equation of the $CaCO_3$ dissolution:

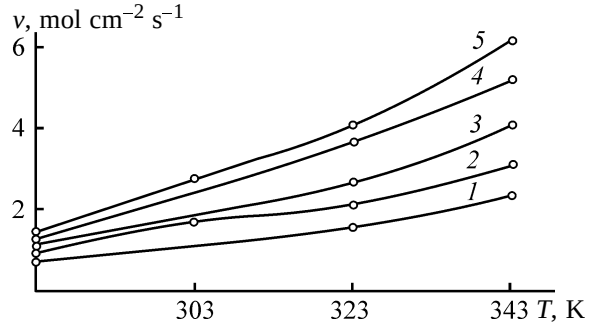

Fig. 3. Influence of temperature T on the rate of $CaCO_3$ dissolution v. Disc rotation frequency, Hz: (*1*) 3.6, (*2*) 6.2, (*3*) 9.4, (*4*) 14.9, and (*5*) 18.5.

$$v = k c_{HAc}^{m} n^{0.5} \exp(-E_a/RT),$$

where v is the specific dissolution rate (mol cm^{-2} s^{-1}); k, rate constant [(mol dm^{-3})$^{0.5}$ cm^{-2} $s^{-0.5}$]; m, reaction order with respect to HAc (0.5); c_{HAc}, HAc concentration (mol dm^{-3}); n, disc rotation rate (Hz); E_a, apparent activation energy (J mol^{-1}); R, universal gas constant (J mol^{-1} K^{-1}); and T, temperature (K).

From the results of 22 experiments performed under different conditions, we obtained $k = (2.46 \pm 0.08) \times 10^{-4}$ (mol dm^{-3})$^{0.5}$ cm^{-2} $s^{-0.5}$. The rates of the $CaCO_3$ dissolution calculated from this value were in satisfactory agreement with the experimental values (see table).

CONCLUSIONS

(1) At c_{HAc} = 3.1 g dm^{-3} and 283–343 K, the dissolution of $CaCO_3$ in acetic acid is a diffusion-controlled process with an apparent activation energy of 17.2 ± 2.6 kJ mol^{-1}.

(2) At 343 K and higher temperatures, the diffusion control of the process may be due to formation of a gaseous CO_2 film on the $CaCO_3$ surface. The order of the $CaCO_3$ dissolution reaction with respect to acetic acid is 0.5.

(3) The obtained kinetic equation of the $CaCO_3$ dissolution is adequate under the following conditions: temperature 283–343 K, HAc concentration 0.3–3.1 g dm^{-3}, and rotation rate 3.6–18.5 Hz.

Abstract—An equation for precision fitting of the temperature dependence of density of any substance in the entire temperature range of its liquid state and an equation for the prediction of the coefficient of thermal expansion, derived from this dependence, was considered. Constants of the equation for 50 liquids were tabulated.

The main applied importance of an equation for precision fitting of the temperature dependence of the density or specific volume of liquids is connected with its use for the prediction of thermal expansion coefficients as functions of temperature, which are required for various process calculations.

The following equation is used today for precision fitting of the specific volume of liquids [1, 2]:

$$V = V_0(1 + at + bt^2 + ct^3), \quad (1)$$

where a, b, and c are experimental coefficients given in reference literature for various liquids with indication of the temperature range of the equation applicability; V_0 is the specific volume at $t = 0$°C; V, specific volume at a current temperature; and t, current temperature (°C).

Various methods for the prediction of thermal expansion coefficients using Eq. (1) are given in [3, 4]. It should be noted that these methods are too cumbersome, which does not count in favor of the prediction accuracy. By definition, the thermal expansion coefficient is

$$\beta = \frac{1}{V}\frac{dV}{dt}. \quad (2)$$

Hence, it follows from Eq. (1) with a mathematical exactitude that the thermal expansion coefficient is

$$\beta = \frac{a + 2bt + 3ct^2}{1 + at + 2bt^2 + ct^3}. \quad (3)$$

The basic disadvantage of Eqs. (1) and (3) is their applicability in rather narrow temperature ranges. For example, the following ranges of the applicability of Eq. (1) are suggested in [1, 2]: for water, $t = 0$–33; for sulfuric acid, 0–30; for isopentane, 0–27, and for methyl formate, 0–10°C. Furthermore, it is assumed that Eq. 1 is applicable in the vicinity of $t = 0$°C. Therefore, Eq. (1) basically is unsuitable for condensed gases, molten metals, and also organic and inorganic substances with high melting points.

Here we suggest Eq. (4) for precision fitting of the temperature dependence of density of any substances on the saturation line within the entire temperature range of their liquid state:

$$\rho = \rho_{cr} e^{[A\theta + B\theta^2 + (C\theta)^n]}, \quad (4)$$

where ρ_{cr} is the density under critical conditions (kg m^{-3}); $\theta = t_{cr} - t = T_{cr} - T$, temperature measured from the critical point (K); t and T, current temperature (°C and K); t_{cr} and T_{cr}, critical temperature (°C and K); and A, B, C, and n, constants depending on the kind of the liquid and determined by regression analysis of a series of experimental data.

Table 1 contains constants of Eq. (4) for various liquids, as determined by regression analysis of the experimental data [1, 5]. When the constants given in Table 1 are used, deviations of Eq. (4) from the experimental data in specific cases exceed 0.1% (Table 2). The experimental data on any liquids starting from hydrogen, including metal melts, up to the highest-molecular-weight organic liquids are equally well described by this equation. The only exception is the temperature range $t = 0$–200°C for water.

Equation (4) can be presented as

$$V = V_{cr}e^{-[A\theta + B\theta^2 + (C\theta)^n]}, \quad (5)$$

where V is the specific volume under critical conditions (m^3 kg^{-1}).

Some examples showing how the results of calculations by Eqs. (4) and (5) agree with the experimental data are given in Table 2.

A high accuracy of the fitting allows us to use Eq. (5) for deriving an equation for predicting thermal expansion coefficients of liquids as functions of temperature. Substituting Eq. (5) in (2), we obtain

$$\beta = A + 2B\theta + n\theta^{-1}(C\theta)^n, \quad (6)$$

Some examples showing how the results of calculations by Eqs. (6) agree with the experimental data [4] are given in Table 3. The deviations, except a few cases, do not exceed ±5%. Such a fitting accuracy provided by Eq. (6) should be considered as acceptable, the more so as experimental data on the thermal expansion coefficients of liquids are not highly accurate.

It was noted above that Eqs. (4)–(6) do not cover the temperature range t = 0–200°C for water. Therefore, we offer special Eq. (7) applicable to this case:

$$\rho = 1000\exp\{a\eta^2 + b[1 - (1 + c\eta)e^{-c\eta}]\}, \quad (7)$$

where $a = -3.325848\times10^{-6}$ K^{-2}, $b = -1.925639\times10^{-2}$, $c = 2.165\times10^{-2}$ K^{-1}, $\eta = t - 4$, and t is temperature (°C).

Equations (4) and (7) are compared with the experimental data for water in Table 4, which shows that Eq. (7) fits the experimental data on the water density at t = 0–200°C with a very high accuracy. Therefore, Eq. (7) can be used to derive an equation for satisfactory fitting of the thermal expansion coefficient even in the vicinity of its zero value. Taking Eqs. (2) and (7) into account, we obtain Eq. (8):

The results of calculations by Eqs. (6) and (8) are compared with the experimental data in Table 5.

Thus, unlike Eq. (3), Eq. (6) allows us to predict the thermal expansion coefficient of any substances except water within the entire temperature range of their liquid state. In the temperature range from 200°C to t_{cr}, Eq. (6) is also applicable to water, whereas in the range 0–200°C Eq. (7) must be applied.

In view of low compressibility of liquids, Eqs. (4) and (6)–(8) are also applicable at pressures moderately exceeding the saturation pressure. For exam-

CONCLUSIONS

(1) A four-constant correlation equation for precision prediction of the density of any substances within the entire temperature range of their liquid state was suggested, and its constants were determined by regression analysis of reference experimental data for 50 elements, inorganic compounds, and organic compounds.

(2) An equation for predicting the thermal expansion coefficients of liquids was obtained on the basis of the suggested correlation equation for density.

Topchiev Institute of Petrochemical Synthesis, Russian Academy of Sciences, Moscow, Russia

Received December 16, 2004; in final form, March 2005

Abstract—A new version of electroosmotic thin-layer chromatography, circular electroosmotic chromatography, was suggested and a prototype apparatus for its implementation was designed.

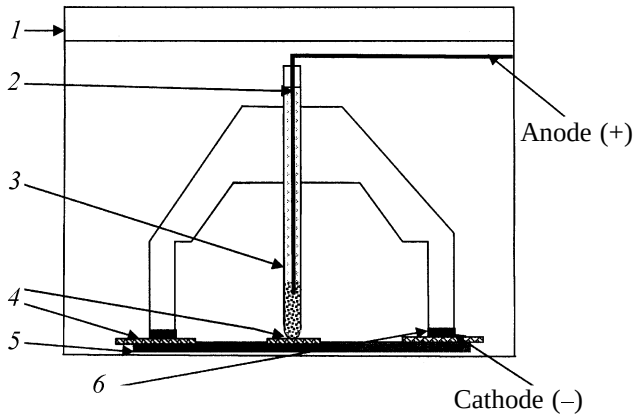
In the recent decade, liquid thin-layer chromatography (TLC) has been under intensive development. The cheapness and high selectivity of the technique, as well as its quite satisfactory performance and simplicity, led to a wide use of TLC in various fields of science and technology and in environmental monitoring [1–3].

One of the most efficient versions of TLC is circular TLC, which was first suggested by Izmailov and Shraiber [4] and is the first known kind of thin-layer chromatography. The theoretical foundations and experimental implementation of circular TLC, as well as the advantages and shortcomings of the method, were considered in detail in [1, 5, 6]. Compared with the linear version of TLC, widely used in chromatographic practice at present, the circular technique has the following important advantages [1, 5]: higher resolution, higher sensitivity of detection of chromatographic bands (as a result of their narrowing, i.e., concentration), and lower expenditure of the mobile phase. However, the version of circular TLC under discussion also shows a number of shortcomings [1, 5]: a decrease in the average flow velocity of the mobile phase, poorer resolution in analyses for compounds with high R_f (0.6), and impossibility of implementation of the two-dimensional version of TLC.

The basic specific feature of the chromatographic process in circular TLC (compared with the linear modification) consists in the existence of a velocity gradient in the flow of the mobile phase along the direction in which compounds being analyzed are eluted. This leads to an automatic narrowing of chromatographic bands in circular TLC, i.e., to a higher efficiency of chromatographic separation, because the velocity at the peak front is smaller than that at its backside.

It would be expected that application of the electroosmotic effect in circular TLC should make higher the motion velocity of the mobile phase, and effect of narrowing of chromatographic bands, characteristic of the conventional circular chromatography, must also be inherent in circular electroosmotic TLC (EO-TLC). Consequently, this version of EO-TLC must be more efficient as compared with linear electroosmotic thin-layer chromatography.

This study is devoted to development of a new chromatographic method and design of a new apparatus for implementation of circular EO-TLC and to analysis of its basic chromatographic characteristics.



EXPERIMENTAL

The figure shows schematically the apparatus for the method under study.[1] The electroosmotic flow of a mobile liquid phase in circular EO-TLC was created using two electrodes: circular (positioned on the periphery; outer diameter ~9 cm, inner diameter ~8 cm; stainless steel) and central electrodes.

The central electrode was placed in a glass tube about 10 cm long, with an inner diameter of 7.5 cm. The end of the glass tube, brought in contact with the adsorption layer of a TLC plate, had a constriction (inner diameter 0.5 mm, outer diameter 3 mm). The glass tube was densely packed with a filter paper moistened with the mobile phase. A Nichrome-wire electrode (anode) was placed at the center of the tube. The mobile phase was delivered to the central part of the plate from the glass tube with the electrode at the center of a circular piece of filter paper (8 mm in diameter), placed in the central part of the TLC plate. As compounds subjected to chromatographic analysis served selected dyes or a mixture of these. The dye mixture to be separated was deposited with a micro-

Schematic of a chamber for electroosmotic circular chromatography: (*1*) poly(methyl methacrylate) chamber; (*2*) electrode (central); (*3*) glass tube with a constriction at end, packed with filter paper moistened with the mobile phase, with an electrode placed within the tube; (*4*) filter paper [(i) filter paper circle 8 mm in diameter, placed at the center, and (ii) filter paper square with a circular cut at the center (this filter paper is placed between the external electrode and the adsorption layer on the TLC plate)]; (*5*) TLC plate (adsorption layer on top); and (*6*) electrode (external).

syringe at a distance of 1 mm from the central filter paper circle. With silica gel as a fixed phase, the electroosmotic flow is directed from the anode to the cathode, with the silica gel surface charged negatively [7]. In accordance with the Joule–Lenz law, heat is released in EO-TLC, when electric current flows across the sorption layer. This leads to an intensive uncontrollable evaporation of volatile components of the mobile phase, with the result that the chromatographic experiment becomes poorly reproducible. Therefore, the plate used in separation in the circular EO-TLC mode was preliminarily moistened with a low-volatile mobile phase with a pulverizer, or a plate with a sorption layer protected from evaporation was used [8].

The study was carried out with Sorbfil plates,[2] with ethanol and dimethyl sulfoxide (DMSO) as mobile phases.

As basic characteristics of the new chromatographic method were chosen, first, the rapidity of the technique (motion velocity of the mobile phase or of the central part of the band corresponding to a dye under study) and, second, its performance, i.e., the effective number of theoretical plates, $N_{\text{eff}} = 16(l/w)^2$. Here l is the distance traveled by the central part of the band in a time t (from the point of sample deposition on the sorption layer), and w is the longitudinal width of the band. It is noteworthy that the experimentally determined number of theoretical plates in TLC and in the method in question should be regarded as an effective characteristic, because, strictly speaking, application of the quantity "theoretical plate" to characterization of the gradient chromatographic technique under study is not substantiated theoretically. However, the quantity used in this study (N_{eff}) undoubtedly enables a comparative evaluation of the real chromatographic processes of band smearing.

The experiments performed confirmed the improved (compared with the linear version) performance of circular EO-TLC.

To illustrate the high performance of circular EO-TLC, the following experimental data are presented. For example, HETP = 14 μm for circular EO-TLC with ethanol as a mobile phase (voltage 1.5 kV) at a displacement of the band of the dye (Rhodamine B) by 20 mm and HETP = 37 μm under conditions of the conventional circular TLC, i.e., the performance of EO-TLC is higher (by a factor of ~2.6). These experimental data were obtained on plates with an adsorption layer protected by a polyethylene film, which virtually terminates evaporation of the mobile phase and improves the reproducibility of the process. Thus, EO-TLC with a protected sorption layer exhibits a higher performance, compared with the conventional circular TLC.

Table 1 lists the experimental data obtained, which allow a comparative evaluation of the basic chromatographic characteristics of circular EO-TLC in which the adsorption layer is protected by a polyethylene film. It is seen that the velocity of motion of the dyes used as test compounds along the layer (rapidity of the method) increases by a factor of 3.5–5.6, and the performance becomes tens of times higher for some compounds. Thus, our experiments demonstrate that the basic chromatographic characteristics of the new method are markedly improved and, consequently, its use in analytical chromatography to solve various analytical problems is advisable.

As is known, a disadvantage of electroosmotic TLC consists in intensive evaporation of the mobile phase in the course of an experiment [9]. Therefore, an additional new version of circular EO-TLC was developed, in which low-volatile DMSO served as the mobile phase. The results obtained are listed in Table 2. It can be seen that the motion velocity of the bands of the compounds subjected to chromatographic analysis increases in the new version of

[2] Sorbpolimer Company (Krasnodar).

Table 1. Comparison of basic chromatographic characteristics of the conventional circular TLC and circular EO-TLC. Mobile phase ethanol, TLC plates with an adsorption layer protected by a polyethylene film

TLC version	Dye subjected to chromatographic analysis	Relative motion velocity of band	N_{eff}, TP	Relative increase in N_{eff}
Conventional circular, protected layer	Rhodamine C	1.0	80	1.0
	Brilliant Green	1.0	50	1.0
EO-TLC, protected layer, voltage 1.0 kV	Rhodamine C	3.5	4100	51
	Brilliant Green	4.6	2100	42

Table 2. Characteristics of the conventional circular TLC and circular EO-TLC in the case of a low-volatile mobile phase (DMSO)

TLC version	Sorbate	Displacement of sorbate band on plate, mm	Average motion velocity of band, mm min^{-1}	Relative average motion velocity of bands	N_{eff}, TP	Relative increase in N_{eff}
Conventional circular	Sudan (II)	13	1.3	1.0	2500	1.0
	Crystal Violet	2	0.18	1.0	50	1.0
	Rhodamine G	7	0.36	1.0	300	1.0
EO-TLC, voltage 1.5 kV	Sudan (II)	19	1.9	1.5	4300	1.8
	Crystal Violet	12	1.2	6.7	1700	34
	Rhodamine G	15	1.5	2.1	970	3.2

EO-TLC by a factor of 1.8–3.4, with a simultaneous pronounced (severalfold) rise in the performance. Thus, in the version of circular EO-TLC with low-volatile mobile phases, suggested in this study, such most important chromatographic characteristics as rapidity and performance are markedly improved, compared with the conventional version of circular TLC.

It is also noteworthy that circular EO-TLC can be used as a concentration technique. In chromatographic analyses of strongly diluted samples, the weight of a sample being analyzed and, consequently, its linear dimensions are raised in order to improve the sensitivity of impurity determination. Therefore, the positive effect can be achieved in this case only if a sample is made only moderately larger, because a further increase in the sample size already leads to a noticeable extension of the initial width of the band, which impairs the efficiency of the subsequent chromatographic separation [10].

The smearing of chromatographic bands in circular TLC automatically decreases because of the existence of a velocity gradient of the mobile phase. Therefore, it would be expected that the effect under discussion, i.e., the narrowing of the broad initial band of a sample, must also be observed in the case of EO-TLC. To confirm the occurrence of this effect under the conditions of circular EO-TLC, special experiments at a voltage of 1 kV were performed with DMSO as a mobile phase to study changes in chromatographic characteristics for Crystal Violet (compound subjected to chromatographic analysis). Under the conditions specified above, the broad initial band of the dye (width 10 mm) decreases to 8.5 mm (–15%) upon elution for 10 min and to 7.0 mm (–30%) upon elution for 20 min. This means that it is, in principle, possible to use in EO-TLC a broad initial band narrowing under the experimental conditions. This effect, combined with an increased sample volume, improves the efficiency of determination of impurity components.

Table 3 compares the basic characteristics of circular EO-TLC and circular conventional TLC. It can be seen that, according to its characteristics, circular EO-TLC is more promising than the classical linear version.

Finally, it should be noted that it is advisable to develop further the suggested version of circular EO-TLC in two ways: (1) to improve further the technique and the apparatus for its implementation and (2) to determine the optimal areas of its practical application.

Table 3. Comparison of circular EO-TLC with the conventional circular TLC

Characteristic of TLC	Conventional circular TLC	Circular EO-TLC
Phenomenon (principle) on which the motion of the mobile phase is based	Wetting of the sorption layer by the mobile phase	Electroosmosis: motion of the mobile phase relative to the adsorption layer under the conditions of formation of an electrical double layer (zeta potential) in an electric field gradient
Implementation conditions of the conventional TLC and EO-TLC	Mobile phase wets the adsorbent layer used	The mobile phase moves in an electric field relative to the solid sorbent (electroosmosis). Development of an electric field gradient and formation of an electrical double layer at the interface between the mobile phase and the sorbent are conditions for implementation of the method. To preclude evaporation of the conventional mobile phases in order to achieve stable operation of the technique, it is advisable to use a plate with a protected layer or a low-volatile mobile phase
Advantages of circular EO-TLC	Conventional circular TLC serves as a basis for comparison with EO-TLC	Positive specific features of circular EO-TLC (compared with conventional circular TLC): (1) higher rapidity and (2) higher performance

CONCLUSION

Compared with circular thin-layer chromatography, the circular electroosmotic thin-layer chromatography (both with a protected sorption layer and with low-volatility mobile phases) suggested in this study has the following advantages: (1) higher rapidity (by a factor of 1.5 –6.7), (2) 1.8–51 times higher performance, and (3) narrowing of the initial broad bands.

Abstract—A method for obtaining sorption-active materials based on a solidifying mineral dispersion composed of nepheline, hydrochloric acid, and water was suggested. The hardening processes and conditions under which sorption-active compounds are formed were studied. The mechanism of sorption of F^- ions on the sorbents developed was determined.

A topical environmental problem of the Kola region is purification of mine water and underground water to remove fluoride ions. All the methods presently used for this purpose can be divided into two groups: (1) coprecipitation and coagulation on freshly synthesized aluminum and magnesium hydroxides and calcium phosphate and (2) ion exchange of fluorine-selective ion exchangers, e.g., activated aluminum oxide, which is a strongly basic anion exchanger. However, use of these expensive ways to defluorinate water is unacceptable in the case of large-tonnage wastes. Defluorination of sewage from mining plants require granulated sorbents, which can be used by creating check dams before discharging, e.g., mine water into natural water basins. To solve this problem, it is suggested to prepare sorption-active materials by the technology of self-hardening binder systems. By binders (self-hardening) are understood systems containing, in certain relative amounts, the solid and liquid phases that can interact to give new condensed phases and are capable of hardening [1, 2]. It is known that condensed reaction products formed in hardening of water-containing binder systems, with aluminosilicates used as a solid phase, are salts of complex composition. These salts contain oxyhydrates, hydrosilicates, and hydroaluminates, which exhibit sorption properties under certain conditions [5].

In development of sorbents for defluorination of wastewater, the mineral phase of the self-hardening binder system should be composed of acid-nonresistant aluminum-containing minerals that can interact with aqueous solutions of acids to give hydroxo compounds of aluminum, which are anion-active sorbents under certain conditions [4]. The search for starting raw materials was limited to the natural resources of the Kola Peninsula. Preference was given to nepheline-containing raw materials, whose advantage over other types of raw materials consists in larger resources, fast decomposition by acids, and high content of alumina (up to 30 wt % Al_2O_3). In view of the fact that aluminum hydroxides exhibiting the highest activity toward fluoride ions are formed in hydrolysis of its oxychlorides [4], a hydrochloric acid solution was chosen as the second component of the binder system for synthesis of a fluorine-selective sorbent.

The aim of this study was to find conditions under which granulated sorption-active materials to be used in treatment of mine wastewater can be formed by the binder technology in the system constituted by nepheline, hydrochloric acid, and water and to determine the optimal application conditions of the materials obtained.

We used a nepheleine concentrate produced by the Apatit Open Joint-Stock Company, ground to a specific surface area of 2600 $cm^2\ g^{-1}$. The concentrate contained up to 80–81 wt % nepheline and had the following chemical composition (wt %): SiO_2 42.60, Al_2O_3 29.30, Na_2O 13.96, and K_2O 7.13. The concentration of hydrochloric acid was varied from 5 to 35%. The degree of nepheline decomposition was controlled by changing the amount of HCl contained in the starting binder system and calculated in accor-

Table 1. Synthesis conditions and strength characteristics of sorbents

Sample no.	α, %	c_{HCl}, %	s : l	c_{F^-}, mg g^{-1}	R_{comp}, MPa
1	6–7	17	3 : 1	20.7	2.5–3.5
2	25	17	1 : 1.5	33.0	1.0
3	50	17	1 : 3	64.5	0.4
4	75	17	1 : 4	65.0	0.2
5	100	39	1 : 4	52.0	0.2
6	100	17	1 : 5.5	22.0	Less than 0.2
7	100	17	1 : 15	24.0	″ ″
8	75	9.5	1 : 8	33.0	″ ″
9	50	3.5	1 : 15	32.0	″ ″

dance with the reaction of complete (stoichiometric) decomposition of nepheline:

$$(Na_3K)O_2 \cdot 2Al_2O_3 \cdot 4SiO_2 + 16HCl \rightarrow 3NaCl + KCl + 4AlCl_3 + 4SiO_2 + 8H_2O.$$

It was assumed that 100% decomposition of nepheline occurs in those reaction mixtures in which the amount of hydrochloric acid corresponded to that required by the stoichiometry. In what follows, the degree of decomposition α is given in percent relative to total decomposition.

The concentration of fluoride ions, c_{F^-}, was measured potentiometrically with an EF-VI fluorine-selective electrode in the presence of a citrate buffer solution. The citrate buffer solution was used to break down complexes formed by F^- ions with aluminum cations, which may be present in solution.

The products formed in the reaction of nepheline with hydrochloric acid were studied by X-ray diffraction analysis, IR spectroscopy, and mass spectrometry.

EXPERIMENTAL

The technique used to obtain materials was the same for all the compositions: finely ground nepheline concentrate was poured-over with an HCl solution, the mixture was agitated for 15 min, and the resulting mass was kept at 22°C for 24 h, and then thermolysis was performed at 105°C to constant weight.

To determine the strength characteristics (compression strength R_{comp}) of the materials synthesized, $2 \times 2 \times 2$-cm samples were fabricated. For this purpose, the mass formed was cast into molds, kept at 22°C for 24 h, and then heat-treated at 105–110°C for 1 h. The water resistance of the materials synthesized was evaluated by the loss of strength by the samples kept in water for 7 days.

The sorption and the kinetics of leaching-out of the sorbent components were determined under static conditions at a sorbent : sorbate ratio of 1 : 100, temperature of 22°C, and intermittent agitation, with the time of contact varied from 15 min to 72 h. The data obtained are listed in Table 1. The results of the study demonstrated that a granulated water-resistant material should be synthesized in a narrow range of compositions of the starting binder system: the amount of hydrochloric acid corresponds to α = 6–7%, and the concentration of water, to an s : l ratio of 2.8 : 1 to 3 : 1. As α increases, the strength and water resistance of grains decrease dramatically. The technique that can be used to obtain the sorbent includes the following operations: grinding of the nepheline concentrate to a specific surface area of 2500–3000 $cm^2\ g^{-1}$, mixing of the ground concentrate with a 7% HCl solution at a phase ratio of 3 : 1, granulation of the resulting mass, and thermolysis at 105°C.

The reaction products responsible for formation of a strong water-resistant stone and sorption-active phases were for the most part studied using physicochemical methods. This is due to difficulties in isolation of the newly formed phases from the whole mass of a solidified dispersion. To make simpler the identification of the reaction products, all the physicochemical studies were carried out with samples synthesized on nepheline crystals ground to a specific surface area of 2600 $cm^2\ g^{-1}$. This is justified by the fact that the main impurity minerals (feldspar, titanomagnetite) contained in the nepheline concentrate are considerably more resistant to solutions of acids, compared with nepheline, and have no effect on the hardening processes.

It is known that the key role in hardening of binder formulations and in sorption interactions in materials synthesized by the technology of binder systems is played by water molecules, which are in a firmly bound state in the reaction products [3–4]. The role played by water molecules in the sorbent synthesized from nepheline was revealed using mass-spectrometric analysis, which makes it possible to record not only the loss of mass by a sample, but also the molecular weight of the thermolysis products being removed and their qualitative composition. The results obtained demonstrated that three temperatures of water removal can be distinguished in the mass spectrum of the

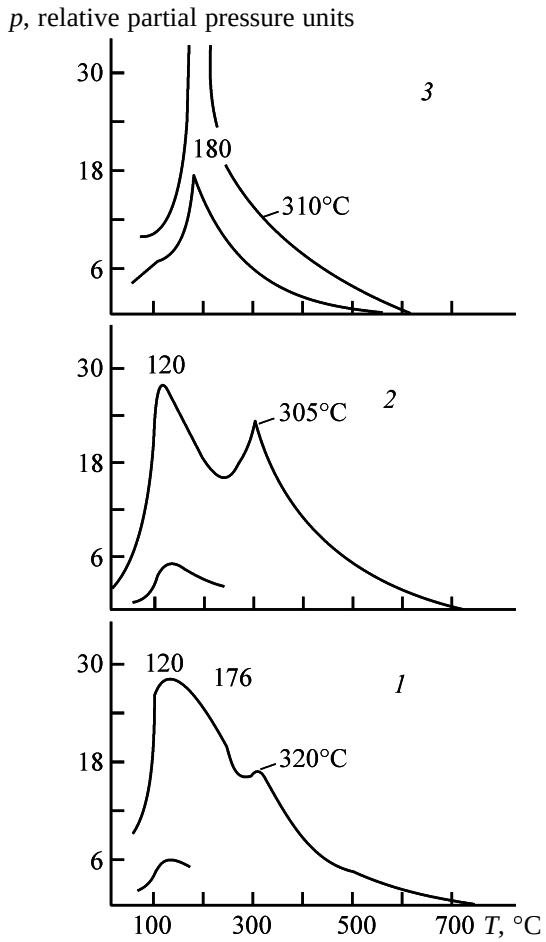

Fig. 1. Mass-spectrometric monitoring of thermal removal of water from the nepheline sorbent synthesized at various α and s : l ratios. (*p*) Relative pressure and (*T*) temperature. (*1*) α = 7% at s : l = 3 : 1, (*2*) α = 50% at s : l = 1 : 2.5, and (*3*) α = 50% at s : l = 1 : 5.

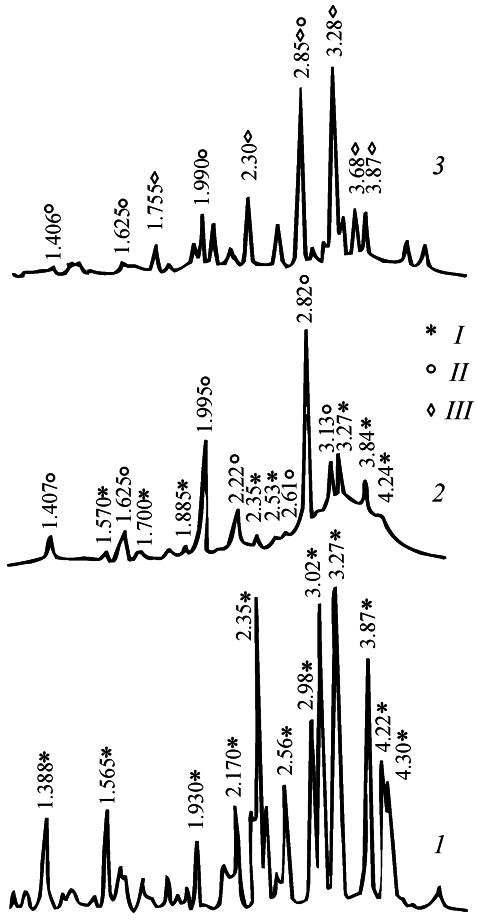

Fig. 2. X-ray diffraction patterns of nepheline and the nepheline sorbent synthesized at various s : l ratios. (*1*) Starting nepheline, (*2*) α = 50% at s : l = 1 : 2.5, and (*3*) α = 50% at s : l = 1 : 5. (*I*) Nepheline, (*II*) sodium chloride, and (*III*) hydrated aluminum chloride.

sample obtained at α = 7% (s : l = 3 : 1), with the following distribution of intensities: 120 > 175 > 320°C (Fig. 1). As α increases to 50%, an increase in the amount of OH_n groups removed at at T > 320°C and a decrease in that of OH_n groups removed at 175°C are observed at a water deficiency (s : l = 1 : 2.5). As the content of water in the starting dispersion increases (α = 50% at s : l = 1 : 5), the fraction of water removed at 175–180°C increases, and the content of firmly bound OH_n groups decreases.

The mass spectra of hydrogen chloride demonstrate that chlorides and hydroxochlorides decomposing at 320, 410, and 520°C are present in a weakly treated material (α = 7%).

Thus, the materials synthesized on the basis of binder systems with a low degree of nepheline decomposition contain, in contrast to materials with a high degree of decomposition, H_2O and HCl in a firmly bound state, which are removed at temperatures exceeding 350°C. This is in agreement with the variation of the strength characteristics of samples with their synthesis conditions (Table 1).

X-ray diffraction studies of the products formed in the reaction of nepheline with a hydrochloric acid solution demonstrated (Fig. 2) that the phase composition of the compounds formed is primarily determined by the amount of water contained in the starting dispersion, which presumably affects the diffusion of mobile elements in the nepheline structure. In the case of an excess of water, separate phases recorded in the X-ray diffraction pattern are formed. In the dispersions synthesized at s : l = 1 : 5, the reflections associated with nepheline disappear already at α = 50% and the phase of aluminum hydrochlorides (Fig. 2, X-ray diffraction pattern *3*) and that of amorphous hydrated silicon oxide are formed in the reaction prod-

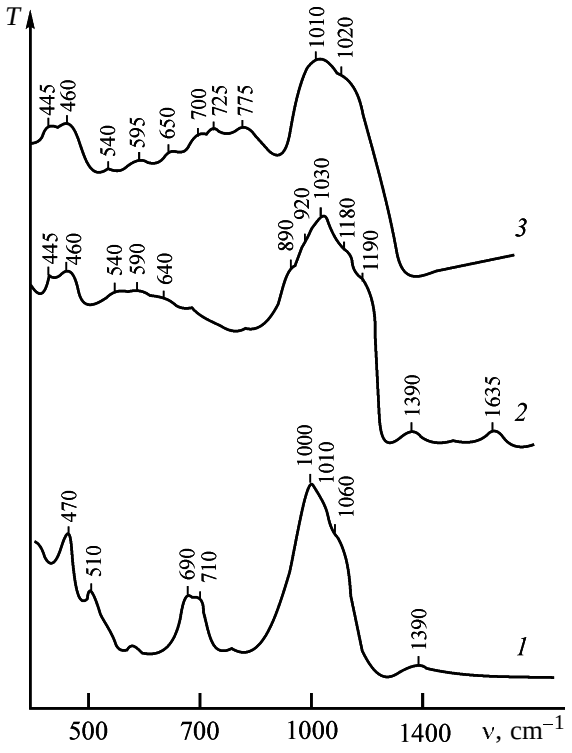

Fig. 3. IR spectra of nepheline and the nepheline sorbent synthesized at α = 50% and s : l = 1 : 2.5. (*T*) Transmission and (ν) wave number. (*1*) Nepheline, (*2*) nepheline sorbent, and (*3*) the sorbent heat-treated at 400°C.

ucts in addition to chlorides of alkali metals. In the case of deficiency of water (s : l = 1 : 2.5), formation of reaction products as separate phases is hindered and a broad band centered at about 3.7 Å is observed on the background of reflections associated with nepheline and alkali metal compounds. This band characterizes the amorphization of the aluminosilicate skeleton: reflections related to $AlCl_3 \cdot 6H_2O$ are absent (Fig. 2, pattern *2*).

The behavior revealed was also observed in a study of the reaction products formed at α = 100% at various s : l ratios: 17% HCl at s : l = 1 : 15 and 36% HCl at s : l = 1 : 3. The X-ray diffraction patterns of the samples obtained with excess water (s : l = 1 : 15) contain reflections associated with chlorides of alkali metals, hydrated aluminum chloride, and hydrated amorphous silicon oxide. With a deficiency of water, only NaCl, KCl, and amorphous aluminosilicates are manifested in the X-ray diffraction patterns. After washing of the reaction products with water, only a broad band associated with amorphous aluminosilicates is observed in both cases. The shift of its center from 3.7 to 3.3 Å in water-deficient systems indicates that this phase is enriched with aluminum oxides [5]. The $SiO_2 : Al_2O_3$ ratio in the reaction products is 1 : 0.04 in the system with an excess of water and 1 : 0.25 in that with a deficiency of water. This indicates that the extent to which aluminum oxides are removed from the aluminosilicate skeleton decreases as the concentration of H_2O in the starting dispersion becomes lower. The nepheline structure disintegrates incongruently: the egress of alkaline cations is ahead of the diffusion of Al^{3+} from the nepheline structure, which leads to formation of a sparingly soluble amorphous phase of aluminosilicates.

The results of X-ray diffraction studies are confirmed by the IR data (Fig. 3). A pronounced increase in the absorption at 960 cm^{-1} and in the range 540–640 cm^{-1} in nepheline treated with hydrochloric acid under conditions of water deficiency (s : l = 1 : 2.5) is due to hydroxylation of the surface and formation of Al–OH and Si–OH bonds [6]. The presence of hydrated aluminosilicates in the products formed in the reaction of nepheline with hydrochloric acid under conditions of water deficiency is indicated by the fact that the IR spectra contain a broad band at 2800–3740 cm^{-1}. The shoulders at 3560–3680 cm^{-1} correspond to stretching vibrations of silanol groups involved in hydrogen bonding and to isolated silanol groups. This interpretation is supported by the fact that the absorption in these spectral ranges decreases upon removal of water from the samples at 400°C. The partial cleavage of Si–O–Al bonds characterizing the ordered isomorphism in the aluminosilicate skeleton of nepheline and the appearance of purely Si–O and Al–O bonds is confirmed by broadening of the band of symmetric stretching vibrations ν_{as} of Si–O–Si and Si–O–Al bonds (920–1200 cm^{-1}) and by weakening of doublets of bending vibrations ν_s (690–710 cm^{-1}) and δ (470–510 cm^{-1}) of these bonds [6]. It should also be noted that all the samples under study exhibit absorption at 590–650 cm^{-1}, suggesting the presence of aluminum compounds with an octahedral coordination [6–9].

The results of physicochemical studies of the reaction products formed in the dispersions composed of nepheline, hydrochloric acid, and water indicate that the amorphous phase of oxyhydrate aluminum-containing compounds is formed on the sorbent surface. These compounds incorporate H_nO and HCl in a bound state, which are removed at temperatures higher than 350°C. These reaction products, formed in a narrow range of compositions, are responsible for the dispersion hardening and sorption processes.

To determine the optimal application conditions of

nepheline sorbents, the kinetics of leaching-out of the main components of the sorbent and its sorption characteristics were studied under varied conditions [4]. As is known, sorption of fluoride ions on oxyhydrate aluminum-containing sorbents occurs via formation of insoluble polymolecular fluoroaluminate complexes AlF_x^{3-x} (x = 1–6) through ion exchange or chemical interaction. The main exchange centers in amorphous aluminum oxyhydrates are molecules of coordination water and bridged and terminal OH groups [10]. Formation of various types of centers and occurrence of one or another sorption mechanism are affected by the solution pH, concentration of active Al^{3+} on the sorbent surface, and concentration of F^- in solution [10]. In the case of the nepheline concentrate, as active aluminum was regarded that contained in the reaction products, i.e., in the active phase. The amount of the active phase was evaluated by the degree of nepheline breakdown, α, i.e., by the amount of hydrochloric acid, with water contained in the dispersion disregarded. The study was carried out with a nepheline concentrate of the optimal composition. The kinetics of leaching-out of the main components was examined under static conditions. The concentration of fluoride ions in solutions, varied from 19 to 190 mg l^{-1}, was measured in the presence of a citrate buffer solution and without this solution. The difference between the concentrations of fluoride ions measured with and without the citrate buffer solution corresponded to the content of fluorine bound in fluoroaluminate complexes [8]. The solution pH was adjusted on the background of a constant concentration of NaCl (1 N solution) by adding NaOH and HCl.

Sorption of fluoride ions is primarily governed by the fundamental aspects of dissolution of aluminum from the active phase under the given conditions. The degree of dissolution of aluminum from the active phase of the sorbent was determined in percent relative to the total amount of aluminum in the active phase and was denoted by $\beta = Al^{3+}_{\text{in sol.}}/Al^{3+}_{\text{act}}$. A study of the kinetics of leaching-out of aluminum from the active phase of the sorbent into solution and of the hydrolytic equilibrium at various pH values and concentrations of the F^- ion revealed the following pattern (Figs. 4, 5; Table 2). It was established that, at $4 < pH_{in} < 10$, the fraction of Al^{3+} ions that passed into solution in the absence of fluoride ions is 20% of their total amount in the active phase (Fig. 4). The pH of the equilibrium solution in this range is 4.8–5.0 (Fig. 5), which indicates that compounds that can be hydrolyzed by the acid or base mechanism, depending on pH_{in}, are contained in the sorbent.

Table 3. Change in the chemical composition of mine water after its treatment with the nepheline adsorbent

Characteristic of water	Content of indicated components, mg g^{-1}									pH
	Na^+	Al^{3+}	Ca^{2+}	Mg^{2+}	Cl^-	SO_4^{2-}	HCO_3^-	F^-	suspension	
Before treatment	600	1.8	0.7	1.0	5	10.5	20.1	60	465	10.15
After treatment to breakthrough	600	2.9	0.7	1.0	15.0	10.5	20.1	0.5	1.2	8.6

In the nepheline sorbent, these salts are, probably, hydrated aluminum oxychlorides. At pH < 3 and pH > 10, the active phase dissolves and the fraction of aluminum passing into solution increases dramatically. In the presence of fluoride ions in solution, the fundamental aspects of aluminum leaching-out from the sorbent vary over the entire range of pH values studied. At pH < 3 and pH > 10, the solubility of aluminum in the presence of fluoride ions somewhat decreases, although no sorption of the fluoride ion occurs. At $4 < pH_{in} < 10$, the solubility of aluminum from the active phase decreases substantially, and this decrease is the stronger, the higher the concentration of fluorine (Fig. 4, Table 2). In this pH range, sorption of fluoride ions is observed. The sorption capacity A (mg g^{-1}) is at a maximum at pH in the range from 9 to 10 (Table 2). The correlation between the sorption processes and the solubility of aluminum belonging to the active phase confirms the previously made assumption that aluminum-containing compounds are responsible for sorption processes involving fluoride ions.

The study performed made it possible to develop a technique for defluorination of mine and pit wastewater from plants for mining and dressing of phosphate and rare-metal raw materials at the Kola Peninsula. The mine wastewater from the Lovozero ore mining and processing combine contains up to 60 mg g^{-1} of fluoride ions at a high total salinity of the discharged water. The defluorination technique developed is based on synthesis and use of nepheline-containing sorbents in sorption filters with a fixed filtering bed, mounted as cartridges in gallery drains. The degree of purification of process wastewater to remove fluoride ions was 98.5–99.0% (Table 3). Spent sorbents are used to fill worked out mine spaces at mines of the Lovozero combine as a fluorine-containing additive to portland cement fill mixtures, which leads to an increase in the strength and water resistance of the fill [2].

CONCLUSIONS

(1) To prepare sorbents for defluorination of large-tonnage sewage formed in mining and processing of rare-metal and phosphate raw materials at the Kola peninsula, a procedure involving the use of a self-hardening dispersed system constituted by a nephe-

line-containing waste, hydrochloric acid, and water is suggested. The synthesis of a solid product exhibiting a sorption activity is governed by incongruent dissolution of nepheline at a high concentration of the solid phase in the initial dispersion (s : l = 3 : 1) and small value of α (7% anhydrous HCl relative to the amount required by stoichiometry for complete decomposition of nepheline). The adsorption-active phase formed under the given conditions is composed of the amorphous phase of aluminosilicates, which contains bound H_2O and HCl (removed at $T > 350°C$). Adsorption of fluoride ions presumably occurs via formation of sparingly soluble aluminosilicofluorides.

(2) The sorbent passed semicommercial tests at the Lovozero ore mining and processing combine. Implementation of the technique suggested in the study makes it possible to organize a closed cycle of processing of mined raw materials.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Characterization of the Electrical Conductivity of Concentrated Suspensions of Silica in Aqueous Solutions of Sulfuric Acid

E. P. Grishina and A. M. Udalova

Institute of Chemistry of Solutions, Russian Academy of Sciences, Ivanovo, Russia

Received February 3, 2005

Abstract—The electrical conductivity of stable concentrated suspensions of SiO_2 in aqueous solutions of sulfuric acid was studied as influenced by the concentration and size of SiO_2 particles.

Electrolytes are an important constituent of any electrochemical system. A particular group of electrolytes is formed by dispersed systems composed of a solid dispersed phase and a liquid dispersion medium, in which the part of conducting elements can be played by solid particles (e.g., particles of carbon black) and by a dispersion medium (electrolyte solutions). An example of their practical use in applied electrochemistry are thickened electrolytes for chemical power cells and tantalum electrolytic capacitors and, in particular, gel-like electrolytes based on silica and H_2SO_4 [1–7]. Use of thickened electrolytes makes it possible to create hermetically sealed chemical power cells and to improve the performance of these devices [1].

Electrolyte systems constituted by an aqueous solution of H_2SO_4 and silica exhibit thixotropy, i.e., ability to be reversibly liquefied under mechanical stress [1]. It was shown in [8] that the magnitude of thixotropy grows with the H_2SO_4 concentration. The duration of the thixotropic period strongly depends on the particle size of the dispersed phase and decreases as SiO_2 grains become larger [9]. After the mechanical load is removed, the viscosity of the thickened electrolyte increases and its electrical conductivity becomes lower because of structuring processes that occur in the heterogeneous system.

The electrical conductivity and its temperature dependence are important parameters of an electrolyte system, which strongly affect the performance of electrotechnical devices. In impregnation of silica gel with an already formed system of pores and capillaries, the amount of absorbed acid grows with the silica gel pore volume and H_2SO_4 concentration [10]. For a 5 M H_2SO_4 solution, the electrical conductivity was at a maximum at 40–60°C and remained high at 100°C owing to physically adsorbed water retained in silica gel pores.

The aim of this study was to examine the electrical conductivity of stable highly concentrated SiO_2 suspensions in strong aqueous solutions of H_2SO_4 in relation to the concentration of components, size of SiO_2 particles, and temperature.

EXPERIMENTAL

Suspensions were prepared from SiO_2 powders with grain sizes of 45–55 and 100–110 μm (which correspond to peaks in the particle size distribution curves, sedimentation analysis was made with Analysette 22 Fritsch Particle Sizer). According to [11], their specific surface area was approximately 0.9×10^3 and 0.4×10^3 $cm^2\ g^{-1}$, respectively. Prior to being used, the SiO_2 powder was dried at 120°C to remove physically adsorbed water [12].

H_2SO_4 solutions were prepared from chemically pure grade H_2SO_4 with a density of 1.83 $g\ cm^{-3}$ and distilled water.

The electrical conductivity was measured for stable suspensions (without any indications of sedimentation of particles of the dispersed phase) with an R5021 ac bridge under a polarizing cell voltage of 10 mV [13]. In accordance with the recommendation of [13], the design of the conductometric cell included platinum electrodes without platinum black to preclude damage inflicted on the porous coatings by solid SiO_2 particles in cell filling. In this connection, the frequency dependence of the cell resistance was measured at ac frequencies in the range 0.3–30 kHz, the frequency-independent resistance of the electrolyte system was determined, and the electrical conductivity χ was cal-

1070-4272/05/7807-1084© 2005 Pleiades Publishing, Inc.

culated using these data. The cell constant was determined with a 1 M KCl solution [14]. The electrical conductivity was measured under isothermal conditions in the temperature range 15–70°C, with temperature maintained constant within ±0.1°C. Tests with aqueous sulfuric acid solutions demonstrated agreement with published data within ±4%.

The temperature coefficient of electrical conductivity, α, was calculated from values of the electrical conductivity of the electrolyte systems under study, using the equation [15]

$$\chi_2 = \chi_1[1 + \alpha(t_2 - t_1)],$$

where χ_1 and χ_2 are the electrical conductivities of the suspension at temperatures t_1 and t_2, respectively.

The structural resistance factor β, which characterizes changes in the conducting properties of heterogeneous systems with a liquid dispersion medium and solid dispersed phase, was calculated using the equation [12]

$$\beta = R_s/R_e,$$

where R_s is the suspension resistance and R_e is the electrolyte resistance in the absence of a nonconducting solid phase.

The calculations were carried out with the electrical conductivity of liquid and thickened electrolytes at the same percentage concentration of sulfuric acid.

A stable state of the suspensions prepared, without any indications of settling, is reached in those cases when the content of the dispersed phase is high (about 30%). These systems exhibit a pronounced thixotropy and, presumably, are pseudogels [16]. Figure 1 shows the experimental values of the electrical conductivity of the systems under study as compared with the concentration dependence of χ of aqueous H_2SO_4 solutions, constructed using the data of [17]. These dependences show a weakly pronounced maximum at H_2SO_4 concentrations of 33–35 wt %, with, on the whole, a more than twofold decrease in χ, which is more pronounced for suspensions with larger SiO_2 particles. For electrotechnical and electronic devices, not only the electrical conductivity, but also the total resistance Z of an electrolyte system used, is important [18]: $Z = [R^2 + (1/\omega C)^2]^{1/2}$. Here R and C are, respectively, the ac resistance and capacitance of the cell; and $\varphi = 2\pi f$ (f is the ac frequency) (Table 1). The values of Z, calculated for suspensions with different initial sulfuric acid concentrations, were found to differ less widely than χ (Table 1).

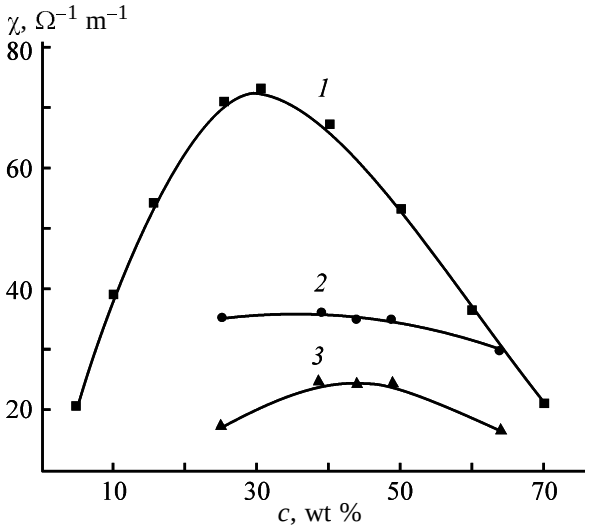

Fig. 1. Electrical conductivity χ of (*1*) H_2SO_4 [17] and (*2*, *3*) SiO_2 suspensions on its basis vs. H_2SO_4 concentration c (18°C). Suspension composition: 10 ml H_2SO_4 + 6.5 g SiO_2. SiO_2 particle size, μm: (*2*) 45–55 and (*3*) 100–110.

Introduction of SiO_2 into an H_2SO_4 solution leads to an increase in the dielectric loss tangent ($\tan\delta = \omega RC$ [18]), which is due to formation of a system of pores and capillaries in the thickened electrolyte (Table 2). Table 2 shows that the structural resistance factor grows with the particle size of the dispersed phase, with the thixotropic period becoming shorter,

Table 1. Values of Z in relation to the initial H_2SO_4 concentration and SiO_2 particle size. Suspension composition: 6.5 g SiO_2 + 10 ml H_2SO_4, 18°C, f = 10 kHz

SiO_2 particle size, μm	Z, Ω, at indicated H_2SO_4 concentration, wt %				
	25	39	44	49	64
45–55	10.2	9.7	9.3	9.0	8.9
100–110	13.7	10.5	9.3	9.7	9.8

Table 2. Effect of SiO_2 additives on the parameters χ and β of a thickened aqueous solution of H_2SO_4 and tanδ (f = 10 kHz) of the cell at 18°C

System, wt %	χ, Ω^{-1} m^{-1}	β	tanδ
H_2SO_4, 27.2	74.58	–	0.159
H_2SO_4, 27.2 + SiO_2 (45–55 μm), 31.5	34.8	2.14	0.173
H_2SO_4, 27.2 + SiO_2 (100–110 μm), 31.5	24.79	3.01	0.174

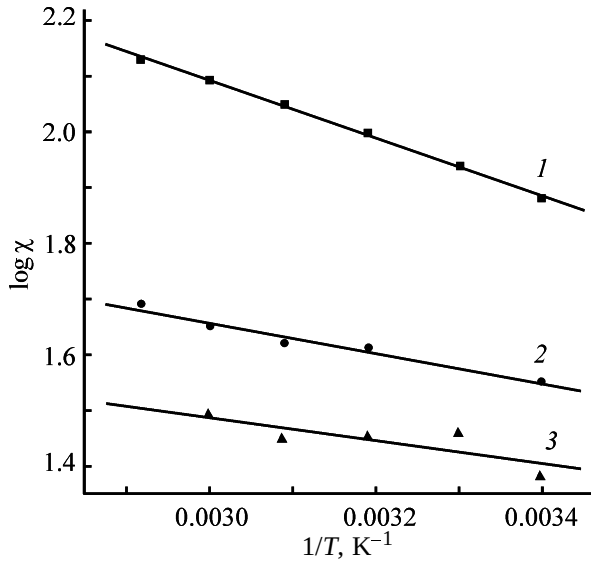

Fig. 2. log χ of the systems vs. 1/*T*. System, wt %: (*1*) 29.5H_2SO_4, (*2*) 29.5H_2SO_4 + 32.7SiO_2 (45–55 μm), and (*3*) 29.5H_2SO_4 + 32.7SiO_2 (100–110 μm).

as demonstrated in [9]. Presumably, large SiO_2 particles can form denser structures because the Coulomb repulsion forces between protonated surface groups of hydrated silica ($\equiv SiOH_2^+$) is overcome in this case more effectively [19].

The temperature dependence of the suspensions under study (Fig. 2), similarly to the case of aqueous H_2SO_4 solutions, is satisfactorily described by the Arrhenius equation [20]: $\chi = \alpha_\chi \exp(-E_{eff}/RT)$. Here, α_χ is the preexponential factor; E_{eff}, effective activation energy of electrical conductivity; R, universal gas constant; and T, temperature (K).

This made it possible to calculate E_{eff} for the systems under study, which were found to be comparable with E_{eff} for H_2SO_4 (Table 3).

Table 3. Values of α and E_{eff} of electrical conductivity of electrolytes based on H_2SO_4

System, wt %	α, Ω^{-1} m^{-1} deg^{-1}	E_{eff}, kJ mol^{-1}
H_2SO_4, 29.5%	0.0157 [21]	9.8 (calculated using the data of [22])
H_2SO_4, 29.5% + SiO_2 (45–55 μm), 32.7%	0.0076	5.1
H_2SO_4, 29.5% + SiO_2 (100–110 μm), 32.5%	0.0077	5.0

Table 3 shows that χ for the system constituted by a solid dispersed phase and a liquid dispersion medium is less sensitive to changes in temperature than an aqueous solution of H_2SO_4, and migration of charged particles and, primarily, H^+ is strongly hindered in the volume-porous structure formed by SiO_2 particles.

CONCLUSION

The electrical conductivity of thickened electrolytes is considerably lower than that of an aqueous solution of sulfuric acid. This is presumably due to appearance of siloxane and hydrogen bonds between SiO_2 particles in the systems studied and to formation of a system of pores and capillaries. The system of pores and capillaries formed by SiO_2 particles creates an additional resistance, and the structural resistance factor strongly depends on the particle size of the dispersed phase.

CATALYSIS

Influence of Regeneration Conditions on the Activity of the Catalyst for Oxidative Chlorination of Ethylene

S. A. Kurta, I. M. Mykytyn, and M. V. Khaber

Stefanik Precarpathian National University, Kalush, Ivano-Frankovsk oblast, Ukraine

Received October 13, 2004; in final form, March 2005

Abstract—The possibility of thermochemical regeneration of an industrial batch of a spent and partially deactivated catalyst to improve its activity and selectivity in oxidative chlorination of ethylene to give 1,2-dichloroethane was studied.

In the existing process for manufacture of vinyl chloride by a balanced scheme, 1,2-dichloroethane 1,2-$C_2H_4Cl_2$ is produced by direct and oxidative chlorination of ethylene. The oxidative chlorination process uses as a catalyst $CuCl_2$ supported by γ-Al_2O_3 [1]. The reaction requires a slight excess of C_2H_4 and occurs in accordance with the overall equation [2]

$$C_2H_4 + 2HCl + 0.5O_2 \rightarrow C_2H_4Cl_2 + H_2O + Q. \quad (1)$$

The main reaction is accompanied by side reactions: complete and incomplete combustion of C_2H_4 to give CO and CO_2 [3]:

$$C_2H_4 + 3O_2 \rightarrow 2CO_2 + 2H_2O, \quad (2)$$

$$C_2H_4 + 2O_2 \rightarrow 2CO + 2H_2O. \quad (3)$$

Other possible side reactions yield CCl_4, chloral, trichloroethane, trichloroethylene, etc. (a total of up to 2% relative to 1,2-$C_2H_4Cl_2$ obtained) [4].

In the course of the process, redox reactions may occur on the catalyst surface [5]:

$$C_2H_4 + 2CuCl_2 \rightarrow C_2H_4Cl_2 + 2CuCl, \quad (4)$$

$$2CuCl + 0.5O_2 + 2HCl \rightarrow 2CuCl_2 + H_2O. \quad (5)$$

The appearance of iron in the catalyst can be accounted for by the following reactions between the reactor walls and the catalyst:

$$Fe + CuCl_2 \rightarrow FeCl_2 + Cu, \quad (6)$$

$$4FeCl_2 + O_2 + 4HCl \rightarrow 4FeCl_3 + 2H_2O, \quad (7)$$

$$2FeCl_3 + 3H_2O \xrightarrow{\Delta} Fe_2O_3 + 6HCl. \quad (8)$$

EXPERIMENTAL

The study was performed on the newly created experimental laboratory installation that operates on real process gases (taken from the stage of ethylene oxychlorination at a shop of Lukor Private Company, Kalush) and adequately models the industrial process.

After two years of operation, the characteristics of the catalyst changed, which led to a decrease in its activity in oxychlorination. Therefore, our goal was to study the possibility of regenerating the oxychlorination catalyst and to analyze methods of such a regeneration under the conditions maximally similar to those used in the industry.

Experiments on catalyst regeneration were performed in two ways: by thermal treatment of the catalyst in a fluidized bed in oxygen-rich gas mixture or in air and by washing the catalyst in dichloroethane. In addition, the physicomechanical properties of catalyst samples before and after regeneration were studied.

The regeneration was performed in two modes: in air with heating to 180, 210, and 250°C and at increased oxygen content (20, 30, and 40 vol %) and nitrogen content of 80, 70, and 60 vol %, respectively. Simultaneously, analyses for the content of copper(I, II, total) chloride and iron(III) in the catalyst were made, with the bulk weight m_b, specific surface area S_{sp}, and pore volume V in the catalyst determined before and after regeneration. The data obtained are listed in the table.

In addition, the table lists data on washing of the catalyst to remove iron(III) chloride by extraction into dichloroethane and describes changes in the physicomechanical properties of the catalyst.

Physicomechanical properties of the catalyst for oxychlorination of ethylene before and after its regeneration in the air and oxygen-rich gas mixture. Regeneration duration 8 h

Catalyst	Cu(I, II) content, wt %	Fe(III) content, wt %	V, $cm^3\ g^{-1}$	S_{sp}, $m^2\ g^{-1}$	m_b, $g\ cm^{-3}$	Color
Fresh	4.2	0.12	0.36	140.0	1.02	Green
Without regeneration	4.15	0.30	0.26	74.5	1.31	Brown
After regeneration:						
180°C	4.10	0.30	0.26	78.5	1.29	Dark green
210°C	4.51	0.301	0.276	85.0	1.28	Green
250°C	4.585	0.30	0.286	99.0	1.27	Lettuce-green
Extraction in dichloroethane:						
80°C	4.75	0.254	0.276	101.2	1.12	Dark green
60°C (agitation)	4.58	0.255	0.269	100.0	1.12	Green
After regeneration with O_2/N_2, vol %:						
210°C 30/70	4.18	0.31	0.27	100.5	1.27	〃
210°C, 40/60	4.76	0.275	0.28	105.0	1.26	Light green
250°C, 40/60	4.77	0.26	0.32	108.0	1.25	Green

As the concentration of oxygen in the regenerating gas increases, the bulk weight of the catalyst decreases from 1.3 to 1.27–1.25 $g\ l^{-1}$, which is due to partial removal of by-products formed in the oxychlorination. This may be confirmed by a simultaneous increase in the pore volume in the catalyst, with this dependence being more pronounced at 250°C.

Gradually raising the temperature from 180 to 250°C in regeneration leads to a considerable increase in the pore volume from 0.25 to 0.3–0.33 $cm^3\ g^{-1}$, and this dependence is stronger at increased concentrations of oxygen, compared with the regeneration in air.

As seen from the table, the content of Fe(III) in the catalyst remains, on the whole, unchanged when the temperature is raised in air and decreases from 0.3 to 0.26 wt % in the case of regeneration in the oxygen-rich gas mixture. The best results, as regards the decrease in the amount of Fe(III), were obtained in extraction washing of the catalyst in boiling dichloroethane. In this case, the content of Fe(III) in the catalyst decreased to 0.25 wt %. Apparently, dichloroethane can dissolve $FeCl_3$ [1], which makes it possible to use this method to partly diminish the amount of Fe(III) formed on the oxychlorination catalyst and poisoning it.

After regeneration for 8 h at a prescribed temperature, the activity and selectivity of the regenerated catalyst in oxidative chlorination of C_2H_4 was studied in the standard operation mode: 225°C, $C_2H_4 : HCl : O_2 = 1.07 : 2 : 0.7$, flow rate of the circulation gas (60% CO_2) 72–80 $l\ h^{-1}$, temperature of the quenching column 87–100°C, pressure in the system 7–12 kPa, total flow rate of exhaust gases 76–86 $l\ h^{-1}$, and experiment duration 1 h. Additionally, the circulation gas was analyzed for the content of CO, CO_2, C_2H_4, and O_2 in the course of an experiment. After the experiment, the weight of the dichloroethane formed was determined, its purity and the content of microimpurities were analyzed chromatographically, and the content of unchanged HCl was measured. After that, the conversion in terms of hydrogen chloride and C_2H_4 and the yield of dichloroethane in percent relative to the theoretical value before and after regeneration in air and in oxygen-rich gas mixture were calculated.

Figure 1 (curves *1*, *2*) shows that the conversion of hydrogen chloride remains unchanged (~98.5%) upon regeneration of the catalyst in air and O_2. At the same time, the conversion of C_2H_4 upon regeneration (curves *3*, *4*) grows from 89 to 94–95% as the content of O_2 in the regenerating gas increases from 20 to 40%, with this trend being particularly pronounced at 250°C.

Figure 2 shows how the combustion of C_2H_4 on the catalyst subjected to regeneration depends on the content of O_2 in the regenerating gas at 210 and 250°C.

After regeneration of the catalyst, the combustion of C_2H_4 in synthesis of 1,2-dichloroethane (Fig. 2)

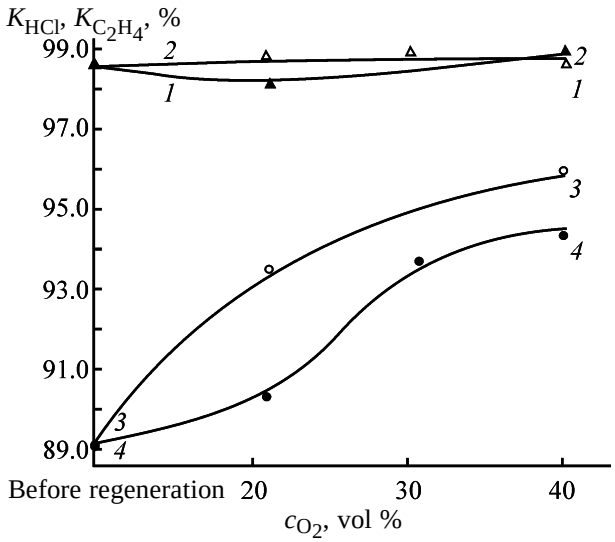

Fig. 1. Conversion of (*1*, *2*) HCl (K_{HCl}) and (*3*, *4*) C_2H_4 ($K_{C_2H_4}$) on a regenerated catalyst vs. the content of oxygen, c_{O_2}, in the regenerating gas. Temperature, °C: (*1*, *3*) 210 and (*2*, *4*) 250.

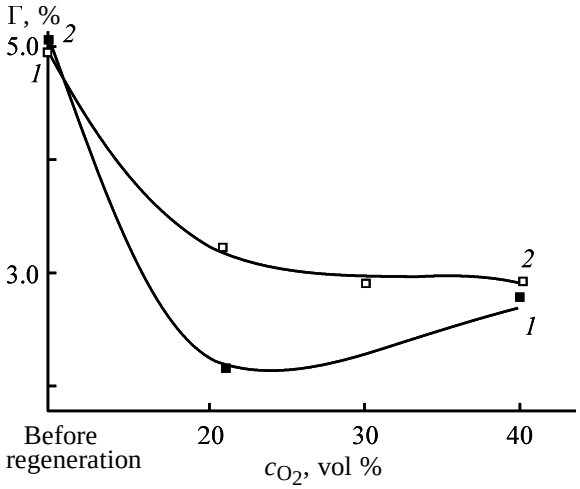

Fig. 2. Combustion Γ of C_2H_4 on a regenerated catalyst vs. the content of oxygen, c_{O_2}, in the regenerating gas. Temperature, °C: (*1*) 250 and (*2*) 210.

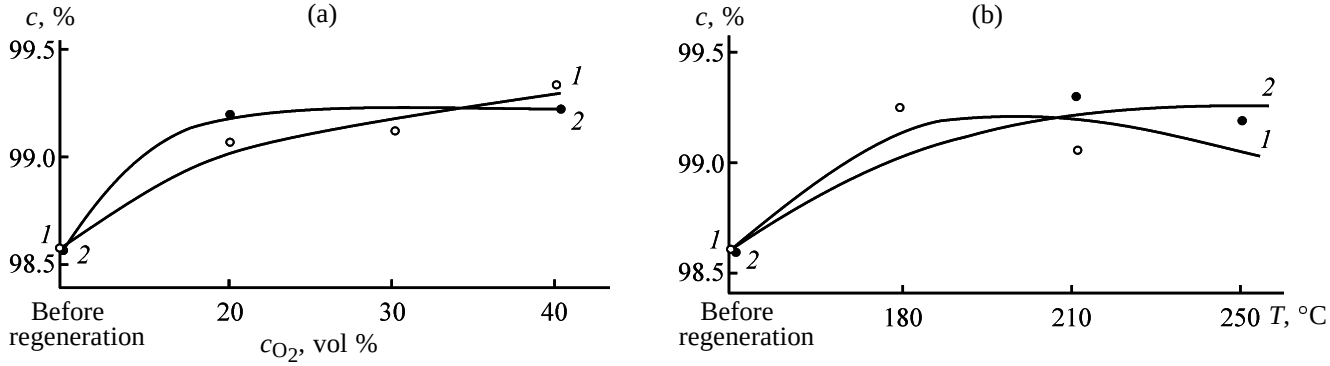

Fig. 3. Purity *c* of dichloroethane obtained on a regenerated catalyst vs. (a) content of oxygen, c_{O_2}, in the regenerating gas and (b) temperature *T* of the catalyst regeneration. (a) Temperature, °C: (*1*) 210 and (*2*) 250. (b) Medium: (*1*) air and (*2*) 40 vol % oxygen; the same for Fig. 4.

decreases from 5 to 2.5–3% in proportion to an increase in the content of O_2 in the regenerating gas. The same trend is observed on raising the regeneration temperature from 180 to 210 and 250°C.

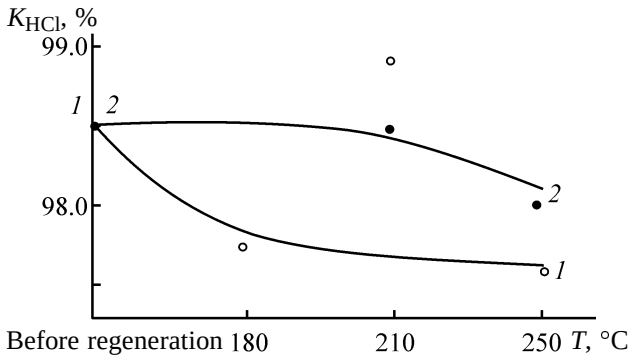

Fig. 4. Conversion of HCl, K_{HCl}, on a regenerated catalyst vs. the temperature *T* of catalyst regeneration.

Figures 3a and 3b show how the purity of dichloroethane in synthesis of 1,2-dichloroethane depends on the content of O_2 in the regenerating gas and on the temperature of catalyst regeneration. It can be seen that the purity of dichloroethane grows from 98.6% before regeneration to 99.5% after regeneration as the temperature is raised or the content of O_2 in the regenerating gas is made higher. In this case, the tendency toward an increase in the purity of dichloroethane is more pronounced when the regeneration is performed in an oxygen-rich gas mixture (Figs. 3a, 3b; curves *2*).

Figure 4 shows how the conversion of HCl in the catalytic synthesis of 1,2-dichloroethane depends on the temperature of the catalyst regeneration in air and in an oxygen-rich gas mixture (Fig. 4, curves *1*, *2*). It can be seen that the conversion of HCl decreases

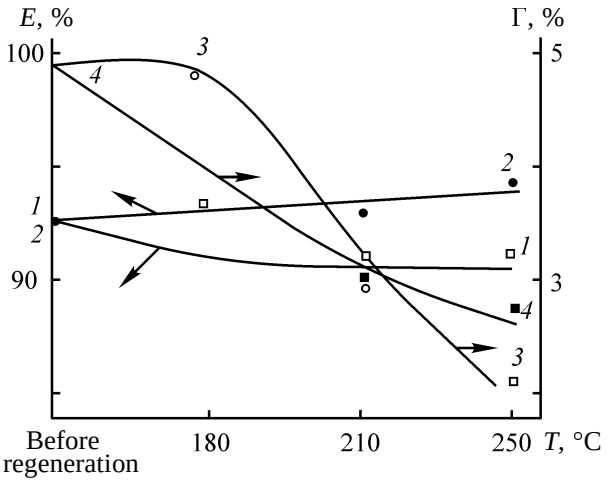

Fig. 5. (*1, 2*) Efficiency E of C_2H_4 conversion and (*3, 4*) C_2H_4 combustion Γ on a regenerated catalyst vs. the temperature T of catalyst regeneration. Medium: (*1, 3*) air and (*2, 4*) oxygen-rich gas mixture; the same for Fig. 6.

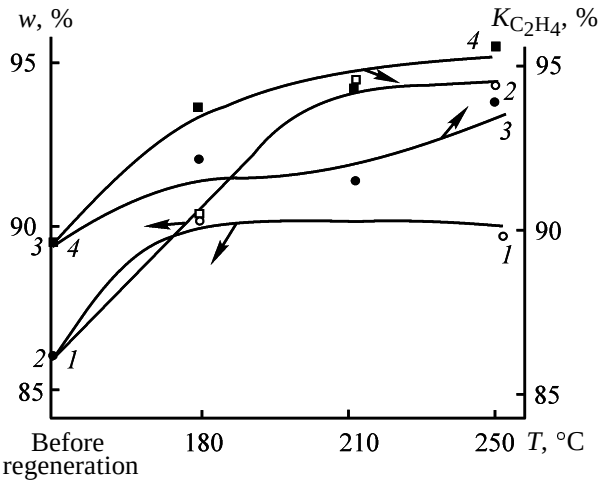

Fig. 6. (*1, 2*) Yield w of dichloroethane (relative to the theoretical value) and (*3, 4*) C_2H_4 conversion $K_{C_2H_4}$ on a regenerated catalyst vs. the temperature T of catalyst regeneration.

from 98.5 to 97.5–98%. This decrease is more pronounced in the case of regeneration in air, compared with that in the oxygen-rich gas mixture.

The increase in the conversion of C_2H_4 and decrease in its combustion after regeneration is understandable, because they are associated with partial restoration of the structure and activity of the catalyst after its thermochemical treatment in an O_2 atmosphere, which is due to oxidation of the catalyst surface and removal of tar and carbon black therefrom. This is, in turn, confirmed by the improvement of the physicomechanical properties of the catalyst, namely, by an increase in the specific surface area and pore volume and decrease in the bulk weight (see table).

Figure 5 shows how the efficiency of C_2H_4 conversion (curves *1, 2*) and C_2H_4 combustion (curves *3, 4*) in synthesis of 1,2-dichloroethane on a regenerated catalyst depend on the temperature of catalyst regeneration in air and an oxygen-rich gas mixture. It can be seen that the efficiency of C_2H_4 conversion into dichloroethane grows from 92.5 to 93–94% as the regeneration temperature increases from 180 to 250°C in the oxygen-rich has mixture (Fig. 5, curve *2*). Simultaneously, the combustion of C_2H_4 decreases from 5% before regeneration to 2–2.5% after regeneration as the temperature of catalyst regeneration is increased to 250°C.

Additionally, we calculated the yield of dichloroethane in synthesis of 1,2-dichloroethane (relative to the theoretical value) and its dependence on the temperature of catalyst regeneration (Fig. 6, curves *1, 2*). These data are compared with the dependence of the ethylene conversion in synthesis of 1,2-dichloroethane on the temperature of the catalyst regeneration (Fig. 5, curves *1, 2*) in the air and oxygen-rich gas mixtures. Figure 5 shows that the C_2H_4 conversion and yield of dichloroethane relative to the theoretical value tend to increase on a regenerated catalyst as the temperature of catalyst regeneration is raised. In this case, the C_2H_4 conversion increases by 5–7% upon regeneration, the yield of dichloroethane also grows by 5–7%. This confirms once more the fact that the catalyst activity in C_2H_4 conversion into dichloroethane increases after regeneration. The yield of by-products, trichloroethane, trichloroethylene, and others, does not increase in the case of a partly regenerated catalyst, and the combustion of C_2H_4 is suppressed.

CONCLUSIONS

(1) A partly deactivated catalyst for C_2H_4 oxychlorination can be regenerated. The regeneration in an oxygen-rich gas mixture (30–40 vol % O_2) is more effective than that in air (20 vol % O_2) under the same treatment conditions (180–210–250°C, 8 h).

(2) The regeneration improved the physicomechanical properties of the catalyst, namely, increased the pore volume and the specific surface area (by 10–20%) and decreased the bulk weight, and thus enhanced the activity and selectivity of a regenerated catalyst in oxychlorination of ethylene into 1,2-dichloroethane.

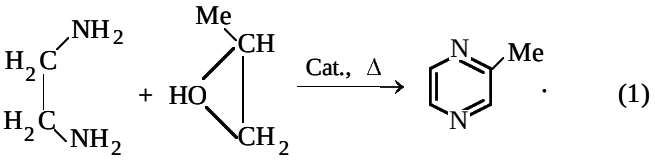
CATALYSIS

Synthesis of 2-Methylpyrazine on Ternary Oxide Catalysts

A. D. Kagarlitskii, L. A. Krichevskii, and D. S. Balpanov

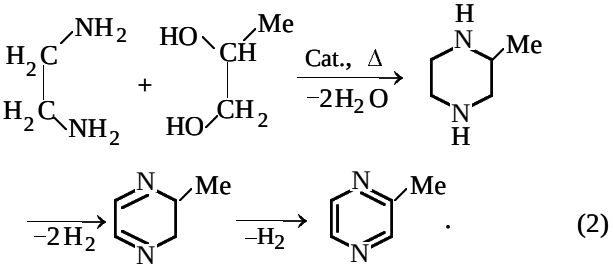


Institute of Phytochemistry, Ministry of Education and Science of the Kazakhstan Republic, Karaganda, Kazakhstan

Received July 20, 2004; in final form, April 2005

Abstract—Synthesis of 2-methylpyrazine by cyclocondensation of ethylenediamine with 1,2-propylene glycol in the presence of zinc–molybdenum–chromium catalysts was studied.

2-Methylpyrazine (MP) is used as an intermediate in synthesis of pyrazine-2-carboxamide (the basis of Pyrazinamide antituberculous drug [1]), but the existing procedures of its preparation are not perfect.



MP can be prepared by the reaction of propylene oxide with ethylenediamine (EDA) in methanol in the presence of zinc–molybdenum–chromium oxide catalyst (yield 63%) [2]:

(1)

The similar process was developed by the Prikladnaya Khimiya Russian Scientific Center [3]. An important draw-back of this process is the use of highly explosive initial products (propylene oxide and hydrogen) and of toxic methanol as a solvent.

From the viewpoint of industrial safety and availability of fairly cheap starting compounds, the catalytic dehydrocyclization of EDA with 1,2-propylene glycol (1,2-PG) is a more promising route to MP:

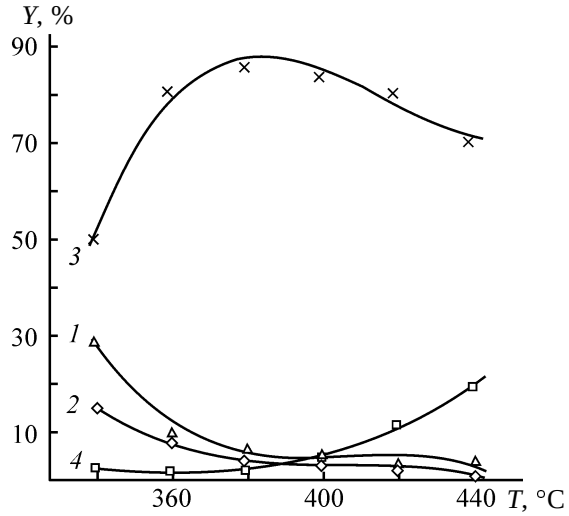
(2)

The attempts to use Al_2O_3 as a catalyst of this process failed due to its low selectivity [4]. However, the purity of alkylpyrazines was improved and the yield of MP was increased to 64% with zinc oxide catalysts [5–7].

In dehydrocyclization of EDA with 1,2-PG on the Pd/Zn–Cr–O catalyst (Zn : Cr = 1 : 3), the limiting stage of the process is the reaction of 1,2-PG adsorbed on the catalyst surface with EDA supplied with the gas phase to form MP (387°C) [8]. The system EDA–1,2-PG is more complicated than that described by the reaction equation, since synthesis of MP is accompanied by formation of by-products [9].

Initially this process was studied in the presence of granulated binary zinc–molybdenum oxide catalysts. The highest yield (75%) was obtained with the catalyst of the composition ZnO : MoO_3 = 1.0 : 0.3 (granule size 1.0–2.0 mm) [10].

EXPERIMENTAL



To increase the yield of the target product through decreasing the amount of polymeric deposits at the catalyst surface, it was suggested to add chromium(III) oxide to binary oxide systems, since Cr_2O_3 has high oxidation and dehydrogenation power. In addition, it was assumed that, owing to its characteristics, it will enhance the mechanical strength of the catalyst granules during thermal drying.

Table 1 shows how the ratio of components of

Table 1. Yield of MP at various catalyst compositions. Temperature 460°C, contact time 3.3 s

mixed zinc–molybdenum–chromium oxide granulated catalyst affects the MP yield.

The yield of the target product on the catalysts tested was from 65 to 82%. When the content of zinc and molybdenum(III) oxides in these catalysts corresponded to the molar ratio of 1.0 : 0.3, they lost their activity and selectivity in 7–10 h, whereas at the molybdenum(III) oxide content of 0.4 and 0.5 mol per mole of zinc oxide they operated without regeneration for a period from 21 to 27 h depending on the amount of chromium(III) oxide added.

Table 3. Yield of MP at various time τ. Temperature 390°C, contact time 4.4 s

τ_c, s	Unchanged, wt %		Yield, %	
	EDA	1,2-PG	PCPs	MP
10	16	2	5	77
20	8	3	3	86
30	4	5	1	90
40	2	8	2	87
50	1	9	5	85
60	5	11	10	74

The best result were obtained with the catalyst of the composition $ZnO : MoO_3 : Cr_2O_3$ = 1.00 : 0.40 : 0.15.

The yield of MP exceeding 70% is reached on this catalyst in a wide temperature range, from 370 to 430°C, and the highest yield (80–90%), at 380–395°C, which is a relatively low temperature for these reactions (see figure).

As regards contact time, it can be varied in a wide range (from 1.5 to 7.5 s), and in this case the yield of MP can be no less than 65% due to decreasing content of polycondensation products (PCPs) in the catalyzate (Table 2). In the range 4.4–6.0 s, the yield of the target product reaches 80–88%.

Evaluation of the working time of the catalyst showed that the catalyst is able to operate for 55–57 h without noticeable variation of selectivity with respect to the target product, ensuring its yield as high as 85–90% (Table 3).

The $ZnO : MoO_3 : Cr_2O_3$ = 1.0 : 0.4 : 0.15 catalyst was prepared by mixing zinc, molybdenum(III), and chromium oxides to obtain a homogeneous mass. Granules were prepared from this mixture on a pan granulator with adding 5% NaOH and 10% aqueous polyvinyl alcohol for strengthening. The granules were sifted through a sieve, and a 1.0–2.0-mm fraction was collected. Then, the granules were dried for 3 h at 105°C. Dry granules were promoted with 3% aqueous $MnSO_4$ and 1% H_3PO_4. After promotion, the granules were subjected to air calcination for 5 h with a stepwise increase in temperature in the range 100–150, 150–250, 250–350, and 350–600°C. The final catalyst consists of greenish porous granules.

MP was synthesized on an installation equipped with a stainless steel flow-type tubular reactor (tube diameter 20 mm, length 80 cm), in which 150 cm^3 of the catalyst was placed. An equimolar mixture of EDA with 1,2-PG, diluted with water (20 vol %) and preliminarily passed through a vapor heater with a temperature of 280–300°C, was fed to the reactor. The experiments were carried out for 1 h. The reaction products were cooled in a trap system. In a typical synthesis, a mixture containing 67 ml of EDTA (1 mol), 73 ml of 1,2-PG (1 mol), and 28 ml of water

(1.56 mol) was fed into the reaction mixture with a dosing pump at a rate of 0.79 ml min^{-1}. MP was isolated from the reaction mixture by distillation on a column in the form of an azeotropic mixture with water (bp 97°C/737 mm Hg, MP content 45% [11]), from which the target product was extracted with chloroform or diethyl ether. After drying and removal of the solvent, MP was extracted by distillation on a column; a fraction with bp 133–135°C was collected. After the second distillation, MP had the following characteristics: bp 135°C, n_D^{20} 1.5050, d_4^{20} 1.030, which is in good agreement with published data [12].

The quantitative content of the unchanged starting components and the reaction product was determined by gas–liquid chromatography (Chrom-5, flame-ionization detector, glass column 3.5 m long with 0.3 cm inner diameter, packed with Chromaton NAW-HMDS and 5% SE-30 silicone elastomer); column temperature 150°C, vaporizer temperature 180°C, detector temperature 190°C; carrier gas argon, flow rate 20 ml min^{-1}.

Quantitative analysis was performed using benzonitrile as internal reference.

CONCLUSION

The catalyst Zn : MoO_3 : Cr_2O_3 = 1.00 : 0.40 : 0.15 was developed. The use of this catalyst in cyclocondensation of ethylenediamine with 1,2-propyleneglycol allows preparation of 2-methylpyrazine in 85–90% yield. The working life of the new catalyst before regeneration reaches 50–55 h, and the total working life of the catalyst is 400–450 h.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Kinetic Characteristics of Reverse-Osmosis Separation of an Aqueous Solution of Aniline in a Flat-Frame Apparatus

V. L. Golovashin, S. I. Lazarev, and V. V. Mamontov

Tambov State Technical University, Tambov, Russia

Received April 5, 2005

Abstract—Reverse-osmosis separation of an aqueous solution of aniline on a flat-frame reverse-osmosis installation was studied for two types of industrial polymeric membranes in relation to the concentration and pressure of the solution in the intermembrane channel. The behavior of the main kinetic characteristics of separation was analyzed and explained for different physical conditions of the process.

The goal of this study was to examine membrane methods in separation of aqueous solutions of low-molecular-weight organic substances in manufacture of intermediates of organic synthesis and in treatment of wastewater from chemical and related plants. An aqueous solution of aniline, which is present in many kinds of industrial solutions and wastewater from production of dyes, served as a model.

Our studies were aimed to reveal the influence exerted by the concentration of a solute and the pressure on the specific flux of a solvent and on the retention factor of the membranes. The experiments were performed on an installation with a closed circulation of the solution in a two-chamber cell of the flat-frame type with industrial composite membranes of MGA-95K and OPM-K brands (manufactured by Vladipor Joint-Stock Company, Vladimir, Russia). The flow velocity of the solution in the intermembrane channel was 0.4 m s^{-1}, and the solution temperature, 22°C. The model solution was prepared using aniline of pure grade and distilled water. The experiments were performed using the procedure and apparatus described in [1].

The retention factor of membranes depends on a large number of factors (material of a membrane, nature of a solute and its concentration, working pressure, temperature, hydrodynamic situation over the membrane, etc.) [2–6] and is an integral quantity.

The dependences of the retention factor of the membranes on the concentration of the solution under study and on the working pressure are shown in Fig. 1. It can be seen that the aniline retention factors and the trends in their variation with the solution concentration strongly differ for the membranes studied (MGA-95K and OPM-K) and have negative and posi-

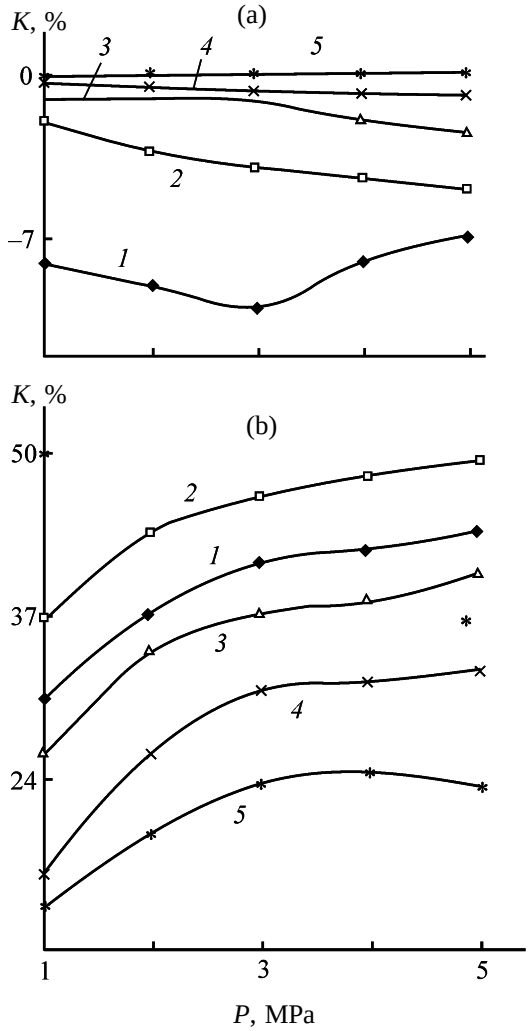

Fig. 1. Retention factor K of (a) MGA-95K and (b) OPM-K membranes for an aqueous solution of aniline vs. pressure P. Concentration of the starting aniline solution (kg m^{-3}): (*1*) 0.507, (*2*) 3.85, (*3*) 7.0, (*4*) 9.63, and (*5*) 14.18; the same for Fig. 2.

tive values. The manner in which the retention factor varies with the solution concentration and pressure applied can be explained using the hypothesis of a solution flow across the membrane as a flow through pores with the potential barrier overcome by the solute [6]. This hypothesis is an outgrowth of the sorption-sieve hypothesis [7, 8].

In the case of the MGA-95K membrane, the retention factor for an aqueous solution of aniline varies with concentration as follows: as the aniline concentration grows, the retention factor of the membrane passes from negative to zero values (Fig. 1). This effect can be understood on the basis of the following considerations: being a polar low-molecular-weight organic compound [9], aniline can form hydrogen bonds with the material of the MGA-95K membrane, and, therefore, a considerable amount of aniline is sorbed on its surface and within its pores (the content of aniline in the near-membrane layer becomes higher than that in the solution bulk, which is indicated by previous studies of sorption [10]). Aniline is mainly transferred across the membrane surface by a convective flow, with a negative retention factor observed in this case. A further increase in the concentration leads to filling of the membrane pores with aniline, with the "finest" pores blocked. The concentration of water decreases and the convective flow rate also becomes lower, with the result that the retention factor of the membrane becomes zero. It is known that, for low-molecular-weight organic substances, there exist narrow concentration ranges of aqueous solutions [11, 12] in which physicochemical parameters of these solutions (viscosity, density, surface tension) have an extremum. Probably, this range for the aqueous solution of aniline is 2–4 kg m^{-3}, and, therefore, the retention factor for the OPM-K membrane has a maximum within this range. As the concentration increases further, the retention factor decreases. At the same time, it should be taken into account that the properties of the solution within fine pores of the membrane may strongly differ from those in the free volume and be dependent on the sign and magnitude of the surface charge. As a result, the energy of interaction between the solute molecules and the surface of membrane pores changes (and, consequently, so does the distribution coefficient), which leads to a change in the retention factor of the membrane.

The above analysis is also valid for the OPM-K membrane. However, it is necessary to take into account a different pore radius distribution in the active layer of the membrane and its higher porosity, which probably leads to higher retention factors (which are all in the positive region), compared with the MGA-95K membrane. It should be noted that the substance is transferred across the membrane by two flows, convective and of the diffusion type. The data previously obtained in determining the diffusion permeability indicated that the diffusion transfer of the substance predominates, because the diffusion permeability coefficient has large values [13].

Table 1. Coefficients for calculation of the retention factor of membranes and the specific flux of the solvent

Membrane	Retention factor			Specific flux	
	k_1	k_2	k_3	k_1	n
MGA-95K	0.29	0.058	5	–0.5	0.6
OPM-K	0.02	1.1	0.1	1.9	–0.06

The retention factor of the membranes was calculated using formula (1) reported in [6]. In this formula, the diffusion coefficient in the membrane is replaced with the ratio of the diffusion permeability of the membrane to the distribution coefficient, and the thickness of the diffusion boundary layer, with the expression taken from [16]:

$$K = 1 - \{1 + [1/(k_d - k_1) - 1][1 - \exp(-J\delta k_d k_2/P_d)] \times \exp[J \times 0.0021 k_3/(D_0 w^{1/2})]\}^{-1}, \quad (1)$$

where J is the specific flux of the solvent across the membrane ($m^3\ m^{-2}\ s^{-1}$); w, solution flow velocity in the intermembrane space ($m\ s^{-1}$); P_d, diffusion permeability of the membrane ($m^2\ s^{-1}$); δ, membrane thickness (m); D_0, diffusion coefficient of aniline in solution ($m^2\ s^{-1}$); k_d, distribution coefficient; and k_1–k_3, numerical coefficients.

The coefficients for the solution and membranes studied are listed in Table 1. The disagreement between the results of calculation by formula (1) and the experimental data, listed in Table 2, does not exceed ±20%.

Let us then consider the influence exerted by the solute concentration on the specific flux of the solvent across the membrane. The dependences of the specific solvent flux across the MGA-95K and OPM-K membranes on the concentration of the solution under study and the working pressure are plotted in Fig. 2. It can be seen that the specific solvent flux across the membrane strongly depends on the concentration and

working pressure. The specific flux of the solvent across a membrane depends on a number of factors: nature of membranes and solutions, solute concentration, solution temperature, working pressure, hydrodynamic situation over the membrane, etc. [1–5].

As the concentration of aniline in the working solution increases, the specific flux of the solvent across the membrane markedly decreases. Probably, the key factor for the solution studied is the interaction of the solute with the material constituting the active layer of the membrane. Being a strongly polar low-molecular-weight organic substance, aniline is sorbed by the surface of pores in the membrane, which makes
