narrower the free cross section of the pores. As the concentration of the external solution grows, total "blocking" of the finest pores becomes possible, which leads to a substantial decrease in the specific flux of the solvent across the membrane. It should be noted that the specific flux of the solvent is affected not only by the decrease in the cross section, but also by an increase in the osmotic pressure of the solution and, as a consequence, by the osmotic flow of the solvent. For an aqueous solution of aniline, which has a low osmotic pressure, the influence of the osmotic flow is insignificant.

As the working pressure is raised from 1.0 to 5.0 MPa, the specific flux of the solvent across the membrane becomes higher. This can be explained as follows. Being the driving force of the reverse osmosis, the pressure is directly related to the specific flux of the solvent across membranes. Therefore, an increase in pressure in the course of reverse osmosis (in the absence of sedimentation or structural changes of the membrane) always leads to a rise in the specific flux of the solvent across the membrane.

The following formula, based on the known expressions from [2, 15, 16], was suggested for calculating the specific flux of the solvent across the membrane as a function of the solution concentration and pressure applied:

$$J = (k\Delta P - P_{osm}\Delta c/\delta)\exp(k_1 c^n), \quad (2)$$

where k is the water-permeability coefficient of the membrane ($m^3\ m^{-2}\ s^{-1}\ Pa^{-1}$); ΔP, pressure applied (Pa); P_{osm}, osmotic permeability of the membrane ($m^5\ kg^{-1}\ s^{-1}$); Δc, difference of the concentrations in the solution bulk and in the permeate ($kg\ m^{-3}$); δ, membrane thickness (m); c, concentration of aniline in the solution bulk ($kg\ m^{-3}$); and k_1 and n, numerical coefficients.

The values of the coefficients for the membranes and solutions studied are listed in Table 1.

The experimental values of the specific flux of the solvent across the membrane and those calculated by formula (2) are listed in Table 2. It can be seen that the experimental and calculated values of J are in rather good agreement (±20%).

CONCLUSIONS

(1) The influence exerted by the concentration of an aqueous solution of aniline and by the pressure applied on the retention factor of MGA-95K and OPM-K membranes was studied. It was established that, as the concentration of aniline in the solution is raised, the retention factor of the MGA-95K membrane increases and shows an inflection point. The retention factor of the OPM-K membrane grows with the concentration of aniline.

(2) The dependence of the specific flux of the solvent across the membrane on the pressure applied and on the solute concentration was studied. It was found that the specific flux of the solvent across the OPM-K membrane markedly exceeds that across the MGA-95K membrane (all other conditions being the same).

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Preconcentration of Simazine from Aqueous Solutions with an Immunosorbent and Its Quantitative Determination

Abstract—The optimal conditions were found for sorption preconcentration of Simazine (herbicide of *sym*-1,3,5-triazine group) from aqueous solution with immobilized antibodies. The main characteristics of immobilized antibodies as sorbents for Simazine were determined.

Virtually all the pesticides applied in agriculture are potential environmental pollutants. Among them Simazine (SM) belonging to the *sym*-1,3,5-triazine group (ST) of herbicides is widely used in agricultural practice. Its content in water, soils, and atmosphere must not exceed the permissible level established by the corresponding regulations [1, 2]. Simazine exhibits high mobility and chemical stability in soils irrespective of the climatic zone. Owing to the above-noted features and large-scale application, SM is the most frequently detectable pesticide in ground and surface water. Therefore, the development of sensitive and selective methods for determining herbicides of the triazine group in the environment and food is an urgent problem.

Microamounts of herbicides (including those of the triazine group) are commonly determined by various kinds of chromatography: thin-layer (TLC) [3], gas–liquid (GLC) [4], high-performance liquid (HPLC) [5], and micellar electrokinetic (MEC) [6]. Although chromatography ensures high sensitivity and selectivity of herbicide determination, this technique requires complicated and labor-consuming pretreatment of samples, highly skilled staff, and expensive equipment.

The demand for more efficient methods for analysis of soils and water for microamounts of *sym*-triazines stimulated development of immunochemical analytical technique based on specific complexation of the herbicide with an antibody (AB). This technique is characterized by very high sensitivity and selectivity, simplicity of sample pretreatment (in some cases, it is not required at all), promptness, and also low cost of equipment and easy automation. Various types of immunochemical technique are used today for determining microamounts of Simazine-group herbicides: polarization-fluorescent [7], chemiluminescence [8], and solid-phase enzyme-mediated immunoassay (EIA), ELISA [9].

A promising technique for analysis of pesticide microamounts is based on their preconcentration on solid sorbents followed by quantitative determination by chromatography [10], mass spectrometry [11], microwave absorption [12], and capillary electrophoresis [13]. These methods were used for determining pesticides of various kinds: phenylureas, triazines, organochlorine and organophosphorus compounds.

A combination of immunochemical analytical technique with solid-phase preconcentration allows development of more sensitive and selective techniques for determining various physiologically active compounds. In this relation, the sorption of herbicides on immobilized antibodies (IAB) shows much promise. These processes, however, are poorly understood today.

To develop an efficient immunosorption method for selective determination of herbicides, e.g. Simazine, in a multicomponent system, we must optimize conditions for their immunosorption recovery from aqueous solutions and determine the main physicochemical characteristics of IAB as immunosorbent.

Our version of immunochemical determination of SM is based on its selective sorption concentration from aqueous solution on immobilized antibodies followed by ammetric determination with a biosensor based on choline esterase. The determination of Simazine with this technique includes the following steps: formation of a sorption complex between immobilized antibody and Simazine on the immunosorb-

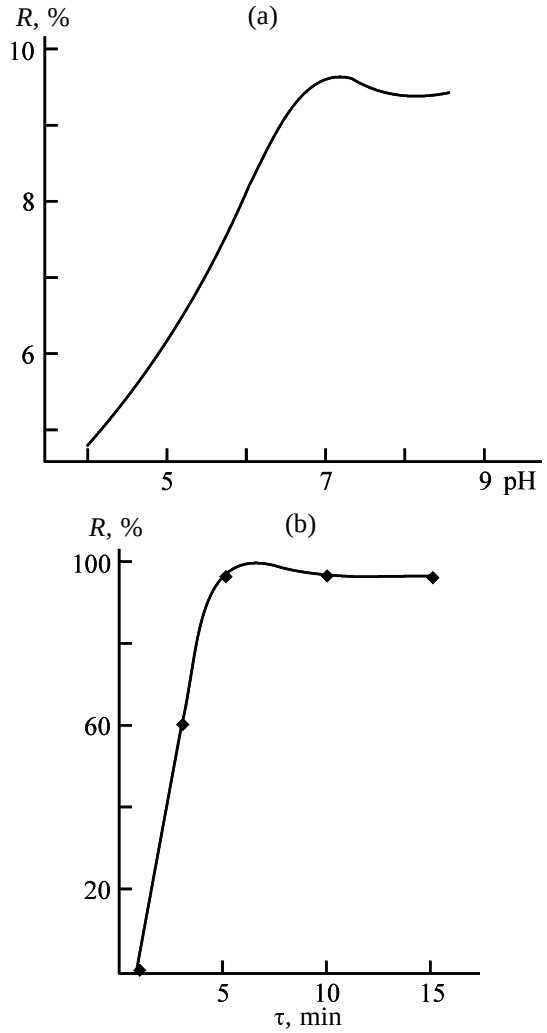

Fig. 1. Degree of Simazine sorption recovery *R* with IAB as a function of (a) pH and (b) contact time τ.

ent surface, breakdown of this complex with the release of Simazine, and ammetric determination of the released Simazine with a biosensor.

The Simazine content was determined ammetrically with a choline esterase (CE) biosensor (ACEBS) consisting of enzyme (choline esterase), appropriate substrate, and mercury electrode. The voltammetric measurements were carried out at cathodic polarization voltage of –0.55 V corresponding to the reversible reduction of Hg(I, II) mercaptide formed by the reaction of thiol with metallic mercury as electrode material [14].

There are different viewpoints on the problem of how herbicides of the triazine group affect the choline esterase catalytic activity. It was found [15] that these compounds inhibit CE with the inhibition factor of 27.7±5.3%. We found that, under identical conditions, Simazine microamounts (10^{-6}–10^{-9} M) also inhibit CE irrespective of its state (native or immobilized in nitrocellulose film). As a result, in the presence of SM the analytical signal of the biosensor (electrical current at polarization voltage $E = -0.55$ V produced by reduction of a redox-sensitive product of hydrolysis of sulfur-containing substrate) decreases.

Thus, Simazine is a relatively weak nonspecific inhibitor for CE. This inhibiting effect may be caused by interaction of SM with hydrophobic parts of the enzyme, making the active sites of choline esterase less accessible to substrate molecules.

We found that Simazine inhibits the enzymatic reaction in the enzyme–substrate system (butyrylthiocholine iodide–choline esterase immobilized in nitrocellulose film) by 27.6±0.6%. This inhibiting effect can be used for quantitative determination of Simazine with an ACEBS.

Mechanism of Simazine preconcentration by sorption on immobilized antibodies. The efficiency of sorption recovery and preconcentration of Simazine with an immunosorbent depends on its physicochemical properties. In our experiments we determined the main characteristics of recovery of Simazine from aqueous solutions with the biosorbent based on immobilized AB.

The degree of Simazine sorption recovery *R* (%) was determined from the residual Simazine content in the aqueous phase after its contact for a certain time (with stirring) with the antibody immobilized in a nitrocellulose film. The *R* value was calculated as the percent ratio of the Simazine amount sorbed on immobilized antibody to the Simazine amount in the initial solution.

To optimize conditions for the sorption preconcentration of Simazine and its quantitative determination, we examined the dependence of *R* (%) on pH (Fig. 1a). Figure 1a shows that in the pH range 7–8.6 Simazine is practically completely recovered from aqueous solution with IAB in single phase contact. In this pH range, choline esterase shows high enzymatic activity in the absence of the pesticide, and the pesticide is chemically stable. Under these conditions, IAB exhibits very high sorption power for Simazine, and, therefore, the repeated treatment of the solution with a fresh portion of the immunosorbent virtually does not affect the biosensor response.

In our experiments, the contact time was varied from 1 to 15 min. Figure 1b shows that, after 5-min contact of the immunosorbent with Simazine, the formation of the sorption complex SM–IAB is com-

plete. Longer contact does not noticeably affect the sorption of Simazine.

The sorption capacity of IAB for Simazine was determined from the Simazine distribution between the immunosorbent and aqueous phase at various Simazine contents.

Figure 2 shows the sorption isotherm of Simazine on immobilized antibodies [sorption capacity SC of Simazine was calculated per unit of the film surface area ($\mu g\ cm^{-2}$)]. It is seen that this isotherm is linear up to the point corresponding to complete exhaustion of the sorption power of IAB for Simazine. The projection of this point onto the abscissa axis is the maximal sorption capacity of the immunosorbent for Simazine. After saturation of the sorbent with Simazine, the sorption isotherm flattens out, i.e., sorption of Simazine stops.

We found that the maximal sorption capacity of IAB for Simazine is $50.3 \pm 0.9\ \mu g\ cm^{-2}$ at the initial concentration of immobilized antibodies in nitrocellulose equal to $0.076\ mg\ ml^{-1}$.

The efficiency of sorption of Simazine with the immunosorbent was characterized by its distribution factor determined as the ratio of the Simazine concentration on IAB to that in the equilibrium aqueous solution. Under our experimental conditions, the distribution factor of Simazine varied from 12 to 49, i.e., the degree of Simazine recovery was no less than $96 \pm 4\%$.

Owing to fairly high sorbability of Simazine on IAB, this immunosorbent can be used for preconcentrating Simazine from its dilute solutions (10^{-9}–10^{-10} M). We studied the recovery of Simazine from its 10^{-10} M aqueous solutions of the following volumes, ml: 25, 35, 100, 500, and 1000.

Desorption of Simazine from IAB samples used in these sorption experiments with water (5 ml) resulted in Simazine preconcentration by factors of 5, 7, 20, 100, and 200, respectively (Table 1).

Procedures for breaking down sorption complexes Simazine–immobilized antibody. The fact that Simazine is virtually completely recovered from its aqueous solutions with immobilized antibodies shows that Simazine forms fairly strong complexes with immobilized antibodies. The same conclusion was made in [16]. In order to determine the Simazine amount accumulated in the immunosorbent, the Simazine–antibody complexes should be broken down to release the Simazine molecules.

It is known that herbicides can be released from their complexes with an immubosorbent by their treatment with buffer solutions of appropriate pH, aqueous urea, sodium thiocyanate, etc. [17].

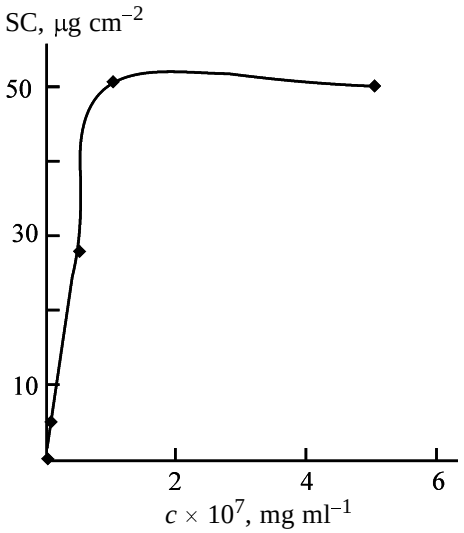

Fig. 2. Sorption capacity of immobilized antibodies SC for Simazine vs. Simazine concentration in the aqueous phase *c*.

In this study, the Simazine–antibody complexes were broken down with aqueous HCl containing 0.15 M NaCl (pH 4). It was found that, under these conditions, the sorption complexes are virtually completely broken down within 20 min.

Determination of Simazine microamounts in aqueous solution involves the following steps: (1) A nitrocellulose film containing immobilized antibodies is placed into a solution (pH 7) containing Simazine to be determined, and this system is stirred for 5 min at 20°C. Under these conditions, Simazine is completely

collected on the antibody sorbent. (2) The Simazine-containing nitrocellulose film is washed with distilled water and transferred into an aqueous solution (5 ml) containing 1 M NaCl + HCl (pH 4), and this mixture is kept for 20 min. Under these conditions, Simazine is completely released from the Simazine–antibody complex. (3) A solution formed after breakdown of the Simazine–anibody complex (0.5–2.5 ml) is placed into a 5-ml volumetric flask, and then 2×10^{-4} M BTCI (0.5 ml) and borate buffer (pH 9.05) (to a mark) are successively added. (4) The resulting mixture is placed into an electrochemical cell, atmospheric oxygen is removed from the solution by purging with hydrogen for 15 min, and then a cyclic voltammetric curve is recorded in the potential range from –0.1 to –0.9 V relative to a saturated calomel reference electrode. The potential sweep rate is V s^{-1}. The electric current at the polarization voltage of –0.55 is measured, and the Simazine concentration is determined using the calibration curve.

The sorption equilibrium in the system Simazine-IAB is characterized by a certain ratio between the antibodies bound with Simazine and occuring in the free state. Therefore, the Simazine concentration can be determined by the calibration plot built in the coordinates Simazine concentration in aqueous phase–electric current. Our experiments showed that the Simazine detection limit was 10^{-10} M.

In the systems under consideration, at the Simazine concentration ranging from 10^{-6} to 10^{-9} M, the relative electric current is a linear function of the logarithm of the Simazine concentration:

$$I_p/I_0 = (27\pm4) + (7.9\pm0.8)(-\log c),\ r = 0.9908.$$

This equation was used for determining the Simazine concentration. The accuracy of Simazine determination was evaluated as the difference between the Simazine amount introduced into a model solution and that determined in this model solution using our technique (Table 2). The determination of pesticides in various natural waters with our technique (n = 5, P = 0.95) revealed the presence of Simazine in some of them.

Water	Initial herbicide content, M	Herbicide content after sorption treatment with immunosorbent, M	S_r
Lake Chistoe	$(1.3\pm0.4)\times10^{-10}$	$(1.8\pm0.3)\times10^{-8}$	0.21
Well no. 20	–	$(2.1\pm0.4)\times10^{-9}$	0.20
Murzinka river	$(2.2\pm0.3)\times10^{-10}$	$(2.0\pm0.5)\times10^{-8}$	0.18

EXPERIMENTAL

The voltammetric measurements were carried out with a PI-50-1.1 potentiostat equipped with a computer. An electrochemical cell was temperature-controlled with a TC-50 thermostat. A saturated calomel electrode was used as the reference electrode. A biosensor based on choline esterase, ACEBS, was used as a working electrode; it was prepared as described in [14]. It consisted of a stationary mercury film electrode applied to a silver support and butyrylcholine esterase immobilized in a nitrocellulose membrane.

The immobilized antibodies were prepared as follows. An antibody-containing solution was applied to commercial nitrocellulose membranes (Sartorius) with the surface area of 2 cm^2 and pore diameter of 0.2 μm, and the membranes were kept over aqueous glutaraldehide (12.5%). Thereafter the membranes were kept for 12 h in a hermetically sealed vessel with humid air. After such pretreatment, the membranes were soaked in a solution of human serum albumin to bind the free reactive groups of glutaraldehyde. The final samples of immobilized antibodies were stored at +4°C. The Simazine-containing solutions to be analyzed were deoxygenated by bubbling electrolytic hydrogen. In the course of voltammetric measurements, hydrogen was passed over the solution.

The substrate based on butyrylthiocholine iodide was prepared by dissolving its accurately weighed sample in the working buffer solution. In the course of experiments, this solution was refreshed after each 3-h use. Butyrylcholine esterase of horse serum (EC 3.1.1.8) with activity of 110 AU mg^{-1} was produced by the Biomed Research and Production Association (Perm).

Choline esterase was immobilized with nitrocellulose of colloxylin type with the mean nitrogen content of 11.5–12.0 wt %, prepared in the form of films. Antibodies were immobilized on commercial nitrocel-

lulose membrane filters with the pore size of 0.2 μm, produced by Sartorius.

The following organic solvents were used in our experiments: butyl acetate, toluene, hexane (high purity), aqueous glutaraldehyde (25%) (ICN), and human serum albumin (Reanal, Hungary). Simazine solutions were prepared from its 0.1 M reference solution produced by the Ural Research Institute of Metrology.

In our experiments we used polyclonal antibodies prepared at the Chair of Chemical Enzymology, Moscow State University. The antibody content in working solution prepared by dissolving antibodies in double-distilled was water determined from its optical density at λ = 280 nm (25°C) by the equation

$$c_{AB} = A_{280} n/1.3,$$

where c_{AB} is the antibody concentration (mg ml^{-1}); A_{280}, optical density of solution; n, dilution factor; and 1.3, recalculation factor determined from the calibration curve. The AB content in the stock solution was 0.076 mg ml^{-1}.

In our experiments pH was adjusted with borate buffer (pH 9.05 ± 0.05). pH was measured on a pH-150 pH meter with a glass electrode calibrated against standard buffer solutions.

It should be noted that, in voltammetric analysis of systems under consideration, no catalytic electrochemical discharge of protons (hydrogen current) was observed. At the same time, this current appears, for example, in solutions of a chemically pure grade Co(II) salt (10^{-2} M) in ammonia buffer (pH 9–10). We believe that this difference in electrochemical behavior is caused by strong binding of immobilized antibodies with the nitrocellulose matrix.

CONCLUSIONS

(1) A technique for determining Simazine microamounts in aqueous solutions was developed. The procedure includes its sorption preconcentration on immobilized antibodies through formation of a strong Simazine–antibody complex, breakdown of this complex, and ammetric determination of the released Simazine with a biosensor.

(2) The Simazine–antibody immunocomplexes are broken down with an aqueous solution containing 0.1 M HCl and 0.15 M NaCl.

(3) The main characteristics of immobilized antibodies as sorbents for Simazine from aqueous solutions (degree of recovery, sorption capacity, distribution factor) were determined.

(4) Sorption of Simazine on immobilized antibodies ensures its preconcentration from dilute aqueous solutions (10^{-10} M) with a factor of 5–200.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Combined Plasma-Induced and Catalytic Decomposition of Phenols

A. G. Bubnov, E. Yu. Burova, V. I. Grinevich, and N. A. Kuvykin

Ivanovo State University of Chemical Engineering, Ivanovo, Russia

Received February 9, 2005

Abstract—Decomposition of phenol and its derivatives, resorcinol and pyrocatechol, was studied in barrier-discharge plasma in the presence of substances exhibiting catalytic properties.

Methods of high-energy chemistry find application in water treatment and purification. In particular, the use of barrier discharge plasma makes it possible to improve the water quality via decreasing the concentrations of organic pollutants by factors of several tens [1]. A new line in this area is application of combined plasma-induced and catalytic processes (CPICPs) accelerating decomposition of organic compounds, i.e., increasing the energy efficiency of the process. When introduced directly into the plasma zone, the catalyst and the solution being treated are exposed to all active species, including short-lived species that are formed in the gas and liquid phases. Active species in plasma can activate the catalyst at low temperatures, or active species capable of initiating and accelerating decomposition of organic compounds in water can be formed on the catalyst.

In this work we studied the kinetics of transformation of phenols when exposed to active species of barrier-discharge plasma (BDP) and in CPICP.

EXPERIMENTAL

The experiments were run on a setup described in [1]. Technical-grade oxygen (99.8 vol % pure, with nitrogen and argon as main impurities) served as plasma-forming gas. The flow rate of O_2 was constant in all the experiments (3.2 $cm^3\ s^{-1}$). Barrier discharge was excited from a high-voltage transformer (alternate current with a frequency of 50 Hz); the voltage applied to the electrodes was 16 kV. As model pollutants we chose phenol (PN) and its derivatives, resorcinol (RS) and pyrocatechol (PC), with different initial concentrations. During the studies we controlled the content of phenol in water before and after plasmochemical treatment.

Aqueous solutions of phenol were treated both in the presence and absence of compounds exhibiting catalytic properties. In the former case, prior to introducing the water being treated into the setup in the plasma burning zone, a catalyst (a nickel-containing compound) was preliminary applied to the hydrophilic inert material (fiber glass) coating the central noninsulated electrode.

The catalyst was applied to the fiber glass fabric by the following procedure. The fabric was leached with an HNO_3 solution (5.5 wt %) at 90°C for 10 min, whereupon it was dried at 110°C and calcined in air at 250°C [2]. Next, the fiber glass fabric was placed into an aqueous NaOH solution (pH 7–11), and a weighed portion of a salt, $Ni(NO_3)_2$, was added to yield 0.2 M solution. After 40 min, the fabric was repeatedly dried at 110°C and calcined at 250°C for 30–40 min [3].

The qualitative characteristics of the initial and treated waters were estimated by the procedures described in [4].

We found earlier [1, 5] that the efficiency α of plasma-induced decomposition of organic compounds dissolved in water depends on a multitude of parameters, including the time of contact of the gas and solution with the plasma zone τ, specific power W contributed to the discharge, and the initial concentration of the solute c_i. Our experiments showed (Fig. 1) that, with increasing initial concentration of the phenols in water, α tends to decrease, most profoundly in the case of PN and least profoundly, in the case of PC.

This is also evident from Fig. 2 demonstrating the efficiency of decomposition of the phenols in BDP. The decomposition rates for PN, RS, and PC (Fig. 2) are related as 1 : 1.2 : 1.4. Thus, PN proved to be the

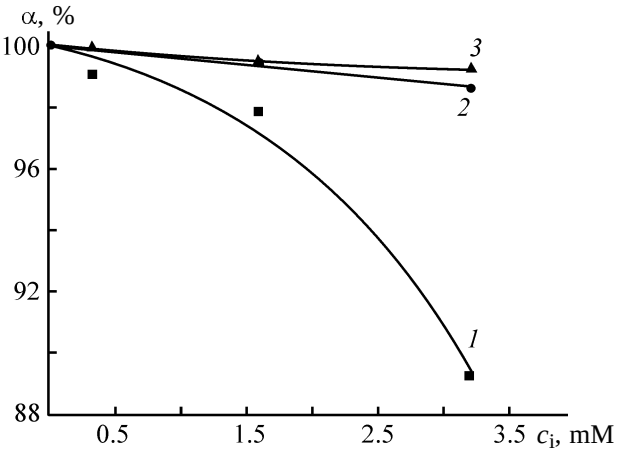

Fig. 1. Efficiency α of decomposition of phenols in BDP as a function of their initial concentration c_i as recalculated for the total content of carbon atoms in the molecules in solution. W = 28 mW cm^{-3}, τ_c = 50 s. (*1*) Phenol, (*2*) resorcinol, and (*3*) pyrocatechol; the same for Figs. 2–4.

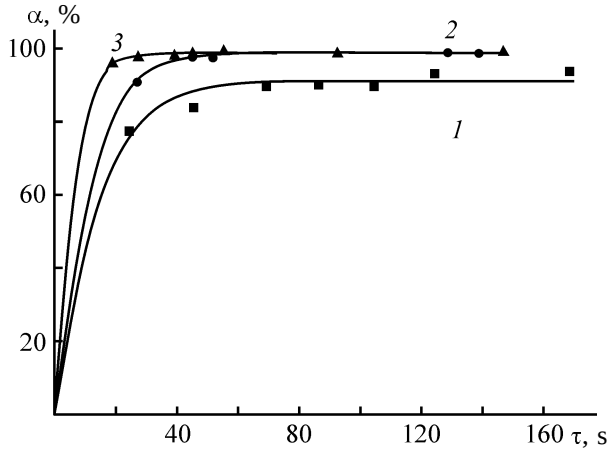

Fig. 2. Efficiency α of decomposition of phenols in BDP as a function of the time of the solution–plasma zone contact τ in BDP (c_i = 3.2 mM).

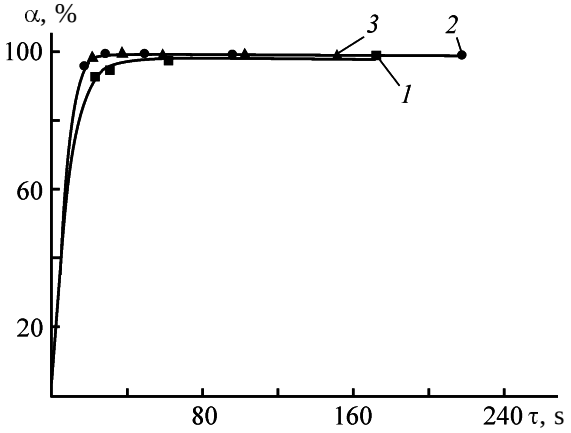

Fig. 3. Efficiency α of decomposition of phenols in CPICP as a function of the time of the liquid–plasma zone contact τ.

most stable and PC, the least stable, under plasma. It should be noted that the previous studies of oxidation of phenols with ozone [6] showed that the apparent rate constants of its reactions with RS and PC are close, with a 12.5% difference in favor of RS. In oxidation processes, PC is capable of forming quinoid structures, which is not characteristic of RS [6]. Evidently, specifically such structures are responsible for the effect observed.

Our measurements showed that the efficiency of decomposition of phenols in CPICP is much higher than in plasma-induced processes. For example, when the initial concentration of PN was increased from 2 to 200 mg l^{-1}, α decreased from 99.9 to 36% (by a factor of 2.8) [in the plasma-induced process], and from 99.9 to 86% (by a factor of 1.2), in the combined process. Similar results were obtained for PC and RS (Fig. 2). In CPICP, the decomposition rate increased by a factor of 1.3 for PN, by a factor of 1.2 for RS, and remained virtually unchanged in the case of PC.

Table 1 presents the calculated apparent rate constants k_{app} of decomposition of phenols in BDP and CPICP.

The apparent rate constants k_{app} of PN, RS, and PC in BDP are related as 1 : 5 : 19, and in CPICP, as 1 : 1.9 : 4.3.

Thus, CPICP proved to be the most efficient in decomposition of PN (k_{app} increases by a factor of nearly 11), and the least efficient in decomposition of PC (k_{app} increases by a factor of 2.5). It should be noted that k_{app} depends on c_i [6]. Comparison of the apparent rate constants for CPICP and ozonation of the phenols showed that combined plasma-induced catalytic decomposition of phenols dissolved in water offers significant advantages over ozonation, since

Table 1. Apparent rate constants of decomposition of the phenols in BDP and CPICP (c_i = 3.2 mM) and by ozonation [6]

Compound	k_{app}, l mol^{-1} s^{-1}		
	BDP	BDP + catalyst	ozonation [6]
PN	291 ± 51	3116 ± 460	1400 ± 500
RS	1501 ± 100	5956 ± 357	4000 ± 300
PC	5434 ± 907	13 546 ± 2050	3500 ± 400

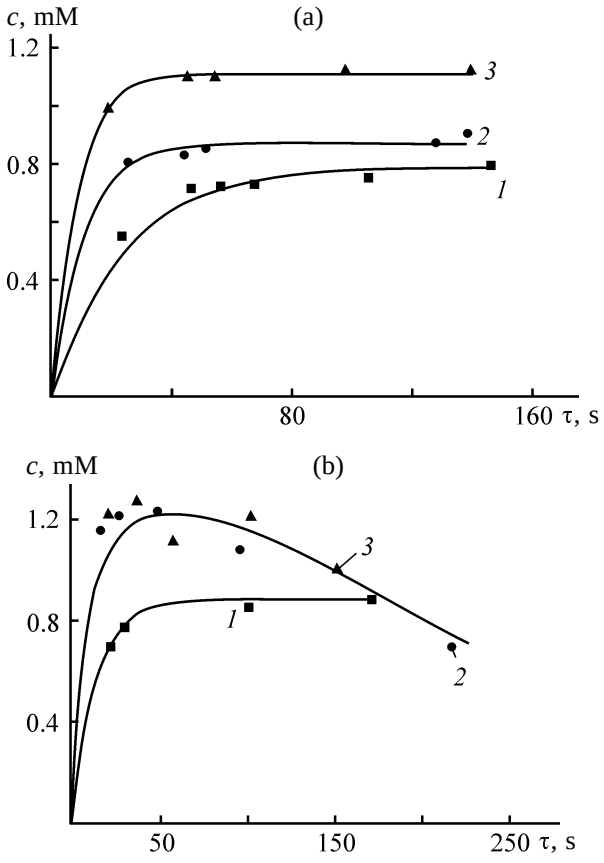

Fig. 4. Kinetic curves of formation of carboxylic acids for treatment of phenols in (a) BDP and (b) CPICP on a Ni catalyst. (*c*) Concentration of carboxylic acids in solution and (τ) solution–plasma zone contact time.

the apparent rate constants in the former case are larger by a factor of 1.5–3.9.

The main active species being formed in BDP is ozone [7]. Ozonation of aromatic hydrocarbons involves cleavage of the aromatic ring and formation of muconic acid derivatives which are further converted into moieties containing 2–4 carbon atoms. These species are oxidized to carbonyl and carboxy compounds containing 1–3 carbon atoms [6]. The main intermediate and final products of the phenol decomposition in the case of ozonation [1] and plasma treatment are carboxylic acids. Figure 4 presents the kinetics of accumulation of these acids (as recalculated for acetic acid). The yield of carboxylic acids is at a maximum when PC is exposed to active plasma species (by a factor of 1.7 larger than in the case of treatment of aqueous solutions of PN).

Table 2. Maximal yield of carboxylic acids (based on the initial content of carbon in solution) in decomposition of the phenols

Compound	Yield of acids (recalculated for acetic acid), %	
	BDP	BDP + Ni
PN	49	56
RS	50	68
PC	61	68

It should be noted that, in going from BDP to CPICP, the kinetics of formation of carboxylic acids remained virtually unchanged for PN. Whereas the kinetics of accumulation of carboxylic acids in BDP for RS and PC are described by an exponential dependence (like in the case of PN), those in CPICP are described by a typical curve with a maximum. This may be due to the fact that, for RS and PC, which are the least stable in plasma-induced processes, carboxylic acids are not the final oxidation products and only further decompose to CO_2 and HCO_3^-. Table 2 lists the maximal yields of carboxylic acids in oxidation of phenols. It is seen that, in CPICP, from 56 (PN) to 68% (RS, PC) of the initial carbon content in solution is converted into carboxylic acids, i.e., their yield is fairly high. In CPICP, the rate of formation of carboxylic acids increases by a factor of 1.4, 1.6, and 1.2 for PN, RS, and PC, respectively.

Thus, decomposition in CPICP is accelerated most efficiently for PN, and least efficiently, for PC.

CONCLUSIONS

(1) Barrier-discharge plasma affords high efficiency of decomposition of phenol and its derivatives (up to 99%), with phenol being the most resistant, and pyrocatechol, the least resistant to plasma.

(2) In combined plasma-induced and catalytic process, the apparent rate constant of decomposition increases relative to plasma-only treatment by a factor of 11, 4, and 2.5 for phenol, resorcinol, and pyrocatechol, respectively. From 56 (for phenol) to 68% (for resorcinol and pyrocatechol) of the initial carbon in solution is converted to carboxylic acids.

(3) Combined plasma-induced and catalytic processes are suitable for treating water to remove plasma-resistant compounds such as phenol or for treating water with high concentrations of phenols.

Abstract—An efficient procedure was developed for preparing bis(3,5-di-*tert*-butyl-4-hydroxyphenyl) polysulfides in the presence of phenolic Mannich bases. The antioxidative activity of the resulting bis(polysulfides) in rubbers of various structures and in their vulcanizates was examined.

Sterically hindered phenols (SHPs) find growing use for antioxidative stabilization of polymeric materials, thanks to the strong protective effect of SHPs and their low toxicity. Today the researchers' attention is focused on molecular structures containing, along with an SHP moiety, also additional groups or atoms suppressing the radical-chain oxidation in various steps and by different mechanisms [1, 2]. Such stabilizers can exhibit intramolecular synergism and substantially surpass in the antioxidative performance classical mixed synergistic stabilizing systems [1]. Among polyfunctional SHP antioxidants are compounds containing simultaneously SHP fragments and sulfide groups [1, 3].

SHP sulfides were prepared previously by reactions of 2,6-dialkylphenols with S_2Cl_2 and SCl_2 [4]. However, this route has certain disadvantages: relatively low yield of the target product, formation of a large amount of the by-product, and release of hydrogen chloride contaminated with sulfur chlorides. SHP polysulfides can also be prepared using elemental sulfur. According to [5], the reactions of SHPs with sulfur are performed in the presence of an at least equimolar amount of alkali relative to 2,6-dialkylphenol and of a large excess of sulfur. This makes the process technologically unfeasible, because of the necessity of utilizing large amounts of acidic aqueous-organic wastes. However, the procedure for preparing SHP polysulfides using elemental sulfur is attractive in connection with the pressing problem of utilization of "gas" sulfur, a by-product of hydrorefining of crude oil and hydrocarbon raw materials.

The goals of this study were to develop a feasible procedure for preparing sterically hindered phenol sulfides by the reaction of 2,6-dialkylphenol with elemental sulfur and to examine their antioxidative (AO) performance in various rubbers and polymeric materials based on them.

EXPERIMENTAL

The following chemicals were used in the study.

2,6-Di-*tert*-butylphenol. White crystals, mp 36–37°C, MW 206. Readily soluble in benzene, acetone, and isopropanol.

Sulfur. mp 112.8°C, density 1960–2070 kg m^{-3}. A yellow crystalline solid, insoluble in water, sparingly soluble in alcohol and ether, and readily soluble in carbon disulfide. The molecular weight of sulfur at low temperatures corresponds to the formula S_8.

2-Dimethylaminomethylphenol. A light yellow liquid; it contained a 1.88% impurity of phenol.

2,6-Bis(dimethylaminomethyl)phenol. A light yellow liquid; it contained a 2.4% impurity of phenol.

4-Dimethylaminomethyl-2,6-di-*tert*-butylphenol. mp 93–95°C (from acetone). MW 263. White or slightly yellowish crystals soluble in the majority of organic solvents.

***N,N'*-Diphenyl-1,4-phenylenediamine (Diafen FF).** mp 152°C. MW 310. Dark gray crystalline powder; soluble in alcohols, acetone, benzene, chloroform, xylene, aniline, and chlorobenzene; insoluble in water.

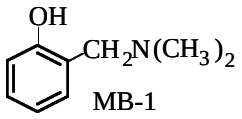
Acetone anil P $(C_{12}H_{15}N)_n$. An oligomer of 2,2,4-trimethyl-1,2-dihydroquinoline. mp 65–75°C. MW 400–500. Soluble in chloroform, benzene, alcohols, and acetone; insoluble in water.

1070-4272/05/7807-1110 © 2005 Pleiades Publishing, Inc.

2,2'-Methylenebis(4-methyl-6-*tert*-butylphenol) (Agidol-2). mp 128–129°C. MW 340. White crystalline powder. Soluble in ethanol, ethyl acetate, and methylene chloride; virtually insoluble in water.

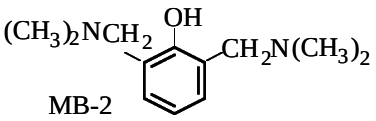
Procedure for preparing bis-SHP polysulfide. A four-necked flask equipped with a stirrer, a reflux condenser, a thermometer, and a tube for feeding a gas was charged with 14 g (0.0679 mol) of 2,6-di-*tert*-butylphenol, 25 g (0.0976 mol) sulfur, a catalyst, and 20 ml of DMF. The mixture was heated to 100–145°C, and the reaction was continued with stirring for 1.5–4 h, under bubbling with an inert gas (N_2, Ar) at a rate of 100 l h^{-1}. Then the mixture was cooled to room temperature and allowed to stand for a day until unchanged sulfur fully settled. The precipitate was filtered off, and the DMF was distilled off in a vacuum. The resulting product was a red-brown glassy resin without odor; softening point 75–80°C. ^{1}H NMR spectrum ($CDCl_3$), δ, ppm: 1.25–1.60 (36H, CMe_3), 6.55–6.80 (2H, OH), 7.25–7.65 (4H, ArH). Aryl proton signals are doublets with ^4J 2.4 Hz.

The ^{1}H NMR spectra were recorded on a Gemini-200 spectrometer operating at 200 MHz.



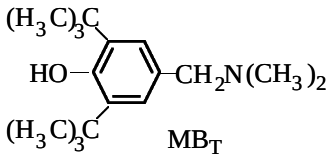
The IR spectra of SKI-3 rubber films were taken with a Perkin–Elmer 16PC-FT-IR spectrometer in the range 4000–400 cm^{-1}. Films 1.0–1.2 μm thick were prepared on a poly(ethylene terephthalate) support (0.04±0.01 mm thick) from a solution of SKI-3 in toluene.

The induction periods of oxidation of the polymer were estimated according to [6] at an oxygen pressure of 250 mm Hg.



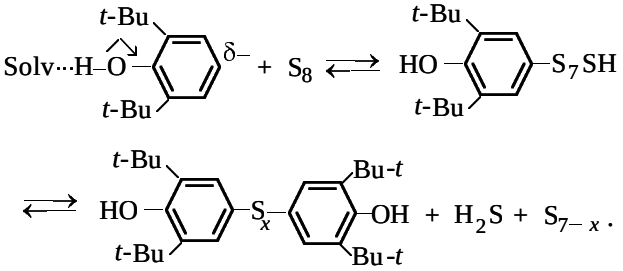
The composition of the rubber stock was as follows (wt parts): BNKS-18 butadiene–acrylonitrile rubber 100, zinc oxide 4, sulfenamide Ts 1, dithiodimorpholine 2, thiuram D 1, PM-50 carbon black 120, stearic acid 1, EDOS plasticizer 45, and stabilizer 3–4.

In the previous studies, we considered a procedure for preparing 2,6-di-*tert*-butylphenol (2,6-DTBP) sulfides by the reaction with elemental sulfur in polar aprotic solvents (DMF, DMSO, HMPA, *N*-methylpyrrolidone) [7]. With these solvents, a base catalyst appeared to be unnecessary. However, the reaction performed at 145–165°C with inert gas bubbling took no less than 6 h.

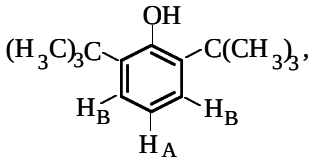


To examine the possibility of making the reaction of 2,6-DTBP with elemental sulfur more feasible (decrease the reaction time and temperature), we made experiments in a polar solvent in the presence of a series of commercially available Mannich bases (MBs): 2-dimethylaminomethylphenol (MB-1), 2,6-bis(dimethylaminomethyl)phenol (MB-2), and *N,N*-dimethyl-3,5-di-*tert*-butyl-4-hydroxybenzylamine (MB_T). We expected that the MBs would behave as base catalysts:

MB-1



MB-2



MB_T

These compounds are attractive in the synthesis of SHP polysulfide as they themselves are stabilizing additives to polymeric materials [8]; therefore, the removal of these catalysts in the commercial synthesis is unnecessary.

The reaction was performed at 100–145°C and was monitored by thin-layer chromatography:

The reaction was stopped when the 2,6-DTBP spot disappeared from the TLC plate. The reaction mixtures after removing the solvent were analyzed by ^{1}H NMR spectroscopy. The intensity of the H_A aryl proton (triplet at 6.90 ppm) of 2,6-DTBP was compared with those of the signals of the H_B aryl protons of bis-SHP polysulfide (singlets at 7.10–7.60 ppm):

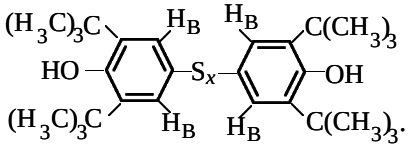


Table 1. Conversion of 2,6-DTBP in the reaction with sulfur in the presence of MB-2 as catalyst (140°C, 210 min, DMF, nitrogen flow)

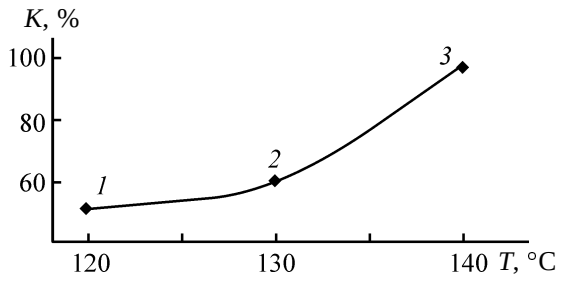
MB-2 concentration, wt % relative to 2,6-DTBP	Conversion, %
10	96.9
5	96.7
3	96.6
1	96.4
0.5	60.8

Table 2. Conversion of 2,6-DTBP in the reaction with sulfur in the presence of 1 wt % catalyst (140°C, DMF, nitrogen flow)



Catalyst	Reaction time, min	2,6-DTBP conversion, %
MB-2*	210	96.4
MB_T**	210	100
	180	98.3
	120	97.3
	90	96.8
MB-1	180	96.1

* When the reaction was performed in a melt, the 2,6-DTBP conversion was 14.3%.

** Without nitrogen bubbling, the 2,6-DTBP conversion was 80%.

First we optimized the amount of the catalyst taken. The MB concentration was varied from 10 to 0.5 wt %. As seen from Table 1, addition of ≥1 wt % MB-2 to the reaction mixture ensured virtually complete conversion of 2,6-DTBP in 3–3.5 h. At lower catalyst concentrations, the reaction rate drastically decreased.

A similar dependence of the 2,6-DTBP conversion on the catalyst concentration was observed with MB-1. With 1 wt % MB_T, the complete conversion of 2,6-DTBP was attained in 90 min.

Conversion *K* of 2,6-DTBP as a function of the reaction temperature *T*. DMF, 1 wt % MB_T, reaction time 120 min. Conversion, %: (*1*) 50.76, (*2*) 60, and (*3*) 96.8.

To ensure efficient conversion of 2,6-DTBP, it is important to remove H_2S (this is provided by inert gas bubbling), because of the reversibility of the reaction. In particular, when the reaction catalyzed with MB_T (1 wt %) was performed for 210 min at 140°C without nitrogen bubbling, the 2,6-DTBP conversion decreased to 80% (Table 2).

It should be particularly noted that the 2,6-DTBP conversion drastically decreases when the reaction is performed in the absence of a polar solvent (Table 2). This fact indicates that the polar solvent plays an important role of a dissociating medium enhancing the nucleophilicity of 2,6-DTBP.

With a decrease in temperature, the reaction rate decreased considerably (see figure).

The synthesized product was tested as antioxidant for various rubbers: both highly unsaturated (SKI-3, SKB) and containing a small amount of multiple bonds (BK, SKEPT). To evaluate the performance of the stabilizer, we used the manometric method for measuring the induction periods of oxidation of the polymers [6]. This method is based on studying the kinetics of thermal oxidation and involves monitoring of the oxygen uptake by the polymer in the course of heating under O_2 or in air. In the first (induction) period, the oxygen uptake is fully suppressed or strongly decelerated depending on the AO performance. The induction period ends at virtually complete consumption of the stabilizer, and its duration can be a measure of both the AO performance and rubber stability.

The performance of the bis-SHP polysulfide prepared was compared with that of commercial AOs used for stabilization of the same polymers. In particular, amine antioxidants Diafen FF (or Diafen FP) and acetone anil are used for stabilization of SKI-3 and SKB, respectively, and phenolic antioxidant Agidol-2, for stabilization of BK and SKEPT rubbers [6].

As seen from Table 3, the additive synthesized is an effective antioxidant for the majority of the polymers studied, increasing (compared to commercial stabilizers) the induction periods of oxidation of rubbers.

The stability of rubbers can also be judged from variation of the IR spectra of the polymer films in the course of thermal oxidation. The process is usually monitored by the >C=O stretching vibration band at 1720 cm^{-1} [9].

In this study, the polymer films were oxidized at 100°C in air. Experimental data showed that thermal

Table 3. Induction periods τ (min) of thermal oxidation of rubbers stabilized with bis-SHP polysulfide

Rubber	Oxidation temperature, °C	Reference stabilizer		τ, min, at indicated bis-SHP polysulfide concentration, wt %

SHP polysulfide	–	4	3

oxidation for 8 h of SKI-3 containing no antioxidant caused the following changes in the IR spectra: bands appeared at 1721 [ν(C=O)] and 3475 cm^{-1} [ν(OH)], and the bands at 1666 (C=C) and at about 890 cm^{-1} (H–C=C) decreased in the intensity. On adding bis-SHP polysulfide to SKI-3, the heating time required for the ν(C=O) band (1721 cm^{-1}) to appear increased by a factor of several tens (Table 4).

We examined the possibility of using the synthesized bis-SHP polysulfide as antioxidant for the vulcanizate based on butadiene–acrylonitrile rubber. The formulation we used corresponds to the commercial rubber stock. As seen from Table 5, replacement of the commercial Diafen FP–acetone anil mixture by the synthesized bis-SHP polysulfide does not impair the initial properties and heat resistance of the vulcanizate.

CONCLUSIONS

(1) A feasible procedure was developed for preparing bis-SHP polysulfide by the reaction of 2,6-DTBP with elemental sulfur in a polar aprotic solvent, in

which the use of catalytic amounts of phenolic Mannich bases allowed the synthesis time to be reduced to 1.5–3 h.

(2) Bis-SHP polysulfide shows a high antioxidative activity in stabilization of various rubbers (SKI-3, SKB, SKEPT, BK, BNSK). This additive increases the induction period of the polymer oxidation and the time in which carbonyl groups started to form. The synthesized SHP polysulfide does not impair the initial properties and heat resistance of the vulcanizate based on BNSK-18.

Abstract—The composition of oligoethers that are components of Laprol-373 and of products of their reaction with 2,4-toluylene diisocyanate were studied by matrix-assisted laser desorption ionization mass spectrometry (MALDI-TOF).

Oligoethers with terminal hydroxy groups prepared by copolymerization of ethylene and propylene oxides in the presence of polyol alcoholates as initiators are widely used in production of polyurethanes [1–3]. The parameters (hydroxy number, viscosity, IR and NMR data) used to characterize these oligoethers (Laprols) reflect their statistical mean properties. They are undoubtedly important for applications of Laprols, but for polymer chemistry it is important to know the structures of specific components of one or another Laprol.

The compositions of Laprol-373 and of products of its reaction with 2,4-toluylene diisocyanate (2,4-TDI) were studied by MALDI-TOF mass spectrometry. This method involves mild ionization of organic compounds, so that the degree of fragmentation of molecular ions is minimal compared to other mass-spectroscopic methods [4]. MALDI-TOF mass spectroscopy involves the following procedure. A substance to be studied is mixed with a matrix substance capable to absorb the laser radiation, and this mixture is applied onto a special metallic plate containing Na and K. The sample is irradiated with a laser beam. In so doing, the molecules of the test substance get ionized. The positive molecular ions formed pass into the gas phase and are recorded with time-of-flight mass-spectrometric detectors [5]. If the test substances are capable of complexing with sodium and potassium ions, they are detected as single-charged positive molecular ions of the complexes. Therefore, the same compound can give three signals in the mass spectrum, belonging to its radical cations and complexes of the neutral molecule with the sodium and potassium ions. This feature of MALDI-TOF mass spectroscopy makes the results obtained more reliable. The problems of ionization of compounds in this procedure were discussed in [6]. The intensity of signals in MALDI-TOF mass spectroscopy depends both on the amount of the test substance in the sample and on its electron-donor properties. Therefore, data obtained by this method furnish reliable information on the composition and structure of molecules but are less suitable for quantitative determinations. As shown by Meier *et al.* [7], the quantitative data obtained in analysis of molecular weights and molecular-weight distribution (MWD) of oligostyrenes by gel permeation chromatography and MALDI-TOF mass spectroscopy are mutually consistent. The possibility of using MALDI-TOF mass spectrometry for analysis of a series of oligoethers and oligoesters was demonstrated in [8].

EXPERIMENTAL

Laprol-373 [Nizhnekamskneftekhim Joint-Stock Company, TU (Technical Specifications) 2226-017-10 488 057–97) was vacuum-dried (133 Pa, 80°C) before use. 2,4-TDI was purchased from Bayer (Germany). The 2,4-TDI samples freshly distilled in a vacuum had the following characteristics: bp 120–121°C/1330 Pa (121°C/1330 Pa [9]), n_D^{20} 1.5680 (1.5678 [9]).

The reaction of Laprol-373 with 2,4-TDI was performed in the bulk under the conditions of a slight excess of isocyanate groups relative to hydroxy groups, without catalysts. Under these conditions, the oligomerization was insignificant, and modified Laprols with terminal isocyanate groups were obtained.

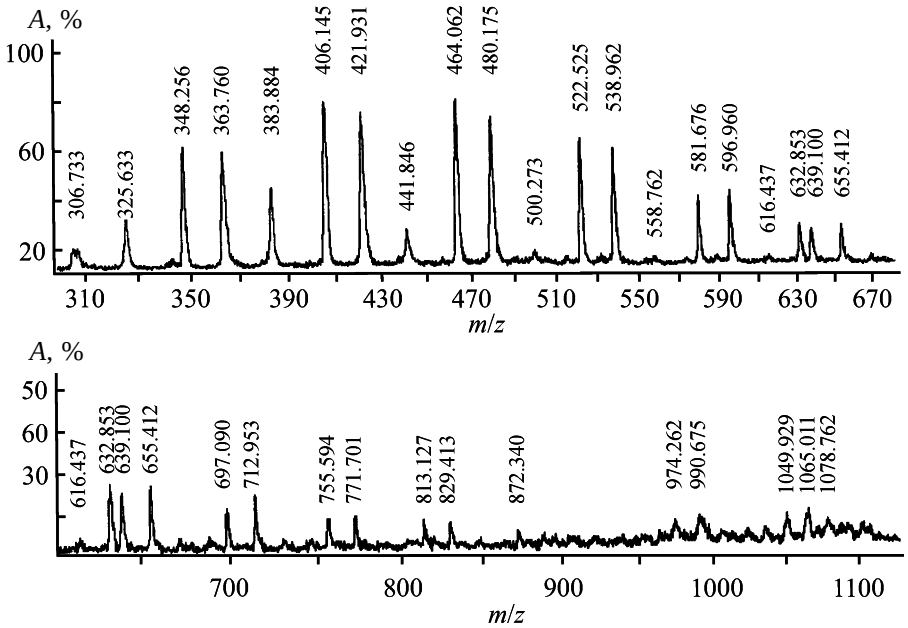

Fig. 1. MALDI-TOF mass spectrum of Laprol-373. (*A*) Intensity; the same for Fig. 2.

Laprol-373 (100 g) was kept for 30 min in a vacuum (residual pressure 18 620 Pa) at 80°C. After that, it was cooled, the pressure was brought to atmospheric pressure, and 130 g of 2,4-TDI was added (molar ratio of the HO and NCO groups 1 : 1.5). In so doing, the mixture spontaneously warmed up to 60°C. The reaction was performed for 30 min with stirring in a vacuum (residual pressure 18 629 Pa) at 60°C. The mass spectra were recorded on a Finnigan MALDI-TOF Dynamo device, using 1,8,9-trihydroxyanthracene as matrix. The weights were determined with an accuracy of ±(1–2) amu.

Table 1. Structure of oligomers **Ia**–**Im**, according to mass-spectroscopic data

Compound	*m*	*n*	*m*/*z*(**I**)	*m*/*z*(**I** + Na)*	*m*/*z*(**I** + K)*

Ig	4	6	616	639	655
Ih	4	7	(674)	697	713
Ii	4	8	(732)	755	771
Ij	4	9	(790)	813	829
Ik	4	10	(848)	871	(887)
Il	5	11	(950)	973	989
Im	7	11	(1038)	1061	1077

* The *m*/*z* ratio is given for complexes of **Ia**–**Im** with sodium and potassium ions.

** The weights of ions that were not detected are given in parentheses; the same for Figs. 2 and 3.

Laprol-373 is a product of copolymerization of ethylene and propylene oxides in the presence of potassium monoglycerate; its structure is described by the formula

$$C_3H_5O_3(CH_2CH_2O)_m(CH_2\text{–}\underset{\displaystyle CH_3}{\underset{|}{CH}}\text{–}O)_nCH_3$$

Ia–**Im**.

Figure 1 shows the mass spectrum of Laprol-373. It is seen that the substance has a broad molecular-weight distribution.

The ions detected (or expected) in the MALDI-TOF mass spectrum of Laprol-373 are given with assignments in Table 1.

Compounds **Ia**–**Im** are detected in the mass spectra not only in the form of molecular ions, but also as complexes with sodium and potassium ions; the intensity of their signals is higher than that of the free molecule. This fact indicates that oligoethers readily form complexes with alkali metal cations [10].

The principal structural unit of **Ia**–**Ik** is an oligoether formed by addition of four ethylene oxide mole-

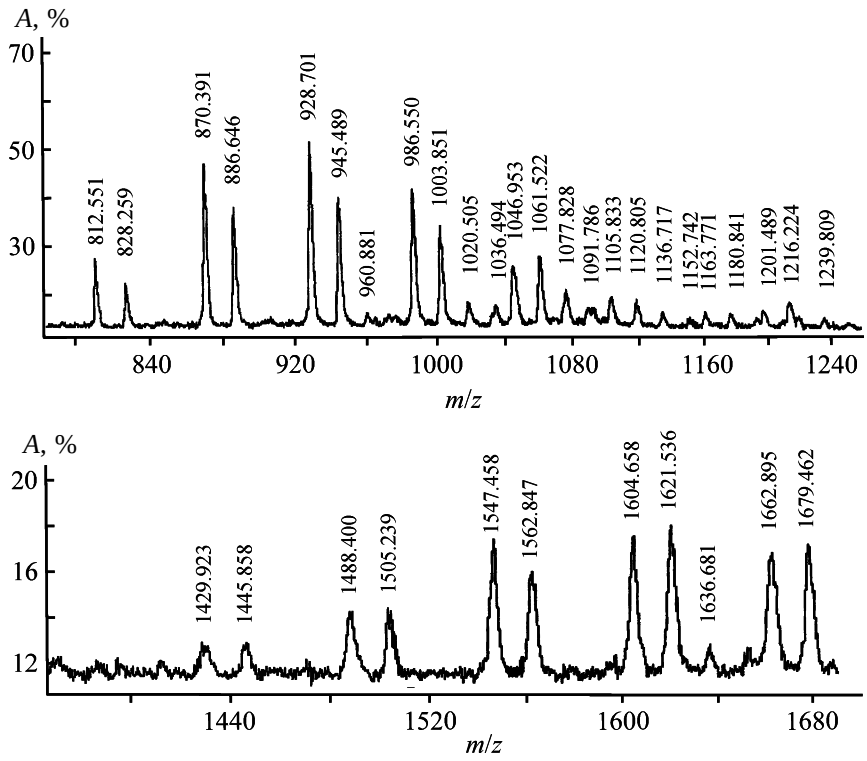

Fig. 2. Mass spectrum of compounds formed in the reaction of Laprol-373 with 2,4-TDI.

cules to a glycerol molecule (compound **Ia**). Further complication of the structure occurs through successive addition of propylene oxide molecules to **Ia**. Laprol-373 contains also compounds **Il** and **Im** of relatively high molecular weights, with more than four ethylene oxide fragments.

Figure 2 shows the mass spectrum of products formed in the reaction of a mixture of **Ia**–**Im** with 2,4-TDI:

$$\textbf{Ia–Im} + 3OCNC_6H_3NCO \rightarrow C_3H_5O_3(CH_2CH_2O)_m\cdot$$

$$(CH_2\text{–}\underset{\displaystyle CH_3}{\underset{|}{CH}}\text{–}O)_n[CONHC_6H_3(CH_3)NCO]_3.$$

Without catalysts, the 4-NCO group in 2,4-TDI is more reactive toward alcohols [11, 12]. The causes of such a selectivity are discussed in [13, 14].

The mass-spectrometric data for preisocyanates **IIa**–**IIh** are given in Table 2.

In the mass spectra, we detected no signals of preisocyanates **IIi**–**IIm**, expected products of addition of 2,4-TDI to oligoethers **Ii**–**Im**. This may be due to a low content of **Ii**–**Im** in Laprol-373.

In most cases, compounds **II** are manifested in the mass spectra only as complexes with sodium and potassium ions. This fact indicates that the addition of 2,4-TDI to oligoethers **Ia**–**Im** enhances their capability for complexation with alkali metal ions.

The products of the reaction of 2,4-TDI with oligoethers **I** contain, along with the above-mentioned compounds, also compounds formed by the reaction of two oligoether molecules with five 2,4-TDI molecules:

$$2(\textbf{I}) + 5(2,4\text{-TDI}) \rightarrow (\textbf{III}).$$

Table 2. Structures of compounds **IIa**–**IIh**, according to mass-spectrometric data (m = 4)

Compound	n	m/z(**II**)	m/z(**II** + Na)*	m/z(**II** + K)*
IIa	0	(790)	813	829
IIb	1	(848)	871	887
IIc	2	(906)	929	945
IId	3	(964)	987	1003
IIe	4	(1022)	1045	1061
IIf	5	(1080)	1103	1119
IIg	6	1138	1161	1177
IIh	7	(1169)	1219	1235

* The m/z ratio is given for complexes of **IIa**–**IIh** with sodium and potassium ions.

Table 3. Structures of compounds **III**, according to mass-spectrometric data

Compound	Fragments of oligoethers **I** in **III**		*m*/*z*(**III**)	*m*/*z*(**III** + Na)	*m*/*z*(**III** + K)
IIIa	**Ia**	**Ia**	(1406)	1429	1445
IIIb	**Ia**	**Ib**	(1464)	1487	1503
IIIc	**Ib**	**Ib**	(1522)	1545	1561
IIId	**Ib**	**Ic**	(1580)	1603	1619
IIIe	**Ic**	**Ic**	(1638)	1661	1677

In the process, two oligoether molecules are bound with two isocyanate groups of one 2,4-TDI molecule; the remaining hydroxy groups, in turn, react with four 2,4-TDI molecules. As a result, large molecules containing four terminal isocyanate groups are formed. Compounds **III** can be formed by coupling of different oligoethers **I** with 2,4-TDI. The detected compounds **III** are listed in Table 3.

Urethane diisocyanates **III**, like the compounds discussed above, are manifested in the mass spectra in the form of complexes with cations.

CONCLUSIONS

(1) The major fraction of oligomers that are components of Laprol-373 are formed by addition of propylene oxide molecules to the product of addition of four ethylene oxide molecules to a glycerol molecule.

(2) Oligoethers **I** in the reaction with 2,4-toluylene diisocyanate without catalysts, even with excess isocyanate, form not only trifunctional but also tetrafunctional urethane diisocyanates containing two fragments of oligoethers **I**.

(3) Both oligoethers **I** and products of their reaction with 2,4-toluylene diisocyanate are capable of complexation with sodium and potassium ions in the gas phase.

Abstract—The synthesis of the dimer and trimer of *N*-adamantanoyl-ε-aminocaproic acid by the reaction of adamantanecarboxylic acid with ε-caprolactam in the presence of a catalyst, *p*-toluenesulfonic acid, was studied.

ε-Aminocaproic acid and its *N*-acetyl derivative are used in medicine [1, 2]. One of the routes to *N*-acyl derivatives of ε-aminocaproic acid oligomers is the acid-catalyzed reaction of carboxylic acids with ε-caprolactam (CL).

The reactions of aliphatic carboxylic acids containing 8–26 carbon atoms with CL are performed in the presence of sulfuric, boric, toluenesulfonic, or methanesulfonic acid, or their mixtures [3, 4]. Water is added to the reaction mixture, which results in the formation of ε-aminocaproic acid; this acid is subsequently acylated at the NH_2 group, and the resulting *N*-acyl derivative reacts with a new CL molecule; the major products of the reaction are oligomers containing 5–10 monomeric units.

Synthesis of low-molecular-weight oligomers of *N*-1-adamantanoyl-ε-aminocaproic acid (AAC) was not studied previously. At the same time, according to the prediction made with the PASS C & T 1.41 program [5], AAC is expected to exhibit antiviral and nootropic activity. Therefore, our goal was to study the synthesis of the dimer (AD) and trimer (AT) of AAC by the reaction of 1-adamantanecarboxylic acid (AC) with CL in the absence of water and in the presence of a catalyst, *p*-toluenesulfonic acid.

EXPERIMENTAL

The IR spectra of liquid substances were recorded with a Specord M82 spectrophotometer from thin films, and those of solids, from mulls in mineral oil. The ^1H NMR spectra were taken on a Varian Mercury Plus spectrometer (300 MHz, CCl_4, internal reference TMS).

The rates of consumption of CL and AC and of formation of *N*-1-adamantanoyl dimer (AD) and trimer (AT) of ε-aminocaproic acid via intermediate monomer (AAC) were estimated by the ampule method.

Ampules containing CL, AC, and a catalyst (*p*-toluenesulfonic acid) in a 1 : 1 : 0.1 molar ratio were placed in a thermostat. At equal intervals (15 min), an ampule was withdrawn, and its contents were analyzed. To this end, the reaction mixture was treated with chloroform in which CL and AC are soluble, after which the precipitate was filtered off. The precipitate consisted of a mixture of AD and AT.

To separate AD and AT, their mixture in ethanol was heated to boil. The solution was filtered while hot and cooled, after which AT precipitated and was filtered off, whereas AD, which is readily soluble in ethanol, remained in the solution; it was isolated by evaporation of the mother liquor, followed by recrys-

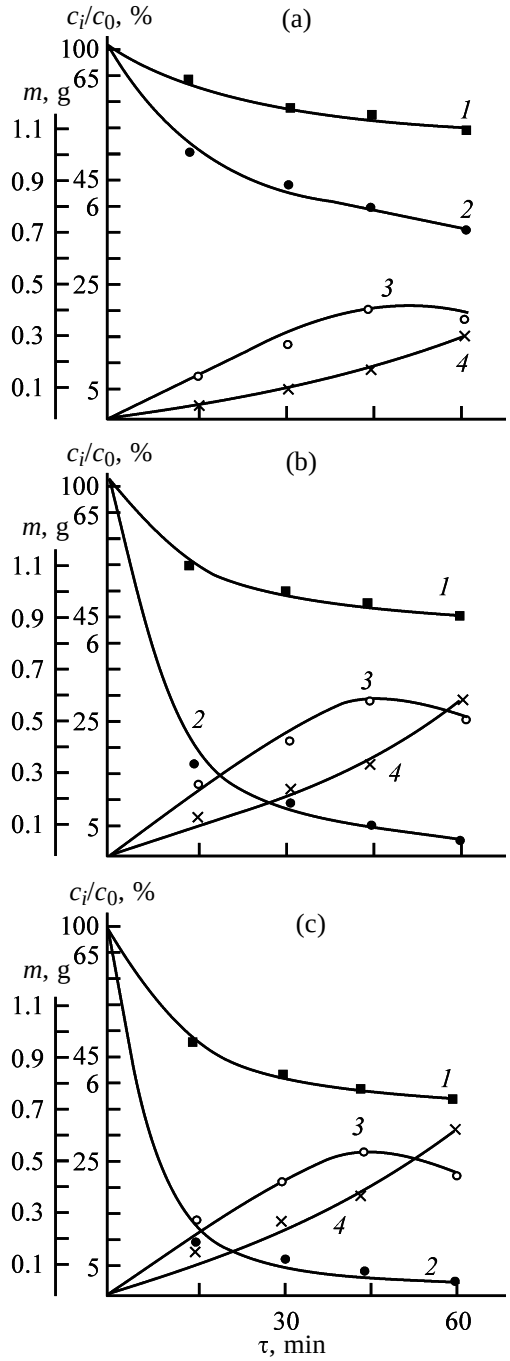

Fig. 1. Consumption of reactants and formation of oligomers in the reaction of CL with AC: (c_i/c_0) content of *i*th compound relative to its initial content (for reactants) or theoretical yield (for products), (*m*) AD and AT weight, and (τ) time. (*1*) AC, (*2*) CL, (*3*) AD, and (*4*) AT. Temperature, °C: (a) 180, (b) 195, and (c) 210.

tallization. The chloroform solution containing CL and AC was evaporated. Then a mixture of CL and AC was treated with hexane, and AC was recovered from the solution.

Nitrogen content in AD, %: found 6.88, calculated for $C_{23}H_{38}N_2O_4$ 6.89; mp 135–138°C. Nitrogen content in AT, %: found 8.23, calculated for $C_{29}H_{49}N_3O_5$ 8.10; mp 172–174°C. The structures of AD and AT were proved by IR and ^{1}H NMR spectroscopy.

The IR spectrum of AD contains amide I and amide II bands at 1680 and 1576 cm^{-1}, respectively, and also the NH stretching band at 3328 cm^{-1}. In the IR spectrum of AT, the amide I and amide II bands are observed at 1640 and 1540 cm^{-1}, respectively, and the NH stretching band, at 3296 cm^{-1}. ^{1}H NMR spectrum of AD (CCl_4), δ, ppm: 7.19 s (H, OH), 6.4 s (2H, NH), 3.1 t (4H, CHNH), 2.3 m [4H, $CH_2C(O)$], 0.8–1.9 m [27H, Ad, $(CH_2)_6$].

Figures 1a–1c show the kinetic curves of the reactant consumption (c_i/c_0, ratio of the current amount of reactant to its initial amount) and product (AD, AT) formation at different temperatures. The initial period is characterized by a high rate of CL consumption. The initial rate of reactant consumption, min^{-1}, is as follows: at 180°C, CL 0.05 and AC 0.03; at 195°C, CL 0.10 and AC 0.04; and at 210°C, CL 0.13 and AC 0.06.

The ratio of consumptions of the reactants in the first 15 min depends on the temperature. The consumptions (%) of CL and AC change as follows: 90 CL and 55 AC (210°C); 85 CL and 45 AC (195°C); and 50 CL and 35 AC (180°C). In this period, the content of AD is 55% of that in a maximum at 210°C (Fig. 1c), 50% at 195°C (FIg. 1b), and 35% at 180°C (Fig. 1a). At the same time, the amount of AT formed in 15 min, relative to that isolated after 60 min, is 30% at 210°C (Fig. 1c), 25% at 195°C (Fig. 1b), and 16% at 180°C (Fig. 1a).

Hence, in the initial period (first 15 min), the major reaction is that of CL with AC, yielding AAC, which subsequently reacts with CL to form AD.

The highest yield of AD is observed 45 min after the start of the reaction (at both 210 and 195°C). The AT content in the system increases monotonically, and in 60 min it starts to exceed the AD content, which tends to decrease after 45 min.

The optimal conditions for preparing AD are 195°C and 45 min; the AD yield is 54% based on CL.

The optimal conditions for preparing AT are 210°C and 45 min; the AT yield is 72% based on CL. Longer heating results in formation of higher oligomers.

The yields of AD and AT under these conditions are considerably higher than under the conditions described in [3, 4]. This is due to the fact that, in the

absence of water, CL reacts directly with AC, without formation of AAC. To prove this assumption, we performed the reaction of AAC with AC under the conditions similar to those described in the Experimental. The reaction of AC with AAC gave higher AAC oligomers containing 10.5–11.20% N, with mp 176–182°C; these products were virtually insoluble in water.

Under the conditions of the reaction of AC with CL, AAC is more reactive than AC. This fact allows preparation of AD (54% yield) and AT (72% yield) under the optimal conditions.

CONCLUSION

Monitoring of the consumption of the reactants (ε-caprolactam and 1-adamantanecarboxylic acid) in the course of the catalytic synthesis of the dimer and trimer of *N*-adamantanoyl-ε-aminocaproic acid revealed significantly larger consumption in the first 15 min of ε-caprolactam (85–90%) relative to 1-adamantanecarboxylic acid (45–55%), which indicates that the forming *N*-1-adamantanoyl-ε-aminocaproic acid is more reactive than 1-adamantanecarboxylic acid in the acid-catalyzed reaction with ε-caprolactam. This fact allows efficient synthesis of the dimer and trimer of *N*-1-adamantanoyl-ε-aminocaproic acid.

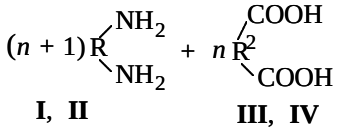
Abstract—The reactions of dicarboxylic acids with di- and triamines were studied, and the properties of the resulting polyamides were examined in relation to the structure and ratio of the starting reactants.

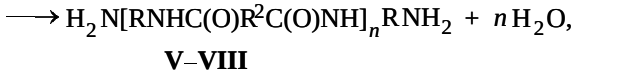
Among numerous polyamide derivatives [1, 2], a particular place is occupied by aliphatic polyimides prepared from dimerized fatty acid (DFA). The presense of a bulky alkylene segments between the carboxy groups of DFA makes the resulting polyamide considerably more elastic, decreases its softening point, and enhances its adhesion properties. This is important for preparing thermoplastic adhesive compounds [3–5].

The possibility of using polyamides derived from DFA for preparing hot-melt adhesives was reported in [6–8]. However, the purposeful development of adhesive formulations with the preset physicomechanical properties was prevented by the lack of data on how the properties of the polyamides depend on the structure of the starting components. Therefore, it seemed important to study the synthesis of polyamides from DFA and to reveal the main parameters affecting the reaction course and the properties of the final product.



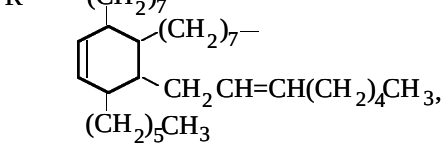
The goals of this study were to optimize the synthesis conditions (so as to attain the maximal conversion of the reactants), examine how the properties of the resulting polyamides depend on the structure and ratio of the reactants, and optimize the process as a whole.

EXPERIMENTAL



In our study we used DFA of PRIPOL 1017 DIMER ACID brand (the Netherlands, CAS registry no. 61788-89-4), sebacic acid [SA, TU (Technical Specifications) 6-02-1091–83], abietic acid [AbA, GOST (State Standard) 14201–83], acetic acid (AcA, GOST 61–75), hexamethylenediamine (HMDA, TU 6-09-36–73), and diethylenetriamine (DETA, EC no. 203-865-4, fraction distilled at 82–85°C/1.33 kPa).

Syntheses of polyamides were performed in a reactor equipped with a stirrer, a thermometer, a descending condenser, and a receiver. As DFA is viscous, after loading the reactants in the required ratio the reactor contents were heated to 120°C, and only after that the stirrer was switched on. The mixture was heated to 160°C with efficient stirring; the condensation with the water release started at this temperature. The temperature was gradually (over a period of 5–6 h) raised to 230°C. The synthesis was performed until the water release ceased.



The general scheme of formation of polyimides in the reaction of DFA with amines can be represented as follows:

I, II **III, IV**

V–VIII

where R = $(CH_2)_6$ (**I**), $C_2H_4NHC_2H_4$ (**II**); R^2 = $C_{34}H_{62}$ (**III**), $(CH_2)_8$ (**IV**); R = $(CH_2)_6$, R^2 = $C_{34}H_{62}$ (**V**); R = $C_2H_4NHC_2H_4$, R^2 = $C_{34}H_{62}$ (**VI**); R = $(CH_2)_6$, R^2 = $C_{34}H_{62}$ and $(CH_2)_8$ (**VII**); R = $C_2H_4 \cdot NHC_2H_4$, R^2 = $C_{34}H_{62}$ and $(CH_2)_8$ (**VIII**); n = 3–30.

The IR spectra of the polyamides obtained were taken on a Specord M 80 spectrometer in the range 4000–700 cm^{-1}. A drop of a sample was pressed between NaCl plates. The NMR spectra were recorded

* The amine number was determined for primary amino groups only [12].

on a Bruker DPX-200 spectrometer operating at 200 MHz for ^{1}H and 50 MHz for ^{13}C; solvent $CDCl_3$, internal reference TMS.

The amine and acid numbers and molecular weights *M* of polyamides were determined by procedures described in [9], and the softening points T_s, by the ring-and-ball method (GOST 11506–73).

The polycondensation progress was monitored by variation of the acid and amine numbers, and also by the amount of the released water. The starting components are mainly exhausted (Figs. 1, 2) in the first 2–3 h; however, as the reactant concentartions decrease and the viscosity of the reaction mixture grows, the reaction decelerates. To attain the maximal conversion of the reactants, the final step of the synthesis was performed in a vacuum at 1.33 kPa and 160–220°C for 1–1.5 h, which favored faster shift of the equilibrium toward formation of the desired polyamide, due to efficient removal of water from the reaction mixture (Fig. 1). It should be noted that the ratio of DFA and amine was chosen so as to obtain products with terminal primary amino groups.

As shown in Fig. 2, in the system DFA–HMDA (0.25 : 0.30 ratio), the amine and acid numbers vary in parallel, and a polyamide with a measurable softening point is formed. However, in the system DFA–DETA, in which the amine contains two primary and one secondary amino groups, at the same ratio of the components, the reaction performed to conversions exceeding 70% yields an insoluble and nonmelting product. This phenomenon is due to involvement of secondary amino groups in the reaction and formation of a network polymer. In view of the undesirable gelation, it is appropriate to use the molar equivalent of DETA equal to 2, taking into account the fact that primary amino groups are more nucleophilic than secondary amino groups and undergo amidation first [10].

Polyamides **V** and **VI** synthesized at various ratios of DFA and amines **I** and **II** are transparent golden yellow solids with a weak amine odor (Table 1).

6	DFA, 0.20; SA, 0.05	DETA, 0.40	49.2*	2.0	2190	46

* The amine number was determined for primary amino groups only [12].

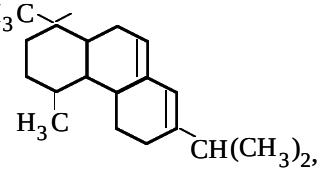
It should be noted that the polycondensation under N_2 yields less colored products than that performed in air.

With DETA taken instead of HMDA, the softening point of the resulting polyamide decreases from ~100 to ~50°C, which is due to the presence of a secondary amino group in DETA [11].

Along with the polyamides prepared from DFA, we also prepared copolyamides **VII** and **VIII** with sebacic acid additionally introduced into the reaction mixture (Table 2). The initial ratio of the sum of DFA and SA to diamines was the same as in Table 1.

As seen from Table 2, introduction of sebacic acid into the copolyamides increases their molecular weight and softening point compared to the products prepared from DFA only. The observed increase in the softening point by 10–15°C is apparently caused by the more ordered molecular structure of the polyamide, due to the presence of normal alkylene fragments of sebacic acid, in contrast to branched alkylenecycloaliphatic segments of DFA. The increased softening point of **VII** and **VIII** may also be associated with their somewhat higher molecular weight, compared to the polyamides prepared from DFA only. This fact is due to the presence of up to 3% monocarboxylic acids, terminating the propagating chain, in the starting DFA. When DFA is partially replaced by SA, the concentration of chain-terminating agents decreases.

The structure of the synthesized products was studied by IR and NMR (^{1}H, ^{13}C) spectroscopy. The IR spectra of **V**–**VIII** contain strong absorption bands in the ranges 1650–1680 cm^{-1} (C=O stretching vibrations, amide I band) and 1550–1640 cm^{-1} (mainly NH bending vibrations, amide II band). In contrast to the products derived from HMDA, the spectra of polyamides derived from DETA contain bands at 3200–3500 cm^{-1} with a maximum at about 3320 cm^{-1}, corresponding to vibrations of the secondary NH groups.



The ^{1}H NMR spectra of **V**–**VIII** contain signals of methylene protons adjacent to amide and carboxy groups [–CH_2C(O)NH–, –CH_2C(O)OH] at 2.2 ppm and to the nitrogen atom [–C(O)NHCH_2–] at 3.2 ppm. The ^{13}C NMR spectra contain strong signals at 173.2, 173.3, and 173.4 ppm, belonging to CONH groups.

As polyamides **V**–**VIII** contain terminal amino groups, their subsequent use as thermoplastics in hot-melt adhesive formulations may involve reactions altering the physicomechanical properties of the products owing to amide interchange [13]. To exclude these processes, the polyamide compounds prepared were stabilized with monocarboxylic acids (abietic or acetic). The required amount of the monocarboxylic acid was calculated from the amine number of the polymer. The monocarboxylic acid was added to the polyamide reaction mixture cooled to 120–150°C, the mixture was stirred for 15 min, and then it was gradually heated to 220–240°C until the water evolution ceased. The reaction with monocarboxylic acids follows the scheme

$$\mathbf{V}\text{–}\mathbf{VIII} + 2R^3COOH \quad (\mathbf{IX}, \mathbf{X})$$

$$\rightarrow R^3C(O)NH[RNHC(O)R^2C(O)NH]_nRNHC(O)R^3 + H_2O. \quad (\mathbf{XI}\text{–}\mathbf{XVIII})$$

where R^2 =

R^3 = $C_{19}H_{29}$ (**IX**), CH_3 (**X**); R = $(CH_2)_6$, R^2 = $C_{34}H_{62}$, R^3 = CH_3 (**XI**); R = $(CH_2)_6$, R^2 = $C_{34}H_{62}$, R^3 = $C_{19}H_{29}$ (**XII**); R = $C_2H_4NHC_2H_4$, R^2 = $C_{34}H_{62}$, R^3 = CH_3 (**XIII**); R = $C_2H_4NHC_2H_4$, R^2 = $C_{34}H_{62}$, R^3 = $C_{19}H_{29}$ (**XIV**); R = $(CH_2)_6$, R^2 = $C_{34}H_{62}$ and

$(CH_2)_8$, $R^3 = CH_3$ (**XV**); R = $(CH_2)_6$, $R^2 = C_{34}H_{62}$ and $(CH_2)_8$, $R^3 = C_{19}H_{29}$ (**XVI**); R = $C_2H_4NHC_2H_4$, $R^2 = C_{34}H_{62}$ and $(CH_2)_8$, $R^3 = CH_3$ (**XVII**); R = $C_2H_4NHC_2H_4$, $R^2 = C_{34}H_{62}$ and $(CH_2)_8$, $R^3 = C_{19}H_{29}$ (**XVIII**); n = 3–30.

Polyamides **XI**–**XVIII** have the following characteristics: amine number (for primary amino groups) 0.5–1.2 (mg KOH) (g polyamide)$^{-1}$; acid number 0.3–1.0 (mg KOH) (g polyamide)$^{-1}$; softening point 43–104°C. It should be noted that the softening point of stabilized compounds **XI**–**XVIII** does not change after heating at 250°C for 2 h, whereas that of **V**–**VIII** changes after heating at 250°C for 1 h. Introduction of the abietic acid residue enhanced the adhesion properties of the polyamides.

CONCLUSION

The conditions for preparing polyamides from dimerized fatty acid, sebacic acid, and aliphatic amines were optimized. The ratio of dicarboxylic acids and amines largely determines the softening point of the polyamides. Replacement of hexamethylenediamine in the reaction mixture by diethylenetetramine decreases the softening point from ~100 to ~50°C, which is associated with the structure of the amine.

Abstract—The $AlCl_3$-catalyzed low-temperature polymerization of α-pinene in the presence of various activating additives was studied.

Polyterpene resins (PTRs) are prepared by acid-catalyzed polymerization in the course of deep processing of turpentine. These resins are widely used in industry, especially beyond Russia. Depending on the composition of the raw materials and preparation procedure, PTRs have different consistency: from viscous liquids to high-melting solids. The wide spectrum of physicochemical properties determines the applications of PTRs. Of most interest are solid high-melting PTRs with the ring-and-ball softening point T_s above 90°C (PTR_{90}). Specifically these products, produced mainly in the United States from turpentine enriched in β-pinene, are successfully used for more than 30 years as thermoplastic adhesive additives in production of hot-melt and pressure-sensitive adhesives, and also of paint-and-varnish, sealing, and insulating materials [1–4]. In oleoresin and sulfate turpentine produced in Russia, the content of β-pinene does not exceed 5%, and the major component is α-pinene, from which it is difficult to prepare PTR_{90} in a high yield [5–10]. This is primarily due to the specific features of the molecular structure of α-pinene, in which the double bond, in contrast to β-pinene, is sterically shielded, which hinders the polymeric chain propagation. Therefore, the development and choice of the best catalytic systems and conditions for α-pinene polymerization, providing high yield of PTR_{90}, is of considerable theoretical and applied interest.

The polymerization of α-pinene was studied in the temperature range from –28 to +10°C in the presence of a mixture of Friedel–Crafts catalysts ($AlCl_3$ and $SbCl_3$), and also of heteropoly acids (HPAs) $H_3PW_{12}O_{40}$ (PW_{12}) and $H_4SiMo_{12}O_{40}$ ($SiMo_{12}$). As a result, we obtained PTR_{90} samples in yields reaching 84%. These samples were solid glassy substances with the color from light yellow to light brown and T_s = 92–115°C (Table 1). The molecular weight (MW) of PTR_{90} is 580–800, and the intrinsic viscosity η at 20°C, 0.0124–0.0289 dl g^{-1}. The PTR_{90} is a mixture of oligomers of monoterpene hydrocarbons with the chain length from 3 to 6 $C_{10}H_{16}$ units (so-called polyterpenes, PTs) and of a small amount of dimers of α-pinene and/or other monoterpene hydrocarbons (diterpenes, DTs).

The DT fraction isolated from PTR_{90} is a transparent light yellow oily liquid with a kinematic viscosity at 20°C of 130–200 $mm^2 s^{-1}$ and a density of 936–942 g dm^{-3}. The boiling point of DT is 150–200°C at 0.5 kPa, refractive index n_D^{20} 1.5126–1.5157, and MW 270–290.

The polymerization of α-pinene is accompanied by its isomerization; along with PTR_{90}, the products contain camphene, dipentene, terpinolene, and *p*-cymene. As shown in [5–7], the same monoterpenoids are formed by polymerization of α-pinene at temperatures exceeding 100°C in the presence of acid catalysts of other types: aluminosilicates, natural zeolites, or titanium catalyst.

The influence of the composition of the catalytic system on T_s of PTRs prepared by polymerization of α-pinene at –(3±2)°C for 3 h is illustrated by Fig. 1. These data show that $SbCl_3$ is an effective cocatalytic additive to $AlCl_3$. On adding even 0.1 wt % $SbCl_3$ to 4 wt % $AlCl_3$, PTR_{90} samples with T_s = 92°C are obtained (Fig. 1, curve *1*). As the $SbCl_3$ content is increased to 0.3 wt %, T_s of PTR_{90} increases to 113°C and does not further change at higher concentrations of $SbCl_3$. The yield of PTR_{90} obtained in the presence of this catalytic system is 78–84%, and MW is in the range 584–790.

When the content of the main catalyst, $AlCl_3$, is decreased to 3 wt %, the noticeable cocatalytic effect of $SbCl_3$ is preserved (Fig. 1, curve *2*). However, in this case $SbCl_3$ should be added in a substantially larger amount (0.9 wt %) to obtain PTR_{90}. The re-

* $SiMo_{12}$.

quired amount of $SbCl_3$ can be appreciably reduced by adding HPAs PW_{12} and $SiMo_{12}$ into the catalytic system. As seen from Fig. 1 (curves *3*, *4*), on adding 0.6–1.0 wt % PW_{12} to the binary catalytic system $AlCl_3$–$SbCl_3$, T_s of PTR sharply increases, especially at the $SbCl_3$ concentration in the range 0.2–0.5 wt %. At higher $SbCl_3$ concentrations, the effect of PW_{12} on T_s of PTR is less significant, and starting from 0.9 wt % $SbCl_3$ additions of HPAs to the catalytic system no longer affect the composition and physicochemical properties of the resins.

It should be noted that $SiMo_2$ behaves in the examined reactions of α-pinene polymerization similarly to PW_{12}. These HPAs have similar structure and similar acid-catalytic properties; therefore, the mechanism of their effect is presumably similar.

Table 1 and Fig. 2 show that the yield and composition of PTR_{90} prepared by polymerization of α-pinene for 3 h in the presence of a mixture of 3 wt % $AlCl_3$ and 1.5 wt % $SbCl_3$ are independent of the reaction temperature in the range from –28 to 0°C. The softening point of the PTR_{90} thus formed is 109–112°C, and MW, 750–764. When the temperature is increased to 3±2°C and then to 8±2°C, the PTR_{90} yield remains constant, and T_s decreases to 101 and 94°C, respectively. When the polymerization temperature is increased further to 15±2°C, T_s of the PTR drastically decreases (to 62°C).

From these data, we plotted the correlation of T_s of PTRs prepared by polymerization of α-pinene with their MW (Fig. 3). This correlation is important for preparing PTRs with preset physicochemical properties. Figure 3 shows that, with an increase in MW

from 450 to 580, T_s of PTR grows considerably, from 40 to 90°C, whereas with a further increase in MW to 800 T_s grows less significantly, from 90 to 115°C. It can be expected that PTR_{90} with MW > 800, if obtained, will have only slightly higher T_s. For comparison, according to [4, 11], T_s of PTR_{90} samples with MW 1500–2000 prepared from α-pinene is 125–130°C.

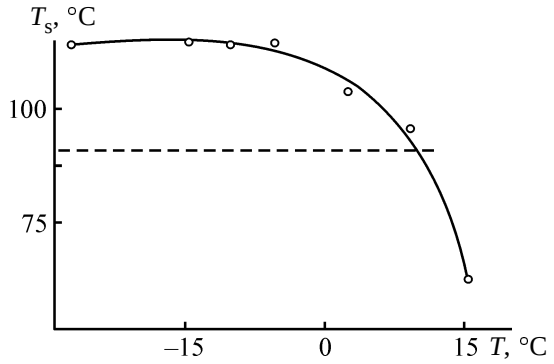

Fig. 2. T_s of PTR as a function of α-pinene polymerization temperature T. Catalyst (wt % of α-pinene) $AlCl_3 : SbCl_3 = 3 : 1.5$; polymerization time 3 h.

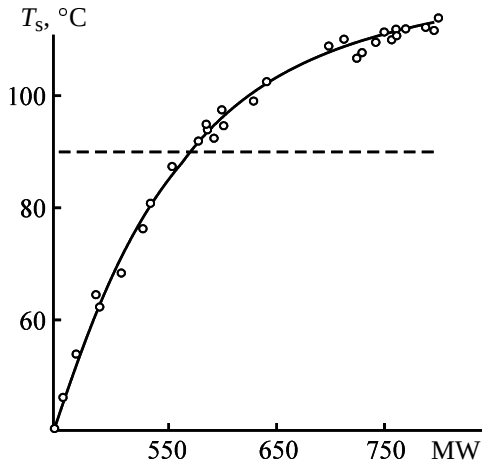

Fig. 3. Correlation of T_s of PTR with its MW.

In Fig. 4 and Table 2 we present the kinetic data on the polymerization of α-pinene in the presence of the catalytic system 3 wt % $AlCl_3$ + 1.5 wt % $SbCl_3$ at –(3±2)°C. It is seen that it is appropriate to perform the polymerization of α-pinene for 3 h, as the content of PT (81.4%) and hence the yield of PTR_{90} under these conditions reach a maximum. Longer reaction (6 h) does not further change the PT content. It should be noted that the physicochemical properties of PTR_{90} prepared from α-pinene under these conditions are independent of the reaction time (Table 2).

As seen from Fig. 4, the kinetic curves of accumulation of α-pinene isomerization products in the course of its polymerization are different. Dipentene and terpinolene (curves *5*, *7*) are rapidly accumulated in the initial period; their content reaches a maximum 0.5 h after the start of the reaction, after which they are virtually completely consumed, especially in the interval 0.5–2 h. Thus, these monoterpenoids undergo secondary transformations. The content of *p*-cymene (curve *6*) in the reaction mixture gradually increases throughout the process, and the weight fraction of camphene (curve *4*) slightly increases in the first hour of the reaction and then remains virtually constant.

The results of this study are well consistent with the well-known and generally accepted cationic mechanism of α-pinene polymerization in the presence of Lewis acids [3].

The cocatalytic effect of $SbCl_3$ and HPA additions to $AlCl_3$ and of HPA additions to an $AlCl_3$–$SbCl_3$ mixture is apparently associated with stabilization of the growing intermediate carbenium ion, i.e., with extension of its "life" during which it can attack the next α-pinene molecule. Simultaneously, the contribution of the reaction pathway leading to DT decreases. A similar hypothesis on the mechanism of the effect of activating additives on the α-pinene polymerization

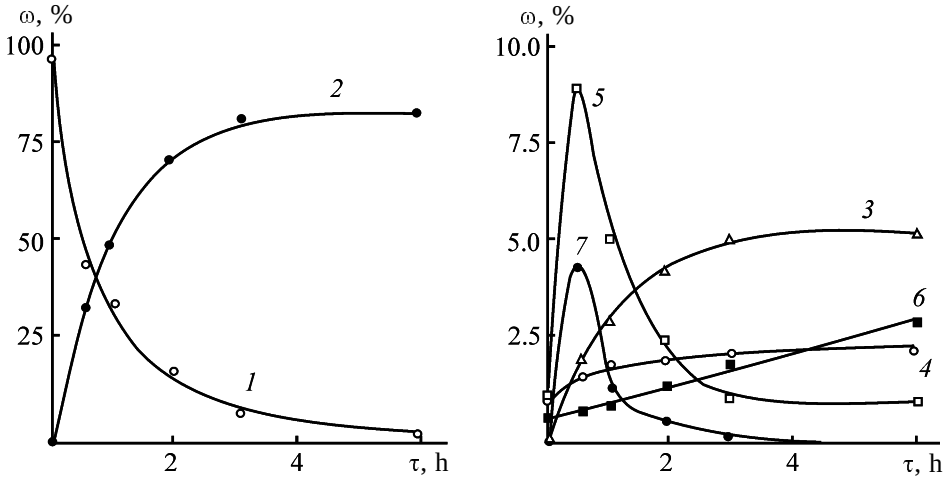

Fig. 4. Kinetic curves of polymerization of α-pinene: (ω) weight fraction of reaction products and (τ) polymerization time. (*1*) α-Pinene, (*2*) PT, (*3*) DT, (*4*) camphene, (*5*) dipentene, (*6*) *p*-cymene, and (*7*) terpinolene.

in the presence of $AlCl_3$ was formulated previously [3, 4, 11] as applied to Sb, Si, and Ge halides.

The stabilization of the growing carbenium ion and propagation of the polymer chain are also favored by the negative temperature of the α-pinene polymerization. The reaction is exothermic (thermal effect 1000–1200 kJ kg^{-1}), and when it is performed at temperatures in the range from –28 to 0°C, the temperature in the reaction zone can be readily controlled; under these conditions, the major pathway is PT formation.

It is well known and generally accepted that acid-catalyzed isomerization of monoterpenoids by the mechanism described in [12] occurs at elevated temperatures. Our results show that, with the examined catalytic systems, the same carbocationic mechanism is realized at low and even negative temperatures.

The kinetic studies show that dipentene and terpinolene formed by isomerization of α-pinene, apparently, polymerize subsequently through the intermediate tertiary carbenium ion to form DT and PT.

The results of this study serve as a basis for the development of a process for preparation of solid polyterpene resins from turpentine produced by Russian coniferous trees.

EXPERIMENTAL

α-Pinene [technical-grade purified sulfate pinene, TU (Technical Specifications) 13-00 281 074-268–96] contained 94–98 wt % main substance and 0.001–0.005 wt % moisture. The other chemicals were of chemically pure or analytically pure grade and were used without additional purification.

Polymerization of α-pinene was performed in a reactor equipped with a descending condenser and a blade stirrer. The temperature in the reactor was maintained constant (±2°C) with a cooling agent. The reactor was charged with the required amount of toluene (solvent), after which the required amounts of the catalyst and additives were added with stirring, and the contents were stirred to obtain a uniform mass. After the required temperature was attained, α-pinene was gradually added at a rate at which spontaneous self-heating could be avoided. The moment of completion of adding α-pinene was considered as the start of the reaction. After a definite time, the reaction was stopped by adding excess water, which caused deactivation of the catalyst. Then the contents were transferred into a separating funnel, and the upper layer (solution of reaction products in toluene) was separated after settling. This solution was treated with CaO, again washed with water, dried over Na_2SO_4, and subjected to fractional distillation at 0.5 kPa. The following fractions were collected: toluene <45°C and monoterpene hydrocarbons 45–110°C. After that, the distillation was stopped, the still was cooled, and the residue was analyzed to determine the weight fraction of DT in PTR_{90} (by GLC) and other physicomechanical parameters of PTR_{90}.

The chromatographic analysis of DT was performed with a Chrom 5 chromatorgaph equipped with a flame-ionization detector and a packed stainless steel column 5 m long, liquid phase SE-30, column temperature 180–200°C, vaporizer temperature 290°C, nitrogen flow rate 60 ml min^{-1}. The fraction of monoterpene hydrocarbons was analyzed with a packed stainless steel column 3 m long; liquid phase tricresyl

phosphate, column temperature 110–115°C, vaporizer temperature 250°C, nitrogen flow rate 60 ml min^{-1}.

The amounts of the reaction mixture components were determined with an internal reference. The components of the reaction mixture were identified using reference compounds or from the relative retention of terpenoids [12]. The relative error of a single analysis at a confidence level of 0.95 was within ±2%. The results of five replicate runs were averaged.

The softening point of PTR_{90} was determined according to GOST (State Standard) 23863–79 with changes 1 and 2 (ring-and-ball method), and the intrinsic viscosity (in toluene), by the procedure described in [13]. The molecular weights of PTR_{90} and DT were determined cryoscopically in benzene [13].

To isolate DT, PTR_{90} was distilled at 0.5 kPa, and the DT fraction boiling at 115–200°C was collected. The density, kinematic viscosity, and refractive index of DT were determined according to TU 2416-018-02067907–2001 "Liquid Polyterpenes."

CONCLUSIONS

(1) Polymerization of α-pinene gave a solid polyterpene resin with a softening point above 90°C in 81–84% yield.

(2) The low-temperature polymerization of α-pinene catalyzed by $AlCl_3$ in the presence of activating additives ($SbCl_3$, heteropoly acids) occurs presumably by the cationic mechanism. The cocatalytic effect of the additives is associated with the stabilization of the growing carbenium ion, which favors formation of polyterpenes and decreases the contribution of the dimerization of the monoterpene hydrocarbons.

(3) The low-temperature polymerization of α-pinene is accompanied by acid-catalyzed isomerization of monoterpenoids by the carbenium ion mechanism with the formation of *p*-cymene, camphene, dipentene, and terpinolene and subsequent polymerization of dipentene and terpinolene.

(4) The results obtained serve as a basis for the development of a commercial process for preparation of solid polyterpene resins from turpentine produced in Russia.

Abstract—The reaction of Mn(0) with benzyl bromide in dimethylformamide was studied.

Coordination compounds of Mn in various oxidation states are used in industry as selective catalysts of various chemical processes [1]. With the aim to optimize the conditions for preparing complexes of manganese(II) bromide with organic ligands, we examined in detail the mechanism and kinetics of the reaction of Mn(0) with benzyl bromide in the presence of dimethylformamide (DMF).

The kinetics of oxidative dissolution of Mn(0) in the system benzyl bromide–DMF was studied resistometrically. This method allows kinetic studies of fast heterogeneous reactions; it ensures high accuracy and reproducibility of the results [2, 3].

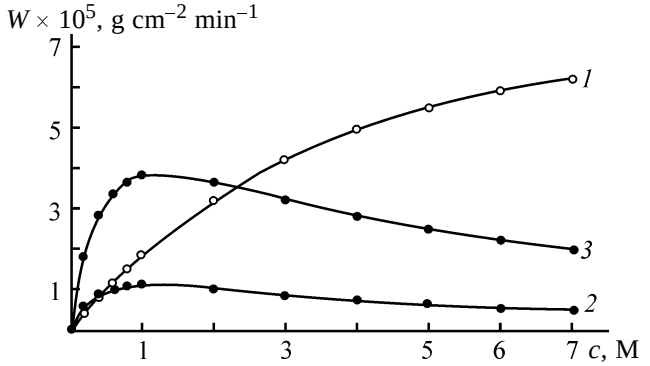
To determine the kinetic characteristics of the process, the reaction was performed in an inert solvent (benzene, $DN_{SbCl_5} = 0.42$ kJ mol^{-1}) [3].

The kinetic curves are shown in the figure. The dependences of the reaction rate on the benzyl bromide concentration at the DMF concentration varied in the range from 0.2 to 2 M have a similar shape with a pronounced maximum, suggesting that the reaction follows the Langmuir–Hinshelwood scheme with the adsorption of the reagent and solvent on the same active centers of the metal surface [4]:

$$PhCH_2Br + S \overset{K_1}{\rightleftarrows} (PhCH_2Br)S, \quad (1)$$

$$DMF + S \overset{K_2}{\rightleftarrows} (DMF)S, \quad (2)$$

$$(PhCH_2Br)S + (DMF)S \xrightarrow{k_3} \text{reaction products}, \quad (3)$$



where K_1 and K_2 are the equilibrium constants of adsorption of benzyl bromide and DMF, respectively; k_3 is the rate constant of the chemical process; and S denotes active centers on which benzyl bromide and DMF are adsorbed.

The kinetic equation for this case includes the degree of the surface coverage, determined from the Langmuir isotherm for the adsorption of each component; the equation for the reaction rate W has the form

$$W = k\frac{K_1 K_2 [PhCH_2Br][DMF]}{(1 + K_1[PhCH_2Br] + K_2[DMF])^2}, \quad (4)$$

where $k = KN^2$, N is the number of active centers of the metal surface on which benzyl bromide and DMF are adsorbed.

Treatment of the experimental dependences (see figure) using Eqs. (1)–(3) allowed determination of the equilibrium constants of adsorption of benzyl bromide (K_1) and DMF (K_2) on the Mn surface and

Rate of oxidative dissolution of Mn(0) W in the benzyl bromide–DMF system as a function of the initial component concentrations c in benzene at 353 K: (*1*) $W = f(c_{DMF})$, $c_{PhCH_2Br} = 0.5$ M; (*2*) $W = f(c_{PhCH_2Br})$, $c_{DMF} = 0.5$ M; and (*3*) $W = f(c_{PhCH_2Br})$, $c_{DMF} = 2$ M.

the reaction constant k. From the kinetic data obtained at different temperatures, we determined E_a of the chemical reactionm and the enthalpies of adsorption of the reactants ($\Delta H^0_{PhCH_2Br}$, ΔH^0_{DMF}) on the Mn surface. The results are listed in Table 1.

The Langmuir–Hinshelwood scheme for this process suggests that the limiting step is the reaction of the reactant molecules adsorbed on the metal surface, i.e., the chemical reaction on the surface.

In the absence of atmospheric oxygen (including oxygen adsorbed on the metal surface), the dehalogenation of benzyl bromide with Mn(0) in DMF yields Mn(II) coordination compounds, 1,2-diphenylethane, and traces of 4,4'-ditolyl (<0.1%):

$$2PhCH_2Br + Mn + 2DMF \rightarrow [MnBr_2 \cdot 2DMF] + PhCH_2CH_2Ph + \underset{<0.1\%}{p\text{-}MeC_6H_4C_6H_4Me\text{-}p}.$$

As proved by ion chromatography, only Mn(II) complexes are formed in the process. Cocondensation of atomic Mn generated by the metal evaporation in a low-voltage electric arc with benzyl bromide (Mn : benzyl bromide ratio 1 : 100) deposited in the molecular-beam mode on a surface cooled with liquid nitrogen gave white films stable at 77 K for no less than 24 h; these films became transparent at the melting point of the samples. The samples were treated with H_2O and D_2O. The melts contained a small amount of white solid inclusions. An analysis by ion chromatography revealed the presence of Mn^{2+} and Br^- in a ratio corresponding to the formula $MnBr_2$.

The formation of 1,2-diphenylethane and traces of 4,4'-ditolyl suggests that the oxidative dissolution of Mn(0) in the benzyl bromide–DMF system occurs by the radical mechanism.

The ESR spectrum of the cocondensate of atomic Mn with benzyl bromide at 77 K is a triplet of quartets with the full width of about 50 G and g-factor of approximately 2.002. Based on data from [5–7], this spectrum was assigned to the benzyl radical in a solid matrix (Table 2).

The fact that the ESR spectrum at 77 K contains no signals from Mn atoms, radical pairs, and tolyl radicals, and also formation of white films suggest that dehalogenation of benzyl bromide with atomic Mn generated by evaporation in a low-voltage electric arc occurs predominantly in the gas phase rather than in the benzyl bromide matrix, and the recombination and isomerization of benzyl radicals and formation of their radical pairs occur at temperatures above 77 K. Indeed, when the Mn–benzyl bromide cocondensates are warmed up to 130 K, the signals of the benzyl radicals decrease in the intensity; at 130–150 K, the resolution of the ESR spectra gets considerably worse because of the superposition of the signals from the benzyl and tolyl radicals and from the corresponding radical pairs.

The detection of small amounts of toluene and polybenzyls (compounds containing no halogen) after the defrosting and hydrolysis of the samples suggests the following reaction scheme:

$$2PhC\dot{H}_2 \longrightarrow PhCH_3 + PhC\ddot{H},$$

$$n PhC\ddot{H} + 2\,PhC\dot{H}_2 \longrightarrow CH_2(Ph)\text{–}\left(CH(Ph)\right)_n\text{–}CH_2(Ph),$$

where n = 1–5.

In the reaction of atomic Mn generated by the metal evaporation in a low-voltage electric arc with benzyl bromide, after defrosting and treatment of the samples with water, we detected molecular hydrogen (<0.02%). This may be due to the reaction of unchanged Mn with water or to hydrolysis of benzylpolymanganese bromide and benzylpolymanganese hydride formed by the scheme [8, 9]

$$PhCH_2Br + Mn_n \longrightarrow \overline{PhCH_2Br^{\bullet-}Mn_n^{\bullet+}} \longrightarrow PhCH(Br)Mn_nH,$$

$$PhCH_2Br + Mn_n \longrightarrow \overline{PhCH_2^{\bullet}\cdots Mn_nBr} \longrightarrow PhCH_2Mn_nBr,$$

where n > 1.

As the amount of hydrogen is small, the content of benzylpolymanganese bromide and/or hydride in the reaction mixture is low or zero. Hence, the reaction of atomic Mn generated by the metal evaporation in a low-voltage electric arc with benzyl bromide does not yield noticeable amounts of the $[Mn_nBr]^{\bullet}$ radical.

Formation of a white matrix in the cocondensation of atomic Mn generated by the metal evaporation in a low-voltage electric arc with benzyl bromide at 77 K suggests that charge-transfer complexes are not noticeably formed on the Mn surface either.

These facts suggest that the Mn atoms react with benzyl bromide already in the gas phase:

$$PhCH_2Br + Mn \longrightarrow PhC\dot{H}_2 + \dot{M}nBr.$$

After the cocondensation, the radicals occur in a cage of solid benzyl bromide (molar ratio $PhCH_2Br$: Mn = 100 : 1); therefore, the radical $\dot{M}nBr$ does not disproportionate at 77 K but reacts with $PhCH_2Br$, abstracting the halogen atom:

$$PhCH_2Br + \dot{M}nBr \longrightarrow PhC\dot{H}_2 + MnBr_2.$$

Toluene detected in the reaction mixtures after defrosting and hydrolysis of the samples may originate from decomposition of $PhCH_2MnBr$ with water or from the reaction

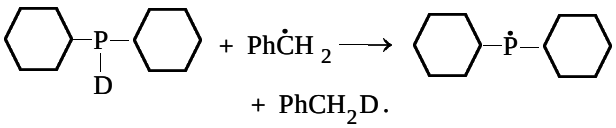
$$PhC\dot{H}_2 + PhCH_2Br \longrightarrow PhCH_3 + PhC\dot{H}Br.$$

However, recombination products of the Ph–$\dot{C}$HBr radical were not detected in the reaction mixtures, and the deuterolysis yielded $PhCH_2D$. Hence, the presence of toluene in the reaction mixture after defrosting and hydrolysis of the samples with water suggests that the reaction of benzyl halide with atomic Mn involves formation of organomanganese compounds:

$$PhCH_2Br + Mn \longrightarrow PhCH_2MnBr.$$

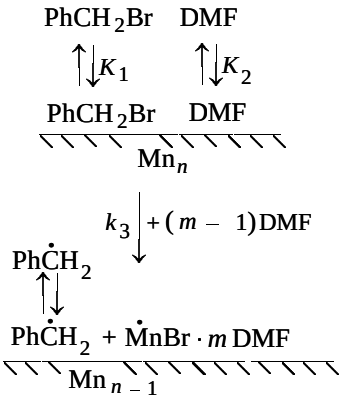
The radical species in solutions were detected and identified using spin traps.

When a stable radical, 2,2,6,6-tetramethylpiperidyl-1-oxyl (TEMPO), reacting with radical intermediates, was added to the reaction mixture, its ESR signals disappeared in the course of the reaction, suggesting the radical mechanism of the oxidative dissolution of Mn(0) in the benzyl bromide–DMF systems, since the ESR signals of TEMPO do not appear after oxidation of Mn(0) to Mn(II) and reduction of the mixtures with KI in acetate buffer solution [10, 11].



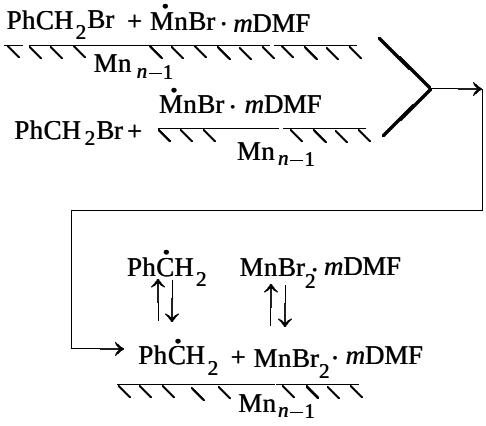
As a chemical radical trap we used dicyclohexyldeuterophosphine (DCPD), which is successfully used for this purpose and allows not only the detection of radical intermediates but also determination of their content in solution [9].

In the dehalogenation of benzyl bromide with Mn(0) in DMF in the presence of DCPD, the composition of the reaction products changes and shows a dependence on the Mn(0) : DCPD molar ratio. At a Mn(0) : DCPD molar ratio of 1 : 5, 1,2-diphenyl-



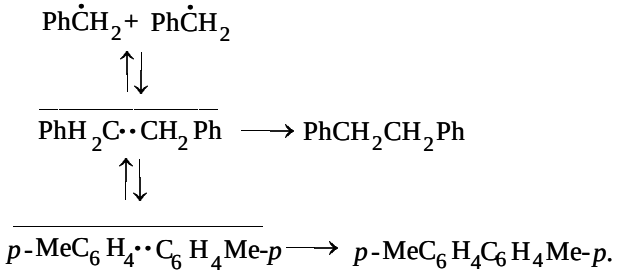
ethane was not detected, but an equivalent amount of α-deuterotoluene (97 ± 1%) was detected instead:

$$2PhCH_2Br + Mn + DMF \xrightarrow{DCPD} [MnBr_2 \cdot 2DMF] + 2PhCH_2D.$$



An analysis of the reaction products in the absence and in the presence of radical traps indicates that the reaction occurs by the radical mechanism via benzyl radical:

Thus, dehalogenation of benzyl bromide occurs on the Mn(0) surface by the radical mechanism via benzyl radicals; their recombination occurs in the solution. The adsorption of the reagent and solvent occurs by the Langmuir–Hinshelwood mechanism on the same active centers of the metal surface:



The $\dot{M}nBr \cdot m$DMF radical rapidly reacts with a new benzyl bromide molecule by the Lamgmuir–Hinshelwood or Ealy–Rideal mechanism:

$$MnBr_2 \cdot m\text{DMF} + (2 - m)\text{DMF} \rightarrow MnBr_2 \cdot 2\text{DMF},$$

where $m = 1, 2$; $n \geq 1$.

In the solution, the benzyl radicals either recombine via formation of a radical pair or again return to the Mn surface:

EXPERIMENTAL

The ESR spectra were recorded on a Radiopan spectrometer at 77 and 293 K by the procedures described in [10–12]. TEMPO was used as a spin trap at 298 K. The IR spectra were taken on an Impact 400d spectrophotometer (Nicolet).

To monitor the purity of the starting compounds and quantitatively analyze the organic products, we used gas–liquid chromatography (GLC); the conditions are described in [8].

White solid inclusions were analyzed by ion chromatography on a Tsvet 3006 chromatograph equipped with a conductometric detector. Anions were analyzed on a steel column (l = 200 mm, d = 4 mm), sorbent KhIKS-1 (Institute of Chemistry, Academy of Sciences of Estonia; particle size 15 μm), eluent 0.03 M Na_2CO_3 in water, elution rate 2 ml min^{-1}, sample volume 10 μl. Cations were analyzed on a Diakat-3 column (Elsiko, Moscow; l = 150 mm, d = 3 mm), mobile phase ethylenediamine : tartaric acid : citric acid = 1.5 : 3.5 : 3.5 (molar ratio), elution rate 1.5 ml min^{-1}.

A GC–MS analysis of the reaction products was performed on a Hewlett–Packard gas chromatograph–mass spectrometer (the United States; HP-5972 mass detector, HP-5890 chromatograph) equipped with a capillary column (l = 30 m, d = 0.25 mm), stationary phase poly[diphenylsiloxane (5%)–dimethylsiloxane]. The column was heated from 40 to 250°C at a rate of 30 deg min^{-1}. The carrier gas was helium (flow rate 1 ml min^{-1}). The vaporizer and detector temperatures were 250 and 280°C, respectively.

The ^1H NMR spectra (δ, ppm) were recorded on a Jeol LTD FX-90Q NMR Fourier spectrometer from 25–30% solutions of samples in CCl_4 or $CDCl_3$, internal reference HMDS. The chemical shifts were determined with an accuracy of ± 0.01 ppm. The reaction products were isolated by preparative liquid chro-

matography on a Tsvet-304 chromatograph equipped with a UV detector (λ = 254 nm) and a steel column (l = 25 cm, d = 4 mm), sorbent Silasorb 600 (Chemapol, Czechia; fraction 15–25 μm). A 5 : 1 (by volume) hexane–diethyl ether mixture was used as eluent.

Manganese powder [99.8% purity, Reakhim, Moscow; GOST (State Standard) 6008–90] was used without additional purification.

Samples of manganese wire used for kinetic studies were prepared by electroplating of a copper wire (0.05 mm in diameter) with Mn metal (coating thickness 0.075 mm). Just before an experiment, the sample was kept for 5–10 s in concentrated HCl and washed successively with water, acetone, and DMF. All the organic compounds were commercial chemicals. Dimethylformamide was purified by slow double vacuum distillation from a large amount of P_2O_5 [13]. Acetone, benzene, and other solvents were purified by standard procedures [14]. All the solvents were degassed by repeated freeze–pump–thaw cycles and stored in ampules without air access.

Manganese(II) complexes. To 1.1 g of Mn(0) powder we added 10 ml of DMF and 10 ml of benzyl bromide. The reaction was performed under pure dry Ar at 70°C for 8 h. After the dissolution of Mn, the reaction mixture was treated with 20 ml of absolute diethyl ether. The crystalline precipitate of [$MnBr_2 \cdot 2DMF$] was separated, washed with hexane, and vacuum-dried. Yield 5.92 g (82%), decomposition point 156°C (published data: decomposition point 156°C [15]). IR spectrum (KBr), ν, cm^{-1}: 1649 (CO), 1445 (CH_3), 1248 (CN), 1113 (CN), 678 (OCN).

Found, %: C 19.94, H 3.95, Br 44.30, Mn 15.21, N 7.74. $C_6H_{14}Br_2MnN_2O_2$.
Calculated, %: C 19.95, H 3.91, Br 44.28, Mn 15.22, N 7.76.

Treatment of the reaction mixture with moist diethyl ether gave [$MnBr_2 \cdot 2DMF \cdot 2H_2O$], yield 6.59 g (87%), mp 85°C (published data: mp 85°C [15]). IR spectrum (KBr), ν, cm^{-1}: 3470 (OH), 1660 (CO), 1620 (HOH), 1450 (CH_3), 1255 (CN), 1120 (CN), 682 (OCN).

Found, %: C 18.11, H 4.58, Br 40.07, Mn 13.82, N 7.09. $C_6H_{18}Br_2MnN_2O_4$.
Calculated, %: C 18.15, H 4.57, Br 40.05, Mn 13.84, N 7.06.

In the ether solution, we detected unchanged benzyl bromide and DMF, and also 1,2-diphenylethane and traces of 4,4'-ditolyl. 1,2-Diphenylethane, yield 3.54 g (97%), mp 51–52°C (published data: mp 51–52°C [16]). ^{1}H NMR spectrum ($CDCl_3$), δ, ppm: 2.82 s (4H, CH_2), 7.02 m (10H, Ph). Mass spectrum (70 eV), m/z [I_{rel} (%)]: 182 $[M]^+$ (23), 91 $[M/2]^+$ (100). 4,4'-Ditolyl. Mass spectrum (70 eV), m/z [I_{rel} (%)]: 182 $[M]^+$ (100), 167 $[M - CH_3]^+$ (56), 152 $[M - 2CH_3]^+$ (15).

The ESR spectra were taken directly from the reaction mixtures at 298 K by the procedure described in [10, 11]. As a stable radical we used TEMPO [10, 11] at the molar ratio Mn : $PhCH_2Br$: DMF : TEMPO = 1 : 5 : 8 : 0.2. 2,2,6,6-Tetramethylpiperidyl-1-oxyl[1] had mp 39°C (published data: mp 39°C [17]). IR spectrum (KBr), ν, cm^{-1}: 1330, 1180, 1060, 975, 950. ESR spectrum: g = 2.0055, a_N = 17.2 ± 0.1 G, a_H = 0.2 ± 0.2 G, ΔH = 1.5 G. After the oxidation of Mn, the reaction mixtures were reduced with KI in an acetate buffer solution or with H_2O_2 in an alkaline solution directly in the ampule placed in the spectrometer cavity.

Experiments in the presence of the spin trap were performed similarly. As spin trap we used dicyclohexyldeuterophosphine (DCPD) [9]. The Mn(0) : DCPD ratio was 1 : 5.

In ether solutions, we detected unchanged benzyl bromide and DMF, and also α-deuterotoluene (yield 97%). ^{1}H NMR spectrum ($CDCl_3$), δ, ppm: 2.32 m (2H, CH_2), 7.15 m (5H, Ph). Mass spectrum (70 eV), m/z [I_{rel} (%)]: 93 $[M]^+$ (100), 92 $[M - H]^+$ (93), 91 $[M - D]^+$ (46), 66 $[M - C_2H_3]^+$ (9), 65 $[M - C_2H_2D]$ (11).

Reaction of atomic Mn with benzyl bromide was performed in a high-vacuum unit similar to that described in [18] and equipped with a device for metal evaporation in a low-voltage electric arc. The reagents were vaporized in an evacuated ($p = 10^{-4}$ torr) reactor (V = 10 l) and condensed on a surface cooled with liquid nitrogen. Atomic Mn was generated by evaporation of the purified metal in a low-voltage electric arc (15 V, 32 A) formed between two Mn electrodes. The vapors of compounds to be condensed together with the evaporated metal were sprayed in the vessel just below the arc. The rate of Mn evaporation was 0.2 mmol min^{-1}. Benzyl halide was evaporated at 273–308 K ($PhCH_2Br$: Mn ratio 100 : 1). The cocondensation was performed for 2–4 h. The cocondensation of atomic Mn generated by the metal evaporation in a low-voltage electric arc with benzyl halides deposited in the molecular beam mode on a surface

[1] Submitted by F. Kayumov.

cooled with liquid nitrogen gave white films stable at 77 K for no less than 24 h.

After the polycondensation completion, the evacuation was stopped, and the reactor was filled with pure dry Ar (p = 760 mm Hg). The samples were warmed up to 298 K. When the melting point was reached, the films became transparent. The resulting melts contained a small amount of white solid inclusions. The reaction mixtures were treated with H_2O and D_2O at 298 K under pure dry Ar. Products in the gas phase were analyzed by gas chromatography; white solid inclusions were filtered off and analyzed by ion chromatography; the liquid phase was analyzed by GLC; organic products were isolated by preparative liquid chromatography. We isolated 1,2-diphenylethane (yield 98%), 4,4'-ditolyl (yield 1%), and hydrogen (yield 0.02%).

The kinetics of the reaction of Mn with benzyl bromide in DMF was studied resistometrically [2] by the procedure described in [19] in an atmosphere of dry deoxygenated Ar, with benzene as inert solvent [3]. The independence of the Mn(0) dissolution rate in the examined media from the stirring rate indicates that the process is kinetically controlled.

CONCLUSION

Oxidative dissolution of Mn(0) in the system benzyl bromide–dimethylformamide in the absence of oxygen occurs on the metal surface by the mechanism of one-electron transfer with the generation of the benzyl radical whose recombination and isomerization occur in the solution.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Excited Biradicals in Thermal Dimerization and Polymerization of Bicyclobutanes

Abstract—The structure and electronic parameters of 1-cyanobicyclobutane and 1-cyano-3-vinylbicyclobutane were determined by RHF, ROHF, and GVB (TCSCF)/6-31G* quantum-chemical calculations.

Theoretical study of the polymerization mechanism at the level of elementary steps gives an insight into the regioselectivity, chemical structure of the products, and reaction rates. Not only well-understood polymerization reactions (i.e., anionic polymerization of 1,3-butadiene or isoprene [1]) but also other little known reactions are of interest in this respect. 1-Cyanobicyclobutane (**I**) and 1-cyano-3-vinylbicyclobutane (**II**) have unusual steric structure and are highly reactive. These are colorless compounds stable at –80°C in the presence of a free-radical inhibitor [2, 3]. Compound **I** in the liquid state or in a solution dimerizes on heating to +80°C. At ~150°C, the trimer of this compound is formed [2]. Carbonitrile **I** polymerizes at room temperature or on mild heating in the presence of a radical initiator, with the polymer skeleton consisting mainly of four-membered carbon monocycles [2, 3]. Carbonitrile **I** can copolymerize with acrylonitrile, styrene, methyl methacrylate, vinyl chloride, isobutene, sulfur dioxide, and other monomers. The products are high-melting thermally stable polymers soluble in polar solvents [2].

This study is based on the theoretical concept on electronically excited biradicals or their complexes formed in thermal reactions occurring on molecular collisions [4]. Generally, neutral or charged excited radicals (biradicals) (thermoexciplexes or thermoexcimers) of various chemical structures should be considered. The main feature of these species is low energy (<1 eV) relative to that of free reagents. These states are populated at ordinary temperatures. The final reaction step is recombination of the radicals to form stable molecular products. Previously, with perfluorinated olefins as example, we showed [1] that electronically excited biradical quasi-degenerate states $(S{\cdot}T)_1$ are involved in thermal dimerization. The experimental heats of formation of the intermediates were correlated with the calculated excitation energies of the olefins.

The existence of these electronic states and the possibility of their thermal population are indicated by instability of bicyclobutanes in the absence of radical initiators at temperatures higher than –80°C. In this study, *ab initio* quantum-chemical calculations of the molecular geometries of **I** and **II** in the ground and lowest excited states were performed with the aim to determine the mechanism of dimerization and polymerization of these compounds.

Calculation procedures. Quantum-chemical calculation of the electronic and steric structure, vibrational spectra, and relative energies of the compounds in the ground (S_0) and triplet (T_1, T_2) electronic states were performed by restricted Hartree–Fock methods (RHF/6-31G* and ROHF/6-31G*) using GAMESS software [5] (version pcGAMESS 6.2 [6]). In the case of lowest excited singlet electronic states (S_1, S_2), we used the generalized two-configuration version of the valence bond procedure (TCSCF GVB/6-31G*). The geometric parameters of the triplet states were calculated by energy minimization at the ROHF level without symmetry restrictions. The geometry of the singlet excited states was assumed to be identical to that of T_1 and T_2 states and then was optimized at the GVB level by minimization of total energies at fixed populations of the active natural MO $n_1 = n_2 = 1$. It should be noted that the two-configuration method of generalized valence bonds, used to calculate the singlet excited state, corresponds to the ROHF calculation of the triplet state.

The valence V_A of each atom A in a molecule or free radical is a sum of the indices of the chemical

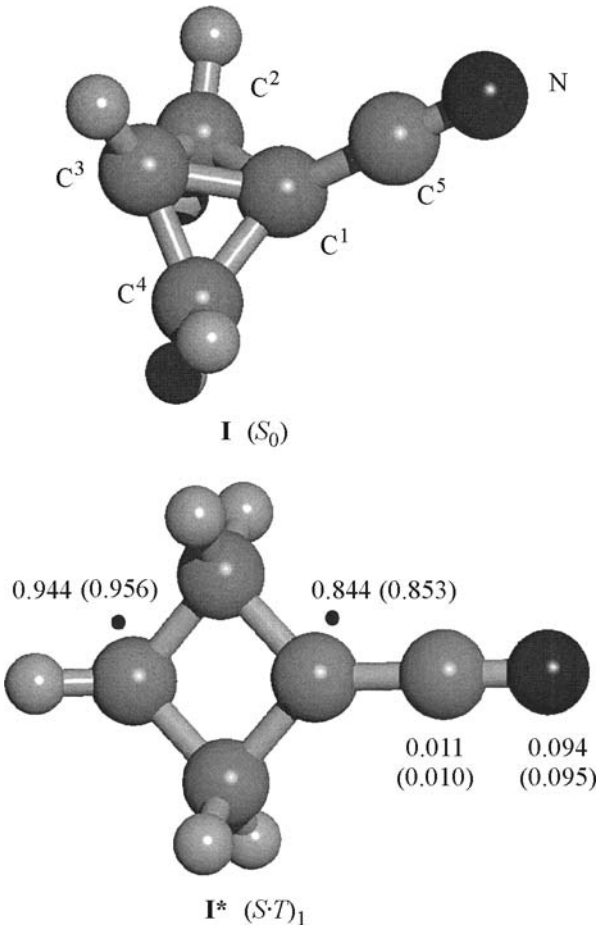

Fig. 1. Molecular structure of 1-cyanobicyclobutane **I** and free valances of the triplet and singlet (in parentheses) states.

bonds I_{AB} and free valence F_A [7], which can be calculated by the equation

$$F_A = V_A - \sum_{B(\neq A)} I_{AB}, \quad (1)$$

where

$$V_A = \sum_{a \in A} [2n_a^M - (n_a^M)^2] - \sum_{a \neq a'} (PS)_{aa'}(PS)_{a'a} \text{ [8]}, \quad (2)$$

$$I_{AB} = \sum_{a \in A} \sum_{A \in B} (PS)_{ab}(PS)_{ba} \text{ [9]}, \quad (3)$$

There are no free valences in the ground electronic state S_0 of a molecule: $F_A = 0$ and $V_{mol} = F_{mol} = 0$. In the excited states T_1 and S_1, the molecule becomes biradical: $V_{mol} = F_{mol} = 2$. Indices F_A characterize the distribution of the total valence of the biradical between its atoms [1]. The parameter F_A can be used to estimate the relative reactivity of atoms and to determine reaction sites in excited molecules, free radicals, and biradicals.

Structure of the monomers. The equilibrium nuclear configuration of **I** and **II** is characterized by nonplanar carbon skeleton and shortening of the interatomic distances typical for small rings. Substitution of hydrogen atoms of the tertiary carbon atom of the ring by a vinyl group has virtually no effect on the structural parameters of 1-cyanobicyclobutane (Table 1).

Quasi-degeneration of the energy levels of triplet T_1 and singlet S_1 states of **I** and **II** and the similarity in their structural parameters indicate that the lowest equilibrium excited states of the molecules are biradicals. The electronic excitation $S_0 \rightarrow (S{\cdot}T)_1$ results in rupture of the C^1–C^3 bond common for the two three-membered rings of bicyclobutanes. The bicyclic system is rearranged into a four-membered monocyclic biradical with a definite localization of free valences (Figs. 1, 2). In the lowest excited states, the C^1 and C^3 atoms of **I** and C^1 atom and terminal C^7 atom of the vinyl group of **II** have free valences. At the same time, the free valence of the biradical of **II** in the higher electronic state $(S{\cdot}T)_2$ is delocalized between vinyl carbon atoms (Fig. 2).

The four-membered rings of **I** and **II** in the lowest excited states $(S{\cdot}T)_1$ are flattened, the bond distances in the rind increase, and the exocyclic bonds with the cyano group are shortened. The bond between the ring and the vinyl group in **II** in the excited state $(S{\cdot}T)_1$ is shortened to the greatest extent and virtually becomes double, $C^3{=}C^6$. The bond angles ∠HCH in methylene groups of the ring appreciably decrease after excitation (Table 1).

Dimerization mechanism of 1-cyanobicyclobutane I. Since a molecule of 1-cyanobicyclobutane **I** contains the polar cyano group, it has a considerable dipole moment: 4.2 D in the ground state and 4.4 D in the excited biradical state $(S{\cdot}T)_1$. The charge distribution is presented in Table 2. The largest negative and positive charges are localized, respectively, on the nitrogen and adjacent carbon atoms of the cyano group. Electrostatic interactions suggest formation of =C–N= intermolecular bonds (with bicyclobutyl substituents at the carbon atoms). However, NMR, IR, and mass-spectroscopic studies showed that the only dimerization product is 1-cyano-3-(3-cyanocyclobut-1-yl)cyclobut-1-ene **VI** (Fig. 3).

Dimerization of 1-cyanobicyclobutane observed experimentally is inconsistent with the charge control of the reaction and becomes clear within the frame-

work of the concept of thermal excitation of **I** to the biradical states. The equilibrium excited state $(S{\cdot}T)_1$ (E = 20 kcal mol^{-1}) can be populated by thermal excitation. The calculated singlet–triplet splitting of the level is 2 kcal mol^{-1}. In biradical **I***, the carbon atom C^3 located at the maximal distance from the cyano group and bound with the hydrogen atom has the maximal index of free valence (Fig. 1). High reac-

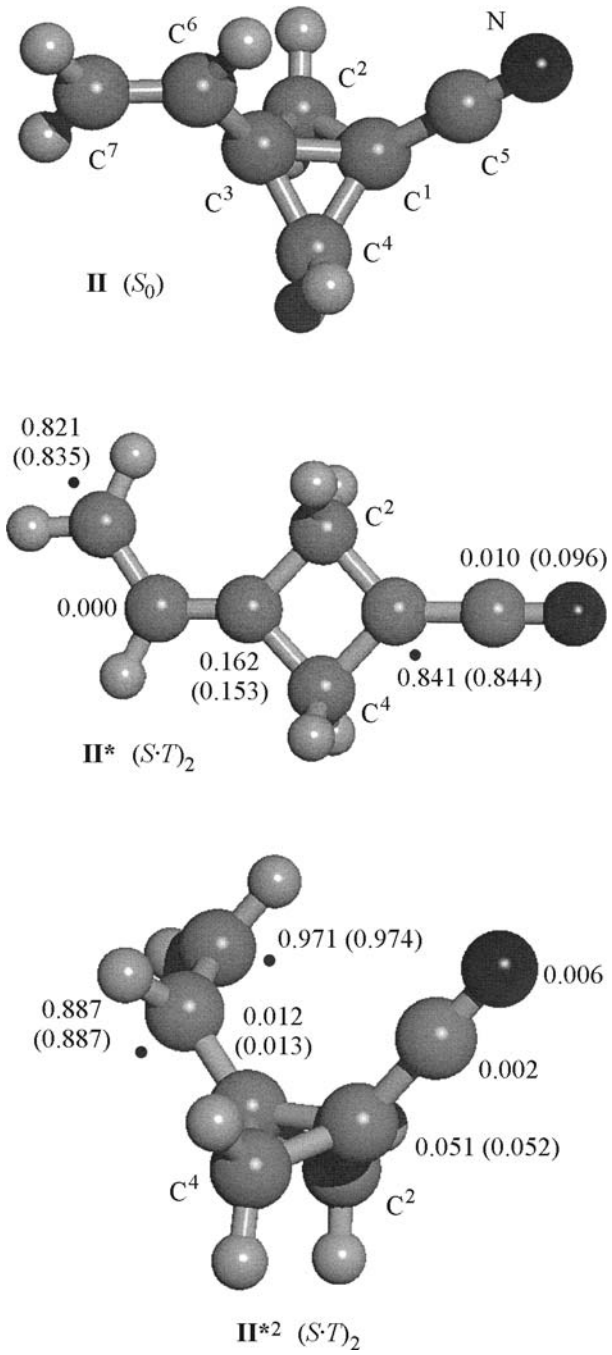

Fig. 2. Molecular structure of 1-cyano-3-vinylbicyclobutane **II** and free valances in its triplet and singlet (in parentheses) states.

tivity of this atom favors formation of a new carbon–carbon bond with the similar atom of another monomer. The radical centers recombine to form biradical **III***. Formation of biradicals **IV*** and **V*** by other coupling routes is energetically unfavorable (Fig. 4) and hence is improbable.

Table 2. Mulliken charge distribution (au) in molecules of **I** and **II** in the equilibrium states S_0, S_1, and T_1, calculated by RHF, GVB, and ROHF/6-31G* methods

	N	–0.460	–0.462	–0.462

The final dimerization step is hydrogen atom transfer from the methylene group of one of the four-membered rings to the valence-active C^1 atom of the adjacent ring, i.e., reaction of two biradicals **III*** to form stable final reaction products: *trans*-**VI** and *cis*-**VI** (Fig. 3). The calculated energies of the stereoisomers of **VI** are similar. However, the dipole moment (5.0 D) and the energy of solvation of the *cis* isomer of dimer **VI** are higher than those of the *trans* isomer (1.4 D). The sterochemistry of dimerization of 1-cyanobicyclobutane was not considered in the experimental study [2].

The energy of hypothetical product **VII** is close to that of experimentally detected dimerization products **VI**. However, the energies of biradical intermediates **III*** and **IV*** differ substantially. Hence, the dimerization pathway **I** $\rightarrow$ **III*** $\rightarrow$ **VI** is more favorable than **I** $\rightarrow$ **IV*** $\rightarrow$ **VII**. Our calculation also showed that the preservation of the bicyclic structure of one of two components in dimer **IX** and the presence of adjacent cyano groups in dimer **VIII** are energetically unfavorable. The energy of hypothetical compound **X** formed by binding of valence-unsaturated carbon atoms of intermediate dimer **IV*** and containing the six-membered ring including two four-membered rings (Fig. 4) is the highest.

Dimerization mechanism of 1-cyano-3-vinylbicyclobutane II. The calculated dipole moments of **II** in the ground S_0 (4.4 D) and excited $(S{\cdot}T)_1$ (4.6 D) states are close to those of **I**. The atomic charges in these molecules are also close (Table 2). However,

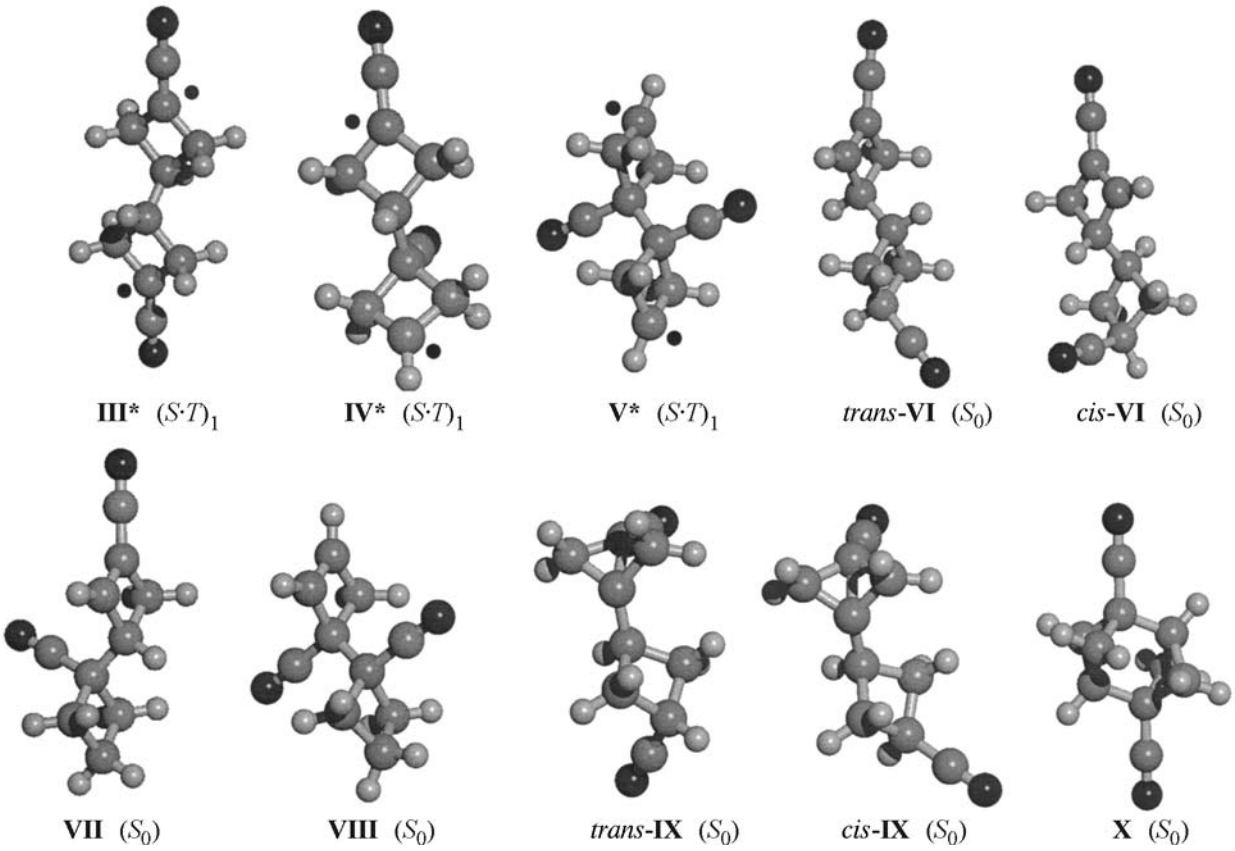

Fig. 3. Structure of biradical intermediates **III***–**V*** and hypothetical final products **VI**–**X** of dimerization of 1-cyanobicyclobutane **I**.

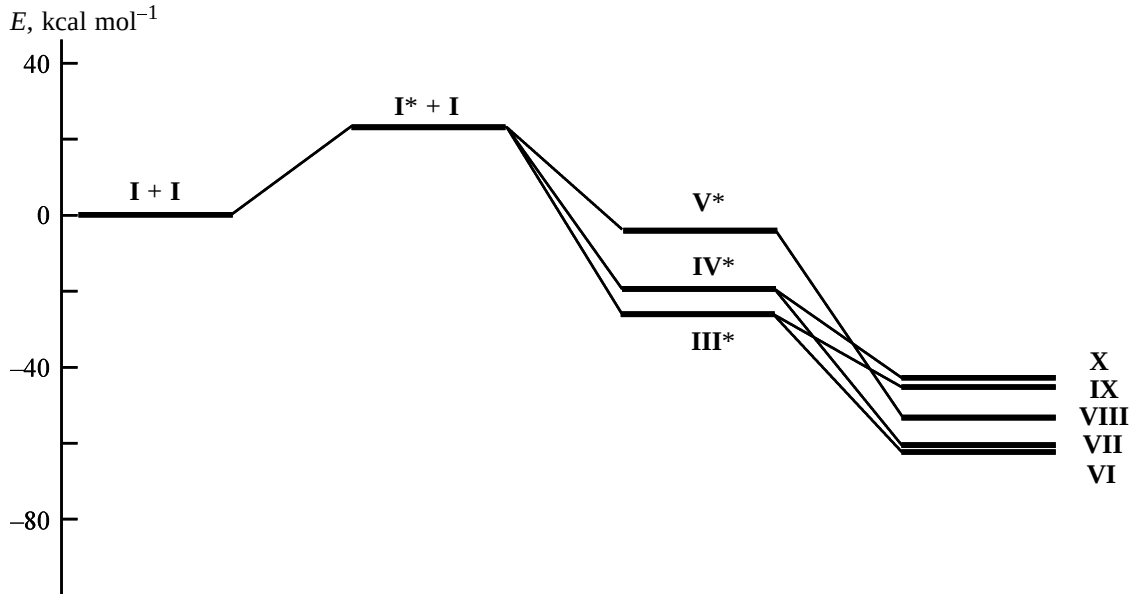

Fig. 4. Energy levels *E* of molecules of 1-cyanobicyclobutane **I**, biradical intermediates **III***–**V***, and hypothetical final dimerization products **VI**–**X**.

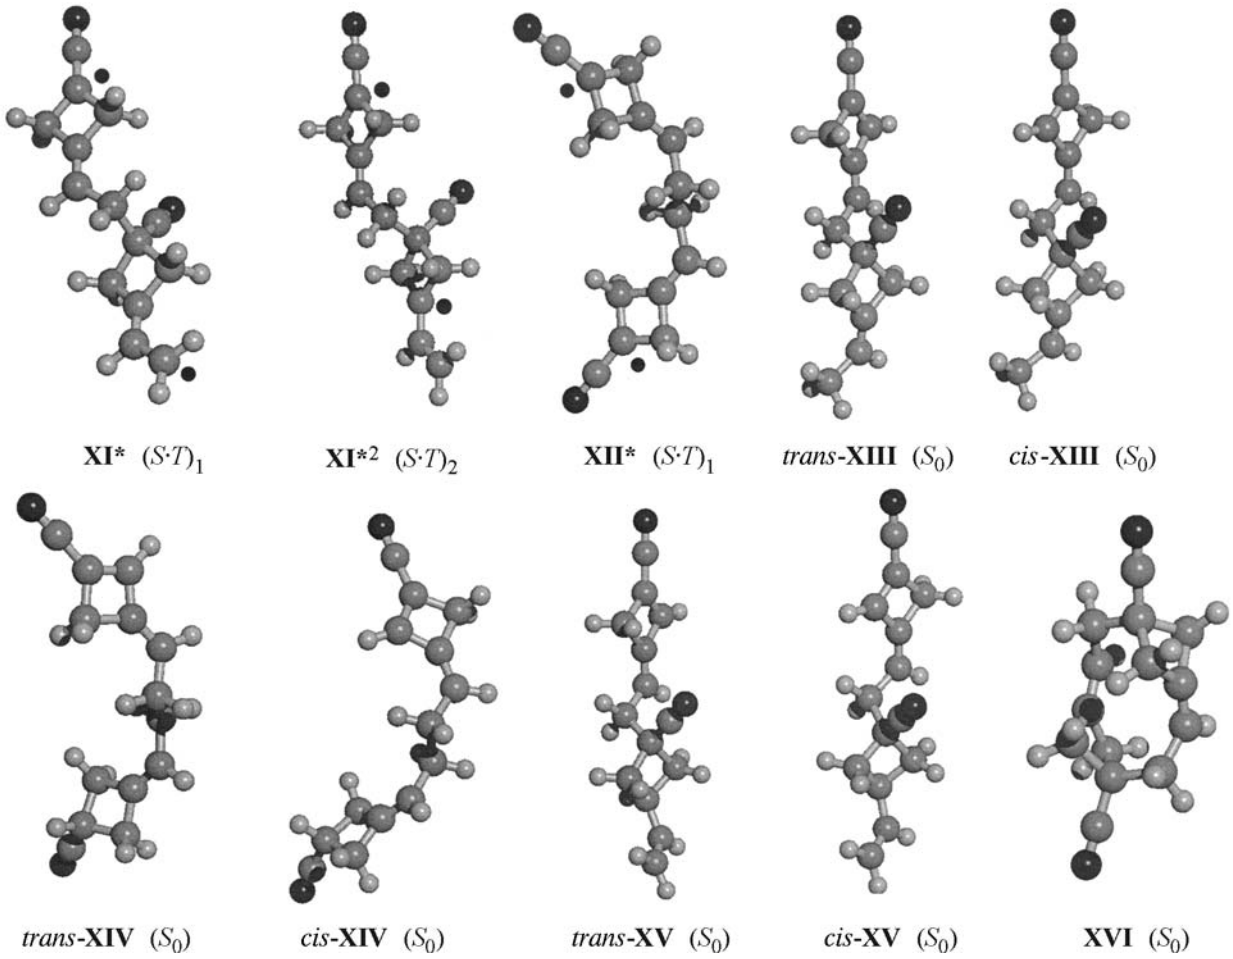

Fig. 5. Structure of biradical intermediates **XI*** and **XII*** and of hypothetical final dimerization products **XIII**–**XVI** of 1-cyano-3-vinylbicyclobutane.

the dimerization mechanism and the dimerization products are determined by free valence distribution and by the energy of the lowest equilibrium excited state, affecting the probability of its thermal population, rather than by the charge distribution (the charge control principle).

The calculated excitation energy of **II** in the biradical state $(S\cdot T)_1$ is as low as 12 kcal mol^{-1}, with the singlet–triplet splitting being negligibly small (0.5 kcal mol^{-1}). Clearly, extremely high reactivity of 1-cyano-3-vinylbicyclobutane, which is manifested in its instability at room temperature in the absence of initiators [3], is due to the low-lying excited state $(S\cdot T)_1$. The valence of biradical **II*** is delocalized almost equally between the C^1 atom of the ring and terminal C^7 atom of the vinyl group. Coupling of the carbonitriles via C^1 atoms is ruled out since, as shown above, formation of biradical **V*** containing two neighboring cyano groups is energetically unfavorable. Other binding types yield dimeric biradicals **XI***–**XII*** (Fig. 5).

Monomolecular binding of valence-unsaturated carbon atoms in intermediate dimer **XI*** does not involve hydrogen transfer and yields tricyclic dimer **XVI** consisting of ten-membered unsaturated ring and two four-membered rings (Fig. 6).

It should be noted that biradical **XI*** can exist in two quasi-degenerate equilibrium states differing in the bond lengths in the vinyl group. The free valence of **XI*** is localized on the terminal carbon atom (Fig. 5), and the free valence of **XI***^{2}, on the carbon atom of the ring bound with the vinyl group. Hence, hydrogen transfer in **XI*** can yield two stable dimerization products of 1-cyano-3-vinylbicyclobutate, namely, **XIII** and **XV**. Biradical **XII*** transforms into stable dimer **XIV**. Since each compound has its stereoisomer, the number of possible dimerization products is doubled (Fig. 6).

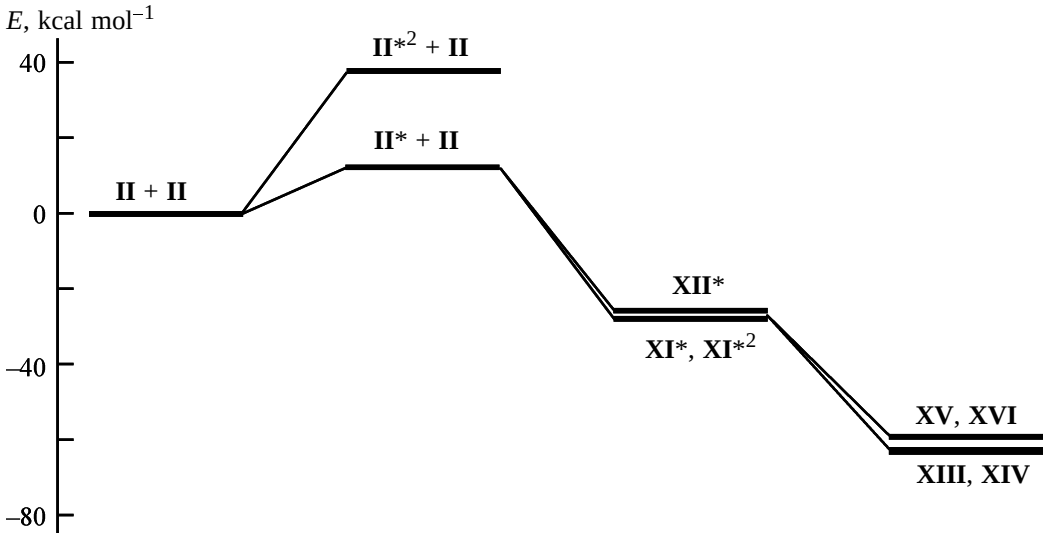

Fig. 6. Energy levels *E* of molecules of 1-cyano-3-vinylbicyclobutane **II**, biradical intermediates **XI***–**XXI***, and hypothetical dimerization products **XIII**–**XVI**.

Since the hydrocarbon chain of the intermediate isomers of 1-cyano-3-vinylbicyclobutane dimerization is flexible and the distance between valence-unsaturated carbon atoms in these compounds is sufficiently long, the energy levels of the intermediates are close. The splitting of the energy levels of all the examined stereoisomers is lower than 0.5 kcal mol^{-1}.

The energy of the biradical state $(S \cdot T)_2$ (39 kcal mol^{-1}, singlet–triplet splitting 1.4 kcal mol^{-1}) is too high for this state to be formed in thermal reactions at room temperature. Generation of this biradical is possible only in photochemical reactions of 1-cyano-3-vinylbicyclobutate.

Polymerization mechanism of 1-cyanobicyclobutanes. An excited monomer whose free valence is only weakly shielded by neighboring atoms can react with a radical initiator R*. Generation of a polymeric chain of 1-cyanobicyclobutane should involve formation of R–CH$(CH_2)_2$C$^{\bullet}$–C≡N radical.

This radical is added to the most reactive atom of thermally excited 1-cyanobicyclobutane to form a dimeric radical:

$$\text{R–CH}(\text{CH}_2)_2\text{C}^{\bullet}\text{–C}{\equiv}\text{N} + \text{H–C}(\text{CH}_2)_2\text{C}^{\bullet}\text{–C}{\equiv}\text{N}$$

$$\rightarrow \text{R–CH}(\text{CH}_2)_2\text{C(CN)–CH}(\text{CH}_2)_2\text{C}^{\bullet}\text{–C}{\equiv}\text{N}. \quad (4)$$

The resulting radical is bound with further monomer molecules in the similar way.

In the case of 1-cyano-3-vinylbicyclobutane, consecutive reactions (5) and (6) are possible. The skeleton of the resulting polymer contains atoms of exocyclic vinyl group

$$\text{R}^{\bullet} + \dot{\text{C}}\text{H}_2\text{–CH=C}(\text{CH}_2)_2\text{C}^{\bullet}\text{–C}{\equiv}\text{N}$$

$$\rightarrow \text{R–CH}_2\text{CH=C}(\text{CH}_2)_2\text{C}^{\bullet}\text{–C}{\equiv}\text{N}, \quad (5)$$

$$\text{R–CH}_2\text{CH=C}(\text{CH}_2)_2\text{C(CN)–CH}_2\text{CH=C}(\text{CH}_2)_2\text{C}^{\bullet}\text{–C}{\equiv}\text{N}$$

$$+ \text{H}_2\text{C}^{\bullet}\text{–CH=C}(\text{CH}_2)_2\text{C}^{\bullet}\text{–C}{\equiv}\text{N}$$

$$\rightarrow \text{R–CH}_2\text{CH=C}(\text{CH}_2)_2\text{C(CN)–CH}_2\text{CH=C}(\text{CH}_2)_2\text{C(CN)–}$$

$$\text{–CH}_2\text{CH=C}(\text{CH}_2)_2\text{C}^{\bullet}\text{–C}{\equiv}\text{N}. \quad (6)$$

These polymers can be cross-linked on exposure to UV radiation owing to the presence of double bonds in the polymeric chain.

CONCLUSIONS

(1) Steric and electionic structures of 1-cyanobicyclobutanes and 1-cyano-3-vinylbicyclobutane and radical intermediate and stable products of their dimerization and polymerization were determined by *ab initio* quantum-chemical calculations.

(2) Low calculated energies (<1 eV) of excitation of bicyclobutanes to $(S \cdot T)_1$ states suggest thermal population of these states under ordinary conditions. Mechanisms of dimerization and polymerization involving biradical states $(S \cdot T)_1$ were suggested, and the structures of the reaction products were determined.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of Allotropic Forms of Carbon on Formation and Cross-Linking of Heat-Resistant Polymer Binders

Abstract—The thermochemical reactions of polyimide binder with various allotropic forms of carbon, fullerene C_{60} and ultradispersed artificial diamonds, were studied by thermal and spectral analyses.

Derivatives of polyimides, which are among the most heat-resistant commercially produced polymer materials, came recently onto use as binders for development of carbon–carbon composites (CCC). The prepolymer of polyimide, polyamido acid (PAA) prepared by the reaction of tetracarboxylic dianhydrides and diamines of various structures, was the first polyimide binder used for this purpose [1]. In the past decade, the variety of polyimide derivatives used as impregnating materials in production of CCC and more advantageous than PAA has extended. Among these derivatives are polyimides synthesized from aromatic tetracarboxylic acids or their anhydrides and tetraacetyl derivatives of various aromatic diamines [2, 3]. The thermochemical cross-linking of the polycondensation product of 3,3',4,4'-benzophenonetetracarboxylic dianhydride (BCDA) and bis(4-acetylaminophenyl) ether (TAA, ITA-31) was studied previously [4], and the mechanism of these reactions depending on process conditions was established. The possibility of formation of composite materials based on pitch using ITA-31 for impregnation of a heat-resistant band from Elur (product of polyacrylonitrile carbonization) was shown. Thus, the active role of ITA-31 in cross-linking of CCC gives grounds to consider the problem of production of CCC using some active additives, among which some allotropic forms of carbon such as fullerene and diamond began to play the leading role in recent years.

The aim of this work is to compare the features of the reactions of polyimide ITA-31 and two different allotropic forms of carbon, fullerene C_{60} (mixed sp^2/sp^3 hybridization of carbon atoms) and artificial diamonds (sp^3 hybridization).

EXPERIMENTAL

To prepare samples of composites of the ITA-31 binder, 40 wt % fullerene C_{60} (or ultradispersed artificial diamonds with the average particle size of 90 nm) was added to the melt of the monomer mixture, and the mixture was heated to 260°C for 12–15 min with vigorous stirring; after that, the thermal imidization of the polymer was carried out with stepwise heating from room temperature to 300°C. After cooling, the resulting composition was milled, sifted, and studied by thermal gravimetric analysis (TGA) and high-resolution solid-state (HR SS) ^{13}C NMR. To compare the thermal effects of cross-linking of filled ITA-31 with the data on formation of ITA-31 itself and to reveal the influence of fillers on this process, we performed TGA and DTA (differential thermal analysis) of a mixture of these compounds.

TGA was performed on an MOM derivatograph (Hungary) at a heating rate of 10 deg min^{-1} with 50-mg weighed portions in a self-generated medium.

The HR SS ^{13}C NMR spectra were recorded at room temperature on a Bruker CXP-100 spectrometer using magic angle spinning (MAS) and cross-polarization (CP). The MAS technique (without polarization transfer from protons) was used to obtain spectra of the samples containing fullerene and diamond, because of the absence of protons in their composition. The ^{13}C NMR spectra were recorded at 25.18 MHz, spinning rate 3–4 kHz. Chemical shifts (ppm) were referred to tetramethylsilane.

Data of thermal analysis (Figs. 1, 2) of a mixture of the starting compounds used for production of ITA-31 (BCDA + TAA) without fillers and also with C_{60} and

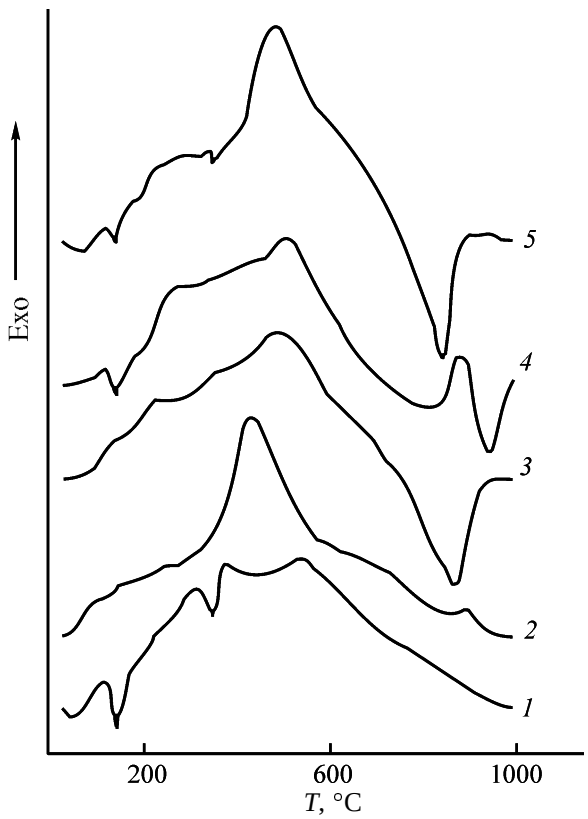

Fig. 2. DTA curves: (*T*) temperature.

diamond show noticeable distinctions in the character of their thermal degradation and cross-linking.

As found previously [4], the reaction of BCDA with TAA after their melting at 140–150°C is accompanied by the release of acetic anhydride and products of its degradation, which comes to the end at 350–360°C with complete removal of volatile substances and formation of cyclochain product having mp 354°C. From 360 to 500°C, there is a noticeable interval of thermal stability, with no weight loss. The resulting compound is cross-linked polymer. Above 500°C, a gradual weight loss accompanied by weak exothermic effects is observed. This pattern is typical for carbonization of polymers of this type [5].

Addition of fullerene to the initial mixture of monomers does not alter the thermal gravimetric characteristics of the resulting polymer, but substantially changes the structure of its intermediates and final products. The analysis of thermal effects proceeding in conversion of ITA-31 in the presence of C_{60} (Fig. 2, curves *1* and *4*) shows that the cross-linking of the reacting substances starts even at 240–250°C. This fact is further confirmed by the absence of the endothermic effect at 354°C. Contrary to the initial mixture, in the presence of fullerene at elevated temperature the exothermic effect of oxidation of the reaction product is enhanced. This phenomenon is apparently caused by superposition of fullerene oxidation (according to DTA, maximum at 410°C, Fig. 2) and polymer oxidation (maximum at 556°C). The most unexpected result is the appearance of a strong exothermic effect in the range 830–910°C. Understanding of this heat release requires additional studies, especially, identification of structural transformation of the carbonizate in this stage.

When finely dispersed diamond powder is added to the initial monomer mixture, in the low-temperature stage of thermal degradation a smooth weight loss is observed over the entire range of release of volatile products formed in the reaction of the monomers. The thermal stability interval is practically absent; the carbonization begins from 400°C and proceeds similarly to carbonization of the other samples considered. The thermal effect reflects the specific features of each component. A peak corresponding to melting of the resulting polymer is observed at 360°C, and after 450°C the effects corresponding to diamond oxidation with a maximum at 500°C and sublimation with an endothermic maximum at 900°C predominate (Fig. 2, curves *3* and *5*).

In the HR SS ^{13}C NMR spectra (Fig. 3a) of the composition with fullerene subjected to heating at

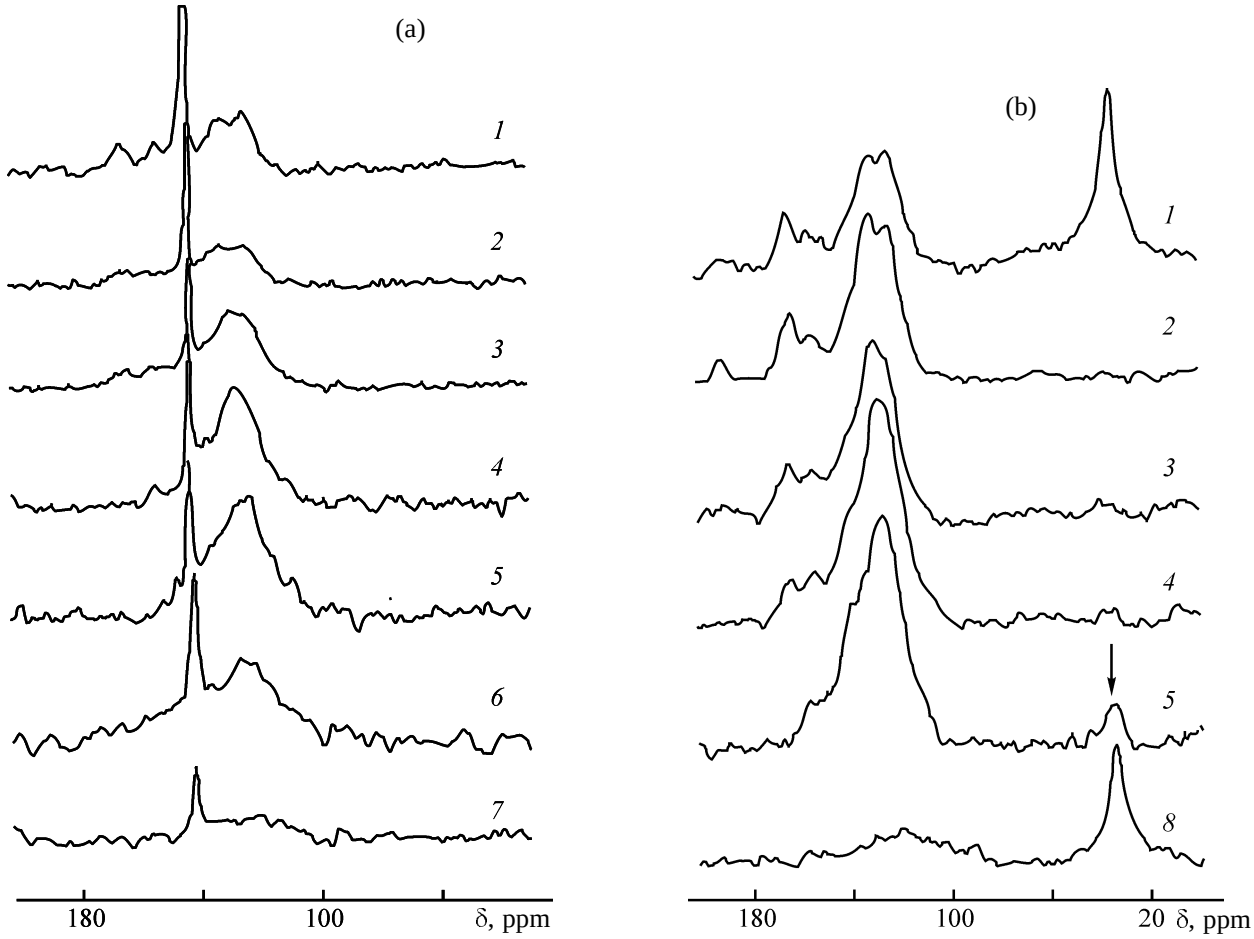

Fig. 3. HR SS ^{13}C NMR spectra of compositions (a) BCDA + TAA + C_{60} and (b) BCDA + TAA + diamond. (δ) Chemical shift. (*1*) Initial mixture; heat treatment of the mixture at temperature, °C: (*2*) 400, (*3*) 550, (*4*) 600, (*5*) 700, (*6*) 800, (*7*) 850, and (*8*) 900.

various temperatures in a vacuum, there is a stable signal at 143 ppm corresponding to C_{60} molecule [6]. This signal is observed in the spectra of the reaction products up to 900°C. The relative integral intensity of the ^{13}C NMR signal of fullerene in the sample obtained at 900°C is more than 30%. After the heat treatment of the composition at 600°C in air, the signal of fullerene disappears from the spectrum, which is apparently caused by oxidation and degradation of fullerene. Experiments on pyrolysis of the initial fullerene C_{60} in a vacuum show that above 600°C it starts to sublime, and by 900°C the weight loss is more than 90%.

Another important characteristic of the HR SS ^{13}C NMR spectra is the linewidth of the fullerene signal ($\Delta_{1/2}$). It should be noted that in the case of crystalline fullerene C_{60} $\Delta_{1/2}$ is extremely low (approximately 10 Hz), which is caused by high rotation mobility of this molecule in the solid state [7]. Therefore, we can judge on the degree of free rotation of C_{60} molecules in the composition. Up to 700°C $\Delta_{1/2}$ remains almost unchanged (approximately 35 Hz) and then abruptly increases by a factor of approximately 2, after which it varies only slightly up to 900°C. It should be noted that, although the increased $\Delta_{1/2}$ for fullerene (60–70 Hz) reflects certain decrease in the mobility of fullerene molecules in this temperature range, its value remains typical for extremely mobile molecular systems.

Thus, a part of fullerene molecules in the composition remains unbonded, i.e., they do not lose extremely high rotation mobility. However, with heating this high mobility somewhat decreases. It can be assumed that, as the carbonizate structure becomes more perfect with increasing temperature, the cavities in the carbonizate accommodating unbonded fullerene molecules decrease in size, which apparently restricts the mobility of these molecules.

In the case of the composition with diamond, the HR SS ^{13}C NMR spectra reflect the process of polymer carbonization, largely similar to carbonization of both unfilled ITA-31 and an ITA-31–fullerene mixture. However, there are some differences, namely, an increase in temperature of stepwise thermal degradation of the polymer in the presence of diamond, compared to the unfilled polymer and fullerene-containing composition.

It is seen from the spectra of the system ITA-31–diamond (Fig. 3b) that the signals of both carbonyl carbon atoms (164 ppm) and aromatic carbon atoms directly bonded to ether oxygen (155 ppm) do not noticeably vary in the intensity after the thermal treatment at temperatures of up to 600°C. The latter signal in the residual form remains up to 700°C, which is a unique fact itself. It should be noted that, in the spectra recorded using the CP MAS technique, a weak signal of diamond (34 ppm) appears at the same temperature (700°C). This means that a fairly large number of diamond atoms protonated with hydrogen atoms from carbonizate appeared in the system. Presumably above 700°C diamond begins to serve as a trap for nitrogen and oxygen heteroatoms living the carnonizate.

CONCLUSIONS

(1) In carbonization of ITA-31 polymer with added fullerene C_{60}, in the first stage (up to 550°C) a part of C_{60} molecules are apparently incorporated in the network structure, which results in a decrease in their mobility to the level of the average mobility of precarbonizate fragments. The other part of C_{60} molecules remains unbonded and does not lose high rotation mobility up to 900°C.

(2) Carbon atoms of finely dispersed diamond partially inhibit thermal degradation of ITA-31 due to retention of degradation products in the crystal lattice of diamond. In the stage of high-temperature carbonization of ITA-31, carbon atoms of diamond get protonated and scavenge a part of heteroatoms of ITA-31.

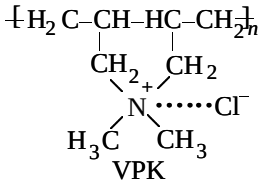
Abstract—Flocculation of kaolin suspension with a binary mixture of cationic polyelectrolytes is studied by optical microscopy and turbidimetry. Interrelation between the thermodynamic compatibility of components in the solution and flocculation conditions is examined.



According to the modern concept of the flocculation, the flocculation efficiency can be increased by adding some mixed reagents. Recently, steadily growing interest was shown in the effect exerted on the flocculation by mixtures of cationic and anionic derivatives of polyacrylamide [1–8] and also of reagents based on nonionic polymers [4–7, 9, 10]. It was demonstrated previously [11] that adsorption of polymers from a mixture depends on the thermodynamic compatibility of components in the solution. It is also well known that it is the adsorption of macromolecules on particles of the dispersed phase that controls the flocculation efficiency and dispersion clarification rate [1–8]. It may be suggested that the conditions of adsorption as well as flocculation considerably change, depending on the thermodynamic compatibility of polymers. Therefore, in this work we studied the hydrodynamic behavior and flocculating capacity of a binary mixture of likely charged polymers.

EXPERIMENTAL

As cationic polyelectrolytes we used poly-1,2-dimethyl-5-vinylpyridinium methyl sulfate (KF) [12–14], poly-*N*,*N*-dimethyldiallylammonium chloride (VPK) [15–17], and their mixtures:

KF

VPK

Characteristics of the polyelectrolytes are given in Table 1.

The intrinsic viscosity of the polyelectrolytes [η] was measured to within 2% with an Ubbelohde glass viscometer (capillary diameter 0.34 mm) at 30°C in 2.0 M NaCl. The relative viscosity η_r was measured in double-distilled water at a polymer concentration of 0.01 wt %. The coefficient of swelling of the macromolecular globule α_η was estimated by Eq. (1):

$$\alpha_\eta = (\eta_r/[\eta])^{1/3}. \quad (1)$$

The flocculation in the presence of a mixture of the indicated polyelectrolytes was studied with an aqueous suspension of kaolin (KSD grade; mean particle size 18 μm) as a model, at a concentration of the dispersed phase of 0.8 wt %.

The flocculation kinetics was studied turbidimetrically. The optical density A was measured on a UNICO 1201 spectrophotometer (United Products&Instruments Inc., the United States). The flocculation rate was determined from the kinetic curves of the optical density as the slope of the initial linear portion $(-dA/d\tau)_{\tau \to 0}$.

The particle-size distribution characteristics of the dispersions [number-average (R_n), surface-average (R_s), and weight-average (R_m) particle radii], and also the polydispersity coefficient k_p and form factor ψ were determined by optical microscopy (OM) as in [13, 14].

The compaction kinetics of the precipitates was determined by the motion of the boundary between

the clarified and unclarified layers of the suspension. The initial compaction rates V were estimated in the presence of both individual flocculants and their mixture.

The interaction between the components in mixed polymer solutions can be characterized using data on their hydrodynamic properties. The simplest and most adequate method is analysis of the viscosity curves in mixtures of various compositions [18]. The viscosity of polyelectrolytes can be determined under conditions of suppressed ionization and the compact conformation of the globule or in the case when the macromolecules are swollen and take the form of unfolded macroions.

Figures 1 and 2 show that the composition dependences of the intrinsic viscosity and coefficient of swelling run below the additivity lines, which, with no specific intermolecular interactions, are estimated by Eqs. (2) and (3):

$$[\eta]_{ad} = [\eta]_{KF} W_{KF} + [\eta]_{VPK} W_{VPK}, \quad (2)$$

$$\alpha_{\eta ad} = \alpha_{\eta KF} W_{KF} + \alpha_{\eta VPK} W_{VPK}, \quad (3)$$

where $[\eta]_{KF}$ and $[\eta]_{VPK}$ are the intrinsic viscosities of the polyelectrolytes KF and VPK, respectively; $\alpha_{\eta KF}$ and $\alpha_{\eta VPK}$, coefficients of swelling; and W_{KF} and W_{VPK}, the contents of the polyelectrolytes in the mixture.

The highest negative deviations are observed at a VPK content in the mixture of 50–70 wt %, suggesting deterioration of the thermodynamic quality of the mixed solvent as compared to the pure solvent. In this case, some compaction of the polyelectrolyte globules occurs, as demonstrated by the decreases in the intrinsic viscosity and coefficients of swelling in the mixed solutions.

Evidently, in the mixtures with 50–70% VPK, the conditions of adsorption of the macromolecules on the surface of the particles and also the flocculation conditions change to a larger extent in the presence of the polyelectrolyte mixture as compared to the individual reagents.

The concentration dependences of the flocculation in the kaolin suspension show that, with increasing concentration, the aggregating capacity of KF and VPK increases, remaining practically unchanged over the concentration ranges 0.3–1.0 and 0.5–1.0 mg l^{-1}, respectively. Therefore, we selected 1.0 mg l^{-1} as the optimal concentration of the binary mixture.

The effects of the individual polyelectrolytes and of their mixture are clearly seen from the optical density curve. In Fig. 3, the flocculation rate is presented as s function of the composition of KF–VPK system. The flocculation rate increases with increasing VPK concentration in the mixture, reaches a maximum, and

then decreases. However, at any KF : VPK ratio, the experimental values are above the additivity curve.

In this connection, it was necessary to analyze the behavior of other parameters characterizing the flocculation in binary polyelectrolyte mixtures. Figure 4 shows that the compaction rate of the kaolin precipitate in the KF–VPK system passes through a maximum. In the individual flocculant KF, the compaction rate is 95, which is about twice that in VPK. Seemingly, addition of straight VPK favors the formation of more compact floccules, which remains practically unchanged in settling, while in the case of KF, the precipitate is further compacted through closer packing of the floccules. Therefore, it was necessary to determine parameters of the floccules formed in the binary cationic polyelectrolyte.

To characterize the aggregating capacity of the polyelectrolyte, we examined the dependences of the degree of aggregation α_s as a function of the polyelectrolyte concentration and composition (Fig. 5). The degree of aggregation of the kaolin particles in the presence of KF amounts to 20–30 (curve *1*), while in the presence of VPK, only to 5–10 (curve *2*) over the experimental concentration range (up to 1 mg l^{-1}). With the binary flocculant KF + VPK (curve *3*), the floccules of an intermediate size are formed. From data on the particle-size distribution obtained by optical microscopy, we also estimated such parameters as the polydispersity of the kaolin suspension k_p and the form factor of the floccules ψ. The latter was used for estimating the Stokes density of the floccules (Fig. 6). As seen, the composition dependence of the density also passes through a maximum located in the same composition range as the clarification rate (Fig. 3). Similar increase in the density of the floccules at low degree of aggregation was observed for the flocculation with 1,2-dimethyl-5-vinylpyridinium methyl sulfate [14], but the absolute values of the density of the floccules formed in the KF–VPK mixtures are higher than those in the presence of individual FK or its copolymers with *N*-vinylpyrrolidone and acrylamide.

Comparison of data on the viscosity of the polyelectrolyte mixture with the parameters characterizing the flocculation suggests a significant effect of the thermodynamic quality of the mixed solvent. The floccules formed upon introduction of the polyelectrolytes are rather loose aggregates containing a large amount of the dispersion medium in addition to kaolin particles. The reason is the adsorption of the macromolecules on the particle surface. Considerable part of the units of these macromolecules can be unbound,

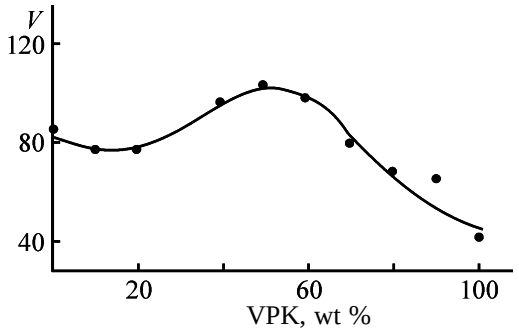

Fig. 4. Compaction rate V of the precipitate in the kaolin suspension in the presence of KF–VPK mixtures.

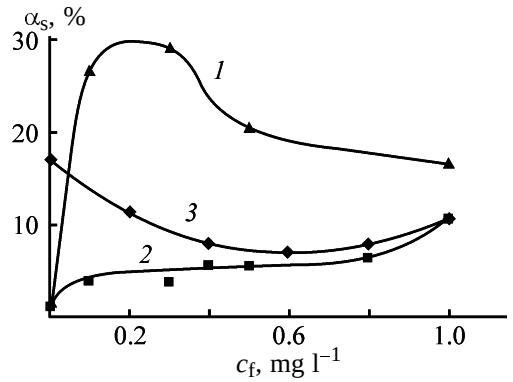

Fig. 5. Degree of aggregation of the kaolin particles α_s as a function of the individual polyelectrolyte concentration c_f and of the composition of the KF–VPK mixture. The concentration of the mixed reagent is expressed in the VPK fractions (KF + VPK = 1 mg l^{-1}). Flocculant: (*1*) KF, (*2*) VPK, and (*3*) KF + VPK.

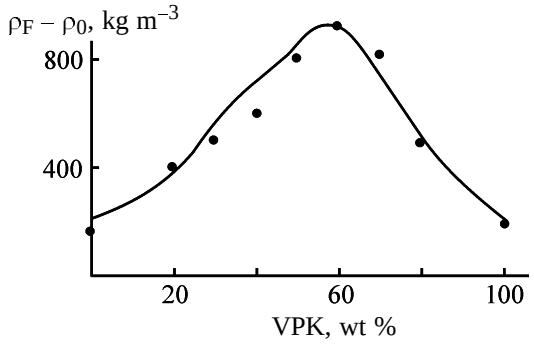

Fig. 6. Density of floccules $\rho_F - \rho_0$ in the kaolin suspension in the presence of KF–VPK mixture.

being arranged in the surface layer as coils and tails. In this connection, it may be suggested that it is conformation of these fragments that controls the structure of the floccules.

Polyelectrolyte chains are strongly swollen in polar solvents at low ionic strength, this effect being more clearly pronounced as compared to the swelling of

uncharged macromolecules in a good solvent. As a result, in flocculation of dispersions with homopolymer polyelectrolytes, the density of the floccules formed is close to that of the dispersion medium. The structure of the floccules can change significantly in the presence of copolymer polyelectrolytes.

Introduction of nonionic groups incapable of dissociation results in remarkable increase in the density of the floccules [13]. However, our experiments show that the compaction of the structure of the floccules occurs also in the presence of a mixture of two homopolymer polyelectrolytes. In this case, the reasons for the compaction of the floccules could not be the same as in the presence of copolymer polyelectrolytes having the units capable of association. Most likely, the observed effects can be attributed to thermodynamic incompatibility of polymers of different nature. Adsorption and aggregation of the particles in the system provide concentration of the macromolecules in the bulk of the floccules. However, the coexistence of the coils of different nature in a microscopic volume is thermodynamically disadvantageous. Furthermore, since the macromolecules are bound to the surface via a cooperative system of chemical and physical bonds, they cannot be desorbed to leave the volume of the floccules. Evidently, in this case, the coils collapse so as to minimize the contacts with "foreign" units. As a result, compaction of the floccule as a whole occurs, increasing the clarification rate. It may be suggested that this trend is typical not only of this particular pair of polyelectrolytes, but of any mixture of thermodynamically incompatible polymers.

CONCLUSIONS

(1) It was demonstrated in studying the flocculation of kaolin suspension in the presence of the cationic polyelectrolytes poly-1,2-dimethyl-5-vinylpyridinium methyl sulfate and poly-*N*,*N*-dimethyldiallylammonium chloride that the flocculating capacity of their binary mixture is higher than that of the individual reagents, which is caused by the formation of more compact floccules. As a result, the clarification rate increases.

(2) The effects observed in flocculation in the presence of the likely charged polyelectrolytes are probably due to thermodynamic incompatibility of these polymers, which is reflected in significant deviations of hydrodynamic parameters of the system from the additivity at a 50–70 wt % content of poly-*N*,*N*-dimethyldiallylammonium chloride in the mixture.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Interaction of a Cationic Polymeric Flocculant with Anionic Stabilizers in Latex

V. N. Verezhnikov, T. V. Min'kova, and T. N. Poyarkova

Voronezh State University, Voronezh, Russia

Received October 26, 2004; in final form, April 2005

Abstract—Turbidimetric titration of aqueous solutions of sodium dodecyl sulfate and Leukanol and coagulation titration of polystyrene and polybutadiene latexes containing various amounts of these surfactants are performed.

In separating rubber from latex by flocculation with cationic polyelectrolytes, it is important to neutralize anions of the surfactants used as stabilizers through chemical binding with cationic groups of the flocculant macromolecules. As a result of such interaction, insoluble undissociated ionic complexes are formed, thus decreasing the surface charge and electrostatic repulsion energy of the particles. It is commonly accepted that the maximum of flocculating activity of a polymer corresponds to the full neutralization of all negative charges on the particle surface, and that adsorption of the macromolecules upon introduction of some excess of the polyelectrolyte (PE) results in the recharge and restabilization of the system reflected in the appearance of a maximum in the concentration dependences of the flocculating efficiency of PE.

The factors complicating such a simple flocculation mechanism are the contribution of bridging to the destabilization of the colloid system and the interaction of surfactant anions with the macromolecules, depending on the nature of latex stabilizers. In the case of commercial latex, the latter factor is significant because of the use of two different types of surfactants responsible for the aggregative stability of the latex. The first type is represented by low-molecular-weight emulsifiers, particularly, salts of fatty and resin carboxylic acids, and alkane- and alkylbenzenesulfonates. Also micelle nonforming oligomeric surfactant known as Leukanol (Lk) (sodium salts of the condensation product of β-naphthalenesulfonic acid and formaldehyde) is used. Leukanol serves as an additional stabilizer; its small additions (mostly 0.3 wt % calculated per monomer) considerably increase the stability of the emulsion in the course of polymerization, at the stage of latex degassing, etc. It is significant that, in contrast to paraffinates and rosin soaps, Lk preserves its stabilizing activity in acidic media also, complicating the rubber separation.

It is interesting how the optimal flocculation conditions relate to the completeness of binding of the anionic groups with the cationic groups of flocculant macromolecules for both types of surfactants. Here we report data characterizing the interaction of sodium dodecyl sulfate (SDS) and Lk with the cationic polyelectrolyte (CPE) in aqueous solutions and in latex flocculation.

EXPERIMENTAL

Sodium dodecyl sulfate was purified by fivefold recrystallization from ethanol [1]. The purity of the product was controlled by disappearance of the minimum in the concentration dependence of the surface tension. Leukanol [GOST (State Standard) 6848–73] was purified by gel filtration on Sephadex G-25.

As a flocculant we used poly(dimethylaminoethyl methacrylate) hydrochloride (PDM·HCl), which was obtained by random polymerization in an aqueous solution [2] and dewatered by freeze drying. The mean molecular weight $\overline{M}$ (2.04×10^5) was determined from the viscometric data ($[\eta] = 0.96$ dl g^{-1}, where $[\eta]$ is the intrinsic viscosity in 0.5 N aqueous KCl) using the Mark–Houwink equation ($[\eta] = K\overline{M}^{\alpha}$ [3] with $K = 6.15 \times 10^{-5}$ and $\alpha = 0.79$) [4]).

In synthesis of polystyrene latex (PSL) we used SDS (4.5 wt % calculated per monomer) as an emulsifier. Its content in the dialyzed latex was determined by coagulation titration with cetylpyridinium bromide (CPB) [6]. Recalculated to the polymer weight, it was

1070-4272/05/7807-1154© 2005 Pleiades Publishing, Inc.

1.5×10^{-4} mol g^{-1}. The polymer concentration in the latex was 9.6 g l^{-1}. The mean particle size was estimated by the Rayleigh equation [5] to be 36 nm.

Additionally we used a sample of polybutadiene latex (PBL) (emulsifier: a mixture of potassium resinate with potassium salts of maleinated α-olefins C_{12}–C_{14}).[1]

The interaction of the components in aqueous solutions and the flocculation of latexes were studied turbidimetrically. The turbidity τ was measured on an NFM visual turbidimeter.

Initially we titrated aqueous solutions of SDS and Lk with PDM·HCl. The dependence of τ on the CPE concentration is given in Fig. 1. In all cases, the curves pass through a maximum, as reported previously, for example, in [7, 8] for interaction of SDS with solutions of quaternized poly-4-vinylpyridine derivatives. The observed increase in the turbidity is caused by increasing amount of the insoluble polymer–colloid complex (PCC) formed as a result of electrostatic binding of the surfactant anions with the cationic centers of the macromolecules [9, 10] and then separated from the aqueous phase. The peak concentration c_m corresponds to saturation of all the cationic centers and maximal hydrophobization of the macromolecular globule. With further increasing CPE concentration (right branch in the τ–c_{CPE} curves), the turbidity decreases, which, according to the modern views [7, 8], is caused by increase in the solubility of PCC through hydrophobic interaction of the surfactant ions with the hydrocarbon fragments of the macromolecules resulting in the orientation of the polar group toward the aqueous phase. Such an "adsorption" of the ions causes hydrophilization of the macromolecules and also their recharging, which, acting in combination, result in progressive degradation of the PCC aggregates. This interpretation of the τ–c_{CPE} curves is supported by the experimental data on the electrophoretic mobility of the PCC aggregates and also on the solubilization of a dye [7].

Figure 2 presents c_m as a function of surfactant (SDS and Lk) concentration. The dotted line corresponds to the equivalent binding of the anionic and cationic groups of the components (z = 1, where z is the anionic to cationic group molar concentration ratio in the mixture). There is certain difference between the low-molecular-weight and oligomeric surfactants in the binding nature. In rough approximation, c_m for SDS corresponds to $z \approx 1$. Similar result was obtained in [8]: the maximum in the turbidimetric titration curves of poly-4-vinyl-*N*-butylpyridinium bromide with SDS approximately corresponds to the full binding of the surfactant (according to the potentiometric

data obtained using a DS-reversible electrode). At the same time, for Lk, the dependence c_m–c_{Lk} is linear with a slope corresponding to $z = 0.6$. In this case, the maximal PCC concentration is attained at a considerable deficiency of the anionic groups of the oligomeric surfactant or with excess of the cationic groups (excess expenditure) of CPE.

To characterize quantitatively the interaction of the flocculant with the latex stabilizers in the course of flocculation, we studied the initial flocculation rate (IFR) as a function of the CPE concentration at various stabilizer concentrations. As a measure for IFR we used the turbudity τ_1 of a dilute ($1 : 10^4$) latex 1 min after the onset of flocculation (1-min turbidity method [5]). The experimental procedure was as follows. A fixed volume of 10^{-2} M CPE was introduced in a 25-ml volumetric flask and the volume was adjusted to the mark with distilled water. Then the estimated volume of 10^{-2} M surfactant or latex (diluted in proportion 1 : 100) was added. The turbidity τ_1 was measured after 1 min of stirring. Latex samples with various SDS and Lk contents were prepared by introducing incremental doses of the corresponding surfactant to the initial and dialyzed latexes. The concentration of SDS in polystyrene latex (PSL) was selected on the basis of the adsorption titration curve of the latex [5]. Leukanol was added in amounts not exceeding 5 wt % relative to rubber, since, according to our data, higher concentrations decrease the aggregative stability of latex [10]. The surfactant concentration in the initial latexes and final samples was determined by coagulation titration with CPB [6].

Figure 3 shows as an example the τ_1–c_{CPE} curves for PSL samples containing various SDS concentrations. Similar curves were also obtained for PSL and PBL containing various concentrations of Lk. In all cases, the curves pass through a maximum (optimum flocculation), which is typical of the flocculation of negatively charged sols with cationic polyelectrolytes [9]. Figure 4 shows the optimum flocculation as a function of the surfactant concentration in the latexes. It is noteworthy that the trend observed for the low-molecular-weight surfactant strongly differs from that for Lk. In the case of SDS, the optimum flocculation is mostly found considerably below c_{CPE} corresponding to the full binding of the surfactant with the flocculant macromolecules (dotted line). Thus, the maximal flocculation is observed when a considerable electric charge (and potential) induced by free dodecyl sulfate anions still remains on the particle surface. This conclusion is supported by the results of analysis of the dependences of the flocculation efficiency and electrokinetic potential of AgI [11], polystyrene latex [12], and kaolin [14] on the flocculant concentration. In such cases, the major factor controlling the flocculation is the formation of molecular bridges via the adsorbed macromolecules of the polymer rather than neutralization of charges on the particle surface [13]. It should be pointed out that, according to [13, 14], the neutralization mechanism of flocculation is observed for low-molecular-weight (~10^3) flocculants with high charge density on the macromolecular chain.

In the case of Lk, over the entire experimental concentration range, the optimum flocculation for both latexes (PSL and PBL) is observed with CPE taken in excess over the equivalent quantity. The dependence c_m–c_{Lk} is linear, z (0.57 and 0.63, respectively) being practically coincident with that found for interaction of the components in aqueous solutions, which can be

probably due to the oligomeric nature of Lk (it is a mixture of homologs containing from 1 to 10 naphthalene units per molecule [15]). The product after gel filtration should be enriched in heavier nuclei. It is natural to suggest that, in interaction of oppositely charged chain macroions, the formation of stoichiometric complexes requires a uniform or nearly uniform charge distribution along the macromolecular chain. However, this condition is not actually fulfilled. In the case of Lk, in accordance with its structure (methylene groups of the backbone are separated by the naphthalene rings), one could expect a longer distance between the charged sulfonate groups than that between the neighboring cationic centers of PDM · HCl, which should hinder approach of the oppositely charged groups to a distance sufficient for strong binding. As a result, the full neutralization of Lk becomes possible only with excess of the cationic groups of the flocculant, i.e., at its excess expenditure (by a factor of about 1.5 relative to the stoichiometry, as demonstrated by the slopes of curves *2* and *3* in Fig. 4).

CONCLUSION

Full binding of sodium dodecyl sulfate with poly(dimethylaminoethyl methacrylate) hydrochloride is attained at the equivalent proportion of the reagents, while in the case of Leukanol, a 1.5-fold excess of the cationic polyelectrolyte is required.

Abstract—The possibility of dehydration (cross-linking) of polyvinyl alcohol upon microwave irradiation of thin polymer films was examined. The properties of polyvinyl alcohol samples treated by convection heating and irradiation were compared. Immobilization of polyvinyl alcohol on polymer matrices by microwave irradiation was studied.

The effect of microwave irradiation (MWI) on chemical reactions, especially on those involving low-molecular-weight substances, is a subject of a growing number of papers; MWI also shows promise in synthesis and modification of polymers [1–5].

Intensification of chemical reactions by MWI is due to the effect of an electromagnetic field on the solvent and reactants. Along with the thermal effect (sample heating), there may be specific effects caused by the excitation effect of the field; these effects in some cases alter the preexponential factor, reaction entropy, etc.

In this study we examined the effect of heating and MWI on reactions of polyvinyl alcohol (PVAl). When heated to 100–150°C, this substrate tends to dehydrate with cross-linking through ether bridges [6]. Heating to higher temperatures (150–220°C) causes formation of double bonds, and the arising conjugated structures impart a dark color to the polymer:

An additional goal of our study was optimization of a process for converting the water-soluble polymer into an insoluble form. Cross-linked PVAl shows promise for use in aqueous media as biosorbent, biological carrier, material for water filters, etc. [6].

EXPERIMENTAL

The electromagnetic field was generated with an MDS-2000 oven (CEM, the United States) operating at 2.45 GHz; the temperature was measured with an optical-fiber probe.

The substrates to be treated by MWI or heating were solid PVAl films 25 to 250 μm thick (molecular weight of the polymer M = 70 000–100 000), formed from an 8% aqueous solutions of the polymer. For the treated films, we determined the limiting swelling and the amount of insoluble (cross-linked) polymer after repeated extraction of the samples at room temperature; the films were analyzed by IR (EGUINOX-55) and UV (Specord M-40) spectroscopy. The double bond content was determined with an ADS-4M double bond analyzer from the amount of ozone taken up by 1 g of the substance (accuracy 2.5%).

The PVAl films were found to warm up under MWI. This fact indicates that the rotations and vibrations of polar groups are excited by the electromagnetic field. In contrast to the behavior of low-molecular-weight compounds in solutions, the motion of a PVAl molecule as a whole in the solid state is impossible; the warming-up of of the polymer film under MWI is more likely due to the mobility (vibration) of a macromolecule segment or its part. At the same time, the segmental mobility of a macromolecule determines its flexibility and the glass transition point of the polymer. An increase in the mobility of a polymer chain results in its more efficient interaction with the radiation, and, after reaching the glass transition point (85°C), as the polymer passes from the glassy to elastic state, the temperature rise accelerates (Fig. 1). A certain role in the change in the mobility of PVAl

macromolecules is apparently played by cleavage of hydrogen bonds on heating the polymer to the softening point (50–60°C), which corresponds to appearance of the hyperelastic properties [6].

Compounds acting as plasticizers increase the mobility of the segment and, correspondingly, the warming-up rate (under equal other conditions). On the contrary, compounds with a high glass transition point decrease the microwave heating temperature. In this connection, polyacrylic acid (PAA) can act as PVAl "antiplasticizer." It is known [7] that the cohesion energies of the hydroxy and carboxy groups are 21.4 and 23.4 kJ mol^{-1}, respectively, and the glass transition point of PAA exceeds that of PVAl (106 and 85°C). The temperature of a film prepared from a PVAl–PAA blend decreases with an increase in the PAA content: at PVAl : PAA = 7.5 : 1, it is 172°C; at 5 : 1, 157°C; and at 3 : 1, 112°C. Also, a decrease in the temperature may be due to formation of an interpolymeric complex of PVAl with PAA, which also decreases the mobility of the macromolecules.

Table 1 shows that, with increasing film thickness, under equal other conditions, the temperature of the polymer increases upon MWI to a greater extent, and the limiting swelling $[(P - P_0)/P] \times 100\%$ (P is weight of the swollen film, and P_0, that of the dry film, g) decreases. Apparently, for a thin film, the contribution of the surface heat exchange and convection cooling of the external layers of the material, affecting the temperature profile of the samples and hence their properties, is more significant.

Introduction into PVAl of compounds that actively interact with the radiation increases the temperature of the system and hence the reaction rate, under equal other conditions. We performed MWI of films preliminarily swollen in water (to 40–45% swelling) and PVAl films containing 10–12 wt % glycerol. As seen from Table 2, both water and glycerol promote the cross-linking.

For comparison, we examined the behavior of PVAl films at thermal heating. Table 3 shows that, with an increase in the temperature and time of the treatment, the degree of cross-linking (amount of the polymer remaining after repeated washing with water) increases and the limiting swelling decreases.

Examination of the IR spectra of PVAl films after MWI and thermal treatment shows that, in both cases, the bands characteristic of OH (3440 cm^{-1}) and CH_2 (2940–2910, 1375, 920 cm^{-1}) groups slightly decrease in the intensity, the absorption of C–H bonds (2840–2850 cm^{-1}) increases, and the absorption in the region characteristic of C–O–C groups (1140 cm^{-1}) increases substantially. Changes in the spectra are proportional to the sample temperature. The IR spectra confirm the published data [6] on the composition of the main products formed by thermal dehydration of

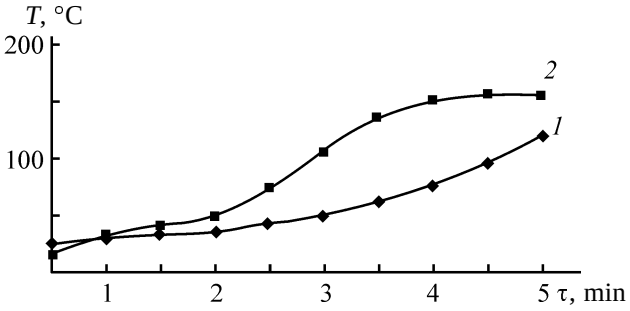

Fig. 1. Temperature T of PVAl films as a function of MWI time τ. Film thickness, μm: (*1*) 50 and (*2*) 100.

Table 2. Influence of water and glycerol on the properties of PVAl upon MWI for 2 min

Sample	T_{MWI}, °C	$(P - P_0)/P \times 100$, %	Content of cross-linked polymer, %
PVAl + water	95	64	96–100
PVAl + glycerol	130	60	100

PVAl. Strong absorption of alcoholic OH groups (3150–3500 cm^{-1}) and the bands of acetate groups and water (1570–1740 cm^{-1}) present in PVAl obscure the bands characteristic of multiple bonds [8–10]; in this case, more information is furnished by UV spectra. Thermal heating of PVAl (178°C) results in its brown coloration, suggesting formation of a conjugated structure [6]. The UV spectra (Fig. 2) show strong absorption in the range 250–400 nm; the growth of absorption at λ = 330 nm assignable to polyconjugated unsaturated structures [10, 11] is more pronounced than at λ = 280 nm. At the same time, when heated to almost the same temperature (170°C) but in the MWI mode, the films became yellow and not brown, and the absorption at λ = 280 nm increased to a greater extent.

The data obtained are in good agreement with the results of determination of the double bond content in the treated samples. The content of double bonds in MWI-treated samples is lower compared to the thermally treated samples. At both heating modes, the content of double bonds increases with temperature, but at thermal heating this trend is more pronounced. In particular, upon MWI, the content of double bonds increases from 1.9 (150°C) to 2.7 rel. units (170°C), and upon thermal heating, from 2.5 (150°C) to 5.4 rel. units (178°C). Furthermore, upon heating to moderate temperatures (70–100°C), C=C bonds formed only at the thermal heating mode (1.2–1.7 rel. units).

Thus, presumably, an electromagnetic field acting on polar groups of PVAl increases the probability of dehydration mainly via intermolecular reaction of hydroxy groups (although intramolecular cyclization also cannot be ruled out). In convection heating, both hydroxy and nonpolar methylene groups (see scheme) get involved in the dehydration, and the process involving methylene groups becomes particularly noticeable at T > 150°C, resulting in active formation of by-products and imparting a dark color to the polymer. At the same time, for MWI, a lower temperature (down to 120°C) is optimal, and addition of glycerol allows the cross-linking time to be decreased to 3–5 min.

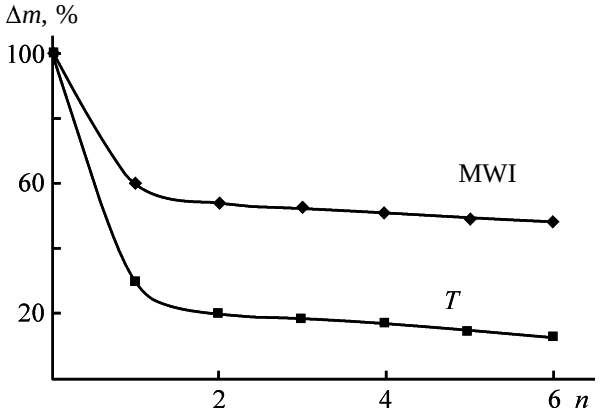

Fig. 3. Weight loss Δ*m* of PVAl samples applied onto polypropylene fiber upon their washing with water after MWI (100°C, 10 min) and thermal treatment (100°C, 10 min). (*n*) Number of washing runs.

A selective action of MFI on the polar groups allows cross-linking of PVAl applied onto polypropylene (PP) or polyethylene (PE) supports, i.e., onto matrices with a low heat resistance (the working temperature should not exceed 100–120°C). As seen from Fig. 3, MWI allows more efficient immobilization of PVAl on the PP fiber, compared to the thermal heating under equal other conditions.

Thus, MWI is a promising procedure for imparting water resistance to PVAl films. Further experimental studies are required to assess the prospects for using MWI in synthesis and modification of other macromolecular compounds.

CONCLUSIONS

(1) Microwave irradiation of polyvinyl alcohol films results in their heating; the temperature attained depends on the film thickness and determines the degree of the polymer cross-linking.

(2) Under equal other conditions, the degree of cross-linking of polyvinyl alcohol films subjected to microwave irradiation is higher compared to convection heating; the difference increases with a decrease in the treatment temperature.

(3) The amount of immobilized polyvinyl alcohol on a polypropylene support upon microwave irradiation is larger than upon thermal heating, other conditions being the same.

(4) The results obtained suggest that the contribution of intermolecular etherification reactions involving hydroxy groups and resulting in cross-linking of polyvinyl alcohol is greater upon microwave irradiation compared to thermal heating.

Received November 23, 2004; in final form, April 2005

Abstract—The influence of various factors on the kinetics of polycondensation of betulin (a triterpene alcohol of the lupane series) with adipic acid was studied.

Extension of the range of polymeric binders for composite materials involves a search for nontraditional sources of monomers. One of such sources can be by-products from processing of vegetable raw materials and from wood-chemical and wood-processing industry. These by-products contain a large amount of various polyfunctional organic compounds.

Of certain interest in this respect is betulin, a triterpene alcohol of the lupane series containing primary and secondary hydroxy and isopropenyl groups, which creates prerequisites for preparing linear thermoplastic polymers [1]. Since the isopropenyl group does not tend to polymerize because of its structural features, the probability of formation of branching polymers in this case will be low. The most acceptable procedure for polycondensation of betulin with dibasic organic acids is polycondensation in the melt, since the agents involved are thermally stable above the melting points of the monomers.

EXPERIMENTAL

Betulin was isolated from birch crust; its characteristics were as follows: hydroxy number 253.1, iodine number 47.6, and acid number 0, which corresponds to 99.5% purity of the product. Adipic acid dried at 80°C met the requirements of GOST (State Standard) 10558–80.

When studying the kinetic features of the process, we used the method of separate samples; to reduce the thermal oxidative degradation, the synthesis was performed in a nitrogen flow. In analysis of the kinetic features of the polycondensation of these monomers, it is difficult to determine with sufficient accuracy the changes in the concentrations of primary and secondary hydroxy groups of betulin separately. Therefore, we determined the overall changes in the concentration of hydroxy groups by acylation with acetic anhydride in pyridine. The carboxy groups were determined by neutralization, and double bonds, by the iodine–bromine method. It should be noted that the concentration of double bonds remained constant in the course of the synthesis, which confirmed the low reactivity of the double bond in betulin. The ratio of the hydroxy and carboxy groups remained equimolar; therefore, the kinetic parameters determined for the hydroxy and carboxy groups coincided.

In this study we considered the kinetic features of polycondensation of betulin with adipic acid in a melt; the upper limit of the polycondensation temperature is determined by the thermal stability of betulin (265°C), and the lower limit (215°C), by the solubility of betulin in adipic acid at the equimolar reactant ratio.

The variation of the concentration of the hydroxy groups at various temperatures is shown in Fig. 1. As seen, the polycondensation shows no deviations; however, the plot of $\ln w$ vs. $\ln c$ (w is the reaction rate, and c, concentration) is not a straight line but consists

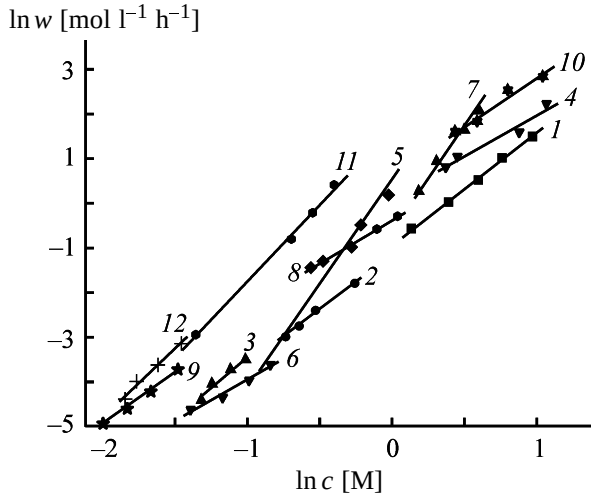

Fig. 2. Plot of ln*w* vs. ln*c* at various temperatures. *T*, °C: (*1*–*3*) 215, (*4*–*6*) 230, (*7*–*9*) 250, and (*10*–*12*) 265.

of three portions (Fig. 2). The plots are shown with breaks corresponding to the transition regions. It could be expected from the different reactivity of the hydroxy groups of betulin that the plot of ln*w* vs. ln*c* would consist of two portions, with the first portion corresponding to the simultaneous transformations of primary and secondary hydroxy groups and the second portion, to the state when the equilibrium has already been attained for the primary OH groups but has not yet been attained for the secondary OH groups. The observed dependence of ln*w* on ln*c* is attributable to a decrease in the molecular mobility in the course of the polycondensation (due to growing viscosity), or to possible manifestation of the thermotropic properties of the polymer (formation of mesomorphic structures in solution, as shown in [2]). Furthermore, when the ln*w*–ln*c* dependences are plotted for different reaction times, different rate constants are obtained (Fig. 2). The changes in the polycondensation kinetics are seen more clearly from the *w/c*–*c* plot (Fig. 3). Moreover, the dependence of *w/c* on *c* allows us to derive a polynomial equation describing the concentration dependence of the reaction rate:

$$d[c]/d\tau = a_1[c^2] + a_2[c],$$

where a_1 and a_2 are constants, *c* is concentration, and τ is time.

The form of this polynomial suggests the occurrence of parallel reactions of different orders with respect to *c*. Furthermore, this equation shows that both hydroxy groups participate in the reaction through out the process (24 h), and the equilibrium is not attained even with primary OH groups. It is also

seen that the reactions are not catalyzed by components of the system.

The reaction rate constants and reaction orders in relation to the reaction time are given in Table 1.

Table 1 shows that, in portion I of the kinetic curve (low conversions), the reaction follows the commonly accepted mechanism and is not complicated by the influence of the forming polymer and by the growing viscosity of the melt [3]. In portion II, the polycon-

215	I	0.381	2.52
	II	0.353	2.64
	III	0.523	2.81
230	I	1.110	1.83
	II	1.298	3.41
	III	0.120	1.84
250	I	0.740	3.84
	II	0.786	1.97
	III	0.191	1.59
265	I	2.338	1.85
	II	5.067	3.41
	III	1.241	3.02

densation rate constant increases (except for 215°C), which may be due to appearance of mesomorphic structures promoting the reaction; this effect is stronger than that exerted by the melt viscosity. At 215°C, the viscosity is so high that formation of ordered structures is hindered; correspondingly, the polycondensation rate decreases. In portion III, the melt viscosity increases to such an extent (owing to an increase in the molecular weight of the polymer) that the effect of mesomorphic structures is not manifested.

Thus, our data allow calculation of the rate constants of the process, but do not allow determination of the equilibrium constants for the whole process at various temperatures and for primary and secondary hydroxy groups. The equilibrium constant K in this case depends only on temperature, which allows determination of K at least for the initial portion, in which the process is controlled only by the rate of reaction of the functional groups. For this purpose, it is sufficient to ensure the pseudo-first-order reaction conditions. According to published data, the error in determining the reaction parameters at a fivefold excess of one of the agents is 5%, which is quite acceptable for kinetic measurements [4]. In this case, the equilibrium constant can be determined only with excess betulin; otherwise, the polycondensation may be catalyzed by the carboxy groups of adipic acid. Figure 4 shows the plot of $\ln c$ vs. τ, confirming the occurrence of parallel first-order reactions with the common product. From the dependence of w on c, we can determine the reaction rate constants for primary and secondary hydroxy groups. Knowing the rate constants, we can obtain the dependence of $\ln(c - c_{eq})$ on time τ. The equilibrium concentration c_{eq} is chosen so as to obtain a linear dependence. The slope of this dependence is equal to $-(k_+ + k_-)$. Knowing the equilibrium concentration of each type of hydroxy groups and the quantity $-(k_+ + k_-)$, we can find the rate constants of the forward and reverse reactions and the equilibrium constant of the polycondensation for primary and secondary hydroxy groups. The results are listed in Table 2.

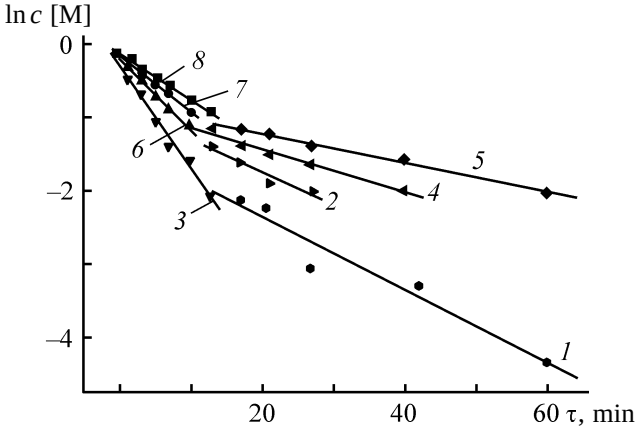

Fig. 4. Plot of $\ln c$ vs. time τ (pseudo-first order). T, °C: (*1*, *3*) 270, (*2*, *6*) 260, (*4*, *7*) 250, and (*5*, *8*) 240.

Table 2 shows that the equilibrium constant, as expected, increases with temperature; also, the rate constants determined allow estimation of the reactivity of the hydroxy groups. The primary hydroxy groups are 5.5 times more reactive than the secondary hydroxy groups, and this reactivity ratio is independent of temperature. The pseudo-first-order reaction parameters found for the 5 : 1 molar ratio allow calculation of the reaction parameters for the 1 : 1 molar ratio. The calculated parameters are listed in Table 3.

As already noted, the equilibrium constants obtained refer not to the whole process but only to the interval from the start of the process to the moment when the concentration of OH groups reaches 0.8 M. If these parameters referred to the whole process up to the maximum attainable conversion, their calculated values would be as follows: 215°C, 0.92; 230°C, 0.94; 250°C, 0.96; and 265°C, 0.97. However, actually the conversion in 24 h reaches 0.98. This is possible only if the equilibrium constant increases with the molecular weight [5].

It is interesting that, at 250°C, the rate constants of the forward and reverse reactions decrease, which may be due to formation of structures in which the reaction of the terminal groups is hindered. This decrease is also observed in other portions of the kinetic plots and is confirmed by Table 1.

CONCLUSIONS

(1) The kinetics of the polycondensation of betulin with adipic acid depends on the molecular weight of the polymer. The kinetic plots consist of three portions, each characterized by specific reaction parameters.

(2) The equilibrium constants were found, and the possibility of using the pseudo-first-order conditions for their determination was demonstrated.

(3) The polycondensation of betulin with adipic acid shows an anomaly at 250°C.

Abstract—The polymerization of methyl methacrylate to high conversion in the presence of a series of disilanes as chain-transfer agents was studied, and the chain-transfer constants at low and high conversions were determined. The molecular-weight characteristics of the polymers were estimated by gel permeation chromatography.

The molecular-weight distribution (MWD) of polymers mainly affects the rheological properties of their solutions and melts. This influence is the most pronounced in the case of a flow under a high shear stress [1]. Therefore, the development of methods for controlling MWD, suitable for industrial applications, is an urgent problem, since polymers are mainly processed in the form of melts.

Recently there has been a considerable progress in the controlled pseudo-living radical polymerization [2, 3] allowing preparation of virtually monodisperse polymers. However, this result is provided by reversible inhibition, which leads to low polymerization rates even at very high temperatures (100–120°C). Therefore, it is urgent to find the conditions of radical polymerization ensuring preparation of polymers with fairly narrow MWD without decreasing the polymerization rate at acceptable temperature. For this purpose, we studied the molecular-weight characteristics of polymers prepared in the presence of polyfunctional silicon hydrides, which are effective chain-terminating agents for polymers [4].

EXPERIMENTAL

The organosilicon hydrides (main substance content 98–99%) were prepared at the Institute of Organometallic Chemistry, Russian Academy of Sciences (Nizhni Novgorod) and were used without additional purification. The procedures for preparing the hydrides were described in [5–8]. Dodecyl mercaptan (DDM) was purified by vacuum distillation; methyl methacrylate (MMA), by vacuum recondensation; and azobis(isobutyronitrile) (AIBN, initiator), by recrystallization from ethanol. The polymerization was performed in sealed dilatometric ampules at 60°C, both to low (≤10%) and to high conversions, at which the reaction mixture lost fluidity. Prior to the experiments, the ampules were treated to remove atmospheric oxygen. The initial polymerization rate was monitored dilatometrically. The resulting polymers were purified by triple reprecipitation from acetone into petroleum ether and were dried to constant weight in a vacuum.

The relative chain-transfer constants C_s and the apparent chain-transfer constants at high conversions C_s^{app} were calculated from the Mayo graphical dependence

$$1/P_n = 1/P_0 + C_s[S]/[M],$$

where P_n and P_0 are the degrees of polymerization of the polymer obtained in the presence and in the absence of the chain-transfer agent, respectively; [S] and [M] are the molar concentrations of the chain-transfer agent and monomer, respectively.

The viscosity-average molecular weights (MWs) of the polymers were determined viscometrically. The measurements were performed with an Ubbelohde viscometer in methyl ethyl ketone (MEK) at 30°C; MW was calculated by the formula $[\eta] = 5.907 \times 10^{-4} M^{0.5716}$ [9]. The previously determined constants of the chain transfer through organosilicon hydrides [4] are given in Table 1. The molecular-weight characteristics of the polymers were determined by GPC

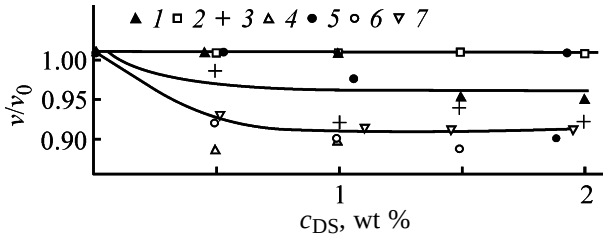
on a Waters chromatograph with a set of five Styrogel columns with the pore diameter of 10^5, 3×10^4, 10^4, 10^3, and 250 Å. The eluent was tetrahydrofuran. An RD-410 differential refractometer was used as detector.



It is known that the necessary condition for processing polymers through the melt is MW of the order of 10^5. As polymerization to high conversions usually yields polymers with MW by an order of magnitude higher, the MW should be controlled. Table 2 presents the results of GPC analysis of PMMA samples prepared using two main methods for decreasing MW: increasing the initiator concentration and adding chain-transfer agents to the formulation. Table 2 shows that, in the polymerization to high conversions, both methods allow the molecular weight of PMMA to be decreased by an order of magnitude. However, polymers prepared in the presence of chain-transfer agents with active S–H and Si–H groups have a narrower MWD. It is important that the polydispersity parameter of such polymers virtually reaches the theoretical value, $M_w/M_n \cong 2$, corresponding to the Flory exponential distribution characteristic of radical polymerization with the chain termination through disproportionation of radicals and/or chain transfer.

The above-indicated limit can be overcome by using polyfunctional silicon hydrides as chain-transfer agents. Table 3 shows that, in polymerization of MMA to high conversions in the presence of trimethylisopropyldisilane (DS-8) containing two Si–H groups in the molecule, the polydispersity index M_w/M_n becomes as low as 1.51.

This value corresponds to the minimal polydispersity of a polymer attainable under the conditions of radical polymerization. It theoretically corresponds to the Schultz distribution characteristic of radical polymerization with recombination (coupling) of radicals and of polycondensation. It can be readily shown that specifically this distribution is characteristic, to one or another extent, of the polymerization performed in the presence of bifunctional disilanes as chain-transfer agents. Assume that both Si–H groups of the disilane

Initial relative polymerization rate v/v_0 of MMA in the bulk at 60°C in the presence of 5×10^{-3} M AIBN as a function of concentration c_{DS} of various disilanes: (*1*) DS-8, (*2*) DS-4, (*3*) DS-9, (*4*) DS-10, (*5*) DS-11, (*6*) DS-12, and (*7*) DS-2.

participate in the chain transfer:

Then it can be assumed that any macromolecule with the degree of polymerization p is formed from propagating radicals with the degrees of polymerization p' and $p - p'$. The probability of formation of such macromolecules is described by an expression similar to that for the chain termination through recombination of radicals:

$$q(p) = A\sum_{p'=1}^{p'=p-1}(1-\varepsilon)^{p'}\varepsilon(1-\varepsilon)^{p-p'}\varepsilon = A\sum_{p'=1}^{p'=p-1}(1-\varepsilon)^{p}\varepsilon^2, \quad (1)$$

where $\varepsilon = \Sigma v_0/(\Sigma v_0 + v_p)$ is the probability of chain termination; v_p, rate of chain propagation; v_0, total rate of chain termination reactions; and $A = 1$, quantity determined from the normalization conditions [10].

Therefore, expression (1) corresponds to the numerical distribution function of macromolecules with respect to the degree of polymerization. Passing to the continuous distribution, we obtain

$$q(p)\mathrm{d}p = p\varepsilon^2 e^{\varepsilon p}. \quad (2)$$

Expression (2) is the Schultz distribution characteristic of radical polymerization with the predominant chain termination through the recombination of radicals. In this case,

$$M_z/M_w/M_n = (k + 3)/(k + 2)/(k + 1), \quad (3)$$

where k is determined by the fraction of radicals participating in the chain termination through recombination; at $k = 1$, $M_w/M_n = 1.5$.

Thus, the existing theory of radical polymerization explains why the polydispersity of polymers prepared by radical polymerization in the presence of silicon dihydrides is lower, compared to the polymerization in the presence of monohydrides and mercaptans.

Data in Table 3, especially for DS-8, suggest that k is close to unity. This means that the Si–H group in the disilane bound to a macromolecule is more reactive than the same group in the initial chain-transfer agent. This conclusion is supported, in particular, by comparison of C_s for the initial polymerization step in the presence of mono- and disilanes (Table 1): $1/2C_s$(DS-8) > C_s (DS-9). This relationship may be due, among other things, to the fact that the terminal organosilicon group as a "foreign" unit is expelled to the border of the coordination sphere of the macromolecular coil, which increases the probability of its reaction with propagating macroradicals from the standpoint of the North's diffusion theory of chain termination [11].

As already noted, the existing methods for "cardinally" decreasing the polydispersity involve, as a rule, a decrease in the polymerization rate, which is unacceptable for the commercial process. Therefore, it is very important that the participation of the Si–H group in the chain transfer exerts virtually no effect on the polymerization rate. As seen from the figure, the polymerization rate does not noticeably change as the concentration of the majority of the tested silanes is increased up to 2 wt %, i.e., to the level exceeding the reasonable concentration of silanes in controlling the MW of the polymers under the conditions of bulk polymerization.

The abnormally high polydispersity of the PMMA sample prepared in the presence of DS-15 deserves certain discussion. This result is undoubtedly associated with the abnormally high chain-transfer constant, $C_s = 8.3$, due to the presence in the chain-transfer agent of a group of four silicon atoms located closely to the hydrogen atom. As shown in [4], polysilicon fragments in silanes activate the Si–H bond. At $C_s \gg 1$, the relative concentration of the chain-transfer agent [S]/[M] rapidly decreases in the course of the polymerization, which results in an appreciable decrease (by more than an order of magnitude in our case) in the apparent chain-transfer constant, in formation of a higher-molecular-weight polymer, and hence in the higher polydispersity of the final product. It should be

noted in conclusion that similar effects can be expected in the case of polystyrene, as judged from the constants of chain transfer through disilanes in polymerization of styrene [4].

CONCLUSIONS

(1) In radical polymerization of methyl methacrylate, addition of disilanes decreases the degree of polydispersity of the high-conversion polymers to M_w/M_n = 1.5–1.89; the performance of the chain-transfer agent depends on its functionality, i.e., on the number of the Si–H bonds. In the presence of silicon dihydrides, polymers with the molecular-weight distribution close to the Schultz distribution (M_w/M_n = 1.5) are formed.

(2) Decreasing the degree of polydispersity of the polymer by adding polyfunctional silicon hydrides to the reaction system does not require high temperatures and is not accompanied by a noticeable decrease in the rate of the radical polymerization.

Abstract—The kinetics of radical copolymerization of sodium 2-acrylamido-2-methylpropane-1-sulfonate with *N*-vinylpyrrolidone in water, water–dimethylformamide (1 : 1) solutions, and dimethylformamide at pH 9 and 60°C in the presence of initiators [azobis(isobutyronitrile) and ammonium persulfate] was studied by dilatometry.

The reaction medium strongly affects both the kinetic parameters of copolymerization of salts of 2-acrylamido-2-methylpropane-1-sulfonic acid (H-AMS) with *N*-vinylpyrrolidone (VP) and the properties of the resulting copolymers. This is due to the features in the behavior of ionic monomers [1, 2] and nonionic VP monomer [3, 4] in the processes of radical (co)polymerization. Previously we studied copolymerization of sodium 2-acrylamido-2-methylpropane-1-sulfonate (Na-AMS) with VP in aqueous [5–7] and dimethyl sulfoxide [8] solutions and examined how the ionic strength of the solution and kind of mono- [9, 10] and bivalent [10, 11] cations affect the copolymerization in aqueous solutions.

In this work we studied the dependences of radical copolymerization of Na-AMS and VP in water, water–dimethylformamide (1 : 1) solutions, and dimethylformamide (DMF). These data are not only of theoretical but also of practical importance because, owing to the valuable properties of copolymers of Na-AMS and VP, they show promise for various branches of industry and medicine.

EXPERIMENTAL

Sodium salt Na-AMS was prepared by neutralization of aqueous solutions of H-AMS [Lubrisol-2404 (Lubrisol Corp., the United Kingdom), mp 185°C, main substance 99%] with NaOH to pH 9. *N*-Vinylpyrrolidone (Merck, Germany) was double-distilled in the presence of 0.1% KOH solution at 63°C in a vacuum (3 mm Hg) [n_D^{20} 1.5117, 99% main substance (GLC data)]. Ammonium persulfate (AP) was twice recrystallized from aqueous solutions [98.7% main substance (redox titration data)]. Azobis(isobutyronitrile) (AIBN) was twice recrystallized from methanol (mp 103.5°C). Dimethylformamide was distilled with a mixture of benzene and water in a vacuum (n_D^{20} = 1.4269). All the solutions were prepared using distilled water; the other chemicals were of chemically pure grade.

Copolymerization of Na-AMS with VP was performed in 7 cm^3 glass dilatometers and in 50 cm^3 weighing bottles for 2 h. The procedures of copolymerization and dilatometric analysis of the reaction kinetics were similar to those described in [6]. The initial sections of the kinetic curves obtained dilatometrically were linear, which allowed calculation of the initial copolymerization rate v_0 at low conversion ($x < 3\%$).

After copolymerization, the resulting polymers were precipitated from aqueous solutions with acetone, filtered off, washed with acetone, and dried to constant weight in a vacuum at 50°C. The yield of the copolymers was determined gravimetrically. The molecular weights of the copolymers (M) were calculated from the intrinsic viscosities [η] of their solutions, which were measured in a 0.5 M NaCl solution at 30°C on a VPZh-3 capillary viscometer (d_c = 0.43 mm). The experimental dependence of the reduced viscosity η_{sp}/c_p on the copolymer concentration c_p was plotted. Then, using the linear dependence $\eta_{sp}/c_p = f(c_p)$, we determined $[\eta] = \lim(\eta_{sp}/c_p)$ at $c_p \to 0$. The content of ionic units in the copolymer

1070-4272/05/7807-1170 © 2005 Pleiades Publishing, Inc.

of Na-AMS and VP was determined from the content of sulfur [12].

The potentiometric titration was carried out with a pH-121 pH-millivoltmeter equipped with an ESL-65-07 working glass electrode and an EVL 1MZ silver chloride reference electrode.

Copolymerization of Na-AMS (M_1) with VP (M_2) was performed in 20% solutions in water, H_2O : DMF = 1 : 1 mixture, and DMF at 60°C and pH 9. In all the solutions, the reaction was initiated by thermal decomposition of ammonium persulfate ([AP] = 7.4×10^{-4} M), additionally AIBN was used in the case of DMF ([AIBN] = 3×10^{-2} M). Maintaining pH 9 during initiation with AP [13] is necessary for providing fairly high and constant initiation rates when the ionic strength of solutions varies (due to changes in the Na-AMS concentration in the initial monomer mixture in the course of copolymerization [14]), and also for preventing hydrolysis of VP [15].

Our experiments showed that Na-AMS and VP did not noticeably polymerize in the absence of initiators in all the systems studied. In the presence of the initiator, the copolymerization in water and water : DMF = 1 : 1 mixture proceeds under homogeneous conditions, whereas in the case of DMF the reaction is heterogeneous: an opalescence appeared in solutions, though a solid phase did not precipitate.

The dependences of v_0 (curves *1*–*3*) and [η] (curves *1*'–*3*') of copolymers on the concentration of Na-AMS [M_1] in the initial monomer mixture in various solutions are shown in Fig. 1. As seen, v_0 decreases in the series water > water : DMF = 1 : 1 > DMF; the same trend is observed for [η]. These changes in v_0 with increasing content of the protic solvents in the reaction mixture well agree with the data on changes in the reaction rate on passing from aprotic to protic solvents in homopolymerization of H-AMS [16] and VP [17, 18]. In accordance with published data on several water-soluble monomers [3] and, in particular, on VP [19], acceleration of copolymerization of Na-AMS and VP in a protic solvent is caused by solvation of the monomers due to formation of hydrogen bonds between the C=O group of the monomer and solvent. This increases the polarity of the vinyl group in the monomers and, thus, enhances their activity in copolymerization.

The dependences of the current concentration of the Na-AMS–VP copolymer at low conversions (x < 3%) on the composition of the initial monomer mixture in different solvents are shown in Fig. 2. The dependences $m_1 = f(M_1)$ for copolymerization in

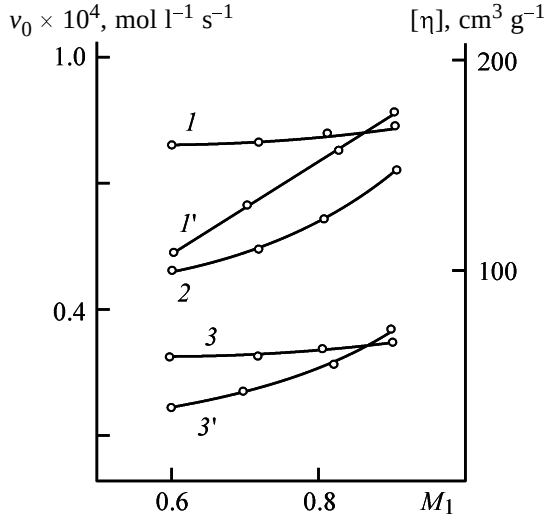

Fig. 1. (*1*–*3*) Initial copolymerization rate v_0 of Na-AMS and VP in the presence of AP and (*1*', *3*') intrinsic viscosity of copolymers [η] as functions of the Na-AMS mole fraction in the initial monomer mixture M_1. Solution: (*1*, *1*') H_2O, (*2*) H_2O : DMF = 1 : 1, and (*3*, *3*') DMF.

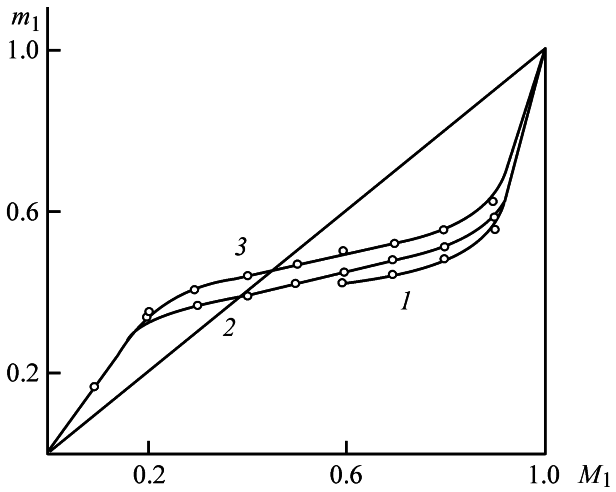

Fig. 2. Mole fraction of Na-AMS units in the copolymer m_1 at conversion x < 3% as a function of the Na-AMS mole fraction in the initial monomer mixture M_1 in copolymerization in (*1*) H_2O, (*2*) H_2O : DMF = 1 : 1, and (*3*) DMF in the presence of AP.

H_2O : DMF = 1 : 1 (Fig. 2, curve *2*) and DMF (Fig. 2, curve *3*) are S-shaped with the corresponding azeotropic points. From these data, using the Mayo–Lewis equation, we calculated the effective relative activities of the monomers in copolymerization $r_1 = k_{11}/k_{12}$ and $r_2 = k_{22}/k_{21}$ for Na-AMS and VP, respectively (see table). These data confirm that, in copolymerization in H_2O : DMF = 1 : 1 and pure DMF, both macroradicals react with the "foreign" monomer more readily than with their "own" monomer. The $r_1 r_2$ values confirm

Effective relative activities of the monomers r_1 and r_2 in copolymerization of Na-AMS and VP in solutions containing DMF at various initiator concentrations

the regular composition of the copolymers formed in the systems studied.

Comparison of the experimental data at M_1 = const shows that the content of Na-AMS units in the polymer chain increases in the following order: H_2O < H_2O : DMF = 1 : 1 < DMF, i.e., on passing from curve *1* to curve *3* (Fig. 2).

The above changes in the composition of Na-AMS–VP copolymer in the above solutions can be due to the effect of the solvent polarity on the ionization equilibrium of the ionic groups in Na-AMS and its units in the copolymer:

$$\underset{\text{I}}{A^-X^+} \overset{\leftarrow}{\rightarrow} \underset{\text{II}}{A^-} \parallel X^+ \overset{\leftarrow}{\rightarrow} \underset{\text{III}}{A^- + X^+}, \qquad (1)$$

where A^- is the anion of the monomer or macroradical; X^+ is the cation; and I, II, and III are the contact ion pairs, ion pairs separated with a solvent, and free ions, respectively.

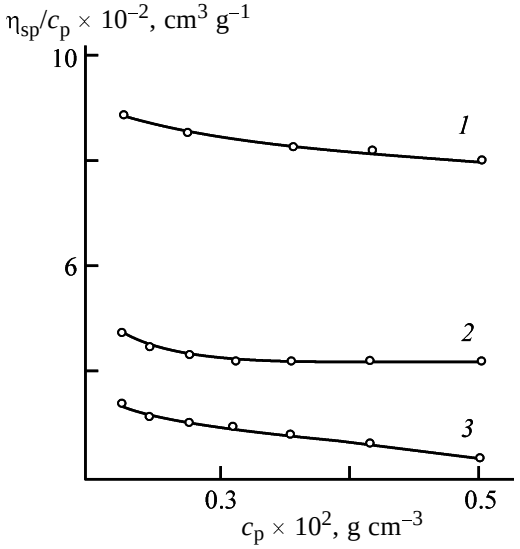

Fig. 3. Reduced viscosity η_{sp}/c_p of Na-AMS-VP copolymer ($[\eta]$ = 260 cm^3 g^{-1}, 33 mol % Na-AMS units) as a function of copolymer concentration c_p in (*1*) H_2O, (*2*) H_2O : DMF = 1 : 1, and (*3*) DMF at 30°C.

Changes in the solvent polarity affect the ionization of the ionic groups of Na-AMS and its units in macroradical. This shifts the ionization equilibrium (1) and changes the content in the reaction mixture of various ionic species and, thus, the intensity of intra- and intermolecular electrostatic interactions between them. As a result, the relative activities of ionic monomers in copolymerization r_1 and r_2 are variable, and the process cannot be described using the Mayo–Lewis equation with fixed r_1 and r_2.

With decreasing solvent polarity in the series H_2O > H_2O : DMF = 1 : 1 > DMF, the ionization equilibrium (1) is shifted to the left, which decreases the electrostatic repulsion between the similarly charged monomer Na-AMS and macroradical with terminal Na-AMS unit and thus increases the elementary constant of chain propagation k_{11} and promotes enrichment of the copolymer with Na-AMS units. On passing from water to DMF, the decrease in the electrostatic repulsion between similarly charged units along the chain decreases the effective size of macromolecular globules, which is indirectly confirmed by viscometry (Fig. 3). With decreasing charge of macromolecules in the series H_2O > H_2O : DMF = 1 : 1 > DMF, the local concentration of Na-AMS monomers in the vicinity of their "own" centers increases in the series H_2O < H_2O : DMF = 1 : 1 < DMF; as a result, the content of Na-AMS units in the copolymer grows. It should be noted that, since the copolymerization in DMF is a heterogeneous process, certain differences in the distribution and diffusion of comonomers in different phases and selective solvation of macroradicals with monomers can affect the kinetic parameters of copolymerization in the systems studied.

The effect of the initiator concentration on the composition of Na-AMS–VP copolymer was studied in the course of copolymerization in DMF in the presence of AP ([AP] = 7.4×10^{-4} M) and AIBN ([AIBN] = 3.0×10^{-2} M), other conditions being equal. For this experimental series, the dependence of the current composition of the copolymer on the composition of the initial monomer mixture is given in Fig. 4. As seen from a comparative analysis of these data at M_1 = const, in a wide range of compositions of the initial monomer mixture the content of Na-AMS units increases with decreasing content of the initiator (Fig. 4, passing from curve *1* to curve *2*), which is due to an increase in r_1 and decrease in r_2 in the system studied (see table). Changes in the copolymer

composition and in r_1 and r_2 values as influenced by AIBN content were also found by Begantseva *et al.* [20] who studied the copolymerization of styrene and acrylamide in DMSO. This suggests that a significant difference in the concentration of initiators (nearly two orders of magnitude) in the system studied provides formation of copolymers with different M, which, in accordance with [21, 22], affects the selective solvation of macroradicals with monomers and changes the composition of the resulting copolymers.

It is known that, in classical systems, the copolymer composition strongly depends on the conversion (except the case when $r_1 = r_2$); however, for some water-soluble polymers certain deviation from this trend in solutions is observed [23, 24], which was attributed to hydrophobic interactions in aqueous polymer solutions. To examine the effect of conversion on the molecular properties of the resulting Na-AMS–VP copolymers, we determined the copolymer composition and [η] in the course of copolymerization in the presence of AIBN in DMF at mole fractions M_1 0.3 and 0.5 (Fig. 5). As seen, in the course of copolymerization [η] increases (Fig. 5, curves *1*' and *2*'), which agrees with the data on the alternating copolymerization in other systems [25]. The copolymer composition at $M_1 = 0.5$ does not significantly change with increasing copolymerization time (Fig. 5, curve *1*), whereas at $M_1 = 0.3$, the changes are more pronounced (Fig. 5, curve *2*). The observed changes in the copolymer composition (Fig. 5) with increasing conversion are probably associated with different rates of consumption of the monomers owing to their different reactivity and with nonisoionic synthesis conditions, which affect the activity of the ionic monomer in copolymerization [2].

The kinetics of copolymerization of Na-AMS with VP in DMF in the presence of AIBN was studied at 60°C. The effect of the Na-AMS content in the initial monomer mixture M_1 on v_0 and [η] of Na-AMS–VP copolymer is illustrated by Fig. 6. As seen, the dependences $v_0 = f(M_1)$ and [η] = $f(M_1)$ show similar trends and pass through a maximum at $M_1 = 0.5$. These dependences well agree with the data on copolymerization of Na-AMS and VP in aqueous solutions [6] and suggest donor–acceptor interaction between Na-AMS and VP, which is confirmed by the IR data for nonaqueous solutions [26].

To determine the total rate of copolymerization of Na-AMS with VP in DMF, we carried out the experiments at different concentrations of the monomers and initiator, other conditions being equal. The dependences of v_0 on the initial concentrations of Na-AMS,

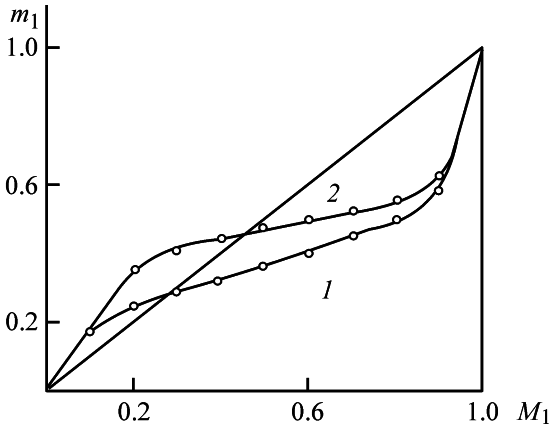

Fig. 4. Mole fraction of Na-AMS units in copolymer m_1 at low conversion ($x < 3\%$) as a function of the Na-AMS mole fraction in the initial monomer mixture M_1 in copolymerization of Na-AMS with VP in DMF in the presence of (*1*) AIBN ([AIBN] = 3.0×10^{-2} M) and (*2*) AP ([AP] = 7.4×10^{-4} M).

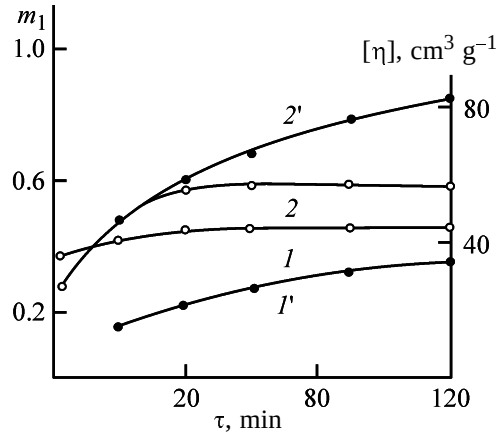

Fig. 5. (*1*, *2*) Mole fraction of Na-AMS units in copolymer m_1 and (*1*', *2*') intrinsic viscosity [η] in copolymerization of Na-AMS and VP as functions of time τ of copolymerization in DMF in the presence of AIBN. Mole fraction of Na-AMS in the initial monomer mixture M_1: (*1*, *1*') 0.5 and (*2*, *2*') 0.3.

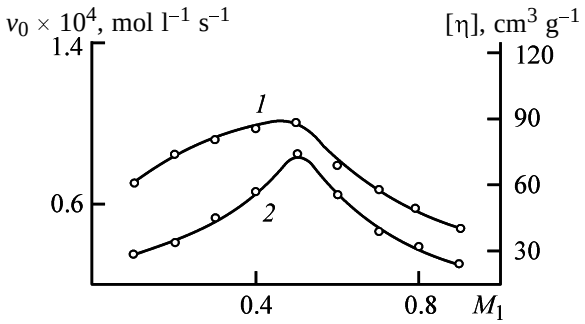

Fig. 6. (*1*) Initial copolymerization rate v_0 of Na-AMS and VP in DMF in the presence of AIBN and (*2*) intrinsic viscosity of copolymers [η] as functions of the Na-AMS mole fraction in the initial monomer mixture M_1.

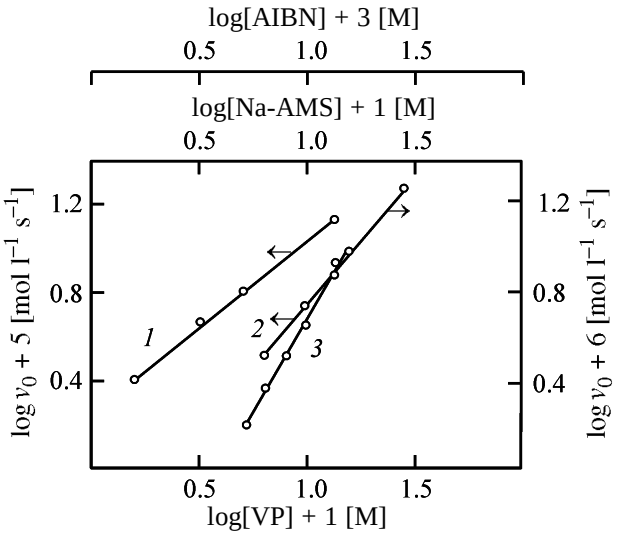

Fig. 7. Initial copolymerization rate v_0 of Na-AMS and VP in DMF as influenced by concentrations of (*1*) VP, (*2*) AIBN, and (*3*) Na-AMS (log–log plots). (*1*) [Na-AMS] = 0.587 and [AIBN] = 0.03 M; (*2*) [Na-AMS] = 0.587 and [AP] = 0.587 M; and (*3*) [VP] = 0.587 and [AIBN] = 0.03 M.

VP, and AIBN are shown in Fig. 7. As seen, v_0 increases with increasing concentrations of Na-AMS (from 0.362 to 0.724), VP (from 0.187 to 0.934), and AIBN (from 0.01 to 0.03 M) (Fig. 7, curves *3*, *1*, *2*). The reaction orders with respect to Na-AMS, VP, and AIBN were 1.5, 0.9, and 1.2, respectively. Using these experimental data, the equation of the total rate of copolymerization of Na-AMS and VP in DMF was evaluated:

$$v = k_c[\text{Na-AMS}]^{1.5}[\text{VP}]^{0.9}[\text{AIBN}]^{1.2}, \quad (2)$$

where k_c is the rate constant of copolymerization.

For the copolymerization of Na-AMS and VP in water, the following equation was given in [6]:

$$v = k_c[\text{Na-AMS}]^{0.9}[\text{VP}]^{0.7}[\text{AIBN}]^{0.5}. \quad (3)$$

Comparison of Eqs. (2) and (3) showed an increase in the reaction orders with respect to the comonomers and initiator on passing from water to DMF, which is probably due to the fact that, in the case of DMF, copolymerization proceeds as a heterogeneous process. The reaction order of 0.5 with respect to the initiator in Eq. (3) suggests bimolecular chain termination, which is typical for homogeneous polymerization. The reaction order of 1.2 with respect to the initiator in Eq. (2) suggests monomolecular chain termination owing to heterogeneous copolymerization of Na-AMS and VP in DMF.

CONCLUSIONS

(1) The copolymerization rate of sodium 2-acrylamido-2-methylpropanesulfonate with *N*-vinylpyrrolidone and molecular weight of the resulting copolymer increase, and the content of the ionic units in the copolymer decreases, on passing from water to dimethylformamide solvents.

(2) In copolymerization in dimethylformamide, the reaction rate increases with increasing concentrations of M_1, M_2, and azobis(isobutyronitrile) and passes through a maximum (similarly as molecular weight of the polymer) with changing $[M_1]/[M_2]$ in the initial monomer mixture (maximum at $[M_1]/[M_2] = 1:1$). The composition of the copolymer and relative activities of the monomers depend on the initiator concentration. With increasing conversion, the molecular weight of the copolymer and the content of the ionic units both increase.

Abstract—The structure and sorption properties of gel films of bacterial cellulose were studied in its interaction with polyvinylpyrrolidone and silver nanoparticles stabilized by this compound.

The influence exerted by the conditions of biosynthesis of *Acetobacter xylinum* cellulose (AXC) by the VKM V-880 strain on the structural properties of gel films of bacterial cellulose (GFBCs), formed in surface cultivation on low-cost nutrient media (industrial hydrolyzates of wood, peat, molasses, etc.) has been studied in the last decade [1, 2]. Particular attention has been given to structural changes of GFBCs at different conditions of their dehydration [3, 4].

Structural studies revealed that mainly highly crystalline cellulose of a polymorphic modification is formed in GFBC [1], and dried films show an axial-planar texture in which the $(\bar{1}10)$ crystallographic plane of the monoclinic cell is parallel to the sample plane. A conclusion was made that the texture of this kind, observed in macroscopic samples of AXC, is formed already in the stage of biosynthesis in microfibrillar bands, which have their primary hydroxy groups facing the surface of the nutrient medium on coming out of the terminal complex of a bacterium. According to electron diffraction data, such a microfibrillar band is a 50–100-nm-wide single-crystal formation with a length exceeding this diameter by a factor of 1000 and more [4, 5]. Motion of bacteria in the course of biosynthesis and growth of microfibrillar bands at the surface of the nutrient medium give rise to a GFBC structure with various types of packing, the densest of which are polycrystalline domains (Fig. 1). The specificity of growth of the crystalline domains of AXC is determined by interaction of microfibrils via primary hydroxy groups, which form a crystallographic plane at the phase boundary between the domain and the nutrient medium. This plane has an interplanar spacing d = 0.59–0.61 nm, which corresponds both to monoclinic I_β and triclinic I_α unit cells [6]. In the process, there arises a network of hydrogen bonds with water, which is preserved in purification and storage of gel films [3, 4].

Thus, microfibrillar bands lying in the film plane serve two functions: form hydrophilic layers that can retain a large amount of water and act as a reinforcing network, which, according to electron-microscopic data, occupies a considerable part of the volume of a gel film (Fig. 1) [3, 4]. Specifically this feature of the supramolecular organization of GFBCs enables their use as a matrix for medicines capable of a specific interaction, via hydrogen bonds, with the crystallographic plane filled with primary hydroxy groups. Such a matrix has a unique axial-planar texture, which favors preservation by GFBC of good sorption and strength characteristic in the course of its purification after biosynthesis to remove bacterial cells and in prolonged storage in distilled water at 5°C or after sterilization, and also after its saturation with various medical preparations [7].

One of the most promising areas of GFBC application in medicine is its use as high-efficiency bandaging materials, especially in curing of burns. This is because GFBCs are elastic, show low adhesion to the wound surface, and do not damage skin when a bandage is removed.

To impart antimicrobial properties to GFBC, a modern highly effective antibacterial agent, Poviargol,

1070-4272/05/7807-1176© 2005 Pleiades Publishing, Inc.

is introduced into its matrix. This agent is composed of nanoparticles of a zerovalent metallic silver, which are stabilized by polyvinylpyrrolidone (PVP–nano-Ag^0). This preparation shows, in addition to the antimicrobial action, also a preparative and immunopotentiating activity [8].

It is known that PVP and its copolymers are widely used in medical practice because they are low-toxic and form complexes with various biologically active substances [9]. Being dissolved in water, PVP acts as a structure-forming agent upon water molecules to form H-bound complexes of various stoichiometric compositions. It has also been shown that water clusters are formed on carbonyl groups of two neighboring pyrrolidone rings, with PVP hydrates being rather thermally stable, and an absolutely anhydrous polymer cannot be obtained even upon heating to 250°C [10]. In this context, it is assumed that PVP is involved in complexation with other substances via bound water molecules.

Therefore, of particular interest is an analysis of sorption and desorption interactions of PVP and Poviargol with the GFBC matrix, which is a network constituted by highly crystalline cellulose microfibrils surrounded by an enormous number of water molecules, and this is the subject of our study.

EXPERIMENTAL

Gel films of bacterial cellulose produced by the VKM V-880 strain of *Acetobacter xylinum* (AXC) were synthesized on a previously described nutrient medium [3]. After 80–90% of the initial amount of water was removed from GFBCs, samples were placed in aqueous solutions of PVP or Poviargol of a required concentration. The amount of substances sorbed in the GFBC matrix varied with their concentration (3–10 wt %) and exposure (1–20 h). The content of adsorbed substances in the composites obtained was monitored by X-ray diffraction analysis after drying the samples at room temperature.

Medicinal PVP of pharmacopoeia grade with a molecular weight MW 12 600 and Poviargol medicine with a silver content of 8%, manufactured by Tekhnolog Special Engineering and Design Office (St. Petersburg), were used in the studies. X-ray diffraction analyses were made on a DRON-2 installation with Ni-filtered copper radiation. For electron-microscopic studies, dry films of GFBC and GFBC–PVP–nano-Ag^0 were embedded in Araldite. Sections were made on an LKB-III ultramicrotome and examined with

a JEM-7A electron microscope at an accelerating voltage of 80 kV at magnifications of 1500 to 21000.

The X-ray diffraction pattern of compacted powders and films of PVP, obtained from various solvents (water, ethanol, acetone, etc.), exhibits two broadened reflections (Fig. 2, curve *1*) at reflection angles 2θ 11.3°–11.7° and 20°–21°. It is commonly believed that this polymer, widely used in medicine, has an amorphous structure. However, the authors of [9–13], who analyzed X-ray data for polymers exhibiting, similarly to PVP, two or three broadened reflections believe that these polymers contain a certain fraction of ordered structures in the amorphous phase. It should be emphasized that such an "amorphous-like" nature of X-ray diffraction patterns is attributed to the two-phase nature of the polymer if the halfwidth of the strongest first reflection, which, as a rule, corresponds to interchain distances, is $\varphi_{1/2}$ = 2°–4°.

The mesomorphic nature of the mutual packing of PVP chains is well confirmed by comparison of two diffraction curves in Fig. 2. Curve *2* was obtained for a film of polyvinylcaprolactam (PVCL), which differs from PVP in the presence of a seven-membered pendant ring [10]. It can be seen that the first reflection is shifted in the case of PVCL to smaller angles (2θ = 9°–9.5°), and the lower-intensity broad reflection is observed at 2θ = 18°–19°. It should be noted that the halfwidth of the first reflections of PVP and PVCL films deposited from different solvents onto different substrates (glass, metal, Teflon) remained virtually unchanged ($\varphi_{1/2}$ = 3°–4°).

As the PVP and PVCL chains have a cylindrical symmetry despite the difference in the content of *cis* and *trans* conformers [9], they can be involved in the formation of a pseudo-hexagonal structure even though the conformational disorder in the arrangement of monomer units along the polymer chains is preserved. This is confirmed by the existence of a high-intensity diffraction peak corresponding to an interchain period $L = 0.76 \pm 0.03$ nm for PVP and $L = 0.95 \pm 0.03$ nm for PVCL. According to experimental X-ray data and conformational calculations, these ordered parts of pseudohexagonal type in PVP and PVCL show a two-dimensional translation order in the plane perpendicular to chain axes and only orientational ordering in the third direction. Indeed, the patterns of X-ray scattering from PVP films stretched by a factor of 3–5 show no reflections associated with periodicity along the polymer chain. Similar results were obtained by Nishio *et al.* [13] in a study of the structure of strongly stretched films formed from a mixture of PVP and polyvinyl alcohol solutions with a mass ratio of 70 : 30.

The information about the PVP structure was used in a study of sorption properties of GFBCs. Figure 3 shows X-ray diffraction patterns of samples (dried at room temperature) of the starting GFBC (curve *1*), PVP films (curve *2*), and GFBC brought in contact with a 10% aqueous solution of PVP for 1 h (curve *3*). It can be seen that, in contrast to the diffraction pattern of the starting GFBC, curve *3* exhibits a broad reflection, similar to the first reflection from the PVP film (curve *2*), at reflection angles 2θ = 10°–12°. The same results were obtained with GFBC samples brought in contact with a 1–3% solution of PVP for 10–15 h. Hence follows that the structural parameters remain unchanged when AXC is introduced into its matrix. The position and intensity of the first reflection from PVP have no effect on the position and shape of the 110 crystal reflection (at 2θ = 17°) for the monoclinic modification of cellulose itself, but masks the 110 reflection (2θ = 15°), whose low intensity (curve *1*) indicates that an axial-planar structure exists in the starting GFBC [3, 4]. The second broad reflection from PVP has no effect, either, on the position of AXC reflections from the 102 and 012 (2θ = 21°) and 200 (2θ = 23°) planes of the monoclinic lattice,

but changes the background ratio in the diffraction curves *1* and *3* at reflection angles of 20°–30°. Indeed, the background intensity $I_b(20°)$ at $2\theta = 20°$ is equal to the background level at $2\theta = 30°$ for the starting GFBC [$I_b(30°)$], but $I_b(20°) \gg I_b(30°)$ for the GFBC–PVP composite (curve *3*). Such a change in the background intensity at 20°, compared with that at 30°, indicates that the second reflection from PVP makes a significant contribution to the total reflection from GFBC–PVP. The distinct reflection at $2\theta = 35°$ is associated with periodicity along the axis of the AXC chain in crystalline domains (004). This reflection is present in diffraction patterns of any modified sample of GFBC.

The sorption properties of GFBC with respect to PVP were studied in more detail by comparing the diffraction patterns obtained for GFBC–PVP samples (Fig. 3, curve *3*) with the patterns for the same sample after treatment with water for 2 (curve *4*) and 12 h (curve *5*). It can be seen that the first reflection, assigned to PVP, markedly decreases in intensity in curve *4* and totally disappears in curve *5*. The fact that the diffuse background level at $2\theta = 20°$ in curves *4* and *5* is substantially higher than that at $2\theta = 30°$ is possibly due to incomplete desorption of PVP from the GFBC matrix.

The most interesting results were obtained in a study of sorption and desorption of Poviargol (PVP–nano-Ag^0) on a GFBC matrix. The diffraction pattern of PVP–nano-Ag^0 (Fig. 4, curve *1*) contains reflections from two individually manifested structural phases: PVP at reflection angles of 5° to 30° and reflections that belong to the crystal structure of silver (2θ 38.4° and 44°) [14]. Figure 4 shows curves for GFBC–PVP–PVP–nano-Ag^0 composite samples obtained upon adsorption of a 3% solution of Poviargol for 1 (curve *2*), 2 (curve *3*), and 19 h (curve *4*) at room temperature with the subsequent drying on glass. Comparison of the diffraction patterns of these three samples shows that the strongest reflection from PVP is observed in curve *3*, i.e., upon exposure of a gel film of AXC in an aqueous solution of Poviargol for 2 h. After a 19-h exposure, the intensity of this reflection ($2\theta = 10°$–$12°$) noticeably decreased (Fig. 4, curve *4*), whereas the reflection associated with silver ($2\theta = 38.4°$) reached its maximum value. Apparently, a prolonged exposure of GFBC to a Poviargol solution leads to irreversible adsorption of silver on the surface and within the matrix of AXC, with PVP partly displaced into the aqueous phase.

To obtain a more detailed information about the phase composition, structure, and sorption properties

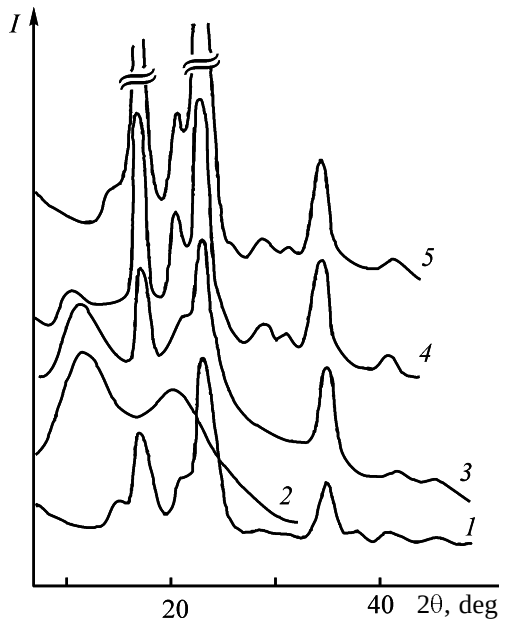

Fig. 3. X-ray diffraction patterns of dried samples of (*1*) GFBC, (*2*) PVP, and (*3*–*5*) GFBC–PVP composites (*3*) after bringing GFBC in contact with a 3% aqueous solution of PVP and subsequent washing of the films with distilled water for (*4*) 2 and (*5*) 12 h.

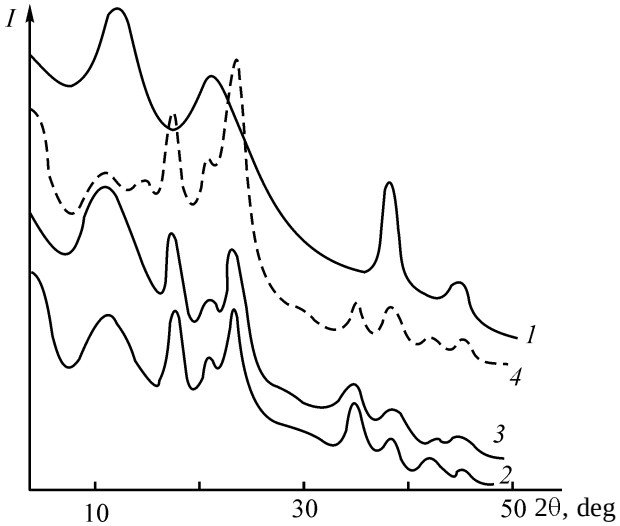

Fig. 4. X-ray diffraction patterns of (*1*) powdered Poviargol and dry films of GFBC–Poviargol composites obtained by bringing GFBC in contact with a 3% solution of Poviargol for (*2*) 1, (*3*) 2, and (*4*) 19 h.

of the GFBC matrix, the kinetics of desorption of PVP and nanoparticles of silver from gel films upon their being submerged in distilled water was studied. For this purpose, diffraction patterns of dry GFBC–PVP–PVP–nano-Ag^0 films were measured and the films were placed in water for 20 h. Then the samples were dried and another set of their diffraction patterns

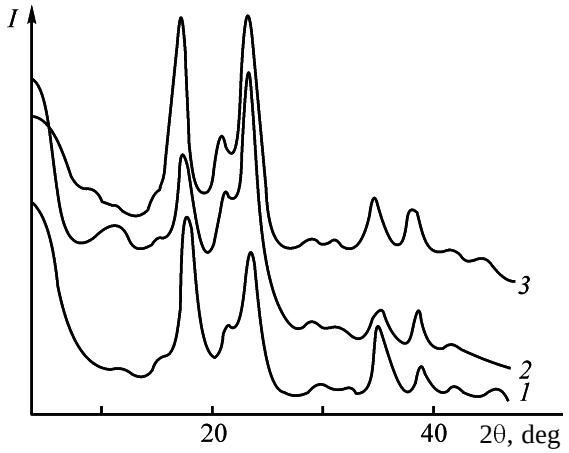

Fig. 5. X-ray diffraction patterns of dried GFBC–Poviargol samples after their preliminary multiple washing with distilled water in the course of 20 h. The initial composite samples were obtained by bringing GFBC in contact with a 3% solution of Poviargol for (*1*) 1, (*2*) 2, and (*3*) 19 h.

was obtained (Fig. 5). It can be seen in the scattering curves obtained after a 20-h treatment of all the samples that the position and sharpness of the reflections associated with crystalline domains of AXC and silver remain unchanged. The reflections associated with the presence of the PVP polymer in the GFBC matrix were observed after desorption only from GFBC–PVP–nano-Ag^0 samples obtained upon a 2-h exposure to Poviargol (Fig. 5, curve *2*).

Figure 6 shows cross-sectional electron micrographs of gel films modified with the PVP–nano-Ag^0 composite. An analysis of micrographs obtained at different magnifications (8000–21 000) revealed that the distribution of silver nanoparticles over the surface (Fig. 6a) and across the thickness (Fig. 6b) of a film is nonuniform. Characteristically, the silver clusters localized on the surface of gel films are larger than those in the film matrix. Presumably, the nonuniformity of the nanoparticle distribution is due to a distribution of water cavities with nonuniform dimensions in the microfibrillar network of GFBC. The difference in the number and size of clusters of adsorbed silver between the outer surface and the interior of the films is probably due to a specific texture of gel films formed in the course of biosynthesis and to its changes in squeezing of the films with removal of 80–90 wt % of water from GFBCs to enable adsorption of PVP–

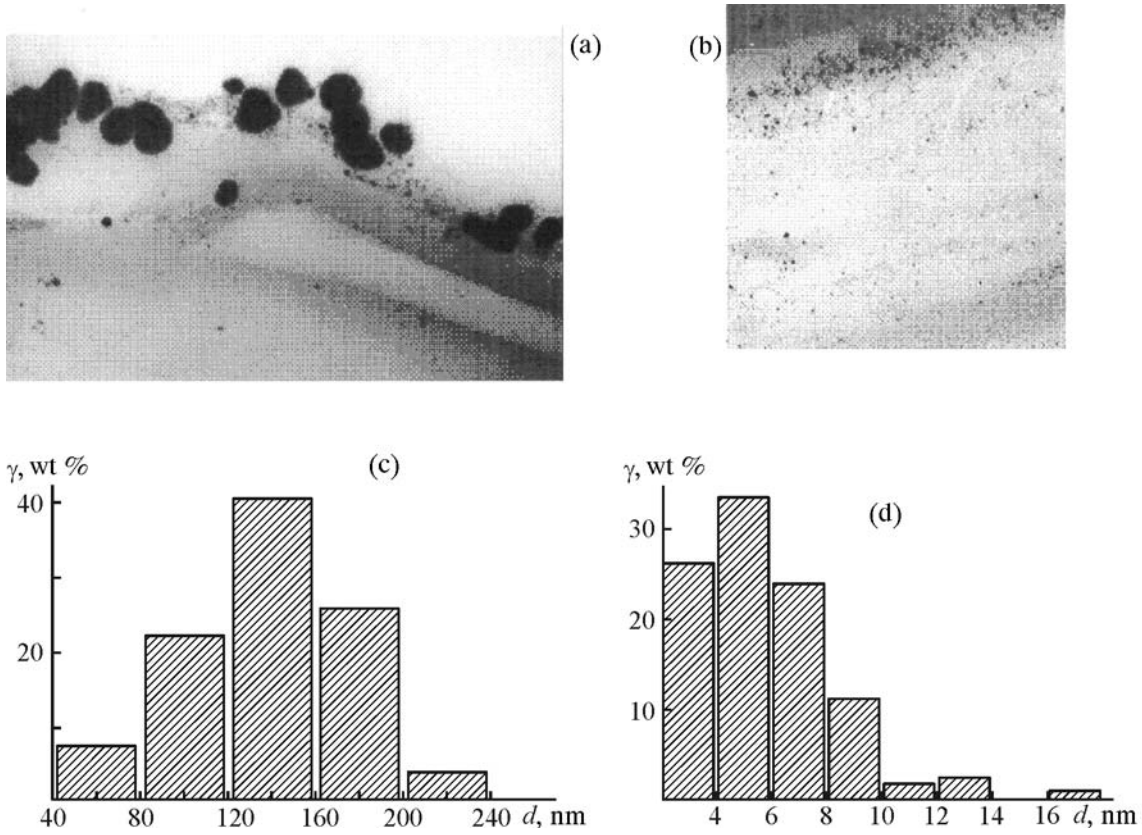

Fig. 6. Electron micrographs and histograms of dry samples of GFBC–Poviargol composites with silver distribution (a, c) over the surface and (b, d) across the film thickness. (γ) Content of grains and (*d*) grain diameter.

nano-Ag^0. The size distribution of silver nanoparticles deep in the cross section in regions with the highest content of silver in the cellulose matrix is shown in Figs. 6b and 6d. It was established that a major fraction of the particles (60%) is constituted by 2–6-nm particles, and 35% of the particles are 6–10 nm in size. The dimensions of the surface clusters of silver fall within the range 40–240 nm, with the maximum content (80%) of particles 100–180 nm in size. It is from these clusters that the diffraction patterns shown in Figs. 4 and 5 were obtained.

CONCLUSIONS

(1) X-ray diffraction analysis shows that the crystal structure of the cellulose under study remains unchanged when polyvinylpyrrolidone or its complex with silver nanoparticles is incorporated into its matrix.

(2) Electron microscopic examination shows that, in intercalation of gel films of bacterial cellulose with the polyvinylpyrrolidone–nano-Ag^0 complex, silver nanoparticles 2–10 nm in size penetrate deep into the matrix and larger clusters of silver are localized on its surface.

(3) Polyvinylpyrrolidone is readily removed from dried composite gel films of bacterial cellulose and polyvinylpyrrolidone or Poviargol by washing with distilled water without any changes in the cellulose structure and amount of adsorbed silver.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Hydrophilic Characteristics of Cellulose Treated with Saturated Water Vapor

I. I. Osovskaya, G. M. Poltoratskii, E. A. Dmitrieva, and Ya. V. Kamyshanskaya

Abstract—The reaction of water with cellulose treated with saturated water vapor at various temperatures for various times was studied. Trends in variation of its sorption and hydrophilic characteristics were examined.

The system of hydrogen bonds, macromolecular mobility, and regularity in arrangement of macromolecules in cellulose can be varied by physical or chemical actions [1–5]. One of the ways is treatment of cellulose with saturated water vapor. Sorption of water vapor with cellulose at various temperatures was considered previously [6, 7]. However, the influence of conditions of cellulose treatment with saturated water vapor on its physicochemical characteristics remains poorly understood, although such a treatment of dry cellulose material can be used in preparation of cellulose for chemical processing and paper production [8].

Formation of hydrogen bonds of water molecules with active groups of the polymer in this treatment and also partial breakdown of the system of intramolecular and intermolecular hydrogen bonds in the glassy component of cellulose affect subsequent sorption activity and reaction of the treated polymer with water.

Therefore, the goal of this study is a search for optimal conditions of cellulose treatment with saturated water vapor to restore its capillary-porous structure lost under drying in production of pulp.

We mainly used thermodynamic methods reflecting sorption and energy characteristics of cellulose fibers. Absorption of water with cellulose from liquid and gas phases was monitored from the enthalpy of wetting and desorption isotherms; variation of the internal surface area was characterized by sorption of a dye.

EXPERIMENTAL

Kraft whitened cellulose (SP-1650, degree of ordering 0.65, α-cellulose content 95.5%) was the subject of the study. The degree of polymerization was determined viscometrically at 298 K. Sodium ferric tartrate complex was used as a solvent. The degree of ordering was determined by X-ray diffraction analysis, and α-cellulose content, by dissolution of cellulose in 17.5% aqueous NaOH. The industrial samples of air-dry cellulose were treated under conditions of constant 100% relative humidity at temperatures T of 353, 373, and 438 K for the time τ from 3 to 15 min. Dehydration of the samples for calorimetric measurements and the study of dye sorption were performed by the inclusion method. Recording of desorption isotherms did not require additional treatment of the samples.

The thermal effects of the interaction of cellulose with water ΔH were obtained on a calorimeter equipped with an isothermal shell; the average relative error was ±1%. The desorption isotherms of water

vapor were recorded at 298 K by the tensimetric method; the relative error was ±3%. The amount of a dye adsorbed with cellulose was determined with a ±3% error. As a dye we used Direct Green Triaza dye (trade mark).

Variations of ΔH depending on duration of pretreatment with saturated water vapor are presented in Table 1, and the isotherms of desorption of water vapor, in Figs. 1 and 2.

The results of calorimetric measurements showed clear dependence of ΔH on T and τ. As seen from Table 1, the dependence of ΔH on τ has an extremum, the most pronounced at 438 K.

As seen from Figs. 1 and 2, the desorption of water vapor *A* also depends on the temperature and time of the pretreatment. It should be noted that, at low relative pressure of water vapor ($p/p_0 < 0.6$), the *A* values of all the samples are small; in this case, water is sorbed by the mechanism of local sorption on polar centers of macromolecules accessible to the sorbate. However, at increased p/p_0, especially at $p/p_0 = 0.975$, when the water desorption with the capillary system of the monofiber becomes noticeable, the influence of the pretreatment conditions is more significant.

Figure 1 shows that desorption isotherms *2* and *5* practically coincide. This suggests complete reconstruction of the capillary-porous structure of cellulose upon treatment with saturated water vapor at 434 K for 5 min. An increase in the action duration to 5 min results in a decrease in the water retention *A*.

The extremum in the dependence of the heat of wetting and the water retention on the duration of pretreatment with saturated water vapor suggests the occurrence of two opposite processes, each affecting the sorption characteristics and hydrophilicity of cellulose. With increasing temperature and treatment duration, the energy of thermal motion of macromole-

6**	–	–	4.0

* Non-dried cellulose.
** Initial cellulose.

cules increases and the system of hydrogen bonds is reorganized toward a decrease in their energy. The rupture of hydrogen bonds promotes swelling of the fiber and opening of pores and capillaries closed in drying. However, with increasing treatment duration the enthalpy of wetting and the water retention decrease due to recrystallization of the polymer and onset of degradation processes, also promoting formation of hydrogen bonds and decrease in the hydrophilicity of the polymer. The dependence of the average degree of polymerization of cellulose (DP) on τ is shown in Fig. 3.

The relationship between the treatment conditions and cellulose characteristics is suggested by variation of the dye sorption (Table 2). An increase in the amount of sorbed dye suggests maximum development of the capillary-porous structure of cellulose in treatment with saturated water vapor at 438 K for 5 min.

CONCLUSION

Studies of the physicochemical characteristics of cellulose treated with saturated water vapor at 353–438 K for 3–15 min by calorimetry, tensimetry, and dye sorption methods showed that the sorption and hydrophilic characteristics of cellulose are improved to the greatest extent by treatment at 438 K for 5 min.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis of Polymer–Colloid Complexes by Polymerization of Ionic Monomers in a Surfactant Solution

Yu. V. Shulevich, A. V. Navrotskii, O. Yu. Kovaleva, V. A. Navrotskii, and I. A. Novakov

Volgograd State Technical University, Volgograd, Russia

Abstract—The possibility of synthesis of polymer–colloid complexes by polymerization of 1,2-dimethyl-5-vinylpyridinium methyl sulfate and *N*,*N*,*N*,*N*-trimethyl(methacryloyloxyethyl)ammonium methyl sulfate in a solution of sodium dodecyl sulfate was examined.

Interaction of linear polyelectrolytes (PEs) with oppositely charged surfactants produces polymer–colloid complexes (PCCs). Such complexes find a broad spectrum of applications, as being efficient emulsifiers, flocculants, foaming agents, and dispersion stabilizers [1].

Polymer–colloid complexes represent compounds stabilized by a system of cooperative ionic bonds and hydrophobic interactions [2]. The common method for their preparation is mixing of PE and surfactant solutions. At the same time, it is known that polymer complexes formed by electrostatically complementary polyelectrolytes can be prepared by template polymerization in the presence of macromolecular matrices [3]. In this case, the role of the matrix could be played by colloid particles [4]. It was suggested that PCCs could be synthesized by polymerization of ionic monomers in surfactant solutions.

It is known that polymeric quaternary salts of vinylpyridinium and *N*,*N*-dimethylaminoethyl methacrylate are effective polyelectrolyte reagents for separating disperse systems [5, 6]. It was demonstrated previously [7] that performing polymerization in the presence of organic peroxides allows preparation of high-molecular-weight polyelectrolytes with a viscosity-average molecular weight M_η of (1–12) × 10^6 in the theoretical yield in the form of concentrated aqueous solutions. The polymerization of the monomers in surfactant solutions can differ significantly from both the polymerization of ionic monomers in aqueous solutions and classical template polymerization.

The goal of this work was to synthesize PCCs by polymerization of monomers in a solution of an electrostatically complementary surfactant.

EXPERIMENTAL

As ionic monomers we used 1,2-dimethyl-5-vinylpyridinium methyl sulfate (M1) and *N*,*N*,*N*,*N*-trimethyl(methacryloyloxyethyl)ammonium methyl sulfate (M2); and as a surfactant, sodium dodecyl sulfate (SDS), whose behavior in complexation is well studied in a number of systems [8].

Monomers M1 and M2 and the surfactant were purified by recrystallization from methanol, acetone, and ethanol, respectively, and vacuum-dried. The critical micelle concentration (CMC) of SDS was found to be 0.008 M, which is well consistent with that reported in [9]. Interaction of the monomers with SDS was studied by the Rebinder method [10] and also by UV spectroscopy. The UV spectra were recorded on an SF-26 spectrophotometer over the range 190–220 nm in a 1-cm cell. In all the experiments we used water distilled under Ar. pH of the SDS and M2–SDS solutions was measured on a Delta 320 pH-meter (Mettler Toledo).

The polymerization was performed in Ar under isothermal conditions at 30 and 50°C for M1 and M2, respectively. As initiators we used *tert*-butylperoxy-2-propanol (TBPP) and potassium persulfate (PP) for M1 and M2, respectively. The polymerization kinetics was studied by microcalorimetry on a DAK-1-2M calorimeter in the mode of direct registration of the heat liberation rate. The limiting conversion was determined photometrically. The current conversion of the monomer and polymerization rate were estimated using the values of 79.4 and 56.8 kJ mol^{-1} for the polymerization enthalpies of M1 and M2, respectively. The experiments were carried out at an initial monomer concentration of 2 M and initiator concen-

tration of 0.001 M; the SDS concentration was varied over the range 0–0.7 M. The composition of the resulting complexes was characterized by the parameter *W* defined as

$$W = [SA]/[M], \quad (1)$$

where [SA] and [M] are the surfactant and monomer concentrations (M).

The PCC solutions (PCC-m) were prepared by mixing the PE and surfactant stock solutions in a common solvent. The stock surfactant solution was added dropwise with vigorous stirring to the PE solution. The solutions were prepared using double-distilled water. In preparing PCC-m, we used PE with $M_\eta = 2.2 \times 10^6$. The insoluble fraction of PCC was separated by centrifugation (1000 rpm) for 30 min. The composition of the resulting solutions *Z* was characterized by the surfactant to PE concentration ratio in the system. The characteristics of the solutions were examined at least a day after preparation. The intrinsic viscosity of the polymer solutions [η] (dl g^{-1}) was determined with an Ubbelohde viscometer at 30°C in 0.005 M NaCl. The intrinsic viscosity was estimated using double extrapolation of the specific viscosity η_{sp} and of the logarithm of the ratio of the relative viscosity η_{rel} to the polymer concentration *c* (M) to the zero concentration of the polymer.

It is known that, under certain conditions, ionic surfactants form micelles, which, on the one hand, hold the counterions around themselves, and on the other hand, are capable of solubilizing hydrophobic compounds. It is also known that ionic monomers are compounds demonstrating surface activity [11]. Therefore, being dissolved in an SDS solution, they can interact with each other by two possible mechanisms. The first mechanism produces so-called mixed micelles through transformation of the initial micelles initiated by surface activity of both components [12]. The second mechanism is driven by the electrostatic complementarity of the components, i.e., by the ability of the monomer to be sorbed at the micellar surface with formation of the monomer–SDS associate.

To study the nature of the interaction, we examined the concentration dependence of the surface tension σ (mJ m^{-2}) of the SDS solution at various M2 contents (Fig. 1). The critical micelle concentration of SDS was found to be 0.007, 0.006, and 0.01 M at a monomer concentration of 2, 0.25, and 0.05 M, respectively. As seen, CMC of SDS remains unchanged within the experimental error, being equal to that in water. The UV spectrum of the M2 solution (Fig. 2, spectrum *1*) shows a maximum at 200–210 nm, which is typical of compounds with double bonds [13]. The spectrum of the SDS solution shows no maximum in the range studied (Fig. 2, spectrum *2*). The spectrum of the M2–SDS mixture demonstrates a maximum in the same region as that of the monomer. However, in this case, the molar extinction increases from 8000 (M2) to 35 000 l cm^{-1} mol^{-1} (M2–SDS). This increase is probably due to intermolecular interaction [13] resulting in most cases in formation of stable associates.

Comparison of the tensiometric and UV spectroscopic data suggests that addition of M2 to the SDS micellar solution initiates partial substitution of

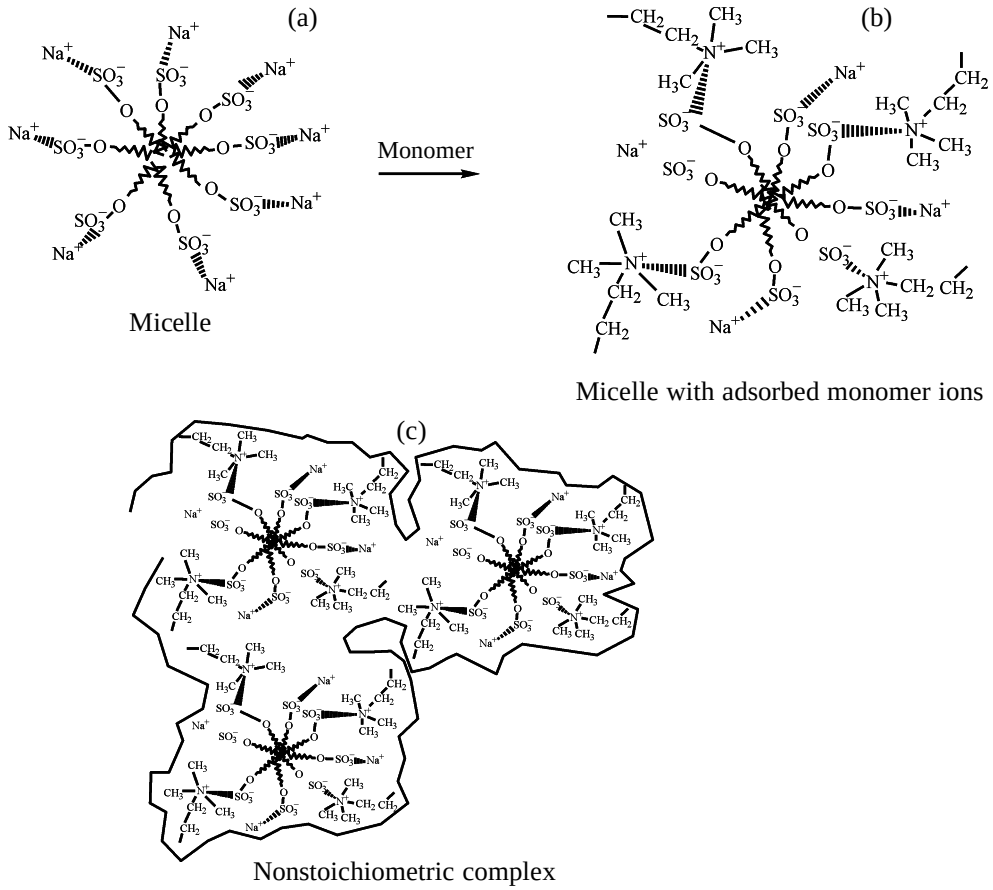

Fig. 3. Structural transformations in the micellar solution of SDS initiated by addition of the monomer and its subsequent polymerization.

the cations of the monomer for the Na^+ counterions of the micelle (Figs. 3a and 3b). Addition of the initiator to such a monomer–micellar system can initiate polymerization of both free and adsorbed monomer.

Keeping in mind the tendency of M2 to hydrolysis, we monitored pH in the M2–SDS system (Fig. 4). The 0.1–0.7 M SDS solutions are characterized by increased pH (7.18–9.48), promoting base hydrolysis of M2 with formation of a copolymer containing methacrylate units. However, addition of M2 to the SDS solutions, to obtain a concentration of 2 M, considerably decreases pH over the entire SDS concentration range, so that pH of the SDS–M2 solutions only slightly changes, remaining within the range 2.41–3.04. It is known [14] that acid hydrolysis of quaternary salts of *N*,*N*-dimethylaminoethyl methacrylate is also possible. However, the methyl sulfate of M2 is subject to hydrolysis to a lesser extent as compared to others. Its hydrolysis can proceed only under rigorous conditions (70°C, H_2SO_4 concentration 0.5 M).

Analysis of the concentration dependences of the initial polymerization rates of M1 and M2 in SDS solutions shows that the effect of SDS on the polymerization kinetics becomes clearly pronounced only at SDS concentrations exceeding CMC. The maximal

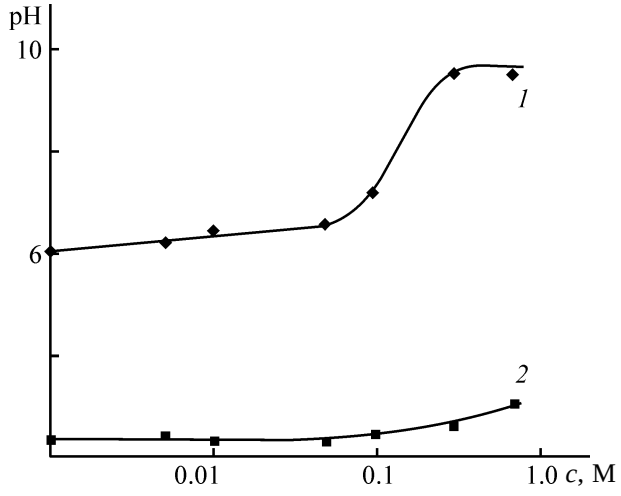

Fig. 4. pH of (*1*) SDS and (*2*) SDS–M2 solutions as a function of the SDS concentration *c*.

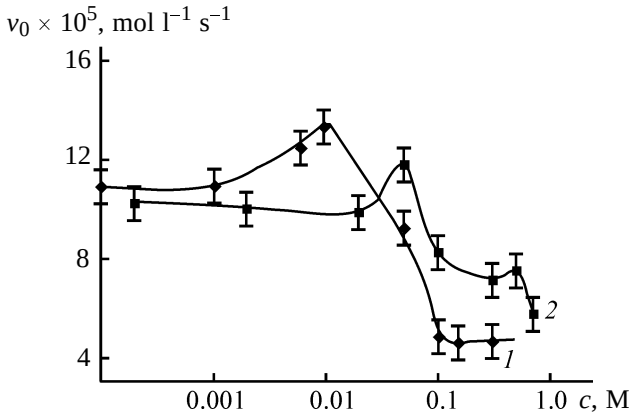

Fig. 5. Initial polymerization rate v_0 of (*1*) M1 and (*2*) M2 as a function of the SDS concentration *c*.

polymerization rate is observed at a surfactant concentration of 0.1 and 0.05 M for M1 and M2, respectively. Further increase in the SDS concentration considerably decreases the rate. Most likely, the observed influence of SDS on the polymerization rate is associated with the template effect and diffusion control.

In contrast to the classical template polymerization, no formation of a stoichiometric complex was observed in the systems in hand. The polymerizate remains homogeneous at any conversion of the monomer. The most probable reason is the detachment of the propagating radical from the SDS micelle in the course of polymerization. Further propagation of the chain proceeds by virtue of the polymerization of both free monomers and monomers adsorbed on other micelles, producing a nonstoichiometric complex (Fig. 3c).

It was demonstrated in [15] that, in formation of the complexes by mixing, PE macromolecules coexist with the nonstoichiometric complex, or stable dispersion of the nonstoichiometric and stoichiometric complexes exists, depending on the PE to surfactant ratio in the system. The M2-based polymeric complexes formed in the course of polymerization at $W \le 0.25$ form a true solution, but at $W \ge 0.25$, they become insoluble in water, being only capable of limited swelling. However, these complexes are soluble in aqueous electrolyte (NaCl) solutions. The solubility of PCCs is controlled by the possibility of migration of the surfactant ions along the PE chain. In the case of hindered migration, PCCs with random distribution of the surfactant ions are formed, making improbable the formation of long sequences of ionized PE units responsible for dissolution of the PCC particles. Being introduced in the reaction mixture, a low-molecular-weight electrolyte competes for the formation of ionic bonds with the reagents, making it possible for the surfactant ions to migrate, so that the PE chain takes the conformation representing a compromise between the maximal number of contacts of hydrophobic groups of the surfactant ions contained in the PCC particles and the minimal entropy stress in the PE chain [16].

* 0.05 M NaCl, 30°C; ($[\eta]$, $[\eta]_0$) intrinsic viscosities of PCC and PE, respectively, dl g^{-1}.

The study of the hydrodynamic properties of the polymer complexes obtained by two different methods (polymerization and mixing of predissolved components) showed (see table) that the intrinsic viscosity of the complexes only slightly depends on the composition (some tendency to increase is observed in the range of low concentrations). The intrinsic viscosities of the PCC-p and PCC-m solutions differ insignificantly from each other. Evidently, the hydrodynamic dimensions of the complexes obtained by different methods are well comparable. Taking into account that $[\eta]$ of PCCs only slightly differ from that of straight PE, it may be suggested that high-molecular-weight complexes are formed in the course of polymerization in the SDS micellar solution, as in the case of preparation of PCCs by mixing.

CONCLUSIONS

(1) The initial polymerization rates of 1,2-dimethyl-5-vinylpyridinium methyl sulfate and *N*,*N*,*N*,*N*-trimethyl(methacryloyloxyethyl)ammonium methyl sulfate in sodium dodecylsulfate solution decreases at the surfactant concentrations in the solution above the critical micelle concentration.

(2) High-molecular-weight complexes are formed in the course of polymerization in the sodium dodecyl sulfate micellar solution, as in the case of preparation

of polymer–colloid complexes by mixing the predissolved components.

Abstract—Complexation of poly(*N*,*N*-dimethyl-*N*-benzyl-*N*-methacryloyloxyethyl)ammonium chloride with oppositely charged amphiphilic compounds was studied. The solubility and hydrodynamic properties of the resulting complexes in chloroform, methanol, and chloroform–hexane and chloroform–toluene mixtures were determined.

Polyelectrolytes (PEs) interact with oppositely charged diphilic ions of micelle-forming surfactants to form polyelectrolyte complexes (PECs) with unique physicochemical properties [1]. Studies of such interactions are necessary for understanding the processes that occur in natural PECs of biopolymers and diphilic compounds [2–4] and the behavior of PECs at flocculation and stabilization of dispersions [5]. It is known [6–9] that stoichiometric PECs (SPECs) formed by anionic surfactants and polydimethyldiallylammonium chloride (PDMDAAC) or poly-*N*-ethyl-4-vinylpyridinium bromide (PEVPB) (M_w 10^4–10^5) are soluble in low-polar organic solvents. However, the features of hydrodynamic behavior of SPECs of macromolecular polyelectrolytes based on aminoalkyl acrylates are still poorly understood. Poly(*N*,*N*-dimethyl-*N*-benzyl-*N*-methacryloyloxyethyl)ammonium chloride (PE-1) shows promise for preparing hydrophobic complexes, as it has higher molecular weight as compared to poly-*N*,*N*-dimethyldiallylammonium chloride (PE-2) and exhibits pronounced hydrophobic properties imparted by the benzyl substituent [10].

In this work we studied the features of interaction between various amphiphilic anions and PE-1 and the hydrodynamic behavior of the resulting SPECs in chloroform, methanol, and mixed solvents.

EXPERIMENTAL

Polyelectrolyte PE-1 was prepared by radical polymerization of the monomer, which was synthesized by alkylation of dimethylaminoethyl methacrylate with benzyl chloride at 0–3°C in acetone and recrystallized from acetone–acetonitrile mixture. Radical polymerization was performed in an aqueous solution (2 M monomer concentration) at 25 ± 0.5°C up to 96–98% conversion. Then, the polymerizate was dissolved in methanol and precipitated with diethyl ether. *tert*-Butylperoxy-2-propanol used as initiator was prepared by the procedure given in [11]. The resulting polymer was additionally purified by recrystallization from methanol with diethyl ether and dried in a vacuum (1.5–2.0 mm Hg, 20 ± 0.5°C) to constant weight.

In our study we used commercial aqueous solutions of PE-2 (40 wt %). The solutions of PE-2 of various concentrations were prepared from the initial solution by successive dilution.

The intrinsic viscosities of PE-1 and PE-2 determined in 0.1 M NaCl at 30°C were 4.7 and 1.4 dl g^{-1}, respectively.

Anionic surfactants such as sodium dodecyl sulfate SDS (chemically pure grade, Merck) and Volgonat-emul'gator (VE) [mixture of sodium salts of alkylsulfonic acids RSO_3Na, R = C_{16}–C_{18}, Khimprom Joint-Stock Company, Volgograd, Russia; STP (Enterprise Standard) 2480-282-05 763 458–99] were used without additional purification.

The stoichiometric polyelectrolyte complexes of surfactants were prepared from the aqueous solutions of components with vigorous stirring. The concentrations of polyelectrolytes and surfactants were 0.01 and 0.1 M, respectively. The resulting precipitate of SPEC was separated, washed with water, and dried in a desiccator to constant weight.

The composition of the reaction mixture *Z* was determined as the ratio of the concentration of the surfactant ions to the concentration of PE units in the

* Reduced viscosity of the chloroform solution of the complex (0.2 g dl^{-1}).

system (*Z* = [surfactant]/[PE]). The composition of PEC φ was characterized by the ratio of the number of diphilic surfactant ions in PEC to the number of PE units in the polymeric complex (φ = $[surfactant]_{PEC}/[PE]_{PEC}$. The composition of the resulting PECs was determined by chemical analysis.

To determine the solubility and hydrodynamic properties of SPECs in organic solvents, the samples were placed in chemically pure grade methanol, chloroform, benzene, toluene, and butyl acetate.

The viscosities of the SPEC solutions in chloroform, methanol, and mixed solvents were measured with an Ubbelohde viscometer (0.34 mm capillary diameter).

A distinctive feature of the interaction of diphilic surfactant ions with oppositely charged macroion is that the phase state of the reaction system depends on the initial reagent ratio *Z*, and certain *Z* values characterize different phase states of PECs [12].

In the reaction of PE-1 with SDS and VE, the precipitate is formed only at the reagent ratio close to stoichiometric.

The table shows that quantitative yield of the insoluble complex is never obtained at the stoichiometric reagent ratio, and with increasing *Z* above the stoichiometric ratio the yield of all the SPECs studied increases. It should be noted that the yields of the complexes in the PE-2–SDS and PE-2–VE systems are lower than those in the corresponding systems with PE-1. The possibility of SPEC formation is determined by the size ratio of the polymer chain and internal surfactant micelles. Moreover, the composition of the precipitated complex can be determined by the polyanion chain length. For example, PEVPB with the degree of polymerization of 1000 yields SPEC with φ = 1.0 [13], whereas the same polymer with the higher degree of polymerization (2000) gives an insoluble SPEC with φ = 0.85. A similar trend is observed with the complexes PE-2–SDS and PE-1–VE (φ = 1.09 and 0.84, respectively). This suggests that certain decrease in φ is associated with the length of the polymeric ion, because the probability of formation of various defects (e.g., loops) increases with increasing length of the polymer chain. These defects are also typical for double-stranded chains of stoichiometric complexes of oppositely charged polymeric ions [14]. These defects are formed owing to conformational noncomplementarity of the polymer chain and surfactant micelles, because the structure of SPEC is a compromise between the conformation of polymeric ion and geometric characteristics of the surfactant aggregates. The mismatch of these parameters will be greater in the case of longer chains, which causes appearance of unlinked sections in the polymer chain. As a result, φ of the resulting complexes is smaller than unity.

It is known that the major factor determining whether the polymer will dissolve or swell is its specific interaction with the solvent. In this connection, we studied the behavior of SPECs in various organic solvents. It was found that these complexes dissolve in chloroform and methanol, whereas in aliphatic and aromatic hydrocarbons and ethyl and butyl acetates they occur in the swollen state. Taking into account the polarity and proton-donor power of methanol and chloroform, we suggest that the dissolution of SPECs in them proceeds owing to the solvation of the ion pairs and ester fragments. The other

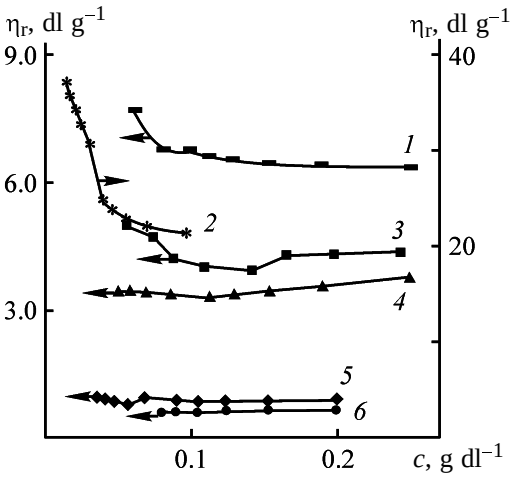

Fig. 1. Reduced viscosity η_r as a function of PEC concentration c in chloroform, methanol, and mixed solvents. (*1*) Chloroform, (*2*) methanol, (*3*) chloroform : hexane = 70 : 30, (*4*) chloroform : hexane = 50 : 50, (*5*) chloroform : toluene = 70 : 30, and (*6*) chloroform : toluene = 50 : 50 (volume ratio in all cases).

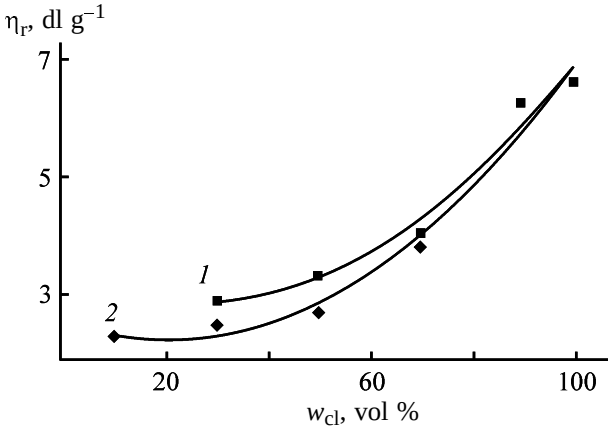

Fig. 2. Reduced viscosity η_r of PE-1–VE in the mixed solution as a function of chloroform concentration w_{cl}; PE-1–VE concentration 0.11 g dl^{-1}. Second component of the solvent: (*1*) hexane and (*2*) toluene.

solvents studied cannot dissolve SPECs, as they are incapable of specific interactions with SPECs.

The dependence of the reduced viscosity on the concentration of the complex in methanol is typical for dissociating polyelectrolytes (Fig. 1). The reduced viscosity of the complex η_r in methanol at a concentration c 0.015 g dl^{-1} is 37.1 dl g^{-1}, which is comparable with η_r for PE-1 (43.3 dl g^{-1}). Thus, in methanol the complex dissociates, and owing to the electrostatic repulsion the complex macromolecules occur in the form of a strongly swollen globule.

The solutions of PE-1–VE in chloroform also exhibit abnormal concentration dependences of η_r (Fig. 2), which strongly increases at concentrations lower that 0.1 g dl^{-1}. Similar effect was observed for complexes of sodium polystyrenesulfonate with alkyltrimethylammonium bromides in ethanol, DMF, and isopropanol [15]. This phenomenon was attributed to the effective charge on the polymer chains even in a low-polarity solvent, which enhances the electrostatic repulsion and increases the hydrodynamic size of the polymer globule. At the same time, in chloroform η_r of the complexes is significantly lower than that in methanol. The η_r values given in the table are comparable with [η] of PE-1 in an aqueous-salt solution (4.7 dl g^{-1}), which suggests that SPECs occur in chloroform as loose swollen globules.

The behavior of the complexes in question strongly differs from that of the complexes based on PDMDAAC or PEVPB for which [η] is 0.35–0.55 dl g^{-1} and their Huggins constants k' = 0.66 are typical for linear flexible-chain macromolecules in thermodynamically good solvents. The η_r values linearly decrease with dilution, which is typical for uncharged polymers.

Since no dissolution of SPECs in individual hydrocarbons was observed, their hydrodynamic behavior was studied using mixed systems with chloroform and toluene or hexane. The viscometric measurements performed in a wide range of solvent compositions showed no phase separation at a chloroform content from 10 to 90 vol %.

It was expected that addition of hydrocarbons exhibiting affinity for surfactant chains and benzyl groups into the mixed solvent would cause solvation of the above fragments and enhance swelling of the polymer globule. However, as seen from Figs. 1 and 2, in the mixed solvents η_r sharply decreases with increasing hydrocarbon content. This is probably due to the deterioration of the conditions of the ion pair solvation. The effect of this factor is more decisive than the increase of the affinity for the hydrocarbon polymer fragments. As a result, more compact polymer globules are formed in the mixed solvents. Thus, the solubility of the complexes and swelling of their globules are primarily promoted by weakening of the interionic interaction.

The revealed features in the hydrodynamic behavior of PE–surfactant complexes suggest the possibility of their use for modifying the rheological properties of organic liquids.

CONCLUSIONS

(1) Complexing of poly(*N*,*N*-dimethyl-*N*-benzyl-*N*-methacroyloxyethyl)ammonium chloride with ani-

onic surfactants gives hydrophobic complexes (yield 63–86%) with φ = 0.8–1.1 at the initial component ratio Z = 1–3.

(2) Solutions of the polymeric complexes in methanol and chloroform exhibit abnormal hydrodynamic behavior typical for polyelectrolytes. The solubility and high viscosity of solutions of the complexes are enhanced by solvation of the ion pair and polar fragments with proton-donor solvents.

CHEMISTRY OF FOSSIL FUEL

Method of Unification of the Relative Measurement Units for the Concentrations of V(IV) and Free Radicals in Crude Oils and Asphaltenes

M. I. Tagirzyanov, M. R. Yakubov, V. I. Morozov, and S. G. Yakubova

Arbuzov Institute of Organic and Physical Chemistry, Kazan Scientific Center, Russian Academy of Sciences, Kazan, Tatarstan, Russia

Received October 20, 2004; in final form, April 2005

Abstract—The potential of the method for unification of the relative units for measuring the concentration of V(IV) and free radicals in crude oils and asphaltenes was examined.

Studies of the macromolecular components of crude oils, natural bitumens, and other oil-like systems are necessary for solving a complex of problems in extraction, preparation, transportation, and processing of oil raw materials. Macromolecular components of oil systems include, above all, asphaltenes and resins, whose structures concentrate most of the heteroatoms contained in crude oils [1]. Moreover, asphaltenes rank among concentrates of oil paramagnetics [2] because of a fairly high content (ca. 10^{19} spin) of stable free radicals. Some metal ions entering into the composition of the macromolecular components of oil exhibit paramagnetism (V^{4+}, Fe^{3+}, Mn^{2+}). The highest concentrations in crude oils are characteristic of vanadium [3], which mainly occurs as paramagnetic vanadyl ion VO^{2+}, entering into composition of complexes with various structures.

Studies of the structure, behavior, and distribution over oil components of free radicals (FRs) and vanadyl complexes (VCs) by ESR have some specific features. As known, one of the main problems in measuring the content of the paramagnetic centers in oil objects is the choice of the reference. It is suggested either to "permanently" place a standard ruby rod into an ESR spectrometer [2], or to calculate the mass of each oil sample in the part of the ampule occurring in the region where the data are taken. It is possible to reject determining the absolute concentrations of the paramagnetics and to base all conclusions on measuring the relative changes in the ESR spectra. This gives rise to another problem: The relative measurement units for the concentration of the paramagnetics in crude oils, resins, asphaltenes, and other oil components will have different "relativities." However, it is possible to use a simple technique for unification of the relative units for measuring the content of paramagnetics in crude oils and asphaltenes so as to avoid errors due to nonideal character of references and the infeasibility of permanently placing a reference sample in the spectrometer cavity.

EXPERIMENTAL

Asphaltenes were precipitated from crude oils with hexane at the crude oil : hexane volume ratio of 1 : 20 and washed in a Soxhlet apparatus until decolorization of the solvent. From the Soxhlet apparatus, asphaltenes were washed out with benzene, which was then distilled off. The resulting asphaltenes were vacuum-dried to constant weight.

The content of vanadium in the crude oils and asphaltenes was determined by direct flame atomic absorption spectrometry on an AAS-IN spectrophotometer. A weighed sample solution was sprayed in acetylene–nitrogen(II) oxide flame. As solvent served a mixture of *o*-xylene (80 vol %), acetone (10 vol %), and ethanol (10 vol %). The concentration of vanadium was determined from calibration curves, with V^{2+} dibutyldithiocarbamate in the above-mentioned solvent mixture as the reference [4].

All measurements of the content of paramagnetics in oil objects were run under identical conditions at 20°C on an SE/X-2544 ESR spectrometer. The content of paramagnetics in crude oils was measured in a quartz glass ampule with the internal diameter of 6 mm, which was filled with crude oil to a full volume within the zone of the ESR spectrometer

cavity. The line intensity of free radicals was determined from the amplitude of a separate line at the center of the ESR spectrum. To calculate the intensity of the lines belonging to vanadyl complexes, we measured the amplitude of the +1/2 line neighboring with that of a free radical in the region of a weaker magnetic field.

To determine the content of paramagnetics in crude oil asphaltenes, we used ampules with the internal diameter of 3 mm made of molybdenum glass which gave no noticeable signal in the ESR spectrum. The ampules were compactly packed with asphaltenes to a height of 13–14 mm; the sample was located in the region corresponding to the maximal sensitivity of the cavity. The signal intensities of free radicals and vanadyl complexes were calculated in relative spin units per gram of a substance (rel. spin units/g). The content of free radicals was additionally recalculated with different signal widths taken into account.

Figure 1 presents the measured contents of FRs and VCs in crude oils and oil asphaltenes. The relativity of the units for measuring the content of paramagnetics in crude oils differs from that for asphaltenes. This hinders comprehensive analysis of our results, and we have to restrict ourselves to the search for general trends in variation of the FR content with increasing VC concentration.

We suggest a method to unify the relative units for measuring the concentration of paramagnetics in crude oils and asphaltenes. To avoid technical problems mentioned in the introduction, we compared the content of vanadium in the oil objects, determined by direct flame atomic absorption spectrometry ("total vanadium"), with that of paramagnetic vanadium, determined by ESR.

Using the concentrations of the total vanadium in crude oils and asphaltenes and the V^{4+} content, we plotted the $\log[VC] = f(\log[V])$ dependence for crude oils and asphaltenes (Fig. 2).

It is seen that, for both crude oils and asphltenes, the plots of the content of the vanadyl complexes vs. the total vanadium content are straight lines with almost identical slopes.

Having solved a system of equations describing the dependences of the content of VCs on the total vana-

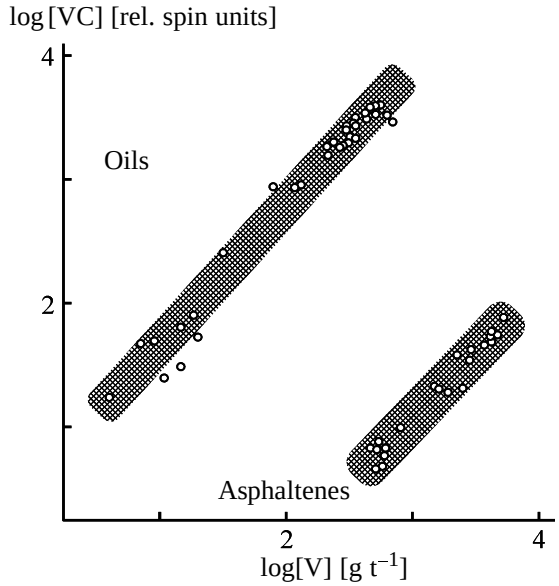

Fig. 2. Variation of the VC content in asphaltenes with the V content in crude oils and asphaltenes. ([VC], [V]) Contents of VCs and V, respectively.

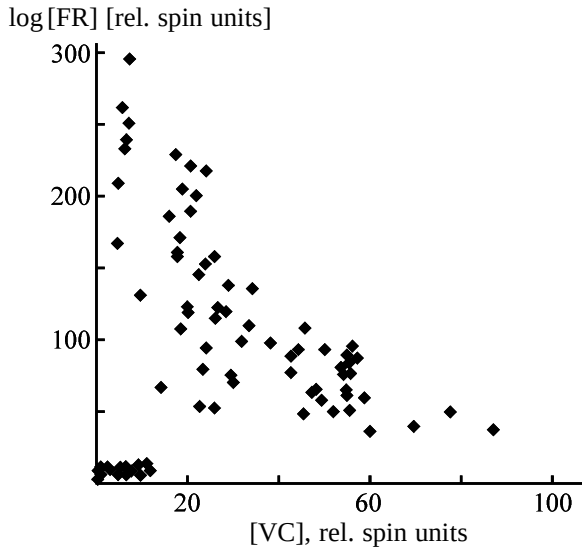

Fig. 3. Variation of the FR content with increasing VC concentration in crude oils and asphaltenes. ([FR], [VC]) Contents of FRs and VCs, respectively.

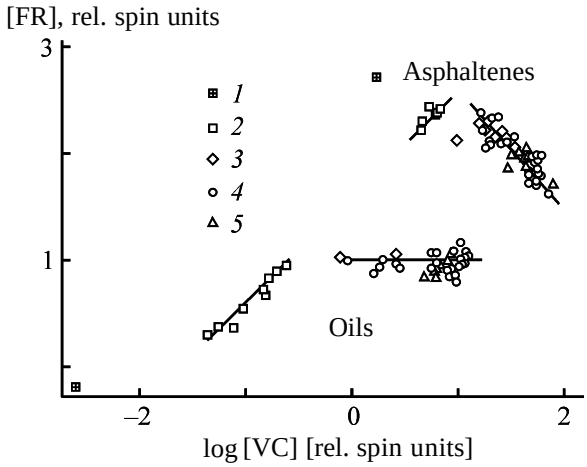

Fig. 4. log[FR] vs. log[VC] plots in crude oils and asphaltenes from deposits of different ages. Geological age of the objects under study: (*1*) Cambrian, (*2*) Middle Devon, (*3*) Upper Devon, (*4*) Lower Carbon, and (*5*) Middle Carbon.

dium content, we found a dimensionless coefficient, $10^{2.5}$, which brings the concentrations of paramagnetics in crude oils to an identity with that in asphaltenes.

Thus, the FR–VC scale for crude oils can be converted to that for asphaltenes using the following equations:

$$\log[VC_c] = \log[VC_i] - 2.5$$

$$\log[FR_c] = \log[FR_i] - 2.5$$

where c refers to the converted values, rel. spin units, and i, to the initial values, rel. spin units.

Recalculation of all the data for crude oils yielded an "integrated" plot of the FR content vs. the VC concentration for crude oils and asphaltenes (Fig. 3).

A huge (by a factor of $10^{2.5}$) difference in the concentrations of paramagnetics in crude oils and asphaltenes hinders visual perception and examination of the resulting dependences. Therefore, it is more convenient to characterize the VC and FR content with logarithms of their relative contents (log[VC] and log[FR], respectively) (Fig. 4).

In crude oils and asphaltenes with a low content of vanadium, the FR and VC concentrations vary in the same direction. In vanadium-rich crude oils, the FR content weakly changes with increasing VC content, and in asphaltenes it decreases.

CONCLUSIONS

(1) A methodical approach to analysis of paramagnetics in crude oils and asphaltenes was suggested. It consists in unification of the relative measurement units for the concentrations of vanadyl complexes and free radicals in crude oils and asphaltenes by comparing the content in oil objects of vanadium, determined by atomic absorption spectroscopy, with that of paramagnetic vanadium, determined by ESR.

(2) The resulting "integrated" pattern of distribution of crude oils and asphaltenes in the coordinates of the concentrations of free radicals and vanadium complexes simplifies studies of distribution of paramagnetics and throws light on a number of structural features of asphaltenes.

Received March 2, 2005

Abstract—Polyvinyloxyalkylammonium chlorides were synthesized in up to 82% yields by alkylation of monoethanolamine polyvinyl ether with higher alkyl chlorides. The suitability of the resulting polyvinyloxyalkylammonium chlorides for treatment of lignin-containing wastewater by pressure flotation was tested.

The suitability of water-soluble polymers for wastewater treatment is well known [1]. One of serious environmental problems in pulp and paper industry is more efficient exploitation of the acting complex facilities for wastewater treatment to remove such a large-capacity waste as lignin. Modern technology of wastewater treatment to remove lignin consists in flotation of lignin sludge with polyacrylamide (PAA) [2].

In this work we synthesized polyvinyloxyalkylammonium chlorides from monoethanolamine polyvinyl ether and tested them as flotation agents in pressure flotation of lignin sludge.

Monoethanolamine polyvinyl ether **I**, prepared by polymerization of monoethanolamine vinyl ether [3], was alkylated with equimolar amount of dodecyl chloride **II** or hexadecyl chloride **III**. The resulting polyvinyloxyalkylammonium chlorides **IV** and **V** were isolated by reprecipitation:

where n = 6–9; R = $C_{12}H_{25}$ (**II**, **IV**) or $C_{16}H_{33}$ (**III**, **V**).

The flotation properties of polyvinyloxyalkylammonium chlorides **IV** and **V** were studied with real lignin sludge currently treated at the Baikal Pulp and Paper Combine (BPPC).

The results of our experiments are presented in the table. It is seen that changing from polyacrylamide to polyvinyloxyalkylammonium chlorides, even in a concentration by a factor of 1.3 lower, allows the flotation rate to be increased by a factor of 1.8–2.5. Furthermore, the wastewater treatment efficiency is improved as regards both the color index (by 5.2–5.7%) and the content of suspended matter (by 3–6.5%). At identical concentrations of these reagents, the flotation rate increases by a factor of 2.37–2.75, and the wastewater treatment efficiency, by 6.5–6.8 and 6.5–11.3% for the color index and the content of suspended matter, respectively.

EXPERIMENTAL

Poly-*N*-(2-vinyloxyethyl)-*N*-dodecylamonium chloride IV. To a solution of 87 g (1 mol of monomeric units) of monoethanolamine polyvinyl ether **I** with a weight-average molecular weight of 720 in 500 ml of isopropyl alcohol, 204.8 g (1 mol) of dodecyl chloride was added, and the resulting mixture was refluxed for 16 h. The solution was cooled, and then petroleum ether was added until the polymer ceased to precipitate. The resulting polymer was isolated and vacuum-dried; 239.4 g (82%) of polymer **IV** was obtained as a viscous dark-brown resin.

Found, %: C 65.31, H 11.03, Cl 12.44, N 4.52. $C_{16}H_{34}ClNO$.
Calculated, %: C 65.84, H 11.74, Cl 12.15, N 4.80.

Poly-*N*-(2-vinyloxyethyl)-*N*-hexadecylamonium chloride V. Similar to **IV**, 87 g of monoethanolamine polyvinyl ether **I** and 260.9 g of hexadecyl chloride

	80	2	92.5	64.8	0.19
		5	94.6	68.8	
		10	95.6	76.1	
		15	96.2	78.8	
		20	96.5	84.8	
V	60	2	90.0	60.0	0.20
		5	92.5	64.8	
		10	93.7	71.2	
		15	95.0	74.8	
		20	95.2	84.8	
	80	2	92.5	64.8	0.22
		5	95.1	68.8	
		10	95.6	76.1	
		15	96.8	80.8	
		20	96.8	89.6	
PAA	80	20	90.0	78.3	0.08

yielded 271.4 g (78%) of polymer **V**.

Found, %: C 69.48, H 12.52, Cl 10.31, N 3.78. $C_{20}H_{42}ClNO$.
Calculated, %: C 69.03, H 12.16, Cl 10.19, N 4.02.

To a 500-ml wastewater sample containing 4 g l^{-1} of lignin sludge (pH 5.3), 6.4 ml of 0.8% solution of ammonium sulfate and 3–4 ml of 1% aqueous solution of polyvinyloxyalkylammonium chloride **IV** or **V** was added. The resulting mixture was fed into a 1-l flotation column and saturated with air at a pressure of 0.2 MPa. Next, the pressure was released, and the rate of compaction of lignin sludge was monitored from migration of its boundary. For each time period, we calculated the first-order rate constant of flotation and then the average constant throughout the flotation period (20 min). The characteristics of the treated water were determined by known methods.

CONCLUSIONS

(1) The polyvinyloxyalkylammonium chlorides synthesized accelerate the pressure flotation by a factor of 2.3–2.75 compared to polyacrylamide.

(2) When polyvinyloxyalkylammonium chlorides are used in identical with polyacrylamide amounts, the efficiency of treatment of lignin-containing wastewaters is 89.6 and 96.8% in the content of suspended matter and color index, respectively. This is, respectively, 11.3 and 6.8% greater than the efficiencies achieved with polyacrylamide.

BRIEF COMMUNICATIONS

Influence of the Components of the Conserving Polymeric Composition on Preservation of a Photographic Image

E. S. Gaikalova and A. N. D'yakonov

St. Petersburg State University of Motion Pictures and Television, St. Petersburg, Russia

Received December 9, 2004; in final form, June 2005

Abstract—The possibility of improving a latex composition for conservation of archival and historically valuable photodocuments by introducing additives was substantiated. The inertness of these additives to the photographic materials during long-term storage was tested.

A vast amount of photographic materials is of historical and art value, and their careful preservation is an important task. Wide application in restoration practice is found by polymeric materials, of which aqueous polymeric dispersions are the most promising.

Along with film-forming substances, latexes contain various functional additives such as, e.g., conservants, making them resistant to mold formation and bacterial degradation, as well as foam quenchers and inhibitors preventing corrosion of the surface being protected.

To impart additional characteristics to latex compositions for conservation of photographic documents, it seems reasonable to introduce into them such additives as biocidal systems and light stabilizers.

A special place is occupied by coalescent additives intended for formation of a uniform polymer phase at lower and more technologically "convenient" temperatures, at which the "barrier" of the glassy state, characteristics of (co)polymers, is overcome. Generally, coalescence of globules consists in their mutual approach, followed by deformation and contacts with one another. When the protecting barrier is eliminated (by introducing coalescents), such mutual approach should have a fluctuation character. If the barrier is preserved, it is overcome owing to moisture evaporation, because the globules are forced to approach one another to distances shorter than the critical distance. The amount of water retained in the interglobular spaces is insufficient for hydration of the protecting layers, and the system gets destabilized [1].

Some latex brands do not require introducing coalescents, while formation of films from other brands requires introducing coalescents. Suitable as coalescents are nontoxic substances dissolving the polymer, which are usually selected taking into account the donor–acceptor mechanism of dissolution. Coalescents should act as solvents and plasticizing agents with respect to polymers and also be volatile, but they should evaporate not very fast and at a controllable rate.

In conservation of photodocuments, one of the most significant criteria governing the choice of coalescents is their absolute inertness to photographic materials during long-term storage. Hence, in this work we chose as conservants methylene chloride (MC), ethanol (E), and acetone (A), used in preparation of the base for film and photographic materials and satisfying the above-mentioned requirements.

Our experiments showed (Table 1) that the coalescent being introduced virtually does not affect the preservation of the image. Thus, the choice of coalescents should be dictated by their physicochemical properties. From the viewpoint of the uniform character of application of the coating and the time of its drying, as well as of the above-mentioned factors, methylene chloride seems the most acceptable coalescent, as confirmed by its solubility parameters ($J^{1/2}$ $cm^{-3/2}$):

PMMA	18.6
MC	19.8
A	20.5
E	26.0

These data show that the solubility parameters are the closest for solid poly(methyl methacrylate) (PMMA) and solvent, MC.

From the viewpoint of the solvency, the most advantageous is the solvent whose solubility param-

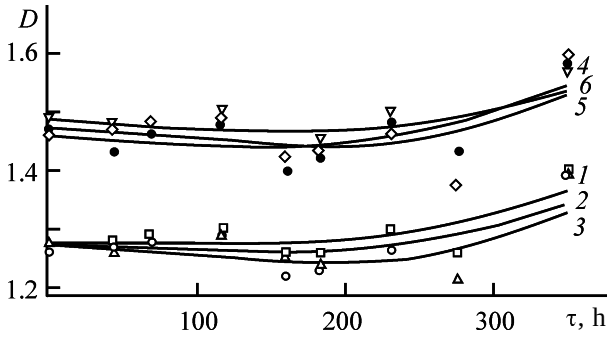
eter is equal to that of the solid substance, which will accelerate coalescence as well.

Protection of archival documents against biodamage is extremely important for their long-term preservation. Microbiological studies in this area are carried out along the following lines: (1) studies of microorganisms; (2) development of methods; and (3) infection prevention.

For restoration and preservation–prevention purposes, film and photographic documents are treated with fungicidal preparations [2].

By imparting antiseptic properties to a latex-based conserving composition, it is possible to prevent not only bacterial damage to the polymer but also mold damage to the archival material intended for long-term storage, as well as repeated damage to the material after the restoration treatment.

There are two lines in protection of film and photographic documents against biodamage. The first line consists in selection of such ingredients for polymeric compositions that do not serve as nutrition sources for fungi and bacteria, and the second line, in introduction of biocides (chemical agents protecting against biodamage) into the polymeric formulation. The latter line is advantageous, since it allows preparation of biostable materials with the desired set of properties.



The biocidal system being introduced must not only prevent biological damage to the material but also be absolutely inert to the material during long-term storage.

In view of the fact that introduction of biocides is required for materials to be stored at elevated humidities, we carried out the experiments in a thermostat at 100% humidity and 60°C. For procedure of monitoring the constancy of the humidity, see [3].

Table 2 shows that the results of our experiments on aging of a coating with and without a biocidal additive at a constant temperature are fairly consistent with each other. This suggests that the biocide does not influence the conservation power of the latex and preservation of the photographic material.

Of no less importance is introduction into the formulation of the conserving composition of substances enhancing the light stability of the polymer.

Light exposure causes various transformations in the polymer, leading eventually to its degradation. Exposure to solar radiation with $\lambda > 290$ nm near the Earth surface leads to formation of radicals and is accompanied by polymer degradation [4].

Influence of the light stabilizer on variation of the optical density *D* of the image of a paper-based positive material under UV radiation exposure. λ = 254 nm. (τ) Time. Copolymer: (*1*, *4*) Styrene–butyl acrylate, (*2*, *5*) styrene–butadiene, and (*3*, *6*) butyl acrylate–methyl methacrylate. Material coated with copolymer: (*1*–*3*) without and (*4*–*6*) with stabilizer.

There are several methods to protect the polymer: (1) light reflection by filling agents reflecting UV or visible radiation; (2) introduction of UV light absorbers, namely, those from a class of substances that absorb light and whose reaction products then emit energy as a heat, whereupon the system returns to the initial state; (3) introduction of the so-called excited state quenchers, i.e., substances converting the polymer from an excited to the ground state; and (4) introduction of highly efficient stabilizers, whose photodegradation yields stable radicals reacting with the primary radicals generated by photolysis of the polymers, thus terminating the photodegradation chains.

Our data (see figure) show that introduction of light-stabilizing additives substantially depresses yellowing of the photographic paper, which is manifested most prominently in variation of the optical density of white samples.

CONCLUSION

The above-mentioned classes of substances are suitable for conservation of archival and historically valuable photodocuments, since they perform the main function of the additives introduced, namely, impart additional characteristics to the conserving polymeric composition and are inert to photographic materials during long-term storage.

OBITUARIES

Florentina Alekseevna Belinskaya

On June 2, 2005, our science suffered a severe loss. Florentina Alekseevna Belinskaya, doctor of chemical science, professor, leading researcher of the Chemical Faculty and the Research Institute for Chemistry of St. Petersburg State University, and, for a long time, active member of the Editorial Board of *Zhurnal Prikladnoi Khimii* (Russian Journal of Applied Chemistry), died at the age of 76.

In 1953, a young graduate from the Chair of Physical Chemistry, Florentina Alekseevna was left at the University as a post-graduate student and, since that time, worked at the Leningrad (St. Petersburg) University. Showing a goal-seeking behavior and persistence in overcoming the difficulties encountered in solving scientific problems, Florentina Alekseevna made a career from a student and post-graduate student, whose work was supervised by Academician B.P. Nikol'skii, to a professor, head of laboratory, and a leading specialist in theory and practice of ion exchange and chromatography.

Having defended her candidate dissertation devoted to electrode properties of membranes made of organic ion-exchange resins in 1959, Belinskaya took active part in the development of work on ionometry and then headed a new promising area of synthesis and physicochemical studies of inorganic ion-exchange materials. Just in this area of research, Florentina Alekseevna's work received ample recognition and support among her colleagues, "ion-exchange researchers," in the Soviet Union and abroad. In 1974, she became head of the Laboratory of Ion Exchange at the Chair of Physical Chemistry, in which whole classes of new inorganic sorbents were synthesized on the basis of oxygen compounds of antimony, titanium, silicon, tin, tellurium, and mixed oxyhydrates of these elements. A generalization of the diverse experimental data obtained enabled Belinskaya to suggest a truly pioneering approach to description of inorganic ion exchangers as polymeric complex compounds. In 1984, Florentina Alekseevna defended her doctoral dissertation "Fundamental Aspects of Ion Exchange on Inorganic Ion-Exchange Materials," in which she formulated for the first time the basic principles of directed synthesis of inorganic compounds with predictable properties and presented an original technique for thermodynamic description of the ion-exchange equilibrium, named the step-exchange method by her.

Florentina Alekseevna Belinskaya had never been an armchair scientist having no idea about what might be the practical importance of her work. Her distinctive feature was persistence in a search for the possible practical implementation of her scientific ideas. She received as a co-author about fifteen inventor's certificates and was awarded the "Inventor of the USSR" badge. The list of scientific-technological and humanitarian programs in which Florentina Alekseevna took direct part is rather extensive: "Sorbents for Radionuclides," "High Technology," "Environmental Safety of Russia," etc. Undoubtedly, the most prominent and interesting practical applications are radioprotective medicinal preparations Polisur'min, an antidote for radioactive strontium, and Ferrotsin, which removes radioactive cesium from human and animal bodies. In addition, Ferrotsin can serve as an antidote in poisoning with thallium salts and can also be used to adjust the electrolyte composition of blood. These preparations were created at the laboratory of ion exchange, in cooperation with medical researchers, on the basis of inorganic ion-exchange materials. After the Chernobyl accident, Florentina Alekseevna Belinskaya went to a special business trip to Perm oblast to rapidly set up a process for manufac-

1070-4272/05/7807-1202 © 2005 Pleiades Publishing, Inc.

ture of Ferrotsin. Later, the ample experience in this area enabled Belinskaya to take part in the humanitarian program "Children from Chernobyl" and to work at the nongovernmental institution "Chernobyl–Help." For her studies of inorganic ion-exchange materials and development of radioprotective medicinal preparations, Belinskaya was awarded II Prize of Mendeleev All-Union Chemical Society in 1988 and II University Prize in 1989.

One more point of practical application of Belinskaya's scientific interests was integrated processing of natural mineral raw materials and large-tonnage industrial wastes. Owing to Florentina Alekseevna's ideas, wastes from a number of industries can be successfully converted into effective sorbents.

For many years of her life, Florentina Alekseevna was engaged in pedagogical activities. In 1991, Belinskaya was given an academic status of a professor in physical chemistry. She delivered courses of lectures on theory of ion exchange and fundamentals of chromatography at the chemical faculty and that of biology and soil science of St. Petersburg State University. An extremely broad-minded person, not confined to her narrow specialization, Florentina Alekseevna always came to understanding with young people and her ideas were captivating for them. She brought up more than 40 specialists, including candidates of science.

During the decades of her scientific activities, Florentina Alekseevna Belinskaya published more than 150 works, was a co-author of the textbook *Fizicheskaya khimiya. Teoreticheskoe i prakticheskoe rukovodstvo* (Physical Chemistry. Theoretical Foundations and Manual), monograph *Ionity v khimicheskoi tekhnologii* (Ion Exchangers in Chemical Technology); she was a scientific editor of 10 issues of the intercollegiate collection of works *Ionnyi obmen i ionometriya* (Ion Exchange and Ionometry) and of the book devoted to the centennial anniversary of Nikol'skii's birthday, *Akademik B.P. Nikol'skii. Zhizn'. Trudy. Shkola* (Academician B.P. Nikol'skii. Life. Works. School) (St. Petersburg State University, 2000).

Belinskaya was an organizer and permanent supervisor of the seminar "Chemistry and Technology of Inorganic Sorbents," which was established in 1972 as an unpretentious meeting of like-minded persons and then became international. It is largely due to her efforts that the city seminar "Ion Exchange, Chromatography, and Alternative Methods," held under the aegis of the Russian Chemical Society and formerly co-chaired by her, still continues to exist. Florentina Alekseevna was an active member of the Editorial Board of *Zhurnal Prikladnoi Khimii* and *Vestnik Sankt-Peterburgskogo universiteta* (Gerald of St. Petersburg University) and a member of specialized dissertation councils at St. Petersburg State University and State Technological University of Plant Polymers.

Florentina Alekseevna was a surprisingly persistent optimist. She was born and grew up in the family of a professional serviceman, she was familiar with the hardship of the migratory mode of life, wartime childhood, and hunger in youth. Maybe, just for this reason she could appreciate all the good that fell to her lot, liked and understood the poetry, painting, and music. Florentina Alekseevna was a person with high moral criteria, who was faithful to her choice not only in the profession, but also in her private life. She was hand in hand with a loving husband for 51 years, brought up wonderful children, son and daughter, three excellent grandchildren, and was lucky to see her great-grandson. It is difficult to Florentina Alekseevna's relatives and colleagues to bear with her death.

Florentina Alekseevna left a firm trace in that area of physical chemistry to which she devoted her whole life. Her works will long serve her disciples and followers as a source of fruitful ideas.

HISTORY OF CHEMISTRY AND CHEMICAL TECHNOLOGY

Professor Aleksandr Aleksandrovich Krakau (to 150th Anniversary of His Birthday)

A.A. Krakau, professor of chemistry at Emperor Alexander III Electrotechnical Institute in St. Petersburg, occupies an honorable place in the history of domestic chemistry owing not only to his studies in the field of organic chemistry, but also to the fact that he was the first who started to deliver a special course of electrochemistry and organized training of electrochemical engineers.

Aleksandr Aleksandrovich Krakau was born on July 30 (August 11), 1855, in St. Petersberg in a rather well-cultured family. His father Aleksandr Ivanovich Krakau was a known architect, and his mother, Anna Vasil'evna (nee Grigorovich) was of artistic origin [1]. Having finished Mai Gymnasium, one of the best in St. Petersburg [2], Krakau entered the natural department of the physicomathematical faculty of St. Petersburg State University in 1873. Already when being a student, he commenced experimental studies in the area suggested by A.M. Butlerov (1828–1886, academician since 1874). On May 4(16), 1887, at a meeting of the Russian Physicochemical Society, Krakau reported on his studies of styrene polymerization under the action of alkali metals [3]. This work was an important part in the investigations of polymerization of unsaturated compounds, carried out by Butlerov and his disciples. At the end of April 1879, Krakau graduated from the university with a degree of candidate and was left at the university for two years to be prepared for pedagogical activities.

In May 1881, Krakau became a laboratory assistant at the chemical laboratory of the Academy of Sciences, where his work was first (till August 1886) supervised by Butlerov and later (till January 1891) by N.N. Beketov (1827–1911, academician since 1886). Beginning in 1888, Krakau occupied the position of a senior laboratory assistant.

Simultaneously, in those same years, Krakau was engaged in pedagogical activities. In 1880–1883, he was Butlerov's lecturer's assistant at St. Petersburg women's (Bestuzhev) courses, and in 1883–1884, supervised laboratory exercises on analytical chemistry. The Bestuzhev courses, opened in 1878, were the first Russia's women's university, at which lectures were delivered and laboratory exercises were supervised by leading scientists of St. Petersburg [4].

Aleksandr Aleksandrovich Krakau

In June 1886, the first Russia's Technical School of the Postal-Telegraph Service was organized in St. Petersburg. In the last quarter of the XIX century, the leading position among all areas of electrical engineering was occupied by telegraphy, and training of specialists in this field undoubtedly satisfied the demand of the country. Krakau was invited to teach chemistry at this educational institution. In June 1891, the technical school was reorganized into Electrotechnical Institute, with the education term increased from three to four years. Finally, in June 1898, a five-year education term was established and the institute was given all the rights of a higher-school institution.

In 1891, Krakau completely turned to teaching of chemical disciplines at the Electrotechnical Institute and became a professor. In addition to the general course of chemistry, he taught, beginning in 1892, foundations of electrochemistry in the form of the course "Study of Voltaic Cells" [5]. Since 1895,

1070-4272/05/7807-1204© 2005 Pleiades Publishing, Inc.

Main building of the Electrotechnical Institute (1905).

Krakau was not only engaged in pedagogical activities, but also occupied the position of the head of studies at the Institute. Krakau made a major contribution to the reorganization of the Electrotechnical Institute into a higher-school institution with a five-tear education term, he took an active part in all meetings at which the corresponding decision was made. The curriculum developed in 1898 included electrochemistry as an independent discipline subdivided into theoretical foundations of electrochemistry and applied electrochemistry. The studies of the course were accompanied by laboratory exercises in the specially designed electrochemical laboratory. The new curriculum also included physical chemistry, taught by the already known, by that time, scientist N.S. Kurnakov (1860–1941, academician since 1913), professor of the Mining Institute. The studies of the course were accompanied by laboratory exercises, supervised by N.A. Pushin (1875–1947), a laboratory assistant of the chair. A graduate from St. Petersburg University, a well-educated specialist, and a closest associate of Kurnakov, Pushin made a major contribution to the development of the chair of chemistry at the Electrotechnical Institute. He became an extraordinary professor in 1909 and ordinary professor in 1913, and emigrated in 1920 [6, 7]. The curriculum also included studies of technical chemistry.

The gradual increase in the number and volume of chemical disciplines led to a fundamental change of the Institute's curriculum. By Krakau's initiative and with an active involvement of Pushin, two departments, electrotechnical and electrochemical, with separate admission of first-year students were organized at the Institute. The necessity for intensive development of the electrochemical industry in Russia required that engineers of the corresponding specialties should be trained in due time. In Krakau's opinion, an electrochemist should not only be well chemically educated, but also be a good physicist and possess a comprehensive knowledge in electrical engineering. Such a combination of chemical and electrotechnical disciplines was characteristic of the curriculum of the newly created electrochemical department. Thus, two higher school institutions in St. Petersburg, Emperor Alexander III Electrotechnical Institute and Emperor Peter the Great Polytechnic Institute, opened in 1902, started training of broad specialists in electrochemical engineering already at the very beginning of the XX century. The Polytechnic Institute had, since the time of its organization, an electrochemical subdepartment as a part of the metallurgical department.

In 1893, Krakau published the first edition of his textbook on electrochemistry (second edition, in 1898). This was the first textbook on electrochemistry written in Russia.

Being head of studies (inspector) at the Institute,

Krakau was, together with the director of the Institute, N.N. Kachalov (1852–1909) and other known scientists, a member of the Commission that supervised the construction of a new complex of buildings for the Institute, at the intersection of Aptekarskii avenue and Pesochnaya street (now Professor Popov street). The construction work was commenced in May 1900, and the Institute moved to its new buildings in 1903. The construction work was carried out under supervision of A.N. Vekshinskii, an academician of architecture. Krakau paid a considerable attention to equipment of chemical laboratories, went to business trips abroad, and visited laboratories at some of the best-known scientific centers. Four laboratories were organized in the new complex of buildings: those of inorganic chemistry, physical chemistry, analytical chemistry, and electrochemistry. In 1903, the Council of the Electrotechnical Institute conferred on Krakau the title of honorary electrical engineer.

Two periods can be distinguished in Krakau's scientific activities: the first, associated with investigations in the field of organic chemistry, and the second, with electrochemistry as new branch of physical chemistry by that time. As already mentioned, Krakau was the first to pay attention to the ability of alkali metals to initiate polymerization of unsaturated hydrocarbons. Unfortunately, the study was not published in full measure. This idea was further developed by M.G. Kucherov (1850–1911) and I.L. Kondakov (1857–1931). Krakau's work and its impact on the development of further studies in the field of polymerization with the use of alkali metals were analyzed in detail by K.B. Piotrovskii [8].

In 1885–1887, Krakau published in *Zhurnal Russkogo Fiziko-Khimicheskogo Obshchestva* (Journal of the Russian Physicochemical Society) and in French chemical journals quite a number of papers devoted to the action of caustic alkalis on cinchonine, quinine, and quinidine. Krakau also observed hindrance to polymerization of unsaturated compounds by iodine, sulfur, and bromine [8].

In 1892 was published first Krakau's electrochemical study. He examined the operation of various types of Meidinger cells, widely used at that time in communication systems [9]. Later appeared a number of Krakau's publications concerned with electrical conductivity and dissociation pressure of palladium compounds with hydrogen. In 1898, he published a paper devoted to the method suggested by Herz for electrochemical ac/dc conversion. At that year, Krakau took part in the congress of electrochemists in Munich and published a detailed report about this event [10].

In early January 1900, Krakau delivered at the first All-Russia electrotechnical congress a detailed report "On the Modern State of the Electrochemical Industry" [11]. The same topic was analyzed with account of new evidence in a large report "An Outline of the Development and Modern State of the Electrochemical Industry" at the First Mendeleev Congress on General and Applied Chemistry, held in St. Petersburg at the end of December 1907 [12]. The author analyzed in detail the processes of refining of copper, silver, gold, and other metals, considered the possibility of manufacture of aluminum, magnesium, sodium, and calcium, and discussed prospects for production of chlorine and alkalis and for electrolysis of water. Krakau's report also considered electrothermal processes (manufacture of calcium carbide, phosphorus, etc.).

Krakau's contemporaries highly appreciated his pedagogical and scientific activities. One of the oldest at that time Russian chemists, academician Beketov, wrote in connection with the election of Krakau a professor of the Electrotechnical Institute in 1891: "...I personally know A.A. Krakau as my former assistant at the Laboratory of the Imperial Academy of Sciences. I could make certain not only of his all-round knowledge in all areas of chemistry, but also of his skill to conduct chemical and physicochemical investigations..." [8]. Krakau's experimental investigations and pedagogical activities in the field of chemistry and electrochemistry were also highly appreciated by Professor D.P. Konovalov (1856–1929, academician of the Academy of Sciences of the USSR since 1923) [8]. The role of Krakau in that St. Petersburg Electrotechical Institute was one of the most prominent centers of electrochemical research in the first quarter of the XX century is difficult to overestimate. Among those who worked at the Institute were, together with Pushin, I.V. Grebenshchikov (1887–1953, academician of the Academy of Sciences of the USSR since 1932), P.F. Antipin (1890–1960, academician of the Academy of Sciences of the USSR since 1939), M.S. Maksimenko (1878–1942), a prominent specialist in technology of electrothermal industries, and their disciples and co-workers. Aluminum and magnesium were for the first time produced from fully domestic raw materials [7] and foundations of manufacture of magnesium and sodium in Russia were laid at the laboratory of the Electrotechnical Institute, headed by Pushin, in 1913–1915.

Aleksandr Aleksandrovich Krakau, an ordinary professor of chemistry and electrochemistry at the Electrotechnical Institute, honorary electrical engineer, and senior state councilor, untimely died on March 16(29), 1909, at the age of fifty-three.

BOOK REVIEWS

Borovichskii kombinat ogneuporov (Borovichi Combine of Refractories)

Mozhzharin, V.A., Ed., Moscow: Ruda i Metally, 2005, 136 pp.

The book, whose publication was timed with the approaching 150th foundation anniversary of the enterprise, briefly describes the historical events associated with the revival of the refractory trade in Russia, development of the refractory industry in Borovichi, Novgorod oblast, and present-day state of affairs at Borovichi Combine of Refractories.

The book comprises an introduction and three parts. The brief introduction (pp. 3–6) gives a general notion of various aspects of the activities of the Borovichi Combine of Refractories, Open Joint-Stock Company and on solution of production-related and social problems. The first park of the book (pp. 7–36) is devoted to the history of manufacture of refractories in Borovichi. The availability of high-quality refractory clays had long been known, but serious attention to this fact was given only in mid-XIX century. After the railway between Moscow and St. Petersburg, passing at a distance of 30 km from Borovichi, was put in operation in 1851, it became possible to ship raw materials to large plants in St. Petersburg. The manufacture of refractories directly in Borovichi, set in 1855, is associated with the activities in Russia of Emmanuel Nobel (1801–1872) and sons. The production volume was approximately up to 100 hundred thousand refractory bricks per year. In view of the comparatively moderate demand for refractories, the plant was cost-inefficient and existed for only several years.

In 1880, a plant for manufacture of refractory bricks and other articles was constructed near Borovichi by K.L. Vakhter, a St. Petersburg businessman. The joint-stock company organized by him later, in 1897, became monopolist in Russia's market of refractories. In 1919, all Borovichi plants and mines were nationalized.

The second part of the book (pp. 37–100) contains comprehensive evidence concerning the operation of Borovichi Combine of Refractories under the present-day conditions. Since 1992, it has been a joint-stock company. The main consumers of its production are the largest plants of domestic ferrous metallurgy, Cherepovets, Novolipetsk, and Magnitogorsk combines, and other metallurgical and metal-working plants and enterprises of nonferrous metallurgy.

The third part of the book (pp. 101–132) is a catalogue of the products manufactured by the combine: a wide variety of aluminosilicate refractories, from fireclay to high-alumina types. In each type of aluminosilicate refractories, manufacture of varied-purpose articles has been mastered. Quite a number of articles of other kinds are produced.

The book provides a comprehensive idea of the creation history and modern state of the first Russia's industrial plant for manufacture of refractories and about its functioning in the conditions of market economy. The book is very well published and it contains a large number of photographs. It may be of use for teachers and students of the corresponding specialties of higher-school and post-secondary educational institutions and to consumers of various kinds of refractories.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

A Study of Viscosity in the Extraction System Constituted by Tributyl Phosphate and Phosphoric Acid

V. M. Lembrikov, V. V. Volkova, L. V. Konyakhina, Z. N. Korneva, and O. V. Pokidova

Voskresenskii NIUiF (Voskresensk Research Institute of Fertilizers and Phosphoric Acid) Open Joint-Stock Company, Voskresensk, Moscow oblast, Russia

Received May 13, 2005

Abstract—Data on the kinematic viscosity of phosphoric acid solutions in technical-grade tributyl phosphate and in an industrial extract from a technological purification system based on tributyl phosphate, which contain 0–18% phosphoric acid in terms of P_2O_5, at 10–70°C are presented.

One of methods used to obtain pure phosphoric acid is purification of extraction phosphoric acid (EPA) with organic solvents. In Russia, Voskresenskii NIUiF (Voskresensk Research Institute of Fertilizers and Phosphoric Acid) Open Joint-Stock Company employs on the industrial scale a purification technique in which tri-*n*-butyl phosphate (TBP) serves as an extracting agent [1].

When working with the installation used to purify EPA, it is necessary to improve the quality of the acid manufactured and to raise the output capacity of the installation. This is achieved by selecting and developing a perfect equipment. Doing so requires that the physicochemical parameters of the extraction system, including the viscosity of an extract from the industrial technological system at various contents of phosphoric acid in the extract, should be known.

This communication presents data on the kinematic viscosity of phosphoric acid solutions in technical-grade tributyl phosphate [2] and in an industrial extract from a technological purification system based on technical-grade TBP, which contain 0–18% phosphoric acid in terms of P_2O_5, at 10–70°C. The choice of these temperature and concentration ranges was governed by real conditions of the industrial process for purification of extraction phosphoric acid. The solutions were prepared by saturating technical-grade TBP and the extracting agent from the industrial system.

The kinematic viscosity ν of organic solutions was measured with a capillary glass viscometer of the VPZh type. The content of phosphoric acid was determined potentiometrically [3]. The temperature of the experiments was maintained by thermostating within ±0.5°C. The resulting values of the kinematic viscosity are listed in Table 1.

A graphical analysis and mathematical processing of the data obtained demonstrated that the dependence $\nu = f(c, t)$ is logarithmic. It can be represented as

$$\ln \nu = ac + b, \quad (1)$$

where ν is the kinematic viscosity ($mm^2\ s^{-1}$); *c*, content of P_2O_5 (wt %); and *a*, *b*, coefficients of the equation.

Table 2 lists values of the coefficients *a* and *b*, as well as the approximation reliability R^2 for each curve. The data of Table 2 were used to plot the temperature dependences of the coefficients *a* and *b* (see figure) for technical-grade TBP and for the extracting agent from the industrial system. It is noteworthy that the temperature dependences of the coefficients are similar for both types of solutions.

The temperature dependence of the coefficient *a* can be described by the equation

$$a = kT + m, \quad (2)$$

and that of the coefficient *b*, by

$$b = n\exp(pT), \quad (3)$$

where *T* is temperature (°C); *k*, *m*, coefficients in Eq. (2); and *n*, *p*, coefficients in Eq. (3).

Table 3. Coefficients and approximation reliabilities R^2 for Eqs. (2), (3), and (4)

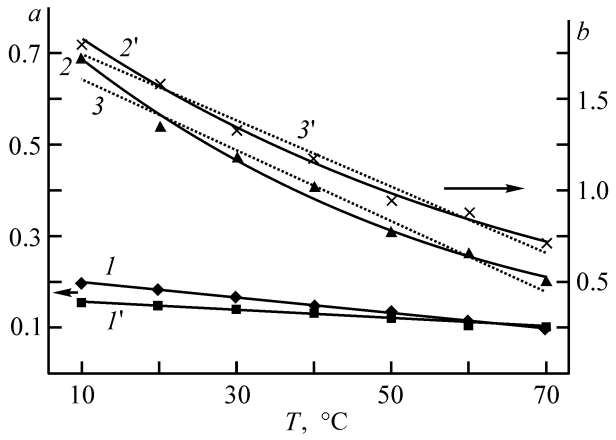
Organic phase	Coefficients of Eq. (2)		R^2	Coefficients of Eq. (3)		R^2	Coefficients of Eq. (6)		R^2
	k	m		n	p		d	q	
Technical-grade TBP	–0.0017	0.2159	0.9945	2.129	–0.0155	0.9936	–0.0194	1.8017	0.9746
Extracting agent from the industrial system	–0.0009	0.1686	0.9852	2.096	–0.0198	0.9926	–0.0182	1.9283	0.9816

Table 3 lists the values of the coefficients in Eqs. (2), (3) and of the approximation reliability R^2 for technical-grade TBP and for the extracting agent from the technological system.

Thus, the kinematic viscosity of phosphoric acid solutions in technical-grade TBP can be calculated by the equation

$$\ln \nu = (-0.0017T + 0.2159)c + 2.129\exp(-0.0155T), \quad (4)$$

and that of phosphoric acid solutions in the extracting agent from the industrial system, by the equation



$$\ln \nu = (-0.0009T + 0.1686)c + 2.096\exp(-0.0198T). \quad (5)$$

For simplicity, the logarithmic dependence of the coefficient b in Eq. (1) can be replaced with a linear dependence (see figure, curves *3* and *3*'). Then, the temperature dependence of the coefficient b can be represented as

$$b = dT + q, \quad (6)$$

where T is temperature (°C), and d, q are the coefficients in Eq. (6).

The values of the coefficients in Eq. (6) and the approximation reliability R^2 are listed in Table 3 for both types of solutions. In the case of simplification, the kinematic viscosity is described by Eq. (7) for solutions based on technical-grade TBP and Eq. (8) for solutions based on the extracting agent:

Coefficients a and b in Eq. (1) vs. temperature T for (*1*–*3*) technical-grade TBP and (*1*'–*3*') extracting agent from the technological system.

$$\ln \nu = -0.0017cT + 0.2159c - 0.0194T + 1.8017, \quad (7)$$

$$\ln \nu = -0.0009cT + 0.1686c - 0.0182T + 1.9283. \quad (8)$$

Both pairs of equations, (4), (5) and (7), (8) can be used to calculate the viscosity, but it should be noted that application of Eqs. (4), (5) yields a smaller discrepancy $\left(\Delta = \frac{\ln \nu_{exp} - \ln \nu_{calc}}{\ln \nu_{exp}} \times 100\%\right)$ between the experimental and calculated values listed in Table 1. (For brevity, the comparison of both the calculation methods is limited to the values at 40°C).

An analysis of the viscosities of organic solutions of phosphoric acid revealed a certain difference between the kinematic viscosity of the extracting agent from the industrial system and the viscosity of technical-grade dibutyl phosphate. This is due to presence of organic impurities in the extracting agent [4, 5].

CONCLUSION

Analytical dependences of the viscosity of phosphoric acid solutions in tri-*n*-butyl phosphate on the temperature and composition of the organic solutions were obtained for the temperature range 10–70°C and P_2O_5 content of the organic phase of 0–18 wt %.

Abstract—The surface activity of higher aliphatic amines and their salts at the interface between their solutions and air, oil, and KCl grains and their influence on the strength characteristics, moisture absorption, and caking of the grains were studied.

The problem of improving the quality of granulated potassium fertilizers and their physicomechanical properties remains a matter of current interest. Modern conditioners for potassium fertilizers contain several components, which most frequently include surfactants and oil hydrocarbons [1–3].

The aim of the present study was to examine the influence exerted by surfactants (higher aliphatic amines and their salts) and moisture on the strength of potassium chloride grains and on their moisture absorption and caking. As objects of study served industrial grains of flotation KCl, manufactured by Belarus'kalii Production Association, Republican Unitary Enterprise. Individual aliphatic amines of Armeen-D brand, their acetic salts of Armac-D brand, and technical-grade amine of Flotigam brand were used as amines; dodecane, vacuum gas oil (VGO), and slop wax served as hydrocarbons.

The quality of grains was assessed by a comprehensive study of their basic physicochemical properties: destructibility, static strength, moisture absorption, degree of hydrophobization, and caking. The destructibility of grains was evaluated by the content of destroyed grains (–0.5-mm fraction) upon a vibrational and impact treatment on the –4…+2-mm fraction in a vibration mill for 30 min. The static strength of grains was found with an IPG-1 instrument intended for determining the strength necessary for grain crushing. The absorption of atmospheric moisture by grains, W (g H_2O/100 g KCl), was determined using the "desiccator" method under the following conditions: air humidity 80%, temperature 25°C, weighing accuracy 1×10^{-4} g, time of sample keeping in a desiccator equal to 1 to 7 days. The degree of hydrophobization, H (%), was calculated from the difference of masses of moisture absorbed by the initial (M_0) and modified (M) samples, using the formula

$$H = \frac{M_0 - M}{M_0} \times 100.$$

The caking was evaluated by the force necessary for crushing a briquette of the granulated material, preliminarily moistened with water to 3% moisture content and kept in molds under a pressure of 0.8 kg cm^{-2} at a temperature of 60°C for 24 h.

EXPERIMENTAL

Higher aliphatic amines and their salts are cationic surfactants. To study the surface activity of the amines, isotherms of surface tension σ at the interface between an aqueous solution of a surfactant and air and the interfacial tension at the interface between the aqueous solution of the surfactant and oil were measured by the Wilhelmi method (Fig. 1). The isotherms obtained were used to calculate the basic parameters of the adsorption layer at solution–air and solution–oil interfaces (Table 1): minimum surface or interfacial tension σ_{min}, surface activity G_m, saturation concentration c_n of the adsorption layer, critical micelle concentration c_{cr}, maximum adsorption Γ_m of a surfactant at the interface, area S_m occupied by the molecule of the sur-

factant under study in the saturated adsorption layer, and the thickness δ of this layer.

It can be seen that the cation-active surfactants exhibit a high surface activity both at the interface with air and at that with oil. For example, the work of adsorption per a methylene group of the hydrocarbon chain of the amines is 0.78 kT at the solution–air interface and 0.66 kT at the solution–oil interface. It is noteworthy that the Traube rule is observed in the C_{12}–C_{16} amine series. However, the variation pattern of the surface activity is violated on passing to the C_{18} amine, which is possibly due to appearance of new conformational states in the longest-chain member of the homologous series under consideration or to presence of associates in its solutions even at low concentrations. Having such a high adsorption activity, amines can reduce the surface tension to 30–40 mJ m^{-2} at the solution–air interface, against 72 mJ m^{-2} for water, and to 5–26 mJ m^{-2} at the solution–oil interface, against 51 mJ m^{-2} for oil (Table 1). The adsorption layer is saturated at such mobile interfaces at amine concentrations an order of magnitude lower than the critical micelle concentration.

In the presence of inorganic electrolytes, such as KCl or NaCl, the surface activity and adsorption increase, and, consequently, so does the packing density of molecules in the surface layer. Also, the satura-

tion concentration of the adsorption layer and the critical micelle concentration decrease, i.e., addition of inorganic electrolytes is equivalent to an increase in the oil-receptivity of surfactant molecules (Table 2) [4]. The effects observed in the presence of inorganic electrolytes are due to the action of three main factors: (i) screening and neutralization of the charge of the polar groups of surfactant molecules by counter-ions (contraction of the electric double layer), (ii) decrease in the degree of hydration of surfactant molecules, and (iii) change in the structure of the solvent (water). As the hydrophobic radical in amine molecules becomes longer, smaller amounts of inorganic electrolytes are to be added to reach the same increase in the surface activity and decrease in c_n and c_{cr}. For example, the concentration of effective NaCl additives is as high as 1–2 M for a salt of dodecylamine C_{12}, and as low as 10^{-3}–10^{-4} M for hexadecylamine C_{16}.

It can be seen in Fig. 2 that salts of higher aliphatic amines also have a high adsorption activity on KCl crystals [5].

The results obtained in a study of the influence exerted by amines on the moisture absorption, degree of hydrophobization, static strength, destructibility, and caking of grains of flotation KCl are listed in Table 3. It can be seen that, being adsorbed on KCl crystals, the amines have an anticaking and water-repellent effect. The hydrophobization processes are based on oriented adsorption of modifier molecules on the solid surface of the crystals to form mono- or polymolecular layers. It is commonly believed that the maximum hydrophobicity of the product is only reached when a saturated layer of a water-repellent agent is formed. The amount of C_{12}–C_{18} amines sufficient for such a monomolecular film to be created on the surface of KCl grains of various fractions (from –4 to +0.25 mm) is 5–20 g per ton of the grained material [6]. In fact, a larger amount of the amine is necessary for creating the sufficient water-repellent and anticaking effect (Table 3).

However, the high activity of the amines adversely affects the strength of KCl grains (Tables 3, 4). The reason is as follows. Surfactant molecules present on the surface of a real solid penetrate close to the predisintegration zone (e.g., crack tip) owing to their high surface activity and surface mobility, diminish the surface tension, and thereby make smaller the work of formation of a new surface (Rebinder effect) [7]. An adsorption event must occur simultaneously with an event of bond rupture at the instant of formation of a new unit cell on the surface. Thus, an obligatory combination of the action of the medium and of mechanical stresses is characteristic of the adsorption-induced depression of the strength of a solid. As is known, the media that can impair the strength of ionic crystals are not only surfactants, but also water and aqueous electrolyte solutions.

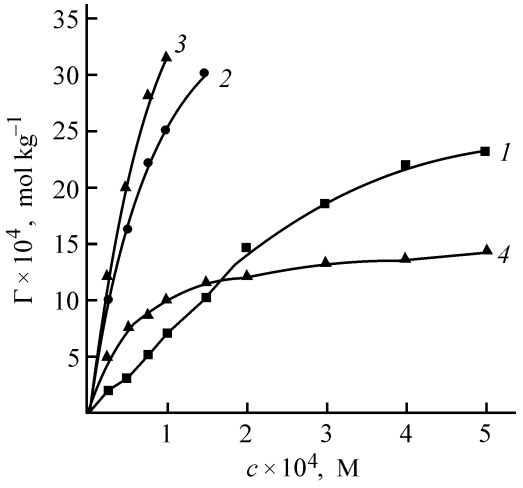

Fig. 2. Isotherms of adsorption Γ of amine acetates on KCl crystals at 20°C. (*c*) Amine concentration. The amines were introduced from starting solutions heated to 70°C.

Table 4. Effect of the moisture content and storage time of grains treated with a formulation composed of VG (2500 g ton^{-1}) and amine (50 g ton^{-1}) on their destructibility

Moisture content, %	Storage time, days	Destructibility of the –0.5-mm fraction, %	Moisture content, %	Storage time, days	Destructibility of the –0.5-mm fraction, %
0_{cond}	1	1.4	0.20	15	2.8
0.20	1	2.2	0.35	1	2.6
0.20	7	2.5	0.50	1	3.0

Tables 3, 4 clearly demonstrate a tendency toward disintegration of KCl grains under the action of amines and moisture. On dry grains, the disintegrating effect of the amines is insignificant. On humid grains, the destructibility of grains is rather strong and becomes more pronounced as the amine expenditure or amount of absorbed moisture grows. At amine expenditure of 50 g per ton of the granulated material, this effect is 2.2% at a fixed moisture content of 0.2%, against 1.4% for the initial, amine-untreated granulated material. As the content of the amine in the system increases, the amount of the –0.5-mm fraction after vibrational crushing grows to become 4.7% at a content of the amine equal to 200 g, and 7.7% at 400 g of the amine per ton of the granulated material. In the presence of moisture, the destructibility of grains under the action of amines and water grows in the course of time (Table 4).

If amine–hydrocarbon mixtures are used to treat KCl grains, the destruction power of amines decreases. Thus, the strength and elasticity of the hydrophobic coating increase in the presence of a surfactant. However, an inverse effect is also observed: apolar compounds favor adsorption of the amine on the KCl surface [8]. When amine–hydrocarbon formulations are used, the distribution of an amine over the grain surface is more uniform and the hydrocarbons and amines are more firmly fixed on the KCl surface, which leads, in the end, to a stronger hydrophobization of the surface.

CONCLUSION

It was established that surface-active modifiers, to which belong higher aliphatic amines and their salts, exert a water-repellent and anticaking action

on the granulated potassium material. However, the strength of KCl grains decreases and their destructibility increases in the presence of moisture. In view of this fact, it is necessary to minimize the expenditure of surfactants in treatment of granulated fertilizers under industrial conditions. This can be achieved by using amine–hydrocarbon mixtures with a low content of an amine (1–2%).

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Thermal Decomposition of the System $CO(NH_2)_2$–H_3PO_4 in the Presence of Nitrate Compounds

N. K. Luneva, L. I. Petrovskaya, I. A. Lyudchik, and T. I. Ezovitova

Received January 26, 2005

Abstract—Chemical, derivatographic, IR spectral, and X-ray diffraction analyses were used to study thermal transformations in the system $CO(NH_2)_2$–H_3PO_4 and in the same system with addition of KNO_3, $CsNO_3$, $LiNO_3 \cdot 3H_2O$, and NH_4NO_3 salts in the temperature range 20–600°C. The influence of the chosen nitrate compounds on the process of reorganization of the constituent ingredients, evolution of nitrogen into the gas phase, yield of the solid residue, and preservation of nitrogen and phosphorus was revealed.

Recently, nitrogen-phosphorus compounds have been widely used as cellulose modifiers and combustion inhibitors for various polymeric materials.

The efficiency of nitrogen-phosphorus fire-retardants depends on the chemical nature of the nitrogen-containing component, degree of condensation of the phosphates used, ratio of the main components (nitrogen to phosphorus), additives introduced, and some other factors [1–7].

It is known that the nature of the metal cation in inorganic additives present in nitrogen–phosphorus systems can strongly modify their fire-extinguishing properties and decomposition temperature [2, 3]. For example, amidophosphate formulations are effective fire-protecting means. However, studies of the thermal decomposition of phosphorus-nitrogen mixtures and of the influence exerted by addition of inorganic salts on the structural-chemical transformations in the course of their heating are virtually not reflected in the literature at all.

EXPERIMENTAL

Systems composed of a mixture of phosphoric acid and carbamide, $CO(NH_2)_2$–H_3PO_4 (NP), at a mass ratio N : P = 1 : 2, and the same formulations with addition of NH_4NO_3, KNO_3, $LiNO_3 \cdot 3H_2O$, and $CsNO_3$ (Table 1) were chosen for study.

The NP systems were prepared by successive introduction of carbamide and appropriate nitrate salts into phosphoric acid. The content of nitrogen and phosphorus after thermal treatment was determined using procedures described in [8, 9].

The X-ray diffraction patterns of the samples studied were recorded with a monochromatic Cu_{K_α} radiation on an IRS-50M installation, and the IR spectra, on a Perkin-Elmer instrument by the sandwich technique [10] in a polyethylene film in the frequency range 400–3900 cm^{-1}. The course of the thermal decomposition process was recorded with an MOM Q-1000 derivatograph (Hungary), with temperature raised at a rate of 10 deg min^{-1} in the interval 20–600°C. In view of the fact that vigorous gas evolution with ejection of the samples under study from crucibles occurred on heating the NP system with nitrate additives, thermograms were only recorded for the additives introduced into the system.

It is known that carbamide forms with phosphoric acid associates of acid carbamide phosphates [1, 11–13].

* System numbers correspond to those of nitrogen–phosphorus systems in Table 1.

It has been shown previously [3, 14] that thermal decomposition of associates of this kind is a complex chemical process that simultaneously involves chemical decomposition of adducts, interaction of the forming gaseous compounds with solid products of decomposition of the systems, formation of new crystalline phases, and condensation of phosphates. The yield of a residue from such systems depends on the temperature to which a formulation is heated, N : P ratio, and nature of the additives introduced.

According to the results of a thermogravimetric analysis, the KNO_3 and $CsNO_3$ salts used as additives in the nitrogen–phosphorus system $CO(NH_2)_2$–H_3PO_4 (NP) are not decomposed in the temperature range under study. $LiNO_3 \cdot 3H_2O$ crystal hydrate loses virtually only the crystallization water; as for the NH_4NO_3 additive, its loss of mass is 44.6 wt %. Table 2 lists data characterizing the thermal decomposition of nitrogen–phosphorus systems. For a system with addition of nitrates, the yield of the solid product decreases, compared with that for the NP system without additives. For example, the yield of the residue (wt %) for the NP system containing no additives was 60.0 at 600°C; upon addition of equal amounts of $LINO_3$, KNO_3, or $CsNO_3$, it was 48.7, 51.4, and 54.8, respectively. At a higher content of $LINO_3$ or NH_4NO_3 in NP formulations, the yield of the solid product at 600°C decreases. For example, as the content of the $LiNO_3$ additive increased (N : P ratio 1 : 9.3 and 1 : 3.8), the yield at 600°C was 53.0 and 48.7 wt %, respectively. For the system containing NH_4NO_3, the yield of residues at 60°C was 58.0 wt % (N : P = 1 : 5.4) and 55.3 wt % (N : P = 1 : 2.2).

Figure 1 shows the content of nitrogen in products of thermal decomposition of nitrogen–phosphorus

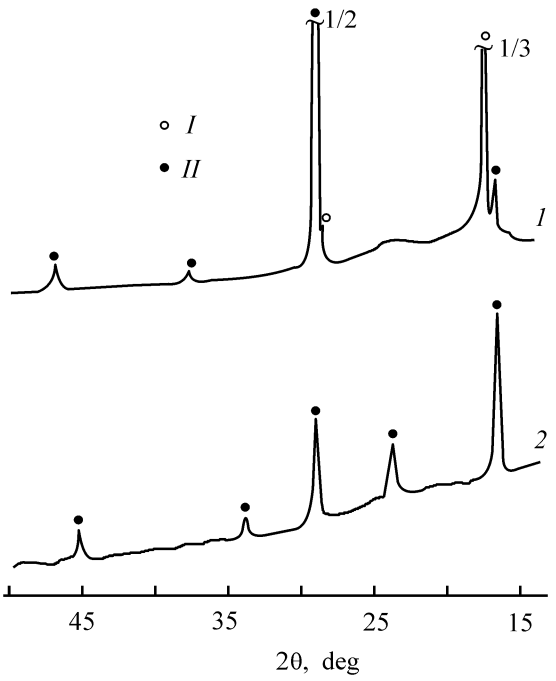

Fig. 3. X-ray diffraction patterns of samples obtained upon thermal decomposition of nitrogen–phosphorus systems. (2θ) Bragg angle. Sample: (*1*) NP, (*2*) NP–NH_4NO_3 (N_a : P = 1 : 2.2). Phase: (*I*) $(NH_4)_2HPO_4$ and (*II*) $NH_4H_2PO_4$.

systems in the temperature interval 20–600°C. All the nitrate additives introduced into the NP system in the interval 180–460°C favor a stronger evolution of nitrogen into the gas phase, compared with a system without additives. Raising the content of the $LiNO_3$ additive in the nitrogen–phosphorus system (N : P = 1 : 9.3 and 1 : 3.8) leads to a decrease in the preservation of nitrogen at 460°C from 86.1 to 77.0 wt %.

At virtually the same content of KNO_3, $LiNO_3$, and $CsNO_3$ additives in NP systems, the smallest amount of nitrogen (36.5 wt %) was observed in products obtained at 460°C with a KNO_3 additive, whereas for systems with $LiNO_3$ and $CsNO_3$ additives, the content of nitrogen was 77.0 and 56.4 wt %, respectively. The preservation of nitrogen in the initial NP system at the same temperature was 84.0 wt %. Here, the total amount of the ammonia and carbamide nitrogen was taken as 100%.

A chemical analysis demonstrated that nitrogen is present in samples of all the systems, thermally treated at 600°C, as NH_4^+ ions. This is also confirmed by the IR spectra of these samples (Fig. 2). For example, the following absorption bands were observed in the IR spectra (cm^{-1}): 1438 (ν_4NH_4), 1667 (ν_2NH), 2876 (ν_1NH), and 3040 (νNH_4). According to [15–19], these bands can be assigned to the NH_4^+ ion.

Thermal treatment of all the nitrogen–phosphorus systems at 180–460°C yields cakes, and that at 600°C, glassy products. Keeping in air samples of NP systems and those with addition of NH_4NO_3, thermally treated at 260°C, leads to crystallization of compounds that belong, according to X-ray phase analysis (Fig. 3), to the crystalline phases $NH_4H_2PO_4$ and $(NH_4)_2HPO_4$ [20]. The formation of these compounds indicates that H_3PO_4 reacts with NH_3 evolved upon heating of nitrogen–phosphorus systems. Further increase in the temperature of thermal treatment (T > 260°C) of nitrogen–phosphorus formulations leads to formation of polyphosphorus compounds, which is confirmed by the IR spectra of thermal decomposition products in Fig. 2, in which the following absorption bands are observed (cm^{-1}): 494 (δ_s PO_3), 725 (ν_s POP), 987 (ν_{as} POP), 997 (ν_s PO_3), 1146 (ν_{as} PO_3), and 1433, 3242 (ν_{as} PO_2), which are characteristic of vibrations of the phosphate groups of chain polyphosphates [17, 18, 21, 22]. The formation of polyphosphates upon heating of nitrogen–phosphorus systems is accompanied by a minor loss of phosphorus.

In the interval 180–600°C, the preservation of phosphorus in thermal decomposition products is

rather high and the minimum retention factor is 0.82 (Table 3). The content of phosphorus is the highest in the system with a KNO_3 additive (retention factor 0.99 at 600°C); in the systems with $CsNO_3$ and $LiNO_3$ it is 0.93 and 0.90, respectively.

Thus, it was established that, when subjected to a thermal treatment, all the systems studied undergo significant transformations, which are due to loss of phosphorus and nitrogen and to reorganization of the phosphate structures. The systems with $CsNO_3$ and KNO_3 show at 600°C a minor loss of mass and higher retention factors for phosphorus, and, therefore, they may be of interest as combustion inhibitors for polymeric materials.

The efficiency of the formulations studied in fireproofing (30 wt % in an aqueous solution) was evaluated by treating wood with these materials [tests in conformity with GOST (State Standard) 16363–98]. Table 4 lists data obtained in evaluating the fireproofing properties of treated wood (150 × 60×30-mm sticks).

It can be seen that the smallest loss of mass (15 wt %) in fire tests is observed for wood sticks (pine) treated with an NP system with addition of KNO_3. Thus, this system is a more efficient combustion inhibitor for cellulose-containing materials.

CONCLUSIONS

(1) It was shown in a study of thermal decomposition of the system $CO(NH_2)_2$–H_3PO_4 with and without addition of KNO_3, $CsNO_3$, $LiNO_3 \cdot 3H_2O$ salts by methods of physicochemical analysis that all the additives introduced affect the yield of the solid product. The mass fraction of the solid product depends on the nature of nitrate compounds and their quantitative content in nitrogen–phosphorus systems. The lowest yield of the product was observed for a nitrogen-phosphorus system with addition of $LiNO_3 \cdot 3H_2O$ or KNO_3.

(2) It was established that the thermal decomposition of nitrogen–phosphorus systems involves, together with evolution of gaseous products into the gas phase, reactions of their interaction with solid thermal decomposition products and reorganization of the latter to form polyphosphorus compounds.

(3) It was revealed that all the nitrate additives introduced intensify nitrogen evolution into the gas phase in the temperature range 180–460°C, with the strongest influence exerted by the KNO_3 additive.

Abstract—Interactions in the Al_2TiO_5–Ti_2O_3 system were studied and the regions of existence of $Al_{2-2x}Ti^{3+}_{2x}Ti^{4+}O_5$ solid solutions with a pseudobrookite structure were determined.

A distinguishing feature of ceramics based on aluminum titanate is their refractoriness and low overall coefficient of linear thermal expansion [1]. Owing to this property, it is expedient to use aluminum titanate, in processes that occur in nonstandard operation modes, as a material resistant to thermal shocks. Aluminum titanate is used as a heat insulator in propulsion engineering, material for crucibles in ferrous and nonferrous metallurgy, and support for catalysts [2, 3].

Aluminum titanate Al_2TiO_5 belongs to an isomorphous series of binary oxides A_2BO_5 with a pseudobrookite structure (also including Fe_2TiO_5, Ti_3O_5, and Ti_2MgO_5), in which A and B atoms may be isovalently substituted by various cations, with continuous series of solid solutions formed [4, 5]. Aluminum titanate has an orthorhombic lattice with a *Cmcm* space group, with the following lattice constants: $a = 0.3591$, $b = 0.9429$, and $c = 0.9636$ nm [4]. A characteristic feature of the representatives of the isomorphous A_2BO_5 series is the anomalously high anisotropy of thermal expansion, caused by distortion of $[MO_6]$ octahedra and different lengths of M–O bonds [6, 7].

Titanium pentoxide Ti_3O_5 has two, high- and low-temperature, modifications [8]. Crystals of anosovite (high-temperature modification of Ti_2O_5) [9, 10] belong to the rhombic crystal system, are characterized by the *Cmcm* space group, and have the following lattice constants: $a = 0.3747$, $b = 0.9465$, and $c = 0.9715$ nm. The crystal structure of the low-temperature modification of Ti_3O_5 belong to the monoclinic system, is characterized by the *C*2/*m* space group, and has the following lattice constants: $a = 0.3808$, $b = 0.9442$, $c = 0.9752$ nm, and $\beta = 91.55°$.

The high- and low-temperature modifications of Ti_3O_5 are rather easily transformed one into the other at a temperature of about 120°C. At slightly higher temperatures [8], the structure Ti_3O_5 is similar to that of orthorhombic anosovite, but is slightly distorted (monoclinic), with lattice constants $a = 0.378$, $b = 0.997$, $c = 0.982$ nm, and $\beta = 91.0°$. At higher temperatures, the monoclinic angle gradually approaches 90°, and the lattice constants, those of anosovite. The crystal structure of the high-temperature modification can also remain stable at low (room) temperatures in the presence of a certain amount (several weight percent) of iron, magnesium, or aluminum. In the absence of admixtures, titanium pentoxide has at room temperature the structure of its low-temperature modification. According to the refined data [11], the lattice constants of the low-temperature modification of Ti_3O_5 are $a = 0.3801$, $b = 0.9441$, $c = 0.9748$ nm, and $\beta = 91.53°$.

The sinterability of aluminum titanate ceramics is commonly improved, and its thermal stability, raised, by introducing mineralizers into the stock [12–14]. The stability of the structure of the high-temperature modification of Ti_3O_5 at room temperature in the presence of a minor amount of Al_2O_3 admixture was confirmed in [13]: solutions of composition $[(Ti_{1-x}Al_x)_2O_3TiO_2]$ with $0 \le x \le 0.4$ have the structure of low-temperature Ti_3O_5, and compounds with $x \ge 0.08$ are structurally similar to high-temperature Ti_3O_5. A transition from the monoclinic crystal system, to which the crystal structure of compounds with $0 \le x \le 0.2$ belongs, to the rhombic crystal system characteristic of compounds with $0.3 < x < 1$ was found [13].

To perform a directed synthesis of ceramic materials, it is necessary to study in detail the structural

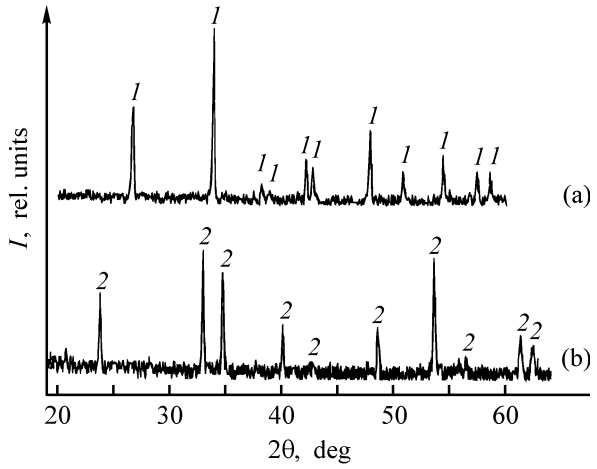

Fig. 1. X-ray diffraction patterns of the starting powders of (a) Al_2TiO_5 and (b) Ti_2O_3. (*1*) Al_2TiO_5 and (*2*) Ti_2O_3. (*I*) Intensity and (2θ) Bragg angle; the same for Fig. 3.

parameters of the forming samples and their correlation with the properties of the samples. A study of real structure of substances with all its defects makes it possible to search for new compounds with valuable properties and to improve processes of their synthesis by using various methods of control over their composition and the distortion of their structure. In this study, we examined the phase formation in the Al_2TiO_5–Ti_2O_3 system and the physicochemical properties of ceramic materials based on $Al_{2-2x}Ti^{3+}_{2x}Ti^{4+}O_5$ solid solutions with a pseudobrookite structure.

EXPERIMENTAL

To prepare the starting mixtures, we used Al_2O_3 of pure grade, TiO_2 of special-purity grade, and BAU-A activated carbon. Aluminum titanate was synthesized at 1400°C in the course of 9 h from an equimolar mixture of aluminum and titanium(IV) oxides (Fig. 1, diffraction pattern a). Ti_2O_3 was prepared by reducing TiO_2 with carbon in a vacuum (residual pressure 10^{-3}–10^{-1} Pa) at 1600°C with an isothermal exposure for 3 h [15]. The correspondence of the material synthesized to the stoichiometric formula Ti_2O_3 was monitored by the weight gain in the oxidation of the material to titanium dioxide by annealing in air at 1000°C for 2 h in accordance with the reaction

$$Ti_2O_{3+x} + \frac{1-x}{2}O_2 \rightarrow 2TiO_2. \quad (1)$$

The discrepancy revealed between the composition of the material synthesized and the stoichiometric formula is rather small (x = 0.011). The presence of an excess oxygen is a consequence of the insufficient amount of carbon in the reduction reaction; an exact calculation of the stock composition is complicated by the fact that the humidity of activated carbon, which is used as a source of carbon, varies from 8 to 10 wt %. The X-ray data (Fig. 1, diffraction pattern b) also confirm that the substance obtained is titanium(III) oxide.

To determine the ranges of existence of $Al_{2-2x}Ti^{3+}_{2x} \cdot Ti^{4+}O_5$ solid solutions, we prepared $Al_2TiO_5 + xTi_2O_3$ mixtures (x is the number of Ti_2O_3 moles, varied from zero to unity with a step of 0.1). Billets 20 mm in diameter and 5 mm high for high-temperature treatment were prepared by semidry compaction under a pressure of 150 MPa. The samples were thermally treated under atmospheric pressure in argon at 1400°C for 4 h.

The phase composition of the samples subjected to thermal treatment was studied by X-ray phase analysis on a DRON-3M installation (Cu_{K_α} radiation), using the JCPDS-ICDD database of powdered standards. We used the Powder Cell software [16] to evaluate the content of crystalline phases in the thermal treatment products (with an accuracy of ±5 vol %) and analyze the line intensities by the Rietveld method. The software makes it possible to construct and predict structural models of a solid solution based on aluminum titanate. The position parameters of the aluminum titanate lattice are listed in Table 1. The construction is based on substitution of a part of Al^{3+} ions

Table 1. Position parameters of the crystal structure of aluminum titanate (*Cmcm* space group) [17]

Atom	Ion	Position	*x*	*y*	*z*	Occupancy
Ti	Ti^{3+}	4*c*	0.0000	0.1863	0.2500	0.3330

in 4*c* and 8*f* positions in the Al_2TiO_5 structure [17] with Ti^{3+}. The occupancy of the specified positions by Al^{3+} was varied in the range 0.6670 – 0.4670, that by Ti^{3+}, in the range 0 – 0.2000. The experimental and theoretical X-ray patterns were compared within the entire pattern profile, and the convergence factor was output as the result of the calculation. The variant with a lower *R*-factor represents the model configuration. The software also makes it possible to compare a description of the structure of a solid solution with experimental data and to carry out a quantitative phase analysis. The lattice constants of the solid solutions based on aluminum titanate (orthorhombic crystal system) were determined using the least-squares method for 12 highest-intensity peaks in the 2θ range from 10° to 80°.

The open porosity *P* and water absorption *W* of the samples were determined in conformity with GOST (State Standard) 18847–84 by hydrostatic weighing. The acid resistance A of the samples synthesized was evaluated, according to GOST 473.1–81, by the change in the mass of the ceramic material after its treatment with concentrated sulfuric acid.

The content of Ti_2O_3 in the calcination products was determined by the method of complete oxidation from the weight gain of samples exposed in air at 1000°C for 2 h. The atomic composition of the crystalline phases of the ceramics was found by electron microprobe analysis using a JSM-6400 electron scanning microscope equipped with a Link X-ray energy-dispersion spectrometer with ISIS-300 software. The volume of the substance analyzed was 1 μm^3. The constituent phases of the samples were analyzed for the content of Al, Ti, and O. To reliably determine the amounts of elements in a phase, we made up to 10 measurements on the sample surface. We used as standards certified Microspec reference samples. The measurement error was ±1%.

Our studies revealed that the phase composition of the samples and the lattice constants of the pseudobrookite phase change, depending on the parameter *x* of the starting Ti_2O_3, upon calcination of the Al_2TiO_5–xTi_2O_3 mixture. The weight loss upon heat treatment of compacts did not exceed 0.5% for the entire range of compositions, $0 \le x \le 1$. According to the results of an X-ray analysis (Table 2), up to 5 vol % α-Al_2O_3 is contained in the heat-treatment products at $x = 0$. All the reflections of the aluminum titanate phase in the X-ray diffraction pattern are shifted to smaller 2θ angles owing to the formation of the $Al_{2-2x}Ti^{3+}_{2x}Ti^{4+}O_5$ solid solution via dissociation of aluminum titanate in the atmosphere of argon:

$$Al_2TiO_5 = (1/1 + 2x)Al_{2-2x}Ti^{3+}_{2x}Ti^{4+}O_5 + (3x/1 + 2x)Al_2O_3 + (x/1 + 2x)O. \quad (2)$$

Analysis for the content of Ti_2O_3 confirms the presence of 1.6 mol % Ti^{3+} in the heat-treatment products. The lattice constants of the $Al_{2-2x}Ti^{3+}_{2x}Ti^{4+}O_5$ solid solution, $a = 0.359$, $b = 0.946$, and $c = 0.967$ nm, exceed those of stoichiometric Al_2TiO_5 [17]. An examination of the profile of the X-ray diffraction pattern demonstrated that the intensity of peaks changes when the occupancy by Al^{3+} of the positions 4*c* and 8*f* decreases through partial substitution by Ti^{3+}. The best result in describing the experimental X-ray pattern was achieved in the case when 5% of Al^{3+} positions in the Al_2TiO_5 structure were substituted with Ti^{3+}.

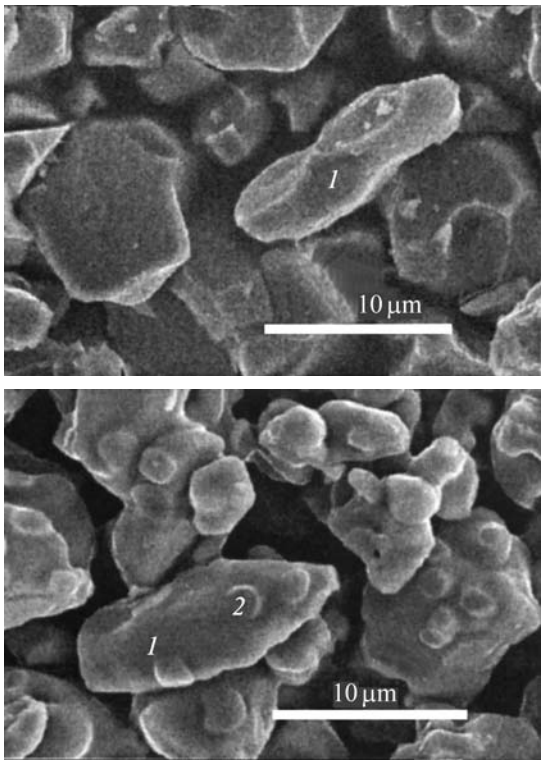

Fig. 2. Electron micrographs of the thermal treatment products (a) Al_2TiO_5 synthesized in air and (b) that calcined in argon. (*1*) Al_2TiO_5 and (*2*) $Al_{2-2x}Ti^{3+}_{2x}Ti^{4+}O_5$.

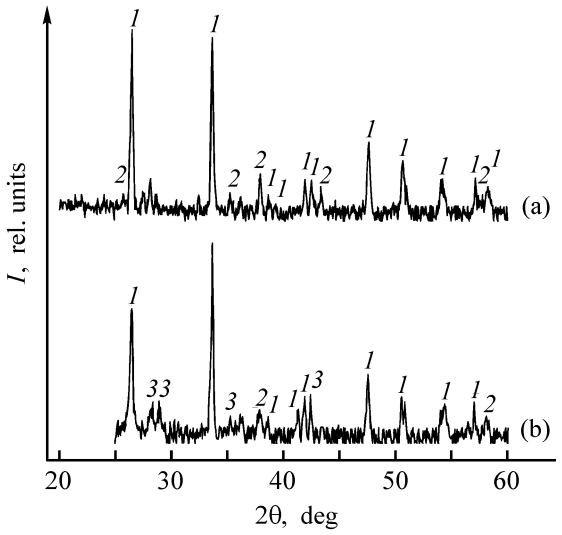

Fig. 3. X-ray diffraction patterns of thermal-treatment products: (a) $Al_2TiO_5 + 0.1\,Ti_2O_3$, (b) $Al_2TiO_5 + 1.0\,Ti_2O_3$. (*1*) $Al_{2-2x}Ti^{3+}_{2x}Ti^{4+}O_5$, (*2*) Al_2O_3, and (*3*) Magneli phases.

According to electron-microscopic data, aluminum titanate synthesized in air is composed of regularly shaped particles less than 10 μm in size, with the following atomic composition (mol %): Al 25.0, Ti 12.0, and O 63.0, which corresponds to that of stoichiometric Al_2TiO_5 (Fig. 2a). Areas with an increased content of titanium (13.0 mol %) are formed on the surface of aluminum titanate particles after annealing of the samples in argon (Fig. 2b). The averaged data of the electron microprobe analysis of the compound correspond to the chemical formula $Al_{1.9}Ti^{3+}_{0.1}Ti^{4+}O_5$.

An $Al_{2-2x}Ti^{3+}_{2x}Ti^{4+}O_5$ solid solution and α-Al_2O_3 (10 vol %) are formed in the thermal treatment products at $x = 0.1$ (Fig. 3, X-ray diffraction pattern a). The reaction of Al_2TiO_5 with Ti_2O_3 can be represented by the following equation:

$$Al_2TiO_5 + xTi_2O_3 = Al_{2-2x}Ti^{3+}_{2x}Ti^{4+}O_5 + xAl_2O_3. \quad (3)$$

Triple-charged titanium atoms isovalently substitute aluminum atoms in the Al_2TiO_5 crystal lattice to form the individual phase α-Al_2O_3. In this concentration range ($x = 0.1$), aluminum titanate partially dissociates in accordance with Eq. (1), because the Ti^{3+} content in calcination products (4.2 mol %) exceeds its amount in the starting stock (3.6 mol %). According to the averaged data of the electron microprobe analysis, the compound synthesized contains (mol %): Al 21.0, Ti 16.0, and O 63.0, which corresponds to the chemical formula $Al_{1.7}Ti^{3+}_{0.3}Ti^{4+}O_5$.

An increase in the Ti_2O_3 content to $x = 0.2$ is accompanied by formation of α-Al_2O_3 (up to 10 vol %) in the thermal-treatment products. As Ti^{3+} ions substitute Al^{3+} ions in aluminum titanate the lattice constants of $Al_{2-2x}Ti^{3+}_{2x}Ti^{4+}O_5$ increase further (Table 2). This is due to the larger ionic radius of titanium(III) in octahedral coordination as compared with aluminum [18]: $R(Ti^{3+}) = 0.67$ Å, $R(Al^{3+}) = 0.53$ Å. In modeling of the structure of the solid solution $Al_{2-2x}Ti^{3+}_{2x}Ti^{4+}O_5$ in the sample under consideration, the best result corresponds to the occupancies by Al^{3+} and Ti^{3+} of 0.557 and 0.110, respectively, in Ti^{3+} substitution for Al^{3+} in the aluminum titanate structure [17]. For the composition $x = 1.3$, the content of α-Al_2O_3 in the final products virtually does not increase. Thus, under the chosen thermal treatment conditions (1400°C), Ti^{3+} occupies no more than 20% of Al^{3+} positions in the Al_2TiO_5 structure, and the region of isovalent substitution is limited to the $Al_{1.6}Ti^{3+}_{0.4}Ti^{4+}O_5$ composition.

In the concentration range $0.3 \le x \le 1$, Magneli phases Ti_nO_{2n-1} ($4 < n < 9$) appear in the thermal-treatment products in addition to the phases of the $Al_{2-2x}Ti^{3+}_{2x}Ti^{4+}O_5$ solid solution and α-Al_2O_3

(Fig. 3, diffraction pattern b). Aluminum titanate reacts with Ti_2O_3 to form Ti_nO_{2n-1} in accordance with the equation

$$(n - 2)Al_2TiO_5 + Ti_2O_3 = Ti_nO_{2n-1} + (n - 2)Al_2O_3. \quad (4)$$

The sum of reactions (3) and (4) has the form

$$(n - 1)Al_2TiO_5 + (x + 1)Ti_2O_3 = Al_{2-2x}Ti^{3+}_{2x}Ti^{4+}O_5 + Ti_nO_{2n-1} + (n - 2 + x)Al_2O_3. \quad (5)$$

The results of an electron microprobe analysis of the products of calcination of the starting Al_2TiO_5–$1.0\,Ti_2O_3$ sample confirm the presence of the Magneli phase (Ti 34.5 mol % and O 65.5 mol %) and that of the $Al_{1.75}Ti^{3+}_{0.25}Ti^{4+}O_5$ solid solution. In the concentration range $0.2 < x < 1$, the lattice constants of the resulting $Al_{2-2x}Ti^{3+}_{2x}Ti^{4+}O_5$ solid solutions are close within the experimental error and independent of the Ti_2O_3 content in the starting stock (Table 2).

The dependences of the physical characteristics of samples on the content of titanium(III) oxide in $Al_2TiO_5 + xTi_2O_3$ starting mixtures, obtained in this study, show that the water absorption by the material decreases from 17.9 to 4.6%, and the open porosity, from 39.0 to 17.7%, as the Ti_2O_3 content in the stock increases, which points to activation of sintering processes (Fig. 4). The strongest effect of the compaction of aluminum titanate ceramics is achieved when 23 mol % Ti_2O_3 is introduced, and further increase in the content of Ti_2O_3 does not improve the physical characteristics. The resistance of the samples synthesized (Fig. 4) to concentrated H_2SO_4 increases as the content of the $Al_{2-2x}Ti^{3+}_{2x}Ti^{4+}O_5$ solid solution enriched with titanium, relative to that of aluminum titanate, in a sample increases. Such a dependence of the acid-resistance on the sample composition can be attributed to a lower mobility of titanium atoms, compared with aluminum atoms, resulting from the difference in their radii [$R(Ti^{3+}) > R(Al^{3+})$]. The improvement of the physical characteristics and the chemical resistance of a ceramic material by introducing Ti_2O_3 enables extension of the application area of materials based on Al_2TiO_5.

CONCLUSIONS

It was found that, under the chosen conditions of thermal treatment (1400°C), Ti^{3+} occupies no more than 20% of Al^{3+} positions in the Al_2TiO_5 structure and the range of isovalent substitution is limited to the $Al_{1.6}Ti^{3+}_{0.4}Ti^{4+}O_5$ composition.

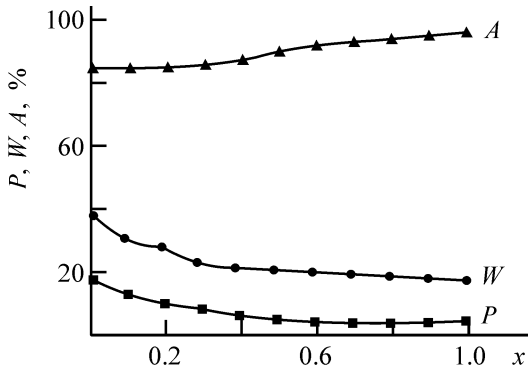

Fig. 4. Water absorption *W*, open porosity *P*, and acid-resistance *A* of the material obtained from the Al_2TiO_5 + xTi_2O_3 starting mixture vs. the parameter *x*.

The strongest effect of compaction of ceramics based on aluminum titanate is achieved by introducing up to 23 mol % Ti_2O_3, and further increase in the content of Ti_2O_3 does not result in any noticeable improvement of physical characteristics. The resistance of a ceramic material based on aluminum titanate to concentrated sulfuric acid increases with the content of titanium(III) in the samples studied.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Comparative Study of the Combustion of Formulations Based on Sodium Chlorate and Polyethylene in the Form of Powder or Tubes

O. N. Kirsanov

Prikladnaya Khimiya Russian Scientific Center, Federal State Unitary Enterprise, St. Petersburg, Russia

Received March 20, 2003; in final form, June 2005

Abstract—A comparative study of the combustion rate under atmospheric conditions, of formulations with different compositions based on sodium chlorate and polyethylene in the form of powder or tubes (layered system) was carried out.

Previously, the combustion rate of formulations based on $NaClO_3$ and polyethylene (PE) and kerogen in the form of powders, which are typical disordered systems for gunpowder and explosives, have been studied [1]. This was done in a narrow range of compositions, evaluated by the oxidant excess coefficient of 0.37 to 1.5 for kerogen and 0.5 to 1.5 for polyethylene as combustibles. It became necessary to carry out studies in a wider range of compositions and with polyethylene in the form of tubes, a layered system. This is due to the necessity to determine the limits of stable combustion of the formulations considered and to examine in more detail the combustion process itself. Based on the data obtained, the present study assessed the possibility of transition of the combustion from deflagration to detonation.

In this stage, we studied the macrokinetics of combustion of formulations based on $NaClO_3$ and PE in the form of a powder, with an oxidant content increased to the point of combustion damping, and with PE in the form of tubes (layered system), also, when possible, as far as the stable-combustion boundaries, on a laboratory setup. The interest in a layered system is due to its presumably higher stability against transition from deflagration to detonation. The study was carried out in order to search for, and create, new materials necessary for mining industry for extraction of block stone and for building industry for safe destruction of natural and artificial objects.

EXPERIMENTAL

We studied the combustion of a formulation composed of $NaClO_3$ and polyethylene experimentally on a setup similar to that used previously [1]: the transit time of a combustion front between two reference points spaced by a distance l = 55 mm (determined when assembling the of contacts). The measuring system included two electric circuits with one dc power source (V = 25 V) connected to the electrically conducting case. Each circuit had an electric contact introduced via a ceramic nonconducting channel into the case. Ionization contacts were mounted at a distance of 10–15 mm from the upper and lower edges of the cylindrical case in order to preclude any influence of transients in ignition and termination of combustion. The instants at which the combustion surface passed the contacts (reference points) were recorded as successive closure of the contacts of two electric circuits connected to a P14M electric stopwatch. The tests were performed under atmospheric pressure at ambient temperature. The combustible formulation included $NaClO_3$ of a 25–150-μm fraction (60% 25–65-μm fraction) as oxidant and PE in the form of a powder of a 10–180-μm fraction (71% 15–65-μm fraction) or as tubes (d 5–7 mm, wall thickness 150–500 μm) as a combustible. The mass of $NaClO_3$ was varied in each experiment within the range 57–82 g. A preliminarily blended mixture of $NaClO_3$ and PE of a prescribed (as regards the oxidant excess coefficient) composition was charged to a height of 80 mm into an experimental steel vessel (d 30 mm, wall thickness 1 mm) made of Kh18N9T steel, and the mass of the experimental vessel and of the formulation charged was measured. The scatter in bulk density did not exceed ±7% for an oxidant excess coefficient equal to unity and ±4% for other compositions. When studying the layered system, we first charged tubes of required dimensions and amount (mass) prescribed by calcula-

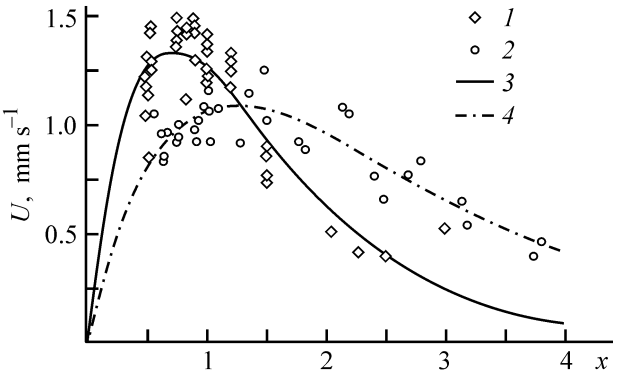

Fig. 1. Linear combustion velocity U of the formulations vs. the oxidant excess coefficient x. Experimental data for formulations: (*1*) $NaClO_3$ + PE (powder), (*2*) $NaClO_3$ + PE (tubes), (*3*) approximation for formulation *1*, and (*4*) approximation for formulation *2*.

tion into the gas-generator case, weighed the vessel on a VLK-500 balance, and charged $NaClO_3$ in several stages, with the vessel tapped from time to time (manual vibration compaction). The scatter in bulk density did not exceed ±7% in this case. The fuel formulation was ignited by lighting a 1-g portion of black powder with a Nichrome coil (V = 12 V, R = 1 Ω). To obtain more reliable results, we performed all the tests at least twice. The linear combustion velocity U (mm s^{-1}) of the formulation was determined by the equation

$$U = l t_c^{-1},$$

where l is the distance between the reference points (mm, absolute measurement error 1 mm), and t_c is the combustion time of the formulation between the reference points (s, absolute measurement error 0.01 s).

The total relative error in measuring the linear combustion velocity did not exceed 3%:

$$3\% \le \left(\frac{100}{55} + \frac{0.01}{50}\right) \times 100\%.$$

The main results of the experiments on the influence exerted by composition (evaluated by the oxidant excess coefficient x) on the linear combustion velocity of combustion of the formulations studied are presented in Fig. 1. The lines in the figure are plotted using regression equations obtained in a polynomial processing of the experimental data by the least-squares method. For a formulation composed of $NaClO_3$ and PE powder, the following regression equation was obtained with a correlation coefficient of 0.92:

$$U = 5.024x \exp(-1.387x).$$

According to the calculation, the maximum linear combustion velocity of the given formulation is 1.33 ± 0.04 mm s^{-1} at an oxidant excess coefficient x = 0.72. The fact that the regression equation of the process differs from that used previously [1] is largely due to the wider variation range of the formulation composition. It follows from these data that the interval of oxidant excess coefficients in which the combustion of the powder system is reliable and stable is $0.5 \le x \le 2.3$.

For the layered system, the regression equation (correlation coefficient 0.91) has the form

$$U = 2.211x \exp(-0.78x), \text{ mm } s^{-1}.$$

For this formulation, the maximum linear combustion velocity is 1.09 ± 0.04 mm s^{-1} at an oxidant excess coefficient x = 1.26. For the layered system, the interval of compositions with a reliable stable combustion is considerably wider than that for the powdered system: $0.5 \le x \le 3.7$, although a stable combustion was observed in a gas-generator 40 mm in diameter even at an oxidant excess coefficient of 5.7. It can be seen from the results presented that, first, the combustion velocity of the powdered formulation in the stoichiometric region exceeds that of the layered system and, second, the interval of stable combustion of the layered system is considerably wider than that for the powdered (disordered) system. This can be attributed to a difference in the rates of processes of purely physical nature: both to a higher rate of gasification of a PE powder and $NaClO_3$, compared with gasification of tubes (thickness 25–65 and 150–500 μm, respectively), and to a shorter time of gas mixing for the powdered system. This time can be evaluated using the Fourier diffusion criterion:

$$\text{Fo} = D_{i,j} \tau l^{-2},$$

where $D_{i,j}$ is the diffusion coefficient of the components (taken to be the same for all the components in the case in question, with only gases involved); τ, time of mixing of the gases; and l, mixing path proportional to the geometrical parameters of the systems (grain size or tube diameter).

Then the ratio of the mixing times will be on the order of

$$\frac{\tau_1}{\tau_2} \approx \frac{D_1}{D_2}\left(\frac{d_1}{d_2}\right)^2,$$

where subscript 1 refers to the layered system, and subscript 2, to the disordered (powdered) system.

Our calculation shows that the maximum mixing time for the layered system (tube diameter 5.0 mm) exceeds that for the powdered system (grain size 60 μm) by two to three orders of magnitude. This is one of the main reasons why the combustion velocity of the powdered system exceeds that for the layered system.

It is necessary to take into account the fact that PE gasification occurs with heat consumption. Therefore, the larger the mass of PE, the lower the overall rate of the process. Probably, the wider interval of stable combustion of the formulation composed of $NaClO_3$ and PE tubes, with an oxidant excess coefficient exceeding 1.5, and its lower combustion velocity in the stoichiometric region can be understood as follows. The combustion of the oxidant and combustible in a layered system undergoing gasification [2, 3] occurs in the mixing zone, similarly to the combustion of unmixed gases, with the same cross-sectional inhomogeneity of the concentration fields and the same composition dependence of the flame jet length (10 to 30 cm). The main source of heat is localized near the surface of PE tubes undergoing gasification. The gasification rate of the components depends on the heat flux. A part of the heat released in the combustion is consumed for gasification of an additional mass of $NaClO_3$. It is necessary to take into account that $NaClO_3$ heated to above 623 K decomposes with release of approximately 54.76 J mol^{-1} [4]. All these factors, combined, provide a wider interval of stable combustion of the layered system. In an ordinary disordered system (with powdered components), heat is released uniformly over the entire cross-section. The experimental data on the relative combustion velocities of the layered and disordered systems, presented here, differ from the results obtained with a model system [2]. Possibly, this can be attributed to the fact that the study [2] was performed on models having the form of separate Plexiglas tubes with oxidants ($KClO_4$, $KClO_3$) compacted within the tubes.

To confirm the hypothesis that the gasification rate affects the whole process, we performed a qualitative numerical experiment to evaluate, under certain assumptions, the time and rate of heating of PE and $NaClO_3$ powders (loose material) and of a PE film. As the diameter of the PE tubes exceeds by approximately an order of magnitude the wall thickness, the latter can be considered a planar thin film. Let us take the grain size of PE and $NaClO_3$ to be 60 μm, and the wall thickness of PE tubes, 300 μm (a size promising for practical implementation). The thermal properties of the material are believed to be constant [4, 5]. All the calculations of nonstationary heat exchange are simplified if the body has a low internal resistance (Bio criterion $Bi = \alpha l \lambda^{-1} < 0.1$ [6]). In this case, the temperatures of the surface and mid-part of a body being heated or cooled are nearly the same [6].

Let us determine the interval in which this criterion varies for a film at the following values of the parameters involved: $\lambda = 0.418–0.440$ W m^{-1} deg^{-1} and $\alpha = 2.5–250$ W m^{-2} deg^{-1}. Then we have for the film $0.002 < Bi < 0.18$. We calculate the interval of variation of the Bio criterion for a $NaClO_3$ powder for the following values of the parameters: $\lambda = 0.64–1.28$ W m^{-1} deg^{-1} and $\alpha = 2.5–250$ W m^{-2} deg^{-1}. The calculation yields $0.00004 < Bi < 0.008$. Thus, the absence of a temperature gradient over the cross-section of the materials under consideration makes it possible to calculate the time (and rate) of heating by the following formulas [6]:

$$\tau = \frac{l}{2}\frac{\rho C_p}{\alpha}\ln\frac{T - T_{in}}{T - T_{fin}},$$

for a PE film and

$$\tau = \frac{r}{3}\frac{\rho C_p}{\alpha}\ln\frac{T - T_{in}}{T - T_{fin}},$$

for $NaClO_3$ and PE grains. Here, ρ is the component density (kg m^{-3}); α, heat-transfer coefficient (W m^{-2} deg^{-1}); l, PE film thickness (m); r, $NaClO_3$ (PE) grain radius (m); C_p, specific heat of the component (J kg^{-1} deg^{-1}); T, flame temperature (K); T_{in}, initial temperature of the component (K); and T_{fin}, final temperature of the component (K).

We take the following values of the parameters: $C_p = 1880$ J kg^{-1} deg^{-1} for polyethylene and 1200 J kg^{-1} deg^{-1} for $NaClO_3$; ρ, 959 and 2490 kg m^{-3}, respectively; initial temperature of the components, 293 K; final temperature equal to the destruction temperature of 763 K for PE [5]; and decomposition temperature of technical-grade $NaClO_3$ equal to 643 K [4]. More reliable results, even for a qualitative numerical experiment, would be obtained by direct measurements on the surface of the components during combustion, as it was done by Zenin [7], or by using the Mikhel'son equation. Experimental data [7] on the temperature profile refer to a layer of a solid substance, gunpowder N, with the temperature gradient in the condensed phase reaching a value of approximately 2000 deg mm^{-1}. Such a temperature gradient is impossible for thin bodies [6]. When using the Mikhel'son equation, it is necessary to calculate the thermal diffusivity of a loose material composed of dissimilar substances (PE and $NaClO_3$). The pres-

It is necessary to take into account that the real combustion temperature is lower than the calculated value by the amount of loss of heat, which is proportional to that presented. Table 1 lists the calculated times of heating of a PE film to the destruction temperature (taken to be equal to the gasification temperature) in relation to the flame temperature and heat-transfer coefficient. The last row presents data for an oxidant excess coefficient $x = 5$ and flame temperature of 1516 K.

The velocity of heating *W* to a prescribed temperature (destruction temperature) can be obtained (Table 2) by dividing the film thickness by the time listed in Table 1.

For comparison, we present data on the time of heating of a $NaClO_3$ powder to the decomposition

temperature (Table 3) at the same heat-transfer coefficients and flame temperatures as those for the PE film.

As can be seen from Tables 1 and 3, the time of PE heating to the destruction temperature exceeds by more than an order of magnitude the time of $NaClO_3$ heating to the decomposition temperature. Consequently, the influence of heating of the $NaClO_3$ powder can be neglected. As the velocity of heating of the PE film must exceed the overall combustion velocity (about 1 mm s^{-1}), it is sufficient to consider only the last two columns in Table 2 in a comparison with the experimentally measured motion velocity of the combustion front. Figure 2 shows, as functions of the oxidant excess coefficient, experimental data on the combustion velocity (curve *1*) and PE film heating velocities for heat-transfer coefficients of 250 and 150 W m^{-2} deg^{-1} (curves *2* and *3*, respectively). It can be seen that the run of the curves describing the PE film heating velocity virtually coincides with the experimental data on the combustion velocity. Thus, there is reason to believe that the heating process noticeably affects the entire process, being, in fact, of the diffusion type. This is not the case for a formulation composed of $NaClO_3$ and powdered PE (typical disordered system). It follows from the calculations that the time of PE powder heating virtually coincides with that of $NaClO_3$ powder heating, being more than order of magnitude shorter than that for the PE film. Therefore, the powder heating process cannot exert the same influence (diffusion hindrance) on the overall process as the process of heating of the PE film.

As another evidence in favor of the influence exerted by the heating velocity (diffusion factor) on the overall process can serve the type of dependence of the reaction rate on the reciprocal temperature, which can be used to determine the region in which the process occurs and to evaluate the activation energy. We can calculate this parameter by the known formula [9], taking the combustion velocity as the reaction rate (which is possible because the velocity ratios are considered):

$$E = \frac{8.314 \ln (u_2/u_1)}{1/T_1 - 1/T_2},$$

where u_1, u_2 are the combustion velocities U (mm s^{-1}) at temperatures T_1 and T_2, respectively.

Let us substitute into the formula the combustion velocities from the regression equations and the corresponding temperatures from a thermodynamic calculation. As the combustion velocity passes through a maximum, parameters referring either to the ascending or to the descending portion of the curve for

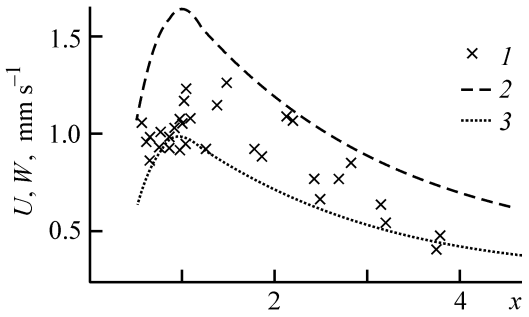

Fig. 2. Comparison of (*1*) combustion velocity *U* of a formulation composed of PE tubes and $NaClO_3$ with (*2*, *3*) heating velocity *W* of a PE film (tubes). (*x*) Oxidant excess coefficient. Heat-transfer coefficient (W m^{-2} deg^{-1}): (*2*) 250 and (*3*) 150.

the combustion velocity can be taken for the calculation. We assume that the activation energy remains constant during the process under study. For the layered system, the flame temperature T_1 = 2545 K and the combustion velocity found from the equation, u_1 = 0.93 mm s^{-1}, for an oxidant excess coefficient x = 2, and T_2 = 1719 K and u_2 = 0.391 mm s^{-1} for x = 4. Substituting these values into the equation, we obtain E = 38 kJ mol^{-1}. The results of the calculation indicate that the combustion of the layered system occurs in an intermediate region that is far from the kinetic zone and is closer to the purely diffusion region. Consequently, the process of combustion of such a system cannot pass from deflagration to detonation under the real application conditions (gas-generator diameter not exceeding 75 mm). For a formulation with powders, the pattern is entirely different: T = 2980 K, u = 1.33 mm s^{-1} for an oxidant excess coefficient x = 0.72, and T = 2545 K and u = 0.63 mm s^{-1} for x = 2.0. Calculation gives E = 141.7 kJ mol^{-1}. This means that the combustion of the powdered system occurs in the kinetic region, and, consequently, a transition of the ordinary deflagration combustion to the detonation mode is possible. The hypothesis suggested was confirmed by the UN test 1(a) (iii), paragraph 5. Two experiments were performed for each formulation, and one, for a neutral mixture (sand + salt). The tube rupture for the layered system was similar to that for the neutral mixture, which classes the layered system under study with nonexplosive materials. The formulation composed of $NaClO_3$ and diesel fuel (tested by the same procedure) belongs to explosives.

CONCLUSIONS

(1) An analysis of how the combustion velocity of formulations based on $NaClO_3$ and polyethylene in the form of a powder (disordered system) or tubes (layered system) depends on the relative content of the oxidant and combustible at an oxidant excess coefficient x varied from 0.5 to 3.7 demonstrated that the combustion velocity depends on the composition of the formulations under study and reaches a maximum in the region close to the stoichiometry.

(2) The maximum linear combustion velocities are 1.33 mm s^{-1} for the powdered system (oxidant excess coefficient 0.72) and 1.09 mm s^{-1} for the layered system (oxidant excess coefficient 1.26).

(3) The formulations exhibit reliable combustion at oxidant excess coefficients in the range 0.5–2.3 for the disordered system and 0.5–3.7 for the layered system, with this range being extendible in the latter case. Making larger the diameter of the experimental vessel extends the range of stable combustion to larger oxidant excess coefficients.

(4) The run of the curves describing the heating velocities of polyethylene films virtually coincides with that of the curves for the combustion velocities of the layered system.

(5) The combustion of the layered system occurs in the diffusion region, which follows from the results obtained in determining the activation energies and from the collinearity of the curves for the combustion and heating velocities. The combustion of systems of this kind occurs only in the deflagration (nondetonation) mode.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Application of the Hole Group Quasi-Chemical Model to Evaluation of Azeotropic Properties[1]

I. V. Prikhodko and A. M. Chudakov

St. Petersburg State University, St. Petersburg, Russia

Received May 12, 2005

Abstract—Azeotropic parameters (composition, boiling point, equilibrium pressure) were calculated in terms of the Viktorov–Smirnova lattice-hole quasi-chemical group model for binary and ternary systems in which there is no stratification of solutions formed by various components (hydrocarbons, alkanols, acetic acid, ethanoates, chloroform, acetone, pyridine, and water). Azeotropes of various kinds (positive, negative, saddle-type) were found using simple algorithms, including composition variation. Thirty binary, nine ternary, and one quaternary systems were considered. New group parameters were evaluated. The results of calculations of azeotropes were compared with published experimental data.

Information about existence of azeotropes and knowledge of their characteristics in binary and multicomponent systems are necessary for analysis of the phase behavior in designing technological schemes for separation processes and, in particular, azeotropic rectification. Because an azeotrope is an important feature of the phase diagram, calculation of parameters of the azeotropic state is an important aspect of the general problem of modeling of the phase equilibrium. Such a calculation is simultaneously an effective means of verification of a method used to model the vapor–liquid equilibrium.

Previously, Storonkin and co-workers carried out extensive studies of azeotropic properties. In particular, they formulated rigorous thermodynamic expressions for Vrevsky rules, found factors determining how the composition of azeotropes varies with temperature and pressure, and derived for systems with solution stratification expressions similar to Vrevsky rules for multicomponent systems. They found experimentally how the composition of azeotropes varies with external conditions for numerous binary and ternary systems. The main results of this set of investigations were summarized in the monograph [1]. No studies devoted to prognostication of azeotropic properties with model equations were carried out at that time because equations of local composition and others had not been known yet.

Since the 1970s, models of local composition (e.g., Wilson, NRTL, and UNIFAC equations) have been the most frequently used in practical calculations of phase equilibria at low pressures [2]. At elevated pressures, equations of the Van der Waals type (Peng–Robinson, Soave–Redlich–Qwong equations etc.) [3, 4] have been widely used. The above models we used to determine parameters of a wide variety of azeotropes [5–16].

In the present study, the azeotropic properties were evaluated using a group equation of state based on the lattice-hole model (HM) suggested by Smirnova and Viktorov [2, 17]. The HM was successfully tested on single-component, binary, and multicomponent systems in widely varying conditions [2, 17–26]. The model satisfactorily describes equilibria of fluid phases in various mixtures in a wide range of temperatures and pressures. However, the problem of determining the ability of HM to prognosticate azeotropic parameters has not been specially considered previously. In addition, the HM has not been tested at all on a number of systems. In particular, the necessary parameters of the model for chloroform, cyclohexane, and perfluorobenzene have not been determined. The aim of the present study was to describe the vapor–liquid equilibrium for a number of binary systems including the above-mentioned substances, evaluate new group

parameters, predict azeotropic properties of mixtures with different numbers of components with the help of HM, and compare the calculated results with experimental data. Homogeneous azeotropes of various kinds were found using simple, well-proven techniques based on successive changes in the molar fractions of the components [2, 6].

According to HM, pressure P is a sum of two contributions, repulsive (P_{rep}) and residual (P_{res}).

The repulsive pressure component, which takes into account differences in size and shape between molecules constituting a system, is evaluated by the Staverman formula. The residual contribution takes into account differences in interaction energy between neighboring pairs of different types and reflects orientation effects appearing because of the energy-nonuniformity of the molecular surface. This contribution is calculated in the quasi-chemical approximation:

$$P = P_{rep} + P_{res},$$

$$P_{rep} = -\frac{RT}{v^*} \times \left\{-\ln(1-\tilde{\rho}) + \tilde{\rho}\frac{\sum_{i=1}^{n} x_i l_i}{\sum_{i=1}^{n} x_i r_i} + \frac{z}{2}\ln\left[1 - \tilde{\rho}\left(1 - \frac{\sum_{i=1}^{n} x_i q_i}{\sum_{i=1}^{n} x_i r_i}\right)\right]\right\},$$

$$P_{res} = -\frac{RT}{v^*}\left\{z \ln X_0\right\}, \quad (1)$$

where v^* is the molar volume per lattice site (volume of a standard segment); x_i, mole fraction of ith component; $l_i = -z(q_i - r_i)/2 - (r_i - 1)$, molecule volume factor; z, coordination number of the lattice; r_i and q_i, geometric parameters of the model, which characterize the volume and surface area of ith molecule and are related to the corresponding quantities for groups constituting the molecule by $r_i = \sum_s \nu_s r_s$ and $q_i = \sum_s \nu_s q_s$, where ν_s is the of groups of sth kind in ith molecule; $\tilde{\rho} = v^* \sum_{i=1}^{n} \nu_i r_i / v$, reduced density ($v$, molar volume); and X_0, solution to a system of quasichemical equations

$$X_s \sum \alpha_t X_t \exp\left(-\frac{\Delta\varepsilon_{st}}{kT}\right) = 1.$$

Here, subscripts s and t designate regions of the molecular surface (group) whose interaction is described by interchange energies $\Delta\varepsilon_{st}$, with $s = 0$ for vacant lattice sites (holes); α_t is the fraction of the surface area occupied by groups of tth kind in the system.

The values of $\Delta\varepsilon_{st}$ are temperature-dependent:

$$\frac{\Delta\varepsilon_{st}}{kT} = w_{st} + h_{st}\frac{T_0 - T}{T} + c_{st}\left(\ln\frac{T_0}{T} - \frac{T_0 - T}{T}\right),$$

where w_{st}, h_{st}, and c_{st} are, respectively, the free energy, enthalpy, and specific heat of interchange (dimensionless energy parameters of the model); and T_0 is the chosen standard temperature.

To carry out calculations in terms of the lattice-hole model, it is necessary to have a set of geometric (r_s, q_s) and energy (w_{st}, h_{st}, c_{st}) parameters of the groups. The HM and the algorithm of calculations in terms of this model were described in most detail in [2, 17].

The geometric and energy parameters of the HM have been obtained previously for quite a number of chemical groups [2, 18–22, 24–26]. In particular, the model has been applied to description of systems containing various hydrocarbons, alkanols, esters (ethanoates), water, acetone, acetic acid, etc. In the group approach used in the HM, component molecules were divided into groups as follows: two

types of groups, CH and 3Cl, were distinguished for chloroform $CHCl_3$, and six CH_2 and CF groups for cyclohexane and hexafluorobenzene, respectively. In the calculations in terms of HM, the molar volume of a standard segment was taken to be v^* = 14.244 $cm^3\ mol^{-1}$, and the coordination number of the lattice, z = 10. For groups of chloroform, the volume factors were evaluated using Bondi tables [27]. For the molecules C_6H_{12} and C_6F_6, which have a cyclic structure, the volume factor l = 1. The values of the group parameters, obtained in this study, and the results obtained in describing the saturated vapor pressure and the liquid phase density for these substances are listed in Table 1. It can be seen that the values of the properties, calculated using the HM, are in a good agreement with experimental data [28].

New energy parameters of group interaction (Table 2) for mixtures containing acetone, benzene, methyl acetate, chloroform, cyclohexane, and perfluorobenzene were evaluated using experimental data on the vapor–liquid equilibrium in binary systems (pressure–solution composition). The results of modeling are listed in Table 3, with the predicted values of the equilibrium pressure denoted by abbreviation "pred." The results obtained in calculating the liquid–vapor equilibria can be considered quite satisfactory. The list of the new parameters (Tables 1 and 2), combined with those obtained previously for other chemical groups, is sufficient for describing the liquid–vapor equilibrium and calculating azeotropes in binary and multicomponent mixtures containing a variety of organic components, including those mentioned above.

Now, the calculation of azeotropes will be described in more detail. The homogeneous azeotrope was found in accordance with the equation

$$x_i = y_i,\ i = 1, 2, ..., n, \qquad (2)$$

where x_i and y_i are the mole fractions of *i*th component in the liquid and vapor phases, respectively; $\sum_{i=1}^{n} x_i = 1$, $\sum_{i=1}^{n} y_i = 1$.

In a search for an azeotrope, it is convenient to introduce the distribution coefficient defined by

$$K_i = y_i/x_i,\ i = 1, 2, ..., n, \qquad (3)$$

and calculated in terms of the model at a given solution composition.

Table 3. Results of description of the vapor–liquid equilibrium for binary mixtures

* $\Delta y = \frac{1}{N}\sum_{i=1}^{2}\sum_{j=1}^{N}\left|y_{i,j}^{\exp} - y_{i,j}^{\mathrm{calc}}\right|$, where $y^{\exp}$ is the experimental vapor composition, and y^{calc}, that obtained by calculation; i = 1, 2 (components); j = 1, ..., N (number of points).

The composition of an azeotrope can be found by minimizing the functional [2, 6]

$$F = \sum_{i=1}^{n} |K_i - 1|. \quad (4)$$

This functional is convenient for calculating azeotropes of various kinds under both isothermal and isobaric conditions and is sensitive to minor changes in the concentration of the mixture. The deviation of F from zero can be used to characterize the precision of solution to system (3).

In the present study, the minimum of the function F was sought using the method of coordinate-wise dichotomy. The search for an azeotrope was continued until the condition $F < 10^{-4}$, which corresponds to the experimental error in determining the azeotropic composition, was satisfied. If the required accuracy could not be achieved by means of this algorithm, the search was continued with other starting composition approximations. Under isobaric conditions, the temperature was calculated by iterations, until the calculated and prescribed values of the total pressure coincided to within $\left|\left(P_i^{\exp} - P_i^{\text{calc}}\right)/P_i^{\exp}\right| \le 10^{-5}$. In a search for the minimum of the target function (4), the equilibrium properties of the vapor–liquid mixture [vapor composition y_i, distribution coefficients K_i, boiling point (P = const) or saturation pressure (T = const)] were calculated at each running value of the solution composition. The clearly pronounced positive azeotropes (with a minimum boiling point and maximum vapor pressure) were also found using another method. Such an n-component azeotrope can be calculated as a final point to which tends the line of conjugated liquid–vapor nodes [2]. In this case, a value of the equilibrium vapor composition, calculated in a preceding step, is assigned to the mole fraction of the solution in any succeeding step of the search. The calculation is continued until the value of F, given by expression (4), becomes smaller than 10^{-4}.

Now the results of the calculation will be discussed. First, several general remarks should be made. It is noteworthy that azeotropic data were not used to determine or refine the HM parameters. The method of coordinate-wise dichotomy proved to be rather effective for finding an azeotrope in the binary, ternary, and quaternary systems under consideration (Tables 4–6) under isobaric and isothermal condi-

tions. As shown in [2, 6], this method successfully works for homogeneous azeotropes of various kinds (positive, negative, and saddle-type) and is suitable for mixtures with a tangential azeotropy. It was found that the method of conjugated nodes is insensitive to the choice of a starting compositional approximation (except at $x_i = 0$) and is quite reliable in determining clearly pronounced positive binary and ternary homoazeotropes. The coordinates of a positive azeotrope, found using the method of conjugated nodes and by successive variation of mole fractions virtually coincide.

The results of a calculation of azeotropic parameters of binary systems are listed in Table 4. The hole lattice model adequately reflects the shift of the azeotrope on changing the pressure (temperature). Also correctly reproduced is the tendency toward variation of the parameters of azeotropes in homologous series of mixtures (e.g., toluene + alkanols, acetic acid + alkanes). The model well reproduces the coordinates of azeotropes at temperatures of 400–500 K. For the mixtures tested, the absolute deviation of a calculated azeotropic composition from the experimental value is within 0.001–0.1 mol fraction. The boiling point and the pressure of the azeotrope, predicted using the HM, are close to the corresponding experimental values.

An interesting system in which an unusual phase behavior was observed (double azeotropy) is a mixture of benzene and perfluorobenzene. However, the HM erroneously predicts the phase diagram of this system: only a single positive azeotrope can be found, with its composition and pressure at a given temperature markedly deviating from the values observed in the experiment.

Table 5 demonstrates the results obtained in prognostication of azeotropic properties for ternary mixtures. As examples were chosen systems with both positive and saddle-type azeotropes; systems with a low content of one of the components in an azeotropic mixture. As in the case of binary systems, the calculated boiling points (equilibrium pressures) are rather close to the experimental values. However, the compositions of the tangential and saddle-type azeotropes, predicted by the HM for a number of mixtures, markedly differ from the experimental values (Table 5, system nos. 5 and 7).

* $\Delta\bar{x} = \frac{1}{4}\sum_{i=1}^{4}\left|x_i^{\text{az.exp}} - x_i^{\text{az.calc}}\right|$, where $x^{\text{az.exp}}$ and $x^{\text{az.calc}}$ are the experimental and calculated values of the azeotrope composition; i = 1–4 (components).

** Designations Wilson 1 and NRTL 1 mean that the corresponding models of local composition and the method of branches and boundaries are used; Wilson 2 and NRTL 2 correspond to use of the above models in combination with the method of interval analysis.

Table 6 compares the results of calculations for a quaternary azeotrope, obtained using different models, with the experimental data for the system acetone + chloroform + methanol + benzene. Among the binary subsystems of this four-component mixture, two are nonazeotropic (benzene + acetone and chloroform + benzene); these subsystems were used to evaluate new energy parameters of the HM (Table 2). As can be seen in Table 6, all the models used describe, for the above mixture, rather reasonably describe the composition and the boiling point of the azeotrope. The results obtained with different models and methods of search for an azeotrope suggest that the HM and the Wilson equation have an advantage. The results obtained in modeling the liquid–vapor equilibrium for the binary mixtures considered, both containing and not containing an azeotrope (Table 3), suggest that the HM is a suitable method for prognostication of a multicomponent azeotrope.

The discrepancy between the calculated and experimental azeotropic properties is due to an inaccuracy of both the model used and algorithm chosen for a search for an azeotrope, which is confirmed by the results of [9–12]. As demonstrated by tests, simple methods of search for azeotropes can be of use in engineering calculations. In particular, the method of conjugated nodes proved to be rather effective for finding a pronounced positive n-azeotrope in an n-component system. However, this method cannot be used for finding saddle-type (and tangential) azeotropes. It should be noted that the method of coordinate-wise dichotomy is devoid of this disadvantage and allows calculation of azeotropes of these types.

CONCLUSIONS

(1) The database of group parameters of the hole model was expanded. It was supplemented with parameters necessary for calculation of phase equilibria in systems containing hydrocarbons (saturated cyclic, aromatic), methyl acetate, chloroform, acetone, alkanols (methanol, ethanol), and perfluorobenzene.

(2) Tests of the Viktorov–Smirnova lattice-hole group model demonstrated that it predicts azeotropic properties for most of binary mixtures with accuracy satisfactory for technological applications.

(3) For ternary systems with a clearly pronounced positive azeotrope, the hole model predicts azeotropic parameters with an acceptable accuracy. For mixtures with tangential or saddle-type azeotropes, the model gives a good agreement between the experimental and calculated boiling points and pressure; however, the composition may show strong deviations.

(4) Simple calculation algorithms of search for homogeneous azeotropes proved to be quite effective for the systems considered.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Calculation of the Critical Parameters of Inorganic Compounds by the Additive Method

I. B. Sladkov and E. V. Pobedonostseva

St. Petersburg State Polytechnic University, St. Petersburg, Russia

Received April 7, 2005

Abstract—A set of 100 substances was studied to obtain data that would allow application of the additive method to calculation of critical parameters of inorganic compounds. An additive scheme that makes it possible to improve the accuracy of calculation of the critical pressure of inorganic compounds was suggested.

At present, methods of the thermodynamic similarity theory are widely used to prognosticate physicochemical properties of substances [1, 2]. In this case, the critical parameters of substances serve as input data for a calculation. Published data on critical parameters are rather scarce. Experimental determination of critical parameters involves severe difficulties. Of particular practical importance in this context is determining the critical parameters by calculation.

A possible way to calculate the critical parameters is to sum up the corresponding increments for the elements constituting the molecule of a compound. This method is attractive in that it is based on the minimum amount of information about the substance under study, which frequently does not include any data except the stoichiometric formula.

The additive method for calculation of critical parameters is widely used for prognosticating the critical parameters of organic substances [1, 3]. The potentialities of this technique, as applied to determination of the critical parameters of molecular inorganic compounds, are unknown. This is because the increments are available in the literature for less than 10 elements. These are nonmetals (C, H, O, S, N, F, Cl, Br, I), which constitute molecules of organic substances. However, data on the increments for metals contained in molecules of inorganic and organometallic substances are lacking completely.

The goals of this study were as follows: (a) to obtain missing information about the increments of metals from experimental data on critical parameters and (b) to determine, using the data obtained, the accuracy of calculation of the critical parameters by the additive method for inorganic and organometallic compounds.

The most widely used in the literature is the additive scheme suggested by Leadersen [1]. In this technique, atomic constituents (increments) of the reduced temperature at the boiling point are summed up for determining the critical temperature:

$$\theta = T_{boil}/T_{cr}, \quad (1)$$

where T_{boil} and T_{cr} are, respectively, the temperatures at the normal-boiling and critical points.

The calculational formula for determining θ for a binary compound of the AB_n type has the form

$$\theta = 0.576 + \Sigma\Delta_T - (\Sigma\Delta_T)^2, \quad (2)$$

$$\Sigma\Delta_T = \Delta_T(A) + n\Delta_T(B), \quad (3)$$

where $\Delta_T(A)$ and $\Delta_T(B)$ are the increments of the reduced boiling point θ for elements A and B, respectively; and n is the number of B atoms in compound AB_n.

The critical volume is found in the Leadersen method by the formula

$$V_{cr} = 40 + \Sigma\Delta_V. \quad (4)$$

The critical pressure (MPa) is given by

$$P_{cr} = 0.101325M/(\Sigma\Delta_P + 0.34)^2, \quad (5)$$

where M is the molecular weight of the compound.

In Eqs. (4) and (5), the sum of increments Δ_V and Δ_P is calculated in accordance with Eq. (3).

$SiClF_3$	0.034	60.0	0.547	$SiBr_3Cl$	0.043	85.0	0.665

In the first stage, it was necessary to find the increments Δ_T, Δ_V, and Δ_P for elements-metals. For this purpose, substances with known critical parameters were chosen and Δ(A) (increment for the element-metal A) was found by an inverse calculation by Eqs. (1)–(5) from the known Δ(B) (increment for element B in compound AB_n).

The values of the critical parameters were taken from the reference book [4], with only experimental data used. The data array under study included experimental values of the boiling point and critical parameters for 100 molecular inorganic compounds, 90% of which were compounds of the AB_n type. The resulting values of the increments are listed in Table 1. For most of elements, the increments were determined for several compounds.

As an example of the scatter of increments obtained for different compounds of the same element, Table 2 lists increments of critical parameters for silicon. Use of averaged values of the increments for silicon

* T_{cr}, critical temperature; V_{cr}, critical volume; and P_{cr}, critical pressure.

(Table 1) leads to calculation errors of the critical parameters of silicon compounds, listed in Table 3.

Table 3 also presents the error of the Leadersen method for a set of 100 molecular inorganic compounds. It should be noted for comparison that the accuracy of the Leadersen method (average error) for organic substances is less than 2% for the critical temperature [1], 3.2% for the critical volume [5], and 3.8% for the critical pressure [1]. Thus, the data on the critical temperature and critical volume, obtained for inorganic substances, are in a good agreement with those for organic substances.

It can be seen from Table 3 that, as applied to inorganic compounds, the Leadersen method provides a high accuracy of prognostication of the critical temperature and a satisfactory accuracy of prognostication of the critical volume.

At the same time, the calculation error is unacceptable in the case of the critical pressure. An additive scheme that allows reliable prognostication of the critical pressure of inorganic compounds was developed in this study. The essence of the additive scheme suggested is in the following.

The critical pressure was calculated from the Van der Waals constant b:

$$P_{cr} = RT_{cr}/8b. \quad (6)$$

The critical temperature in Eq. (6) was calculated by the Leadersen equations (1)–(3), and the Van der Waals constant was found using the conventional additivity rule:

$$b = \Sigma\Delta_b = \Delta_b(a) + n\Delta_b(B).$$

The increments of the Van der Waals constant, determined in the study, are listed in Table 1.

As can be seen in Table 3, the method suggested provides a significantly improved accuracy of prognostication of the critical pressure.

The increments obtained in this study make it possible to reliably prognosticate the critical parameters of molecular inorganic compounds with any stoichiometry, as well as those of organometallic compounds (Table 4).

CONCLUSIONS

(1) Data were obtained, which allow application of the additive method to calculation of the critical parameters of inorganic compounds.

(2) The accuracy of prognostication of the critical parameters was established for a set of 100 compounds.

(3) It was shown that the accuracy of data on the critical temperature and critical volume exactly coincides with that of published data for organic compounds.

(4) It was found that the additive scheme suggested makes it possible to improve the accuracy of calculation of the critical pressure for inorganic compounds.

SORPTION AND ION-EXCHANGE PROCESSES

Synthesis, Structure, and Thermal Stability of a Sulfonic Cation Exchanger Grafted to Carbonized Fiber

Yu. G. Egiazarov, L. N. Shachenkova, V. Z. Radkevich, G. N. Lysenko, and B. Kh. Cherches

Institute of Physical Organical Chemistry, Belarussian National Academy of Sciences, Minsk, Belarus

Received January 14, 2004; in final form, February 2005

Abstract—A new kind of sulfonic cation exchanger based on carbonized fiber modified with poly(styrene–divinylbenzene) was prepared by radiation grafting. The structural features and thermal stability of the cation exchangers prepared were studied.

The reduction of toxicity of the automobile exhaust is a topical environmental problem. The solution of this problem includes the exclusion of tetraethyllead as an antiknock additive to gasoline. With this aim, benzine from catalytic craking and reforming is modified by adding high-octane oxygen-containing compounds: methyl *tret*-butyl ether (MTBE) and methyl *tret*-amyl ether (MTAE). In industrial production of these additives, granulated sulfonic cation exchangers Amberlyst 15, Dowex msm 31, KU-23, etc. are used as catalysts [1–3].

It has been reported [4, 5] that FIBAN K-1 gel-like sulfonic cation exchanger based on polypropylene fiber [6] more effectively catalyzes MTBE and MTAE formation than KU-2 × 8 granulated gel-like and Dowex msm 31 macroporous sulfonic cation exchangers.

In this context, it was of interest to develop a catalyst for preparing MTBE and MTAE based on carbonized fiber. Owing to several features (high porosity, small thickness, non swelling in polar solvents), carbonized fibers are more favorable for preparing grafted cation exchangers. In addition, these fibers exhibit a high electrical conductivity. Therefore, we can expect that sulfonic cation exchangers grafted to carbonized fiber will exhibit electrical conductivity irrespective of the moisture content. No data have been reported on sulfonic cation exchangers grafted to carbonized fibers.

EXPERIMENTAL

In our experiments, a nonwoven carbonized fabric Carbopon prepared by carbonization of viscose fiber was used as a fibrous base for a sulfonic cation exchanger.

The main characteristics of Carbopon were as follows: fiber diameter 5–10 μm, capillary moisture capacity 0.64 ml g^{-1}, average pore diameter d_{av} 23 Å, average surface area determined from low-temperature sorption of nitrogen 780 $m^2 g^{-1}$.

In preparing sulfonic cation exchanger grafted to Carbopon, the following procedures were used. A weighed sample of air-dried Carbopon (5 g) was placed on the bottom of a 50-ml test tube and kept under vacuum (1 mm Hg) for 2 h at 90°C. Two identical Carbopon samples were used in parallel experiments. The test tubes containing Carbopon were cooled to room temperature, and a mixture of monomeric styrene and divinylbenzene (10 ml) in methanol (25 ml) was added. The styrene to divinylbenzene molar ratios in the reaction mixtures were 98 : 2 and 75 : 25, which corresponded to their relative content in gel-like (sample no. I) and maroporous (sample no. II) cation exchangers, respectively. The test tubes containing Carbopon and monomer mixture were closed, kept for 4h at 20°C and then placed in a channel of a RKhM-gamma-20 cobalt (Co^{60}) unit for radiation grafting of styrene and divinylbenzene to Carbopon and their simultaneous copolymerization. In these experiments, the exposure time was 15 h, and the irradiation dose up to 4.5 Mrad. After the radiation treatment was complete, the test tubes were removed from the unit, the liquid phase was decanted, and the resulting matrix [poly(styrene–divinylbenzene) grafted to Carbopon] was washed with methanol and then dried at 90 °C.

The content X (weight fraction) of grafted poly(styrene-divinylbenzene) is commonly determined gravimetrically. However, because the resin samples obtained in our experiments are small and their loss is inevitable, the gravimetric measurements are unsuitable. Therefore, we developed a new technique ensur-

ing correct determination of *X* under our experimental conditions. According to this method, the C/H ratios in both the thoroughly dried initial Carbopon [$(C/H)_{Carb}$] and the matrix based on poly(styrene–divinylbenzene) grafted to Carbopon fiber [$(C/H)_{matr}$] were determined. Taking into account that the C/H ratio in poly(styrene–divinylbenzene) is 12, *X* was determined from the equation

$$12X + C/H_{Carb}(1 - X) = C/H_{matr}.$$

We found that $(C/H)_{Carb}$ is 36.7, and $(C/H)_{matr}$, 27.2 and 27.9, for sample nos. I and II, respectively. The calculated *X* values were 0.38 and 0.35 for samples nos. I and II, respectively. The degree of grafting (the weight ratio of the grafted copolymer to the initial Carbopon) was 61 and 54 for sample nos. I and II, respectively.

A matrix based on poly(styrene–divinylbenzene) grafted to Carbopon was sulfonated with concentrated sulfuric acid (d = 1.84 g cm^3) in a glass reactor for 4 h at 90–95°C. The resulting sulfonated matrix was washed with water to neutral reaction to remove H_2SO_4 and dried at room temperature.

The sorption exchange capacity of sample nos. I and II, determined by procedure reported in [7], was 1.7 and 1.3 mg-equiv g^{-1}, respectively.

The distribution of cation-exchange groups across the fibers of the sulfonic cation exchangers was determined as follows. An excess of 1 N aqueous $BaCl_2$ was passed though a column packed with a weighed sample of the cation exchanger tested until the pH of both the eluent and eluate became equal [8]. Under these conditions, the initial sulfonic cation exchanger is converted to the Ba^{2+} form. This resin was washed with water to complete absence of chloride anions in the wash water and then was air-dried at room temperature. The distribution of Ba across the fiber was determined X-ray fluorescence microanalysis on a Cam Scan electron microscope equipped with an AN-10 000 energy-dispersive spectrometer (Link Analytical, UK).

The X-ray fluorescence microanalysis showed that the gel-like cation exchanger (sample no. I) has uniform distribution of cation-exchange sites across the fiber (Fig. 1a). At the same time, the macroporous cation exchanger is characterized by increased functional group concentration on the fiber periphery (Fig. 1b).

A thermogravimetric analysis of cation exchangers was carried out in air within the temperture range 20–250 °C at a heating rate of 5 deg min^{-1}. The heating of initial Carbopon from room temperature to 90–100 °C is accompanied by large weight loss due to vaporization of water from pores. In going to a grafted sulfonic cation exchanger, the temperature range corresponding to intensive weight loss is shifted to higher temperatures (130–150°C) (Fig. 2a). The weight loss

by sample no. I is larger than that by sample no. II. In the temperature range 150–220 °C, the weight loss is small. Taking into account that the cation exchangers are anhydrous within this temperature range, a certain decrease in their weight may be due to weak thermal degradation of the resin. Further heating is accompanied by a sharp weight loss caused by intensive thermal degradation of resins.

Comparison of the temperature dependences of the weight loss by FIBAN K-1 and Dowex msm 31 shows that FIBAN-1 is less heat-resistant (Fig. 2b). The sulfonic cation exchangers grafted to Carbopon show a higher heat resistance at elevated temperatures. The weight of resin sample nos. I and II decreases at 250°C by 12 and 18%, respectively. Under identical conditions, the weight of Dowex msm 31 and FIBAN K-1 decreases by 23 and 32%, respectively.

Our results show that the sulfonic cation exchanger starts to degrade before the resin dehydration is complete. Therefore, we cannot correctly determine the onset temperature of the degradation of functional groups. In order to overcome this difficulty, we developed a method sensitive to the onset of degradation of functional groups.

This method is based on the following procedures. An air-dry weighed sample of tested resin (approximately 0.5 g) is placed in a U-shaped reactor immersed in an oil thermostat, and nitrogen is passed through the reactor at a rate of 30 ml min^{-1}. The nitrogen is preliminarily dried and purified to remove atmospheric oxygen by passing through a column packed with calcined $CaCl_2$ and reduced Ni catalyst. After passing through the reactor, the nitrogen flow is directed into a Drechsel bottle (20 mm in diameter and 80 mm high) filled with 0.003 N aqueous acidified (pH 1) $KMnO_4$ (10 ml). Thereafter the reactor temperature is raised to 120 °C with a temperature-control unit. At this temperature the cation exchanger is kept in a nitrogen flow for 1 h. If the $KMnO_4$ solution is not decolorized, the temperature is raised by 10°C, and the procedure is repeated. These stepwise heating runs are repeated until aqueous $KMnO_4$ becomes colorless. Taking into account that $KMnO_4$ decolorization is caused by its reaction with gaseous reductants formed by thermal degradation of the sulfonic cation exchanger (sulfur dioxide, hydrocarbon fragments), the temperature at which the released gases causes decolorization of the $KMnO_4$ solution can be accepted as the onset temperature of resin degradation.

To refine the onset temperature of resin degradation found in the first experiment, this factor was determined repeatedly. In doing so the reactor containing the cation exchanger being tested was heated to a temperature 10°C lower than the onset temperature of resin degradation, determined in the first experiment. Thereafter, the reactor temperature was raised by 5°C, and the resin sample was kept at this temperature for 1 h in a nitrogen flow. If aqueous $KMnO_4$ retained its color under these conditions, the reactor temperature was raised again by 5°C. This procedure was repeated until aqueous $KMnO_4$ became colorless. This technique allows determination of the temperature of the resin degradation with an accuracy of about ±5°C.

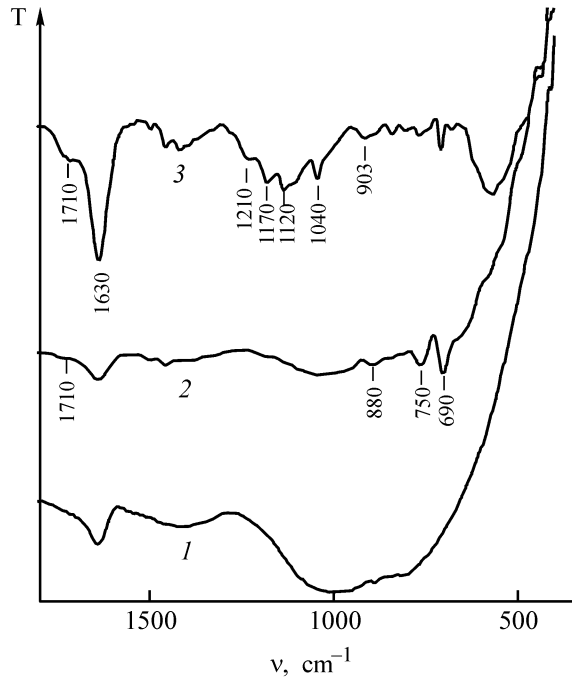

Fig. 3. IR spectra of Carbopon, carbonized fibers modified with poly(styrene–divinylbenzene), and sulfonic cation exchangers grafted to Carbopon. (T) Transmission and (ν) wave number. (*1*) Carbopon, (*2*) carbonized fiber modified with poly(styrene–divinylbenzene), and (*3*) sulfonic cation exchanger (sample no. I).

The thermogravimetric studies showed that Carbopon was heat resistant within the temperature range 120–250°C. The grafted gel-like and macroporous sulfonic resins start to degrade at 135 and 145°C, respectively, which virtually coincides with the related characteristics of the structurally similar resins FIBAN K-1 (130 °C) and Dowex msm 31 (145°C).

The IR spectra of the initial Carbopon and poly(styrene–divinylbenzene)–Carbopon matrix (sample no. I, styrene to divinylbenzene ratio 98 : 2) before and after sulfonation were studied. The samples were ground,

mixed with KBr powder dehydrated by heating at 150°C for 2 h, and compacted into thin pellets by the standard technique. The sample content in the KBr pellet was 0.4 wt %. The IR spectra were recorded on a Protege 460 IR Fourier spectrometer (Nicolet, USA). The scan number was 128, and the spectral resolution, 4 cm^{-1}. The IR spectra were processed using OMNIC software.

The IR spectrum of the initial Carbopon (Fig. 3, spectrum *1*) contains a broad unresolved absorption band of glycoside bond vibrations (1200–700 cm^{-1}), the band of bending vibrations of the CH groups (1500–1300 cm^{-1}), and the absorption band of the H_2O bending vibrations (1630 cm^{-1}).

The IR spectrum of the matrix based on Carbopon modified with poly(styrene–divinylbenzene) contains several narrow absorption bands of different intensities, belonging to the out-of-plane CH vibrations of the benzene ring [9] (690, 750, 880 cm^{-1}) (Fig. 3, spectrum *2*) against the broad background of the skeleton vibrations. The CO stretching vibrations νCO are manifested as a weakly pronounced shoulder (1710 cm^{-1}) on the high-frequency wing of the absorption band of the H_2O bending vibrations at 1630 cm^{-1}.

The IR spectra of sulfonated matrix contain an intensive absorption band of the H_2O bending (Fig. 3, spectrum *3*) vibrations and a series of well-resolved absorption bands belonging to vibrations of deprotonated sulfonic groups with iequivalent SO bonds (1210, 1170 and 1040 cm^{-1}) [10], [11]. The planar skeleton vibrations of the benzene ring with the SO_3H substituent are manifested as the absorption band at 1120 cm^{-1}. The absorption band at 903 cm^{-1} can be assigned to the S–OH vibrations. The presence of this band shows that some sulfonic groups are present in the protonated state. The absorption band at 560 cm^{-1} is caused by the C–S vibrations. Generally, the IR spectra of sulfonic cation exchangers grafted to Carbopon are similar to those of known fibrous and granulated sulfonic cationexchange resins.

CONCLUSIONS

(1) A new kind of sulfonic cation exchangers was prepared by radiation grafting of poly(styrene–divinylbenzene) to nonwoven carbonized fabric Carbopon, followed by sulfonation of the resulting matrix.

(2) The degree of grafting and exchange capacity of gel-like grafted sulfonic cation exchangers exceed those of macroporous grafted resins. The cation-exchange groups of grafted gel-like resins are uniformly distributed across the fiber, whereas those of grafted macroporous resin are mostly concentrated on the fiber periphery.

(3) The IR spectra of grafted sulfonic cation exchangers are similar to those of the known fibrous and granulated sulfonic resins.

SORPTION AND ION-EXCHANGE PROCESSES

Manufacture of Carbon Materials of Aerogel Type from Carbon Blacks of Various Origins

S. S. Stavitskaya, V. E. Goba, A. N. Tomashevskaya, and N. T. Kartel'

Institute of Sorption and Endoecology Problems, National Academy of Sciences of the Ukraine, Kiev, Ukraine

Received April 20, 2004; in final form, March 2005

Abstract—The influence exerted by the structure and origin of samples of technical grade carbon, conditions of their thermal treatment (temperature, nature of a gas medium) and preliminary impregnation with activating additives, and other factors on the final characteristics of carbon aerogels: density, specific surface area, and sorption capacity, was studied.

Of particular interest among new carbon materials, which may have, depending on the starting raw material and treatment methods, widely diverse forms and physicomechanical and chemical properties, are low-density carbon materials of the aerogel type.

Low-density carbon materials, carbon aerogels, were first synthesized in 1989 [1] by pyrolysis of a resorcinol–phenol-formaldehyde resin, with subsequent high-temperature activation of the resulting carbonizate in an inert atmosphere. Later, carbon aerogels were obtained from various organic polymers [2–8], including those of the expanded type, by using various treatments, organic additives, fillers [NaCl, Na_2CO_3, $Ca(OH)_2$], and cross-linking agents (e.g., melamine) Primary attention was given to properties of the starting oligomers, their thermal stability, and relative content of their components; also, the effect of solvents and catalysts used in synthesis of the starting organic aerogels on the final properties of the carbon aerogels obtained and, for the most part, on their porous structure and electrical conductivity was studied [2–4, 9].

In recent years, the interest in this class of compounds has increased because of the widely diverse possibilities of their use (owing to the uniquely high porosity, chemical stability, and electrical properties) as effective sorbents-fillers in chromatographic columns and materials for absorption and accumulation of small gas molecules, e.g., of hydrogen, which may be rather promising for obtaining a fuel of a new generation. Carbon aerogels are used in electrical engineering for fabrication of new electrodes in high-capacity power cells, molded articles with prescribed electrical properties, as well as heat insulators, various filters, catalyst supports, and catalysts themselves [2–9].

However, it should be noted that the literature on carbon aerogels has virtually no reports devoted the possibility of changing or controlling their porous structure or, the more so, the chemical nature of the surface of the carbon aerogels by its direct modification with special treatments, impregnations, etc.

A search for new ways to create carbon aerogels with unique properties by using unconventional sources of raw materials and new forms of low-density carbon materials of the aerogel type is of permanent current interest.

In this study, samples of finely dispersed carbon blacks (technical-grade carbon) were used as a starting substance to obtain carbon aerogels. The blacks were prepared by thermal decomposition of natural gas (C-1) or by thermal-oxidative decomposition of liquid hydrocarbons, as it has become usual in recent years (henceforth C-2). These samples differed in the initial apparent density (d = 470 and 240 mg cm^{-3}, respectively) and in the degree of graphitization, which was substantially higher for C-2, compared with C-1.

The specific features of the structure of technical-grade carbon as a most finely dispersed material give reason to believe that its thermal oxidative-destructive treatment as a starting substance can yield carbon aerogels. Indeed, carbon blacks have a strongly developed chain structure; it is known that any carbon

black particle contains a large number of pseudographite carbon crystallites and amorphous ("unorganized") carbon. Separate elementary particles have an approximately spherical shape. Rigid chains of particles, which determine the degree of cross-linking of carbon black, are composed of particles with about the same diameter in the range from 100 to 2500 Å.

In an oxidative atmosphere, the inner part of the particles must burn out under the action of a high temperature considerably faster, to give voids. The reactivity and properties of technical-grade carbon blacks are largely determined by the size of primary carbon black aggregates. It was assumed that the density of these substances can be changed (lowered) via formation of voids in burning-out of the inner part of carbon black particles, which is commonly represented by the so-called unorganized carbon, whereas the outer part is, as a rule, composed of more ordered, thermally stable carbon crystallites [10]. Such a process, occurring in an oxidative atmosphere at high temperatures, can be affected by the temperature mode, treatment duration, type of a gas atmosphere, etc.

EXPERIMENTAL

The aim of this study was to examine the preparation conditions of carbon materials of the aerogel type and to reveal the influence exerted by the type of the starting carbon material, gas atmosphere, temperature mode, treatment duration and other factors on the final properties of the carbon aerogels synthesized (apparent density, burnout, sorption capacity for a benzene vapor), determined by the standard methods [11]. In addition, the stability of these samples of technical-grade carbon against the action of ultrasound and gamma irradiation and the possibility of a "chemical" activation of carbon-black particles were analyzed. In the latter case, the samples were preliminarily treated with substances that could decompose, in the course of the subsequent thermal treatment, into gaseous products directly within the carbon black particles, which also had to promote their loosening and to impair their strength. For this purpose, samples of technical-grade carbon were impregnated with solutions of ammonium acetate or hydrocarbonate or subjected to a two-stage impregnation with sulfuric acid and ammonium hydrocarbonate. The thermal treatment was done in air or in the atmosphere of CO_2, water vapor, hydrogen, or argon.

To raise the dispersity, carbon blacks of varied origin were subjected to the action of ultrasound or to gamma irradiation. In doing so, the effect of the treatment time and irradiation dose on the dispersity of blacks and on their properties was studied (Table 1).

It was found that the action of ultrasound (30 min) on C-1 carbon black is similar to that of vibration milling, in which the chain structure disintegrates into separate fragments and a decrease in porosity is observed [10]. The higher dispersity of the system is also indicated by an increase in the apparent density d (i.e., the packing density) and decrease in the porosity (sorption capacity) for benzene, W_s [11].

High-energy gamma irradiation (50–500 rad) also leads to an increase in dispersity. The change in the degree of cross-linking of C-1 carbon black samples subjected to irradiation treatment was also confirmed by the results of X-ray diffraction analysis. For the carbon black of C-2 brand, the above-mentioned parameters remain virtually unchanged under similar conditions (Table 1).

A strong difference between the final parameters of the materials obtained was also observed upon thermal treatment of C-1 and C-2 samples at 600–900°C in the presence of water vapor, CO_2, or air. Such an oxidative-destructive treatment, high-temperature activation, was used to raise the density of finely dispersed blacks in order to obtain aerogels on their base. In the process, the optimal preparation conditions of carbon aerogels were studied, the main activation parameters were determined, and the effect of various factors (temperature mode, time of contact

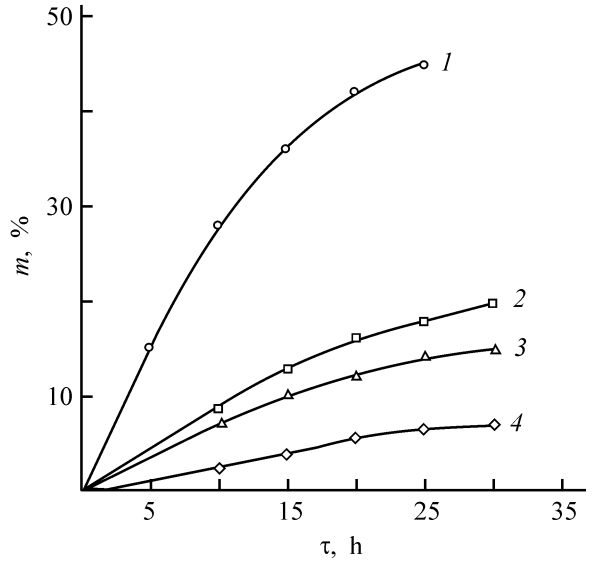

Fig. 1. Burnout m of (*1*, *3*) C-1 and (*2*, *4*) C-2 carbon blacks in the atmosphere of argon vs. the time τ of an experiment on thermal treatment. Temperature (°C): (*1*, *2*) 800 and (*3*, *4*) 600.

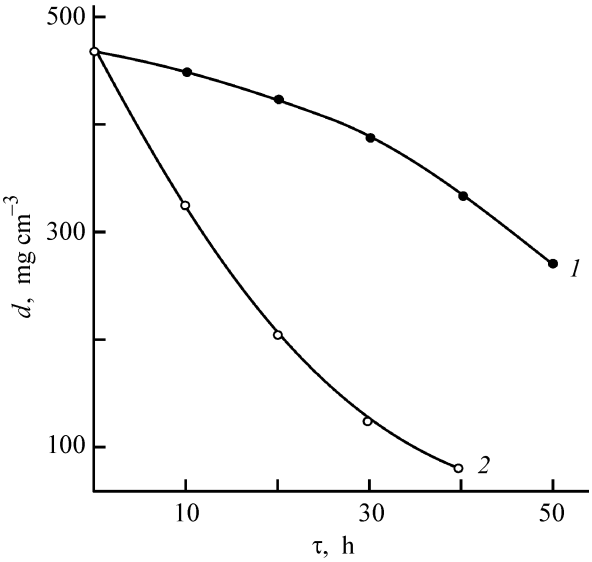

Fig. 2. Variation of the apparent density d in thermal activation of C-1 carbon black in a flow of CO_2 at temperatures of (*1*) 800 and (*2*) 900°C with time τ.

between a sample and the activating agent, and nature of the starting material and the oxidant used) on the final properties of carbon were revealed. The quality of the samples obtained was monitored by their density d, burnout m, and sorption capacity for C_6H_6, W_s. The data obtained are listed in Table 2 and shown in Figs. 1 and 2.

The porous structure (not to be confused with the degree of cross-linking, i.e., extent to which carbon black particles are connected [10]), by which the internal structure of particles is understood, is manifested in carbon blacks only upon their prolonged, deep oxidation with atmospheric oxygen at 450°C for 50 h [10]. In the present study, such conditions were used only in exceptional cases (Table 2). For this reason, the porous structure parameters (volume of pores of a certain size, pore radius distribution, geometric surface area of pores, etc.) are not given in this communication. The specific surface areas [11] of the initial samples and of the most promising materials of the aerogel types were obtained to be 25 and 21 $m^2 g^{-1}$ for C-1 and C-2, respectively, and 106 and 191 $m^2 g^{-1}$ for low-density samples with d = 80–90 mg cm^{-3}.

It can be seen from Table 2 and Figs. 1 and 2, which show typical curves of variation of the burnout and apparent density of samples in their thermal treatment, that the less graphitized samples C-1 exhibit, together with the burnout caused by formation of phase oxides of carbon, a significant increase in the sorption capacity for benzene and a decrease in the apparent density. The processes are strongly affected by the treatment temperature (Table 2, Fig. 2). Under certain conditions (900°C, treatment with water vapor or CO_2), samples with an apparent density of 160–80 mg cm^{-3}, i.e., carbon aerogels, can be obtained. A strong difference was revealed between the final parameters of samples thermally treated in the presence of water vapor and CO_2 (Table 2): the low density, characteristic of aerogels, was reached fast, but at very high burnout (up to 90%). Thus, use of water vapor for activation of technical-grade carbon to obtain aerogels was found to be inexpedient because of the resulting low yield of the product.

A considerably smaller burnout and lower density of final samples were observed in the case of thermal

Table 2. Parameters of C-1 carbon black samples after thermal treatment (initial density d = 470 mg cm^{-3}, benzene sorption with W_s = 0.026 $cm^3 g^{-1}$)

Gas medium	T, °C	τ, h	m, %	d, mg cm^{-3}	W_s, $cm^3 g^{-1}$
H_2O	600	30	45	460	0.126
	700	20	69	320	0.170
	900	30	90	160	1.100
CO_2	800	50	30	270	0.440
	900	40	54	80	0.730
Air + CO_2	900	20	50	90	0.700

Table 3. Parameters of carbon black samples after preliminary impregnation and thermal treatment (thermal treatment duration 1 h, calcination temperature 900–950°C)

Impregnating agent	Gas medium in thermal treatment	d, mg cm^{-3}	W_s, cm^3 g^{-1}
	C-1 carbon black		
NH_4HCO_3 + H_2SO_4	Air	360	0.04
H_2SO_4 + NH_4HCO_3	"	320	0.07
	C-2 carbon black		
H_2SO_4 + NH_4HCO_3	Argon	180	0.02
CH_3COONH_4	"	240	0.04

CH_3COONH_4	Hydrogen	310	0.05
NH_4HCO_3	"	340	0.07

treatment in the atmosphere of CO_2. A thermal treatment of C-2 samples failed to yield similar results. It can be seen from Fig. 1, that, all the conditions being the same, a considerably smaller burnout of C-2 carbon black was observed as compared with that for C-1. In this case, the apparent density changed only slightly, from 240 to 225 mg cm^{-3} at a 50% burnout; no aerogels were formed.

It was found preferable to obtain carbon aerogels from C-1 carbon black by a combined treatment: with atmospheric oxygen at 450°C to destroy the ordered outer shell of carbon black particles and the subsequent treatment in the atmosphere of CO_2 at 900°C to remove unorganized carbon from the inner part. Samples with density conforming to the term aerogel (80–90 mg cm^{-3}) were obtained in a considerably shorter time (Table 2). It is also noteworthy that the carbon aero-gels obtained exhibited a considerably higher sorption capacity for benzene vapor, compared with the initial samples (Table 2).

Further, it was found in special-purpose experiments that an additional high-temperature (~1000°C) treatment with hydrogen of a gas black preliminarily subjected to an oxidative activation yields sorbents with a very high sorption capacity W_s for benzene, 0.8 to 1.1 cm^3 g^{-1}, which considerably exceeds the same parameter for ordinary activated carbon [11]. However, this leads to a significant decrease in the dispersity of the samples obtained, presumably, because of aggregation of their particles, caused by formation under these conditions of rather active surface radicals [10].

Substances of the aerogel type were also synthesized from technical-grade carbon by the method of chemical activation. Samples saturated with ammonium acetate and hydrocarbonate solutions or those impregnated in two stages with sulfuric acid and ammonium hydrocarbonate were first thermally treated in an inert atmosphere (Ar, H_2) and then subjected to the action of an oxidizing agent.

The studies demonstrated (Table 3) that the sorption capacity of samples obtained by thermal treatment of carbon blacks preliminarily impregnated with various substances (chemical activation) increased. However, the decrease in the apparent density of the more reactive C-1 was comparatively small, whereas for C-2, this parameter even somewhat increased, probably because of an incomplete removal of impregnating impurities. The results obtained with the chemical activation demonstrated that the most efficient technique is that involving a two-stage saturation (H_2SO_4 + NH_4HCO_3) combined with thermal treatment, which yielded a sample with a density d = 180 mg cm^{-3}.

CONCLUSIONS

(1) The possibility of obtaining carbon materials of the aerogel type from separate samples of finely dispersed carbon blacks with a lower degree of graphitization in their thermal-oxidative treatment was demonstrated.

(2) It was found preferable to obtain carbon aerogels (with a density of 80–90 mg cm^{-3}) by combined treatment with atmospheric oxygen at 450°C and then in the atmosphere of CO_2 at 900°C.

(3) It was established that the more ordered (graphitized) C-2 samples, which are stable against physical (ultrasonic and gamma irradiation) and chemical ac-

tions, show no tendency toward a change in the density of the material obtained (no aerogel formation).

Abstract—Electron microscopy and adsorption-structural, X-ray phase, and thermal analyses were used to determine the density, porosity, microstructure, electrical conductivity, and reactivity of new carbon aerogels based on phenol-formaldehyde polymers.

Low-density carbon materials, carbon aerogels (CA), were first produced by pyrolysis of organic aerogels [1–3]. All the subsequent studies were devoted to synthesis and analysis of the structural parameters and adsorption and electrical properties of carbon aerogels [4–8]. Carbon aerogels were obtained by the classical scheme in three steps: sol-gel polymerization of organic oligomers (synthesis of organic aerogels), high-efficiency drying in a flow of CO_2, and high-temperature carbonization of the resulting organic aerogels (synthesis of carbon aerogels).

In the first stage, the influence exerted by the relative content of starting components [4], thermal stability of chosen resins [5] and solvents (mostly alcohols) [6], and presence in the course of polymerization of catalysts [$Ca(OH)_2$, Na_2CO_3] [7] and cross-linking agents (e.g., melamine) [8] on the final properties of the carbon aerogels obtained was studied in detail. Commonly, resorcinol–formaldehyde, phenol–furfural, melamine–formaldehyde, polyurethane, and, less frequently polyvinyl chloride systems are used as starting components [9].

The interest in materials of the aerogel type is due to the wide opportunities for their use in chemical technology and electrical engineering, provided by their uniquely high porosity, electrical conductivity, corrosion and acid resistance, and biological stability [3, 4, 7, 8, 10–14].

Published studies have been mainly concerned with methods for synthesis of carbon aerogels and properties of these materials, with little attention given to the possibility of controlled variation of the porous structure and chemical nature of the surface of the resulting carbon aerogels, e.g., by special treatment and directional modification. Therefore, a search for new ways of synthesis and new forms of carbon aerogels is a matter of current interest.

EXPERIMENTAL

This study is concerned with properties of new carbon aerogels prepared from phenol-formaldehyde oligomers (PFO) and with changes in the structural parameters, porosity, nature of the surface, and electrical properties upon their thermal treatment (activation) in the atmosphere of CO_2 and oxidation with nitric acid.

Carbonized products differing in degree of branching, porosity, and other structural parameters and texture can be obtained by using in synthesis the phenol-formaldehyde resin, which can form 3*D* hexagonal carbon networks in carbonization, and various relative amounts of the same components and additives.

PFO was carbonized in a flow of N_2, with the treatment time of the starting polymer varied within 2–4 h and the carbonization temperature gradually elevated from 400 to 600°C. The activation was done in the atmosphere of CO_2 at 850°C during a varied time and the oxidation was performed with concentrated HNO_3 [15]. The porous structure was characterized by electron microscopy and adsorption-structural analysis by sorption of benzene vapor and H_2O, and low-temperature (77 K) sorption of N_2. The gas-chromatographic method of thermal desorption of argon was used to measure the specific surface area S_{sp} of the samples studied. The nature and amount of oxygen-containing functional surface groups was determined by chemical

titration [15]. The structure and reactivity of carbon aerogels was also subjected to X-ray phase and thermographic analyses [16, 17].

Phenol-formaldehyde resins with prescribed texture and varied ratio of the components were used as starting materials to obtain, after carbonization in the atmosphere of N_2, carbon aerogels with a widely variable apparent density d, which was in the range 20–150 mg cm^{-3} for different samples. It should be noted that the density of the carbon aerogel samples obtained is considerably lower than that of an untreated, additionally expanded graphite (d = 350 mg cm^{-3}) and aerosils (150–180 mg cm^{-3}).

Compared with the conventional activated carbons, synthetic low-density carbon aerogels exhibit rather high sorption parameters (Table 1) (specific volume of sorption pores, W_s, found by the desiccator method from the of sorption of a benzene vapor is 0.35 cm^3 g^{-1}) and a high total porosity U_Σ [16], which, in some cases, exceeds that of BAC and activated phenol-formaldehyde carbons by an order of magnitude (Table 1) [15, 18].

Electron-microscopic studies demonstrated that carbon aerogels have a strongly inhomogeneous microcellular structure. The surface of the aerogels is pierced by coarse macropores (2×10^3–1×10^4 nm and more, up to several tens of micrometers, depending on the sample density). It is the presence of a large number of macropores that is responsible for the high total porosity and 90–95 : 100 ratio of the apparent and true densities. The electron-microscopic data obtained were used to calculate the wall thickness of carbon aerogels, which varied widely, from 10 to 600 nm.

As indicated by the sorption data (for benzene and water vapor, Table 2), carbonizates of carbon aerogels

of the same nature have, in contrast to low-porosity raw carbon based on phenol-formaldehyde resins, a rather developed system of micropores, which is formed already in the carbonization stage. In activated carbons prepared from phenol-formaldehyde resins, micropores appear only in the course of activation.

The benzene sorption isotherms obtained (Fig. 1) and the structural parameters calculated from these isotherms (Table 2) indicate that all the carbon aerogel samples contain micro- (V_{micro}), meso- (V_{meso}), and macropores (V_{macro}), whose volume *V* strongly depends on the sample density. An increase in the density of carbon aerogels makes larger the volume of the sorption space (amount *A* of adsorbed benzene vapor, Fig. 1), that of mesopores (V_{meso}), and specific surface area S_{sp}.

An additional activation of carbon aerogels also makes higher their sorption capacity via development of micropores, with, however, strongly decreasing mesoporosity.

The presence of micropores in carbon aerogels is confirmed by the values of the main parameters of the microporous structure [19], structural constants *B* and W_o in the equation of the theory of volume filling of micropores and the characteristic adsorption energy E_o, which are found from data on water sorption at $P/P_s = 1$ (Table 2). Constant W_o is the limiting volume of the adsorption space, and constant *B* characterizes the size of micropores [19]. An increase in constant *B* indicates that micropores become larger; at small *B*, W_o is close to the volume of micropores.

As the density of carbon aerogels increases, the surface area of the samples becomes larger. In some cases, it reaches values typical of activated carbons. An increase in the characteristic energy E_o, with a simultaneous decrease in the structural constant *B*, indicates that small micropores and even ultramicropores are predominant in the structure of aerogels with a sufficiently high density ($d \approx 100$ mg cm^{-3}) [15, 18].

The presence of a microporous structure in the carbon aerogels synthesized is also confirmed by the results of a study of their structural-sorption parameters for N_2, obtained on a Quantachrome NOVA 2200E high-speed gas sorption analyzer. Figures 2a–2c show pore radius distributions for, respectively, the starting sample (carbonizate), activated CA–A, and oxidized CA–O, which were calculated using the Barrett–Joyrnal–Halenda (BJH) method [20]. The initial nonacti-

vated aerogel contains micropores of various sizes, whereas in the activated and oxidized sample, only 3–5-nm micropores were observed, i.e., the carbon aerogels synthesized are nanosize and uniformly microporous, which is a rater valuable property as regards their practical application. Table 3 lists the structural-sorption parameters of some of the samples under study, found from the low-temperature adsorption of N_2, using the BJH method.

In order to study the possibility of controlling the structure and chemical nature of the surface of carbon aerogels and imparting new properties to these materials, the reactivity and thermal stability of carbon aerogels were examined in various oxidizing media (CO_2, O_2) at different temperatures.

To develop the microporosity and raise the sorption capacity, samples of varied density were subjected to a high-temperature (850°C) activation with carbon dioxide. In doing so, the main activation parameters were determined and data on how the density of carbon aerogels varies in the process (Fig. 3) were obtained.

High-temperature treatment of finished samples of carbon aerogels in the atmosphere of CO_2 makes higher the total porosity, number of micropores, absorption capacity for benzene and water, and S_{sp}, but diminishes the number of meso- and macropores (Table 2). As the BJH method yields clear-cut data on the content of micro- and mesopores [20], the volume of macropores in the carbon materials studied was determined [20] as the difference between the total volume of pores, found from the moisture absorption capacity of the carbons, and the maximum volume of sorbed benzene, W_s. The following specific features of the process of thermal treatment of the carbon aerogels prepared are noteworthy. It was found, in particular, that d is virtually the same for samples with a low initial density, subjected to activation for different periods of time (Fig. 3). At the same time, the density of samples with an initial density $d > 50$ mg cm^{-3} decreases during thermal treatment till a certain instant of time, presumably via burning-out of the most reactive amorphous part of carbon and further development of porosity, whereas at longer treatment, a structural transformation of the skeleton occurs and the density increases to nearly its initial value. This may be due to changes in the texture of carbon aerogels in prolonged thermal treatment.

Thus, the optimal activation conditions and, in particular, the time of activation for aerogels of varied density, at which the quality of the aerogels is markedly improved, were revealed.

The reactivity of carbon aerogels toward oxygen was determined from the results of a thermogravimet-

ric analysis (Fig. 4), performed both in air and in an inert atmosphere (Ar) [21] on an MOM derivatograph (Hungary). The weighed portions were 100 mg, the temperature was raised at a rate of 5 deg min^{-1}. Heating of carbon aerogels first leads to a minor endothermic effect at 40–55°C. This effect should be attributed to removal of sorbed water. As the temperature is raised to 540–600°C, the carbon mass of all of the samples studied burns out, which is accompanied by an exothermic effect. The rates of carbon destruction at different times of contact with the oxidant are not the same, which is indicated by the TG curves showing the loss of the carbon mass. The higher the density of carbon aerogel samples, the better their thermal stability: a low-density sample (curve *1*) burns out faster than do aerogels with d = 140 mg cm^{-3} (curves *2*, *3*). In the inert medium, the thermal stability of carbon aerogels is considerably higher.

The reactivity of carbon materials depends not only on their porous structure, but also on the forms in which carbon exists in their structure and on its valence state.

According to the results of an X-ray phase analysis on a DRON-2 instrument, the carbon skeleton of low-density aerogels (d = 30–50 mg cm^{-3}) is mostly composed of disordered amorphous carbon.

In this case, however, the intensity of the diffuse halo increases with the sample density and diffraction peaks appear on its background, which points to a crystalline ordering of carbon, compared with the very diffuse halo from activated carbon of the same nature (Fig. 5). In the X-ray scattering curves of carbonizates of aerogels with a comparatively high density (d > 100 mg cm^{-3}), the intensity of the diffraction peaks grows, which points to predominance of the crystalline form size and larger of carbon crystallites.

Particularly strongly different are the X-ray spectra of activated samples of carbon aerogels and phenol-formaldehyde carbon (Fig. 6). The X-ray diffraction patterns of an activated aerogel show a clearly pronounced diffraction peak of the 002 band, which indicates a considerable increase in the content of crystalline carbon in the microstructure upon activation, untypical of the ordinary activated carbon.

The position of the 002 band in the X-ray diffraction patterns of aerogel samples and its halfwidth were used to calculate by the Warren equation [22] the average size of carbon crystallites in the micro-

structure of the aerogels: L_a, height of packets of atomic networks; L_d, diameter of these packets (Table 4).

As can be seen in Table 4, the parameters of the microstructure of carbon aerogels significantly differ from the same parameters of the known carbon materials (e.g., in the larger interplanar spacing L = 4.1 Å. This fact can account for the discrepancy between the true densities of activated phenol-formaldehyde carbon (1.65 g cm^{-3}) and of the carbon skeleton of carbon aerogels (0.9–1.25 g cm^{-3}).

Growth of crystallites and their ordering are favored by an additional high-temperature activation, which is indicated by an increase in the height of atomic-network packets to 60 Å and in their diameter to 115 Å at a constant interplanar spacing.

The considerable fraction of crystalline carbon in the carbon aerogels synthesized leads to their higher (compared with the corresponding samples of PF-A activated carbon) electrical conductivity (Table 5).

As is known [15], the conduction in carbons as graphite bodies is mainly effected by π-electrons moving along planes of hexagonal networks (via the system of conjugated bonds). The electrical resistance of powdered carbon materials is determined, as in other crystalline bodies, by their internal microstructure and contacts (barriers) between particles. The electrical resistance of the barriers depends both on the state of the particle surface (presence of functional groups, adsorbed substances, impurities on the surface) and on the particle size and pressure applied to the powder [21, 23]. To exclude the influence of the last factors, which are not related to the nature of a material under study, the electrical resistance was measured under identical conditions (grain size, pressure, etc.).

To determine the electrical resistance, carbon aerogels and carbons were taken in the form of a ground (D = 0.25 mm) freely poured powder. A weighed portion of a powder was placed in a 1-cm-long porcelain tube with an inner diameter of 6 mm and the tube was clamped between two metallic cylinders. The measurements were carried out under constant pressure at 20°C in the ac mode. The electrical resistance was determined by the voltmeter-ammeter method [23]. A G3-43 generator working in the frequency range 0.15–30 MHz served as a voltage source. The voltage drop across a sample was measured with a V3-4 valve voltmeter.

As demonstrated by the data obtained, the highest electrical conductivity χ (lowest electrical resistivity ρ) was observed for low-density carbon aerogels. As the density of the aerogels becomes higher, their electrical resistance increases, possibly because of the higher content ratio of amorphous and crystalline carbon in the microstructure of the aerogels. In this case, however, ρ of carbon aerogels is an order of magnitude lower than that of activated carbon. Additional activation of carbon aerogels (Table 5, samples CA_1–A and CA_2–A) diminishes their electrical resistance.

* Activated CA additionally treated in a flow of H_2 at 850°C to remove possible surface oxides.

** Activated in a flow of CO_2.

It should be noted that the possibility of obtaining carbon aerogels with a sufficiently high electrical conductivity is rather important for technology, especially for fabrication of molded articles of prescribed configuration on the basis of carbon aerogels.

It is known [15] that presence of acidic surface functional groups on the carbon surface strongly changes not only the sorption and catalytic properties of carbon materials, but also the electrical parameters and performance of articles containing various modifications of free carbon.

In this context, the possibility of changing the chemical nature of the surface of carbon aerogels and

obtaining their oxidized forms by treatment of activated carbon aerogels with concentrated HNO_3 solutions was also analyzed [15]. In the process, samples with a high cation-exchange capacity of up to 4 mmol g^{-1} and different compositions of surface functional groups with varied acidity were prepared. It should be noted that preparation of oxidized carbons with SEC exceeding 2 mmol g^{-1} is commonly accompanied by destruction of the carbon substance to give fulvic acids and coloring humic acids [15], which is untypical of oxidized aerogels.

The relative contents of surface functional groups in carbon aerogels, obtained here, approximately correspond to the known distributions of such groups, observed on ordinary oxidized carbons [15]. The change of the chemical nature of the surface in oxidized carbon aerogels, compared with activated carbons of the same density, is also confirmed by the results of a thermogravimetric analysis. These data indicate that the onset of the reaction between oxygen and the carbon mass is observed in oxidized carbon aerogels at a higher temperature (540–560°C) than that in activated carbons (440–470°C). Presumably, this results from the shielding effect of oxygen-containing surface functional groups. It should be noted that there is no evidence concerning the synthesis and analysis of properties of their oxidized forms in the literature devoted to carbon aerogels.

CONCLUSIONS

(1) New low-density carbon materials, aerogels with a widely controllable apparent density (20–150 mg cm^{-3}), were synthesized from phenol-formaldehyde polymers by carbonization.

(2) It was shown that the carbon aerogels synthesized show high sorption capacity (for benzene, water, and nitrogen) and total porosity. In addition to a large number of macropores, the materials under study possess a rather well-developed microporous structure. In contrast to that of ordinary carbons based on phenol-formaldehyde oligomers, this microporous structure is formed already in the carbonization stage and leads to a high sorption capacity and large specific surface area comparing well with that in industrial carbons.

(3) An X-ray phase analysis demonstrated an increased content of crystalline carbon in the microstructure of carbon aerogels after their activation, which is untypical of the ordinary activated carbon. The samples synthesized also differ from those of ordinary activated carbon in the parameters of microstructure, considerably larger interplanar spacings (up to 4.1 Å), which leads to their lower true density, compared with that of ordinary carbons based on the phenol-formaldehyde resin.

(4) It was found that the aerogel samples studied exhibit a high electrical conductivity typical of carbon materials of this kind. The electrical conductivity exceeds that of phenol-formaldehyde carbons by a factor of 2–5.

(5) Cation-exchange (oxidized) forms of carbon aerogels with a high sorption capacity (SEC of up to 4 mm g^{-1}) and various compositions of acidic surface functional groups were obtained. It was established that, when such an exchange capacity is reached, no destruction of the carbon substance occurs and no coloring humic and fulvic acids are formed. This points to a high chemical stability of the carbon skeleton obtained.

(6) The study of the properties of the carbon aerogels synthesized made it possible to suggest that materials of this kind can find use as effective adsorbents, various filter media, fillers of chromatographic columns, etc.

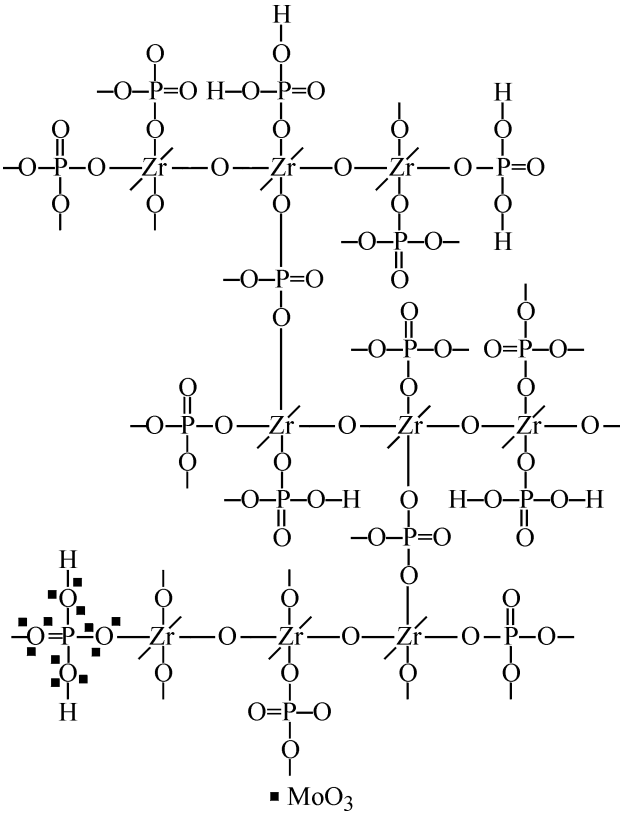
SORPTION AND ION-EXCHANGE PROCESSES

Sorption of Some Metal Ions on Inorganic Electron and Ion Exchangers Based on Zirconium(IV)

T. S. Bondarenko and E. S. Boichinova



St. Petersburg State Technological Institute, St. Petersburg, Russia

Received July 19, 2004; in final form, July 2005

Abstract—Conditions of sorption of nonferrous metal ions on inorganic electron and ion exchangers based on zirconium(IV) were analyzed. The sorption capacity was evaluated as influenced by pH, concentration, and temperature of the contacting solutions and nature and chemical composition of the ion exchanger.

Sorbents operating under severe conditions are required in many branches of science and industry. In contrast to organic sorption materials, inorganic sorbents show high chemical resistance to aggressive solutions and high stability at elevated temperatures and pressures or under irradiation. Therefore, a study of the properties of these materials as influenced by various operation factors is rather urgent. Synthesis of inorganic sorbents based on zirconium–oxygen matrix involves formation of polymers with Zr–O–Zr units on adding polybasic acids or their salts in aqueous solutions of zirconium(IV). The residues of polybasic acids link with zirconium–oxygen chains to form simple or complex functional groups exhibiting ion-exchange, redox, and some other properties.

In this study, we examined the effect of some factors on the ion-exchange properties of inorganic electron and ion exchangers (EIEs) based on zirconium(IV), with functional groups containing phosphorus(V) and molybdenum(VI) (zirconium phosphomolybdate, ZPM[1]), tungsten(VI) and vanadium(V) (zirconium tungstovanadate, ZTV [2], and silicon(IV) and molybdenum(VI) (zirconium silicomolybdate, ZSM [3]). The ion-exchange properties of these sorbents are due to the residues of polybasic acids of molybdenum(VI), phosphorus(V), tungsten(VI), and silicon(IV) and hydroxy groups, and the redox properties are associated with the formation of the corresponding heteropoly acid residues in the course of synthesis. In this study, we analyzed only the ion-exchange power of EIEs in comparison with hydrated zirconium dioxide (HZD) [4]. The structure of EIE based on zirconium(IV), molybdenum(VI), and phosphorus(V) is given below.

It is known that the sorption properties depend not only on the nature and composition of a sorbent, but also on the sorption conditions, such as the solution pH, ionic composition of the solution (nature of anions, impurity electrolytes), contact time (sorption kinetics), temperature, etc.

All the sorbents were prepared from zirconium oxynitrate by the procedures given elsewhere [1–4].

1070-4272/05/7808-1266 © 2005 Pleiades Publishing, Inc.

The sorption capacity Q was determined under the static conditions and calculated as the difference of the concentrations of the adsorbed ion in the contacting solution before sorption and after attainment of a quasi-equilibrium (chelatometry [5]).

The solid to liquid ratio was 1 : 100; the working fractions of the sorbent were 0.25–0.50 and 0.50–0.80 μm and sorption time τ = 24 h (unless otherwise indicated). The required pH of the initial contact solution was adjusted with an appropriate acid. The half-time of exchange was determined from the kinetic curves. The temperature was maintained with a Universal Termostat U-8 unit with an accuracy of ±0.02°C. In our experiments, we used the sorbents in the H form.

The time in which the equilibrium is attained (sorption kinetics) is of practical importance. As can be seen from Table 1, the half-time of exchange of various sorbents changes with their composition. The time of attainment of the quasi-equilibrium in the distribution of a given ion between the sorbent and solution depends on the nature of the adsorbed ion. A comparison of the data on several three-component inorganic EIEs based on zirconium(IV) [1–3] showed that ZSM sorbents exhibit the best kinetic parameters in sorption of nonferrous metals.

In the case of ZSM, the half-times of exchange of copper(II) and nickel(II) ions are shorter than those with ZPM and ZPM (Table 1). The sorption capacity of the sorbents in question changes in the following order: ZSM, $Ag^+ > Co^{2+} > Cu^{2+} > Ni^{2+}$; ZTM, $Cu^{2+} > Co^{2+} > Ni^{2+}$; and ZPM–$Ag^+ > Cu^{2+} > Co^{2+} > Ni^{2+}$.

Only in the case of ZSM the degree of exchange changes in accordance with the increasing ionic radius of metals, whereas for ZPM and ZTV this trend is broken: $Co^{2+} > Cu^{2+} > Ni^{2+}$ [7].

It is known that the sorption capacity of weakly basic and weakly acidic exchangers depends on the pH of the contacting solution. With increasing pH, the sorption capacity of ZTV and ZSM grows (Table 2), which is due to stronger dissociation of the functional groups of the exchanger. Thus, our experimental data confirm that sorbents of this type are cation exchangers [1–3].

In contrast to ZTV, the sorption capacity of ZSM depends on the electrolyte composition (Table 3). It has been found that the salt anion in the solution from which sorption is carried out strongly affects the sorption capacity [8]. For example, ions of cobalt(II), nickel(II) and copper(II) are readily recovered by alumina from sulfate solutions, whereas

		–	6.10	5×10^{-2}	10.40

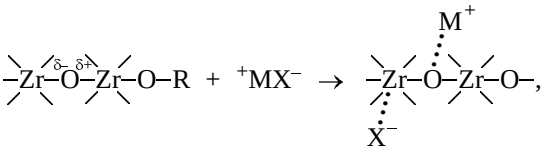
* c is the concentration of the adsorbed ion and K_d is the distribution coefficient.

** Acidified with hydrochloric acid.

*** Acidified with sulfuric acid.

no sorption is observed from nitrate solutions. In the case of HZD, the sorption capacity with respect to transition metals is also determined by the kind of the anion. The same phenomenon was found for ZSM: The distribution coefficients of Co(II) and Cu(II) in sorption from sulfate solutions differ from those in sorption from chloride solutions. This difference in sorption on exchangers with the zirconium-oxygen matrix is probably due to the nature of the elements forming its functional groups and to the ion-dipole interaction of the sorbed ions with polar matrix.

Table 3. Sorption capacity of ZTV and ZSM sorbents as influenced by the electrolyte anion (electrolyte concentration 5×10^{-2} M)



Sorbent	Electrolyte	pH		K_d, ml g^{-1}	Sorbent	Electrolyte	pH		K_d, ml g^{-1}

	$CuCl_2$	4.26	3.10	4.8		$CoCl_2$	5.04	3.15	18.4

* ZTV was prepared from zirconium(IV) sulfate.

Table 4. Sorption capacity of ZSM and HZD sorbents as influenced by temperature (electrolyte concentration 5×10^{-2} M)

Sorbent	Sorbed ion	τ, h	Q, mmol g^{-1}, at indicated temperature, °C				
			20	40	50	65	80
HZD [4]	Cu^{2+}	6	0.92 ± 0.10	1.10 ± 0.1	–	–	1.48 ± 0.11
		12	1.03 ± 0.11	1.26 ± 0.12	–	–	1.79 ± 0.13
	Ni^{2+}	12	0.58 ± 0.06	0.48 ± 0.05	–	–	0.53 ± 0.05
	Pb^{2+}	6	0.13 ± 0.06	0.53 ± 0.05	–	–	No sorption
ZSM [3]	Cu^{2+}	5	0.50 ± 0.01	–	1.70 ± 0.01	2.80 ± 0.01	–

The contribution of the ion-dipole interaction is probably rather high, because the activity coefficients of sulfate solutions are smaller than those of nitrate and chloride solutions. As a result, although the sorption from nitrate and chloride solutions should seemingly be higher, the sorption capacity of the sorbent is actually higher in sulfate solutions owing to significant contribution of the ion-dipole interaction to the total sorption. The high polarity of the zirconium–oxygen matrix increases the dispersion interaction and promotes penetration of the electrolyte into the sorbent phase, i.e., the so-called molecular sorption proceeds and electrolyte interacts with the matrix dipoles by the ion-dipole mechanism. In this case, the sorption capacity is determined not only by the strength of binding between a cation and the negative end of the dipole of the matrix, but also by that between an anion and the positive end of the dipole. The complexing power of chloride and nitrate ions with respect to zirconium(IV) are similar, and their contribution to the molecular sorption are also similar. Complexes of zirconium(IV) with sulfate anions are significantly stronger. Since secondary sorption can proceed on the HSO_4^- groups, the stronger the complexes formed by sulfate anions with the sorbed cation, the stronger the sorption of cations from sulfate solutions. At the same time, the sorption capacity of ZTV sorbent is independent of the electrolyte anion (Table 3). Probably, formation of functional groups with a weaker electron-acceptor power diminishes the effective charge on zirconium(IV); as a result, interaction of the anion with Zr(IV) becomes weaker. The higher the electron-acceptor power of the functional group, the stronger the ion-dipole interaction. As compared to ZTV, the ion-dipole interaction of the ZSM matrix with the electrolyte ions is somewhat stronger, probably due to the functional groups containing Mo(VI) and Si(IV), which make the matrix somewhat more polar. The sorption by the ion-dipole mechanism can be represented as:

where R are the residues of molybdic, tungstic, phosphoric acids, and heteropoly acids.

Temperature is an important factor affecting the sorption properties of ion exchangers. A systematic study of the ion-exchange equilibrium as influenced by temperature was performed in [9]. The qualitative data on the effect of temperature on sorption of copper(II) ions on ZSM showed that, with the sorption temperature increasing from 20 to 65°C, the static capacity for copper(II) grows by nearly a factor of 5.6 [10]. An increase in the sorption capacity of HZD for copper with temperature was found in [4].

At the same time, at the temperature increases to above 40°C, the sorption of lead(II) sharply decreases. As for sorption of nickel(II) on HZD, no significant changes in the sorption capacity were observed in the entire temperature range studied (Table 4). It is difficult to explain the effect of temperature on the sorption capacity, because it is determined by the relative contribution of different sorption mechanisms, influenced by solvation (hydration), dissociation of the functional groups, etc. In our experiments, copper(II) was sorbed on HZD and ZSM from sulfate solutions, and nickel(II) and lead(II) on HZD, from nitrate solutions. Apparently, with increasing temperature, the ion-dipole interaction is enhanced, strengthening the bond between zirconium(IV) and sulfate ions; as a result, sorption of sulfate and, thus, copper(II) ions increases. Moreover, owing to close radii of Zr(IV) and Cu(II), copper ion can penetrate into the sorbent matrix, increasing the total content of copper in the exchanger phase.

Natural aging of ion exchangers based on zirconium(IV) depends on a particular sorbent. This is especially the case for the redox sorbents exhibiting both ion-exchange and redox properties. The ion-exchange properties of inorganic three-component redox sorbents based on zirconium(IV) are rather stable. For example, the sorption capacity for copper(II) of the ZSM sorbent remained unchanged even after storage for 3 years.

Our experimental data show that the sorption activity of EIEs based on zirconium(IV) is close to that of HZD type sorbents. These sorbents can be recommended as ion exchangers for sorption of single- and multicharged metal ions from solutions of various compositions.

CONCLUSIONS

(1) The sorption capacity of Zr(IV)-based sorbents with respect to Cu(II), Co(II), and Ni(II) depends on the concentration, pH, and temperature of the contacting solution.

(2) The decrease in pH in the course of sorption of Cu(II), Co(II) and Ni(II) ions on the electron and ion exchangers confirms the cation-exchange mechanism of sorption.

(3) The effect of the anion in the contacting solution depends on the chemical composition of the ion exchanger.

SORPTION AND ION-EXCHANGE PROCESSES

Adsorption of Amino Acids on Cellulose Diacetate Membranes

V. M. Sedelkin, A. N. Surkova, G. P. Denisova, and L. F. Ramazaeva

Received October 5, 2004; in final form, May 2005

Abstract—Adsorption of a series of amino acids on cellulose diacetate membranes was studied. Adsorption isotherms were constructed and thermodynamic characteristics of adsorption (chemical potential of the adsorbent and Gibbs energy) were determined.

In separating curdy whey albumin, a cellulose diacetate (CA) membrane retains soluble and other dispersed particles for several reasons, including the adsorption on the membrane surface. The contribution of this process is not clearly understood yet.

Flory and Huggins were first who derived, using statistical thermodynamics, theoretical relationships that take into account these effects, with certain assumptions made, for highly elastic polymers in athermic or quasiathermic processes. At the same time, glassy polymers characterized by S-shaped sorption isotherms cannot be described in the framework of this theory. Until now, a considerable success has been achieved in the development of the physicochemical theory of adsorption through application of thermodynamic, semiempirical, and empirical approaches to description of the formal statics of sorption. The most rigorous approaches are based on the osmotic and stoichiometric theories of adsorption. The consequences of these theories for swellable polymers with nearly zero porosity are presented in [1]. The adsorption on swellable porous sorbents, e.g., in baromembrane processes has been studied to a lesser extent [1, 2]. In particular, this is true for cellulose acetate membranes, which are widely used in processing of dairy products [3]. In this study, we examined the adsorption properties of cellulose diacetate membranes with respect to a series of amino acids.

EXPERIMENTAL

To improve the efficiency of utilization of curdy whey, we experimentally studied the adsorption from model systems containing amino acids (isoleucine, threonine, phenylalanine, methionine, lysine, and valine) on CA membranes. The membranes were produced from a 10% solution of cellulose diacetate in aqueous–acetone mixtures (95 : 5 by volume) using dry-wet formation procedure. The solution was placed in a specially designed cylindrical mold with a face ground-in to a glass plate. Acetone was evaporated for 12 h at 20 ± 2°C in a draft, using a draft hood for acetone recovery. In this way, we prepared isotropic membranes with a 0.05–0.8-μm filtering layer (commercial CA ultrafiltration membranes, e.g., UAM-500, have a filtering layer of 0.01–0.05 μm) and a through-pore diameter of 0.01–0.1 μm (0.03 μm in the case of UAM-500). The membrane thickness and pore size were varied by adjusting the concentration and volume of the initial CA solution. The resulting UAM-SF membranes (dry-wet formation ultrafiltration cellulose diacetate membranes) were tested in separating curdy whey albumin. The ultrafiltration was carried out on a laboratory unit at a pressure of 0.15 MPa and 20°C. The permeability of the membranes to distilled water was 2.6–2.8 $l\,m^{-2}\,min^{-1}$, and to curdy whey, 0.72–1.0 $l\,m^{-2}\,min^{-1}$; the selectivity with respect to curdy whey albumin was 70–72%.

In practice, the separation processes are performed in aqueous solutions. Therefore, we subjected the membranes to swelling in distilled water for 10 h prior to the experiments. Then the membranes were immersed in solutions of amino acids.

The adsorption was determined interferometrically. The error of determination of the refractive index was 1×10^{-4} [1, 2]. In the static experiments, the specific adsorption (amount of adsorbed substance per gram of adsorbent) was estimated by Eq. (1):

$$n = \frac{c_0 - c_1}{m} V, \qquad (1)$$

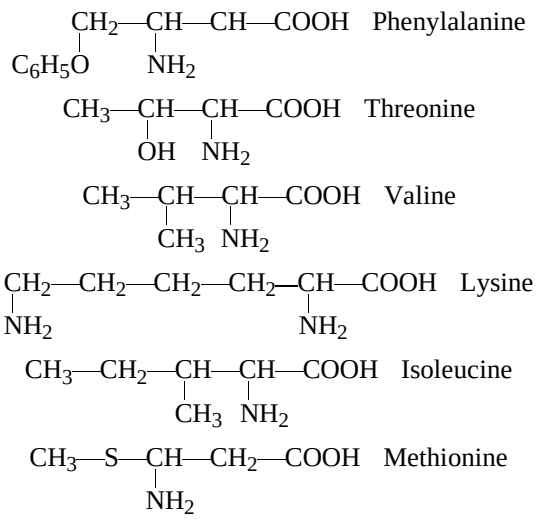
1.6	1.43	1.39	1.38	1.45	1.41	1.41
4.0	–	–	–	0.0120	–	–



where c_0 and c_1 are the initial and equilibrium solution concentrations (M); m, weight of the adsorbent sample (g); and V, solution volume (l).

The initial concentrations of amino acids, c_0, were selected taking into account their solubility (Table 1).

It was demonstrated that 24 h is a sufficient time for the adsorption equilibrium to be attained in the cases of isoleucine and methionine (Fig. 1a). Similar results were obtained for the other amino acids.

In the adsorption experiments, the equilibrium concentrations of amino acids were estimated from the experimental optical densities of the solutions (Table 2).

The adsorption of amino acids decreases in the order

The presence of two amino groups as well as of sulfur in the backbone decreases the adsorption on CA membranes.

Figure 1b shows the adsorption isotherms at 20°C for three amino acids (isoleucine, threonine, and phenylalanine). All of them are S-shaped. Similar isotherms were obtained for the other amino acids

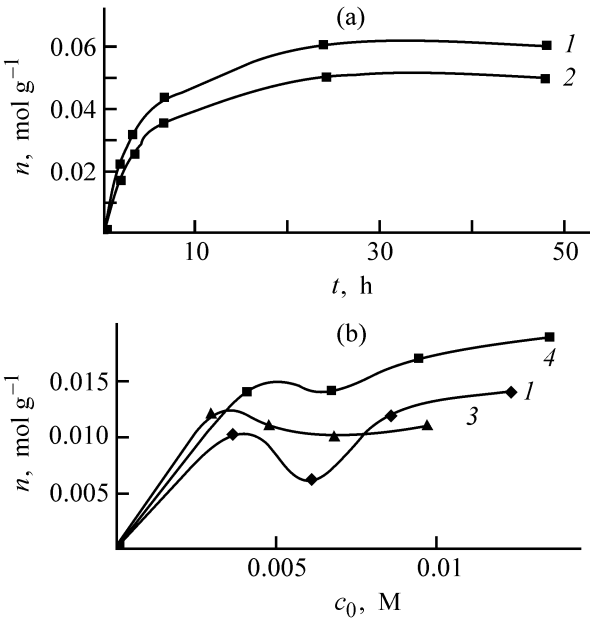


Fig. 1. Adsorption n vs. (a) adsorption time τ and (b) solution concentration c_0: (*1*) isoleucine, (*2*) methionine, (*3*) phenylalanine, and (*4*) threonine.

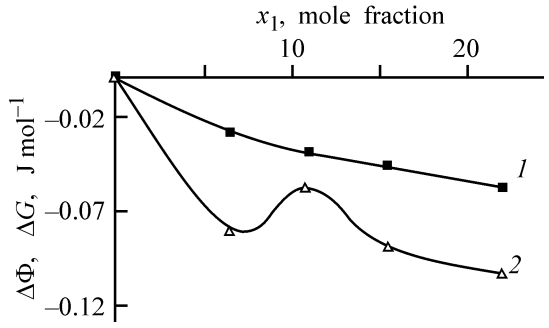

Fig. 2. (*1*) Chemical potential of the sorbent $\Delta\Phi$ and (*2*) Gibbs energy ΔG vs. the solution concentration x_1 in the system threonine–CA membrane.

studied. Arbitrarily, the isotherms could be divided into three groups. In the initial stage of adsorption, the amino acids form monolayers on the membrane surface. The decrease in the adsorption with increasing concentration of the amino acid can be attributed to its reorientation in the adsorption layer, which is particularly clearly pronounced for threonine containing a hydroxy group. With the concentration increasing further, the adsorption noticeably grows, which is probably due to formation of the second and next layers. For isoleucine, as a less adsorbable amino acid, this stage is not pronounced. We found no correlation between the adsorption and molecular weight of the amino acids.

We analyzed the experimental data using excess Gibbs functions [4]. Adsorption is accompanied by a decrease in the free energy of the system. We estimated the free Gibbs energy ΔG and the chemical potential of the sorbent $\Delta\Phi$ in the systems in hand. The change in the chemical potential of the sorbent can be written as

$$\Delta\Phi = \Phi_{x_1} - \Phi_{x_2} = RT\int_0^x \frac{n}{x(1-x)}\,dx_1,$$

where $R = 8.314$ J mol^{-1} K^{-1}; T, temperature (K); n, adsorption (mol g^{-1}); and x_1, mole fraction of the component (initial concentration).

The change in the free energy can be found as the difference between the free energies of the system before and after brinding the adsorbent in contact with the solution:

$$\Delta G = -(\Phi_x - \Phi_X) + n_0 RT\sum_{n=1}\left(x_i \ln\frac{X}{x}\right),$$

where $X_i = 0.1n_1 + x_i$, $n_0 = 10$.

Using the calculated data, we constructed the concentration dependences of the chemical potential of the sorbent $\Delta\Phi$ and of the free Gibbs energy ΔG for the system constituted by threonine and the CA membrane at 293 K over the entire experimental concentration range (Fig. 2). The calculations were also done for the other investigated systems amino acid and the CA membrane. Our results show that the chemical potential of the sorbent and the free Gibbs energy of the systems decrease with increasing amino acid content in the solution.

Finally, in separating curdy whey albumin on CA membranes, adsorption of the protein containing the amino acids investigated on the membrane surface can contribute to the process efficiency.

CONCLUSIONS

(1) Adsorption of a series of amino acids (isoleucine, threonine, phenylalanine, methionine, lysine, and valine) on the surface of cellulose diacetate membranes was studied. The adsorption isotherms were constructed and the thermodynamic characteristics of adsorption (chemical potential of the adsorbent and Gibbs free energy) were determined.

(2) The adsorption of amino acids on cellulose diacetate membranes depends on the structure of an amino acid. Two amino groups and sulfur in the backbone decrease the adsorption.

Abstract—The sorption power of divinyl sulfide–4-vinylpyridine copolymer toward Hg(II) ions was studied. The influence of the kind and concentration of an acid on the sorption characteristics is examined. Mechanisms of the interaction of the active sorption centers of the copolymer with Hg(II) ions are discussed.

Polymeric complexing sorbents are successfully used for determining low concentrations of toxic heavy metals in multicomponent samples. With such sorbents, the effect of the sample matrix is substantially weaker, and the detection limit of the target components is lower [1]. The use of divinyl sulfide as a cross-linking agent allows preparation of porous polymers resistant to acids, and the sulfur atom exhibiting donor properties affects the sorption characteristics [2, 3].

In this study, we examined the properties of a new sorbent, a divinyl sulfide–4-vinylpyridine copolymer, toward Hg(II) ions.

Divinyl sulfide (DVS) was prepared according to [4] and was distilled just before use. Commercial 4-vinylpyridine (VP) was purified by repeated vacuum distillation. The purity of the monomers was monitored chromatographically.

Radical copolymerization was performed in ampules in the presence of AIBN at 60°C. Insoluble DVS–VP copolymers were washed with solvents (benzene, acetone, water) and dried to constant weight in a vacuum. The compositions of the copolymers were found by elemental analysis. The degree of swelling of DVS–VP copolymers was determined gravimetrically. The IR spectra were measured for KBr pellets or mulls in mineral oil on an IFS-25 spectrometer.

The sorption of Hg(II) ions from aqueous solutions was studied in a static mode at room temperature. Mercury(II) was taken as a nitric acid solution with the initial Hg(II) concentration of 2.79 mg ml^{-1}. The solid phase was separated by filtration, and the residual Hg(II) concentration in solution was determined by an extraction-photometric procedure [5].

The DVS–VP copolymers were obtained as yellow powders stable in prolonged storage and insoluble in organic solvents and solutions of acids and alkalis. The copolymerization results are listed in Table 1.

Table 1. Copolymerization of DVS with VP (AIBN concentration 0.5 wt %, 60°C, 6 h)

Copolymer no.	Initial mixture composition, mol %		Content, wt %		Copolymer composition, mol %		Yield, %
	VP	DVS	N	S	VP	DVS	
1	20.00	80.00	5.01	23.42	32.11	67.89	65
2	40.10	59.90	7.90	16.83	54.36	45.64	75
3	50.00	50.00	8.78	12.67	61.23	38.77	92
4	80.00	20.00	12.11	3.45	88.75	11.25	80

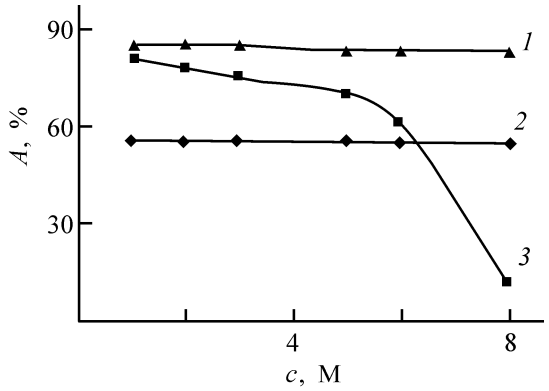

Fig. 1. Influence of the kind and concentration c of acid on the recovery of Hg(II) ions, A, from solutions. m_{sorb} = 10 mg, $m_{Hg^{2+}}$ = 5.6 mg, sorption time 2 h. Acid: (*1*) H_2SO_4, (*2*) HNO_3, and (*3*) HCl; the same for Fig. 2.

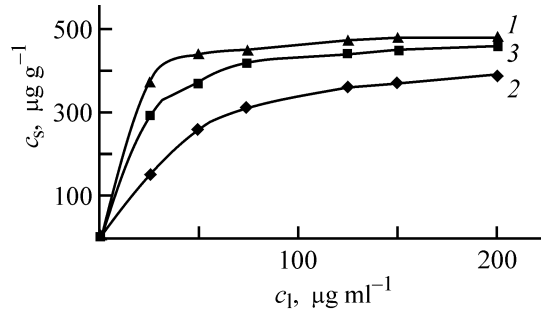

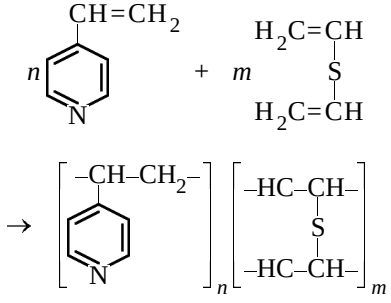

Fig. 2. Curves of equilibrium distribution of Hg(II) at its different concentrations in 1 M acids. m_{sorb} = 10 mg, sorption time 2 h. Hg(II) concentration: (c_l) in solution and (c_s) in the solid phase.

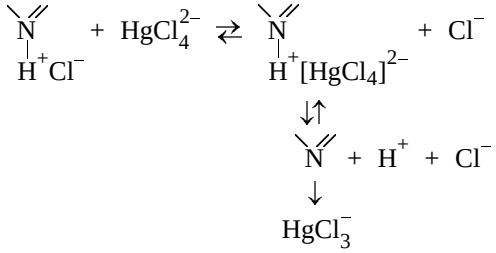
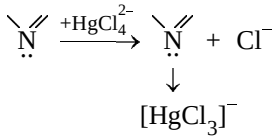
The IR spectra of the copolymers contain no bands characteristic of the VP vinyl group (1640 cm^{-1}), but the pyridine absorption bands (1600, 1555, 1490, 1068 cm^{-1}) remain unchanged. The band at 660 cm^{-1} is assignable to the C–S stretching vibrations.

Calculation of the copolymer compositions from the N and S contents gave reasonably consistent results.

The formation of the insoluble product, as well as the IR spectra and analytical data, suggest that the copolymerization of DVS with VP involves cleavage of two double bonds in DVS, yielding a network copolymer:



The resulting copolymers swell in organic solvents (to 500% in acetone and 300% in hexane).



Copolymer no. 3 (Table 1) in the preliminary tests showed the highest activity in the sorption of Hg(II) ions from aqueous solutions. Therefore, this copolymer (38.77 mol % divinyl sulfide units) was chosen for a more detailed study of the sorption characteristics. The sorption equilibrium in solution was attained in 2 h, with the sorption half-time being 10–15 min.

To find the optimal sorption conditions, we studied the sorption of Hg(II) from HNO_3, H_2SO_4, and HCl solutions in relation to the acid concentration (Fig. 1). We found that the recovery of Hg(II) was virtually independent of the concentrations of HNO_3 and H_2SO_4 (Fig. 1, curves *1*, *2*). At the same time, with increasing concentration of HCl, the sorption activity drastically decreased (Fig. 1, curve *3*). These trends are associated with the sorption mechanism. From HNO_3 and H_2SO_4 solutions, the sorption occurs through donor–acceptor interaction of Hg(II) with both S and N atoms. At the same time an ion-exchange sorption mechanism becomes operative in HCl solutions, in which anionic chloride complexes are formed, and at high HCl concentrations the sorption is suppressed because of the competing effect of chloride ions. However, the coordination interaction is also possible along with the ion-exchange interaction.

To confirm the sorption mechanism, we recorded the IR spectra of the initial sorbents, sorbents treated with acids, and the concentrates. We found that the band at 1600 cm^{-1} in the spectrum of the initial copolymer shifted to 1630 cm^{-1} in going to the concentrate and acid-treated sorbent. This shift points to protonation of the N atom with the formation of the pyridinium ion, or to a coordination interaction of this atom with a metal ion. As shown in [6], sorption of metals that occur in solutions in the form of anionic complexes involves first anion exchange and then coordination. Thus, the ionic interaction is followed by the displacement of the chloride ion from the first coordination sphere of the metal:

The sorption on the nonprotonated form occurs exclusively as replacement of chloride ions with the ligand groups of the copolymer:

To estimate the sorption capacity, we studied the equilibrium distribution of mercury between the solid phase and solutions of Hg(II) in 1 M acids (Fig. 2). From the sorption isotherms, we determined the sorption capacities of the polymer and distribution coefficients of Hg(II) (Table 2).

The sorption capacities show that the copolymer is highly active toward Hg(II) ions. It effectively takes up Hg(II) from sulfuric and hydrochloric acid solutions (SC 480 and 460 mg g^{-1}, respectively). The relatively high distribution coefficients, especially in HCl solution, show that the sorbent can recover trace amounts of Hg(II) from solution.

Iron(II), cobalt(II), nickel(II), and zinc(II) ions are not sorbed under the conditions of Hg(II) recovery, but copper(II) ions are sorbed.

The applicability of a sorbent is largely determined by the possibility of the metal desorption from the concentrate, allowing regeneration of the sorbent.

As can be seen from Fig. 1, the recovery of Hg(II) decreases with increasing concentration of HCl, to become as low as 12% in 8 M HCl. Therefore, we examined the possibility of mercury desorption with various volumes of 9 M HCl at various treatment times. We found that 5 ml of 9 M HCl desorbs 65% of Hg(II) from the concentrate, and 10 ml of 9 M HCl desorbs Hg(II) quantitatively within 30 min.

We also examined the possibility of recycling the sorbent. After a sorption cycle, the sorbent was regenerated by treatment with 9 M HCl, washed with distilled water, dried, and reused for the sorption of Hg(II) ions under the optimal conditions. In four cycles, the recovery of Hg(II) was 56–49% at the initial Hg(II) concentration of 2.5 mg in 20 ml.

The stable high performance of the sorbent after the desorption may be due to the elasticity of the cross-linking fragment (DVS). When a mercury(II) atom is coordinated, a sort an energy cell is formed in the vicinity of the S atom; the parameters of this cell match the characteristics of Hg(II) ions only [7], and, apparently, the introduction and removal of Hg(II) ions can occur repeatedly.

Table 2. Sorption capacities of the copolymer and distribution coefficients of Hg(II) in sorption from 1 M acids

Acid	Sorption capacity (SC), mg g^{-1}	Distribution coefficient *D*, cm^3 g^{-1}
HNO_3	380	4.5×10^3
H_2SO_4	480	6.0×10^3
HCl	460	1.6×10^4

CONCLUSIONS

(1) A divinyl sulfide–4-vinylpyridine copolymer containing 38.77 mol % divinyl sulfide units was prepared by radical copolymerization of the monomers.

(2) It was found that the copolymer has a high sorption capacity for Hg(II) ions and can recover trace amounts of Hg(II) from solutions.

(3) It was shown that the sorption activity of the copolymer is fully restored after its regeneration with 9 M HCl.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Express Monitoring of $MgCl_2$ Concentration in the Electrolyte of Magnesium Electrolyzers

O. A. Lebedev, I. Yu. Brusakov, and N. P. Shkuryakov,

St. Petersburg State Electrotechnical University, St. Petersburg, Russia

Received May 12, 2005

Abstract—A method and apparatus were developed for express monitoring of the $MgCl_2$ concentration in a molten electrolyte and of the temperature conditions in electrolytic manufacture of magnesium.

In electrolytic production of magnesium from chloride melts, the most significant influence on the technological parameters of the process is exerted by the electrolyte temperature and the concentration of magnesium chloride in a melt [1, 2]. Therefore, the technological schedule of the electrolysis process includes a systematic monitoring of the above parameters in order to control the processing conditions. The working temperature of the electrolyte is measured three or four times a day with a displaceable Chromel–Alumel thermocouple and a millivoltmeter,[1] and the electrolyte samples are taken and then analyzed by a chemical laboratory for the content of magnesium chloride and, if necessary, other components of the electrolyte.

The main drawback of the existing monitoring system is the long lag (several hours) between the time of sampling of the electrolyte and that when the results of analysis are obtained, which makes virtually impossible any online control over the processing conditions.

The difficulties encountered in maintaining the optimal processing conditions (with a simultaneous on-line monitoring of the efficiency of separate electrolyzers) are strongly aggravated if magnesium is manufactured by electrolysis in the flow-line mode. In this case, the current efficiency is taken into account as a batch-average, because doing so for each electrolyzer is impossible. The temperature conditions in separate electrolyzers are largely equalized owing to circulation of the electrolyte between electrolyzers via overflow channels.

[1] Fixed Chromel–Alumel thermocouples can also be installed in the electrolyzers, with their signals displayed at the central control panel.

A method and the corresponding apparatus were developed for determining the magnesium chloride concentration in the electrolyte 3–4 min after electrolyte sampling.

The method developed consists in the following. A melt sample taken with a special sampler is allowed to cool in air, which makes it possible to measure the cooling curve of the electrolyte and to determine the liquidus temperature. The working temperature is accurately recorded immediately after extracting a sample.

The concentration of magnesium chloride is determined using the formula:

$$c = c_0 - (T_l - T_{l.r})/K, \quad (1)$$

where c is the magnesium chloride concentration (wt %) in the electrolyte sample; c_0, magnesium chloride concentration (wt %) at the liquidus temperature of the electrolyte, taken as the reference point; T_l, liquidus temperature of the working electrolyte (°C); $T_{l.r}$, liquidus temperature of the electrolyte, taken as the reference point (°C); and K, coefficient that is found from the ternary fusibility diagram of the KCl–NaCl–$MgCl_2$ system as a function of the KCl : NaCl ratio in the working electrolyte and characterizes the extent to which the liquidus temperature depends on the magnesium chloride concentration (°C / %).

It should be emphasized that K is mostly affected by such components of the electrolyte as NaCl and KCl, whereas the effect produced by $CaCl_2$ and CaF_2 additives is insignificant. A study of the regions with 15–5 wt % $MgCl_2$ in the KCl–NaCl–$MgCl_2$ ternary diagram [3, 4] at various KCl : NaCl ratios

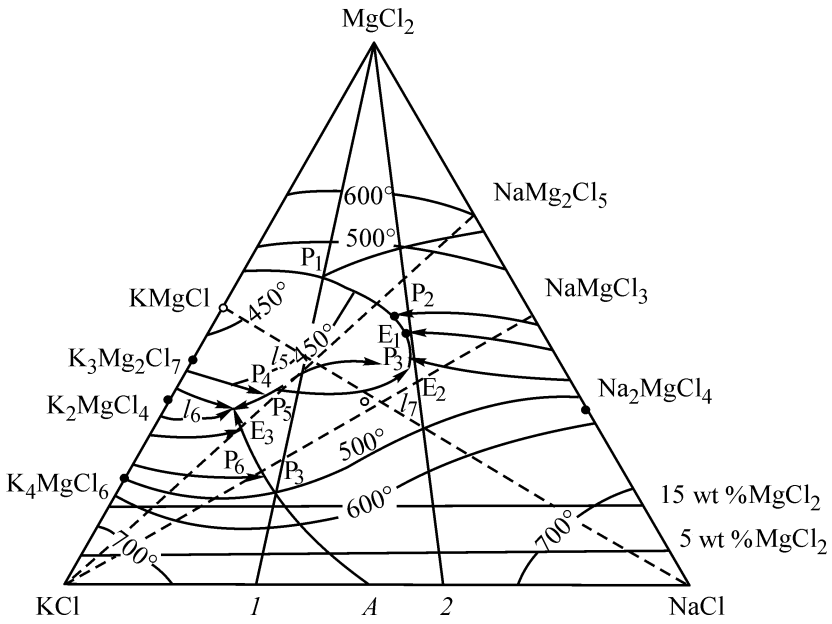

Fig. 1. Fusibility diagram of the system KCl–NaCl–$MgCl_2$. Electrolyte: (*1*) potassium and (*2*) sodium–potassium.

in the working electrolytes led to a conclusion that the dependence of the liquidus temperature on the $MgCl_2$ concentration is nearly linear, which predetermined the type of Eq. (1).

Figure 1 shows the fusibility diagram for the KCl–NaCl–$MgCl_2$ system [4]. The $MgCl_2$–*1* line corresponds to variation of the $MgCl_2$ concentration during electrolysis of the so-called potassium electrolyte with a KCl : NaCl ratio of ~3 (by mass). The $MgCl_2$–*2* line corresponds to electrolysis of a sodium–potassium electrolyte with a KCl : NaCl ratio of ~0.8–1.0 (by mass). The lines corresponding to variation of the $MgCl_2$ concentration from 15 to 5 wt % are also plotted in Fig. 1.

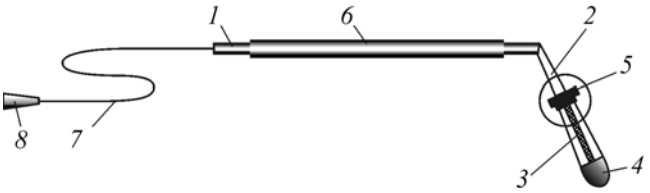

Fig. 2. Measuring probe. (*7*) Connection cable and (*8*) connector; [for explanation of (*1*–*6*, see text].

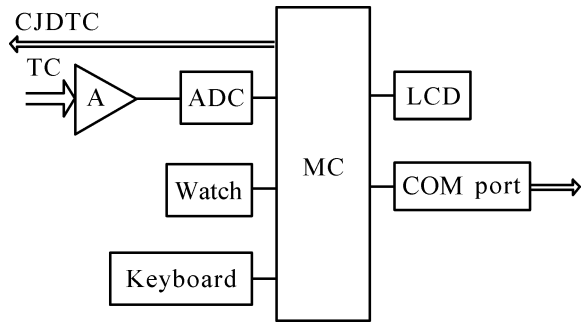

Fig. 3. Block diagram of the electronic unit. (CJDTC) cold junction of a differential thermocouple, (TC) thermocouple, (A) amplifier, (ADC) analog-to-digital converter, (MC) microcontroller, (LCD) liquid-crystal display, (COM port) connection to a computer.

A system for express determination of the magnesium chloride concentration in the electrolyte of a magnesium electrolyzer [5] comprises two main subsystems: (1) a probe with a sensor and sampler (Fig. 2) and (2) an electronic unit (Fig. 3).

The major element of the probe is pipe *1*, to which pipe *2* is jointed, with a cable thermocouple *3* passed through the pipes. The cold junction of the thermocouple is fixed within the unit serving for compensation of the cold junction temperature (not shown in Fig. 2), which is situated at the left-hand (in figure) end of pipe *1*. The working junction of the thermocouple is placed within sampler *4* and secured against a shift in the mounting unit *5*.

Operator's handle *6* serves as a probe extender and an insulator to improve the safety of the operator. It can be freely moved along pipe *1* and fixed in a desired position with a tightening nut.

The absolute error in determining the liquidus temperature does not exceed ±2°C, and the resolution in measuring the points of the cooling curve is 0.1°C.

c_{MgCl_2} is determined with an error not exceeding 0.5% at a resolution of 0.1%.

The apparatus is $110 \times 100 \times 40$ mm in size and has a weight of 0.7 kg.

In sampling the melt, the electronic unit records the working temperature of the electrolyte, determined by the thermocouple, and then the temperature measured at prescribed intervals of time, and the values obtained are loaded into the memory of a computer. Simultaneously, the electronic unit analyzes the resulting temperature curve to find the inflection point, which is recorded as the liquidus temperature of electrolyte, and, based on the prescribed values of K, c_0, and $T_{l.r}$, indicates the magnesium chloride concentration on an LCD.

The apparatus design developed was first tested in laboratory conditions on synthetic electrolytes of the $MgCl_2$–KCl–NaCl system for a long time. In the concentration range 5–10%, the difference in the $MgCl_2$ concentrations measured by the apparatus and determined by chemical analysis of the electrolyte did not exceed 0.3–0.5% (see table).

The apparatus was successfully tested in industrial electrolyzers at the Solikamsk Magnesium Plant (SMP) and Berezniki Titanium-Magnesium Plant.

In Solikamsk, the apparatus was tested on four diaphragmless electrolyzers with carnallite feeding. It was established that at high concentrations of $MgCl_2$ in the electrolyte (~14–15%), which occurred after the main filling, the discrepancy between the values measured by the apparatus and those furnished by chemical analysis of electrolyte samples at the central laboratory of the plant is about 2%. As the $MgCl_2$ concentration in the electrolyte is lowered to 9–10% and 6–7% %, the discrepancy becomes 0.6–0.8 and 0.2–0.3%, respectively.

The wider discrepancy at 14–15% $MgCl_2$ can be accounted for by a deviation of the dependence of the liquidus temperature on the $MgCl_2$ concentration from linearity in these regions of the fusibility diagram. A certain role was played by the fact that the apparatus was calibrated for the KCl : NaCl ratio, which was somewhat different from that in the SMP electrolytes. The time necessary for an analysis with the apparatus is 2–3 min.

An appropriate adjustment of the apparatus software to measurements at concentrations of 15–10% $MgCl_2$ showed that the values measured deviate from the data of chemical analysis by no more than 0.2% over the entire concentration range (5–15%)

Results of the study

Run no.	$MgCl_2$ concentration, wt %	
	results of analysis	measured by apparatus
Potassium electrolyte, KCl : NaCl = 3		
1	5.2	5.1
2	6.8	7.0
3	7.6	8.0
4	10.3	10.8
Sodium–potassium electrolyte, KCl : NaCl = 0.8–1.0		
5	4.8	4.7
6	6.8	7.0
7	8.3	8.6
8	9.85	10.3

Measurements were also made on diaphragmless electrolyzers with magnesium chloride feeding, for which the KCl : NaCl ratio differed for an even greater extent from the calibration ratio as compared with the potassium electrolytes used at SMP. Nevertheless, the apparatus demonstrated a clearly pronounced tendency toward variation of the $MgCl_2$ concentration with time on separate electrolyzers, with a certain systematic difference between the data furnished by the device and the results of a chemical analysis.

The tests showed that, with a certain modification, the apparatus can successfully operate in electrolyzers with magnesium chloride feeding.

The main advantage of the apparatus developed is that the loss of $MgCl_2$ with spent electrolyte can be substantially reduced when working with carnallite. According to the technological schedule, the concentration of $MgCl_2$ in a spent electrolyte discharged from electrolyzer baths should not exceed 5%. However, this value is frequently as high as 6–7% in actual practice.

The express determination of the $MgCl_2$ concentration will make it possible to strictly satisfy the technological requirements and to diminish the loss of $MgCl_2$ with spent electrolyte.

The apparatus will be rather useful for analysis of electrolyzers in the start-up period (in the case of separate feeding with raw materials) and for a comparative analysis, based on loss of $MgCl_2$, of the influence exerted by various parameters (electrolyte temperature, draw-off flow from the cathode, $MgCl_2$ concentration in the working electrolyte, and concentration of F^- ions) on the technical and economical efficiency of the electrolysis process.

Use of the apparatus in a flow-line mode will allow an on-line control of the current efficiency and fast determination of the working efficiency both for any separate electrolyzer and for the entire production line [6]. For this purpose, it is necessary to measure the temperature and concentration of magnesium chloride with samplers (equipped with thermocouples connected to an electronic unit) installed at the inlet of each electrolyzer of the production line and at the outlet of the last electrolyzer.

The samplers are mechanically extracted with a pneumatic system (or in some other way) on a prescribed schedule. Then, the cooling rate of the electrolyte is analyzed by the electronic unit, and the current efficiency in each electrolyzer is determined by the formula:

$$\eta = a\eta_\Sigma / b, \quad (2)$$

where η is the current efficiency of a given electrolyzer (%); a, difference between the magnesium chloride concentrations at the inlet and outlet of the given electrolyzer (%); η_Σ, current efficiency averaged over all the electrolyzers of the production line (%); b, difference between the magnesium chloride concentrations at the inlet of the head electrolyzer and at the outlet of the last electrolyzer, divided by the number of electrolyzers in the line (%).

Mounting mechanically extractable samplers with thermocouples on all electrolyzers of a production line will make it possible to feed the signals of the thermocouples into the electronic unit at the central control panel, which is successively connected to the samplers of different electrolyzers on a prescribed schedule.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Determination of Residual Alkalinity in Positive and Negative Electrodes of a Worked-out Nickel–Iron Battery

A. I. Demidov, M. S. Kokhatskaya, and Sun Lyu Bin

St. Petersburg State Polytechnic University, St.Petersburg, Russia

Received May 12, 2005

Abstract—The content of sodium carbonate and sodium hydrocarbonate in the active paste of the positive and negative electrodes of a worked-out nickel–iron battery after their prolonged storage in air was determined by means of a conductometric analysis.

Nickel–iron battery suggested by Edison at the beginning of the last century belongs to alkaline lamellar cells, in which potassium and sodium hydroxide solutions with a reasonably high electrical conductivity in a wide temperature range are commonly used as electrolytes [1]. The use of the sodium electrolyte is due to its favorable influence on the nickel oxide electrode at elevated temperatures. The potassium electrolyte is preferable at low temperatures owing to its higher electrical conductivity and lower freezing point [2]. The drawback of alkaline electrolytes is their susceptibility to carbonization, which mainly occurs via absorption of atmospheric carbon dioxide and results in accumulation of a carbonate in the electrolyte in the course of operation of a battery [1].

Prolonged storage of positive and negative electrodes of worked-out nickel–iron batteries in air leads to further carbonization of the electrolyte remaining in pores of the active paste. As a result, sodium hydroxide is converted into carbonate and then hydrocarbonate by the reaction:

$$2NaOH + CO_2 \rightarrow Na_2CO_3 + H_2O,$$
$$Na_2CO_3 + H_2O + CO_2 \rightarrow 2NaHCO_3.$$

In hydrometallurgical processing of worked-out electrodes of nickel–iron batteries, it is necessary to know the residual content of carbonate and bicarbonate in the active paste, because their amount affects the expenditure of sulfuric acid for recovery of positive electrodes containing nickel hydroxide and the quality of the active paste of the negative electrode, obtained in processing.

In this study, the content of sodium carbonate and bicarbonate in the active paste of the positive and negative electrodes of a worked-out nickel–iron battery was determined by conductometric titration.

Titration, which underlies the classical titrimetric analysis, is a virtually versatile technique widely applied in physicochemical analytical techniques. In these methods, the electrical parameters of the systems being analyzed, which change as a result of chemical reactions, are measured and recorded [3]. To these techniques belongs conductometric titration, in which the equivalence point is found by measuring the change in the electrical conductivity of a solution during the reaction of the titrant with the substance to be determined. The equivalence point is determined from the sharp break in a titration curve, which reflects the change in the electrical conductivity of the solution being analyzed upon addition of a titrant in the course of titration [4].

We used in the study the active paste extracted from lamellas of a worked-out nickel–iron battery of the TNZh-250-U2 type and chemically pure sulfuric acid. The content of carbonate and hydrocarbonate in the active paste of the worked-out electrodes kept in contact with air for a long time was determined by conductometric titration of the filtrate obtained upon treatment of the active paste with distilled water. In the course of the experiment, the solution was vigorously agitated with a magnetic stirrer and its resistance was measured using an E7-15 immittance meter with the use of graphite electrodes. No less than 5–7 experiments were carried out in parallel.

During the titration of a filtrate containing sodium carbonate and hydrocarbonate with a standard solution of sulfuric acid, first, sodium carbonate reacts with the strong acid to yield sodium hydrocarbonate and sulfate. Then, sodium bicarbonate contained in the ini-

1070-4272/05/7808-1280 © 2005 Pleiades Publishing, Inc.

tial solution and sodium carbonate obtained in titration are neutralized to give sodium sulfate.

To construct the theoretical dependence of the electrical resistivity of the solution on the number of titrant equivalents, we suggested in this study that the electrical conductivity of the initial solution is a sum of the electrical conductivities of the corresponding salts, i.e., $\chi_\Sigma = \chi_{Na_2CO_3} + \chi_{NaHCO_3}$, where χ_Σ is the total electrical conductivity of the initial solution, and $\chi_{Na_2CO_3}$ and χ_{NaHCO_3} are the electrical conductivities of sodium carbonate and sodium hydrocarbonate solutions, respectively. The calculation was performed for solutions containing equivalent amounts of sodium carbonate and hydrocarbonate (0.01, 0.02, 0.05, and 0.1 N) [5].

During titration, the electrical conductivity of the solution varies as follows: Before the first equivalence point, at $0 < y < 1$,

$$\chi_\Sigma = \chi_{Na_2CO_3}(1 - y) + \chi_{NaHCO_3}(1 + y) + \chi_{Na_2SO_4}y,$$

where $\chi_{Na_2SO_4}$ is the electrical conductivity of the sodium sulfate solution, and y, the number of titrant equivalents.

At the first equivalence point, at $y = 1$,

$$\chi_\Sigma = 2\chi_{NaHCO_3} + \chi_{Na_2SO_4}.$$

In titration to the second equivalence point, at $1 < y < 3$,

$$\chi_\Sigma = \chi_{NaHCO_3}(3 - y) + \chi_{Na_2SO_4}y.$$

At the second equivalence point, at $y = 3$,

$$\chi_\Sigma = 3\chi_{Na_2SO_4}.$$

In titration after the second equivalence point, at $3 < y < 5$,

$$\chi_\Sigma = 3\chi_{Na_2SO_4} + \chi_{H_2SO_4}(y - 3),$$

where $\chi_{H_2SO_4}$ is the electrical conductivity of sulfuric acid.

The resulting values of the total electrical conductivity were used to construct the theoretical dependences of the electrical conductivity of the solutions on the number of titrant equivalents (Fig. 1). As can be seen, the titration curves for dilute solutions of sodium carbonate and sodium hydrocarbonate (0.01 and 0.02 N) show two clearly pronounced inflections at the first and the second equivalence points, respectively.

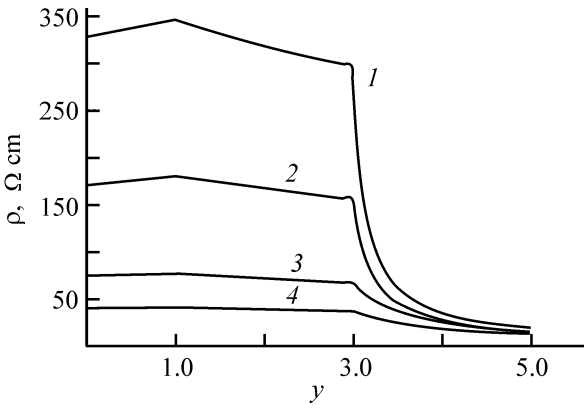

Fig. 1. Theoretical dependence of the electrical resistivity ρ of the solution on the number of titrant equivalents, *y*, taken during titration of a solution containing sodium carbonate and sodium hydrocarbonate at a ratio of 1 : 1 with 0.1 NH_2SO_4 at 25°C. Concentration (g-equiv l^{-1}): (*1*) 0.01, (*2*) 0.02, (*3*) 0.05, and (*4*) 0.1.

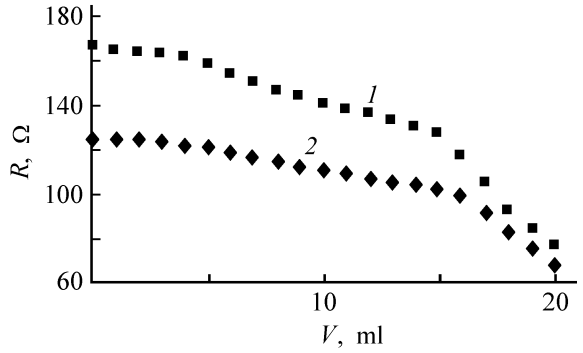

Fig. 2. Conductometric titration curves of the filtrate obtained by treating the active paste of the positive electrode with distilled water. (*R*) Resistance; (*V*) titrant volume. Experiments: (*1*) initial and (*2*) after half a year.

In the experiments, a 2-g portion of the active paste was placed in distilled water, the solution was filtered, and the titration was performed with a standard solution of 0.1 N sulfuric acid. In each titration, the readings of the immitance meter were recorded and the values obtained were used to plot the titration curves and to calculate the residual alkalinity of the solution. The dependences obtained in conductometric titration are shown in Fig. 2. As can be seen, the curves have two inflections at the two equivalence points.

Comparison of the calculated titration curves with the experimental curves shows their identical character. As can be seen from Fig. 2, the amount of carbonate in the solution decreases in the course of time, whereas the amount of bicarbonate increases.

The amount of sulfuric acid spent for titration was calculated from the curves of conductometric titration,

and the amount of sodium carbonate and bicarbonate in a weighed portion of the active paste was calculated from the equivalence law. The content of sodium carbonate and hydrocarbonate was $(6.1 \pm 1.0)\%$ and $(7.3 \pm 1.0)\%$ in the positive electrode and (0.8 ± 0.2) and $(2.2 \pm 0.2)\%$, respectively, in the negative electrode.

It was established for the example of the active paste of the positive electrode that sodium carbonate is converted into bicarbonate in electrodes of worked-out nickel–iron batteries stored in air for a long time. As a result, the content of sodium carbonate in the active paste decreases, and that of sodium hydrocarbonate, increases. A repeated analysis of the active paste of a worked-out positive electrode, made in half a year, demonstrated that the content of sodium carbonate and hydrocarbonate in the active paste changed to $(5.7 \pm 0.6)\%$ and $(9.0 \pm 0.6)\%$, respectively.

CONCLUSIONS

(1) The content of sodium carbonate and sodium hydrocarbonate in the active paste of positive and negative electrodes of a worked-out nickel–iron battery was determined by conductometric titration.

(2) It was established for the example of the active paste of a positive electrode that the content of sodium carbonate in the active paste in electrodes of worked-out nickel–iron batteries stored in air for a long time decreases, and that of sodium bicarbonate increases.

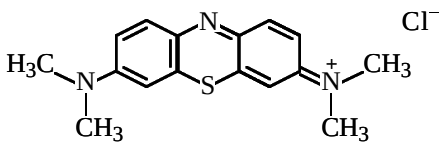
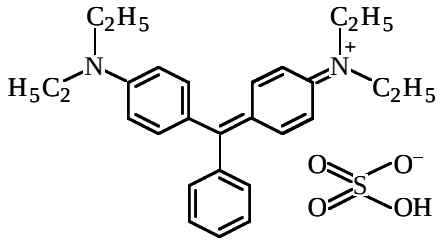
APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Determination of Antiseptic Dyes with Ion-Selective Electrodes



E. V. Nizhnikova and A. P. Podterob

Belarussian State University, Minsk, Belarus



Received October 5, 2004; in final form, April 2005

Abstract—The possibility of determining Methylene Blue and Brilliant Green antiseptic dyes in solutions with the use of ion-selective electrodes based on trioctyl oxybenzosulfonic acid was examined. Data on application of the electrodes fabricated to analysis of powdered dyes are presented. A gravimetric method for analysis for Brilliant Green was suggested and used as a comparative technique.

Methylene Blue (MB, *N*,*N*,*N*',*N*'-tetramethyl thionine chloride) and Brilliant Green [BG, bis(*para*-diethylamino)-triphenyl anhydrocarbinol oxalate) are used as antiseptics:

MB

BG

Methylene Blue is effective as an antidote in poisoning with hydrocyanic acid and its salts and as an agent for neutralization of hemiglobin-forming poisons (nitrites, aniline, and their derivatives) [1, 2]. Together with other dyes of the thiazine series, MB is contained in reagents for hematological analyses and, in particular, in the Eosin-methylene Blue solution by Mey-Grunwald. It is also used to determine the content of carboxy groups in oxidized celluloses [3]. Brilliant Green finds wide use in various fields of science: analytical [4–6], physical [7], and radiation chemistry [8], microbiology [9, 10], neurophysiology [11], veterinary science [12], and medicine [1, 13, 14].

MB is commonly determined by spectrophotometry [15], redox colorimetric titration [16, 17], nonaqueous acid–base titration and gravimetry [18], polarography [19–21], potentiometric titration [17, 18, 22–25], and direct potentiometry [26]. Methods for determining MB with electrodes are indirect [17, 18, 22–25] (in most cases, this is back titration), which undoubtedly impairs the accuracy of determination. An ion-selective electrode (ISE), selective with respect to MB, was first suggested in [26]. This electrode, containing an ionic complex of MB with phosphoric-tungstic acid as an electrode-active substance, can be used in direct potentiometric determination of MB. However, it is known that the determination error strongly depends in this case on the accuracy with which the potential is measured. The 10th edition of the State Pharmacopoeia recommends performing quantitative analyses for MB by its precipitation with potassium dichromate and subsequent iodometric determination of the excess amount of potassium dichromate [16, 27]. The method includes several stages and requires visual indication of the equivalence point. Similar disadvantages are also characteristic of the method of iodometric determination of MB [28]. Direct photometry is not used to determine MB mainly because the shape of the absorption spectrum and the molar absorption coefficient are concentration dependent [28, 29]. As BG is a quaternary ammonium salt and belongs to dyes of the triphenylmethane series, information about methods for its quantitative analysis can be found in the literature [16, 30, 31]. These reports present the general procedures used in analysis for medical preparations belonging to the group of quaternary ammonium salts [31], de-

scribe methods for quantitative determination of quinoid dyes by reduction of the quinoid ring with titanium(III) [16], and give a direct description of a method for quantitative iodochlorometric determination of BG [30].

Analysis of published data suggests that most of the known methods for determination of MB and BG are either labor-consuming or insufficiently accurate. Therefore, development of new techniques is a matter of current interest.

This study analyzes the possibility of employing ISEs for determining the antiseptic dyes MB and BG, widely used in medical practice. Data are presented on their application in a variant of potentiometric titration, which improves its accuracy. In the case of MB, results of potentiometric titration are compared with those furnished by the pharmacopoeic method; a gravimetric comparative method is suggested for BG.

EXPERIMENTAL

All the substances used in the study were of no less than analytically pure grade. The solutions used were prepared with distilled water.

Polyvinyl chloride membranes plasticized with dibutyl phthalate were prepared using the standard procedure [32]. Trioctyl oxybenzosulfonic acid was used as a cation exchanger, with its concentration in the membrane equal to 1×10^{-2} M in terms of dibutyl phthalate. Prior to being used, ISEs were soaked in a saturated solution of an appropriate antiseptic dye.

The characteristics of the ISEs were studied in aqueous solutions of the dyes. The calibration plots are shown in Figs. 1a and 1b. A standard silver chloride electrode filled with a saturated solution of NaCl (EVL-1 M3.1) served as an external reference. All the measurements were carried out at 20 ± 2°C. The resistances of galvanic cells were 1–2 MΩ, which is characteristic of film electrodes plasticized with dibutyl phthalate. The stability of operation of the electrodes was monitored during a month, with all the parameters being well reproducible (Table 1). The response time was less than 1 min at concentrations of 10^{-2}–10^{-4} M and 1–2 min at 10^{-5}–10^{-6} M. In going from concentrated to dilute solutions, it is necessary to wash the electrodes with distilled water for 5–10 min. The washing quality can be monitored visually.

The influence exerted by the pH value on the potential of film electrodes selective toward antiseptic

Table 1. Parameters of ISEs selective toward MB and BG

Parameter	MB	BG
Slope of the electrode function, mV/log *c*	53.3 ± 0.5	39.0 ± 0.7
Const	250.7 ± 5.9	166.6 ± 9.8
Region of linearity of the electrode function, M	1×10^{-6}–1×10^{-4}	5×10^{-6}–5×10^{-4}
Lower detection limit, M	$(6.17 \pm 0.80) \times 10^{-7}$	$(3.24 \pm 0.75) \times 10^{-6}$

dyes was studied at pH 1–12 by adding minor amounts of HClconc and NaOH to a solution of the corresponding ye. A study of the effect of the medium on the electrode potentials demonstrated that, as the concentration of an aseptic dye decreases, the range of pH values at which the ISE potential is constant becomes narrower. For example, the ISE potential remains constant at a BG concentration of 1×10^{-2} M in the range pH 3–12, whereas at a BG concentration lowered to 1×10^{-4} M, this range becomes narrower: pH 4–8. For MB, passing from a concentration of 1×10^{-3} to 1×10^{-5} M results in that the range of constant ISE potential narrows down from pH 4–11 to pH 7–8. The decrease in the ISE potential in an acid medium (at pH $\leq$ 3–4) is possibly due to protonation of the tertiary nitrogen atom in the molecule of an antiseptic dye to give a double-charged cation, toward which the selectivity of ISE is lower. The decrease in the ISE potential in an alkaline medium is due to formation of a sparingly soluble base of MB or BG [28, 29].

The selectivity coefficients of the ISEs toward cations of alkali and alkaline-earth metals were determined by the method of mixed solutions at a fixed concentration of an interfering ion in the range 0.01–0.1 M (Table 2). The method used was described in [33].

The MB and BG solutions prepared by dissolving weighed (with an accuracy as good as 0.0001 g) portions of a powder in distilled water were analyzed by precipitation potentiometric titration with sodium tetraphenylboron (STPB) (the titration curves are shown in Fig. 2), using the electrodes fabricated, and, additionally, by the pharmacopoeic method in the case of MB and by gravimetry in the case of BG (Table 3) [34].

In measurement by the method of precipitation potentiometric titration, a weighed portion of a powder, with a mass m (g), was dissolved in a volumetric flask of volume V (mm), with m and V chosen in such a way that the solution prepared contained about 10^{-3} M of MB and 10^{-4} M of GB. An aliquot for titration, of volume V_{al} (ml), was taken from the solution prepared. The variation of the potential was recorded with an EV-74 ion meter. The precise concentration of the STPB solution was determined by precipitation potentiometric titration with a K-valinomycin electrode as an indicator. The results obtained in the titration were used to calculate the content of a dye in the powder, ω (wt %):

$$\omega = \frac{c_{TPBS} V_{TPBS} M_{BG^+HSO_4^-} V}{V_{al} \times 1000 m} \times 100,$$

Table 2. Selectivity coefficients K_s of electrodes selective toward antiseptic dyes, with respect to inorganic cations

Dye	K_s for indicated interfering ion			
	K^+	Na^+	Mg^{2+}	Ca^{2+}
MB	2.1×10^{-5}	2.0×10^{-5}	1.9×10^{-5}	5.1×10^{-6}
BG	1.2×10^{-5}	1.2×10^{-5}	1.1×10^{-5}	5.5×10^{-5}

where c_{STPB} is the concentration of the tetraphenylborate titrant (M); V_{STPB}, volume of the titrant consumed for titration (ml); $M_{BG^+HSO_4^-}$, molar mass of BG hydrosulfate (g mol^{-1}); V_{al}, volume (ml) of the aliquot of a dye solution prepared by dissolving a dye powder of mass m (g) in a volumetric flask of volume V (ml), taken for titration; and 1000 is the scaling factor for recalculation of the mass into grams.

The gravimetric method for determining BG consists in that it is precipitated with iodine in the presence of CH_3COONa and the forming tetraiodine derivative is weighed after purification and calcination at 110°C. The content of BG in the powder, ω (wt %), was calculated by the formula

$$\omega = \frac{m_{precipitate} M_{BG^+HSO_4^-} V}{m_{weighed.portion} M_{C_{27}H_{29}N_2I_4^+I^-}} \times 100,$$

where $m_{weighed.portion}$ is the mass of the weighed portion of the dye powder (g); $m_{precipitate}$, mass of the precipitate of BG hydrosulfate formed; $M_{BG^+HSO_4^-}$, molar mass of BG hydrosulfate (g mol^{-1}); and $M_{C_{27}H_{29}N_2I_4^+I^-}$,

molar mass of a tetraiodine derivative of BG ($g\,mol^{-1}$).

The results obtained in the analysis are listed in Table 3.

CONCLUSIONS

(1) Ion-selective electrodes with a film membrane containing polyvinyl chloride, dibutyl phthalate, and a salt formed by the cation of an antiseptic dye and anion of trioctyl oxybenzosulfonic acid (1×10^{-2} M in terms of dibutyl phthalate) have the following parameters: sensitivity for Methylene Blue and Brilliant Green dyes of 53.3 and 39.0 mV/log c, respectively; detection limit, 6.17×10^{-7} and 3.24×10^{-7} M; and linearity range of the calibration plot, 1×10^{-6}–1×10^{-4} and 5×10^{-6}–5×10^{-4} M. The lower sensitivity of the electrodes fabricated with respect to the theoretical value is, in all probability, due to partial extraction of the dye by the membrane in the form of an ionic associate, rather than by the exchange mechanism.

(2) The potential of an ion-selective electrode exhibiting selectivity toward antiseptic dyes depends on the pH value of the medium, with this dependence becoming more pronounced as the solution is diluted. Consequently, a strict control over the pH value is necessary in the case of a direct potentiometric determination of the dyes. Inorganic cations (sodium, potassium, magnesium, calcium) virtually do not interfere with determination of antiseptic dyes.

(3) Determination of antiseptic dyes in solution by titration with sodium tetraphenylboron with a potentiometric indication of the equivalence point has high accuracy, reproducibility, rapidity, and simplicity. To assess the significance of differences between the results obtained in determining the dyes by different methods, their standard deviations and average values were compared by statistical criteria. The difference between the results obtained by the two methods in the case of both the antiseptic dyes studied is nonsignificant.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Analysis of Preparation Conditions of H_2SO_4 and NaOH from Sodium Sulfate Solutions by Electrodialysis

B. Pisarska and R. Dylevski

Institute of Inorganic Chemistry, Gliwice, Poland
Silesian Technical University, Gliwice, Poland

Received February 7, 2002

Abstract—Preparation of sulfuric acid and sodium hydroxide from solutions containing sodium sulfate was studied by the electrodialysis method in a three-chamber (?three-compartment) electrodialyzer equipped with two membranes, an anion-exchange membrane AESD-2a and a cation-exchange membrane Nafion 427.

Manufacture of some fatty acids [1, 2], synthetic fibers, and inorganic and organic compounds [3] and integrated processing of worked-out lead batteries [4] yield spent solutions containing sodium sulfate, which are considered nontoxic and are discharged as wastewater. In most cases, sodium sulfate is formed in spent solutions when sulfuric acid and sodium hydroxide are used as technological solutions. Hence follows that it would be possible to solve the ecological problems associated with the formation and discharge of spent solutions containing sodium sulfate if there existed an effective and cost-efficient method for their processing to obtain sulfuric acid and sodium hydroxide. This would enable development of integrated (conjugated) closed cycles. H_2SO_4 and NaOH of purity and concentration sufficient for recycling can be obtained at a plant using sulfuric acid and sodium hydroxide, with sodium sulfate solutions formed along with the target product [5, 6].

The possible technologies based on this principle of processing of spent solutions containing sodium sulfate were described in [4]. It was suggested to use for this purpose electrodialysis in a three-chamber apparatus (electrodialyzer) with two, anion-exchange and cation-exchange, membranes.

The aim of this study was to determine how the current density in the range 2.5–10.0 A dm^{-3}, initial concentration of sodium sulfate (50 and 100 g dm^{-2}), and dialyzate composition affect the current efficiency by sulfuric acid and sodium hydroxide and the direction of transfer and amount of water transferred across the membranes in the course of electrodialysis.

EXPERIMENTAL

The electrodialyzer is shown schematically in Fig. 1. It comprises clamping plates *1, 9*, anode chamber *2*, anode *3* made of perforated lead sheet, anion-exchange membrane *4*, central chamber *5*, cation-exchange membrane *6*, cathode *7* made of perforated nickel sheet, and cathode chamber *8*. The separate elements are connected via 2-mm-thick rubber sealing gaskets. The whole set is assembled into a rigid stack by means of steel coupling bolts. The working size of each membrane and electrode is 5×20 cm.

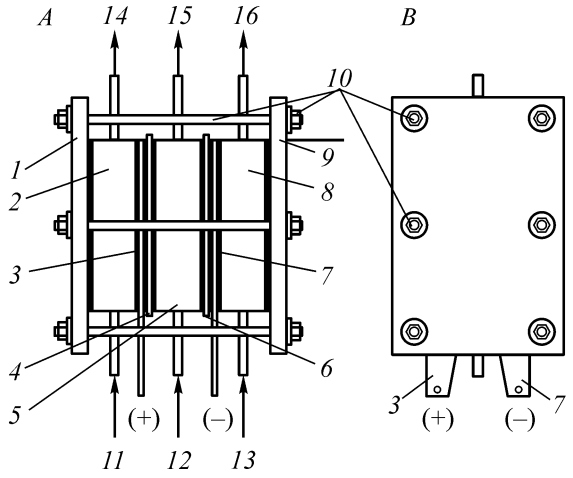

Fig. 1. Schematic of the electrodialyzer unit. (*A*) Front view and (*B*) side view. (*10*) Coupling bolts, (*11*) inlet for water (dilute H_2SO_4), (*12*) inlet for Na_2SO_4 solution, (*13*) inlet for water (dilute NaOH), (*14*) outlet for H_2SO_4 solution and oxygen, (*15*) outlet for dialyzate, and (*16*) outlet for NaOH solution and hydrogen. The rubber separators are colored black.

The AESD-2a membrane manufactured by GALENA pharmaceutical plant (Wroclaw) is a single-layer anion-exchange membrane used without a reinforcing grid at temperatures of up to 45°C [7]. The membrane is fabricated from polyethylene modified with a copolymer of styrene and divinylbenzene, functionalized with $–NH(CH_3)$ groups, and has thickness of 170 μm. The formal selectivity of the membrane is 0.93, and the swelling capacity, 22–24%.

The Nafion 427 membrane manufactured by E.I. Du Pont de Nemours & Co (USA) is a single-layer cation-exchange membrane composed of a perforated mass with $–SO_3H$ functional groups. The membrane has a thickness of 127 μm, mass equivalent ME = 1200, and a reinforcing Teflon fabric of T-12 brand. Nafion 427 membranes are intended for regeneration of technological media, including acids and alkalis [8].

The installation is shown schematically in Fig. 2. It comprises three reservoirs preliminarily filled with an anolyte, a Na_2SO_4-containing solution, and a catholyte. The anolyte (H_2SO_4 solution of initial concentration 16 g dm^{-3}) is delivered from a reservoir *1* by a dosing pump *2* and passes through an anode chamber *3* into a sulfuric acid collector *4*. The catholyte (NaOH solution of initial concentration 12 g dm^{-3}) from a reservoir *5* is delivered by a dosing pump *6* and passes through a cathode chamber *7* into a collector *8*. The sodium sulfate solution from a reservoir *9* is delivered by a dosing pump *10* into a central chamber *11* and then into a dialyzate collector *12*. Gaseous products of electrodialysis (oxygen and hydrogen) are released into the atmosphere.

The volume of the solutions obtained (anolyte, catholyte, and dialyzate) was measured at certain intervals of time. The concentration of sulfuric acid was measured in the anolyte, and that of sodium hydroxide, in the catholyte. A selective determination of SO_4^{2-} ions in the catholyte gave a negative result. SO_4^{2-} ions and an excess amount of free acid or hydroxide were found in the dialyzate. These data were used to calculate the concentrations of Na_2SO_4 and H_2SO_4. The results obtained were used, together with the data furnished by direct determination of the products concentration and dialyzate composition, to calculate the current efficiency by sulfuric acid and sodium hydroxide, as well as the amount of water transferred across both the ion-exchange membranes.

The results obtained were mathematically processed using the procedure suggested by Kafarov [9]. For this purpose, equations describing the dependences of the current efficiency on the process parameters

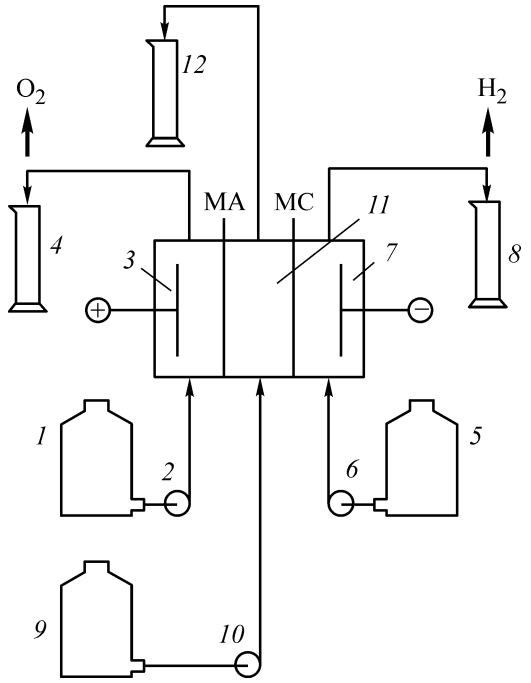

Fig. 2. Schematic of the installation for electrodialysis. Membrane: MA, of anion-exchange, and MC, of cation-exchange types.

were set up in the form of second-degree polynomials including all combinations of the process parameters (as independent variables). Statgraph software was used to calculate the numerical coefficients of individual terms and to analyze their significance. Using terms with a significance level higher than 0.05, we derived functions with only significant terms, which makes it possible to determine the influence exerted by separate parameters on the current efficiency. As two products (sulfuric acid and sodium hydroxide) are formed in the course of electrodialysis, the equations for sulfuric acid for sodium hydroxide were set up and processed independently

$$CE_{H_2SO_4} = f(K_1,\ j_m,\ c_{H_2SO_4}), \quad (1)$$

$$CE_{NaOH} = f(K_2,\ j_m,\ c_{NaOH}), \quad (2)$$

where $CE_{H_2SO_4}$ and CE_{NaOH} are the current efficiencies by sulfuric acid and sodium hydroxide, respectively (%); K_1 and K_2, constants (free terms reflecting the influence of the membrane characteristics); j_m, current density recalculated to the geometric area of the membrane (A dm^{-2}); and $c_{H_2SO_4}$ and c_{NaOH}, concentrations of H_2SO_4 and NaOH in the solutions flowing out of the respective chamber of the electrodialyzer (g dm^{-3}).

The data obtained for the initial Na_2SO_4 concentrations c_0 of 50 and 100 g dm^{-3} are listed in Tables 1 and 2. The sign (+) stands for water transfer from the central chamber into the electrode chamber, and the sign (–), for water transfer from the electrode chamber into the central chamber.

It follows from the data in Table 2 that the current efficiency by sodium hydroxide increases from 78 to 85% as the current density is raised from 2.5 to 10.0 A dm^{-2}. Simultaneously, the current efficiency by sulfuric acid increases from approximately 72.3 to 74%. The increase in the current efficiency can be explained as follows. The product yield is determined by competition of two processes. These are, first, an increase in the amount of the product as a result of electrodialysis and transfer of Na^+ and SO_4^{2-} ions under the action of electric current, and, second, loss of the product via exchange with the membrane, which results from the fact that the true selectivity of the membrane is always lower than inity (frequently, even lower than the formal selectivity given in the data sheet). The ion transfer in an electric field, e.g., across a membrane, is associated with the transport of an electric current and depends on its density. At the same time, the effects of exchange of solution components via diffusion and osmosis mainly depend on the solution composition and time of exchange. Hence follows that the higher the current density, the faster the accumulation of the product obtained and, thereby, the smaller the amount of loss.

With some simplification, the current density can be considered a factor determining the processing rate of the substrate (Na^+ and SO_4^{2-} ions) fed into the central chamber. The throughput of this processing depends on the content of the substrate in the dialyzate.

Comparison of the data in Tables 1 and 2 shows that the current efficiencies by both the products are

lower at a lower initial concentration of Na_2SO_4 and a lower concentration of the dialyzate. The difference is the larger, the higher the current density. The current efficiency by H_2SO_4 and NaOH at the initial Na_2SO_4 concentration of 50 g dm^{-3} is determined by the transfer of Na^+ and SO_4^{2-} ions. This is indicated by the fact that the current efficiency decreases as the current density increases from 7.5 to 10.0 A dm^{-2} (Table 1). This behavior is observed at c_0 = 100 g dm^{-3} Na_2SO_4 (Table 2).

The concentrations of sodium sulfate in the solution fed into the central chamber of the dialyzer, which are used in the study, are comparable with the concentrations in spent solutions and have comparatively low values: the Na_2SO_4 concentration of 100 g dm^{-3} corresponds to a concentration of about 0.7 mol dm^{-3}, and 50 g dm^{-3}, to 0.35 mol dm^{-3}. In the central chamber, the concentration decreases to the value found for the dialyzate. As the rate of the solution flow through the central chamber was 1–2 cm min^{-1}, it may be suggested that a concentration gradient is formed: the highest concentration of the solution is observed in the bottom part and the lowest, in the top part (on the feed side).

The current efficiencies by sodium hydroxide and sulfuric acid are different, with that by sodium hydroxide higher in all cases. Accordingly, the dialyzate outflowing from the central chamber contains, in addition to sodium sulfate, also sulfuric acid, whose concentration depends on the transport number and on the solution flow rate. Generalization of this fact shows that, if the current efficiencies by the products

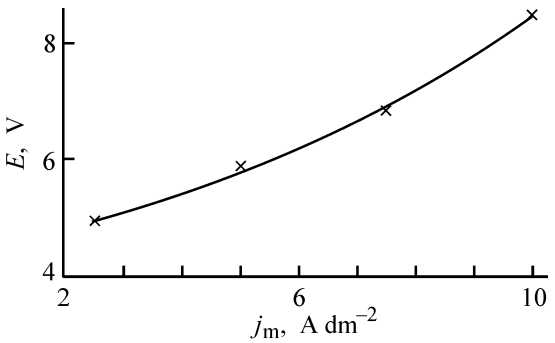

Fig. 3. Electrodialyzer voltage E vs. the current density on the membrane j_m. Initial solution contains 50 g dm^{-3} Na_2SO_4.

obtained in the electrode chambers of the electrodialyzer are different (which is primarily determined by the characteristics of the membranes used), then the product with a lower current efficiency will be also present in the dialyzate.

The presence of sulfuric acid in the central chamber, which results from the lower selectivity of the anion-exchange membrane, may be responsible for the decrease in the current efficiency by sodium hydroxide obtained in the cathode chamber. This is because the solution contains, in addition to Na^+ cations, also hydroxonium ions H_3O^+ involved in the transfer across the cation-exchange membrane. The transfer of H_3O^+ ions from the central chamber to the catholyte does not yield sodium hydroxide and only promotes transport of water, thereby diluting the catholyte. Each hydroxonium ion that passes into the catholyte across the membrane interacts with a hydroxy ion to form water:

$$H_3O^+ + OH^- = 2H_2O.$$

Analysis of Eqs. (3)–(6) confirms the above observations. In these dependences, the influence of the membranes on the CE is reflected by the free term, with this effect being predominant. It may be considered that use of membranes with certain characteristics predetermines the limiting current efficiency, whereas changing the electrodialysis parameters produces a considerably weaker effect.

The numerical coefficients in the terms containing the current density j_m are positive, which confirms the character of their influence on the current efficiency. The presence of j_m terms (with considerably smaller numerical coefficients) shows that this influence is not linear. However, use of very high current densities in the process under discussion is unfeasible for economic reasons and the optimal current density is considerably lower than its highest admissible value indicated by membrane manufacturers. Thus, the solution in the central chamber (dialyzate) should change its concentration in the course of the electrodialysis to an as low value as possible and its electrical conductivity should be low. Under the conditions described in Table 1, the process performed at a current density j_m = 2.5 A dm^{-2} occurred at a voltage E = 4.9 V, and that carried out at j_m = 7.5 A dm^{-2}, at 6.8 V. Hence follows that the rise in the current efficiency by a value not exceeding 4 % was determined by an increase in the voltage by more than 1.9 V, i.e., by approximately 39 % (Fig. 3). Although the dependence of the voltage E on the current density is determined by the electrodialyzer design and can be improved, it would be expected that the optimal current densities in an industrial process should be the same as those in a typical electrodialysis process, i.e., in the range from one to several amperes per square decimeter.

Varying the concentration of sulfuric acid in the anolyte and that of sodium hydroxide in the catholyte at a constant current density within the range studied has no significant effect on the current efficiency.

The purpose of application of electrodialysis is to process sodium sulfate solutions to obtain reusable sulfuric acid and sodium hydroxide. However, a dialyzate containing sodium sulfate and a minor amount of sulfuric acid or sodium hydroxide is also formed, in addition to these products. The desire to obtain in electrodialysis a dialyzate of purity conforming to, at least, the requirements to wastewater commonly leads to gross energy expenditure because of the low current efficiency and the low electrolytic conductivity of the solution in the middle chamber. This adverse effect can be diminished by making the middle chamber very narrow (about 2 mm). The problems encountered when using the dialyzate can be solved in many cases in integrated systems. Commonly, at least one of these products can contain sodium sulfate in an industrial process using sulfuric acid and sodium hydroxide. If this is, i.e., sulfuric acid (as it occurs when obtaining pure silica), then the dialyzate can be used to feed the anode chamber. In this case, all the dialyzate components remain in the closed cycle of the solutions. If, however, the resulting sulfuric acid is of high purity (as is the case in integrated processing of scrap lead batteries [3]) and a sodium hydroxide solution used for desulfation of the sulfate–oxide fraction contains sodium sulfate, then the dialyzate is fed into the cathode chamber. In systems of this kind, the electrolytic conductivity of the dialyzate may be reasonably high at a low energy

expenditure (depending on the admissible Na_2SO_4 concentration), and sodium sulfate does not penetrate into wastewater at all.

CONCLUSIONS

(1) Electrodialysis is the process that makes it possible to obtain sulfuric acid, sodium hydroxide, and a dialyzate from a spent solution containing sodium sulfate, and is especially suitable for closed integrated systems. The current efficiency by the products primarily depends on the parameters of ion-exchange membranes and, to a considerably lesser extent, on the process parameters.

(2) If the membranes used in electrodialysis have different selectivities, the dialyzate contains, in addition to the residual sodium sulfate, also the product (acid or hydroxide) obtained in an electrode chamber with a lower current efficiency.

(3) In the case when one of the electrodialysis products contains sodium sulfate, the dialyzate can be used to feed that electrode chamber in which this product is formed. This makes it possible to diminish the energy expenditure, facilitates enables closed circulation of the solutions, and prevents penetration of sodium sulfate into wastewater.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Effect of Rheological Properties of the Dispersion Medium on Separation of Suspensions in Hydrocyclones with Various Working Space Configurations

V. O. Yablonskii

Volgograd State Technical University, Volgograd, Russia

Received March 16, 2005

Abstract—The model of separation of suspensions with a non-Newtonian dispersion medium in a cylindroconical hydrocyclone, which takes into account the effect of the Coriolis force on solid particles, was constructed and applied to analysis of the rheological properties of the dispersion medium on separation of suspensions in hydrocyclones with various working space configurations.

Hydrocyclones are one of multi-purpose types of apparatus for separation of heterogeneous systems in chemical, microbiological, food, and other industries. Use of hydrocyclones yields a pronounced economic effect through intensification of technological processes. The economic feasibility and efficiency of separation processes are determined by the degree of thickening of the dispersed phase and by its loss. In this context, optimizing the design parameters of hydrocyclones and determining the optimal modes of their operation are important problems, which can lead, when solved, to intensification and accelerated development of numerous branches of industry.

Until now, there has been no rigorous theory of motion of two-phase systems in a swirling vortex flow. The overwhelming majority of modern studies [1–6] are based on the equation of a unidimensional motion of a small spherical particle suspended in a viscous incompressible turbulent flow.

In [1], methods for calculation of predictable separation parameters and other important performance characteristics of cylindroconical hydrocyclones were developed in the framework of a unified stochastic approach. As noted by the authors, an exact analytical description of particle motion in a centrifugal field, based on Navier–Stokes and flow continuity equations, requires that a number of not quite correct assumptions should be made, because of the complexity of the hydrodynamic situation in hydrocyclones, which impairs the adequacy of the suggested analytical descriptions of the real hydrodynamic pattern.

In [2, 3], fundamental aspects of a calculation of turbulent particle transport in a hydrocyclone, based on the continuity equation for the solid phase flow, were considered. Such an approach makes it possible to calculate both the amount of the solid phase recovered in a hydrocyclone and its parameters (concentration, granulometric composition) at any point of the apparatus. In [4], a numerical study of the flow structure and separation processes in a hydrocyclone was carried out using the Navier–Stokes equations. The momentum transfer by the dispersed phase was described in terms of the theory of multispeed continuum. By now, the equation of radial motion of particles in hydrocyclones of various designs has been solved with account of the action of inertia and Coriolis forces on a particle [5–7]. This made it possible to calculate the size distribution of particles of the dispersed phase and to determine their content in target separation products.

The difficulty encountered in solving equations that characterize sedimentation of solid particles in a hydrocyclone consists in that, in order to satisfy the requirement that the system of equations should be closed, it is necessary to use those solutions to equations of hydrocyclone hydrodynamics, which rigorously relate the circumferential, radial, and axial components of the fluid velocity over the entire working space of the apparatus. In addition, suspensions separated in chemical industry are, in most cases, non-Newtonian media whose effective viscosity decreases as the intensity of deformation rates becomes higher, which affects the hydrodynamics of apparatus.

It was concluded in [8, 9] that the rheological equation of state of a non-Newtonian liquid, which is commonly written in the form of the Ostwald–de Weyl power law, is applicable to multiphase heterogeneous systems.

A numerical study of the flow of a film of a non-Newtonian fluid in a cylindroconical hydrocyclone, based on solution of complete equations of rheodynamics, was carried out in [10]. Description of separation processes in a hydrocyclone with a freely forming surface of a non-Newtonian fluid phase by solving complete equations of rheodynamics has not been provided until now, but it is of considerable theoretical and practical interest.

The hydrocyclone comprises a cylindrical chamber, into which a suspension to be separated is fed tangentially through the inlet pipe mounted in its upper part, and a conical section. The height of the cylindrical chamber of the hydrocyclone is equal to its diameter. The suspension delivered into the hydrocyclone flows down, swirling, along its walls, having a radial (V_r), circumferential (V_φ), and axial (V_z) velocity components. Solid particles are thrown by the centrifugal force to apparatus walls and are then removed via an unloading device at the bottom discharge. The clarified suspension is also removed via the bottom discharge.

The efficiency of suspension separation in a hydrocyclone is determined by hydrodynamic parameters of a preliminarily swirled suspension film flowing down along the case walls under the action of the gravity force and pressure created by centrifugal forces.

The problem was mathematically formulated under the following assumptions: particles of the substance being recovered are uniformly distributed in the inlet pipe of the hydrocyclone; their concentration at the hydrocyclone inlet is c_0; for a film-type flow of a suspension with a non-Newtonian dispersion medium with a high effective viscosity, the flow mode is laminar and the sedimentation mode of solid particles is laminar [11].

The mathematical modeling of the concentration field in a flow of a suspension with a non-Newtonian dispersion medium in a cylindroconical hydrocyclone is performed by using the differential equation of convective diffusion in cylindrical coordinates, which can be written at a molecular diffusion coefficient equal to zero as follows [12]:

$$\mathrm{div}(\mathbf{V}_\mathrm{h} c) = 0, \tag{1}$$

where $\mathbf{V}_\mathrm{h}$ is the vector of velocity of solid particles, and c is the concentration of these particles (kg m^{-3}).

Equation (1) can be brought to the form

$$\mathbf{V}_\mathrm{h}\,\mathrm{grad}\,c + c\,\mathrm{div}\,\mathbf{V}_\mathrm{h} = 0. \tag{2}$$

As the velocity of solid particles differs from the velocity of a continuous flow of the dispersion medium, $\mathrm{div}\,\mathbf{V}_\mathrm{h} = \dfrac{1}{r}\dfrac{\partial[r(V_{r\mathrm{h}} - V_{r\mathrm{l}})]}{\partial r}$ and Eq. (2) takes the following form:

$$V_{r\mathrm{h}}\frac{\partial c}{\partial r} + V_{z\mathrm{h}}\frac{\partial c}{\partial z} = -c\left\{\frac{1}{r}\frac{\partial[r(V_{r\mathrm{h}} - V_{z\mathrm{h}})]}{\partial r}\right\}, \tag{3}$$

where $V_{r\mathrm{h}}(r, z)$ and $V_{z\mathrm{h}}(r, z)$ are the radial and axial velocity components of solid particles (m s^{-1}); $V_{r\mathrm{l}}(r, z)$, radial velocity component of the dispersion medium (m s^{-1}); r, z, radial and axial coordinates (m); h, solid particle; and l, dispersion medium.

This equation is solved together with the equation of motion of a solid particle.

It is assumed that the solid phase of a suspension being separated is monodisperse, which makes it possible to achieve a required degree of thickening of solid particles in modeling the separation process for the finest fraction. The inertia force acting on a solid particles in the axial direction, gravity force, and Archimedes buoyancy force are neglected by assuming that the axial component of the velocity of a solid particle, $V_{z\mathrm{h}}(r, z)$ is equal to the axial component of the velocity of the dispersion medium, $V_{z\mathrm{l}}(r, z)$. This assumption is well justified in practice because separation in hydrocyclones with a non-Newtonian dispersion medium having high effective viscosity occurs at larger Froude numbers Fr (separation factors).

Taking into account that suspensions with a non-Newtonian dispersion medium are separated in hydrocyclones under the conditions in which the Reynolds number, which characterizes the sedimentation mode of a solid particle, is not large, the Magnus force can be neglected. If a centrifugal Archimedes force, resistance force, and a Coriolis force act upon a solid particle, the equation of motion of a solid particle can be written, in projections onto the r and φ axes, as

$$\left.\begin{aligned} V_{r\mathrm{h}}\frac{\mathrm{d}V_{r\mathrm{h}}}{\mathrm{d}r} + V_{z\mathrm{h}}\frac{\mathrm{d}V_{r\mathrm{h}}}{\mathrm{d}z} &= \frac{V_{\varphi\mathrm{h}}^2}{r}\left(1 - \frac{\rho_\mathrm{l}}{\rho_\mathrm{h}}\right) - \frac{3}{4}\frac{K_{fr}\rho_\mathrm{l}(V_{r\mathrm{h}} - V_{r\mathrm{l}})|V_{r\mathrm{h}} - V_{r\mathrm{l}}|}{\rho_\mathrm{h} d_\mathrm{h}\Phi(B)}, \\ V_{r\mathrm{h}}\frac{\mathrm{d}V_{\varphi\mathrm{h}}}{\mathrm{d}r} + V_{z\mathrm{h}}\frac{\mathrm{d}V_{\varphi\mathrm{h}}}{\mathrm{d}z} &= \frac{V_{\varphi\mathrm{h}}V_{r\mathrm{h}}}{r} - \frac{3}{4}\frac{K_{f\varphi}\rho_\mathrm{l}(V_{\varphi\mathrm{h}} - V_{\varphi\mathrm{l}})|V_{\varphi\mathrm{h}} - V_{\varphi\mathrm{l}}|}{\rho_\mathrm{h} d_\mathrm{h}\Phi(B)}, \end{aligned}\right\} \tag{4}$$

where K_{fr}, $K_{f\varphi}$ are the coefficients of resistance to particle motion in the radial and circumferential directions; $V_{\varphi h}(r, z)$, circumferential velocity component of solid particles (m s^{-1}); d_h, diameter of solid particles (m); ρ_h, ρ_l, densities of solid particles and dispersion medium, respectively (kg m^{-3}); and φ, circumferential coordinate (deg).

The resistance coefficients for radial motion of a particle in a non-Newtonian fluid, K_{fr}, can be calculated using the empirical formula [13]

$$K_{fr} = \frac{24f_1(n)}{\mathrm{Re}_{nr}} + \frac{f_2(n)}{(\mathrm{Re}_{nr})^{f_3(n)}}, \quad (5)$$

where

$$f_1(n) = 3^{1.5(n-1)}\frac{2 + 29n - 22n^2}{n(n+2)(2n+1)},$$

$$f_2(n) = 10.5n - 3.5, \quad f_3(n) = 0.32n + 0.13.$$

$\mathrm{Re}_{nr} = [\rho_l(d_h)^n(V_{rh} - V_{rl})^{2-n}]/k$, local Reynolds number characterizing the sedimentation mode of solid particles; k, consistency index (Pa s^{n-1}); and n, nonlinearly index of the flow curve.

The resistance coefficient for circumferential motion of a particle, $K_{f\varphi}$, is calculated using similar dependences, but with the corresponding difference of particle and fluid velocities in the circumferential direction taken as a characteristic velocity difference.

The coefficient $\Phi(B)$, which accounts for the hindered conditions of particle sedimentation, is calculated using the formula suggested by Sokolov [14]:

$$\Phi(B) = 10^{-1.82(1-B)}, \quad (6)$$

where $B = 1 - c_0/\rho_h$, is a part of a unit volume of the suspension that is occupied by the dispersion medium, and c_0 is the concentration of solid particles in the inlet pipe of the hydrocyclone (kg m^{-3}).

The initial fraction of the suspension volume occupied by solid particles, equal to $1 - B$, was taken to be 0.05.

In accordance with the method of characteristics [15], the system of differential equations in partial derivatives, (3) and (4), is reduced to an equivalent system of ordinary differential equations, which can be represented in dimensionless form as

$$\frac{dR}{dZ} = \frac{G_h}{H_h},$$

$$\frac{dC}{dZ} = -\frac{C}{H_h}\left[\frac{d(G_h - G_l)}{dR} + \frac{G_h - G_l}{R}\right],$$

$$\left.\begin{aligned}\frac{dG_h}{dZ} &= -\frac{\Theta_h^2}{H_h R}(1-P) - \frac{3}{4}\frac{K_{fr}P(G_h - G_l)|G_h - G_l|}{D_h\Phi(B)},\\ \frac{d\Theta_h}{dZ} &= \frac{\Theta_h G_h}{H_h R} - \frac{3}{4}\frac{K_{fr}P(\Theta_h - \Theta_l)|\Theta_h - \Theta_l|}{D_h\Phi(B)},\end{aligned}\right\} \quad (7)$$

where $G_h(R, Z) = [V_{rh}(r, z)]/U_0$, $H_h(R, Z) = [V_{zh}(r, z)]/U_0$, $\Theta_h(R, Z) = [V_{\varphi h}(r, z)]/U_0$, are the dimensionless radial, axial, and circumferential velocity components of particles of the solid phase; $\Theta_l(R, Z) = [V_{\varphi l}(r, z)]/U_0$, $G_l(R, Z) = [V_{rl}(r, z)]/U_0$, dimensionless circumferential and radial velocity components of the dispersion medium; $C = c/c_0$, dimensionless concentration of solid particles; $P = \rho_l/\rho_h$, density parameter; $D_h = d_h/r_k$, dimensionless diameter of solid particles; $R = r/r_k$, $Z = z/r_k$, dimensionless radial and axial coordinates; U_0 average suspension velocity in the inlet pipe of the hydrocyclone (m s^{-1}); and r_k, radius of the cylindrical chamber of the hydrocyclone (m).

The boundary conditions for the system of ordinary differential equations (7) has the form

$$Z = 0, \quad 1 - F \le R \le 1, \quad C_0 = 1, \quad (8)$$

where C_0 is the dimensionless concentration of solid particles in the inlet pipe of the hydrocyclone; $F = f/r_k$, dimensionless width of the inlet pipe of the hydrocyclone; and f, width of the initial pipe of the hydrocyclone (m).

The approximating dependences for the radial $[H_l(r, z)]$ and axial $[\Theta_l(r, z)]$ velocity components of the dispersion medium can be represented as

$$\left.\begin{aligned}H_l(R, Z) &= H_{ls}(Z)\left[1 - \left(1 - \frac{1-R}{\Delta(Z)}\right)^{M(Z)}\right],\\ \Theta_l(R, Z) &= \Theta_{ls}(Z)\left[1 - \left(1 - \frac{1-R}{\Delta(Z)}\right)^{M(Z)}\right],\end{aligned}\right\} \quad (9)$$

where $H_l(R, Z) = V_{zl}(r, z)/U_0$ is the dimensionless axial velocity component of the dispersion medium; $H_{ls}(Z)$, $\Theta_{ls}(Z)$, dimensionless axial and circumferential velocity components of the dispersion medium at the film surface; $\Delta(Z) = \delta(z)/r_k$, dimensionless thickness of the suspension film; $L(Z)$, $M(Z)$, completeness coefficients of the radial distributions of the circumferential and axial velocity components; $\delta(z)$ suspension film thickness (m).

The values of $H_{ls}(Z)$, $\Theta_{ls}(Z)$, $M(Z)$, $L(Z)$, and $\Delta(Z)$ were approximated with fourth-order polynomials.

The first equation of the system (7) determines the motion trajectory of a solid particle, which de-

pends on the place of particle entry into the apparatus, i.e., sets the direction of the characteristic. The second equation yields the value of the function, i.e., the dimensionless concentration of solid particles, which indicates the degree of concentration of solid particles, on the characteristic. The remaining equations make it possible to find the radial (G_h) and circumferential (Θ_h) velocity components of the particle.

The system of differential equations (7) was solved by the fourth-order Runge–Kutta method with a fixed step. The rate of variation of the axial coordinate for a trajectory approaching the wall is many times that of the radial coordinate in the case of a small Re_{nr} number. Therefore, the given system of equations is a stiff set [16] and its solution requires a very large number of steps. the integration interval from the lower boundary of the inlet pipe of the hydrocyclone to the outlet orifice of the conical part of the case was divided into $M = 3 \times 10^5$ steps along the Z axis and the system of differential equations (7) was integrated using a software composed in Compaq Visual Fortran language. The error in solving the system, evaluated by doubling the number of steps, did not exceed 1×10^{-5}.

The separation of suspensions with a non-Newtonian dispersion medium in a hydrocyclone was simulated by modeling the velocity and pressure component fields in a flow of a non-Newtonian fluid in a cylindroconical hydrocyclone [10] and then approximating the results obtained. This was done by solving the system of differential equations (7) at a boundary condition (8) for widely varied defining similarity numbers and rheological constants of the dispersion medium. The flow of a non-Newtonian fluid in the hydrocyclone is characterized by a centrifugal Froude number Fr (separation factor), modified Reynolds number Re_n, dimensionless flow rate parameter Q, and nonlinearity index n of the flow curve. Sedimentation of solid particles in the field of centrifugal forces in a non-Newtonian dispersion medium is characterized by a local Reynolds number Re_{nr}, which varies along the trajectory of a particle.

The defining similarity numbers [10] were calculated as follows:

$$\mathrm{Fr} = \frac{U_0^2}{gr_k}, \quad \mathrm{Re}_n = \frac{\rho_l U_0^{2-n} r_k^n}{k}, \quad Q = \frac{q}{\pi r_k^2 U_0} = \frac{ef}{\pi r_k^2}, \quad (10)$$

where q is the suspension flow rate ($m^3\ s^{-1}$); e, height of the inlet pipe of the hydrocyclone (m); and g, acceleration of gravity ($m\ s^{-2}$).

The width F of the inlet pipe of the hydrocyclone was divided in the radial direction into 20 equal intervals and, for each point at boundaries between the intervals, a calculation of the corresponding trajectory and concentrations of solid particles along this trajectory was commenced. This was done so because the trajectory of a particle at prescribed hydrodynamic parameters of a suspension film is uniquely determined by the place of its entry into the apparatus. The arrival of a solid particle to the wall was determined from the condition $1 - R \le D_h$ with account of the accumulation of a deposit layer on the wall. As a solid particle arrived to the wall, the calculation for the given trajectory was terminated and a calculation of the next trajectory was commenced. The results obtained in the numerical simulation are shown in Figs. 1, 2.

Fig. 1a (*I*) shows the trajectories of solid particles, and Fig. 1b (*I*), the distributions of the concentrations of solid particles along the respective trajectories at Fr = 85, $Re_n = 4 \times 10^3$, $Q = 3.98 \times 10^{-2}$, $n = 0.6$, and $\alpha = 5°$. Analysis of Fig. 1a (*I*) demonstrates that the most intense sedimentation of solid particles in a centrifugal field occurs in the cylindrical chamber of the hydrocyclone, in which solid particles are in the zone of high values of the circumferential velocity component of the dispersion medium, Θ_l, near the surface of the suspension film. In the bottom zone of the conical part of the case, the film becomes considerably thicker and the radial velocity component of the dispersion medium, G_l, directed toward the apparatus axis, grows, with the result that particles move away from the case wall.

The concentrations of solid particles grow along the trajectories because of the thickening of the solid phase, and this increase is the most pronounced in regions close to the boundary between the thickened and clarified suspension.

Fig. 1 (*II*, *III*) shows the trajectories and concentration distributions for Fr, Re_n, Q, and n corresponding to Fig. 1 (*I*) at $\alpha = 10$ and 15°, respectively. Analysis of Fig. 1 (*I–III*) demonstrates that the maximum dimensionless concentration of solid particles, characterizing the degree of its thickening, is observed for $n = 0.6$ at $\alpha = 5°$. This is due to the low rate of decay of the circumferential velocity component of the dispersion medium, Θ_l, in the direction of the Z axis and to the high value of the completeness coefficient L of the radial distribution of Θ_l at a more pronounced anomaly of the non-Newtonian

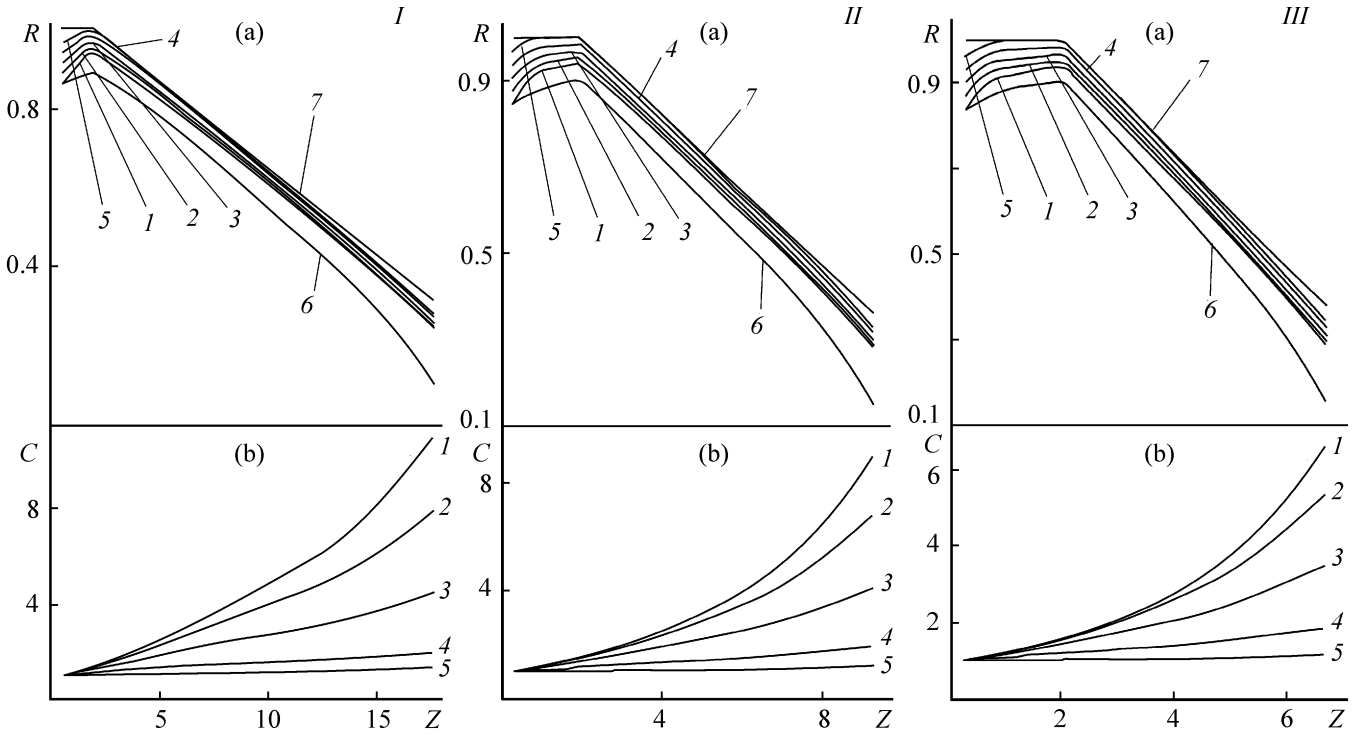

Fig. 1. (a) Trajectories of solid particles and (b) distribution of the concentrations C along the trajectories at Fr = 85, $\mathrm{Re}_n = 4 \times 10^3$, $Q = 3.98 \times 10^{-2}$, $n = 0.6$, $D_\mathrm{h} = 1.75 \times 10^{-3}$, and $P = 0.5$. (R) Dimensionless radial coordinate and (Z) dimensionless axial coordinate; the same for Fig. 2. α (deg): (*I*) 5, (*II*) 10, and (*III*) 15; the same for Fig. 2. (*1*) Trajectory corresponding to the boundary between the zones of clarified and thickened suspension, (*2*–*5*) trajectories of solid particles, (*6*) boundary of the suspension film, (*7*) wall of the hydrocyclone case; the same for Fig. 2.

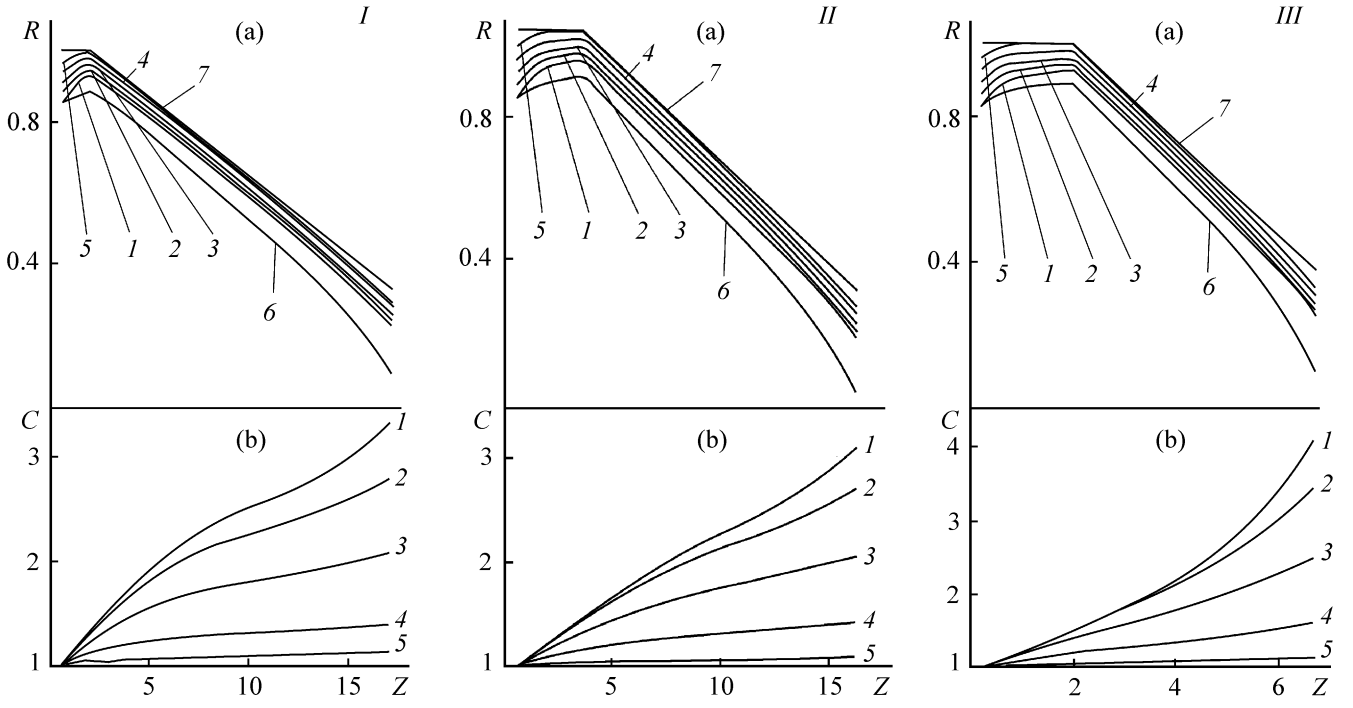

Fig. 2. (a) Trajectories of solid particles and (b) distribution of the concentrations C along the trajectories at Fr = 85, $\mathrm{Re}_n = 4 \times 10^3$, $Q = 3.98 \times 10^{-2}$, $n = 0.8$, $D_\mathrm{h} = 1.75 \times 10^{-3}$, and $P = 0.5$.

properties of the dispersion medium (n = 0.6). This yields a high degree of thickening of solid particles, because the length of the conical part of the hydrocyclone case is larger in the direction of the Z axis at $\alpha = 5°$, which makes longer the residence time of the suspension in the separation zone.

Fig. 2 (*I–III*) shows the trajectories and concentration distributions for Fr, Re_n, and Q corresponding to Fig. 1 (*I–III*) at n = 0.8 and $\alpha = 5°$, 10°, and 15°, respectively. Comparison of the concentration distributions at n = 0.8 [Fig. 2 (*I–III*)] and n = 0.6 [Fig. 1 (*I–III*)] shows that the degree of thickening of solid particles is lower at n = 0.8, which can be attributed to a faster decay of the circumferential velocity component Θ_1 in the direction of the Z axis and to a lower completeness coefficient L of the radial distribution of Θ_1 at a less pronounced anomaly of the non-Newtonian properties of the dispersion medium. Comparison of the data in Fig. 2 (*I–III*) suggests that the highest degree of thickening of solid particles at n = 0.8 is observed at $\alpha = 15°$, because this angle of conicity provides the minimum decay of the circumferential velocity component Θ_1 in the direction of the Z axis. At $\alpha = 5°$, the degree of thickening of solid particles exceeds that at $\alpha = 10°$, because the strong decay of the Θ_1 component along the Z axis at 5° is compensated for by the large length of the conical part of the hydrocyclone case in the direction of the apparatus axis.

As follows from the analysis of the calculated data for Fr, Re_n, and Q corresponding to Fig. 1 (*I–III*), even lower degrees of thickening of solid particles are obtained at n = 1.0 (Newtonian fluid), compared with the case of n = 0.8, because the rate of decay of the circumferential velocity component Θ_1 in the direction of the Z axis increases as the anomaly of the non-Newtonian properties of the dispersion medium becomes less pronounced. The lowest degree of thickening of solid particles is observed at $\alpha = 5°$ because of the strong decay of the Θ_1 component along the Z axis. At α = 10 and 15°, the degrees of thickening of solid particles are approximately the same because of the opposite kinds of influence exerted on the degree of thickening by such factors as the rate of decay of the circumferential velocity component Θ_1 of the dispersion medium along the Z axis and the length of the conical part of the hydrocyclone case in the direction of the apparatus axis.

CONCLUSIONS

(1) The degree of thickening of solid particles of the suspension in a cylindroconical hydrocyclone grows as the anomaly of the non-Newtonian properties of the dispersion medium becomes more pronounced because of the decrease in the rate of decay of the circumferential velocity component of the dispersion medium along the hydrocyclone axis and increase in the completeness coefficient of its radial distribution.

(2) The influence exerted by the angle of conicity of the hydrocyclone case on the degree of thickening of solid particles depends on the rheological properties of the dispersion medium, which determine the rate of decay of the circumferential velocity component of the dispersion medium along the hydrocyclone axis, because the rate of decay decreases and, simultaneously, so does the length of the conical part of the case along the apparatus axis, which makes shorter the residence time of the suspension in the separation zone.

(3) The mathematical model of separation of suspensions with a non-Newtonian dispersion medium in a cylindroconical hydrocyclone, constructed in the study, makes it possible to calculate the degree of thickening of solid particles as a function of the defining similarity numbers and rheological properties of the dispersion medium and can be used as a basis for developing a procedure for engineering calculations of hydrocyclones for separation of rheologically complex media.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis of *N*-Substituted Oxazolidines and Morpholines

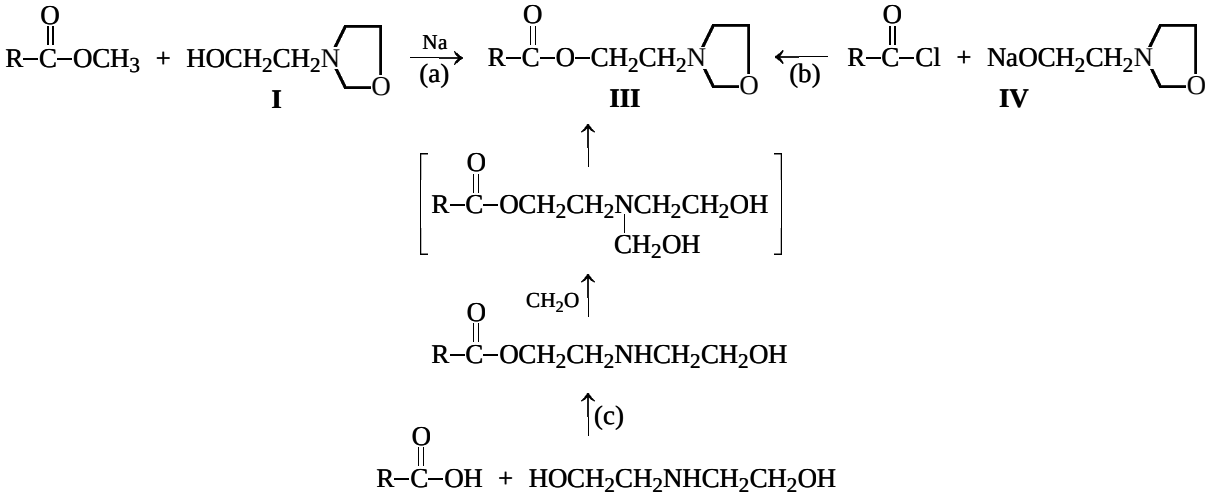
Abstract—A series of *N*-substituted oxazolidines and morpholines were prepared and characterized.

Among synthetic antioxidants, amine and diamine derivatives are the most similar to natural antioxidants in the antiradical activity [1]. Therefore, it was of interest to prepare new oxazolidine and morpholine derivatives and to study their antioxidant properties.



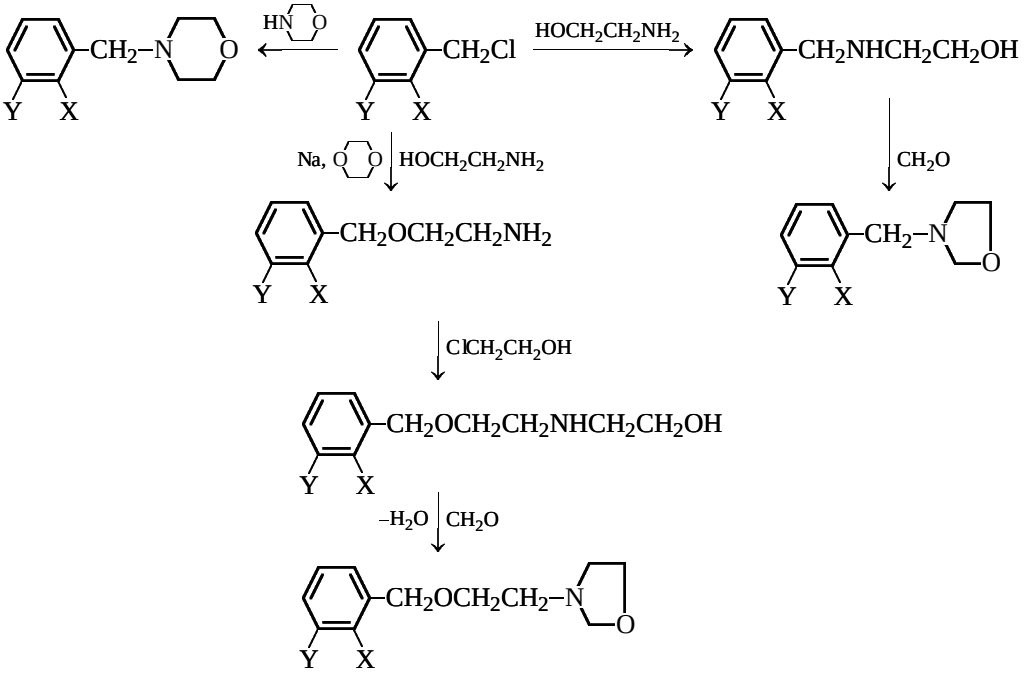
Condensation of *N*-methylethanolamine with aldehydes yielded *N*-methyloxazolidines [2]. Among *N*-substituted morpholine derivatives, 4-(2-hydroxyethyl)-, 2-methyl-4-(2-hydroxyethyl)-, and 2,2-dimethyl-4-(2-hydroxyethyl)morpholines and 4-benzyl-4-(2-benzyloxyethyl)morpholinium chloride are known [3].

In this study, we prepared new nitrogen-containing compounds, *N*-(2-alkanoyloxyethyl), *N*-(halobenzyl), and *N*-(halobenzyloxyethyl) derivatives of 1,3-oxazolidine and morpholine by reacting carboxylic acids and halobenzyl chlorides with ethanolamine, diethanolamine, ethylene chlorohydrin, morpholine, *N*-(2-hydroxyethyl)-1,3-oxazolidine, and *N*-(2-hydroxyethyl)-1,3-morpholine.

As a route to *N*-(2-alkanoyloxyethyl) derivatives of 1,3-oxazolidine and morpholine, we first examined the thermal esterification of carboxylic acids with *N*-(2-hydroxyethyl)oxazolidine **I** and *N*-(2-hydroxyethyl)morpholine **II**. Oxazolidine **I** was prepared by condensation of diethanolamine with formaldehyde [4], and morpholine **II**, by the reaction of morpholine with ethylene chlorohydrin.

The esterification was performed by the procedure described in [5]. We found that, in the reactions of carboxylic acids with oxazolidine **I**, the oxazolidine ring is cleaved first, yielding a complex mixture of products; in esterification of propionic acid, we isolated a product identified by ^{1}H NMR spectroscopy as $(CH_3CH_2COOCH_2CH_2)_2NCH_3$.

We succeeded in preparation of *N*-(2-alkanoyloxyetyhyl)-1,3-oxazolidines **III** by three routes: ester interchange of carboxylic acid methyl esters with *N*-(2-hydroxyethyl)-1,3-oxazolidine **I** (route a), reaction of carboxylic acid chlorides with *N*-(2-hydroxyethyl)-1,3-oxazolidine sodium derivative **IV** (route b), and esterification of carboxylic acids with diethanolamine, followed by condensation of the resulting ester with formaldehyde (route c):



1070-4272/05/7808-1301 © 2005 Pleiades Publishing, Inc.

Synthesis of esters **III** by the reaction of carboxylic acids with diethanolamine is complicated by formation of a minor amount of *N*-acyldiethanolamine, which is difficult to separate.

In contrast to oxazolidine **I**, thermal esterification of carboxylic acids with morpholine **II** occurs without complications and yields *N*-(2-alkanoyloxyethyl)morpholines **V** in high yield (80–90%).

Then we prepared new *N*-substituted 1,3-oxazolidine and morpholine derivative by the reactions of halobenzene chlorides with ethanolamine or morpholine:

where Y = H, X = F: Y = Cl, X = H.

Among the compounds synthesized, *N*-(2-ethanoyloxyethyl)-1,3-oxazolidine was tested as antioxidant in studying the photosynthetic activity of *Synechococcus sp*. PCC 7942 (*Cyanophyceae*) cells as influenced by various doses of UV-C radication and the effect of various chronic doses of UV-C radiation on the duplication cycles of the population density of these cells. We found that the antioxidant deactivates the radicals generated in the cell throughout the experiment and thus increases the relative contribution from stimulation of cell fission by small doses of UV-C radiation; upon a single introduction into the cultural medium, the antioxidant restores the suppression of the fission rate of the irradiated cells by chronically high UV-C radiation doses to the level of the control population.

EXPERIMENTAL

The ^{1}H NMR spectra were recorded on a Bruker-300 spectrometer.

***N*-(2-Hydroxyethyl)-1,3-oxazolidine I**. a. A 55-g portion of diethanolamine was added dropwise over a period of 20 min to a stirred mixture of 15 g of paraform and 50 ml of benzene, heated to 80°C. After that, the stirring was continued for an additional 1.5 h. After the reaction completion, the solvent was distilled off; by distillation of the residue in a nitrogen flow under reduced pressure, we isolated 53 g (87%) of *N*-(2-hydroxyethyl)oxazolidine **I**, bp 79–80°C (4 mm Hg), d_4^{20} 1.1236, n_D^{20} 1.4764. ^{1}H NMR spectrum, δ, ppm: 2.68 (2H, NCH_2), 2.98 (2H, NCH_2), 3.61 t (2H, OCH_2), 3.75 t (2H, OCH_2), 4.25 s (2H, NCH_2O), 4.7 s (H, OH). ^{13}C NMR spectrum, δ_C, ppm: 52.5, 57.0, 62.0, 66.0, 87.0.

Di(2-propanoyloxyethyl)methylamine. b. A mixture of 11.7 g of oxazolidine **I** and 22.2 g of propionic acid was stirred at 130°C for 6 h. After the reaction completion, the mixture was neutralized with KOH and filtered to remove the potassium propionate precipitate. By distillation in a nitrogen flow under re-

duced pressure, we isolated 4 g (25%) of di(2-propanoyloxyethyl)methylamine, bp 102–103°C (2 mm Hg), d_4^{20} 1.0202, n_D^{20} 1.4400. ^{1}H NMR spectrum, δ, ppm: 1.18 t (6H, $2CH_3$), 2.32 q (4H, $2CH_2$), 2.4 s (3H, CH_3), 2.71 t [4H, $N(CH_2)_2$], 4.15 t (4H, $2OCH_2$). ^{13}C NMR spectrum, δ_C, ppm: 9.9, 27.0, 43.0, 56.0, 62.0, 172.5.

***N*-(2-Alkanoyloxyethyl)oxazolidines**. c. A solution of 0.09 ml of **I** in *m*-xylene was added dropwise to 0.005 mol of finely divided Na in 20 ml of *m*-xylene. After the completion of the initially vigorous reaction, the mixture was heated to 60°C, and the stirring was continued at this temperature until the sodium fully dissolved. Then 0.08 mol of appropriate carboxylic acid methyl ester was added dropwise at 120°C to the alcoholate, and the released methanol was distilled off. After cooling, the organic matter was separated, the residue was washed with benzene, and, after common work-up, the target products were isolated by distillation in a nitrogen flow under reduced pressure.

N-(2-Butanoyloxyethyl)-, *N*-(2-pentanoyloxyethyl)-, *N*-(2-hexanoyloxyethyl)-, and *N*-(2-octanoyloxyethyl)-1,3-oxazolidines were prepared (see table).

N-(*o*-Fluorobenzyl-oxyethyl)oxazolidine	76	134–135 (2)	1.5070	1.1349	–
N-(*m*-Chlorobenzyl-oxyethyl)oxazolidine	72	148–149 (2)	1.5370	1.1786	^{1}H NMR: 2.66 t, (2H, NCH_2), 2.86 t, (2H, NCH_2), 3.49 t, (2H, OCH_2), 3.61 t, (2H, OCH_2), 4.15 s, (2H, NCH_2O), 4.4 s, (2H, $C_6H_4CH_2$), 7.0–7.3 m, (4H, C_6H_4). ^{13}C NMR: 53, 54, 62, 71, 73, 87, 125, 129, 134, 141

***N*-(2-Ethanoyloxyethyl)-1,3-oxazolidine**. A solution of 5.7 g of **I** in benzene was added dropwise to 1.124 g of finely crushed Na in 20 ml of benzene. After the completion of the initially vigorous reaction, the mixture was heated to 60°C, and the stirring was continued at this temperature until the sodium fully dissolved. Then 3.82 g of acetyl chloride was added dropwise to the alcoholate at 20–22°C over a period of 2 h, after which the mixture was stirred for an additional 4 h. After the reaction completion, the organic phase was filtered to remove NaCl, the solvent was distilled off, and the residue was distilled in a nitrogen flow under reduced pressure to obtain 4 g (40%) of *N*-(2-ethanoyloxyethyl)-1,3-oxazolidine, bp 90°C (2 mm Hg), d_4^{20} 1.0998, n_D^{20} 1.4520. ^{1}H NMR spectrum, δ, ppm: 2.1 t (3H, CH_3), 2.75 t (2H, NCH_2), 3.0 t (2H, NCH_2), 3.72 t (2H, OCH_2), 4.15 t (2H, OCH_2), 4.21 s (2H, NCH_2O). ^{13}C NMR spectrum, δ_C, ppm: 20.0, 54.0, 62.5, 87.0, 170.0.

***N*-(2-Pentanoyloxyethyl)-1,3-oxazolidine**. A mixture of 10.5 g of diethanolamine, 10.2 g of valeric acid, and 30 ml of toluene was refluxed until the release of water was complete, after which the mixture was neutralized with KOH and filtered to remove KCl; the solvent was distilled off, and distillation of the residue in a nitrogen flow under reduced pressure gave 5 g (26%) of 2-(2-hydroxyethyl)aminoethyl valerate, bp 135–137°C (2 mm Hg), d_4^{20} 1.0816, n_D^{20} 1.4730.

The condensation of 2-(2-hydroxyethyl)aminoethyl valerate was performed by procedure a. The yield and physicochemical constants of *N*-(2-pentanoyloxyethyl)-1,3-oxazolidine coincided with those of the same product obtained by method c.

***N*-(2-Hydroxyethyl)morpholine**. To a mixture of 34.8 g of morpholine and 32.2 g of ethylene chlorohydrin, we added dropwise at 40–45°C over a period of 1.5 h 32 g of a 50% NaOH solution. After the reaction completion, the organic layer was separated and dried over sodium sulfate; by distillation in a nitrogen flow under reduced pressure, we isolated 35 g (67%)

of *N*-(2-hydroxyethyl)morpholine, bp 104°C (10 mm Hg), d_4^{20} 1.0742, n_D^{20} 1.4766. ^{1}H NMR spectrum, δ, ppm: 2.52 t (2H, NCH_2), 2.53 t [4H, $N(CH_2)_2$], 3.66 t [4H, $O(CH_2)_2$], 4.23 s (H, OH). ^{13}C NMR spectrum, δ, ppm: 54.0; 58.0, 61.0, 66.5.

***N*-(2-Alkanoyloxyethyl)morpholines** were prepared by esterification of carboxylic acids with morpholine **II**. The reactions were performed similarly to the preparation of *N*-(2-pentanoyloxyethyl)-1,3-oxazolidine. *N*-(2-Ethanoyloxyethyl)-, *N*-(2-propanoyloxyethyl)-, *N*-(2-butanoyloxyethyl)-, *N*-(2-pentanoyloxyethyl)-, *N*-(2-hexanoyloxyethyl)-, and *N*-(2-octanoyloxyethyl)morpholines were prepared (see table).

***N*-(Halobenzyl)morpholines**. To a stirred solution of 0.125 mol of morpholine in 60 ml of benzene, heated to 80°C, we added dropwise over a period of 1 h 0.125 mol of halobenzyl chloride, after which the mixture was stirred for an additional 3 h. After the reaction completion, the mixture was neutralized with a 5% $NaHCO_3$ solution, washed with water to neutral reaction, and dried over sodium sulfate. After distilling off the solvent, the desired compounds were isolated by distillation in a nitrogen flow under reduced pressure.

***N*-(*o*-Fluorobenzyl)- and *N*-(*m*-chlorobenzyl)morpholines** were prepared (see table). Data on *N*-(halobenzyl)-1,3-oxazolidines are listed in the table.

***N*-(*m*-Chlorobenzyl)- and *N*-(*o*-fluorobenzyl)ethanolamines**. Halobenzyl chloride (0.12 mol) was added dropwise to a stirred mixture of 1 mol of ethanolamine and 30 ml of benzene, after which the mixture was refluxed with stirring for 4 h, neutralized after cooling with KOH, and filtered to remove KCl. The benzene was distilled off, and the target products were isolated by distillation in a nitrogen flow under reduced pressure.

***N*-(*m*-Chlorobenzyl)- and *N*-(*o*-fluorobenzyl)oxazolidines** were prepared similarly to *N*-(2-hydroxyethyl)-1,3-oxazolidine. Data on *N*-(halobenzyloxyethyl)-1,3-oxazolidines are listed in the table.

β-(*m*-Chlorobenzyloxy)- and β-(*o*-fluorobenzyloxy)ethylamines. Ethanolamine (0.1 mol) was added dropwise to 0.25 mol of finely divided Na in 25 ml of dioxane. After the completion of the initially vigorous reaction, the mixture was heated to reflux and stirred at this temperature until the sodium fully dissolved. Then, while cooling below 15°C, 0.19 mol of halobenzyl chloride was added dropwise, and the resulting mixture was stirred for 5 h. After the reaction completion, the mixture was filtered to remove NaCl, the dioxane was distilled off, and the desired products were isolated by distillation in a nitrogen flow under reduced pressure.

***N*(*m*-Chlorobenzyloxyethyl)- and *N*-(*o*-fluorobenzyloxyethyl)ethanolamines** were prepared similarly to *N*-(*m*-chlorobenzyl)- and *N*-(*o*-fluorobenzyl)-1,3-oxazolidines.

***N*-(*m*-Chlorobenzyloxyethyl)- and *N*-(*o*-fluorobenzyloxyethyl)oxazolidines** were prepared similarly to *N*-(2-hydroxyethyl)-1,3-oxazolidine.

CONCLUSION

Thermal esterification of carboxylic acids with *N*-(2-hydroxyethyl)morpholine gives *N*-(2-alkanoyloxyethyl)morpholines in high yield (80–90%). With *N*-(2-hydroxyethyl)-1,3-oxazolidine, a complex mixture of products is formed; the desired products were obtained in 50–80% yield by indirect procedures.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Mechanochemical Synthesis of Nitrogen-containing Derivatives of Flax Boon

M. V. Efanov, D. V. Dudkin, and A. I. Galochkin

Altai State University, Barnaul, Russia

Received March 10, 2005; in final form, May 14, 2005

Abstract—The influence exerted by the conditions of the mechanochemical synthesis [time (100–100 min), air pressure (1–9 atm), temperature (30–90°C), amount of ammonia (0.5–3.0 g g^{-1} raw material)] on the content of nitrogen and functional groups in the products of oxidative ammonolysis of flax boon was studied. The resulting products were tested as nitrogen-containing ion exchangers in sorption of heavy metals.

In processing of plant raw materials, the modern trends are toward integrated chemical processing of the whole biomass to obtain polymeric compounds with prescribed properties. One of the ways of utilizing plant wastes is their use as raw materials for preparing fertilizers and sorbents [1, 2].

To obtain a nitrogen-containing fertilizer from wood bark, Deineko et al. suggested a process involving chemical treatment of the plant raw material with oxygen in aqueous ammonia (oxidative ammonolysis) [3]. The main disadvantages of this process are high temperature (75–200°C), high oxygen pressure (up to 8 MPa), and relatively low nitrogen content in the resulting fertilizer (1.0–3.5%).

Oxidation of lignocarbohydrate materials with ammonium persulfate in ammonia under mild conditions yielded valuable nitrogen-containing derivatives suitable as nitrogen-containing organic fertilizers and ion exchangers [4]. However, commercial use of this process is restricted by the high cost of ammonium persulfate and its large consumption. We have developed a new mechanochemical procedure for preparing nitrogen-containing derivatives of lignocarbohydrate materials by oxidation with atmospheric oxygen in aqueous ammonia [5].

Flax boon is a fairly valuable plant raw material; it is available in large amounts as a waste from flax processing in Altai krai and finds no proper use today. The possibility of using flax boon oxidation products as nitrogen-containing organic fertilizers was shown in [6].

In this study, we examined how the conditions of flax boon oxidation with atmospheric oxygen in aqueous ammonia affect the composition and properties of the resulting nitrogen-containing derivatives.

EXPERIMENTAL

As the raw material we used finely cut flax boon from the Biisk Flax Joint-Stock Company as air-dry particles ~0.5 mm in size.

According to chemical analysis [7], the raw material contained 37.2% cellulose, 25.6% hemicellulose, and 35.8% lignin.

The oxidative ammonolysis was performed as follows. A 5.0-g sample of air-dry flax boon was placed in a 300 cm^3 cylindrical reactor of a vibration mill (IV-98B vibrator, frequency 2800 cm^{-1}) with 15 steel rods (10 × 100 mm).

The temperature-controlled reactor was charged with 25% aqueous ammonia in an amount of 0.5–3.0 g of NH_3 per gram of the raw material, air was pumped in with a compressor to the final pressure of 1–9 atm, and the mixture was vigorously milled for 10–100 min. The temperature in the reaction chamber was 30–90°C. After the process completion, the products were unloaded, separated from the rods, washed with water to neutral reaction, and dried in a desiccator to constant weight.

The products were analyzed for the content of fixed nitrogen by the Kjeldahl method [8], for the content of carboxy groups by conductometric back-titration, and for the content of phenolic hydroxy groups by a chemisorption method as described in [9]. The sorption power of the nitrogen-containing flax boon derivatives

1070-4272/05/7808-1306 © 2005 Pleiades Publishing, Inc.

toward Cu(II) and Cd(II) ions was determined under the equilibrium conditions as described in [2].

Figure 1a shows how the duration of the mechanochemical synthesis affects the functional composition of the products of oxidative ammonolysis of flax boon. It is seen that the mechanochemical treatment for a time exceeding 60 min does not lead to further changes in the content of fixed organic nitrogen and functional groups.

In the first 30 min of the process, the content of phenolic hydroxy groups steadily decreases, and carboxy groups are accumulated. The nitrogen content grows insignificantly. However, the content of carboxy groups increases to a greater extent than decreases the content of phenolic groups. Apparently, carboxy groups in the macromolecular components of the boon are formed not only by oxidation of phenolic groups but also by demethoxylation. This was shown in our previous study [10].

In the interval from 40 to 60 min, fixed organic nitrogen is accumulated, and the content of carboxy groups decreases. This is apparently due to the reaction of ammonia with carboxy groups to form amide groups.

Figure 1b shows that the dependence of the content of fixed nitrogen on the air pressure flattens out. An increase in the oxygen pressure above 6 atm does not result in a significant increase in the content of fixed nitrogen. The content of carboxy groups varies insignificantly, which is apparently due to possible decarboxylation and formation of amide groups at 70°C under the conditions of mechanochemical synthesis.

Table 1 shows how the amount of ammonia affects the functional composition of the products of the

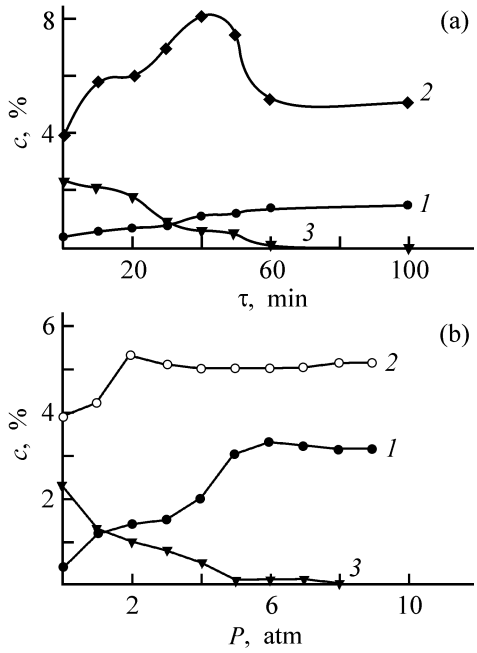

Fig. 1. Content *c* of (*1*) nitrogen, (*2*) COOH groups, and (*3*) phenolic OH groups in the products of oxidative ammonolysis of flax boon vs. the (a) duration *t* of mechanochemical treatment and (b) air pressure *P*.

oxidative ammonolysis. With an increase in the ammonia amount from 0.5 to 1.5 g g^{-1} raw material, the content of fixed nitrogen increases from 1.6 to 5.6%. A decrease in the content of carboxy groups is apparently due to decarboxylation or formation of amide groups. A further increase in the ammonia content to 3.0 g g^{-1} does not lead to significant changes in the content of fixed nitrogen and carboxy groups.

We examined the influence of temperature on the functional composition of the products of oxidative ammonolysis of flax boon (Table 2) and revealed no definite trends.

Table 1. Influence of the ammonia amount on the content of fixed nitrogen and carboxy groups in products of oxidative ammonolysis of flax boon (reaction time 60 min, air pressure 6 atm, temperature in the reactor 70°C)

NH_3, g g^{-1} raw material	Content, %	
	N	COOH
0.5	1.6	5.7
1.0	3.5	5.1
1.5	5.5	4.1
2.0	5.5	3.8
2.5	5.5	3.5
3.0	5.6	3.4

Table 2. Influence of temperature on the content of fixed nitrogen and carboxy groups in products of oxidative ammonolysis of flax boon (reaction time 60 min, air pressure 6 atm, 1.5 g of ammonia per gram of the raw material)

T, °C	Content, %	
	N	COOH
30	3.0	4.1
40	3.8	4.4
50	4.2	3.9
60	4.4	4.0
70	5.5	4.0
80	4.1	4.4
90	3.8	3.9

Table 3. Content of cellulose and lignin in the product of oxidative ammonolysis of flax boon. (treatment time 60 min, air pressure 6 atm, amount of ammonia 1.5 g per gram of the raw material)

Component	Content, wt %	
	initial flax boon	oxidative ammonolysis product (5.5% N)
Cellulose	37.2	34.2
Lignin	35.8	35.3

Table 4. Sorption power of nitrogen-containing flax boon derivatives toward transition metal ions (MSO_4 concentration 0.05 g-equiv l^{-1})

Sample	Pressure, atm	Content, %		SEC, mg-equiv g^{-1}	
		N	COOH	Cu^{2+}	Cd^{2+}
Initial boon	–	0.5	3.9	0.8	0.6
1	1	1.2	4.2	2.2	2.8
2	6	3.5	5.1	3.4	3.9

The content of fixed nitrogen is maximal (5.5%) upon treatment at 70°C. Thus, the following conditions of oxidative ammonolysis should be considered as optimal: treatment time 60 min, temperature 70°C, and air pressure 6 atm.

Formation of various forms of fixed nitrogen was confirmed by IR spectra. The spectra of the products contain absorption bands characteristic of carboxy groups (1720 cm^{-1}), amide groups (1650 cm^{-1}), and heterocyclic structures of the indole type (1585 and 1550 cm^{-1}).

In the product of oxidative ammonolysis of flax boon, containing 5.5% nitrogen, we determined the cellulose content by the Kürschner method and the lignin content by the Komarov method [7] (Table 3). The content of lignin in the initial flax boon and in the product of its oxidative ammonolysis is the same, i.e., no delignification occurs in the solid phase. The cellulose content changes insignificantly (by 3%).

Data on the sorption power of nitrogen-containing flax boon derivatives toward Cu(II) and Cd(II) cations are given in Table 4. As seen, the static exchange capacity (SEC) of the products of oxidative ammonolysis of flax boon for Cu(II) and Cd(II) cations increases with the content of nitrogen and COOH groups.[1]

CONCLUSIONS

(1) A procedure was developed for preparing nitrogen-containing derivatives of flax boon by its oxidative ammonolysis with atmospheric oxygen in aqueous ammonia by a mechanochemical procedure. Products containing up to 5.5% fixed organic nitrogen and up to 8.0% carboxy groups were obtained.

(2) The products exhibit high sorption power toward Cu(II) and Cd(II) ions and can be used as ion exchangers and nitrogen-containing fertilizers of prolonged action, increasing the yield of food grains by 19–24%.

[1] The product containing 5.5% fixed nitrogen was tested as a nitrogen-containing organic fertilizer for spring wheat of the Altaiskii Prostor strain (1.5 t ha^{-1}). According to the results of the field tests, the effect of the fertilizer based on the product of oxidative ammonolysis of flax boon is comparable with the effect of ammonium sulfate. The products obtained are nitrogen-containing organic fertilizers of prolonged action, increasing the yield of spring wheat by 19–24% during a period of 2–3 years.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Quick Determination of the Total Content of Aromatic Hydrocarbons in Reformer Naphthas by ^{1}H NMR Spectroscopy

V. P. Talzi, S. S. Doronina, and A. S. Belyi

Institute of Problems of Hydrocarbon Processing, Siberian Division, Russian Academy of Sciences, Omsk, Russia

Received April 20, 2005

Abstract—A procedure for fast determination of the total content of arenes in reformer naphthas by ^{1}H NMR spectroscopy was developed and tested. Their content is determined from the ratio of the integral intensities of the signals of aromatic protons and alkane methyl protons, using a calibration plot constructed on the basis of GLC data.

The procedure suggested for fast (<10 min) and relatively accurate determination of the total content of aromatic hydrocarbons in reformer naphthas by ^{1}H NMR spectroscopy may be of use not only for research but also plant laboratories, since the GLC analysis is relatively complex and time-consuming. As a rule, laboratories of oil refineries are not equipped with NMR spectrometers. This is caused by insufficient demand, rather than by the high cost of these devices: The analytical problems that could be efficiently solved by NMR and could justify the use of this method under industrial conditions are yet few. Fast and accurate determination of the total content of aromatics in reformer naphthas could be one of such problems. Also, we have recently developed a procedure [1] based on ^{1}H and ^{13}C NMR for monitoring the composition (and thus the service characteristics) of aqueous monoethanolamine solutions used at the majority of oil refineries for treating process gases.

Quantitative analysis of mixtures of organic substances by ^{1}H NMR spectroscopy, from the integral intensities of nonoverlapping signals of components, is a routine procedure that has been used for many decades [2]; it is not inferior to GLC in the accuracy.

Figures 1a and 1b show the ^{1}H NMR spectra of a reformer naphtha sample obtained on a laboratory rig. All the aromatic protons of its components, from mesitylene (upfield border of the range) to naphthalene (downfield border), give signals in the range from 6.6 to 7.7 ppm; no other protons give signals in this range. Thus, the integral intensity of signals in this range of the ^{1}H NMR spectra can be an adequate measure of the total content of aromatic hydrocarbons in the sample. As the absolute intensities of signals, as a rule, do not bear analytical information, it is necessary to choose an appropriate reference signal in the

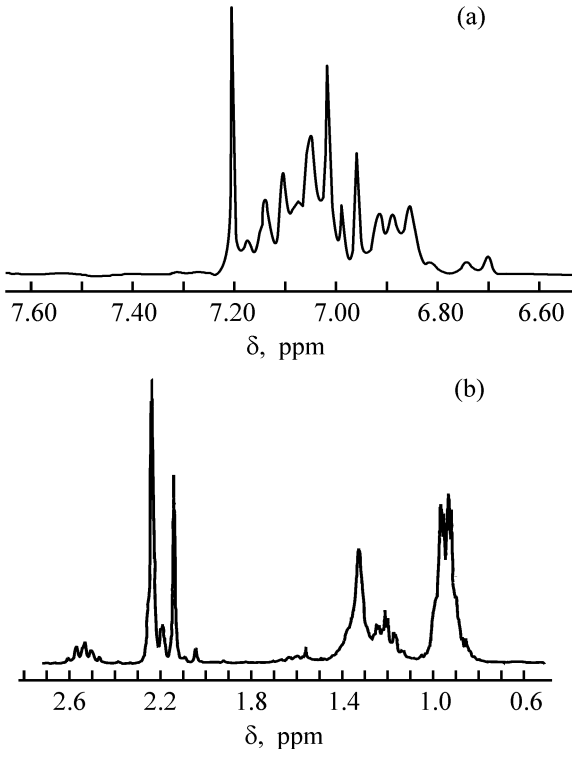

Fig. 1. (a) Low-field (aromatic protons) and (b) high-field parts of the ^{1}H NMR spectrum of a reformer naphtha sample. In the range 3.0–6.6 ppm, there are no signals. (δ) Chemical shift.

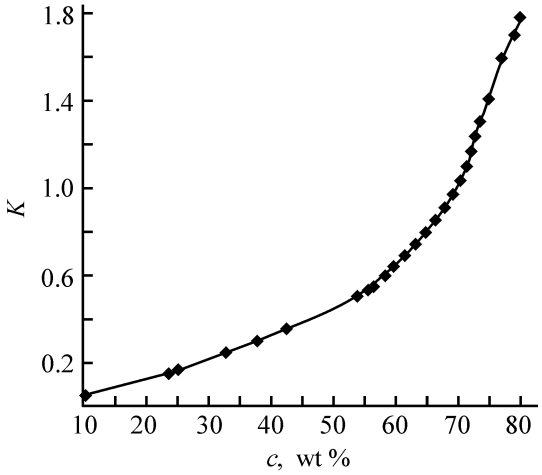

Fig. 2. Calibration curve plotted to determine total content of arenes in reformer naphthas, according to ^{1}H NMR spectrum. (*K*) Ratio of the integral intensities of the signals from the aromatic and aliphatic protons at 6.7–7.7 and 0.8–1.0 ppm and (*c*) total content of arenes in the samples produced by GLC.

^{1}H NMR spectrum, so that the ratio of the intensities of the signals from aromatic protons and the reference signal should be the measure of the content of arenes. As such a reference signal we chose a broad signal at 0.7–1.0 ppm belonging to methyl groups of the aliphatic components. Among aromatic compounds, only methyl groups of *n*-propylbenzene, butylbenzenes, and higher alkylbenzenes contribute to the absorption in this range. Since the content *n*-propylbenzene, the most abundant among these compounds, does not exceed 1%, this contribution can be neglected, i.e., the ratio of the integral intensities of the signals at 6.6–7.7 and 0.7–1.0 ppm can be considered as adequately reflecting the ratio of aromatic and aliphatic hydrocarbons in a sample and can be used, after appropriate calibration, as the measure of the total content of arenes in reformer naphthas.

Total content of arenes in reformer naphthas, according to GLC and NMR data

Run no.	Content, %	
	NMR	GLC
1	59.2	62.5
	66.0	66.0
	71.5	69.7
	75.1	75.3
2	63.2	62.4
	69.4	68.9
	71.3	71.1
	77.6	77.2
3	65.2	63.1
	70.5	70.2
	72.6	72.8
	77.5	80.6
4	58.3	59.9
	62.3	62.5
	63.8	64.9
	69.9	69.9
5	59.0	59.3
	61.3	62.3
	65.9	67.4
	68.0	69.2

According to reference data [3], the narrow singlet at 7.20 ppm belongs to benzene (Fig. 1a); the singlet at 7.02 ppm, to *p*-xylene; the next singlet at 6.95 ppm, to *p*-ethyltoluene; and the fourth singlet at 6.99 ppm, presumably to *p*-diethylbenzene or *p*-*n*-propyltoluene. The weak signals at 7.30 and 7.65 ppm belong to naphthalene, and the high-field signals at 6.70 and 6.75 ppm, to mesitylene and durene, respectively.

The weak signals at about 2.8 ppm belong to aliphatic protons of indan (Fig. 1b); the signals at 2.6–2.4 ppm, to α-CH_2 groups of alkylbenzenes (ethylbenzene, ethyltoluenes, *n*-propylbenzene, etc.); the signals at 2.0–2.34 ppm, to CH_3 groups of methylbenzenes; the signal at 1.25–1.40 ppm, mainly to CH_3 groups of alkanes; the triplet at 1.1–1.2 ppm, to CH_3 groups of ethylarenes; and the signal at 0.8–1.0 ppm, to CH_3 groups of alkanes and some alkylbenzenes [3].

Figure 2 shows a calibration curve plotted as the intensity ratio of the above-indicated signals of aromatic and methyl protons in the ^{1}H NMR spectra (along the ordinate) vs. the total content of aromatic hydrocarbons in the reformer naphthas according to GLC data (along the abscissa).

The curve in Fig. 2, though having numerous inflection points, is steadily ascending. The steep slope of the curve in the range of arene content typical of reformer naphthas (60–80%) means that the intensity ratio of the analytical signals appreciably changes even upon minor changes in the total content of arenes, which makes the suggested method highly accurate.

Representative data on the total content of arenes in various reformer naphtha samples, determined by NMR with the calibration curve shown in Fig. 2 and by GLC, are listed in the table. The agreement is quite reasonable, the more so as we deal with the concentrations determined by two different methods, rather than with "introduced–found" data. If similar raw materials are fed and the same catalyst is used in the reforming, the analysis accuracy is determined by

the accuracy of construction of the calibration curve. In the case of a correct calibration, the concentrations determined by NMR may be even more correct and reproducible than those determined by GLC, because recording of an NMR spectrum is not accompanied by decomposition of the sample and does not alter the results of the subsequent determinations, and the relative intensity of the signals does not appreciably depend on the quality and working status of the spectrometer and, in particular, on the uniformity of the magnetic field. Furthermore, only two groups of signals are integrated in the NMR procedure, whereas a GLC analysis involves integration of several tens of peaks, sometimes ill-resolved.

When the feed source and catalyst are replaced in a laboratory or industrial reforming installation, it is not necessary to construct a new calibration curve (Fig. 2) provided that the fractional composition of the feed with respect to major components remains similar and the new catalyst does not alter significantly the ratio of different arenes in the reformer naphtha. The data listed in the table were obtained with similar feed from several oil refineries and with several batches of commercial and experimental catalysts. At the same time, when a considerably lower-boiling benzine fraction (C_6) is used as a feed, the content of arenes in the reformer naphtha obtained by GLC (e.g., 20%) appears to be appreciably lower than that determined by NMR using the calibration curve in Fig. 2 (31%). Thus, a new calibration curve should be constructed in this case.

The approach suggested can also be used for fast estimation of the benzene content in reformer naphthas. Because the benzene signal in the ^{1}H NMR spectrum (Fig. 1a) only slightly overlaps with signals of other arenes, the ratio of the integral intensity of this signal to the total integral intensity of signals of aromatic protons can be correlated with the relative content of benzene in the sum of arenes, determined by GLC. By determining the total content of arenes (by the procedure suggested) and multiplying it by the ratio of the integral intensity of the benzene signal (7.2 ppm) to the total integral intensity of signals of aromatic protons in the ^{1}H NMR spectrum and then by the calibration factor (0.5–0.6, estimated by comparing the GLC and NMR data), it is possible to determine the benzene concentration with a relative accuracy of about 10%, at least for reformer naphthas containing 60–80% arenes.

EXPERIMENTAL

Reformer naphtha samples were obtained on an OL-120 pilot installation under typical conditions of catalytic reforming of a hydrorefined 85–120°C benzine fraction from Omsk Oil Refinery. Before measurements, naphtha samples were stabilized by the standard procedure.

The content of specific hydrocarbons and of the sum of arenes in naphtha samples was determined by gas–liquid chromatography on a Tsvet-800 analytical gas chromatograph equipped with an RTX-60 capillary column and a flame-ionizattion detector (for more detail, see [4, 5]).

The ^{1}H NMR spectra were recorded on a Bruker ACP-200P spectrometer.

CONCLUSION

Provided that similar feed and similar catalysts are used for reforming, the total content of arenes and the relative content of benzene in reformer naphthas can be determined rapidly and fairly accurately by ^{1}H NMR spectroscopy.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Colloid-Chemical Properties of Organic–Aqueous Surfactants

V. I. Chursin

Research Institute of Tanning Industry, Federal State Unitary Enterprise, Moscow, Russia

Received March, 24, 2005

Abstract—The colloid-chemical properties of organic–aqueous formulations including a nonionic surfactant, an organic solvent, and polyethylenepolyamine were studied. The most efficient methods for preparation of a new degreasing material, Skianol, were determined.

Efficient degreasing of leather and fur raw material implies use of surfactants with high dispersing and washing properties, whose components promote dissolution of natural skin fats. We suggested the compositions for such formulations in [1]. However, development of a universal organic–aqueous composition affording the maximum extent of fat removal requires optimization of both the method of its preparation and its composition.

In this study, we examined how an organic solvent and an amine-containing additive affect the colloid-chemical properties of an organic–aqueous formulation and its preparation in the optimal, from the viewpoint of the technological use, consistency, namely, as a gel. We showed in [1] that introduction of an organic solvent into aqueous solutions of surfactants decreases the surface tension of the system formed. It can be assumed that other properties of these systems will change as well. Organic-aqueous systems are of both scientific and practical interest. It is known that the nature of the intermolecular interactions and morphological structures formed in such systems depends on the content of the organic solvent [2]. A study of the electrical conductivity of organic–aqueous formulations can facilitate the choice of the optimal composition.

We studied the properties of aqueous solutions of Neonol 9-10 and Neonol 9-12 in the presence of an organic solvent (turpentine) and an amine-containing compound (polyethylenepolyamine, PEPA). The concentration of the surfactant in the aqueous solutions was 50%, and that of PEPA, 2 %. The electrical conductivity of the solutions was measured on a Hanna conductometer.

Figure 1 shows the results of conductometric titration of an aqueous solution of the surfactant with an organic solvent in the presence of an auxiliary amine-containing additive. It is seen from Fig. 1 that, upon addition of the organic component to the aqueous solution of the surfactant, the electrical conductivity of the latter decreases. This is due to a decrease in the dielectric constant of the system. On the whole, the electrical conductivity of the solutions in the presence of the amine-containing compound is higher than that in the systems containing solely the surfactant. Introduction of the solvent into the system without a surfactant also causes the electrical conductivity to decrease; but this process is characterized by the lack of kinetic stability of the system owing to a nonuniform distribution of the organic component throughout of the system.

When a certain amount of the organic solvent was introduced into the system during conductometric titration of the surfactant solutions, the system turned

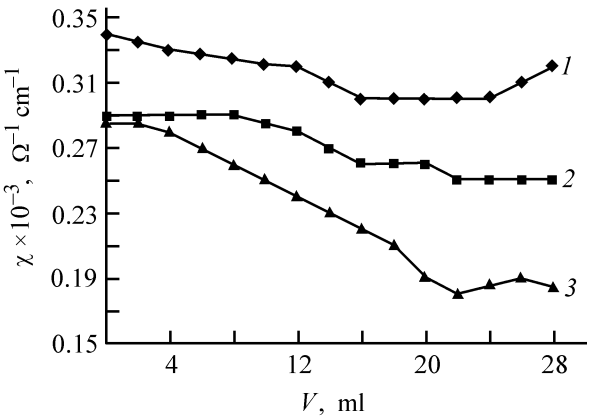

Fig. 1. Electrical conductivity χ of the surfactant solutions vs. the volume V of the solvent. (*1*) PEPA–Neonol 9-10, (*2*) PEPA–Neonol 9-12, and (*3*) Neonol 9-12.

1070-4272/05/7808-1312 © 2005 Pleiades Publishing, Inc.

turbid, and this was followed by gelation. The dip in the plot for the electrical conductivity may be due to presence in the system of large micelles and, according to published data, can be interpreted as the critical micelle concentration (CMC). In the case of Neonol 9-12, this dip in curve *3* (Fig. 1) corresponds to 22 ml of the organic solvent. Characteristically, the presence of the amine-containing auxiliary additive does not affect the amount of the organic solvent, required for gelation. However, the pattern of variation of the electrical conductivity near the CMC suggests that, in the system constituted by a surfactant, an amine-containing additive, and an organic solvent, the mechanism of intermolecular interactions has some distinctive features. This may be due to changes in the structure and shape of the mixed micelles.

The specific interactions of the surfactant with the organic component of the formulation can be judged from variation of the cloud point, a characteristic parameter of nonionic surfactants (CMC). The curves in Fig. 2 furnish information on the state of colloid solutions constituted by a surfactant, an organic component, and water. It is seen that, for the systems studied, the cloud point, corresponding to formation of a micellar solution, is below that for a binary solution of the surfactant in water. In this case, the turbidity is due to formation of a complex of the surfactant with the organic solvent. A decrease in the cloud point is most likely caused by distribution of the organic component between two other components and by an increase in the size of the micelles as a result of adsorption of surfactant molecules on nonpolar segments of terpene compounds or via formation of molecular associates. The resulting mixed micelles act as surfactants, thereby reducing the CMC in solutions [3].

The cloud point decreases the most steeply upon introduction of minor (4–8% relative to the weight of the surfactant) amounts of the organic solvent. Further addition of the organic solvent causes a proportional decrease in the cloud point of the system. The onset of gelation virtually coincides with the inflection point on the plot of the cloud point against the amount of the solvent.

In the presence of PEPA, the cloud point of the organic–aqueous systems tends to decrease, to the greatest extent with Neonol 9-12 as surfactant. This may be due to cleavage of the hydrogen bonds between water molecules and ether oxygen atoms in the surfactant molecule with a large number of oxyethyl units.

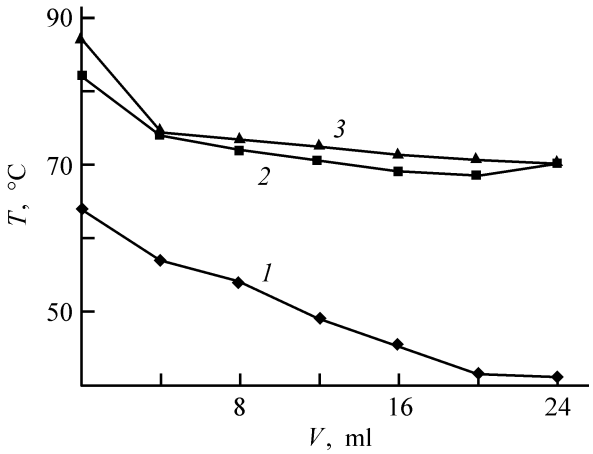

Fig. 2. Effect of the organic solvent volume *V* on the cloud point *T* of the surfactant solution. (*1*) PEPA–Neonol 9-10, (*2*) PEPA–Neonol 9-12, and (*3*) Neonol 9-10.

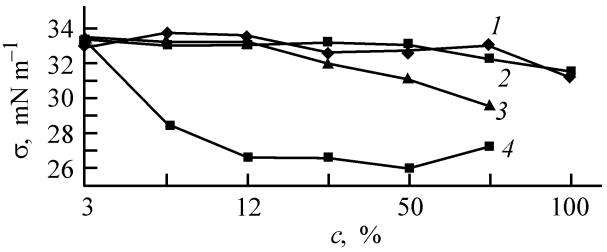

Fig. 3. Surface tension σ vs. the concentration *c* of the solutions of the surfactants in the presence of organic solvent. *V*, ml: (*1*) without solvent, (*2*) 2, (*3*) 21, and (*4*) 30.

Thus, from the physicochemical viewpoint, the gels formed in organic–aqueous systems can be regarded as dispersed systems consisting of a component forming a three-dimensional structure (surfactant) and a liquid component (organic solvent), immobilized in this matrix as a coherent medium. In terms of the basic classification, the gels formed can be attributed to ordered gel mesophases [4].

We studied how the concentration affects the surface tension of organic–aqueous surfactants containing different amounts of the organic solvent. We found that, on the whole, the surface tension of the organic–aqueous compositions is lower than that of an aqueous solution of the surfactant. This is consistent with published data on the influence of hydrophobic additives on the properties of surfactant solutions [5]. Figure 3 shows that, with increasing proportion of the organic solvent in the system, the surface tension of the solutions tends to decrease and reaches the minimum value upon introduction of 30 ml of the organic component. The CMC is shifted toward lower concentrations, namely from 23% without the solvent to 13%. Interestingly, at formulation concentrations

Table 1. Characteristics of the samples

Sample	Preparation procedure	Changes observed	Appearance
Skianol 1	The surfactant was mixed with the organic solvent, whereupon a special additive was introduced, and the resulting mixture was diluted with water	After addition of water into the composition, a gel was formed, which passed to a viscous solution in the course of time under stirring	Transparent liquid
Skianol 2	The surfactant was mixed with hot water, whereupon the additive was introduced, and, next, the organic solvent	The components formed a transparent solution. Upon addition of the organic solvent, the composition got turbid and later became transparent again	A liquid with white embedded particles and clots
Skianol 3	The surfactant was introduced into hot water, whereupon the additive and the organic solvent were introduced	Formation of a gel. Upon introduction of the organic solvent, the system got turbid	A stiff white paste
Skianol 4	The organic solvent and the auxiliary additive were introduced into hot water, whereupon the system was emulsified with the surfactant	First, the system got stratified; then a turbid gel was formed	A liquid with gray inclusions and clots
Skianol 5	The surfactant was emulsified in hot water, whereupon the additive was introduced, and the organic solvent was added	Upon introduction of the organic solvent, a milky-white viscous system was formed	A stiff white paste

Table 2. Colloid-chemical properties of the samples

Sample	Solution density d, g cm^{-3}	Surface tension coefficient σ, mN m^{-1}	Wetting coefficient $K \times 10^{-4}$, m s^{-1}
Skianol 1	1.015	31.78	2.33
Skianol 2	1.08	32.89	1.43
Skianol 3	1.010	32.22	1.6
Skianol 4	1.07	32.00	1.97
Skianol 5	1.010	31.33	1.77

above CMC, the surface tension continues to decrease, which suggests an increase in the content of the surfactant in the surface layer [6, 7].

Based on our experimental data, we developed a composition of the organic–aqueous degreasing formulation which was termed Skianol. Table 1 summarizes various methods of preparation and characteristics of the samples of the organic–aqueous formulations. These formulations differed in the physical state, and the surface tension was measured in 50% aqueous solutions. The experimental results are listed in Table 2.

Our data suggest that the lowest surface tension is characteristic of sample nos. 5 and 1. Thus, we showed that, despite the components of all the preparations are identical, their surface-active properties depend on the method of introduction of individual components during preparation of the end product. Based on the surface tension, the samples studied can be ranked as follows: $5 < 1 < 4 < 3 < 2$.

An important characteristic of the efficiency of the surfactants used or of their systems is the wetting power with respect to the material being processed. We estimated the influence of the method of preparation of organic–aqueous systems on the wetting power from the rate at which the front of the liquid ascends along a filtering paper. Table 2 confirms the existing relationship between the surface tension coefficient of the solution and the wetting power of the surfactant. Certain differences in these parameters for sample nos. 1, 5, and 4 are, probably, due to the differences in the physical condition of the initial preparations.

Probably, particles of the liquid preparation Skianol 1 more easily penetrate into the structure of the filtering paper, which affects the rate at which the front of the liquid ascends. For the gel form of the sample of Skianol 5, such penetration is sterically hindered.

Thus, our experiments suggest that, from the viewpoint of the preparation methods, the optimal preparations are sample nos. 1, 5, and 4. However, sample no. 4 does not satisfy the requirements concerning the outward appearance (Table 1). Considering the unstable consistency of sample no. 1 in storage and taking into account the colloid-chemical characteristics of Skianol 5, this formulation was chosen as the optimal composition. The comparative assessment of the degreasing power of this material with pork skins showed a high efficiency of Skianol 5, for which the degree of degreasing was over 65 %. This parameter is almost twice that achieved with Neonol.

CONCLUSIONS

(1) The organic solvent and amine-containing additive affect the colloid-chemical properties of nonionic surfactants.

(2) The formulation and method of preparation of a new organic–aqueous composition Skianol were developed. Skianol efficiently removes natural fat from the tanning raw material.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis of Copolymers of Vinylformamide with *N*-Methacryloylglucosamine

E. F. Panarin and N. P. Ivanova

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

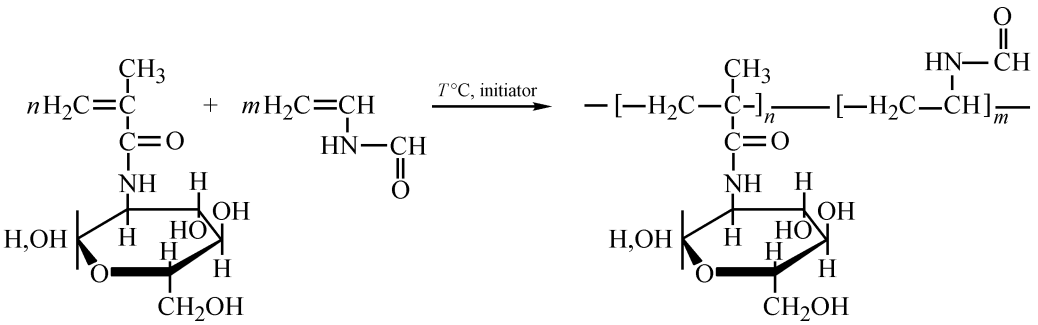
Received July 12, 2005

Abstract—Copolymers of vinylformamide with *N*-methacryloylglucosamine were prepared. Acid hydrolysis of these copolymers yielded terpolymers of vinylformamide, vinylamine, and *N*-methacryloylglucosamine. A ^{1}H NMR study showed that the hydrolysis of the vinylformamide homopolymer under the same conditions is virtually complete.

Poly-*N*-vinylamides derived from cyclic *N*-vinylamides are widely used in medicine, biotechnology, and engineering [1], whereas poly-*N*-vinylamides derived from fatty carboxylic acids are poorly studied. Some of them are water-soluble and can be used as synthetic precursors of functional polymers owing to the presence of an acyl-protected amino group. Of particular interest is polyvinylformamide, in which the formyl group can be removed fairly readily. Copolymerization of vinylformamide (VFA) with other vinyl monomers opens prospects for preparing reactive polymers containing a primary amino group, including new water-soluble polymers suitable as carriers of biologically active substances.

The possibility of preparing *N*-vinylpyrrolidone (VP)–vinylamine copolymers by copolymerization of VP with VFA, followed by acid deformylation, was demonstrated in [2].

The goal of this study was to prepare water-soluble copolymers of *N*-methacryloylglucosamine (MGA) with VFA and to examine the possibility of selective deformylation with the aim to obtain a polyvinyl saccharide containing primary amino groups.



VFA and MGA are active comonomers and readily copolymerize. Copolymerization occurs with a high yield both in water and in organic solvents (see table). By varying the copolymerization conditions (primarily solvent and initiator), it is possible to prepare copolymers of different compositions with a widely varying molecular weight.

When choosing the conditions (reaction time, solvent, monomer concentrations) of copolymerization

Copolymerization conditions and characteristics of copolymers (1 wt % initiator relative to sum of monomers in all runs)

Initiator	Composition of monomer mixture, mol %		Solvent, wt %	Time, h	Yield, %	Copolymer composition, mol %		$[\eta]^{25}$, dl g^{-1}

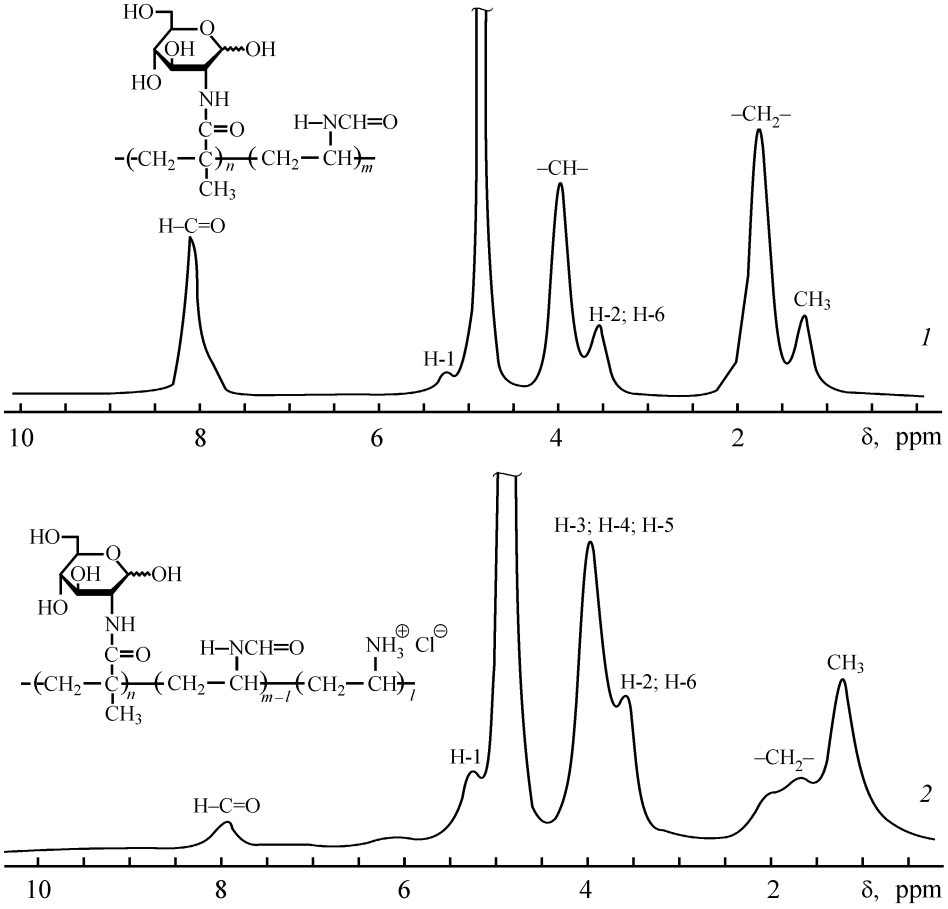
Scheme of copolymerization of VFA with MGA.

of VFA with MGA (see scheme), we took into account published data on the synthesis of polyvinylacetamide [3] and on the hydrodynamic properties of poly-*N*-methacryloylglucosamine (PMGA) [4].

Experiments on copolymerization of VFA with MGA at various monomer ratios (90 : 10, 70 : 30, 50 : 50 mol %) in different solvents showed that both monomers are fairly active in copolymerization, which allowed preparation of copolymers of different compositions with a widely varying molecular weight. The strongest effect on the molecular weight is exerted by the solvent used for the reaction. The copolymers prepared in DMF have the lowest intrinsic viscosity.

The structures of the copolymers were confirmed by ^{1}H NMR spectroscopy (Fig. 1). The spectra contained signals assignable to the carbohydrate and amide units. The copolymer compositions were determined from the intensity ratio of the formyl proton signal at δ 8 ppm (VFA fragment) and



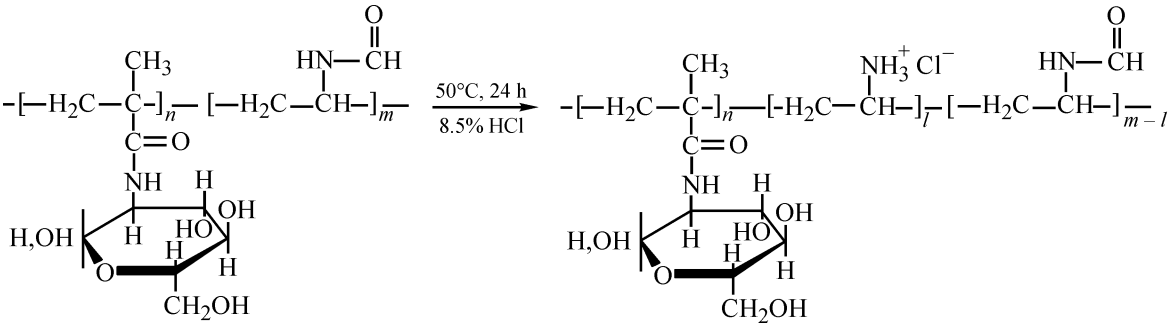


Fig. 1. ^{1}H NMR spectra of VFA–MGA copolymer (90 : 10 mol %) in D_2O: (*1*) before and (*2*) after hydrolysis.

the CH signals of the carbohydrate fragments at δ 1.3 ppm.

VFA–MGA copolymers were subjected to acid hydrolysis with HCl to obtain products containing reactive NH_2 groups. The hydrolysis conditions were chosen so as to avoid the hydrolysis of MGA units. First we studied the hydrolysis of PVFA and PMGA. Poly-*N*-methacryloylglucosamine was dissolved in 8.5 wt % HCl and heated at 50°C for 24 h. The occurrence of hydrolysis was judged from the appearance of glucosamine in the reaction products. To detect glucosamine, samples of the reaction mixture were analyzed by TLC on silica gel plates. The resistance of PMGA to hydrolysis under these conditions was also confirmed by the absence of the proton signal of the carboxy group in the ^{1}H NMR spectrum in D_2O, which should appear after removal of the glucosamine moiety.

The PVFA hydrolysis kinetics was monitored by taking hydrolyzate samples and analyzing them by ^{1}H NMR spectroscopy after dialysis and freeze drying (from the loss of the intensity of the formyl proton signal at δ 8.0 ppm) and by conductometric titration with silver nitrate. The kinetic curve is shown in Fig. 2. Heating of a PVFA solution in 8.5% HCl at 50°C for 3 days results in virtually complete deformylation, with the degree of hydrolysis as high as 90–95%. In VFA–MGA copolymers, irrespective of the composition, the hydrolysis of VFA units under the same conditions occurs to 50% only, probably because of steric effects of bulky carbohydrate fragments. Partial hydrolysis of VFA units in VFA–MGA copolymer yields terpolymers containing, along with VFA and MGA, also vinylamine (VA) units:

EXPERIMENTAL

N-Vinylformamide (Aldrich) was vacuum-distilled; bp 80°C (10 mm Hg), n_D^{20} 1.4940.

Azobis(isobutyronitrile) initiator (AIBN) was twice recrystallized from ethanol–chloroform (3 : 1), mp 103°C; 2,2'-azobis(2-methylpropanediamine) dihydrochloride (AMPDDC) was prepared according to [4].

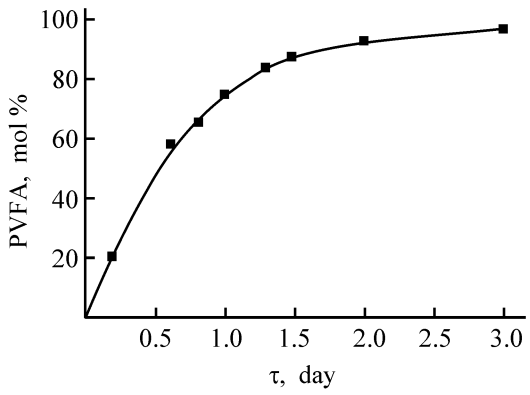

Fig. 2. Degree of PVFA hydrolysis vs. time τ.

N-Methacryloylglucosamine was prepared by treatment of glucosamine hydrochloride with methacryloyl chloride in methanol in the presence of triethylamine [5].

Dimethylformamide was purified according to [6].

Polymerization was performed in sealed ampules at 60°C. The polymers were isolated by precipitation from DMF into diethyl ether and from aqueous solutions into acetone and were purified by reprecipitation from water into methanol. Hydrolyzed VFA–MGA copolymers were purified by dialysis.

Thin-layer chromatography was performed with ATSKh-st. plates (Lenkhrom), eluent ethyl acetate–isopropyl alcohol–water (5.0 : 3.2 : 1.6), development with aniline–diphenylamine mixture [7].

The intrinsic viscosity was measured in 0.1 M CH_3COONa with an Ubbelohde viscometer.

The ^{1}H NMR spectra were recorded on a Bruker AC 200 spectrometer (Germany) at a working frequency of 200 MHz in D_2O.

CONCLUSIONS

(1) *N*-Vinylformamide–*N*-methacryloylglucosamine copolymers of various compositions and molecular weights were prepared.

(2) It was found that acid hydrolysis of *N*-vinylformamide–*N*-methacryloylglucosamine copolymers allows preparation of *N*-vinylformamide–vinylamine–*N*-methacryloylglucosamine terpolymers.

Abstract—The possibility of thermochemical cocarbonization of polyacrylonitrile with chitin and chitosan by combined heat treatment of their blends was examined. It was concluded that the components form complexes in dimethylformamide and dimethylacetamide at the temperature of polyacrylonitrile cyclization (230–300°C). The main thermal characteristics and the coke numbers of the cocarbonization products were determined.

Preparation of carbon composites with valuable properties is a topical problem of applied organic chemistry. One of important lines in this field is the use of polymers commercially produced on a large scale, such as polyacrylonitrile (PAN) and cellulose derivatives, for which the raw materials are readily available. In [1], we substantiated theoretically and experimentally the thermochemical reactions of PAN with chitin (CT) and chitosan (CTS), nitrogen-containing cellulose derivatives. As shown in [2, 3], cellulose derivatives containing nitrile groups and graft copolymers of PAN with cellulose ethers or esters are promising as raw materials for preparing cocarbonizates with a high coke number (CN). However, preparation of cyano derivatives of cellulose involves certain problems, and alternative routes should be sought for.

In this study, we examined the cocarbonization of CT and CTS with PAN by heat treatment of a blend of these polymers in the solid phase and in solution. Based on the previous data [1], we chose for the reaction the temperature range 200–350°C. At these temperatures, the thermal degradation and cross-linking of PAN and polysaccharides are the most intense. In this temperature range, PAN undergoes cyclization (initial step) with release of such volatile products as HCN, ammonia, acrylonitrile, acetonitrile; CT and CTS undergo degradation with release of large amounts of water, methanol, acetamide, pyridine, levoglucosan, and other compounds. Such a set of reactive substances released from the polymer blend in the above temperature interval may initiate formation of new structures serving as carbonization nuclei in the subsequent high-temperature process. It is known that, as carbonization of polymer blends is usually diffusion-controlled, it is necessary to ensure the maximally efficient contact of the components in an isolated volume to attain a high CN of the products.

EXPERIMENTAL

PAN was prepared by radical polymerization [4], $[\eta] = 6$ (in DMF). Chitin and chitosan were prepared by processing of crab shells (CT: mean molecular weight 282 kDa, ash residue 0.1%: CTS: mean molecular weight 245 kDa, degree of deacetylation 0.79).

To study the thermochemical reactions of PAN with CT and CTS, the initial polymers were taken as blends of powders (1 : 1 by weight, total weight 5 to 100 mg), pressed pellets, or films or blocks prepared from DMF solutions of the polymer blends. Samples were arranged in special holders of thermoanalytical devices and tested under the conditions described previously [2, 3], with the gravimetric and thermal characteristics of the intermediate and final cocarbonization products recorded.

Experiments with blended powders, performed in open crucibles, revealed no changes in the gas evolution kinetics and in the rate and value of the weight

* $\Delta m_{tot} = 0.5(\Delta m_{PAN} + \Delta m_{CT\,or\,CTS})$.

** SE = $\Delta m_{tot} - \Delta m_{bl}$, stabilizing effect.

loss throughout the experiment, compared to the polymers taken separately. Certain changes in the character of thermal degradation in the self-generated atmosphere at a constant heating rate were observed with large samples of the polymer blend, exceeding the standard samples in weight by a factor of 2–3. However, these changes are attributable to the scale effect, rather than to fundamental changes in the mechanism of the reaction between the starting polymers.

Experiments on heat treatment of powdered blends of PAN with CT and CTS in a vacuum in the isothermal mode at 200, 250, and 300°C (see table) revealed the effect of PAN on the thermal characteristics of the blends. Comparison of the total weight loss of the individual polymers at fixed temperatures, Δm_{tot}, with the weight loss of the blend, Δm_{bl}, allows evaluation of the stabilizing effect of PAN (positive quantities) in the blend. It can be readily seen that the strongest stabilizing effect of PAN is observed at 300°C, i.e., at a temperature corresponding to the onset of PAN cyclization. In particular, the weight loss of CT and CTS at 300°C decreases by 15–20% in the presence of PAN, compared to the polymers taken separately. Apparently, certain reactions of thermal degradation of CT and CTS at this temperature are inhibited; formation of intermediate bonds between the PAN and CT (or CTS) macromolecules at the instant of their thermal degradation is also possible. The strongest effect is observed with the PAN–CTS blend, for which the CN at 900°C is comparable with that of PAN. This fact is due to the increased reactivity of the amino group of CTS, compared to the *N*-acetyl group of CT, at the temperatures of thermal degradation of these polymers.

Then we studied the influence exerted by compaction of the polymer blends, intended to facilitate the mutual diffusion of the components in the course of the thermal degradation. We compacted pellets from 1 : 1 (by weight) blends of PAN and CT (or CTS) powders. A thermal analysis showed that the compaction of the components facilitates their reaction. Processing of the TG and DTA curves reveals changes in the gravimetric and energetic parameters of the exothermic step of the process, indicating that the degradation–cross-linking balance of macromolecules is shifted toward cross-linking. In particular, the weight loss of the blend in the interval 230–300°C is 21.6%, whereas the additive value is 26.8%. The heat release from the blend sample under the same conditions is almost equal to that from pure PAN, and the exothermic peak is shifted by 8°C to lower temperatures. It should also be noted that an increase in CN for the blend does not correspond to the additive value: CN is 24.8% for the blend, 45.6% for PAN, and 10.6% for CTS.

Comprehensive thermal analysis of blends prepared as films from mixed solutions of PAN and CT in DMF reveals a difference in the thermochemical reactions of the blends and individual compounds (Fig. 1). The mixed solutions show a tendency to react at lower temperatures on their keeping for a long time (curves *1*, *3*, *4*).

To sum up, the predominant reaction in the temperature range examined is cyclization of PAN, accompanied by a strong exothermic effect. It is known [4, 6, 7] that the magnitude of this effect is propor-

tional to the amount of oxygen coming to the reaction system from air, and also to the amount of oxygen-containing compounds formed during synthesis and isolation of PAN. Apparently, oxygen prevents, to a certain extent, the reaction of PAN with CT and CTS, shifting the reaction balance toward formation of volatile products of thermal oxidative degradation. To reveal the effect of atmospheric oxygen, we made a series of experiments on the thermochemical reaction of the components in a nitrogen atmosphere.

Figure 2 shows the TG and DSC curves obtained with PAN, CT, and PAN + CT blend film in the course of heating in air and in a nitrogen flow. The most interesting fact is the enhanced heat resistance and increased CN of the film prepared from mixed solutions of PAN and CT in DMF and subjected to prolonged drying and keeping at an elevated temperature. Comparison of the TG curves shows that the composite film (curves *3*, *4*) noticeably differs from the samples of the individual polymers in the thermal and

gravimetric characteristics. The behavior of the weight loss in the range 20–600°C suggests the occurrence of a thermochemical reaction of PAN with CT. The initial step, Δm = 5–6%, is observed in the interval 130–270°C. It can be assigned to removal of residual DMF, which is known [8, 9] to participate in the formation of interpolymeric complexes upon heat treatment of polymers. Above 270°C, the weight loss accelerates owing to the development of thermal degradation. A distinctive feature of the degradation of the composite films in this step is that Δm is appreciably smaller, compared to powdered PAN and CT samples. In particular, in the range 270–315°C, Δm is 2.5–4% for the composite film, 1–7.5% for PAN, anmd 11–6% for CT. Thus, in the region of the maximum intensity of thermal reactions (250–320°C) involving the individual polymers, the thermal degradation reactions characteristic of CT are almost fully inhibited, and the balance of volatile products of PAN degradation is altered.

One more feature of this process is a weak effect of thermal oxidation reactions on the degradation of the composite film, compared to the thermal oxidation of CT (the above-given quantities refer to TGA in air and in a nitrogen flow, respectively). Heating to higher temperatures (315–400°C) induces the carbonization of PAN and the film composite, characterized by a decrease in the weight loss rate and in the amount of the released volatile products. Chitin undergoes, in the same temperature interval, further degradation slightly decelerating at temperatures above 400°C. In the step of formation of the coke residue (above 600°C), the CN of the film composite is 58 and 71% (heating in air and in a nitrogen flow, respectively) and is comparable with CN of PAN (66 and 80%, respectively). At 1000°C, the CN of the film composite in nitrogen is 43%. These facts suggest that complex thermochemical reactions involve the reaction of CT with PAN to form a cross-linked structure differing from the structure of the starting polymers.

Similar conclusions follow from analysis of the effects that accompany the thermochemical reactions of the samples in hand. The DSC curves (Fig. 2b) demonstrate significant differences in the temperature and energy characteristics of the individual polymers and the composite film. When choosing components for cocarbonization, it is essential that the temperature intervals of the most intense thermal transformations of both polymers should coincide. In our case, this rule is observed: The exothermic maxima in the DSC curves of PAN and CT (curves *1*, *5*) are observed at 317.9 and 350.0°C, respectively; the ranges of these peaks are 232–400°C for PAN and 246–405°C for CT. The overall activation energy of these processes is 344.15 and 198.66 kJ mol^{-1}, respectively. In the case of PAN, this energy is the sum of the contributions from cyclization and partial oxidation, and in the case of CT, a superposition of oxidation, thermal degradation, and evaporation of volatile degradation products. In a nitrogen atmosphere, the values are appreciably lower: 70.52 kJ mol^{-1} for PAN and 67.28 kJ mol^{-1} for CT, which is due to the absence of oxidation reactions. The pattern of the heat release in the case of the film composites essentially differs from that observed with the individual polymers. For the composites, the temperatures of the peak maxima are lower by 40–60°C, and the boundaries of the range of the thermal effect, by 70–120°C; the activation energies are lower by 40 kJ mol^{-1} on the average, irrespective of the gas medium.

Thus, the best procedure for thermochemical cocarbonization of PAN with CT consists in combining their solutions in DMF and keeping the resulting blend to obtain stable complexes with the solvents. Prolonged low-temperature heat treatment (120–200°C) results in a gradual decomposition of the complexes, apparently with the formation of an intermediate compound of CT with PAN, in which CT (namely, its *N*-acetyl or free hydroxy groups) acts as an initiator of PAN cyclization. The possibility of formation of intermediate PAN compounds was discussed in detail in [10]; the existence of ionized structures involving solvent (DMF) molecules was confirmed. Similar structures may also initiate the reaction of PAN with CT, which occurs at lower temperatures than the PAN cyclization.

To reveal the role of the *N*-acetyl group in CT, we performed experiments on combined heat treatment of PAN and CTS solutions. For this purpose, we prepared a mixture of concentrated (~10 wt %) solutions of PAN and CTS in DMF; this mixture was subjected to prolonged drying in the stepwise heating mode at temperatures of 140 to 400°C for 45 h. In the first step of the heat treatment (24 h), an interpolymeric complex of the starting component with DMF molecules was formed, and this was accompanied by evaporation of the excess solvent. As a result, a viscous inhomogeneous product containing 12–14% solvent in a complex with the polymer blend was obtained. The subsequent heating at 160°C for 7 h did not result in destabilization of the complex, and its noticeable degradation occurred only upon heating at 200°C. In the interval 250–300°C, thermochemical reactions of PAN with CTS occurred with the release of ~26–28% volatile products apparently formed by the cyclization of PAN, degradation of

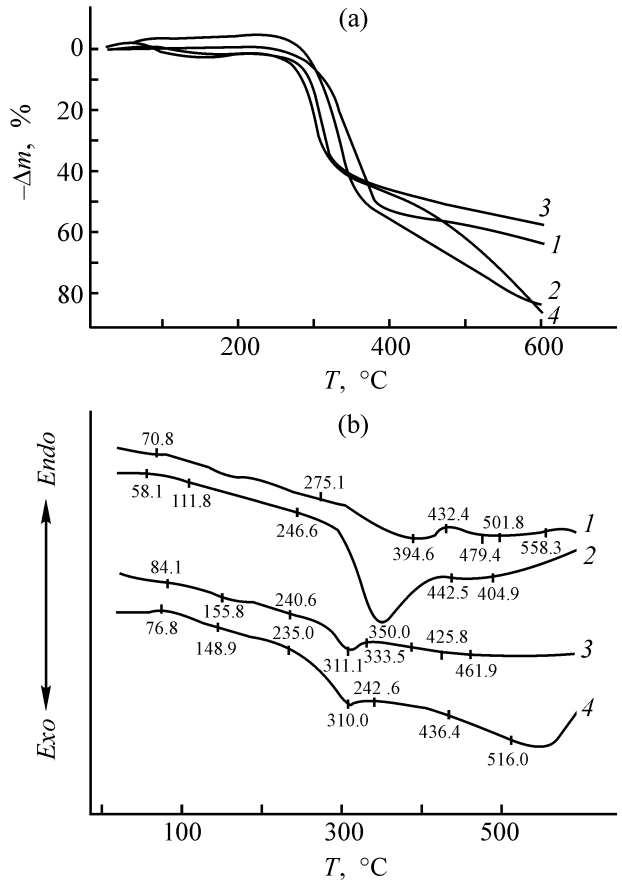

Fig. 3. (a) TG and (b) DSC curves (*1*, *2*) CT and (*3*, *4*) CTS powders (*1*, *3*) under nitrogen and (*2*, *4*) in air.

CTS, and probably reaction of PAN with CTS. As shown previously [11], replacement of the acetylamino group in CT with the amino group favors rapid cross-linking of CTS at elevated temperatures. Furthermore, the reaction of the amino groups with the nitrile groups of PAN becomes possible, by analogy with the results of our previous study [12] in which PAN was modified with ethanolamine at temperatures above 100°C; the process started with a nucleophilic addition of the amino group to the cyano group and formation of *N*-hydroxyethylamidine units. The same conclusion followed from a comparison of the results of a thermal analysis of CT and CTS under the conditions of the dynamic heating in air and in a nitrogen flow (Fig. 3). According to TGA, the thermal degradation of CTS starts in an inert atmosphere at a temperature 20°C higher, compared to CT, and is complete at 315°C, with a total weight loss of 32%, whereas the weight loss of CT is about 50%. The CNs at 600°C are 50 and 60%, respectively. In air, the differences are noticeable only in the step of thermal degradation, in which the weight loss of CT and CTS is appreciably larger than that in nitrogen, and the degradation is accompanied by an exothermic effect with a maximum at 350°C, especially strong for CT.

CONCLUSIONS

(1) A laboratory procedure was developed for cocarbonization of polyacrylonitrile with chitin and chitosan, based on thermochemical transformations of the starting polymers in the step of an interpolymeric complex with an aprotic polar solvent in the temperature range of polyacrylonitrile cyclization (230–300°C).

(2) The cocarbonization of the polymer blend differs in the thermal characteristics from the carbonization of the individual polymers, and the coke numbers at 800°C are close to that of polyacrylonitrile (70–80%).

Abstract—The effect of (allylbenzene)tricarbonylchromium on the kinetic parameters of radical polymerization of methyl methacrylate and styrene and on the molecular-weight characteristics of the resulting polymers was studied.

Control over the kinetic parameters of radical polymerization of vinyl monomers and over the molecular-weight characteristics of the resulting polymers under the conditions maximally similar to those of their commercial synthesis is an urgent line of macromolecular chemistry [1, 2].

Nitroxyl radicals and their sources [3, 4] and organometallic compounds [2, 4], including metal-containing monomers [5, 6], are actively used today to control the chain propagation in radical polymerization processes. In particular, (α-methylstyrene)tricarbonylchromium affects the propagation step in polymerization of methyl methacrylate (MMA), styrene (ST), and butyl acrylate [6]. The controlling effect of organochromium additives is due to their reaction with initiator radicals and propagating macroradicals to form relatively stable carbon-centered organometallic radicals directly affecting the polymerization rate and molecular weight of the polymers [5, 6].

In this study, we examined the polymerization kinetics of MMA and ST and the molecular-weight characteristics of the resulting polymers, as influenced by addition of (allylbenzene)tricarbonylchromium (ABC). It is known [7] that the polymerization of allyl monomers has certain specific features associated with the formation of stabilized allyl radicals in the course of chain propagation. Therefore, it is of indubitable interest to examine the effect exerted on elementary steps of polymerization by compounds containing simultaneously an allyl fragment and a stabilizing tricarbonylchromium group.

EXPERIMENTAL

(Allylbenzene)tricarbonylchromium was prepared by the procedure described in [8]; its physicochemical constants were consistent with published data. The monomers were purified by standard procedures [9]. Commercial azobis(isobutyronitrile) (AIBN) used as initiator was recrystallized from methanol. Nitrosodurene used as spin trap was prepared according to [10].

The polymerization of MMA and ST was performed in evacuated temperature-controlled ampules. The polymerization kinetics was monitored derivatographically and thermographically [11]. The polymers formed were purified to remove residual monomers by reprecipitation with hexane from a solution in ethyl acetate under argon. The ABC content in double-reprecipitated samples was determined from the chromium content evaluated spectrophotometrically [12]. The molecular weight (MW) and molecular-weight distribution (MWD) of poly(methyl methacrylate) (PMMA) and polystyrene (PS) were estimated by gel permeation chromatography (GPC) [13] using, respectively, a single Phenogel column (Linear-2 Phenomenex) and a set of five Styrogel columns (Waters). As detectors we used R-2301 (Knauer) and R-403 (Waters) differential refractometers. The eluents were THF for PS and chloroform for PMMA.

The ESR specrta were taken on an AE-4700 commercial radiospectrometer in special ampules. As reference for magnetic field calibration we used Mn^{2+} ions incorporated in the MgO lattice.

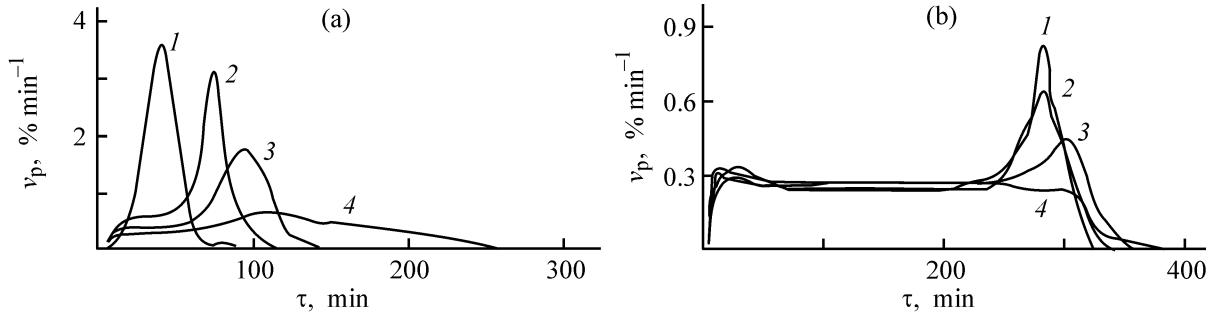

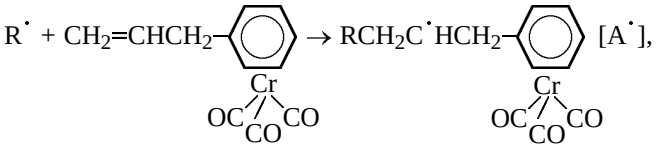

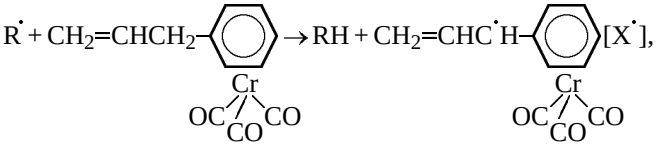

Fig. 1. Differential kinetic curves of the polymerization of (a) MMA and (b) ST in the presence of ABC at 70°C: (v_p) polymerization rate and (τ) time. Initiator AIBN; concentration, mol %: (a) 0.1 and (b) 0.8. ABC concentration, mol %: (a) (*1*) 0, (*2*) 0.5, (*3*) 0.8, and (*4*) 1.0; (b) (*1*) 0, (*2*) 0.5, (*3*) 2.0, and (*4*) 5.0.

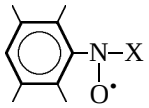
A kinetic study of the radical polymerization of MMA and ST in the presence of AIBN (initiator) and ABC showed that ABC appreciably decelerates the polymerization and exerts a significant effect on the polymer chain propagation, decreasing the polymerization rate and simultaneously eliminating the gel effect at moderate temperatures (70°C) (Figs. 1a, 1b). However, to suppress the autoacceleration virtually fully, relatively high concentrations of ABC are required: 1.0 mol % in the synthesis of PMMA and 5.0 mol % in the polymerization of ST.



The strong effect of ABC on the kinetic parameters of the polymerization is apparently associated with the direct involvement of the organochromium compound in the chain propagation step. It is known [7, 14] that the reactivity of allyl monomers is appreciably lower than that of vinyl monomers, which is due, on the one hand, to isolated position of the π bond and lack of conjugation between the π bond and the functional group and, on the other, to formation of a relatively stable allyl radical in reactions of allyl compounds with the propagating radical or radical generated from the initiator. Apparently, these reactions are also possible in the polymerization of MMA and ST in the presence of ABC:

where R$^{\cdot}$ is the propagating radical or radical generated from the initiator.

Using ESR with nitrosodurene added as spin trap, we detected in the reaction system a spin adduct of radical X$^{\cdot}$ [scheme (2)], giving a triplet of doublets (a_N = 13.8 Oe, a_H = 0.5 Oe), which allows this adduct to be identified as radical B$^{\cdot}$. This fact unambiguously confirms that ABC is involved in the polymerization and gives a sterically hindered carbon-centered radical stabilized, on the one hand, by a conjugated π bond (π–e conjugation) and, on the other, by an arenetricarbonylchromium moiety:

[B$^{\cdot}$]

The propagating radical of (allylbenzene)tricarbonylchromium [radical A$^{\cdot}$, scheme (1)] was not detected by the spin trap technique.

Experiments on MMA polymerization in the presence of various concentrations of ABC showed that this chromium-containing monomer does not noticeably copolymerize with MMA. In particular, when 5 to 25 mol % (allylbenzene)tricarbonylchromium was added to a solution of 0.1 mol % AIBN in MMA, the polymer obtained at ≤10 wt % conversion contained only traces of chromium, irrespective of the initial amount of the chromium-containing monomer in the reaction mixture. This fact indicates that the copolymer of MMA with ABC is not formed in this case.

The failure of attempts to prepare (allylbenzene)tricarbonylchromium copolymers is well consistent with the ESR data. Furthermore, comparison with the published data on the reactivity of the organic analogue of ABC, allylbenzene, which copolymerizes with acrylic and methacrylic monomers under the conditions of radical initiation [15], indicates that introduction of

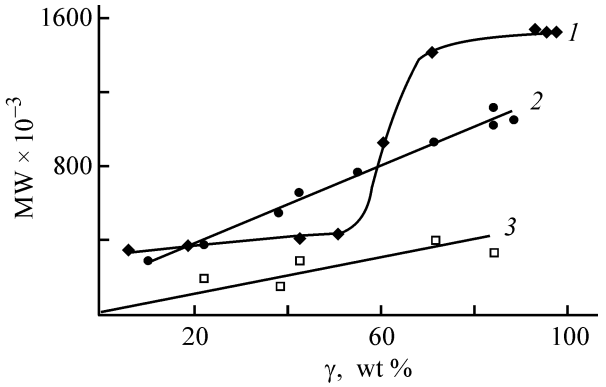


Fig. 2. (*1*, *2*) Viscosity-average and (*3*) number-average MW of PMMA formed in the presence of ABC vs. conversion γ. [AIBN] = 0.1 mol %, T = 70°C. ABC concentration, mol %: (*1*) 0 and (*2*, *3*) 1.0.

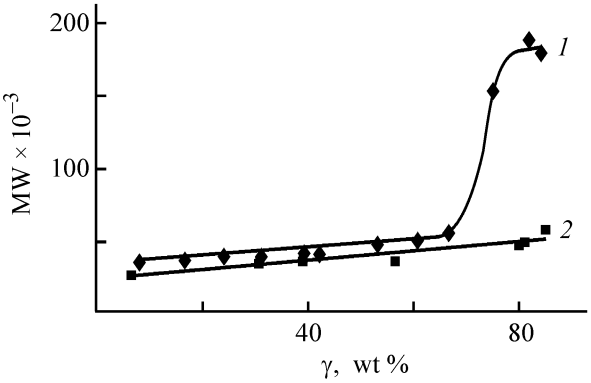

Fig. 3. (*1*) Viscosity-average and (*2*) number-average MW of PS formed in the presence of ABC vs. conversion γ. [AIBN] = 0.8 mol %, T = 70°C. ABC concentration, mol %: (*1*) 0 and (*2*) 5.0.

a bulky arenetricarbonylchromium group decreases the polymerization activity of the allyl fragment.

As noted above, addition of ABC to the reaction mixture appreciably affects the polymerization kinetics of ST and MMA, which is apparently due to the reaction of propagating radicals with the chromium-containing monomer to form a sterically hindered carbon-centered radical stabilized by the arenetricarbonylchromium group [scheme (2)]. It is reasonable to expect that stabilized radicals of this type can efficiently control the molecular-weight characteristics of polymers.

We found that the ST and MMA polymers formed in the presence of ABC have an appreciably decreased molecular weight (see table). As shown by the example of PMMA, this effect is determined by the ABC concentration. In particular, as the ABC concentration is raised from 5 to 25 mol %, the number-average MW M_n of the polymer regularly decreases from 11.1×10^4 to 4.7×10^4. The M_n of PMMA prepared under the similar conditions, but without adding ABC, is 20.6×10^4.

Furthermore, the table and Figs. 2 and 3 show that, when ABC is added in amounts comparable with the initiator concentration, M_n linearly increases with the monomer conversion. The dependences of M_n of PMMA and PS on the conversion in the absence of ABC, with AIBN as initiator, are shown in Figs. 2 and 3 for comparison. As seen from these data, in the absence of ABC M_n shows a spontaneous uncontrollable growth in the course of the polymerization.

It is known [2–4] that specifically the linear dependence of the molecular weight of a polymer on the conversion is one of the major evidences of polymerization in the "living" chain mode. This means that, starting from low conversions, the molecular weight of the polymer continuously increases in the course of the synthesis owing to the fragmentary chain propagation, and specifically M_n linearly increases with the conversion. Hence, the synthesis of PMMA and PS in the presence of ABC follows the chain propagation scheme (3) characteristic of controlled radical polymerization:

$$\sim P_n^{\bullet} + {}^{\bullet}X \rightleftarrows \sim P_n\text{---}X,$$

$$\wedge\!\wedge P_n\text{—}X \underset{k_c}{\overset{k_d}{\rightleftarrows}} \wedge\!\wedge P_n^{\bullet} + {}^{\bullet}X,$$

where $\sim P_n^{\bullet}$ is the propagating radical and ${}^{\bullet}X$ is the carbon-centered chromium-containing radical.

Molecular-weight characteristics of PMMA and PS synthesized in the presence of ABC at 70°C (AIBN initiator, 0.1 and 0.8 mol %, respectively)

Starting monomer	ABC added, mol %	Monomer conversion, wt %	$M_n \times 10^{-3}$	$M_w^* \times 10^{-3}$	M_w/M_n
MMA	0	90.3	661	1604	2.4
	1	9.5	123	227	1.8
		22.1	199	417	2.1
		42.3	319	715	2.2
		84.6	360	856	2.4
ST	0	84.0	77	246	3.2
	5	6.4	26	39	1.5
		30.8	35	51	1.5
		39.3	37	54	1.5
		79.6	44	86	1.9
		80.6	47	95	2.0
		84.9	58	128	2.2

* (M_w) Weight-average MW.

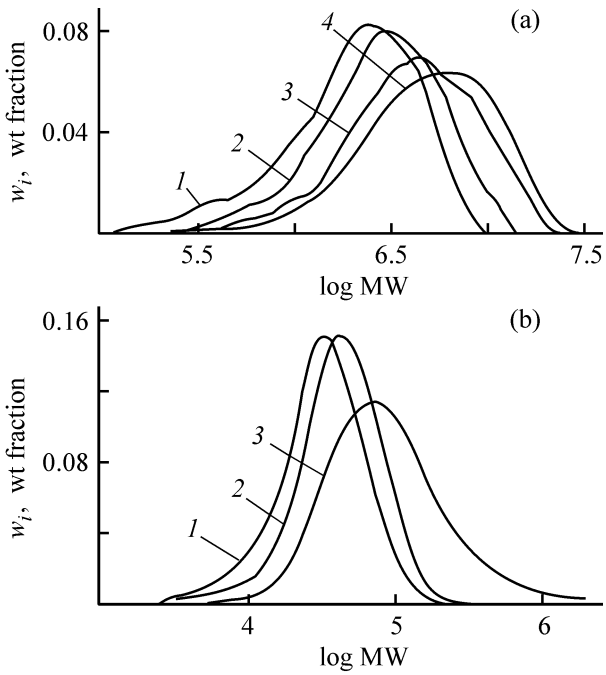

Fig. 4. MWD curves for (a) PMMA and (b) PS samples synthesized to various conversions at 70°C in the presence of (a) 0.1 and (b) 0.8 mol % AIBN and of (a) 1.0 and (b) 5.0 mol % ABC. (w_i) Weight fraction of molecules of the given MW. γ, wt %: (a) (*1*) 9.5, (*2*) 22.1, (*3*) 42.3, and (*4*) 84.6; (b) (*1*) 6.4, (*2*) 30.8, and (*3*) 84.9.

Figures 4a and 4b show the MWD curves of PMMA and PS samples prepared in the presence of ABC. A trend characteristic of "pseudoliving" polymerization is observed: The MWD curves shift toward higher MW as the conversion increases, which also counts in favor of the occurrence of a controlled chain propagation in the polymerization of MMA and ST in the presence of ABC [scheme (4)].

It should be noted that, at high conversions, the MWD curves get broadened (Figs. 4a, 4b), and the polydispersity coefficients increase (see table). This trend is untypical of classical polymerization in the living chain mode and is apparently due to formation of a "dead" polymer in the system as a result of bimolecular termination of the propagating chains. This process can occur in parallel with the pseudoliving polymerization and is observed, e.g., in controlled radical polymerization in the presence of triphenylmethyl and some other sterically hindered carbon-centered radicals [16].

CONCLUSION

A sterically hindered organochromium allyl monomer, (allylbenzene)tricarbonylchromium, is a novel agent for controlling the chain propagation in radical polymerization of vinyl monomers at temperatures optimal for the commercial synthesis of macromolecular compounds.

Abstract—The features of emulsion polymerization of styrene in the presence of a mixture of potassium stearate and oleate was studied. The effect of these salts on the polymerization rate and the yield and molecular weight of polystyrene was examined.

Making the existing processes for latex production more feasible and efficient remains a topical problem. This goal can be accomplished, in particular, by choosing effective emulsifiers that could provide a high conversion of the monomers and aggregative stability of the latexes.

It is known that effective emulsifying systems for synthesis of diene–styrene and styrene–acrylate dispersions contain mixtures of different types of surfactants [1]. At the same time, impurities of potassium myristate, palmitate, stearate, or linoleate in the commercially used emulsifier, potassium oleate, decrease the polymerization rate and mechanical stability of butadiene–styrene latex [2].

We found previously that a 40 : 60 (by weight) mixture of stearic and oleic acids exhibits synergism in its effect on some properties of rubber stocks and vulcanizates [3–5]. This fact suggests that these surfactants may affect nonadditively the preparation and properties of other polymers.

As a model for examining the effect of a mixture of stearic and oleic acids in the form of potassium salts on the emulsion polymerization, we chose polymerization of styrene.

EXPERIMENTAL

The emulsion polymerization was performed at 80°C for 90 min. The composition (wt parts) of the reaction mixture was as follows: styrene 100, fatty acid 1.2, KOH 0.18, $K_2S_2O_8$ 0.5, and water 160. The reaction progress was monitored gravimetrically. Samples were taken at definite intervals and analyzed to determine the polymer yield (%) by the formula [6]

$$N = P_p \times 100/P_m,$$

where P_p is the polymer weight in the sample (g), and P_m is the monomer weight in the sample (g), calculated from the initial monomer concentration.

The viscosity-average molecular weight of the isolated polystyrene was determined by the procedure described previously [7].

The surface tension of aqueous solutions of potassium soaps of fatty acids was determined by the Du Nouy method [8]. The limiting adsorption Γ_∞ was determined graphically from the adsorption isotherms of the surfactants [9, 10]. The negative logarithm of the surfactant concentration at which σ decreases by 20 mN m^{-1} (pC_{20}) was determined by a procedure described in [11], and the critical micellization concentration (CMC), according to [12, 13].

Figures 1a–1c show that the polymerization kinetics depends on the emulsifier composition, namely, on the ratio of stearic (St) and oleic (Ol) acids in the potassium salts [K(St : Ol)]. The styrene conversion as a function of the emulsifier composition passes through a maximum at the K(St : Ol) ratio ranging from 40 : 60 to 60 : 40 wt %, with the polystyrene yield (Fig. 2, curve *1*) equal to 99.9%.

The viscosity-average molecular weight ($\bar{M}_\eta$) of polystyrene as a function of the K(St : Ol) ratio also passes through a maximum, 460 000, observed at K(St : Ol) = 40 : 60 wt % (Fig. 2, curve *2*).

The dependences of the mean reaction rate (W_m) on the styrene conversion (Fig. 3) are, on the whole, similar at different emulsifier compositions, with the highest W_m attained at 60% conversion. However,

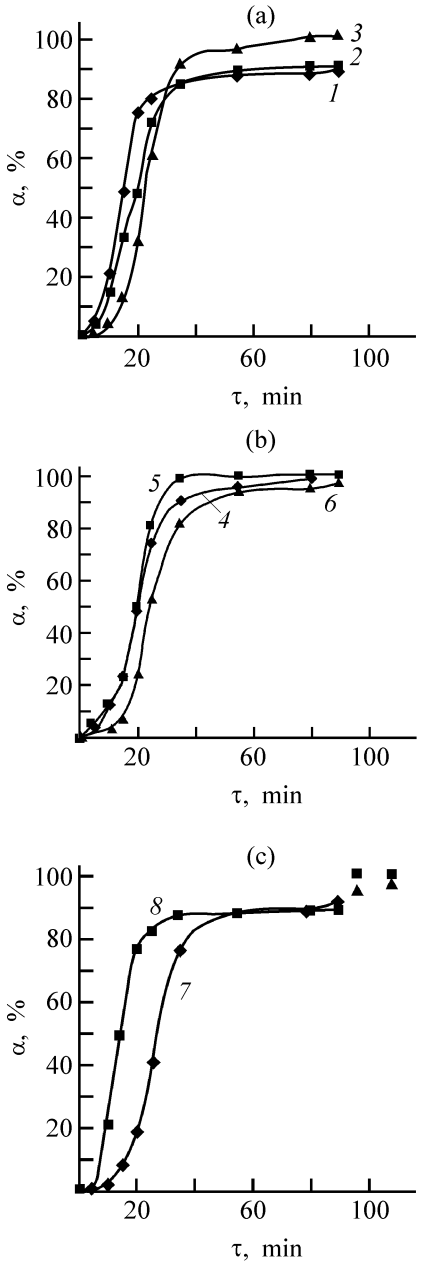

Fig. 1. Styrene conversion α vs. time τ at various ratios of stearic and oleic acids in the emulsifier. St : Ol, wt %: (*1*) 100 : 0, (*2*) 0 : 100, (*3*) 40 : 60, (*4*) 70 : 30, (*5*) 60 : 40, (*6*) 30 : 70, (*7*) 10 : 90, and (*8*) 90 : 10.

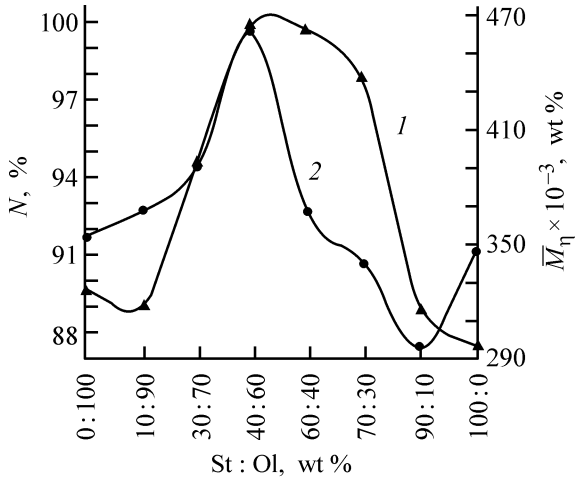

Fig. 2. (*1*) Yield *N* and (*2*) viscosity-average molecular weight $\bar{M}_\eta$ of polystyrene vs. the ratio of stearic and oleic acids in the emulsifier.

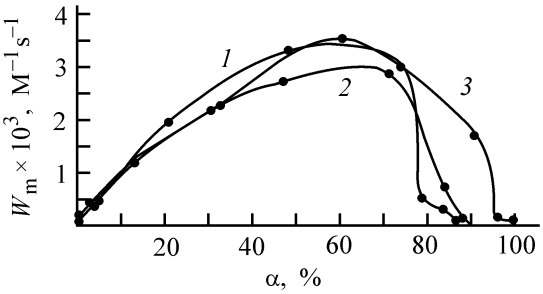

Fig. 3. Variation of the mean rate of styrene polymerization W_m with the conversion α. Emulsifier: (*1*) potassium stearate, (*2*) potassium oleate, and (*3*) potassium salts of a mixture of stearic (40 wt %) and oleic (60 wt %) acids; the same for Figs. 4 and 5.

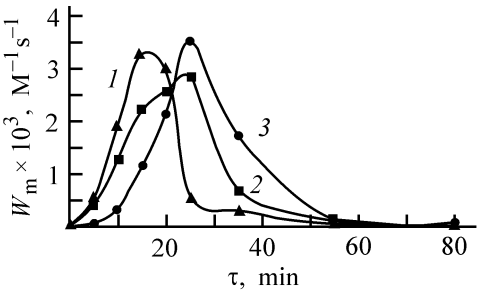

Fig. 4. Mean rate of styrene polymerization W_m vs. polymerization time τ.

the curve shape depends on the emulsifier composition. This effect is especially pronounced at high monomer conversions when the mean polymerization rate in the presence of the mixed emulsifier (Fig. 3, curve *3*) is higher than that observed with the individual surfactants. With the mixed emulsifier, virtually 100% conversion of styrene is attained in 1.5 h.

The plots of W_m vs. polymerization time (Fig. 4) show that the K(St : Ol) = 40 : 60 wt % mixture has a nonadditive effect on the reaction kinetics.

It should be noted that, although the mean polymerization rates observed in the presence of the individual emulsifiers are different, the monomer conversions and viscosity-average molecular weights of

Colloid-chemical properties of aqueous solutions of potassium salts of fatty acids

Surfactant	σ, mN m^{-1}	C_{20}, g dm^{-3}	$\Gamma_\infty \times 10^6$, mol m^{-2}	CMC, g dm^{-3}
Potassium stearate	43.0	0.041	3.3	0.48
Potassium oleate	33.5	0.007	4.6	0.75
Mixture of potassium salts of St (40 wt %) and Ol (60 wt %)	33.0	0.003	5.0	0.50

the polymer samples prepared in the presence of both emulsifiers are virtually equal.

The nonadditive effect is most probably associated with the colloid-chemical characteristics of the surfactants used. Stearic and oleic acids do not differ in the length of the hydrocarbon substituent, but differ in its nature: In oleic acid, the hydrocarbon substituent contains a double bond.

It has been found previously that the surface tension of a mixture of stearic and oleic acids is lower than the additive value and has a minimum in the composition range St : Ol (33–40) : (67–60) wt % at temperatures of 60 to 80°C [14]. Similar effects would be expected with aqueous solutions of the potassium salts of St and Ol and of their mixture (40 : 60 wt %). In this connection, we constructred the isotherms of surface tension at the aqueous solution|air phase boundary (Fig. 5).

The lowest σ (11.5% lower than the additive value) was observed with the K(St : Ol) = 40 : 60 wt % mixture (see table). With pure potassium stearate, the surface tension was the highest.

The C_{20} value for potassium stearate is higher by factors of 6 and 11 than that for potassium oleate and K(St : Ol) = 40 : 60 wt % mixture, respectively (see table). Hence, this mixture exhibits synergism with respect not only to an absolute quantity (surface tension) but also to a relative parameter (concentration providing a given decrease in σ).

The dispersing and stabilizing effect of a surfactant is due to its adsorption at the phase boundary. The limiting adsorption can be considered a criterion of the surfactant performance. As can be seen from the table, potassium stearate shows the lowest adsorption, and the K(St : Ol) = 40 : 60 wt % mixture, the highest, and hence it is a more effective dispersant and stabilizer for emulsions, compared to the individual potassium carboxylates.

The critical micelle concentration (CMC) is one of the most important physicochemical characteristics of surfactants. Among the surfactants studied, potassium oleate has the highest CMC, and potassium stearate, the lowest (see table). The CMC of the K(St : Ol) = 40 : 60 wt % mixture is lower than the additive value and approximately equal to that of potassium stearate. The lower CMC of potassium stearate, compared to oleate, is most probably due to lower degree of dissociation of this soap.

Since the emulsion polymerization of styrene was studied in the range of emulsifier concentrations exceeding CMC of all the emulsifiers examined, the observed effects should be attributed to differences in the amount and size of the micelles, as it is known [15] that the rate of emulsion polymerization depends, under equal other conditions, on the solubilizing power of aqueous solutions of emulsifiers.

CONCLUSIONS

(1) The yield of polystyrene in emulsion polymerization reaches a maximum (99.9%) when a mixture of potassium stearate and oleate (ratio from 40 : 60 to 60 : 40 wt %) is used as emulsifier.

(2) In emulsion polymerization of styrene in the presence of potassium stearate and oleate taken in a ratio of 40 : 60 wt %, the high mean polymerization rate is preserved at high conversions of the monomer, in contrast to the process performed in the presence of each of these salts taken separately.

(3) Polystyrene prepared using a mixture of potassium stearate and oleate in a ratio of 40 : 60 wt % has

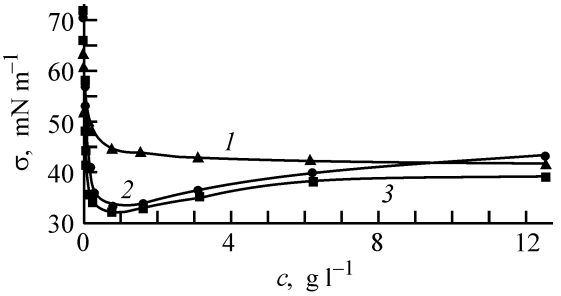

Fig. 5. Surface tension isotherms. (σ) Surface tension and (*c*) emlusifier concentration.

the highest viscosity-average molecular weight ($\overline{M}_\eta$ = 460 000), whereas $\overline{M}_\eta$ of polystyrene prepared in the presence of potassium stearate or oleate taken separately is about 350 000.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Degradation of Hardwood Sulfate Pulp in Aqueous Dioxane

E. V. Udoratina and V. A. Demin

Institute of Chemistry, Komi Scientific Center, Ural Division, Russian Academy of Sciences, Syktyvkar, Komi Republic, Russia

Received March 2, 2005

Abstract—Degradation of unbleached hardwood sulfate pulp in aqueous dioxane in the presence of catalytic amounts of HCl was studied. The kinetic constants and the apparent activation energy of pulp degradation in the range 343–363 K were calculated.

Treatment of cellulose with organic solvents containing a mineral acid in the presence or in the absence of water results in cleavage of glycoside bonds between its monomeric units, which leads to a decrease in the degree of polymerization, i.e., to degradation [1]. In production of fibrous semifinished products for paper, the pulp degradation is undesirable. By contrast, preparation of powdered cellulose products, including microcrystalline cellulose, is based on the pulp degradation.

The objectives of this study are determined by the growing researchers' interest in the development of nonaqueous processes for pulp production, based on organic liquids, with complete regeneration and recycling of the solvents [2, 3]. These processes show much promise, as they decrease the consumption of natural water and energy for the process. Although delignification of wood with organic solvents has been the subject of numerous studies, the effect of organic solvents on sulfate pulp and the possibilities of using these processes for pulp bleaching are insufficiently understood. In this study, we examined the degradation of unbleached sulfate pulp in aqueous dioxane. This treatment was used in [4] for recovering residual lignin with the aim to study its properties. In [5], we showed that, depending on treatment conditions, 29–80% of residual lignin dissolves on treatment of sulfate pulp with aqueous dioxane in the course of its bleaching.

EXPERIMENTAL

Experiments were performed with unbleached hardwood sulfate pulp with a Bjorkman hardness of 77 permanganate units and a degree of polymerization of 1031. The pulp was treated in a 9 : 1 dioxane–water mixture in the presence of an acid catalyst (0.0–0.2 M HCl) at a slurry concentration of 5 wt % absolutely dry pulp. Treatments were performed at 343–363 K for 1–5 h. The treated pulp was washed with warm distilled water and dried. The pulp degradation was evaluated by a decrease in its degree of polymerization, determined viscometrically in Cadoxen [6]. The resulting pulp samples were also analyzed photometrically for lignin [7].

We examined how the degradation of sulfate pulp is influenced by the acid catalyst (HCl) concentration (first series of experiments) and temperature (second series). The first series was performed in the course of 1 h at 343 K, and the acid catalyst concentration was varied from 0.00 to 0.20 M. Preliminary studies of sulfate pulp delignification in this medium showed that, at lower temperatures, the degree of removal of residual lignin is unsatisfactory. Data on the intrinsic viscosity in Cadoxen and degree of polymerization of the pulp are listed in Table 1.

Table 1. Intrinsic viscosities in Cadoxen [η] and degrees of polymerization $[DP]_\eta$ of hardwood sulfate pulp after its treatment in aqueous dioxane at various HCl concentrations

Run no.	HCl concentration, M	[η]	DP_η^*	Relative lignin content
1	Initial pulp	4.95	1031	1.00
2	0.000	4.30	910	0.90
3	0.005	4.23	890	0.74
4	0.010	3.68	770	0.69
5	0.020	3.12	650	0.63
6	0.050	2.92	600	0.60
7	0.200	2.01	400	0.45

* The degree of polymerization was estimated from the equation $[\eta] = DP^{0.04} \times 7.1 \times 10^{-3}$ [5].

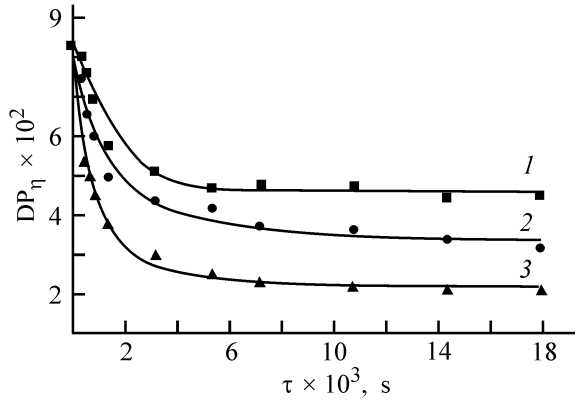

Fig. 1. Degree of polymerization DP_η of pulp vs. the treatment time τ at various temperatures. Temperature, K: (*1*) 343, (*2*) 353, and (*3*) 363; the same for Figs. 2 and 4.

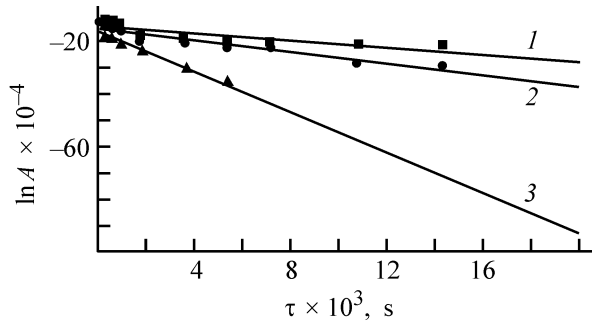

Fig. 2. Semilog kinetic plots of pulp degradation at 343–363 K. $A = (DP^n - 1)/DP^n$; (τ) treatment time.

In the absence of an acid and at its small amounts in the system (run nos. 2, 3), the degree of polymerization of the pulp after an 1-h treatment decreased, on the average, by 12% relative to the initial values, and at HCl concentrations of 0.01–0.05 M, by 25–42% (to 770–600, respectively). At the HCl concentration increased to 0.20 M, the degree of polymerization decreased drastically, to 400, i.e., by almost a factor of 3, compared to the initial sample.

Table 2. Calculated kinetic parameters of delignification of hardwood sulfate pulp in aqueous dioxane

Treatment temperature, K	Calculated kinetic parameters		
	$k_{app} \times 10^8$, s^{-1}	$-\ln k_{app}$	E_{app}, kJ mol^{-1}
343	6.9	16.5	
353	11.4	16.0	88.6 ± 11.8
363	38.4	14.8	

Data on the relative content of lignin in the pulp treated with aqueous dioxane solutions are also listed in Table 1. As the acid catalyst concentration is increased from 0.00 to 0.05 M, the residual lignin content decreases from 0.90 to 0.60 relative to the initial level. At the highest tested concentration of HCl, the residual lignin is removed by half. Taking into account published data [8], we can suggest that, in the solvent system examined, residual lignin of sulfate pulp undergoes degradation with partial dissolution.

The dependence of the DP of pulp on the treatment temperature was examined in the range 343–363 K at an acid catalyst concentration of 0.02 M. At this acid content (which is ten times lower than that in classical acidolysis of wood), lignin undergoes relatively deep degradation (Table 1, run no. 5), but the DP of pulp remains sufficient for the use in paper production. The upper limit of the temperature range examined corresponds to the boiling point of the solvent mixture.

The kinetic curves of pulp degradation are shown in Fig. 1.

The kinetic curves indicate that a major decrease in the degree of polymerization of pulp occurs in the initial period of the treatment. Within 5 h, the DP of the pulp decreases to 541 at 343 K, to 328 at 353 K, and to 219 at 363 K; in the last case, the pulp loses the fibrous structure.

To determine the kinetic parameters of degradation of sulfate pulp, we used a first-order equation characterizing the concentration of bonds in the cellulose macromolecule, which has the following form in the logarithmic coordinates [9]:

$$-\ln[(DP^n - 1)/(DP^n)] = -\ln[(DP_0^n - 1)/(DP_0^n)] + k\tau,$$

where DP^n is the number-average degree of polymerization, determined using the formula for the mean polydispersity coefficient: $n = DP_\eta/DP^n$.

According to [10], $n = 1.25$.

The rate constants of pulp degradation were calculated from the equations for the kinetic curves linearized in the semilog coordinates (Fig. 2). When plotting these straight lines, we used the initial DP of the pulp.

The apparent rate constants k_{app} of pulp degradation in aqueous dioxane increase from 6.9×10^{-8} to 38.4×10^{-8} s^{-1} in going from 343 to 363 K (Table 2).

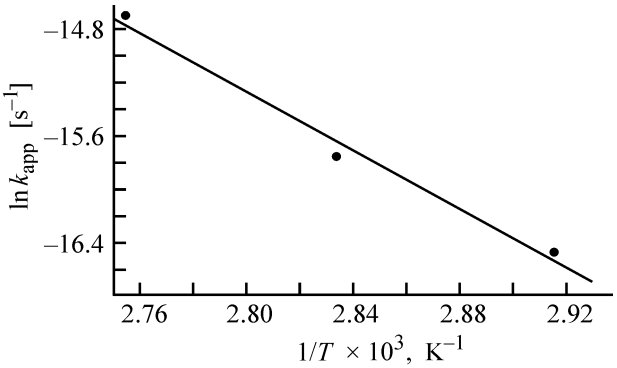

Fig. 3. Arrhenius plot for degradation of sulfate pulp in the range 343–363 K. Fitting equation: $\ln k_{app} = (14.50 \pm 4.04) - (10.66 \pm 1.42) \times 10^3/T$, $R = 0.99$; (T) temperature.

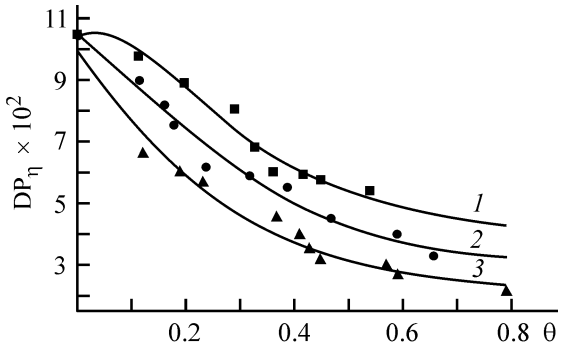

Fig. 4. Selectivity of treatment of hardwood sulfate pulp in aqueous dioxane containing 0.02 M HCl at various temperatures. (DP_η) Degree of polymerization and (θ) degree of delignification of pulp.

The temperature coefficient $\alpha(T^{10})$, i.e., the factor by which k_{app} increases as the temperature is elevated by 10 K, is 1.7–3.4.

From the slope B of the Arrhenius dependence $\ln k_{app}$–$1/T$ (Fig. 3),

$$B = \ln(k_1/k_2)/(1/T_2 - 1/T_1)$$

we calculated the apparent activation energy E_{app} by the equation

$$E = BR,$$

where R is the universal gas constant. We obtained $E_{app} = 88.6 \pm 11.8$ kJ mol^{-1}, which is comparable with E_{app} of oxidative hydrolysis and acid hydrolysis reactions [11], ~95–100 kJ mol^{-1}.

We assessed the feasibility of aqueous-dioxane treatment of sulfate pulp in the course of bleaching, in particular, in the first steps of delignification. The major parameter of the bleaching process is the delignification selectivity. It can be characterized by the dependence of DP_η on θ, where θ is the degree of pulp delignification (Fig. 4).

The curves obtained show that both lignin and cellulose undergo simultaneous and substantial degradation even under mild treatment conditions (343 K). Raising the temperature to 353–363 K favors degradation of cellulose to a greater extent, compared with residual lignin.

Thus, treatment of sulfate pulp in aqueous dioxane occurs with a low selectivity and may be of limited use in pulp treatment for paper production. However, treatment under mild conditions can be used for delignification in production of fibrous cellulose, and treatment under more severe conditions, in production of powdered cellulose materials for chemical processing, e.g., of microcrystalline cellulose.

CONCLUSIONS

(1) Treatment of unbleached hardwood sulfate pulp in a dioxane–water–HCl solution results in degradation and partial delignification of the pulp.

(2) With an increase in the temperature by 10 K, the rate of degradation of hardwood sulfate pulp grows by a factor of 2–3. The apparent activation energy of the process is 88.6 ± 11.8 kJ mol^{-1}.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

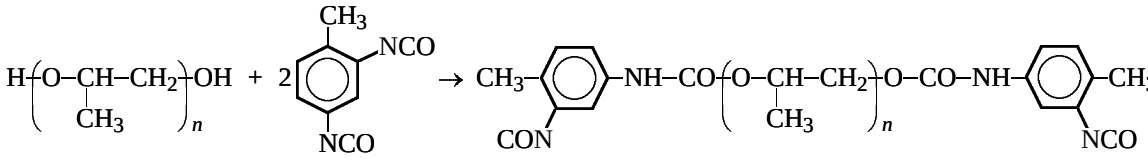
Composite Polymeric Materials Based on Polyisocyanurates and Polyurethanes

L. V. Luchkina, A. A. Askadskii, and K. A. Bychko

Nesmeyanov Institute of Organoelement Compounds, Russian Academy of Sciences, Moscow, Russia

Received October 14, 2004

Abstract—Network poly(urethane–isocyanurate) systems were synthesized from polyurethanes and polyisocyanurates, and the process for preparing composite materials based on them was examined.



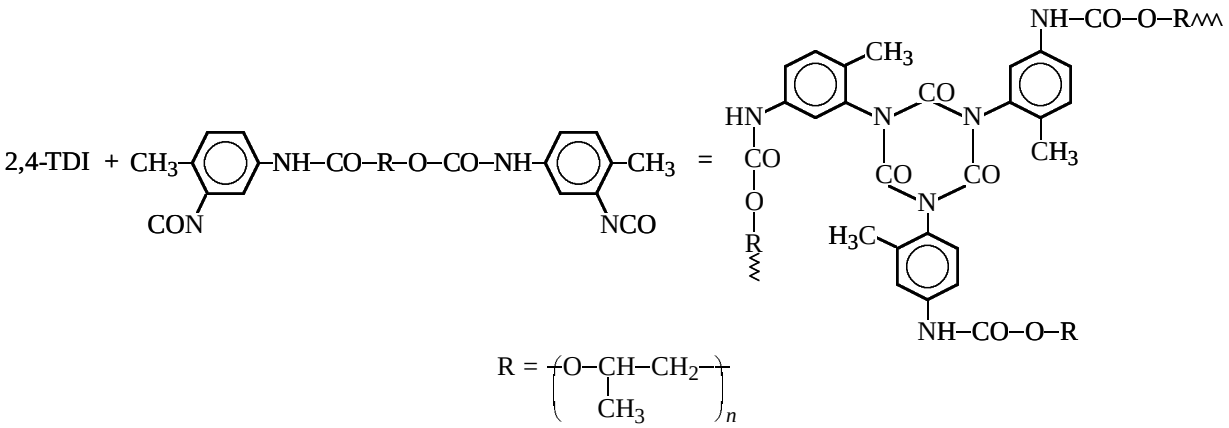
Polyurethane materials find growing applications, primarily thanks to a unique combination of high hardness and elasticity, and also to the exceedingly high tear and wear resistance. Composite polymeric materials (CPMs) have been prepared from polyisocyanurate and polyurethane compounds. These materials preserve elasticity at any elastic modulus and contain a voluminous highly porous support exerting no effect on the elastic properties of the CPMs. Previously CPMs have been prepared from polyisocyanurates, but these materials show poor wear resistance, and the low-modulus samples based on them exhibit an accelerated weather aging. Therefore, it seemed appropriate to prepare materials containing a polyurethane component [1, 2].

In this study, we examined the process for preparing composite polymeric materials from polyisocyanurate and polyurethane compounds.

EXPERIMENTAL

As polymeric binders we used compounds of varied composition, based on 2,4-toluylene diisocyanate (TDI), a diamine [di(3-chloro-4-aminophenuyl)methane], and an oligomeric rubber with terminal hydroxy groups, polypropylene glycol (PPG) [Bayer, MW 2200, hydroxyl number 56.7 (mg KOH) g^{-1}, n_D^{30} = 1.4500, moisture content ≤0.03%]. The prepolymer, oligoether diisocyanate (OEC), was prepared as described in [3]. The reaction progress was monitored by IR spectroscopy from the intensity of the band at 2280 cm^{-1} and from the bands of hydroxy groups at 3500–3600 cm^{-1} [4]. The content of isocyanate groups (%) was estimated from their reaction with dibutylamine; excess amine was titrated with an acid [5]. According to the potentiometric titration data, in the course of the OEC synthesis (T = 70°C, 5 h) the content of isocyanate groups decreases by approximately a factor of 2 (from 10.1 to 4.7%, Fig. 1).

The IR spectrum of the reaction product contained characteristic bands of urethane groups at 3300–3400 cm^{-1} [6]. OEC was obtained as a viscous colorless liquid (at room temperature); n_D^{30} 1.4711, ρ 1.057 g cm^{-3}. The prepolymer is formed by the following reaction:



(1)

where n = 38.

In the second step, the prepolymer was mixed with a varied amount of TDI and di(3-chloro-4-aminophenyl)methane. A calculated amount of carbon black (P 803 brand) was added to obtain black articles. The reaction occurred in the presence of a complex catalyst prepared by mixing dimethylbenzylamine (DMBA) with ED-22 epoxy oligomer in a 1 : 20 molar ratio [3]:

1070-4272/05/7808-1337 © 2005 Pleiades Publishing, Inc.

(2)

In turn, the reaction of the macrodiisocyanate with the diamine initially yielded linear polyurethane–ureas, as confirmed by a spectroscopic analysis (intensity of the band at 1550 cm^{-1}) [6]:

$$\text{OCN}\sim\text{NCO} + \text{H}_2\text{N–R–NH}_2 + \text{OCN}\sim\text{NCO} + \text{H}_2\text{N–R–NH}_2$$
$$\rightarrow \text{–OC–NH}\sim\text{NH–CO–NH–R–NH–CO–NH}\sim\text{NH–CO–NH–R–NH–}, \quad (3)$$

where ∼ is a macrodiisocyanate molecule.

An excess unchanged macrodiisocyanate caused cross-linking of the chain. At temperatures above 100°C, the macrodiisocyanate added to the preliminarily formed urea bonds, which are sufficiently reactive toward diisocyanate groups. As a result, a new kind of fragments, biuret groups, appeared in the cross-linked rubbers:

$$\text{–OC–NH}\sim\text{NH–CO–NH–R–NH–CO–NH}\sim\text{NH–CO–NH–R–NH–} + \text{OCN}\sim\text{NCO}$$
$$+ \text{ –OC–NH}\sim\text{NH–CO–NH–R–NH–CO–NH}\sim\text{NH–CO–NH–R–NH–}$$
$$\rightarrow \text{ –OC–NH}\sim\sim\text{NH–CO–N(C=O–NH≋NH–C=O)–R–NH–CO–NH}\sim\sim\text{NH–CO–NH–R–NH–} \quad (4)$$
$$\text{–OC–NH}\sim\sim\text{NH–CO–N(C=O–NH≋NH–C=O)–R–NH–CO–NH}\sim\sim\text{NH–CO–NH–R–NH–}$$

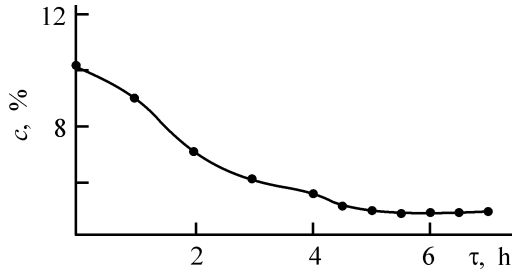


Fig. 1. Variation of the concentration of isocyanate groups *c* in the course of OEC synthesis. (τ) Time.

The IR spectra of the resulting polymers contained bands at 1310 cm^{-1}, characteristic of allophanate structures [6] and suggesting that the reaction between the urethane and isocyanate groups in the course of the synthesis of the poly(urethane–isocyanurate) materials is quite probable at temperatures increased to 120–140°C.

The reactions of urea and urethane group with isocyanate are very important in the synthesis of poly(urethane–isocyanurate) gradient materials, as they give rise to branched and cross-linked structures in

polyurethanes; this is, apparently, one of the factors providing the high strength and wear resistance of these materials. The above reactions are slow (they take 5–6 h), but occur at temperatures commonly used in syntheses of polyisocyanurates, including the commercial synthesis.

Materials with different elastic moduli were obtained by varying the ratio of the prepolymer, TDI, and diamine.

The dynamic and "conventional" viscosities (η^{30}) of polymer solutions were determined by standard procedures using VPZh-2 capillary viscometers (inner capillary diameters 3.00 and 1.31 mm) and a VZ-246 viscometer (orifice diameter 2, 4, and 6 mm). The density of the solutions was determined pycnometrically [7].

The success in preparation of CPMs based on polyisocyanurate and polyurethane compounds and the quality of these materials are governed by a proper choice of highly porous supports and of conditions for their impregnation with prepolymeric binders. The course of impregnation, in turn, depends on the support structure and process conditions, namely, on the pressure, temperature, and time of impregnation, and also on the viscosity of the polymeric binder and conditions of its penetration into support pores. In this context, taking into account data from [1], we chose the following supports for the polymeric compounds: a highly porous nonwoven fibrous framework material continuous in two directions (synthetic felt, Synthepon, PET fiber) and a gas-filled foamed material with an open-cell structure [elastic polyurethane foam of PPU-EM-1 brand, Porolone (PUF)]. Additional experiments on the choice of supports for the polymeric compounds suggested that Hollowfan and Shersticron are also suitable (Table 1). Shersticron is a nonwoven fabric, a thermally bound material consisting of 60% natural wool and 40% polyester fibers. Hollowfan is a nonwoven fabric produced from hollow highly tortuous polyester fibers bound by a two-component fiber. These supports do not noticeably affect the elastic modulus of poly(urethane–isocyanurate) materials, because their own elastic modulus is low and the content in the composite material does not exceed 3–4% because of the high porosity (96–98%).

The porosity of the supports and press materials was determined pycnometrically. The content of open pores in supports of polymeric compounds was determined from the acetone absorption, according to [1].

The supports were impregnated with the compounds at room temperature and atmospheric pressure. The samples were pressed by the procedure from [3].

Table 1. Characteristics of supports for precursors of reactive poly(urethane–isocyanurate) compounds

Support	Support thickness *h*, mm	Support density ρ, g cm^{-3}		Porosity, %
		true	apparent	
Porolone	50	1.27	0.0193	98.5
	20	1.28	0.0147	98.85
	10	1.22	0.0185	98.5
Shersticron	50	1.35	0.0351	98.2
Hollowfan	50	1.41	0.0191	98.6

We examined the conditions for preparation of composite materials based on polyisocyanurates and polyurethanes, using a "solution" method of combining the binder with the support, and also for the subsequent processing of the materials into articles with prescribed properties by hot pressing (a process yielding an article of the required shape in one pressing cycle).

The process for preparing such materials consists of the following steps: (1) compounding of the ingredients for the impregnation; (2) impregnation of the support; (3) prepolymerization (gelation); (4) polycyclotrimerization and chain elongation reactions at 100–140°C; and (5) pressing.

To determine the optimal parameters of the impregnation, drying, and pressing, we obtained unimodular samples at various ratios of OEC, TDI, and diamine.

We considered the influence exerted on the degree of filling of the supports by the following factors: viscosity of the starting compounds, impregnation time, and porosity (initial and residual) of the supports.

In the synthesis of CPMs based on polyisocyanurates and polyurethanes, OEC has the highest viscosity (η^{30} = 2.7 Pa s), and with addition of TDI (η^{30} = 2.5×10^{-3} Pa s) the viscosity of the polyisocyanurate compound correspondingly decreased, which allowed the use of this compound for impregnating the supports without preliminary dilution with acetone. However, when the catalyst was added to the polyisocyanurate compound and the resulting formulation was mixed with the polyurethane compound, the viscosity of the impregnation solutions increased owing to the occurrence of the polycyclotrimerization even at room temperature, and rapid cross-linking of the compound hindered the impregnation. Therefore, we controlled the viscosity of the compounds by adding a diluent (acetone) [1], which had to be removed from the material just before pressing.

Table 2. Density of poly(urethane–isocyanurate) solutions at various TDI contents in formulations

100% solution		90% solution	
TDI content, wt %	density, g cm^{-3}	TDI content, wt %	density, g cm^{-3}
60	1.126	54	1.063
48	1.115	43	1.045
36	1.108	32	1.023
30	1.105	27	1.015
24	1.085	22	1.005
12	1.050	11	0.995
0	0.995	0	0.985

Our experiments showed that the decisive factor governing the degree of support impregnation was the viscosity of the impregnating solutions. However, a too high content of the diluent was undesirable, as it led to a decrease in the amount of the polymer in the CPM, and evaporation of a large amount of the diluent caused formation of pores unfilled with

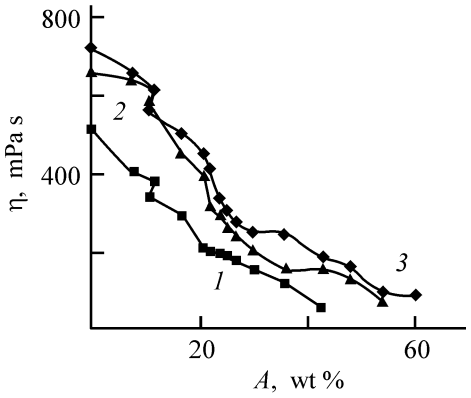

Fig. 2. Viscosity of precursors η vs. the TDI content in solution *A*. Concentration of solutions in acetone, %: (*1*) 70, (*2*) 90, and (*3*) 100.

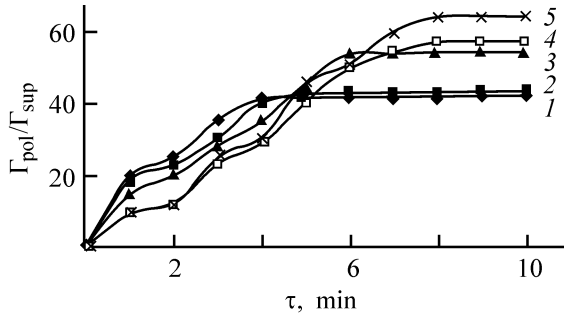

Fig. 3. Precursor uptake $\Gamma_{pol}/\Gamma_{sup}$ by the support (PUF, h = 20 mm) vs. the impregnation time τ. Solution concentration, %: (*1*) 60, (*2*) 70, (*3*) 80, (*4*) 100, and (*5*) 90.

with the polymer. By varying the concentration of the impregnating solutions (60, 70, 80, 90, and 100%), we found that the amount of the polymer introduced is at a maximum, and the residual porosity at a minimum, with 90% solutions. The concentration dependence of the degree of impregnation passes through a maximum. At low concentrations (and, hence, low viscosity), the impregnation is faster, but the polymer flows out from the support pores. As a result, most of the polymer remains on the support surface and retains air inside the prepregs, which adversely affects the uniformity of the pressed composite materials.

It is known [8, 9] that the elastic modulus of polymeric materials depends on the TDI content in reaction formulations. As the TDI content in the compounds increases, the viscosity of the polymer solutions decreases (Fig. 2). The densities of the polymer solutions show the same trend (Table 2). We used for the impregnation 60–100% solutions (10% step) containing 0.5 wt % catalyst relative to TDI. The impregnating solutions (except 100% solutions) were kept at room temperature before the impregnation to ensure the prepolymerization in solution. The experimental data show that the prepolymerization in solution in this step does not noticeably affect the elastic modulus of the resulting samples. However, this step is required to reduce the gelation time of the poly(urethane–isocyanurate) polymeric materials. The reaction is faster in more concentrated (90–100%) solutions and in formulations containing more TDI. In 90% solutions, an increase in the viscosity with increasing TDI content is more pronounced than in the less concentrated solutions.

We determined the optimal time of impregnation of the highly porous supports (5–7 min), in which the constant degree of filling was attained at all the concentrations and compositions of the solution. The support is impregnated most rapidly with a 60% solution (Fig. 3). This solution is the least viscous, and the impregnation time increases with the solution concentration. Thus, the amount of the polymer (so-called degree of filling, DF) introduced in one impregnation cycle increases with the polymer content in the solution. Despite the longer impregnation time, it is preferable to use 90% solutions, which ensures high degree of filling (63 g of polymer per gram of support) and high impregnation quality. As for 100% polyisocyanurate compounds, the apparently larger size of the oligomeric molecules, high viscosity, and fast cross-linking of the compound hinder its penetration into the finely porous structure of the support; as a result, the polymer content is lower: 50–56 g g^{-1} support.

Table 3. Characteristics of poly(urethane–isocyanurate) polymeric materials prepared by hot pressing*

Sample no.	Content, wt %		Carbon black P 803, wt %	Precursor support density, kg m^{-3}	Elastic modulus E, MPa	Sample density, kg m^{-3}

* Compound: (PU) polyurethane, (PIC) polyisocyanurate, and (PUIC) poly(urethane–isocyanurate).

** The sample contains 3 wt % phthalocyanine blue pigment.

At all the solution concentrations, more porous supports take up more polymer; hence, such supports will exert a weaker effect on the properties of the composite materials. In preparation of composite materials, it is also necessary to take into account the residual porosity of the prepregs after the impregnation. It should be as low as possible. When comparing the quality of impregnation of Porolone and Synthepon with compounds based on PPG under the same conditions, we noted that the residual porosity of Porolone was 10%, and the degree of filling, 40–60 g of the polymer per gram of support. For Synthepon (including Shersticron and Hollowfan), the residual porosity was 8–12%, and the degree of filling, 30–35 g of the polymer per gram of support.

The polycyclotrimerization continued in the materials in the step of acetone removal, and the compounds transformed from the liquid viscous-flow state into a gel-like state. The materials lost stickiness and became suitable for the subsequent hot pressing. However, the polycyclotrimerization rate depended not only on temperature, but also on the compound composition. The support impregnated with a TDI-rich compound lost stickiness after keeping for 1 h at 60–65°C; with a decrease in the TDI content and an increase in the content of the polyurethane component, the gel time increased, and the stickiness did not disappear. Therefore, taking into account the conditions of polyurethane synthesis [10], we heated the impregnated samples at 120°C for 4.5–5 h prior to pressing; this step did not impair the molding properties of the materials.

The formation of the network structure and the molding of articles are completed in the step of hot pressing. By varying the temperature, pressure, and time, taking into account the process features of the polyurethane synthesis, we found the following pressing conditions to be the best: T = 120–140°C and specific pressure of 25 kg cm^{-2}. The pressing time was determined as 1 min of pressing per 1 mm of sample thickness. The characteristics of some poly(urethane–isocyanurate) polymeric materials prepared by hot pressing are listed in Table 3.

CONCLUSIONS

(1) Conditions were found and optimal parameters determined for preparing prepregs (pressure, temperature, impregnation time, viscosity of polymeric binder, conditions of its penetration into support pores) based on polyisocyanurate and polyurethane compounds.

(2) Polymeric materials of desired shape, with an elastic modulus of 3.6 to 1250 MPa, were prepared by hot pressing at varied ratio of the prepolymer, TDI, and diamine.

(3) Synthepon, Porolone, Hollowfan, and Shersticron were chosen as highly porous supports exerting no effect on the properties of the resulting materials.

Abstract—The chemical structure of dioxane lignins recovered from Gramineal plants, wheat and oats, was studied by IR, ESR, and ^{13}C spectroscopies, and elemental and chemical analyses. The antioxidant characteristics of lignins were estimated.

Lignins are natural heterochain copolymers composed of structural units of the guaiacyl, syringyl, and *p*-coumaric types. The specific feature of lignin is a variety of chemical and topological structures, which are mainly governed by the taxonomic origin and poorly investigated processes of dynamic self-organization, which occur in biosynthesis of this polymer by plants functioning under conditions of a variable exogenous situation. In this connection, many aspects of structural organization of lignins remain unstudied. The influence of lignins on the human health has not been established either. As is known, a significant amount of lignins of various botanic origins are supplied to the human body with vegetable food. According to published data [1], some types of lignins can suppress the free-radical oxidation of biopolymers, acting as natural antioxidants. Considering modern views on the nature of malignant tumors and other aging pathologies [2, 3] establishment of a relationship between the structure and physicochemical, among them antioxidant, characteristics of lignin polymers is a topical problem.

The goal of this study was to estimate antioxidant characteristics and chemical structure of lignins recovered from Gramineal plants.

EXPERIMENTAL

As the initial plant material served mature stalks of oats *Avena sativa L.* and wheat *Triticum sp.* The raw materials were prepared at a pilot plantation of the Sysola strain-testing plant of the Komi Republic at the end of the vegetation period. The composition of oat stalks was as follows (%): lignin 22.5, cellulose 48.7, readily hydrolyzable polysaccharides 20.9, ash 5.0, and nitrogen 0.7. The composition of wheat stalks was as follows: lignin 22.0, cellulose 48.7, readily hydrolyzable polysaccharides 20.5, ash 3.1, and nitrogen 0.8.

The samples of oat lignins (DL-O) and wheat lignins (DL-W) were recovered by the dioxane procedure [4]. The samples were purified by twofold precipitation from dioxane into diethyl ether. The amount of carbohydrate impurities in DL-O was 2.0%, and in DL-W, 2.4%. The samples were freeze-dried. The yield of DL-O was 20% and that of DL-W, 25% relative to the content of Komarov lignin in the initial raw material. An elemental analysis of the recovered samples was performed on a Hewlett–Packard analyzer (USA). The standard methods of wood chemistry were used for quantitative estimation of functional

Fungus Betulinus	Aqueous extract	4.9 ± 0.2	0.03
Hydrolyzed industrial lignin	Polyphen	1.7 ± 0.1	0.04
–	Mitofen	87.6 ± 6.6	0.07

* X is the arithmetic mean of five determinations of AOA ($n = 5$); S, standard deviation; and S_r, relative standard deviation (confidence level $p = 0.95$).

groups. The content of methoxy groups was determined by the Viebock-Schwappach method, and that of phenolic and carboxy groups, by the barium chloride method [5].

The ^{13}C NMR spectra were recorded in a pulsed mode on a Bruker AM-300 spectrometer operating at 75.5 MHz. The spectrum width was 18 kHz, pulse length, 2 μs, and pulse separation, 6 s. DMSO-d_6 containing 0.02 M chromium triacetylacetonate (relaxing agent) served as a solvent. The solution concentration was 30%. The acquisition number was 20000. The ^{13}C NMR were quantitatively interpreted according to the procedures described in [6]. The results of calculations are presented as a number of carbon atoms of certain type per aromatic ring (AR) n_x:

$$n_x = (p_x/f_a) \times 6,$$

where $p_x = I_x/I_{tot}$ is the relative content of carbon atoms of the given type; I_x, integral intensity of the signal from the given type of atoms; I_{tot}, total intensity of the spectrum; f_a, aromaticity of lignin, evaluated as the ratio of the integral intensities of signals from aromatic carbon atoms I_a (at 103–160 ppm) to the total intensity of the spectrum, $f_a = I_a/I_{tot}$; and 6, number of carbon atoms in an aromatic ring.

The ESR spectra of the compounds were recorded on an SE/X-2547 spectrometer (RadioPAN, Poland) in the X-frequency range with 100-kHz HF modulation at room temperature; the UHF field power was 2.2 mW. An RX102 rectangular cavity with the TE102 mode was used. The concentration of free radicals was estimated using reference samples of diphenylpicrylhydrazyl with spin concentrations of $(7.0 \pm 0.7) \times 10^{16}$ and $(2.7 \pm 0.3) \times 10^{18}$ spin g^{-1}. The error in determining the concentration of paramagnetic centers (PMCs) was 15%.

The IR spectra were recorded from KBr pellets on a Specord M80 spectrometer and MIR8000 Fourier IR spectrometer equipped with a DTGS detector. The IR spectra were processed by the well-known procedure [7] using the baseline method and normalization with respect to the strongest absorption line.

The antioxidation activity (AOA) was estimated by coulometric titration [8]. The quantity of electricity expressed in coulombs, consumed per 100 g of the product, was calculated by the formula

$$Q = 100It/V_{al},$$

where I is the current strength; t, time in which the final point of titration is reached; and V_{al}, aliquot volume.

Lignins, along with cellulose and hemicelluloses, are components of plant food fibers. Lignins are polyphenolic compounds containing phenolic groups of various types with different acidities, and also stable radicals. This creates prerequisites for manifestation of antioxidant characteristics.

For quantitative estimation of AOA, we used a coulometric procedure allowing estimation of the total content of antioxidants in various substrates. This procedure is based on coulometric titration of substances with electrolytically generated bromine species (Br_3^-, Br_2, and $Br^\bullet$), which are able to enter into various reactions: radical, redox, electrophilic substitution, and addition to multiple bonds [8]. It should be noted that comparative studies of AOA of a series of samples by coulometric titration and chemiluminescence, one of the classical ways to determine AOA, revealed a high degree of correlation of the results furnished by these two methods ($r = +0.94$).

Table 1 shows the results of measurements of AOA of the lignin samples from wheat and oats and also of a number of other samples of plant and synthetic origin. As the studies showed, the AOA value of the DL-W sample was 61.3 ± 2.1 kC per 100 g. The higher value of AOA, 69.4 ± 2.8 kC per 100 g, was found for the DL-O sample. For all other samples, including medical lignin Polyphen, the antioxidant activity was noticeably lower. The exception is Mitofen [sodium poly(*p*-dihydroxy-*p*-phenylene)-thiosulfonate], which is not surprising since this medication belongs to a number of the most effective and acknowledged antioxidants and is widely used in medical practice. Among drawbacks of Mitofen is,

apparently, its synthetic origin. The results obtained suggest that lignins prepared from grassy cereals may be of interest for development of pharmaceutical medications with tumor- and gerontoprotective effects. It is evident that high andioxidant characteristics of DL-W and DL-O lignins are caused by the features of molecular structure of these biopolymers. In this context, one of the topical problems of the development of highly effective natural antioxidants is elucidation of various aspects of the lignin structure and, primarily, of the chemical structure of the macromolecules.

The lignin content in plant substances depends on the vegetation period and exogenous natural factors. For a ripe plant, the lignin amount in grass xylem is usually 17–23%. In this case, plant raw materials, oak and wheat stalks, contain 22.5 and 22.0% lignin, respectively. The DL-O and DL-W lignin samples recovered by freeze-drying are light cream-colored porous powders readily soluble in dilute alkalis and polar solvents with a Hildebrand parameter 9–13 $(\text{cal cm}^{-3})^{0.5}$.

A study of lignins by the molecular hydrodynamics methods showed that the DL-O and DL-W samples are typical macromolecular compounds. The macromolecular characteristics of the samples are listed in Table 2.

The molecular weights of lignins, $M_{D\eta}$, determined by the sedimentation-diffusion analysis of fractionated DL-O and DL-W samples are 12.4×10^3 and 14.4×10^3, respectively. A large body of data on characteristics of dioxane lignins of various botanic origins shows that the molecular weight of the lignins studied does not noticeably differ from that of lignins of coniferous wood.

As is known [6, 9], lignins are characterized by diversity of the chemical structure of macromolecules, which is caused by a variety of monomeric precursors and the absence of genetic control over biosynthesis in the stage of growth of macromolecules. Macromolecules of lignins consist of phenylpropane units; the monomeric precursors of these polymers are derivatives of hydroxycinnamic alcohols: *p*-coumarol, coniferol, and sinapol

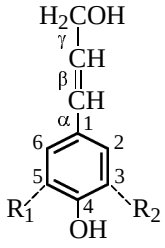

Table 2. Hydrodynamic characteristics of DL-O and DL-W lignins*

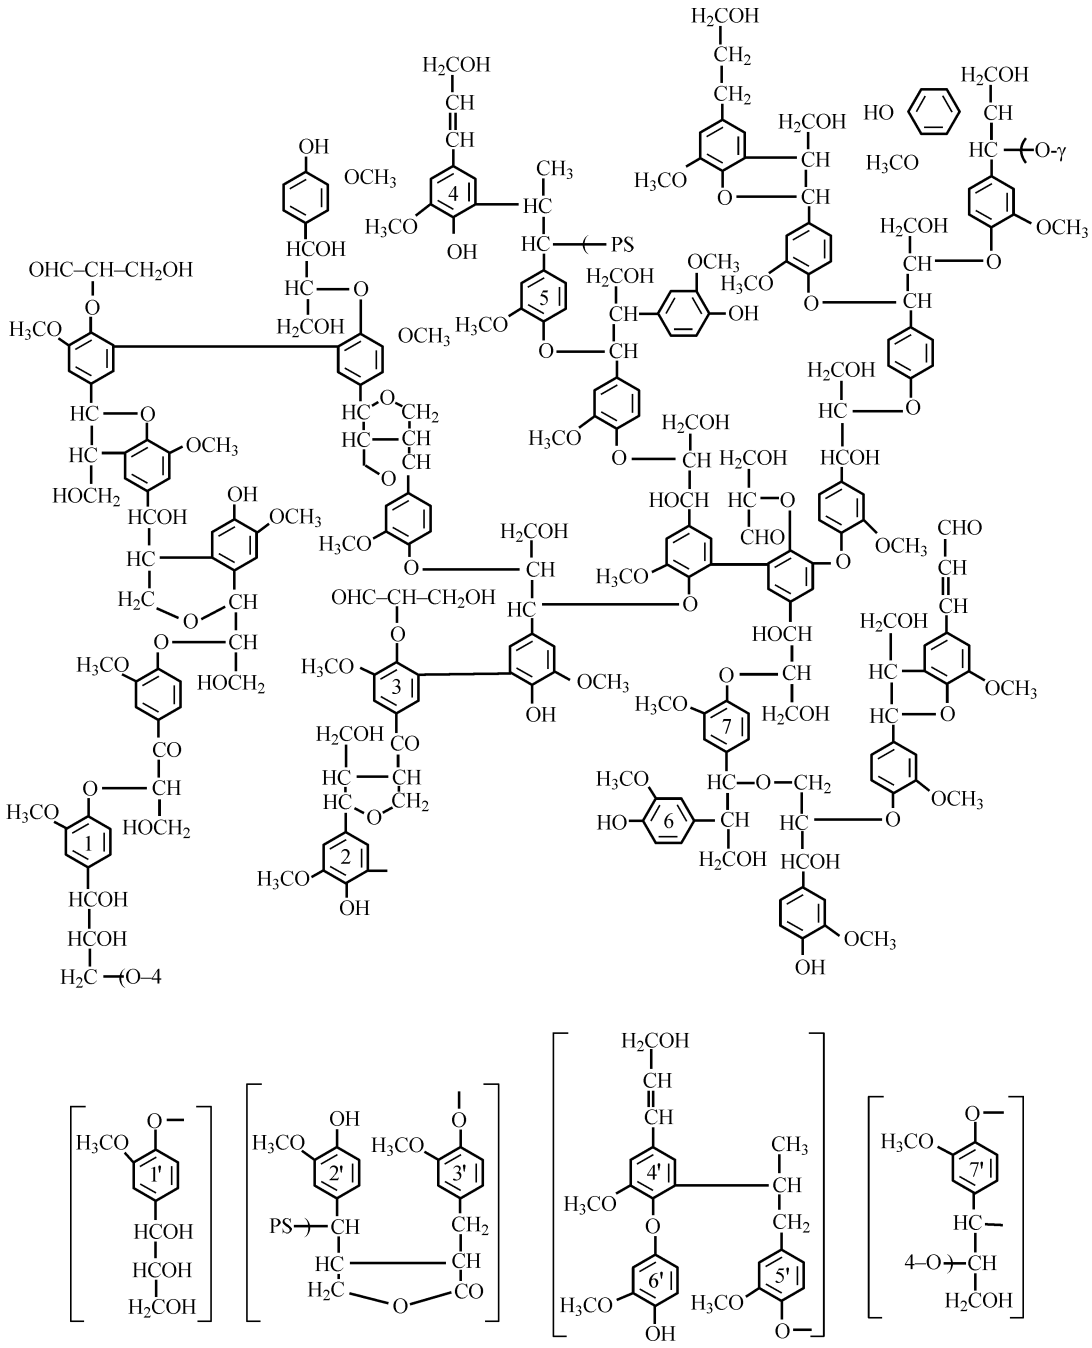
Polymer	$[\eta]$, $\text{cm}^{-3}\,\text{g}^{-1}$	$D \times 10^7$, $\text{cm}^2\,\text{s}^{-1}$	$(1 - \bar{\nu}p_0)$	$M_{D\eta} \times 10^{-3}$
DL-O	5.9	13.5	0.334	12.4
DL-W	6.2	12.5	0.338	14.4

* $[\eta]$ is the intrinsic viscosity; D, coefficient of translation diffusion; $(1 - \bar{\nu}p_0)$, factor of Archimedean floatability, where $\bar{\nu}$ is the specific partial volume of polymer, $\text{cm}^3\,\text{g}^{-1}$; p_0, solvent density, g cm^{-3}; and $M_{D\eta}$, molecular weight.

Table 3. Elemental composition and content of functional groups with account of the presence of carbohydrate impurities in DL-O and DL-W samples



Sample	Content, %				
	OCH_3	COOH	OH_{phen}	C	H
DL-O	16.3	4.3	2.7	59.2	5.26
DL-W	15.4	4.2	2.6	60.3	5.66

where $R_1 = R_2 = H$ (*p*-coumarol); $R_1 = H$, $R_2 = OCH_3$ (coniferol); and $R_1 = R_2 = OCH_3$ (sinapol).

At present, all natural lignins are subdivided according to their botanic attribution into three groups: coniferous, deciduous, and grassy lignins. Coniferous lignins are mainly composed of guaiacylpropane structural units (monolignol coniferol); macromolecules of deciduous and grassy lignins contain units of all three types, with their ratio varies depending on the taxonomic origin. The structural units of various types are bonded by numerous bonds of various types [9]. The diversity of structural units, fragments, and functional groups of macromolecules hampers interpretation of the chemical structure of natural lignins. One of the numerous hypothetical and theoretically possible models describing the molecular structure of lignin of the guaiacylsyringyl type, suggested in [10], is presented below.

It should be noted that structural schemes have not yet been developed for grassy lignins.

A topical problem of the lignin chemistry today is elucidation of the structural features of lignins within the framework of individual taxonomic group of botanic classification. In this context, it is of interest to compare the chemical compositions and structural features of DL-O and DL-W macromolecules. The elemental compositions and contents of functional groups of these lignins are listed in Table 3.

(1)

(2)

Model of the structure of spruce lignin [10]: (1) general structure and (2) possible additional alternative structural fragments.

An elemental analysis of the samples showed that, in the carbon content, DL-O and DL-W correspond to guaiacylsyringyl lignins, for which the established carbon content is 57–61%. However, in the degree of methoxylation these lignins should be classed with guaiacyl lignins, i.e. coniferous lignins, since the number of OCH_3 groups per phenylpropane unit does not exceed 1.1. This follows from the evaluation of the average empirical formulas of the monomeric unit, $C_9H_{10.0}O_{3.9}(OH_3)_{1.1}$ (DL-O) and $C_9H_{10.2}O_{3.3}(OH_3)_{1.0}$ (DL-W).

Nevertheless, there are no contradictions between these data, since, as the studies show, the monomeric units of the guaiacyl type predominate in grassy lignin macromolecules at a noticeable amount of *p*-coumaric units. At the same time, these lignins have

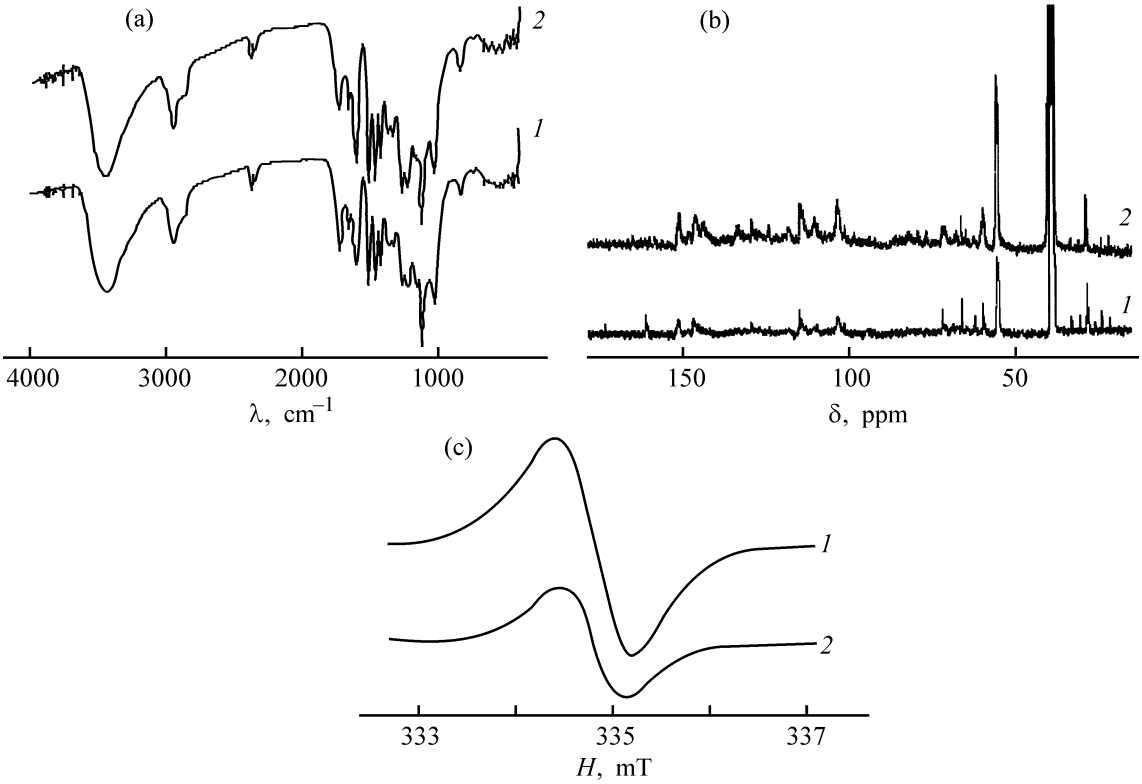


Fig. 1. (a) Fourier IR, (b) ^{13}C NMR, and (c) ESR spectra of (*1*) DL-O and (*2*) DL-W samples. (λ) Wave number, (δ) chemical shift, and (*H*) magnetic induction.

an increased content of such oxygen-containing functional groups as carboxy and phenolic (Table 3). Of special interest is that phenolic groups of several types differing in acidity (p*K* value) have been found in lignin macromolecules [11].

The IR spectra of the lignins studied (Fig. 1a, Table 4) contain a series of characteristic bands (cm^{-1}): 3440, 1725, 1600, 1520, 1470, 1430, 1330, 1270, 1140, 1035, and 840. Analysis of the spectra allows estimation of the amount of some func-

tional groups and structural fragments. As follows from Table 4, DL-O and DL-W lignins have approximately the same content of aliphatic carboxyls (1720–1730 cm^{-1}), which is confirmed by chemical analysis (Table 3). The samples do not differ in the content of conjugated C=O groups in the coniferyl aldehyde groups (1660 cm^{-1}). The ratio of intensities of the bands at 1470 and 1430 cm^{-1} can be used for chemotaxonomic identification of lignins. In this case, the relationship is typical of guaiacyl (i.e. coniferous) rather than guaiacylsyringyl lignins: $A_{1500} > A_{1470} > A_{1430}$ cm^{-1}. In addition, as can be seen from Table 4, $A_{1270} > A_{1230}$, for DL-O and DL-W lignins although an inverse ratio of the intensities of these bands would be expected according to the Kawamura–Higuchi (K–H) chemotaxonomic classification [12]. Without any sophisticated analysis of all the spectral criteria, it should be noted that oat and wheat lignins are difficult to class with the well-known types of lignins N_s, L_s, and L_m within the framework of the K–H concept.

The ^{13}C NMR spectra of the DL-O and DL-W samples are shown in Fig. 1b. The chemical shifts and assignments of the signals are listed in Table 5. The signals of aliphatic carbon atoms in the CH, CH_2, and CH_3 groups not bonded to oxygen atoms are found in the range 5–45 ppm. In this range, there are numerous signals, suggesting the diversity of chemical structures of side aliphatic chains; however, the number and positions of these signals in the spectra of both samples coincide. Nevertheless, the lengths of side chains in two lignins are not equal: $n_{\Sigma\,10-35}$ = 2.0, for DL-O and less than 1.0 atom/AR for DL-W. In the spectra of the lignins studied there are signals at 53.5 and 53.8 ppm, assignable to the C_β atoms of the coumaran and pinoresinol structures. Table 6 shows that, according to the $n_{\Sigma\,54.5-53}$ values, the total amount of these structures in the DL-O and DL-W samples is the same. Carbon atoms in aromatic methoxyls give rise characteristic signals at 55.7 and 55.9 ppm. Integration of these signals (Table 6) shows that the number of C atoms in Ar–OCH_3 in the DL-O sample is higher than that in DL-W. This result agrees qualitatively with the estimation of the number of C-2 and C-6 atoms in the syringyl units S and S' from the integral intensity in the range of 108–103 ppm. Their amount is 1.1 in DL-O and 0.9 atom/AR in DL-W. In dioxane lignin of wheat stalks, $n_{\Sigma\,102-108}$ = 0.675 atom/AR [13].

A unique feature of lignin as a natural polymer is its paramagnetism caused by the presence of stable free radicals in the macromolecule. The ESR spectra can be characterized by the signal intensity, *g*-factor, and the shape and width ΔH of the resonance line (Fig. 1c). As the studies showed, the ESR signals of DL-O and DL-W lignins are virtually iso-

tropic singlets with a *g*-factor equal to 2.0042–2.0045 (Table 7).

The nature of lignin paramagnetism remains the matter of discussion. In studying the influence of various procedures of chemical treatment on lignin, Lin and Dence [14] concluded that radicals contained in lignins can be classed with semiquinone macroradicals. Semiquinone radical ions of benzoide structure were detected in samples of lignin treated with alkali [15]. The certain role of phenolic hydroxyls and, correspondingly, phenoxy radicals in lignin paramagnetism is suggested by published data [16], which show that, after methylation of pine lignin samples with diazomethane, the concentration of free radicals decreases by approximately a factor of 10. However, it should be noted that a decrease in the concentration of paramagnetic centers from the initial value of approximately 1.5×10^{17} to 1.4×10^{16} spin g^{-1} is scarcely significant. Based on studies of dioxane lignins, Chudakov and co-worker [17] cast doubt on the fact that paramagnetic characteristics of lignins are caused by the radicals of the phenoxyl or semiquinone type. They believe that the ESR spectra of lignins result from intermolecular and intramolecular interactions caused by the presence of conjugated double bonds. As shown previously on the basis of ozonolysis data [15], the number of double bonds in hydrolyzed lignin reaches 3×10^8 mol g^{-1}. Having analyzed published data and the ESR spectra of lignins measured by them in the 2-mm and 3-cm wavelength ranges, Kuzina and co-workers [15] concluded that singlet signals in the ESR spectra of lignins in the range of a *g*-factor of approximately 2.0 belong to radicals having a system of conjugated C–C bonds.

It should be noted that virtually all studies of paramagnetic properties have been performed with samples of lignins recovered from wood of guaiacyl type. In this context, the ESR spectra of lignins recovered from grassy plants with Gramineal plants as an example, are of considerable interest. As is known, the singlet linewidth is governed by the degree of delocalization of the spin density; therefore, the ΔH values characterize the difference of lignins in the size of the conjugated C–C bond system in lignin macromolecules. For DL-O lignins, the linewidth measured between the extremal points ΔH is 0.78 mT, which mainly coincides with the ΔH value for the samples of other grassy lignins. In particular, ΔH = 0.81, for lignin recovered from rye and ΔH = 0.63 mT for lignin from Fescue meadow. As a rule, the width of the ESR signal of lignins from wood is in the range 0.5–0.65 mT. The concentration of PMCs strongly depends not only on the origin of a lignin, but also on the procedures of its recovery. For example, spruce lignin has the following concentrations of radicals (spin g^{-1}): Browns lignin, 0.5×10^{17}; milled wood lignin, $(0.23–1.0) \times 10^{17}$; and dioxane lignin, 0.83×10^{17}. It should be noted that the concentration of PMCs in the samples studied is noticeably higher than that in wood lignins. However, for adequate comparison of lignins of various origins with respect to this characteristic, it is necessary to determine the concentration of PMCs in parallel in different samples under absolutely identical conditions. As the results obtained show (Table 1), the samples of grassy lignins are rated in the order of increasing AOA as follows: AOA(DL-FM) < AOA(DL-W) < AOA(DL-O). The concentration of PMCs increases in the same order (Table 7).

Table 7. Parameters of ESR spectra and PMC concentrations in various lignin samples

Sample	*g*-factor	ΔH, mT	$c \times 10^{-17}$, spin g^{-1}
DL-O	2.0044	0.78	2.2
DL-W	2.0042	0.81	1.2
DL-FM	2.0042	0.63	0.9

CONCLUSIONS

(1) The structure of natural lignins recovered from stalks of oats *Avena sativa L.* and wheat *Triticum sp.* was studied. The results of the IR, ESR, and ^{13}C NMR spectroscopic studies of lignins and also of chemical analysis suggest a similarity in the structural organization of lignins.

(2) Antioxidant characteristics of lignins and a series of other preparations of plant and synthetic origins were estimated. The results show that the development of new natural antioxidants based on lignins is promising.

Abstract—The effect of addition of viscose fiber on the recovery of butadiene–styrene rubber from a latex and on the properties of the commercial rubber and vulcanizates based on it was examined.

Preservation of the environment is one of the major problems of the mankind. This is connected with the increase in the extraction and processing of natural resources. The rise in the industrial potential is accompanied by the formation and accumulation of large amounts of wastes. Only 1/3 of the raw materials consumed goes for production of target products, with 2/3 giving wastes and by-products. The enhancement of the industrial impact on the nature gave rise to environmental problems [1, 2].

In Russia, the annual volume of wastes containing chemical fibers and threads in the 1980–1990s was, on the average, 9–10 thousand tons. Use of these wastes in industrial rubber and latex items and in various formulations not only would give a considerable profit due to production of additional items but also could solve environmental problems.

A certain part of textile wastes is used in various branches of industry. However, the major fraction of these wastes is not properly used as a secondary raw material and is dumped. Therefore, utilization of textile wastes is a topical problem [3].

It is suggested to use fibers of various origins in tire and rubber industry [4, 5]. In particular, textile materials can be reinforcing elements in many industrial rubber items for which the strength, durability, low weight, and wide range of operation temperatures are essential parameters [4].

In the above-mentioned studies, fibrous fillers were introduced on rollers in the course of compounding of rubber stocks. However, this procedure does not ensure uniform distribution of the fibrous filler in the bulk of the rubber stock, which, in turn, adversely affects the physicomechanical characteristics of the vulcanizates.

In this study, we examined the effect of viscose fiber introduced into SKS-30 ARK butadiene–styrene rubber (BSR) latex on the latex coagulation, rheoligocal and vulcanization properties of the rubber and rubber stock, and physicomechanical characteristics of the vulcanizates.

EXPERIMENTAL

The apparatus for studying the recovery of the rubber from the latex was a vessel equipped with a stirrer and placed in a thermostat to maintain the required temperature. The coagulator was charged with the butadiene–styrene latex (dry residue about 18 wt %) and thermostated at the required temperature for 15–20 min. The fibrous filler was introduced with an acidifying agent in the final step of rubber recovery from the latex [6–8]. The coagulation was performed with a 24 wt % NaCl solution; the constant pH of the coagulation (~2.0) was adjusted by adding 1–2 wt % H_2SO_4 solution.

Our experimental study consisted of two stages. In the first stage, we examined the effect of viscose fiber added with the acidifying agent (sulfuric acid) on the rubber recovery from the latex. The viscose fiber length was 2, 5, and 10 mm, and the fiber content, 0, 0.1, 0.3, 0.5, 0.7, and 1.0 wt % based on the rubber. The results are listed in Tables 1–3.

5	0.7	154	–1.19	312	–1.33	614	–1.43

The experimental data show that the coagulum yield increased in all the cases. This is most probably due to a decrease in the rubber loss with the finely dispersed coagulum and wash waters and to the capture of the fibrous filler by the forming coagulum.

It should be noted that the size and content of the fibrous filler, varied in the ranges examined, have no effect on the degree of rubber recovery from the latex. However, with large amounts of the fibrous filler (more than 1.0 wt % based on the rubber), the slurry of the fiber in a sulfuric acid solution became too thick, which made its use unfeasible because of problems with transportation along pipelines and with dispersion in the latex in the final step of the rubber recovery from the latex.

Then we examined the influence exerted by the viscose fiber on the properties of rubber stocks and vulcanizates.

The rubbers were tested according to the requirements of GOST (State Standard) 15 627–79 to SKS-30 ARK rubber, in comparison with the reference sample.

Table 2 shows that, upon addition of the viscose fiber, the viscosity of the rubber and rubber stock slightly decreases (from 55 ro 51–53 and from 57 to 53–56 units, respectively), and the minimal torque increases from 4.8 (reference sample) to 5.5–6.5 N m (Table 3). The lack of orientation of poorly wettable viscose fibers in the rubber stock matrix in the direction perpendicular to the load direction (calender effect) accounts for the increase in the recovery of the samples from 1.4 to 1.8 mm (Table 2) and the corresponding decrease in the creep of rubber stocks. The fiber additions increase the scatter of the plasticity of the rubber stock within the limits 0.31–0.38 units.

The adsorption of a part of components of the vulcanizing group on the fiber surface (2-mm viscose fibers) causes an increase in the optimal vulcanization time from 27.5 (reference sample) to 29–30 min. The vulcanizates filled with 2–10-mm fibers show a decrease in the strength and stress at 300% elongation, compared to the samples without fiber, because of the lower degree of cross-linking.

A substantial increase in the tear resistance (from 53 to 71–96 kN m^{-1}) and in the resistance to multiple cyclic deformations from 70 to 96 thousand cycles is proportional to the content and length of the fibers and is due to their reinforcing effect, revealed previously for vulcanizates filled with fibers in the step of rubber compounding [9].

An increase in the resistance to aging (100°C, 72 h) may be due to the completion of the vulcanization as a result of desorption of the vulcanizing group components from the fiber surface.

Thus, we revealed an effect of small additions of a fiber on the viscosity and vulcanization characteristics of the rubber and rubber stock and on the service properties of the vulcanizates. An important parameter for evaluating the properties of the resulting composites is the occurrence or absence of the interphase interaction of the rubber matrix with the surface of viscose fiber introduced in the step of rubber recovery from the latex.

To evaluate the interphase interactions of small fiber additions with the rubber matrix, we examined, in the second stage of our study, the kinetics of swelling of BSR-based vulcanizates in solvents of various polarities.

The interphase interactions were evaluated by the equilibrium degree of swelling α_{max} and the rate constant of swelling k (h^{-1}) of vulcanizates containing the viscose filler in such solvents as *n*-octane, toluene, and chloroform (Table 4).

Irrespective of a particular solvent, the influence of the fiber content (varied in the range 0.3–0.7 wt %) on α_{max} was insignificant. With an increase in the sol-

vent polarity (octane, solubility parameter ρ_{oct} 15.4 $MJ^{0.5}\,m^{-1.5}$; toluene, ρ_{tol} 18.2 $MJ^{0.5}\,m^{-1.5}$; chloroform, ρ_{chl} 18.8 $MJ^{0.5}\,m^{-1.5}$ [10]), α_{max} grows from 154–168 to 312–369 and 614–675 wt %, irrespective of the fiber content. The highest α_{max} of BSR vulcanizate with the fibrous filler in chloroform indicates that the vulcanizate polarity increases and its solubility parameter approaches that of chloroform, ρ_{chl} 18.8 $MJ^{0.5}\,m^{-1.5}$, against 17.4 $MJ^{0.5}\,m^{-1.5}$ for the starting BSR, due to the presence of the fiber and appearance of the vulcanization network.

The apparent driving force equal to α_{max} did not affect the swelling rate. The difference in the thermodynamic compatibility of the solvents and BSR vulcanizate with the fiber determined the swelling rate. For the BSR vulcanizate–octane system, for which the compatibility parameter $\beta = (\rho_p - \rho_s)^2$ [10, 11] (4–12 $MJ\,m^{-3}$) is larger, the swelling rate is lower (k = 0.93–1.19 h), and for the BSR vulcanizate–toluene (or chloroform) system with lower β (0.4–2.0 $MJ\,m^{-3}$), k is higher (1.07–1.43 h^{-1}).

For viscose fibers, we revealed no significant effect of their content and size on the swelling rate, apparently because of the weak interphase interaction of the boundary layers as a result of large difference in ρ_{BSR} and ρ_f = 31.9 $MJ^{0.5}\,m^{-1.5}$ [$\beta = (\rho_{BSR} - \rho_f)^2 \approx$ 170–210].

CONCLUSIONS

(1) The optimal length of the viscose fiber is 2–5 mm, and its optimal content in the rubber, 0.3–0.7 wt %.

(2) Addition of viscose fiber in the step of the latex coagulation ensures uniform distribution of the fiber in the rubber bulk, which positively affects such properties of the resulting vulcanizates as tear resistance, resistance to repeated strains, and resistance to thermal aging.

(3) Addition of viscose fiber affects the rheological and vulcanization properties of rubbers and rubber stocks and the physicomechanical parameters of the vulcanizates.

(4) The fiber length (varied in the range 2–10 mm) and content (varied in the range 0.3–0.7 wt %) do not noticeably affect the viscosity of the rubber and rubber stock.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of Modification on the Elastic-Relaxation Properties of Rubbers Based on Binary Blends of Diene Rubbers

N. I. Kurbanova

Institute of Polymeric Materials, Azerbaijan National Academy of Sciences, Sumgaiyt, Azerbaijan

Received April 21, 2005

Abstract—The elastic-relaxation properties of rubbers based on binary blends of diene rubbers were studied as influenced by the modifier, trichloroacetic acid.

The current trends in the development of chemistry and technology of composite materials are largely determined by the search for ways to develop materials with an improved set of properties. An efficient way to prepare new materials with desired properties consists in mixing of two or more polymers [1–3]. The conditions of preparation and processing of blends and introduction of various modifying additives strongly affect their structure and properties [4–6]. Polymer blends offer a number of advantages over conventional polymeric materials and often stimulate rapid scientific and technological progress in their application fields.

We have demonstrated earlier [7] how fillers affect the elastic-relaxation and strength properties of rubbers based on binary blends of diene rubbers [7]. In this study, we elucidated how the modifier affects the properties of binary blends of divinyl (SKD) and butadiene-styrene (SKS) rubbers with polyisoprene (SKI).

We used Cariflex IR309 polyisoprene available from Shell, cis-132 (96% cis) SKD, SBR-1500 SKS (styrene 23%) available from BSL Olefinverbund GmbH, Schkopau, and carbon black no. 330. Trichloroacetic acid (TCAA) (mp 58°C, bp 196.5°C) served as modifier.

The component ratio, mass fractions, in the formulations was as follows: SKD (SKS) : SKI : carbon black : TCAA = 50 : 50 : 50 : 5. Vulcanizing system, mass fractions: sulfur 2.0, stearic acid 2.0, ZnO 3.0, thiuram 0.65, Altax 1.0, Captax 1.25 for SKD/SKI blend, and sulfur 2.0, stearic acid 2.0, ZnO 2.0, and Altax 2.75 for SKS/SKI blend.

The rubbers were mixed under laboratory conditions in a 60-cm^3 Brabender Plasticorder mixer (initial temperature 50°C, degree of filling 0.75) for 6 min in the case of systems without the filler and for 7, 10, and 15 min in the case of formulations with the filler. The time, s, of introduction of the components into the mixer was as follows: SKD (SKS) 0, TCAA 60, SKI 120, carbon black 180 (in three portions), sulfur + stearic acid + ZnO + accelerators 240.

The blends were pressed in 1-mm-thick molds at 145°C.

The tensile tests were carried out on a tensile-testing machine at room temperature and a strain rate of 200 mm min^{-1}.

A dynamic mechanical analysis was carried out on a Gabo Qualimeter Eplexor 500 N (T from –120 to 120°C, frequency 1 Hz) at a heating rate of 1 deg min^{-1}.

We studied the physicomechanical properties of the initial filled and unfilled, as well as modified, vulcanizates of the resulting formulations under quasi-static and dynamic loads. The compositions and properties of the binary blend formulations (average of five measurements) are listed in the table.

As is known [8], of greatest interest in the case of elastomeric formulations is introduction of minor additives of highly polar compounds. They spread over the surface of the structural elements of the macromolecules, increase their mobility, and accelerate relaxation processes, thereby improving the properties of the polymeric materials.

With a modifier containing chlorine atoms and a carboxy group, it is possible to introduce into the elastomers functional groups creating new reactive centers that enhance their interaction with isoprene rubber and other components of the rubber stock.

* σ_t is tensile strength; ε, relative elongation at break; M_{100}, M_{200}, and M_{300}, stresses at 100, 200, and 300% elongation, respectively; and τ_v^{143}, vulcanization time at 143°C.

We showed in [7] that the optimal time of mixing of filled formulations based on binary rubber blends is 10 min. Introduction of a modifying agent allows preparation of vulcanizates with improved properties, when formulations are mixed for 7 min in the case of SKS/SKI and 10 min in the case of SKD/SKI system.

Table shows that, upon introduction of TCAA into an unfilled SKD/SKI (SKS/SKI) blend, the strength σ_t increases by a factor of 3.8 (1.25), but relative elongation at break ε decreases by a factor of 2.5 (1.77), and the stress at 300% elongation M_{300} increases from 0.3 to 2.9 MPa (from 0.1 to 2.3 MPa).

Combined use of the modifier and filler improves the properties of the formulations. Evidently, polar groups of the modifier enhance the general intermolecular interaction by making stronger the interaction with the filler through formation of chemical bonds and absorption binding, which increases the deformation stress and also accelerates crystallization.

It is known [6, 9] that the major factor in the modification, essential for improving the physicomechanical properties of rubbers, is the formation of chemical and intermolecular bonds in the filled elastomeric matrix when the rubber interacts with the filler or substrate, or the involvement in formation of additional vulcanization bonds. In this context, many researchers direct their efforts toward increasing the number of bonds being formed in rubbers, enhancing their strength, and creating cross-linked structures with different chains. In the context of increasing the resistance of rubbers to fatigue failure, of much importance is the capability of the broken bonds to recover after removal of the load. Consequently, rubbers with a set of strong and labile transverse bonds exhibit a high resistance to multiple deformations.

As is known [3, 6, 8], the structure of the vulcanizate results from various chemical and physicochemical interactions of the rubber stock components, governing eventually the properties of the rubbers. Polar functional groups (carboxy, chloride) introduced into the polymer chains should affect the nature of such an interaction.

The nature of the interaction of the polymeric chains of the elastomer with carbon black (filler) is very important in rubber reinforcement. This interaction is due to the formation of both physical and chemical bonds whose number and ratio may vary with the properties of the interacting components. Modification of polymers affects their interaction with carbon black.

Presumably, interaction of the functional groups of the polymer with active centers on the surface of the filler particles improves their wetting with the polymer and facilitates penetration of the polymer chain segments into the space between aggregates of carbon black. All this accelerates the disintegration of such aggregates during mixing and improves the dispersion of the primary particles of carbon black within the polymer matrix [9]. Evidently, with this type of dispersion of carbon black, new active centers appear on its particles, capable of further interaction with

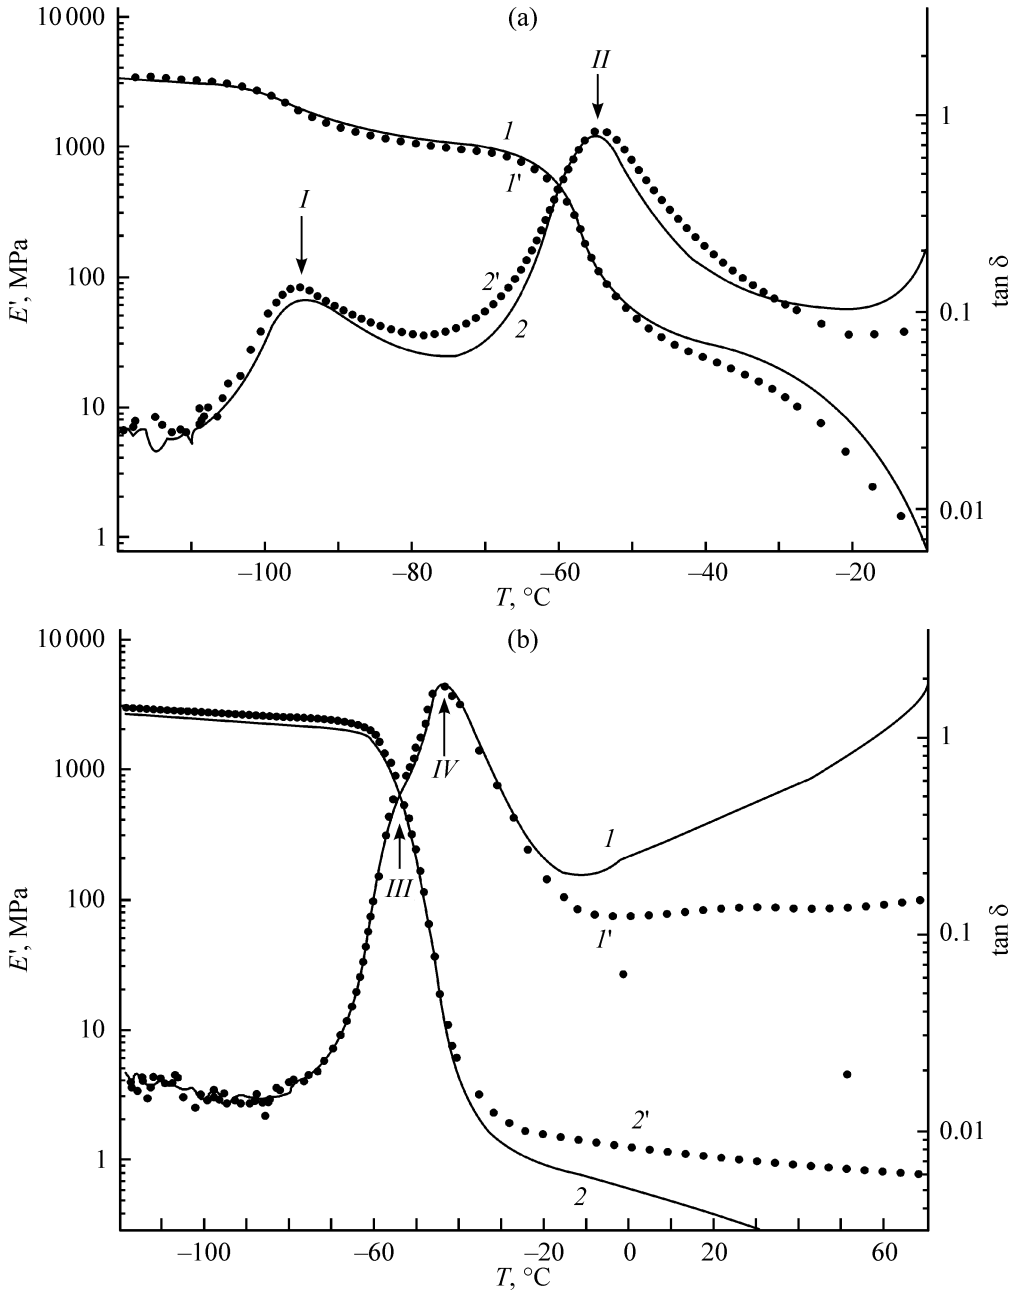

Fig. 1. Temperature dependences of the dynamic modulus of elasticity, E', and the mechanical loss tangent $\tan\delta$ of (a) SKD/SKI and (b) SKS/SKI unfilled formulations and (c) SKD/SKI and (d) SKS/SKI formulations filled with carbon black no. 330. ν = 1 Hz. Formulation: (*1*, *2*) unfilled and (*1*', *2*') modified with TCAA. Glass transition point, °C: (*1*) –94, SKD; (*II*, *III*) –54, SKI: and (*IV*) –44, SKS.

the polymer chains. All this favors a more uniform distribution of carbon black within the polymer matrix, as evidenced by an optical microscopic analysis. The enhancement of the interphase interaction in the systems based on modified rubbers plays the key role in improvement of such important characteristics as elastic properties of rubber stocks and elastic-relaxation properties of vulcanizates.

The results of the dynamic studies of the formulations obtained are presented in Fig. 1.

The dynamic studies of the vulcanizates of the binary blends of rubbers at temperatures of –120 to 70°C revealed two glass transition points T_g [T_g(SKD) = –94 and T_g(SKI) = –54°C for SKD/SKI system; T_g(SKS) = –44 and T_g(SKI) = –54°C for SKS/SKI

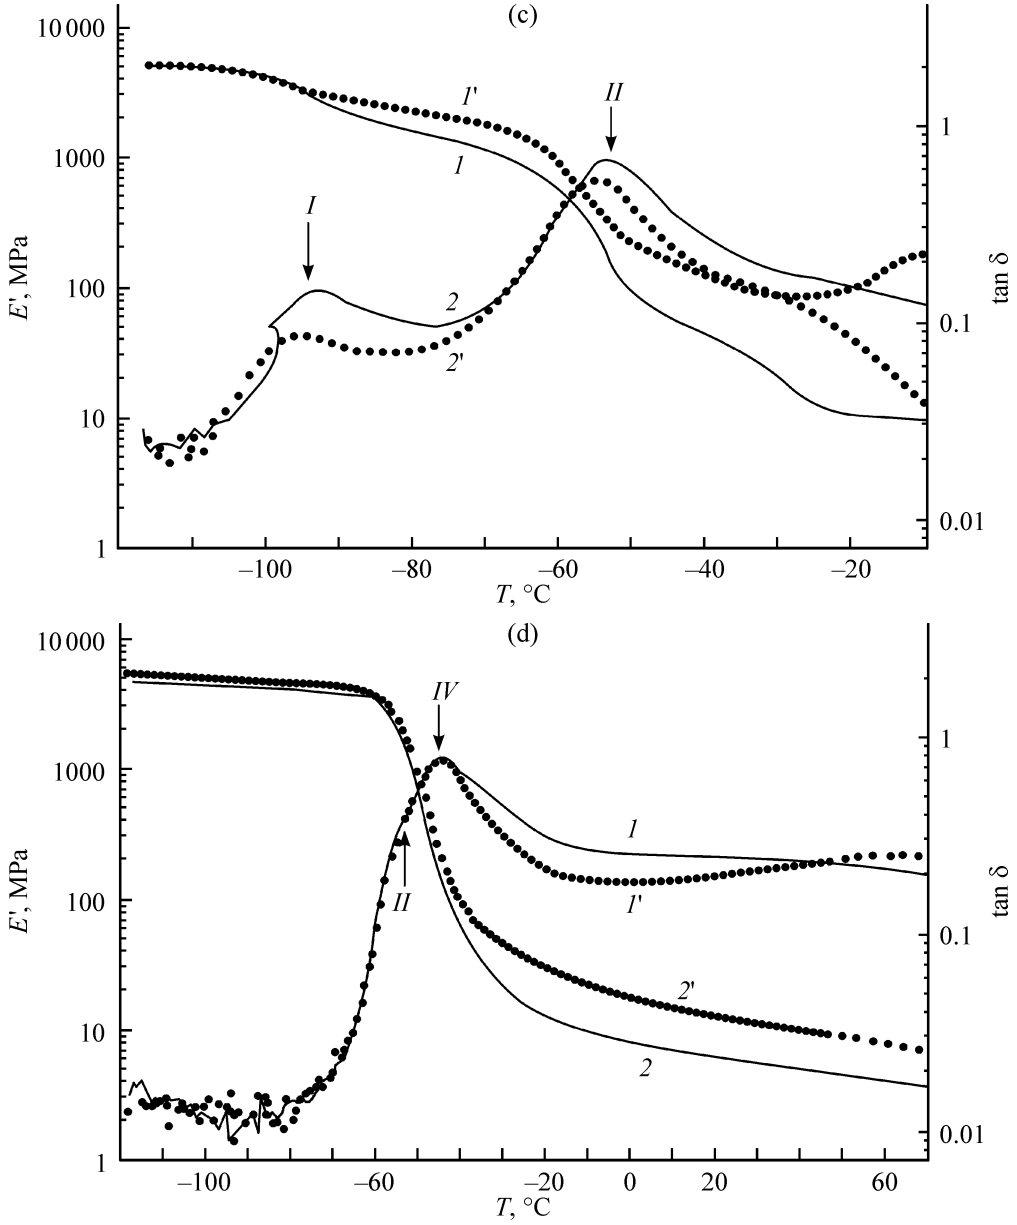

Fig. 1. (Contd.)

system] corresponding to each specific polymer; this means that these are two-phase systems. The temperature dependence of the modulus of elasticity, E', of the formulations exhibited a two-step pattern, and the curve describing the variation of the mechanical loss tangent tan δ had two peaks. For the SKS/SKI system, the glass transition points are close for both polymers, which is responsible for overlapping and broadening of the mechanical loss curve near the peak.

We have shown earlier [7] that the introduction of the filler, carbon black no. 330, does not affect the glass transition point of the polymers under study. Hence, the mobility of the chain segments is independent of the presence of filler particles; otherwise, T_g whould shift owing to changes in the macromolecular mobility. This suggests that the forces responsible for improvement of the mechanical properties of rubbers containing an active filler are of predominantly physical nature, and, evidently, chemical bonds are of minor significance.

Figures 1a and 1b show the temperature dependences of E' and tan δ for SKD/SKI and SKD/SKI/TCAA (SKS/SKI, SKS/SKI/TCAA) systems.

Figure 1a shows that introduction of TCAA into an unfilled SKD/SKI formulation only weakly affects

the modulus of elasticity, E' (1 MPa), but causes tan δ to decrease from 0.2 to 0.08 at $T = -10°C$. Figure 1b shows that, upon introduction of TCAA into the unfilled SKS/SKI formulation, E' increases from 0 to 1 MPa, and tan δ decreases by an order of magnitude, from 1.8 to 0.15 at $T = 30°C$. Figures 1a and 1b show that introduction of TCAA increases the modulus of elasticity of the system and decreases the mechanical loss tangent. The parameters E' and tan δ preserve improved values over a wide temperature range from –10 to 70°C, which extends the temperature range of applicability of the formulations.

Figures 1c and 1d show the temperature dependences of E' and tan δ for SKD/SKI/carbon black, SKD/SKI/carbon black/TCAA, SKS/SKI/carbon black, and SKS/SKI/carbon black/TCAA formulations. They suggest that combined introduction of TCAA and filler into the formulations based on binary rubber blends increases to the greatest extent the characteristics of the systems: E' increases from 1 and 4 to 10 MPa for SKS formulations and from 1 and 11 to 16 MPa for SKD formulations.

It is seen that the introduction of the modifier results in a shift of the glass transition point of the polymers by 2–3°C. This suggests that, in the structure of the vulcanization network, there are not only physical (owing to the filler) but also chemical [owing to the functional groups (carboxy, chloride) of the modifier] bonds.

We showed that combined introduction of the filler and modifier into formulations based on binary blends of rubbers significantly increases the modulus of elasticity and decreases by an order of magnitude the mechanical loss tangent. This is, evidently, due to an enhanced degree of crystallinity or a higher degree of cross-linking of the resulting vulcanizates.

The influence of the functional groups on the structure of vulcanizates can be analyzed from the viewpoint of the change in the degree of cross-linking and the type of the bonds being formed. In this context, of special interest is the possibility of formation of specific labile bonds via interaction of the functional groups of the elastomer with the vulcanizing agents. As is known [9], carboxy groups reacting with metal oxides or hydroxides form a network of labile, the so-called salt bonds. These are associates of charged particles, characterized by a relatively low energy, compared to disulfide bonds. The ability of these bonds to undergo rearrangement makes possible dissipation of overstresses arising in such systems, both during formation of the vulcanization network and during deformation of the final vulcanizates. The dissipation of overstresses is responsible for the increased resistance of rubbers to aging, tear, and multiple deformations.

CONSLUSIONS

(1) Introduction of carboxy groups and chlorine atoms into elastomers favors directed complex improvement of the properties of rubbers by changing the structure of the vulcanization networks, i.e., via creation of a combination of strong valence and labile bonds.

(2) Preparation of formulations with an improved set of properties extends the applicability field of the resulting materials in various branches of industry such as tire, cable, and industrial rubber articles.

ACKNOWLEDGMENT

The author is grateful to H.-J. Radusch (Institute of Materials Science, Martin-Luther University, Halle-Wittenberg, Germany) for assistance in preparation of formulations from binary blends of diene rubbers and in investigation of their properties.

Received March 2, 2005

Abstract—The possibility of chemical modification of peat humic acids in order to increase their bioactivity by reduction with tin(II) chloride and sodium borohydride and also by carboxylation using the Kolbe method was analyzed.

It was demonstrated in [1–3] and our previous studies [4–6] that the bioactivity of humic acids (HA) is due to the presence of phenolic (PG) and carboxy (CG) groups, whereas the keto (KG) and quinoid (QG) groups have virtually no effect on this property of HA.

Therefore, it was of interest to modify the HA structure by converting some functional groups into groups responsible for bioactivity (BA). In this case, it is undesirable to use such destructive methods as oxidation with nitric acid or peroxide, etc., since oxidative degradation leads to a considerable decrease in the molecular weight of HA.

EXPERIMENTAL

In the study, we used humic acids extracted from peat obtained from Tver oblast (Russia). These humic acids are high-molecular-weight polyfunctional compounds (aromaticity 0.69, naphthenic index 0.10, and degree of alkylation 0.21). Their elemental composition (wt % daf) was as follows: C 59.11, H 5.09, N 3.01, O + S 32.79.

Reduction of HA with tin(II) chloride was carried out in alkaline solutions in air or in a CO_2 atmosphere, to reduce HA more deeply (Tables 1–3).

A study of the process at 20°C, HA : $SnCl_2$ = 2 : 1, and a reaction time of 2 to 6 h (Table 1) revealed that, in air, quinoid groups are reduced into phenolic groups, whose content increased from 3.86 to 5.12 mg-equiv g^{-1} in 6 h. Simultaneously, the QG content decreased from 2.34 to 1.48 mg-equiv g^{-1}. Under these conditions, the carboxy groups were virtually not reduced. The content of keto groups decreased significantly (from 0.28 to 0.07 mg-equiv g^{-1}). Apparently, these groups were converted into the alcoholic groups (AG). The iodine number (IN) changed from 0.27 to 0.20 mg-equiv g^{-1}. The molecular weight decreased in the course of reaction from 1400 to 1210, the decrease being virtually independent of the reaction time.

The bioactivity of humic preparations was determined by the standard fermentation test based on the capability of biostimulants to increase the fermenting capacity of yeast. The bioactivity is expressed in fraction units relative to the bioactivity of distilled water. The bioactivity tests with the initial humic acid and reduced humic preparations were positive: for humic preparations, BA increased by 14%.

As expected, performing the reduction under the same conditions, but in the CO_2 atmosphere, increased not only the efficiency of reduction of QG, but also increased the content of carboxy groups. For example, in 4 h, the PG content increased to 5.52 mg-equiv g^{-1} (against 4.90 mg-equiv g^{-1} in air). In turn, the QG content decreased to 1.06 (1.62 mg-equiv g^{-1} in air), and the CG content increased from 2.73 in the initial HA to 3.42 mg-equiv g^{-1} in the resulting humic preparation. Accordingly, the bioactivity factor also increased after reduction of HA under CO_2. The unexpected increase in the CG content under the reducing conditions can be attributed to a parallel occurrence of the Kolbe reaction involving the phenolic fragments of the HA molecule, since, as known, this reaction occurs more readily in alkaline solutions. It should also be noted that, under CO_2, two practically important reaction proceed in parallel: reduction and carboxylation with virtually no change in the molecular weight of HA. Evidently, atmospheric oxygen promotes oxidative degradation of HA.

The effect of temperature on the reduction of HA is shown in Table 2. The experiments were carried

Table 4. Contents of functional groups *c* and bioactivity of humic preparations in the course of carboxylation of humic acids

Parameter	Initial HA	HP	
		$HA + SnCl_2$ (20°C, 2 h, 2 : 1)	$HA + NaBH_4$ (25°C, 1 h, 10 : 1)

** BA was measured in 1×10^{-3} wt % HP.

out under similar conditions at 20, 40, and 60°C in air and CO_2 atmosphere. The general trends in the reduction and carboxylation of HA remained unchanged. As expected, the reduction rate increased with temperature. At the same time, because of the low heat resistance of HA, its molecular weight decreased to 1090 and 1140 at 60°C in air and under CO_2, respectively. Therefore, it is advisable to perform the reduction at 20–40°C under CO_2. The effect of the HA : $SnCl_2$ ratio is shown in Table 3. It was varied over a wide range from 10 : 1 to 1 : 1. The increase in the reductant concentration only slightly affected the functional composition of HA. Therefore, the 10 : 1 ratio can be recommended for the process.

Reduction of HA with sodium borohydride ($NaBH_4$). The reaction was performed in an alkaline solution at 25°C to prevent decomposition of the reagent (Tables 1 and 3).

When studying the effect of the reaction time, the reduction was carried out at HA : $NaBH_4$ = 10 : 1 for 1, 2, and 3 h. Table 1 shows that, like $SnCl_2$, $NaBH_4$ reduces QG into PG, and KG into AG, the CG content remaining unchanged.

A comparison of the two reducing agents studied revealed a higher efficiency of $NaBH_4$ under similar conditions (Tables 1 and 3). For example, the PG content increased upon reduction with $SnCl_2$ and $NaBH_4$ from 3.86 to 4.22 and 4.86 mg-equiv g^{-1}, respectively, with the QG content coming to equal to 0.55 and 1.00 mg-equiv g^{-1}, and the KG content, to 0.08 and 0.24 mg-equiv g^{-1}. Note that, with $NaBH_4$, the reduction in air had a smaller effect on the molecular weight of HA. In this case, it decreased by 4.5% against 7% with $SnCl_2$, which is probably due to evolution of hydrogen in the borohydride reduction. Indeed, data on IN revealed a partial hydrogenation of the multiple bonds.

Data on the effect of the reaction time on the reduction efficiency (Table 1) suggest that 1 h is a time sufficient for obtaining a satisfactory result.

Further, we studied the effect of the HA : $NaBH_4$ weight ratio, varied from 10 : 1 to 2 : 1, on the reduction efficiency (Table 3). The PG content and the degree of QG and KG reduction were at a maximum at HA : $NaBH_4$ = 3 : 1. In this case, the keto groups were fully reduced. In parallel, we carried out experiments in a CO_2 atmosphere (Table 3). As expected, the CG content increased under these conditions in parallel to that of PG (by 28–37%). The 3 : 1 proportion also provided the maximum bioactivity, which increased by 27%.

Carboxylation of HA by the Kolbe reaction. Positive results obtained in the reduction under CO_2 stimulated further experiments on carboxylation as a method for chemical modification of HA aimed at improving their bioactivity. This process was applied to the initial HA and also to the humic preparations obtained by reduction with $NaBH_4$ and $SnCl_2$ (Table 4). As a result, the CG content increased from 2.73 mg-equiv g^{-1} in the initial HA to 3.70–4.12 mg-equiv g^{-1}, the best result being obtained after the borohydride reduction. Comparison of these results with those obtained by the reduction under CO_2 (Table 1) shows that the carboxylation is a more efficient process. For example, the reduction with $SnCl_2$ and $NaBH_4$ under CO_2 increased the CG content to 3.35 and 3.50 mg-equiv g^{-1}, and the carboxylation of the reduced humic preparations, to 3.85 and 4.12 mg-equiv g^{-1}, respectively. Note that the carboxylation had virtually no effect on the molecular weight of the products, which can be attributed to intensive decomposition of potassium hydrocarbonate in the course of the reaction and also to the anaerobic conditions.

CONCLUSIONS

(1) Nondestructive reduction of peat humic acids with $SnCl_2$ and $NaBH_4$ increases (by 26–33%) the content of phenolic groups, influencing the bioactivity, without degradation of humic acid molecules. The best results were obtained with $NaBH_4$.

(2) Treatment of humic acids with $SnCl_2$ and $NaBH_4$ in a CO_2 atmosphere allows two practically important processes to be performed simultaneously: reduction and carboxylation without significant change in the molecular weight of the initial humic acids. In this case, the carboxy group content increased by 40%.

(3) Bioactivity of humic preparations obtained by reduction of humic acids with $NaBH_4$ under CO_2 at a humic acid to $NaBH_4$ weight ratio of 3 : 1 (25°C; 1 h) increased by 27%.

Abstract—The substances extracted from peats were studied by IR spectroscopy and gas chromatography–mass spectrometry.

Peat is the product of partial degradation of bog plants. The properties of peat formed in different regions of Russia are diverse because of different peat-forming plants and widely varying conditions of peat accumulation. Peat contains both relatively simple and macromolecular organic compounds typical of plants, and these compounds may be useful for the national economy [1].

Peat contains a large amount of biologically active substances [2, 3] of the humus origin and of other classes. It is of scientific and practical interest to study organic compounds extractable from peat with organic solvents. The chemical composition and properties of extracts depend on the kinds of the peat and extractant. Extraction of peats, especially of those from Belarus, with various solvents has been studied previously [4, 5]. An ethanol extract from peat wax resin, exhibiting high antiphlogistic and antiviral activity, is used in medicine and cosmetology. Torfenal antiallergic agent, which is a component of ointments, lotions, and detergents, is commercially produced from these extracts [3].

The composition of extracts from Siberian peats has been poorly studied. In this study, we examined the extracts from some peats of the Tomsk oblast.

EXPERIMENTAL

Peats chosen for the study had different bedding depths and different degrees of degradation *R*. We took lowland peat from the Taganskoe deposit ($R \sim 30\%$), raised-bog peat from the Temnoe deposit ($R \sim 0$–5%), raised-bog peat from the Svetloe deposit ($R \sim 0$–5%), and mechanically activated raised-bog peat from the Svetloe deposit. The mechanical activation was performed with a vibrocentifugal mill. This treatment induces changes in the porous supramolecular structure, physical state, and properties of peats and enhances the efficiency of extraction with organic solvents [6, 7].

The extraction of peats was performed in a Soxhlet apparatus heated on a water bath (about 15 h). The elemental composition of peats and extracted substances was determined on a Carlo Erba Model 1106 CHN analyzer; the ash residue was determined gravimetrically. For the extracts, we determined the acid, iodine, carbonyl, and saponification numbers [8–11] and the content of triterpenic acids [12, 13]. The IR spectra were recorded on a Bruker Vector-22 IR Fourier spectrometer from thin films or KBr pellets in the range >400 cm^{-1}.

IR spectroscopy alone does not allow exhaustive determination of the structure of a compound; furthermore, we analyzed mixtures rather than individual compounds. Therefore, we used the IR spectra to search for structural fragments that could be present in the samples and to identify some compounds whose spectra taken from the database closely matched the experimental spectra of the samples.

The search for structural fragments in the database was performed in two modes: with Euclidean metrics (point-by-point comparison of spectral curves) and with IR descriptors (comparison of the positions and intensities of absorption bands). An analysis using the IK Ekspert (IR Expert) system [14] allowed us to find structures of the most probable fragments. The fragments were chosen on the basis of statistical

evaluation of the so-called noncontingency factors of appearance of a fragment in search response structures. When calculating the noncontingency factors, we took into account the incidence of fragments in the search response structures and in database structures [15].

A GC–MS analysis was performed with a Hewlett–Packard 5890/II gas chromatograph (the United States) interfaced with an HP MSD 5971 quadrupole mass spectrometer. A 30-m quartz column was coated with polyphenylmethylsiloxane (HP-5MS, 5% phenyl groups); the carrier gas was He, flow rate 1 ml min^{-1}. The column temperature was programmed as follows: 50°C, 2 min; heating to 280°C, 4 deg min^{-1}; 280°C, 15 min. The molecules were ionized by electron impact (70 eV).

The extracted substances were separated into neutral and acid fractions; the acid fraction was methylated by standard procedures [16]. To choose an extractant, we extracted raised-bog and lowland peat samples with solvents of various polarities. The results of sequential extraction of peats with solvents, from low-polarity hexane to strongly polar methanol, are listed in Table 1, together with the total yield of the extracted substances.

We also tested as extractant methyl *tert*-butyl ether (MTBE), which appeared to be more efficient and more readily available than certain nonpolar solvents (hexane, petroleum ether) and was not inferior to some polar solvents like chloroform (extract yield about 4 wt %). Therefore, further extraction experiments were performed with MTBE.

The elemental composition of the peats and the elemental composition and characteristics of the extracted substances (averaged over 3–5 measurements) are listed in Tables 2 and 3. Sulfur was detected neither in peats nor in their extracts.

Table 3 shows that the substances extracted from different peats are similar in the content of free acids

Table 2. Results of C, H, N analysis of peats and extracts

and esters, but differ in the content of unsaturated compounds (iodine number from 30 to 44 g I_2 per 100 g substance). For the mechanically activated peat, all the parameters are somewhat higher.

The peat extracts were separated into the neutral and acid fractions. The yield of the neutral fraction of nonactivated peats was 45–50% of the total amount of the extracted substances. In the extract from the mechanically activated peat, the content of the neutral fraction was 35.1%, and that of the acid fraction, 64.8%. Apparently, the mechanical activation results in partial oxidation of the peat dust by atmospheric oxygen [7].

The IR spectra of the substances extracted from the peat samples examined show that extracts are similar in the chemical composition and structure of the components. The major components of virtually all the extracts (total, neutral fraction, and acid fraction) are aliphatic carboxylic acid esters R^1COOOR^2, where R^1 and R^2 are long aliphatic chains containing a double bond, and products of their hydrolysis, free carboxylic acids R–COOH.

It should be noted that the keto group R^1COR^2, and not carboxy group, is often detected as a non-occasional fragment, i.e., ketones with long aliphatic chains (possibly branched) may be present in the samples.

The structures of components of the neutral and acid fraction, including the methylated acid fraction, were determined by GC–MS. The major components of the extracts, according to the GC–MS data (the content was calculated from the peak areas without correction factors), are listed in Table 4.

The percentages given in Table 4 for certain components are estimates; however, these estimates give a qualitative pattern of the extract composition. The identified complex polycyclic structures, e.g., vitamin E, friedelin, and other steroid compounds, may have isomers with simlar mass spectra; therefore, conclusions about the presence of specific compounds were made only if a closely similar mass spectrum was found in the database.

CONCLUSIONS

(1) An IR and GC–MS study of the substances extracted from peats showed that the extracts are closely similar in the qualitative and quantitative composition. The extracts contain a large set of alkanes, aromatic compounds, esters, polyhydric alcohols, aliphatic fatty acids (including keto acids), and steroid compounds (including γ- and β-sitosterols).

(2) In the extract from the mechanically activated peat, the content of the acid fraction is appreciably higher, compared to the extract from the nonactivated peat, apparently because of the partial oxidation of aldehydes and ketons in the course of peat milling.

(3) Friedelin, phytol, triterpene acids, steroid compounds (including γ- and β-sitosterols), and the compound identical to vitamin E, identified in peat ex-

tracts, may be of interest as raw materials for preparing biologically active substances.

ACKNOWLEDGMENTS

The study was supported by the Siberian Division of the Russian Academy of Sciences (integration project no. 35) and, in part, by the Russian Foundation for Basic Research (project no. 04-03-32374).

Complexation of Lead(II) Ions with Hydroxide Ions in Nitrate-Chloride Solutions

V. P. Yurkinskii, E. G. Firsova, and N. V. Petrova

St. Petersburg State Polytechnical University, St. Petersburg, Russia

Received April 19, 2005

Abstract—Complexation of lead(II) ions with hydroxide ions in nitrate-chloride solutions at 298 K was studied using potentiometric titration.

The search for the optimal composition of the alkaline electrolyte is an important technological task in processing of scrap lead accumulators with an active paste containing lead(II) oxide [1].

The high solubility of PbO in alkaline solutions is known to be due to formation of strong lead(II) hydroxide complexes [2, 3]. The presence of both organic and inorganic admixtures and, in particular, chlorides in alkaline solutions strongly affects the complexation of lead(II) ions [1–5]. For example, it was found in [4] that mixed lead(II) hydroxidechloride complexes are formed at low alkali concentrations (<0.4 M) in a solution containing a mixture of sodium chloride and hydroxide.

Proceeding with the studies [4, 5], we examined the complexation of Pb(II) in mixed nitrate-chloride solutions containing sodium hydroxide as an additive in order to analyze the effect of the concentration of chloride ions on the formation of lead hydroxide complexes and, if possible, to determine the composition of mixed chloride-hydroxide complexes.

EXPERIMENTAL

The complexation of lead(II) ions was studied by potentiometric titration at 298 K. The experimental technique and the electrochemical cell have been described earlier [4, 5].

We used as a supporting electrolyte aqueous solutions containing a mixture of sodium nitrate (0.3–1.0 M) and sodium chloride (0–0.7 M) with concentrations that allowed us to obtain a solution with an ionic strength equal to unity (in the limiting case, no sodium chloride was present, and the nitrate concentration was 1.0 M).

The potentiometric titration was carried out with a sodium hydroxide solution containing sodium chloride, the concentrations of NaOH and NaCl being equal to the concentrations of $NaNO_3$ and NaCl, respectively, in the supporting electrolyte. This allowed us to maintain a constant ionic strength in a solution under study during all the experiments.

The half-cell of the electrochemical cell under study can be represented as:

$$-\mathrm{Pb(Hg)}\,|\,\mathrm{Pb(NO_3)_2},\ \mathrm{NaNO_3},\ \mathrm{NaOH},\ \mathrm{NaCl}, \qquad (1)$$

where Pb(Hg) is a lead amalgam electrode.

A typical dependence of the potential of the amalgam electrode on the logarithm of the alkali concentration in solutions containing sodium chloride is shown in Fig. 1. It can be seen that the E–$\ln c_{OH^-}$

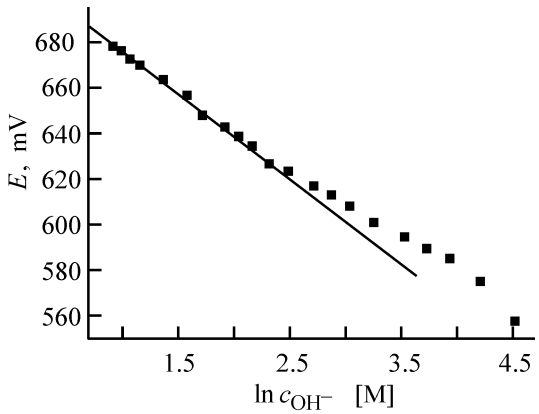

Fig. 1. Potential of the indicator electrode, E, vs. the logarithm of the total concentration of hydroxide ions $\ln c_{OH^-}$ in solution. Supporting electrolyte (M): 0.7 $NaNO_3$ + 0.3NaC1 + $1 \times 10^{-3}Pb(NO_3)_2$. ($c_{OH^-}$) Total concentration of hydroxide ions.

1070-4272/05/7808-1370 © 2005 Pleiades Publishing, Inc.

dependence deviates from linearity at low NaOH concentrations (0.05–0.25 M). The run of the curve is virtually independent of the sodium chloride content (0.1–0.7 M) in the solution. The range of NaOH concentrations at which the E–$\ln c_{OH^-}$ dependence is linear is shifted to higher concentrations of hydroxide ions as the concentration of chloride ions increases. In a solution containing only sodium chloride, a linear dependence is observed at NaOH concentrations $c \geq 0.4$ M [4].

It was found that such a run of the dependence under study can be accounted for by the low solubility of lead hydroxide in these solutions. At low sodium hydroxide concentrations, a $Pb(OH)_2$ precipitate appeared in solution. Its solubility in the aqueous solution is 1×10^{-4} wt % at 298 K [6] and, obviously, decreases when sodium chloride is added to the solution. The appearance of a lead hydroxide precipitate in the solution changes the concentration of potential-determining Pb(II) ions and leads to deviation of the E–$\ln c_{OH^-}$ curves from linearity. However, the solubility of $Pb(OH)_2$ increases with the concentration of NaOH and the E–$\ln c_{OH^-}$ dependence becomes linear.

It was noted in [3, 4] that mixed lead(II) chloride-hydroxide complexes can exist at low NaOH concentrations. Unfortunately, the presence of a $Pb(OH)_2$ precipitate in solution gave no way of determining their composition in the present study.

Lead(II) hydroxide complexes are formed at alkali concentrations for which the E–$\ln c_{OH^-}$ dependence is linear [4]. We determined the number n of ligands, OH^- ions, involved in Pb(II) complexation from the slope of the linear portion. The average number $\bar{n}$ is 2.96 ± 0.03. Therefore, lead(II) hydroxide complexes with coordination numbers 2 and 3 are present in a solution with a sodium hydroxide concentration $c >$ 0.05–0.4 M (depending on the concentration of sodium chloride), with the coordination number 3 predominating. Data for nitrate-chloride solutions, obtained in this study, are in a satisfactory agreement with the results of the earlier studies of individual nitrate and chloride solutions [4].

Thus, the joint presence of competitive ligands (hydroxide and chloride ions) in solution does not affect noticeably the composition of the forming lead(II) hydroxide complexes.

The stability constants of lead(II) hydroxide complexes, β_2 and β_3, were calculated using our experimental data (Fig. 1) and a standard software package by Eq. (2) [7, 8].

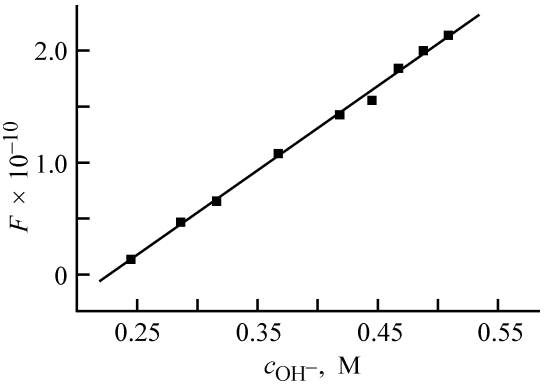

Fig. 2. Function $F = (\Phi - 1)/[OH^-]^2$ vs. the concentration of free hydroxide ions c_{OH^-}. Supporting electrolyte (M): $0.5NaNO_3 + 0.5NaCl + 1 \times 10^{-3}Pb(NO_3)_2$.

$$\Delta E = \frac{RT}{zF} \ln \frac{c^0_{Pb^{2+}}}{[Pb^{2+}]} = \frac{RT}{zF} \ln \Phi. \quad (2)$$

Here ΔE is the difference of the potentials of the amalgam electrode in the supporting electrolyte and in solutions with addition of a solution containing hydroxide ions; $c^0_{Pb^{2+}}$, total concentration of lead ions in solution (M); $[Pb^{2+}]$, concentration of free lead ions (M); Φ, function describing the degree of complexation of lead ions; and β_1, β_2, and β_3, stability constants of lead(II) hydroxide complexes containing one, two, or three hydroxide groups, respectively.

$$\Phi = 1 + \beta_1[OH^-] + \beta_2[OH^-]^2 + \beta_3[OH^-]^3. \quad (3)$$

We found that the constant β_1 in the system under consideration is virtually zero, in agreement with the data of [2–4].

Using the data of Fig. 1 and Eq. (2), we calculated values of the function Φ and analyzed the dependence of the type

$$(\Phi - 1)/[OH^-]^2 = f[OH^-]. \quad (4)$$

We determined constants β_2 and β_3 from this dependence (Fig. 2) with account of Eq. (3). The values of β_2 appeared to be one-and-a-half to two orders of magnitude lower than those of β_3. Introduction of sodium chloride into the solution leads to a noticeable decrease in the degree of complexation of lead(II) ions and, hence, in the values of the stability constants β_2 and β_3 of hydroxide complexes. The dependence of β_3 on the content of sodium chloride in solution

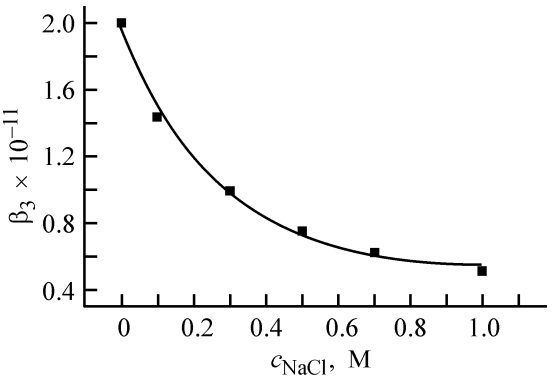

Fig. 3. Stability constant β_3 of a lead(II) hydroxide complex vs. the concentration c_{NaCl} of sodium chloride in solution.

is shown in Fig. 3. It can be seen that this constant noticeably decreases as the concentration of sodium chloride in solution grows. A similar dependence is also observed for the constant β_2. The results of the present study are in a reasonable agreement with the data [4] for individual sodium nitrate and chloride solutions.

CONCLUSIONS

(1) It was shown that a mixture of lead(II) hydroxide complexes, with a strong predominance of $Pb(OH)_3^-$ complexes, is formed in mixed nitrate-chloride solutions with addition of sodium hydroxide at NaOH concentration exceeding 0.05–0.4 M (depending on the content of sodium chloride in these solutions).

(2) It was found that the degree of complexation of lead(II) ions and, hence, the stability constants β_2 and β_3 steadily decrease as the concentration of sodium chloride in solution grows.

Abstract—Solubility and stability of peroxosolvates of sodium phosphates in polyatomic alcohols (glycerol and ethylene glycol) and in water–alcohol mixtures, as well as their applicability in development of disinfectants, were studied.

Salts of inorganic acids solvated by hydrogen peroxide show bactericidal activity. A series of disinfectants with a wide-range antimicrobial action have been created on the basis of potassium fluoride peroxosolvates $KF \cdot nH_2O_2$, n = 1, 1.5 [1, 2]. Use of viscous organic liquids, in addition to water, to produce such chemicals expands the opportunities for their application in disinfection. In a slow evaporation of the solvent, a viscous organic medium creates a reserve of hydrogen peroxide, from which it gradually diffuses to a surface being treated. This leads to a prolonged contact of the disinfectant with the object under treatment and improves the disinfection efficiency. It was found in [3] that KF peroxosolvates and disinfectants created on their basis are rather well soluble and stable in polyatomic alcohols (glycerol and ethylene glycol), and also in water–alcohol mixtures.

In this study, we examined the solubility and stability of peroxosolvates of sodium phosphates in the above-mentioned solvents. According to the data of [1], peroxosolvates of phosphates surpass peroxosolvates of potassium fluoride in bactericidal activity.

EXPERIMENTAL

Peroxosolvates of sodium diphosphate and hydrophosphate were synthesized by the reactions of their hydrates (of chemically pure grade) with hydrogen peroxide solutions of a concentration 47 wt %. Water and the excess of H_2O_2 were removed with a flow of air heated to 40–50°C over a solution placed in a polymeric pan. The content of H_2O_2 in the products obtained and in the saturated solutions prepared was determined by permanganatometric titration:

Found, %: H_2O_2 27.7.
$Na_4P_2O_7 \cdot 3H_2O_2$.
Calculated, %: H_2O_2 27.73.

Found, %: H_2O_2 32.3.
$Na_2HPO_4 \cdot 2H_2O_2$.
Calculated, %: H_2O_2 32.40.

Found, %: H_2O_2 19.0.
$Na_2HPO_4 \cdot H_2O_2$.
Calculated, %: H_2O_2 19.32.

It was found in the course of synthesis that sodium hydrophosphate yields, upon a prolonged drying, a stable monoperoxosolvate in addition to the previously obtained diperoxosolvate [4].

Solvents of chemically pure grade, glycerol and ethylene glycol, were used without additional purification and dehydration. Saturated solutions were pre-

70	5.97	51	0.49 ± 0.16*	2.4 ± 0.9

* Solutions do not lose H_2O_2 in the first 20–30 days; the figures above refer to subsequent storage.

Table 2. Solubility and stability of $Na_2HPO_4 \cdot H_2O_2$ in polyatomic alcohols (glycerol and ethylene glycol) and in mixed alcohol–water solvents

Alcohol content, wt %	Solubility, wt % of H_2O_2	Storage time, days	Loss of H_2O_2, % day^{-1}	$k \times 10^4$, day^{-1}
Glycerol–water				
100	2.02	20	3.69 ± 1.38	2.1 ± 0.6
90	2.13	24	1.30 ± 0.47	0.6 ± 0.1
80	3.28	24	2.54 ± 0.63	1.2 ± 0.2
70	4.77	26	3.09 ± 0.58	1.7 ± 0.1
Ethylene glycol–water				
100	1.19	24	2.33 ± 0.29	1.2 ± 0.2
90	1.72	48	1.10 ± 0.34	0.4 ± 0.2
80	3.17	48	2.24 ± 0.34	1.4 ± 0.1
70	4.64	48	1.09 ± 0.12	0.5 ± 0.0

pared as described in [3] at 20°C and kept in closed polymeric reservoirs. The solutions were analyzed at intervals of 3–5 days. The decomposition rate constants were calculated by the equation $c_0/c = k(\tau - \tau_0)$.

The solubility of peroxosolvates of the sodium phosphates under study in glycerol and water–glycerol mixtures, as well as in ethylene glycol and its mixtures with water, is much lower than that of KF peroxosolvates in the same media. A saturated solution of $KF \cdot H_2O_2$ in a solvent composed of 85 wt % glycerol and 15 wt % water contains 9.06 wt % H_2O_2, whereas the content of H_2O_2 in a saturated solution of $Na_4P_2O_7 \cdot 3H_2O_2$ in a solvent composed of 90 wt % glycerol and 10 wt % water is 3.26 wt % (Table 1). A saturated solution of $Na_2HPO_4 \cdot H_2O_2$ in the same solvent (Table 2) contains 2.13 wt % H_2O_2. As the content of water in a solvent increases, the solubility of peroxosolvates of phosphates grows, as it occurs in all the previously studied systems.

The solutions are sufficiently stable. In the system $Na_4P_2O_7 \cdot 3H_2O_2$, the average loss of H_2O_2 in 30–60 days is 0.5–2.1 % day^{-1} relative to its initial content (Table 1).

In the systems constituted by $Na_4P_2O_7 \cdot 3H_2O_2$, ethylene glycol, and water, no loss of H_2O_2 is observed within the first 20–30 days. Then, a slow H_2O_2 decomposition (0.1–0.5) begins. The stability of $Na_2HPO_4 \cdot H_2O_2$ in the systems constituted by an alcohol and water is noticeably lower, and the loss of H_2O_2 is 1.3–3.7 and 1.1–2.4 % day^{-1} for glycerol and ethylene glycol, respectively.

Diperoxosolvate $Na_2HPO_4 \cdot 2H_2O_2$ is unstable in glycerol and in water–glycerol mixtures. The content of H_2O_2 decreases to almost zero already during preparation of saturated solutions. Hydrogen peroxide completely decomposes within 2–3 days in dissolution of $Na_2HPO_4 \cdot H_2O_2$ in ethylene glycol–water mixtures initially containing 1–2 wt % H_2O_2.

Water–alcohol solutions of $Na_4P_2O_7 \cdot 3H_2O_2$ seem to be promising for application in disinfection. Solutions of this kind can be used both under normal conditions and at low temperatures.

CONCLUSION

The solubility of peroxosolvates of sodium phosphates in polyatomic alcohols (glycerol and ethylene glycol) at 20°C is 2.16 wt % H_2O_2 for $Na_4P_2O_7 \cdot 3H_2O_2$ and 3.05 wt % for $Na_2HPO_4 \cdot H_2O_2$. The solubility of the solvates in water–alcohol systems increases, to become a factor of 2–4 higher for solvents with a water content of 30 wt %. The solutions are stable. The average rate of decomposition of sodium peroxosolvate diphosphate in a water–glycerol mixture is 0.3–2.1 % day^{-1}, whereas solutions in water–ethylene glycol solvents are completely stable within 20–30 days, after which the decomposition rate is 0.1–0.5 % day^{-1}. For monoperoxosolvate of sodium hydrophosphate, these values are 1.3–3.4 and 1.0–2.4 % day^{-1}, respectively.

BRIEF COMMUNICATIONS

Use of Polymeric Coatings for Conservation of Archival and Historically Valuable Documentary Photographs

E. S. Gaikalova and A. N. D'yakonov

St. Petersburg State University of Cinematography and Television, St. Petersburg, Russia

Received December 9, 2004; in final form, June 2005

Abstract—The possibility of conservation of archival and historically valuable documentary photographs with polymeric coatings was substantiated. Coatings obtained from aqueous dispersions of polymers were considered. A dependence of the shelf life of the material on the coating thickness was established.

Conservation of documentary photographs is an important task of state archives. The main goal of a set of procedures for preservation of documents in storage is to slow down the process of aging and protect documents from the action of detrimental factors.

Of particular importance in preservation of the whole set of properties of a photographic system are a number of factors associated with the storage conditions and influence of atmospheric gases. In recent years, work has been conducted on development of digital technologies, which enabled restoration of many documents via their digitalization. This made it possible to significantly accelerate the restoration process, to lower its cost, and to solve the problem of transportation and storage of replicas. However, in the opinion of experts in restoration, digital technologies actually hinder true restoration of original documents, many of which are of historical and artistic value [1].

Chemical methods for restoration of documentary photographs may cause loss of image or impair the quality of the original image. For example, the method of autoradiography inevitably leads to a complete loss of the original [2]. Therefore, a copy is made before chemical treatment of a document, which makes it possible to retain the image, but not the document itself, which frequently is more valuable than the image.

The most important factor that affects the preservation of a photographic material is electromagnetic radiation in the ultraviolet and visible spectral ranges. Among other factors affecting the stability of photographs are temperature, humidity, and atmospheric contaminants. The presence of moisture catalyzes all undesirable chemical and biological processes. A relative humidity of more than 60% leads to fungal damage [3].

However, it was noticed as far back as 1888 [4] that the action of light is rarely the reason, by itself, for photochemical changes in materials of artistic and historical value. In most cases, decoloration occurs with active involvement of atmospheric oxygen and water vapor, which accelerate the process.

Analysis of the literature shows that the problem of preservation of documentary photographs can be solved in a simpler way by protection, rather than by restoration. The exceedingly high historical and artistic value of documentary photographs and motion pictures created during the years of development of photography and cinematography has been noted all over the world. However, the unsatisfactory storage conditions have been the reason for loss of, or damage to, numerous documents. Therefore, the more important is the work on preservation of the existing documentary photographs and motion pictures, of both color and white-and-black types.

The world's experience in storage of photographic materials is based on construction of depositories in which the materials are kept in the dark at the optimal temperatures under conditions of controlled humidity. Air is purified to the maximum possible extent to remove noxious impurities, and particularly valuable exhibits are stored in the atmosphere of an inert gas. However, invaluable historical-and-artistic articles are concentrated in museums, state institutions, architectural monuments, libraries, and private collections,

1070-4272/05/7808-1376 © 2005 Pleiades Publishing, Inc.

where the optimal storage conditions cannot be created in all cases. This huge wealth is also subject to aging, but, at present, there is no evidence concerning the preservation of documents stored outside specialized depositories.

Despite the large body of the accumulated factual material on use of polymers in the restoration practice [5], there is only limited evidence concerning the influence of polymers on the entire set of properties of a photographic material and on preservation of images. This makes studies of the conservation of documentary photographs by deposition of polymeric coatings a matter of current interest.

The most promising materials for this study are aqueous dispersions of polymers. As the liquid aggregative state of systems of this kind is provided by use of water as a dispersion medium, these systems have a number of advantages over solutions of synthetic resins.

Aqueous polymer dispersions with a high concentration (50%) have the minimum viscosity, whereas polymer solutions with such a concentration cannot be obtained at all [6]. Because of their low viscosity, they have a high penetrating power, dependent of the size of dispersion particles. The low surface tension of water, favors strong wetting of any surface by these dispersions [7].

Aqueous polymer dispersions are more technologically effective. Coatings of synthetic caoutchoucs have a number of advantages over other kinds of chemically stable coatings. They not only sustain prolonged action of various chemical media (solutions of acids, alkalis, salts), but also better withstand abrasive wear [8].

Taking into account the preservative nature of latexes and their availability, nontoxicity, convenience of use, transparency, and resistance to external action, latexes can be recommended for use in a study of the influence exerted by polymeric coatings on the efficiency of preservation, photographic properties, and aging of photographic materials. Polymer materials, of which aqueous polymer dispersions seem to be the most promising, are widely used in restoration practice.

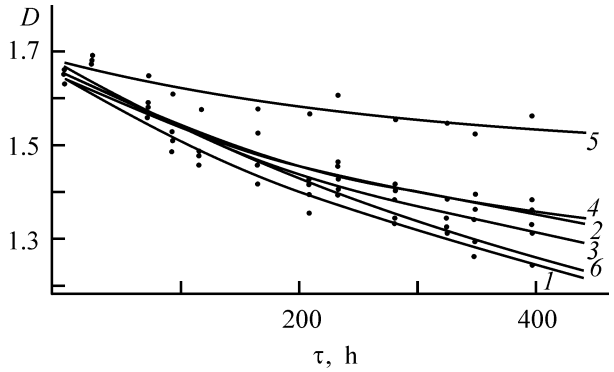
Thus, the advantages of water-based polymeric films and coatings are determined by the technological effectiveness and ecological safety of their formation. The most promising are latex coatings deposited from high-concentration, low-viscosity systems at room temperature.

Variation of the optical density of a white sample of color photographic paper relative to the initial value under prolonged (450 h) UV irradiation with a wavelength λ = 254 nm

Dilution	Copolymer				
	S–BA			BA–MMA	S–B
5	0.88	1.00	0.88	0.80	0.63
10	1.55	1.55	1.55	1.55	1.55
15	1.77	1.66	1.77	1.88	1.77
20	2.11	2.37	2.57	2.22	2.22

For effective use of this class of compounds as preservative agents for photographic materials, it is necessary to reveal the influence of these substances on the physicochemical and service characteristics of the materials and to examine their influence on the process of image preservation.

Latex coatings are commonly prepared from dispersions of the following types: copolymers of acrylates, homo- and copolymers of vinyl acetate, and copolymers of styrene with butadiene. One of the main properties determining the choice of latexes as preservative agents for photographic materials is the nearly 100% transparency of latex coatings.



The following latex formulations were chosen for the study: copolymers of butyl acrylate (BA) and methyl methacrylate (MMA); styrene (S) and BA; and S and butadiene (B).

The formation conditions of a latex film coating may strongly affect the physicomechanical properties of a polymer: for example, it is important to select the optimal thickness of the coating obtained. The coating thickness can be controlled both by diluting the initial latex dispersion or by depositing several latex layers on a dried surface.

The table illustrates the influence exerted by the layer thickness on the variation of the optical density in prolonged storage of a white sample of color photographic paper.

The conclusion that raising the layer thickness makes the variation of the optical density in prolonged storage considerably narrower is confirmed by data obtained by coating a material with several layers of a 20-fold diluted latex.

The influence exerted by preservative polymeric coatings based on various latexes on the image stability was revealed by carrying out the experiment under severe conditions, with densitometric monitoring.

Effect of a preservative coating on the process of image aging in a paper-based positive material under UV irradiation at a wavelength λ = 254 nm. (*D*) Optical density and (τ) time. Copolymer: (*1*–*3*) styrene–butyl acrylate, (*4*) butyl acrylate–methyl methacrylate, (*5*) styrene–butadiene, and (*6*) control sample.

According to the data obtained (see figure), the smallest decrease in optical density *D* is observed for samples coated with a latex composed of copolymers of butadiene and styrene. This can be accounted for by the fact that the absorption spectra of both butadiene and styrene lie in the range 240–290 nm. For butadiene, this is due to the presence of various chromophore groups in the polymer chains [9]. For styrene, the absorption is due to a transition of the benzoic ring to the singlet state under the action of photons [10]. The mechanism of photooxidation of copolymers of butadiene and styrene is determined by a set of processes occurring in irradiation of polystyrene and butadiene. Thus, the copolymers readily absorb light with wavelengths of up to 350 nm, with the absorption rate proportional to the light intensity [11].

By contrast, polymethyl methacrylate exceedingly weakly absorbs light in the UV spectral range, and, consequently, incident light can penetrate deep into a polymer sample [12]. This makes polymethyl methacrylate highly resistant to the action of light, which indicates that the coatings themselves, rather that the surface protected by these coatings, is stable at a rather small coating thickness.

CONCLUSION

Use of polymeric coatings deposited from aqueous-dispersion systems can strongly affect the shelf life of a photographic material. With account of the ability of latexes to have low viscosity at high concentrations, the optimal coating thickness can be controlled by varying the initial concentration of latexes.

Ivan Ivanovich Andreev (To 125th Anniversary of His Birthday)

An engineer-technologist Ivan Ivanovich Andreev went down in the history of domestic chemistry and chemical technology owing to his vigorous activities in the organization of the nitrogen and other important industries during World War I (1914–1918), a hard time for Russia.

Andreev was born on July 20, 1880, in the town of Belozersk, an uezd center in Novgorod Province (now district center in Vologda oblast) into a wealthy landowners' family. He received his primary education at home and then studied at Novgorod gymnasium, which he finished with a gold medal. Having early lost his parents, Andreev was distinguished by self-dependence and sense of duty during his entire, unfortunately very short, life. In 1899, he entered the natural department of the physicomathematical faculty of St. Petersburg University, but, after seven semesters, left Russia for political reasons without completing his studies. He continued his education at the Polytechnic Institute (Higher Technical School) in Karlsruhe, Germany, wherefrom he graduated as an engineer-technologist-electrochemist. Having become a certified engineer, Andreev did not consider his education complete. According to the scarce available biographic evidence, he was engaged in 1906–1908 in research work at the laboratory of physical chemistry (St. Petersburg Polytechnic Institute), headed by professor V.A. Kistyakovskii (1865–1952, academician of the Academy of Sciences of the USSR since 1929) and at Leipzig University in Germany. For his study "Growth Rate and Dissolution of Crystals," published both in Germany (1907) and in Russia (1908), Andreev received from the Polytechnic Institute in Karlsruhe the degree of a doctor-engineer. To extend his knowledge in the field of mathematics and physics, Andreev passed a state graduation examination at the physicomathematical faculty of St. Petersburg University. In this way, the young scientist received a very good theoretical and engineering training.

In 1908, Andreev became a laboratory assistant at the chair of technology and merchandising at St. Petersburg Polytechnic Institute. During the time free from his basic duties, he commenced a set of investigations of the chemical action of ultraviolet light. The first results were published in *Izvestiya Sankt-Peterburgskogo politekhnicheskogo institute* (Transactions of St. Petersburg Polytechnic Institute) in 1911 and 1914. As noted by B.V. Byzov (1880–1934) in Andreev's obituary [1], the scientist was deeply interested in the influence exerted by ultraviolet light on chemical processes; the results of his studies in this field were published only in part and largely remained in the form of manuscripts.

In 1912, Andreev passed his master's examination at St. Petersburg University. In the same year, he took part in studies aimed to synthesize caoutchouc. The preliminary results obtained and the possible ways to solve this most important problem were analyzed by Andreev in the monograph *Sinteticheskii kauchuk* (Synthetic Caoutchouc, 1914).

In 1913, the scientist was sent to a business trip abroad to be prepared for professorship. He spent most time at the Polytechnic Institute in Zurich (Switzerland) and continued there his studies concerned with the chemical action of ultraviolet light

1070-4272/05/7808-1379 © 2005 Pleiades Publishing, Inc.

and with dissolution of gold and silver in potassium cyanide solutions. However, Andreev's dream to head a chemical chair at a higher school institution in Russia remained unfulfilled. In view of the beginning of World War I, the Central scientific and engineering laboratory was created by the Military ministry and Andreev headed its department of inorganic chemistry [2]. In 1914–1918, he took most active part in solution of extremely important defense-related problems, the central of which was the development of an industrial technology for manufacture of nitric acid [3–5].

In the early XIX century (1809), an exceedingly rich deposit of saltpeter $NaNO_3$ was discovered in Chile. In more than a hundred of years that followed, the Chilean saltpeter became the main source of fixed nitrogen all over the world. Ammonia was obtained in very small amounts as a by-product in coal coking. The manufacture of nitric acid in Russia was based solely on Chilean saltpeter, which was imported duty free. Saltpeter was also used as a nitrogen fertilizer. In 1900–1914, the import of saltpeter in Russia increased from 14.7 to 53.9 thousand tons. The war between Russia and Japan led to an increase in manufacture of nitric acid for production of explosives. The agrarian reforms carried out in Russia, beginning in 1906, also made higher the consumption of nitrogen fertilizers. It was necessary to have Russia's own sources of fixed nitrogen. It was also necessary to take into account that the whole amount of Chilean saltpeter was imported across the western boundary and via Baltic ports. It would be expected that, in case of military operations in this region, the import of saltpeter could be completely terminated, which would cut-off primarily the military industry from an exceedingly important source of raw materials.

Already in December 1905, a rather representative interdepartmental Commission for Manufacture of Nitric Acid by Oxidation of Atmospheric Nitrogen was created at the Main engineering directorate of the Military ministry [6, 7]. The organization of the Commission was initiated by professor A.I. Gorbov (1859–1939), a broadly educated chemist, A.M. Butlerov's pupil, and close friend of D.I. Mendeleev. Gorbov became the secretary of the Commission. Gorbov and professor V.F. Mitkevich (1872–1951, academician of the Academy of Sciences of the USSR since 1929), a specialist in electrical engineering, were charged with a task to consider the possibility of construction in Russia of a plant for oxidation of atmospheric oxygen in an electric-arc furnace. Such a plant existed in Norway, which possessed, already at that time, resources of low-cost hydroelectric power. Despite the successful work of the scientists, this project could not be rapidly carried out in Russia because of the exceedingly high consumption of electric power, which made necessary construction of a hydroelectric power plant [7].

Based on economical calculations, Andreev convincingly demonstrated that the method of ammonia oxidation to give nitric acid is considerably more cost-efficient than the arc method, even though being substantially less studied. Data necessary for designing Russia's first plant for manufacture of nitric acid by oxidation of ammonia were obtained at a laboratory of the Technological Institute in Petrograd and on a pilot installation in Makeevka (Donetsk basin). The plant was designed by engineer N.M. Kulepov, who also supervised its construction and put it in operation. Andreev, the creator of the technology, was actively involved in the designing work and in solution of problems associated with the construction of the plant and putting it in operation. In February 1917, less than a year after its construction was commenced, the plant yielded the first amounts of its product. Gaseous ammonia was delivered in a mixture with air into the catalytic apparatus, in which an alloy of platinum and rhodium served as a catalyst. A single apparatus hourly produced 16 kg of nitric acid (in terms of monohydrate). The daily output was up to 17 tons of nitric acid containing 33 wt % HNO_3. The yield of nitric acid was as high as 93% and more [3, 9, 10].

In addition to production of nitric acid, Andreev was engaged in those same years in studies and tests of gas masks. The main results he obtained were published in *Sbornik materialov po protivogazovym voprosam* (Coll. of Works on Gas Masks; first issue 1917; second issue, 1918). Andreev studied the dynamic activity of carbons toward various poison gases [11]. In particular, he revealed factors determining the dynamic activity of absorbents. The priority in the development of catalysts and universal absorbents based on activated carbons belongs to Andreev, together with N.D. Zelinski (1861–1953, academician of the Academy of Sciences of the USSR since 1929).

Andreev devoted a considerable attention to a search for sources of toluene necessary for manufacture of explosives. His considerations concerning this issue, which are both valuable and constructive, were summarized in the paper "Maikop Oil as a Source of Toluene." The country's demand for fuel forced Andreev to take active part in organization and work of the Sapropel Committee, aimed to study methods for utilization of the silt of our northern lakes. Andreev

constantly taking an active interest in domestic agriculture, its needs, and the possibility of its provision with various kinds of nitrogen fertilizers.

Andreev started his work on some of these problems at the Institute of Applied Chemistry, created in Petrograd in 1919. However, a long severe illness resulted in the scientist's death on December 16, 1919, at the age of only 39. Lieutenant-general V.N. Ipat'ev (1867–1952, academician since 1916), who, in fact, headed the whole military-chemical complex of Russia during World War I, highly appreciated Andreev and the results of his works [2, 12, 13]. During only several war years, Andreev showed himself as an erudite and talented scientist who could implement results of his studies in the industry. The premature death terminated his vigorous and efficient activities.

BOOK REVIEWS

Tsar'kov, V.A., *Opyt raboty zolotoizvlekatel'nykh predpriyatii mira* (Experience of Work of World's Gold-Recovery Plants), Moscow: Ruda I Metally Publ. House, 2004, 112 pp.

The small monograph analyzes the practice of 29 foreign and 14 domestic plants processing gold-bearing ledge ores. Rather valuable is the detailed information about resources of ore at various deposits, its quality, processing techniques, and production scale. The book comprises an introduction, three chapters, conclusion, and a combined list of references for all the chapters.

The brief introduction (pp. 5, 6) notes that the annual world's production of gold is about 3.5 thousand tons, of which more than 70% is recovered by processing of gold-bearing ledge ores. The world's leading countries in gold mining are South Africa, US, and Australia. The gradual depletion of the resources of rich ores and the increasing demand for gold force the gold mining companies all over the world to process lean ores having a complex mineralogical composition and containing noxious admixtures. The book considers modern technologies for recovery of gold from rich and lean ledge ores.

The first chapter (pp. 7–29) describes the general trends in the development of the technology for recovery of gold from ledge ores, discusses ore pretreatment, gravity concentration, flotation dressing, hydrometallurgical processing, cyanidation, and sorption technology. The recovery cost of a gram of gold at different plants depends on the content of gold in ores, conditions of ore occurrence, and technology of ore mining and processing and is commonly within the range 3.4–10 US dollars.

The second chapter (pp. 29–84) discusses the working practice of foreign gold-mining plants processing ledge ores. These plants are distributed among countries as follows: US 7, Canada 4, Indonesia 3, Uzbekistan 3, and Kazakhstan 2. Evidence is given concerning 10 more plants from other countries, but there is no information about such gross gold-mining countries as South Africa and Australia. No comments concerning this issue can be found in the text of the monograph.

For each of the gold-mining plants considered, a brief description of the deposit (type of ore, conditions of occurrence, proven resources, content of gold in the ore), basic technological procedures in processing of raw ore, and scale of gold mining are given. Mostly sorption-cyanide technology with activated carbon is used in ore recovery. For lean ores (with gold content less than 2.5 g per ton of ore) the heap leaching method is employed. Most of the 29 plants described in the second chapter were created at deposits discovered 10–15 years ago.

The third chapter (pp. 85–105) contains similar information about Russia's 14 gold-recovery plants, which are situated in the eastern part of the country, from South Urals to Chukotka.

The conclusion (pp. 106, 107) emphasizes that the basic process for gold recovery from easily dressed ledge ores is cyanidation with subsequent sorption from slurry onto activated carbon or ion-exchange resins. It is noted that 92% of gold is recovered from ores by this process. A steady tendency is revealed toward depletion of the resources of rich easily dressed ores and involvement of lean difficultly dressed ores of complex composition into processing, which makes necessary autoclave oxidation, calcination, or bacterial leaching. The author of the monograph notes that Russia is second in the world in gold resources. At the same time, only 165 tons of gold were produced in 2001 (sixth place in the world), which is largely accounted for by the uncoordinated work of our gold-mining plants. According to the data presented in the monograph, there were 639 gold-mining plants in Russia in 2001, 80% of which produced less than a ton of gold in a year. The recovery of gold at small-scale Russian plants is 75–80%, whereas at larger plants, such as Olimpiadinskaya (Krasnoyarsk krai) or Kubaka (Magadan oblast) the recovery is as high as 92–98%.

V.A. Tsar'kov's monograph gives a summary of data that are of indubitable interest for a wide audience of specialists in chemical metallurgy and for teachers from high-school institutions training specialists in chemical engineering and metallurgy.

Abstract—Slowly soluble phosphate glasses are a promising material for new environmentally safe fertilizers. The kinetics of the dissolution of phosphate glasses used for the development of fertilizers was studied.

Modern nature management is impossible without application of mineral elements, because ions of potassium, magnesium, calcium, phosphorus, boron, and trace elements are irrevocably withdrawn from soil together with agricultural products. Existing mineral fertilizers have a number of principal drawbacks connected with their crystal structure and constant composition. These fertilizers are easily washed away and weathered from the soil, which gives rise to extreme workloads on soil microorganisms and root systems of plants. Annual world production and application of fertilizers reaching 400 million tons is not only prodigal, but also environmentally dangerous, as no less than 50% of fertilizers goes to subsoil waters and is weathered, causing environmental pollution.

The cardinal way of overcoming these drawbacks is to abandon traditional crystalline fertilizers and to develop essentially new highly effective fertilizers based on glassy amorphous materials. Glass is one of the most promising among these materials because of its favorable physical and chemical properties and feasibility of processing.

In the early 1980s, phosphate glasses were used to develop a new generation of fertilizers [1]. These fertilizers of the prolonged action are based on glassy potassium, magnesium, and calcium metaphosphates doped with microelements. Their preparation was based on long-term experience in the field of development of optical glasses and ion-exchange processes.

As a result of these studies [1, 2], a new type of glassy fertilizers (AVA) was developed; their high efficiency and environmental cleanliness are due to the high-temperature synthesis of phosphate systems, quenching of the structural state of the components in the form assimilable by plants, and their variable composition providing easy adaptation to regions of use, to types of soils, and to the kind of crops.

The rate of dissolution of such glasses depends on their chemical composition. Glass components, K, Ca, and P oxides, are nontoxic. Such glasses provide egress of the required compounds from the glass into the environment. The dissolution of a glass in water is accompanied by a chemical reaction between the glass and water, which results in cleavage of the >P–O–P< bonds and passing of phosphate ions into solution. Metal ions contained in the glass together with P_2O_5 pass simultaneously into the solution at a rate determined by the rate of the glass dissolution. The soluble phosphate glass can be used for delivering fertilizers with a specified intensity and substances for protection of plants.

According to published data [3, 4], the dissolution of phosphate glasses involves several steps: selective passing into a solution (leaching) of cations within the framework of internal diffusion and hydrolytic degradation of the anionic skeleton. However, the most important is the thermodynamically nonequilibrium structure of glasses, so that all the components remain in the cytosoluble state and are accessible to plants, and the glass dissolution is slow, with a constant thickness of the destroyed granule layer.

Various macro- and microelements are necessary for successful vital activity of plants. They are introduced in a balanced proportion and are not subject to selective leaching.

Owing to specific physicochemical properties, the rate of dissolution of a glassy fertilizer granule strongly depends on temperature. For example, at 50°C they are dissolved within 3 months and at 20°C, within 27 months (Fig. 1).

After introducing the fertilizers into a soil, they slowly (within several years) dissolve to release consecutively chemical components feeding plants.

1070-4272/05/7809-1383 © 2005 Pleiades Publishing, Inc.

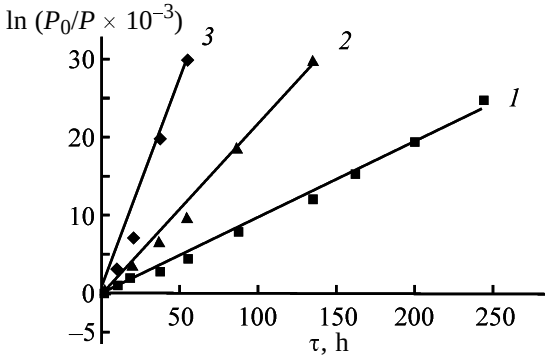

Fig. 1. Kinetics of dissolution of AVA fertilizer. (τ) Time. Temperature, °C: (*1*) 20, (*2*) 30, and (*3*) 50.

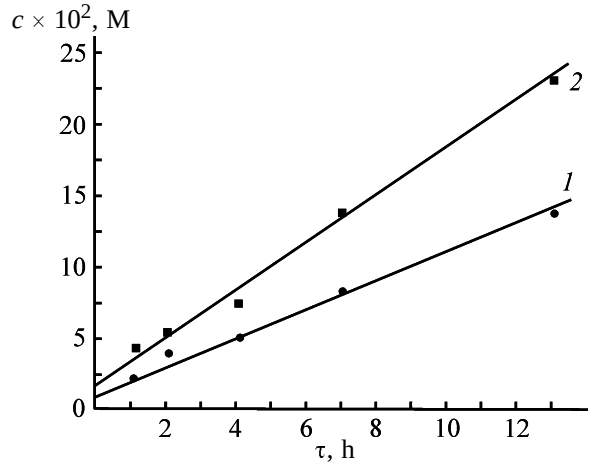

Fig. 2. Concentrations *c* of (*1*) K^+ and (*2*) PO_3^- ions in solution as functions of time τ at 60°C.

The time of dissolution at various temperatures is 90% dependent on the soil moisture content, heterogeneity of the structure of glasses, and the granule size distribution determining the specific surface area.

Successful application of glassy metaphosphate fertilizers has demanded a deeper study of the kinetics of passing of all fertilizer components into solutions. The monitoring of the kinetics of AVA dissolution by the weight loss of granules of various fractions suggested that two processes occur consecutively: the electrolytic dissociation connected with passing of metal cations into the solution and hydrolytic degradation of the polyanionic framework providing passing of phosphate ions and microelements into the solution.

The simulation of the dissolution kinetics for AVA is complicated by the long time of complete dissolution; therefore, our experiments involved dissolution of 2–3% of the initial weight, with the subsequent calculation of the dissolution parameters (rate and activation energy for each component).

EXPERIMENTAL

Samples of complex metaphosphate glassy systems under study had the following composition:

Compound	Content, wt %
P_2O_5	50
K_2O	20
CaO	10
MgO	6
SiO_2	2.5
Microelements: Na, Co, Zn, Mn	11.5

Granules of the samples (sample weight 0.5 g) were dissolved in water within 1–14 h at 60°C. The sampling (up to 5 ml) of solution for the capillary electrophoretic analysis [5] was carried out at 2-h intervals.

The principal possibility of determining chemically the structure of alkali metal phosphates was shown in [6]. Glassy $NaPO_3$ or a glass with the ratio Na : P ≥ 1.25 was dissolved in water under strictly controlled conditions. Polyphosphates were precipitated from aqueous solutions with acetone. The mobility of phosphate ions was determined by chromatography or electrophoresis [7].

In the case of glassy AVA fertilizers, K, Ca, and Mg cations and PO_3^- anions were separated in solution by capillary electrophoresis (CEP). This method is based on examination of the ion mobility in a thin capillary after the separation in a strong electric field; the detection was carried out at a wavelength of 254 nm [5]. The examination of the time dependences of the concentration of ions in solution (c_a–τ and c_c–τ) within the first hours of dissolution, as given by the CEP method, allows us to extrapolate the simulated dependence to the entire process of glass breakdown.

We studied the solubility of glassy KPO_3 under the same conditions to compare passing of metaphosphates into solution.

The time dependences of passing of potassium and phosphate ions into the solution within 14 h of granule dissolution are shown in Fig. 2. The kinetic curves for this period are approximated by a straight line, the fraction of the dissolved substance being approximately 1%. Two processes are observed: cation exchange and breakdown of the anionic framework of glassy metaphosphate, which is characteristic of dissolution of phosphate glasses [1, 2].

The slope of the kinetic curves of the dissolution (Fig. 3) for single-charged K^+ cations differs from that for double-charged Ca^{2+} and Mg^{2+} cations, showing

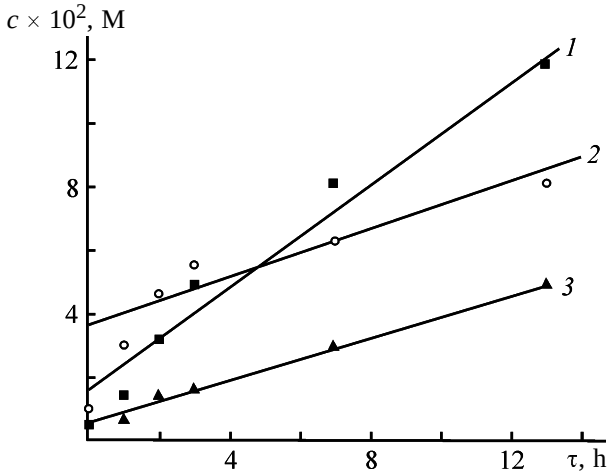

Fig. 3. Concentration c of cations in solution as a funciton of time τ at 60°C. (*1*) K, (*2*) Ca, and (*3*) Mg.

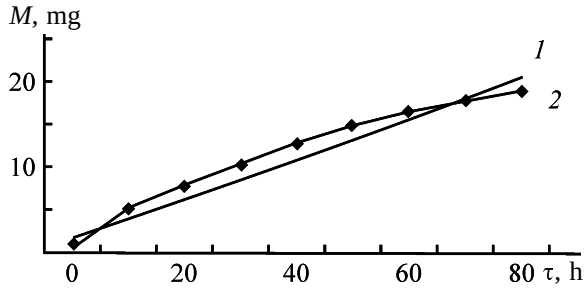

Fig. 4. Weight loss in the dissolution of glassy fertilizers: (*1*) calculation and (*2*) experiment. (*M*) Weight and (τ) time.

that single-charged cations (which have a higher weight fraction in the glass) preferentially pass into the solution compared to double-charged cations upon the dissociative rupture of ionic bonds with the anionic framework. Examination of the c–τ dependences for K^+ and PO_3^- for glassy KPO_3 and the data of [2] confirm the assumption that the corrosion stability of a phosphate glass increases with the concentration of oxides of double-charged metals.

We found that the dissolution of glassy fertilizers in water is described by a first-order kinetic equation, i.e., by the law $\ln(M_0/M) = k\tau$, where M_0 is the initial weight, and M, current weight of granules; k, rate constant of dissolution exponentially dependent on temperature; and τ, time.

When the reaction is of the first order, the total weight loss for a glass granule in time is described by the dependence

$$M_{sum}(\tau) = m_{01}F_1(1 - e^{-k_1}) + m_{02}F_2(1 - e^{-k_2}), \quad (1)$$

where m_{01} and m_{02} are weight fractions of components; $F_1(\tau)$ and $F_2(\tau)$ are functions describing the rate of egress of each component; k_1 and k_2 are rate constants [8].

Transformed equation (1) for the first-order reaction appears as

$$M(\tau) = m[1 - \exp(-km\tau/\rho d)], \quad (2)$$

where m is the initial weight of granules; ρ, their density; d, size of glass granules, and k, rate constant.

The initial conditions are as folllows: m = 0.5 g, d of a granule 0.2 cm, and ρ = 2.6 g cm^{-3}. The experimental constant ($k = 3 \times 10^{-1}$ h^{-1}) is used for calculating the weight loss of a fertilizer granule. The calculation by Eq. (2) gave the results consistent with the experiment (Fig. 4). The results obtained show that the approximations of the model are suitable for estimating the initial step of the dissolution of glassy fertilizers.

CONCLUSIONS

(1) The kinetics of the dissolution of glassy fertilizers AVA and of passing of K, Ca, and Mg cations into solution is described by a first-order equation.

(2) Equations (1) and (2) allow estimation of passing of ions into solution within the entire period of the dissolution of glass granules.

Received April 15, 2005

Abstract—Thermal reaction of platinized fullerene soot and platinum(II) acetylacetonate occurs in the combustion mode. As shown by ESR, the combustion products contain compounds of platinum with fullerene. Water-soluble fullerene-containing platinum complexes with the parameters g_{eff} = 2 and ΔH = 84 mT were synthesized by the hydroxylation of combustion products with a nitric acid solution.

Carbon clusters, fullerenes and their compounds, have extremely wide spectrum of biological activity: antiviral, antimicrobial, and antitumor; they are active against HIV infection [1–4]. However, both fullerenes and overwhelming majority of their derivatives are insoluble in water, which makes them incompatible with physiological media and is one of the main obstacles in their use for biomedical purposes.

Polyhydroxylated fullerenes $C_{60}(OH)_x$ and $C_{70}(OH)_x$ (fullerenols) are water-soluble [4–7] and biologically active [8] compounds. As a rule, fullerenes are isolated with a large number of hydroxy groups as a mixture of isomers. The number of hydroxy groups in $C_{60}(OH)_x$ can reach 36. Recently the diols $C_{60}(OH)_2$ and $C_{70}(OH)_2$ were synthesized in the individual form [9]. Water-soluble metal-containing fullerenols were synthesized by the hydroxylation of endohedral fullerides C_{82} of *f* metals (Gd, Ho, Pr) [10, 11], but they are poorly accessible for wide-scale studies because of the lack of efficient procedures for the synthesis of higher fullerenes and their endohedral complexes. The formation of exohedrally bound compounds with metals is characteristic for more readily accessible fullerenes, C_{60} and C_{70}. They are described in numerous papers, but no water-soluble compounds of this type were reported. Anions C_{60}^{n-} were hydroxylated in lithium fullerides [12] to give fullerenol $C_{60}H_2(OH)_{24}$ readily soluble in water. It was interesting to carry out the hydroxylation of fullerides of *d* metals as a possible route to water-soluble fullerene-containing complexes of metals.

The aim of this work was to synthesize and study fullerene-containing platinum complexes.

EXPERIMENTAL

Platinized fullerene-containing soot (Pt/FS) [13] was the starting reagent. It was prepared in a plasmochemical reactor. Its operation is based on the vaporization of graphite under atmospheric pressure in an long plasma jet with a longitudinal (~1 m) temperature gradient from 5000 to 2000 K [14]. A metallic platinum powder was placed in the orifice of one of graphite electrodes between which the carbon plasma jet is formed. The reactor was cooled to room temperature. The resulting condensate (Pt/FS) contained approximately 8% of a mixture of fullerenes with the ratio C_{60}/C_{70} = 4/1 (the content of higher fullerenes in the fullerene mixture was less than 1%), approximately 5% of platinum in the form of finely dispersed metal particles, more than 80% of ultradispersed carbon not bound in fullerenes, and residual graphite [13].

Pt/FS with an addition (about 3–4%) of platinum acetylacetonate $Pt(acac)_2$[1] was heated to initiate the combustion of the reagents. On the reaction termination, the combustion products (Pt/FS_{comb}) were treated with a concentrated HNO_3 solution. The dissolved part of the products was separated by filtration. The solution was evaporated on a water bath to dryness, with full removal of acid vapor. The resulting amorphous brown-black powder **I** was readily soluble in water and insoluble in organic solvents. The yield was ~40% based on the weight of fullerenes in Pt/FS.

[1] Platinum acetylacetonate was prepared by G.I. Zharkova (Institute of Inorganic Chemistry, Siberian Division, Russian Academy of Sciences, Novosibirsk).

1070-4272/05/7809-1386 © 2005 Pleiades Publishing, Inc.

The electron spin resonance spectra (ESR) of the products isolated in the course of the synthesis were recorded on an SE/X-2544 ESR spectrometer at 77 and 293 K. The IR spectra were recorded on a Bruker spectrometer in KBr pellets. The electronic absorption spectra were taken on a Specord UV-VIS instrument from aqueous solutions. The X-ray phase analysis was carried out on a DRON-4 diffractometer using CuK_α radiation.

Previous studies showed that thermal reactions in solid-phase mixtures of fullerene C_{60} and metal acetylacetonates proceed in a catalytic combustion mode [15, 16]. The fullerene initiates the exothermic thermolysis of a metal complex. Reaction of the combustion products formed in the C_{60}/Fe(acac)$_3$ mixture with hydrochloric acid yielded iron fullerene complexes containing hydroxy groups [15]. The yield of the target product in the similar synthesis of platinum complexes was very low. Therefore, in this study, to prepare platinum fullerenol complexes, we used products of the thermal reaction of platinized fullerene soot and platinum acetylacetonate.

Heating a solid-phase mixture Pt/FS + Pt(acac)$_2$ results in combustion of the reagents [15] at ~200°C. In the absence of Pt(acac)$_2$, no combustion of Pt/FS was observed even above 400°C. Addition of platinum acetylacetonate to "empty" soot (fullerenes were extracted beforehand with toluene) does not give rise to combustion, i.e., the combustion of a Pt/FS + Pt(acac)$_2$ mixture is a consequence of the exothermic decomposition of platinum acetylacetonate initiated by fullerene. Ultradispersed carbon from Pt/FS is gasified in the course of the combustion. The total weight loss of the reagents is about 70%.

Phases of metallic platinum and residual graphite were detected in the X-ray diffraction patterns of the starting Pt/FS and combustion products of the Pt/FS + Pt(acac)$_2$ mixture. Fullerene reflections were observed in the Pt/FS pattern against the background of a halo from ultradispersed soot but were absent from the pattern of Pt/FS$_{comb}$. The ESR spectra suggest the presence of fullerenes both in Pt/FS and in Pt/FS$_{comb}$, as they both have an intensive absorption line characteristic of a radical of solid-phase fullerenes (fullerites) [17] (Fig. 1, line *3*). The line of the radical in the spectra of Pt/FS and Pt/FS$_{comb}$ is somewhat shifted and broadened as compared to the C_{60}/C_{70} sample, which is attributable to the presence of paramagnetic centers. Broad line *1* observed in the spectrum of the starting soot at 77 K refers to platinum compounds. In the spectrum of combustion products, this line becomes more intense (line *2*) and clearly observable

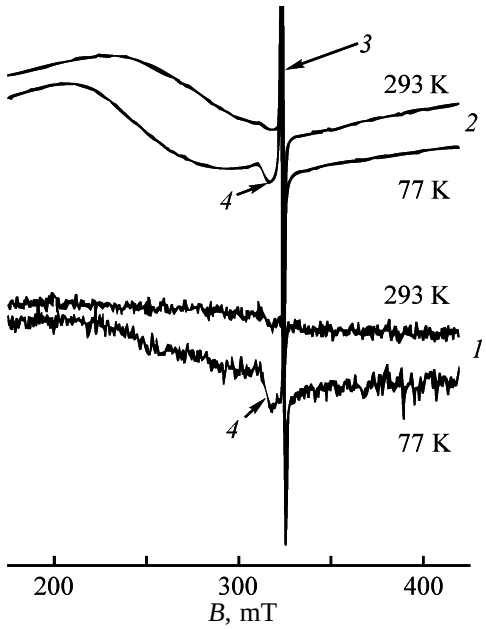

Fig. 1. ESR spectra: (*1*) Pt/FS, (*2*) Pt/FS$_{comb}$, (*3*) fullerite radical, and (*4*) platinum nanoparticles. (*B*) Magnetic field; the same for Fig. 3.

at room temperature. The parameters of the spectrum g_{eff} = 2.27, ΔH = 94 mT (293 K) and g_{eff} = 2.57, ΔH = 82 mT (77) correspond to Pt^{3+} [18]. Line skewness, which is more noticeable at 77 K, is due to a low-symmetry surrounding characteristic for Pt^{3+} ions; the increase in the ESR line symmetry at 293 K is caused by a high molecular mobility. As the temperature decreased, no increase in the line intensity, characteristic for paramagnetic centers, was observed. Presumably, there is an interaction between platinum ions, which is also proved by the downfield shift of the line at 77 K. The line narrowing at 77 K is attributable to an increase in the spin–lattice relaxation time. We believe that Pt/FS$_{comb}$ contains platinum fullerides Pt_nC_{60} and Pt_nC_{70} in an amorphous state typical of them [19].

Absorption lines (g_{eff} = 2.06, ΔH = 6 mT) in the spectra of starting soot and combustion products have an asymmetric shape characteristic of small metallic particles [20, 21], which allows them to be assigned to platinum nanoparticles of sizes no greater than 1 nm.

To hydroxylate fullerides in Pt/FS$_{comb}$, we used their reaction with concentrated HNO_3 [10]. When Pt/FS$_{comb}$ was treated with nitric acid, a part of the substance passed into solution, which became bright brown. The action of HNO_3 on Pt/FS yielded only a trace amount of a soluble product. This fact suggests that product **I** (in view of its rather high yield) is formed owing to the dissolution of the platinum-

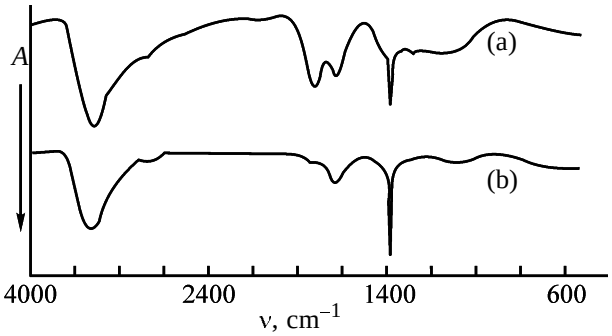

Fig. 2. IR spectra: (*A*) absorption and (ν) wave number. (a) Product **I** obtained by Pt/FS_{comb} hydroxylation and (b) product **II** obtained by the reaction of **I** with water.

containing products of combustion of the Pt/FS + $Pt(acac)_2$ mixture in HNO_3.

The elemental analysis and thin-layer chromatography of product **I** (two major components are detected in a freshly prepared aqueous solution) allow us to conclude that **I** is a mixture of derivatives of (60)- and (70)-fullerenes with the composition $Pt_2(C_{60}/C_{70})\cdot N_{2.5}H_{42}O_{44}$ (C_{60}/C_{70} = 4/1).

Found, %: N 1.78, H 2.17, C 39.96, Pt 19.9.
Calculated, %: N 1.79, H 2.15, C 39.98, Pt 20.0.

We failed to isolate pure complexes by column chromatography of aqueous solutions (eluent: water–alcohol mixtures) because of smearing of the bands, their mixing, and increase in their number.

The IR spectra of products **I** and **II** are shown in Figs. 2a and 2b, respectively. Product **II** was prepared by the dissolution of **I** in water followed by evaporation of the solution. Both spectra resemble those of fullerenols [5, 6, 12] and the spectrum of the water-soluble endohedral complex $Pr_2C_{82}O_m(OH)_n$ ($m \sim 10$, $n \sim 10$) [10]. Strong bands at 3425 (broad) and 1384 cm^{-1} (narrow) correspond to stretching and bending vibrations of OH groups, respectively, and bands of medium intensity at 1634 (1629 cm^{-1} in the spectrum of **I**) and 1050 cm^{-1} correspond to C=C and C–O stretching vibrations. Very weak bands of C–H vibrations are also observed at 2852 and 2928 cm^{-1}. The absorption at 1580 cm^{-1} (shoulder), in the region of 1150–1290, and at 720 cm^{-1} (C=O vibrations), disappearing in the spectrum of **II**, is attributable to the substitution of water for nitrate groups bound to platinum [22] and by the hydrolysis of complexes **I**. As vibrations of any functional groups, except for OH, C–O, C=C, and C–H, are absent from the spectrum of **II**, it is most probable that product **I** is transformed into the corresponding aqua or aquahydroxofullerenol platinum complexes $Pt_2(H_2O)_n(C_{60}/C_{70})H_m(OH)_x$. The evaporation of the solution of **I** resulted in a partial loss of the solubility of the isolated product **II**, but at room temperature no precipitate was detected in a saturated solution of **I** even after storage for more than 10 days.

The ESR spectrum of **I** is shown in Fig. 3. The resonance from platinum ions is recorded at room temperature. The line is symmetric; ΔH = 84 mT and g = 2.1. A change in the g-factor as compared to Pt/FS_{comb} is due to a change in the local surrounding of ions and increasing splitting of platinum orbital levels, which results in a decrease in the contribution of orbital motion of electrons to g-factor of the observed Pt^{3+} spectral line and in approach of its value to 2. The position of the resonance line of the radical (g = 1.997, ΔH = 0.35 mT) corresponds to the radical anion of fullerene C_{60} [17], suggesting the formation of charge-transfer complexes. An absorption line referred to nanoparticles of metallic platinum (line *2*) is also present in the spectrum, which seems to be due to insignificant decomposition of the complexes to Pt(O) during their isolation from a nitric acid solution by evaporation.

The transformation of product **I** into **II** practically does not noticeably change the ESR spectrum. However, after a prolonged heating of solution **I** and its subsequent evaporation, the intensity of the resonance line of platinum ions in the spectrum of the isolated solid product decreases, which is attributable to the reduction of the complexes. The line of the radical of fullerenes becomes stronger.

Complexes **I** are reduced with ethanol at room temperature. When product **I** is treated with alcohol, it partially dissolves. Lines of Pt^{3+} ions are absent from the ESR spectra of the fractions insoluble (product **III**)

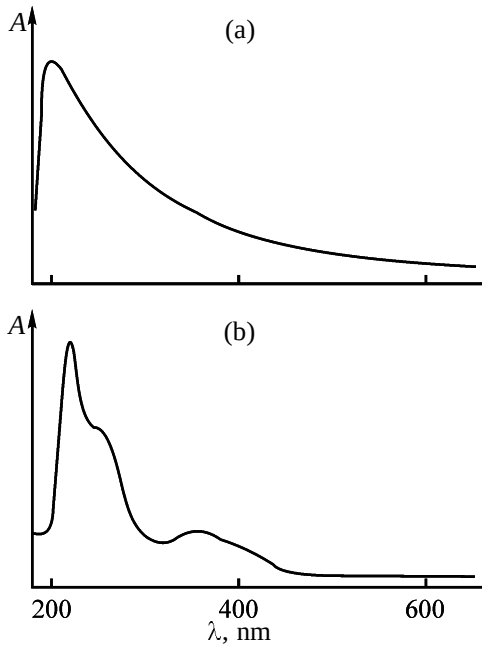

Fig. 4. UV and visible absorption spectra of aqueous solutions of products (a) **III** and (b) **IV**. (*A*) Absorption and (λ) wavelength.

and soluble in alcohol (product **IV**), which is a due to their reduction; the line of radicals increases in the intensity. The *g*-factor shifts relative to the radical of substance **I** (g = 2.0025, ΔH = 0.54 mT for **III** and g = 2.0027, ΔH = 0.34 mT for **IV**), which is probably due to a decrease in the charge of the radical anion.

It should be noted that products **III** and **IV** preserve the water solubility. The electronic absorption spectra of aqueous solutions of **III** (a) and **IV** (b) are shown in Fig. 4. These spectra are similar to the spectra of the fullerenols $C_{60}(OH)_2$ and $C_{70}(OH)_2$ [9], respectively, but the bands are shifted to the UV region owing to bonding of fullerenol groups with platinum. We believe that the difference in the solubility in alcohol makes it possible to separate the derivatives of (60)- and (70)-fullerenols in product **I**, but the separation is accompanied by reduction and probably by exchange processes.

CONCLUSIONS

(1) Products of the combustion of a mixture of platinized fullerene soot and platinum acetylacetonate contain platinum fullerides, which are hydroxylated when treated by nitric acid to form magnetic (60)- and (70)-fullerene-containing platinum complexes.

(2) The resonance from platinum ions is recorded in the ESR spectra of the starting fullerides and the hydroxylation products at room temperature. Parameters of the spectra are characteristic for Pt^{3+}. The position of the resonance line of the radical corresponds to the fullerene radical anion, suggesting the formation of charge-transfer complexes.

(3) The resulting complexes are readily soluble in water, preserve the solubility during transformations in aqueous solutions, and are fairly stable with respect to reduction. The separation of the complexes into C_{60} and C_{70} derivatives using a difference in their solubility in alcohol is accompanied by reduction, with the solubility in water of the reduced complexes being preserved. The synthesized water-soluble platinum fullerenol complexes are suitable for operation in physiological media. The suggested route of their synthesis excludes traditional steps of the extraction of fullerenes from fullerene soot by toxic organic solvents.

Received April 7, 2005

Abstract—The electrochemical synthesis and properties of polymeric copper complexes with tetradentate (N_2O_2) Schiff bases were studied. The effects of the metal center and ligand surrounding of the starting compounds on the mechanism and kinetics of the charge transport in the polymers are discussed.

Polymeric complexes of transition metals (M) with tetradentate (N_2O_2) Schiff bases {poly-[M(Schiff)]} have a number of unique properties, such as directed redox conductivity, electrochromism, and the capability of selective catalysis of important chemical processes involving organic compounds [1–3]. This set of properties of poly-[M(Schiff)] polymers makes them promising for development of new optoelectronic and sensory devices and energy-storing and catalytic systems.

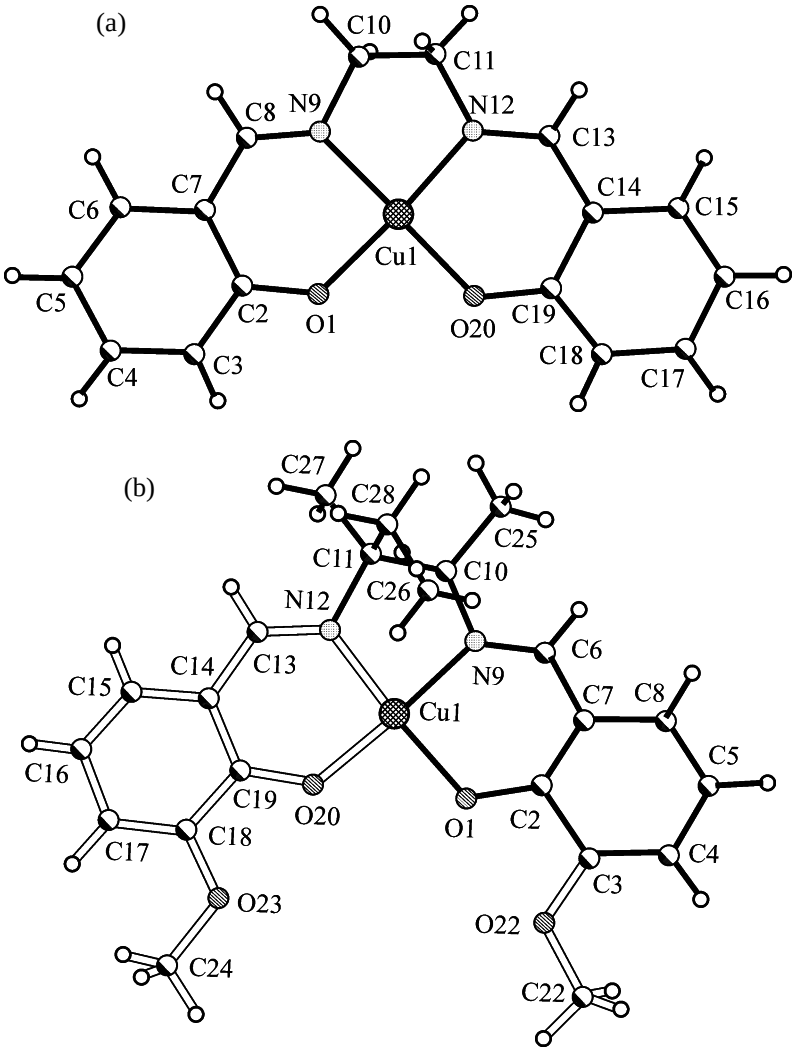
Nickel(II) and copper(II) compounds are the most practically significant among poly-[M(Schiff)] polymers owing to a relatively low cost. Papers devoted to nickel-containing polymers are numerous, but only a few studies [4–6] concerned poly-[Cu(SalEn)] polymers

where M is Cu; R, R' = H, [Cu(SalEn)]; R = OCH_3, R' = H, [Cu(CH_3O–SalEn)]; R = H, R' = CH_3, [Cu(SaltmEn)]; R = OCH_3, R' = CH_3 [Cu(CH_3O–SaltmEn)].

Here we made a first systematic study of the formation and properties of [Cu(Schiff)] polymeric complexes. These results make it possible to carry out a purposeful synthesis of materials with preset properties for various applications.

EXPERIMENTAL

The complexes [Cu(CH_3O–SalEn)] and [Cu(SalEn)] were synthesized by the procedures from [5, 7], and [Cu(SaltmEn)] and [Cu(CH_3O–SaltmEn)], by the following procedure.



The ligands H_2SaltmEn and H_2CH_3O–SaltmEn were prepared by mixing hot saturated alcoholic solutions containing stoichiometric amounts of the corresponding aldehydes and diamino derivatives: salicylaldehyde (Aldrich) and 2,3-diamino-2,3-dimethylbutane (H_2SaltmEn) or *o*-vanillin (Aldrich, 97%) and 2,3-diamino-2,3-dimethylbutane (H_2CH_3O–SaltmEn). 2,3-Diamino-2,3-dimethylbutane was obtained by the reduction of 2,3-dimethyl-2,3-dinitrobutane (Aldrich) with hydrogen [8]. The resulting ligands were filtered under vacuum, washed with cold distilled water and ethanol, and dried in air.

To prepare the complexes, a saturated acetonitrile solution of appropriate ligand was added to a saturated aqueous solution of $Cu(CH_3COO)_2$ (Vekton, chemically pure grade); the solutions contained stoichiometric amounts of the reactants. Then the mixture of the reactants was refluxed for 20–30 min; the precipitates were washed with water and acetonitrile, filtered off, and recrystallized from acetonitrile. The yield of [Cu(CH_3O–SaltmEn)] and [Cu(SaltmEn)] was 44 and 49%, respectively.

All the complexes were identified by X-ray diffraction analysis using a Bruker D-5000 diffractometer. The composition and structure of the synthesized complexes [Cu(SaltmEn)] (a) and [Cu(CH_3O–SaltmEn)] (b) are shown below.

To prepare supporting electrolyte solutions, we used the following salts: tetraethylammonium tetrafluoroborate $(Et_4N)BF_4$, tetraethylammonium perchlorate $(Et_4N)ClO_4$, and tetraethylammonium hexafluorophosphate $(Et_4N)PF_6$ (all purchased from Merck, 97%). Before preparing the solutions, the salts

1070-4272/05/7809-1391 © 2005 Pleiades Publishing, Inc.

were dried at 125°C for 12 h in an inert atmosphere. Solvents were acetonitrile (AN, Kriokhrome, 0 grade) and dimethylformamide (DMF, Merck, 98%).

To determine the number of electrons participating in electrochemical processes, we used ferrocene $Fe(C_5H_5)_2$ (Merck, 98%) as a reference.

We used a computerized complex based on an Epsilon 2 (BAS) potentiostat for electrochemical experiments, which were carried out in a hermetically sealed three-electrode cell with separated electrode compartments. A working electrode was a BAS MF 2012 glassy graphite disk 3 mm in diameter (surface area 0.07 cm^2). The surface of the working electrode was polished prior to the experiments using diamond powders with particle sizes of 3 and 1 μm (BASi PK-4 polishing kit), washed with acetonitrile, and dried in air. The reference electrode was AgCl/Ag filled with a saturated NaCl solution (RE-5B BAS). All potentials are given relative to this reference electrode. An auxiliary electrode was a platinum grid (surface area about 5 cm^2). The voltammograms of the processes involving some of the complexes under study in acetonitrile solutions are given as an example in Fig. 1. The voltammograms were recorded by single scanning of the potential from 0 to the anode region up to 1.2–1.4 V and back. The anode part of the voltammograms is the most informative for studying electrolytic oxidation of the compounds under consideration, as the reverse potential scanning is accompanied by reduction of the forming polymeric complexes immobilized on the electrode surface, which is described by the relationships characteristic of thin-layer voltammetry. The voltammograms of all the complexes under study are characterized by the presence of two anode maxima; the overall shape of the anode branches of the voltammograms corresponds to the EEC [9] mechanism of the electrolytic oxidation

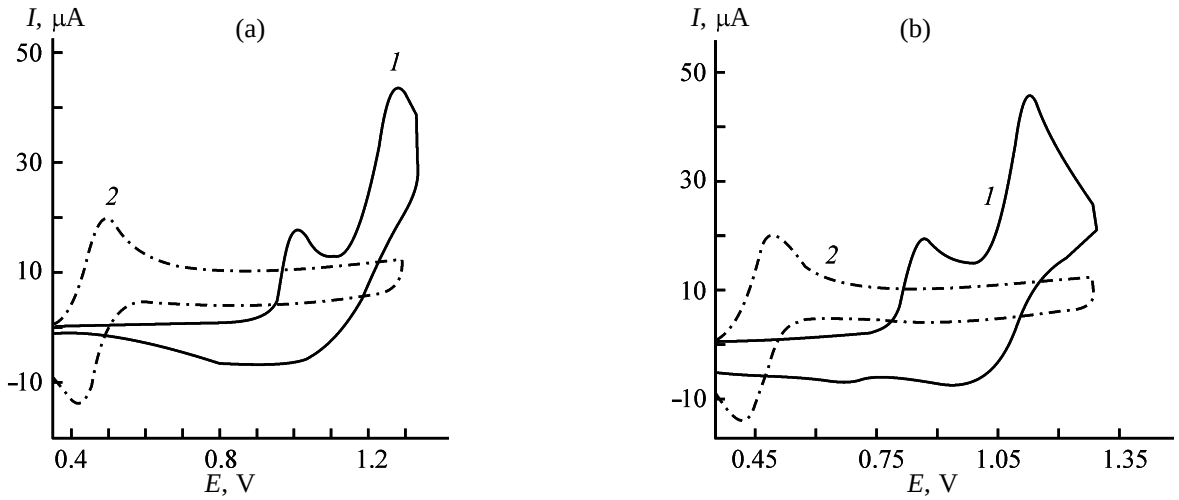


Fig. 1. Voltammograms of redox processes involving (*1*) complexes and (*2*) ferrocene, recorded with a glassy graphite electrode (S = 0.07 cm^2) in an AN solution. Potential scanning rate V_s = 0.05 V s^{-1}; the same for Fig. 2. Concentration (M): complexes and ferrocene 1×10^{-3}, $(Et_4N)BF_4$ 0.1. (*I*) current strength and (*E*) potential; the same for Fig. 2. (a) [Cu(SaltmEn)] and (b) [Cu(CH_3O–SaltmEn)]; the same for Fig. 2.

(E is an electrochemical stage, and C, a chemical reaction conjugated with it). Comparison of the oxidation voltammograms of the copper complexes and ferrocene used as a reference shows that both electrochemical steps are one-electron. The potentials of the anode maxima in the voltammograms of the complexes and individual ligands in AN and DMF solutions are given in Table 1.

An electrochemical study of the oxidation of [Cu(Schiff)] complexes revealed the following facts.

The formation of polymeric compounds on the electrode surface was observed only when the complexes were oxidized in a solvent with a low coordinating power (AN). As shown previously [10, 11] for the related nickel and palladium complexes, passing from AN to DMF having a higher donor number [10] favors stabilization of the electrochemical oxidation products in the form of inert octahedral complexes containing axially coordinated solvent molecules.

Using the reference compound, we found that the electrolytic oxidation of all the complexes under study is a two-electron process in both acetonitrile and DMF. When the complexes [Cu(SalEn)] and [Cu(SaltmEn)] are oxidized in DMF solutions, the potentials of the maxima of both oxidation waves are close to each other, and, as a result, only one anodic current maximum is observed in the voltammograms. At the same time, it was found by *in situ* microgravimetry [12] that the electrochemical oxidation of the copper complexes under consideration in acetonitrile solutions involves one electron per fragment of a [Cu(Schiff)] polymer. The whole set of these facts indicates that, when a polymer is formed, the two-electron oxidation of the starting complex is accompanied by a chemical reaction of the coordination of a [Cu(Schiff)] molecule to the product of the electrolytic oxidation.

The potentials E_{pa1} for [Cu(SalEn)] and [Cu(SaltmEn)] and E_{pa2} for [Cu(CH_3O–SalEn)] and [Cu(CH_3O–SaltmEn)] in the voltammograms of the complexes in acetonitrile solutions are close to each other (1.00–1.12 V), irrespective of the presence of electron-donor methoxy groups in the phenyl moiety. A similar fact is observed also in the voltammograms recorded in DMF (1.05–1.08 V).

Table 1. Potentials of anode maxima E_{pa1} and E_{pa2} of voltammograms of the complexes [Cu(Schiff)] and ligands H_2(Schiff). V_s = 0.05 V s^{-1}

Complex, ligand	AN		DMF	
	E_{pa1}	E_{pa2}	E_{pa1}	E_{pa2}

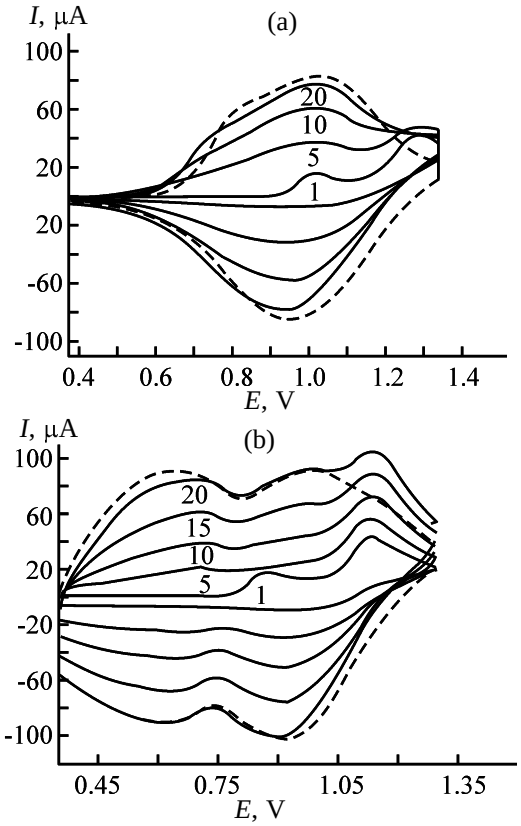

Fig. 2. Voltammograms of redox processes involving complexes, recorded with a glassy graphite electrode (S = 0.07 cm^2) in acetonitrile solutions. Concentration (M): complexes 1×10^{-3}, $(Et_4N)BF_4$ 0.1. (a) [Cu(SaltmEn)] and (b) [Cu(CH_3O–SaltmEn)]. Numbers at curves correspond to successive cycles. Dashed lines: voltammograms of polymers recorded after polymerization termination (20 cycles) and transfer of the modified electrode into a supporting electrolyte [0.1 M $(Et_4N)BF_4$, AN, V_s = 0.05 V s^{-1}].

Presumably, these oxidation waves correspond to the electron transfer from predominantly metal-centered orbitals of the complexes. Apparently, the second oxidation waves of the complexes [Cu(SalEn)] and [Cu(SaltmEn)] and the first oxidation waves of [Cu(CH_3O–SalEn)] and [Cu(CH_3O–SaltmEn)] are determined by the electron transfer from predominantly metal-centered orbitals. This is proved by the fact that the maxima of potentials of these waves are considerably shifted toward the negative region when electron-donor methoxy groups are introduced into the phenyl moieties.

The introduction of four methyl groups into the diamine bridge connecting the phenyl moieties does not result in a noticeable change in the electron density on the ligands, as methyl groups are weak donors. Therefore, the potentials of the current maxima in the oxidation voltammograms of the complexes [Cu(SalEn)] and [Cu(SaltmEn)] are close to each other. The same is also true for [Cu(CH_3O–SalEn)] and [Cu(CH_3O–SaltmEn)].

The limiting step of the polymerization of the complexes under study is the diffusion of the starting compounds to the electrode surface, which is confirmed by the fact that the currents of the anode maxima in the voltammograms increase linearly as the concentration of the starting substances in solution increases (in the range 1×10^{-4}–3×10^{-3} M).

On the whole, the experimental data for the complexes [Cu(Schiff)] agree with the general mechanism of the electrochemical oxidation of complexes [M(Schiff)] suggested previously [10, 11].

The formation of the polymeric complexes poly-[Cu(SaltmEn)] and poly-[Cu(CH_3O–SaltmEn)] on the surface of a glassy graphite electrode in the case of potential cycling is shown in Fig. 2. The voltammograms of the polymers recorded after the polymerization was complete and the modified electrode was transferred into the supporting electrolyte are also shown in Fig. 2 for comparison.

The regular increase in the currents of the anode and cathode maxima in the voltammograms correspond to the growth of polymeric compounds on the electrode. In the course of the formation of polymers, starting from the second cycle, a new broad anodic wave of the oxidation of polymers on the electrode surface is observed in the voltammograms at potentials more negative than E_{pa1}. At the same time, the anode wave corresponding to the transfer of the second electron, after which the formation of the polymer was observed according to [13], is absent from the voltammograms recorded in the supporting electrolyte solution with electrodes modified with the polymers (Fig. 2, dashed curves). The common trend for all the polymers studied is a shift of the region of redox processes to the side of less positive potentials when donor methoxy groups are introduced into the ligand. The introduction of methyl groups into the diamine bridges between phenyl moieties does not noticeably affect the shape and position of the voltammograms of the polymers. Thus, the voltammograms of the polymeric complexes poly-[Cu(SalEn)] and [Cu(SaltmEn)] only slightly differ from each other in the specified parameters.

Two pairs of anode and cathode waves are observed in the voltammograms of all the polymeric complexes studied. At the same time, it was found previously for nickel [14] and copper [12] polymeric complexes that the reduction–oxidation of polymers

in the range of potentials 0–1.3 V is characterized by the transfer of one electron per fragment. At present, the nature of processes giving rise to two pairs of waves in the voltammograms of the polymeric complexes under discussion is not determined unambiguously. A possible reason for the observed shape of the voltammograms can be the presence of two polymeric forms on the electrode surface, which are bound to the surface owing to the interaction between predominantly metal- or ligand-centered orbitals of the surface fragments of stacks and are correspondingly oxidized (or reduced) at different potentials. The other probable reason for the appearance of the broadened oxidation waves corresponding to the redox processes in the polymers can be the presence of polymeric stacks of different length on the surface, having different resistance to charge transfer.

Polymeric complexes can be formed also in a static mode when an electrode is polarized in a solution of the starting compound at a constant potential. In this case, the most important parameter is the polymer formation potential providing, on the one hand, a sufficient rate of the electrochemical process and, on the other hand, the absence of side reactions resulting in the degradation of the polymer or in the loss of its electrochemical activity. The criterion for choosing the optimal potential of the formation of polymers can be the charge diffusion coefficient D_{ct} reflecting the redox conductivity of the polymeric compounds.

To choose an optimal formation potential, we have prepared polymer films at various potentials in the range 0.9–1.2 V. The coefficients of charge diffusion in polymers were calculated by the Randles–Sevcik equation [15] on the basis of voltammograms recorded at potential scanning rates that provided the occurrence of redox processes in the polymer in the mode corresponding to the conditions of semiinfinite diffusion of current carriers. The calculation of the charge diffusion coefficients implies the exact knowledge of concentration of redox centers in the polymer, i.e., of the density of the polymeric film [16]. The density of the polymeric films based on the complexes with the ligand SalEn, about 1 g cm^{-3}, was determined previously by *in situ* ellipsometry [13]. Certainly, the density of the polymers depends on the presence of various substituents in the ligand surrounding, altering the geometry of the starting monomeric fragments. The exact values of the density of the polymers containing SaltmEn and CH_3O–SaltmEn ligands are unknown; therefore, the density of the polymers in these calculations was taken equal to 1 g cm^{-3}. This assumption does not allow us to compare the charge transfer rates in various polymers. Nevertheless, the resulting D_{ct} values can be used for comparison of charge transfer rates in the same polymer formed under different conditions.

The resulting D_{ct} values for all the complexes under study are close to each other and fall into the range $(1 \pm 0.5) \times 10^{-10}$ $cm^2\ s^{-1}$ for the range of the formation potential 1.00–1.10 V. This range of the polymer formation potentials is more positive than the potential of the first anodic maximum in the oxidation voltammograms of the starting complexes and, at the same time, overlaps with the range of potentials of the second oxidation process (Table 1). The formation of polymers at potentials lower than 0.95 V apparently results in the fact that the primary product of the electrolytic oxidation of the starting compound is partially stabilized owing to side processes involving a solvent, instead of the transfer of the second conduction electron. Monomeric and oligomeric fragments forming by the side processes can be captured by the growing polymeric film, which disturbs its structure and results in a decrease in the efficiency of the motion of charge carriers (in this case, the resulting D_{ct} values are close to 10^{-11} $cm^2\ s^{-1}$).

The formation of polymers at potentials higher than 1.2 V is accompanied by the irreversible oxidation of the ligand surrounding of the complexes and results in the loss of the polymer electrochemical activity.

The nature of the limiting step of charge transfer processes in the films of the polymers under study was determined by studying the effect of the size of charge-compensating ions (BF_4^-, ClO_4^-, and PF_6^-) [17] and concentration of supporting electrolytes (0.05–0.5 M) on D_{ct}. The experiments showed that the charge transfer rate in all the polymers studied is independent of the size of charge-compensating anions and of their concentration in solution. The results obtained show that the charge transfer in these films is limited not by the stage of diffusion of counterions in them, but by the rate of electron motion along polymeric stacks; therefore, the resulting D_{ct} values characterize the rate of specifically this process.

To compare characteristics of the charge transport in the polymeric complexes with various ligands and metallic centers, we can use the products of the concentrations of redox centers in a polymer c (mol cm^{-3}) by $D_{ct}^{1/2}$ values dependent on changes in the structure of polymers with variation of their composition and on the efficiency of the motion of charge carriers. The $cD_{ct}^{1/2}$ values for the poly-[Cu(Schiff)] polymers calculated by the Randles–Sevcik equation are given in Table 2; the related characteristics of nickel- and

palladiuim-containing polymeric complexes obtained previously [18] are given for comparison.

Our results allow the following conclusions: (i) $cD_{ct}^{1/2}$ parameters for the copper complexes studied are lower than those for the polymeric nickel and palladium complexes; (ii) poly-[Cu(Schiff)] polymers are characterized by slow electron transport in stacks in contrast to nickel- and palladium-containing polymers, in which the limiting step of the charge transport is the motion of charge-compensating ions [18]; (iii) the effect of substituents in ligand surroundings on the behavior of compounds in polymeric complexes poly-[Cu(Schiff)] essentially differs from that in the nickel- and palladium-containing polymers owing to a change in the nature of the limiting step of the charge transport. In particular, for poly-[Ni,Pd(Schiff)] complexes, $cD_{ct}^{1/2}$ substantially increases on passing from the polymers with the SalEn ligand to those with the SaltmEn ligand. As shown in [19], the introduction of four methyl groups into the structure of the diamine bridge between the phenyl moieties results in a noticeable increase in the repulsive interactions between the polymer stacks and in the formation of a less compact polymeric film. For [Cu(Schiff)] polymers, such a change in the ligand surrounding results in increasing efficiency of the motion of charge-compensating ions, but does not noticeably affect the charge-transfer rate.

It is known that [Cu(Schiff)] complexes, unlike the related nickel and palladium compounds, form intermolecular associates in the solid phase, in which copper atoms are bound to each other through the oxygen atom of a Schiff base. In the associates, the length of the bond between the copper atom of one molecule and the oxygen atom of another molecule is 2.41 Å [20]. Presumably, in [Cu(Schiff)] the bonds between separate fragments in a stack are similar in nature [21]. At the same time, it was found that in the nickel and palladium polymeric complexes with Schiff bases, the bonds between separate fragments of stacks are formed by interaction of the metallic centers with the phenyl moieties of the ligands [22, 23]. The difference in the nature of bonds between fragments of stacks in the copper polymeric complexes compared to nickel- and palladium-containing polymers offers an explanation for the data obtained in this study, in particular, for a lower electronic conductivity of poly-[Cu(Schiff)] complexes.

CONCLUSIONS

(1) Previously unknown polymeric copper complexes with the ligands *N*,*N*'-2,3-dimethylbutane-2,3-diylbis(salicylidenimine) and *N*,*N*'-2,3-dimethylbutane-2,3-diylbis(3-methoxysalicylidenimine) were prepared. The conditions for the electrochemical synthesis of the polymers with the highest redox conductivity [optimal potentials of the formation of copper(II) polymeric complexes with Schiff bases, nature and concentration of the supporting electrolyte] were determined.

(2) The oxidation of the poly-[Cu(Schiff)] complexes occurs by the two-electron mechanism with the subsequent chemical step of the coordination of a starting complex molecule to the product of the electrochemical oxidation; the limiting step of the polymerization is the diffusion of the starting compounds to the electrode surface.

(3) A study of the mechanism and kinetics of charge transport showed that the electron transfer in a stack occurs through an oxygen atom. Therefore, these polymeric compounds are characterized by a slow electron transport along stacks, and the parameter $cD_{ct}^{1/2}$ for the copper(II) complexes studied is lower than for the related nickel and palladium polymeric complexes.

(4) Variation of the ligand surrounding does not affect the charge-transfer rate.

(5) The trends revealed in this study allow purposeful synthesis of electroactive polymeric materials with a preset range of potentials of the electrochemi-

cal activity and with the required rate of charge transport.

ACKNOWLEDGMENTS

This study was financially supported by the Russian Foundation for Basic Research (project no. 04-03-32979).

The authors are grateful to Dr. Dale Svensson (University of Iowa, the United States) for the assistance in X-ray diffraction analysis of the compounds.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Phase Diagram and Properties of Glasses of the System Sb_2S_3–AgI

Mokhammad Arif, G. V. Samoilenko, Yu. G. Sergeev, and L. N. Blinov

St. Petersburg State Polytechnic University, St. Petersburg, Russia

Received February 16, 2005

Abstract—The phase diagram of the system Sb_2S_3–AgI was constructed from data of the differential thermal and X-ray phase analyses. The physicochemical properties of glassy and crystalline alloys were studied.

The studies performed in Russia show that introduction of halides of heavy *p, d* elements into an Sb_2S_3 melt allows preparation of glassy alloys within a considerably extended region. The glasses show high stability and have high refractive index, which is necessary for manufacturing fiber optic elements for the IR range [1–4].

The system Sb_2S_3–AgI was also studied by Mentus *et al*. [5]. They measured the electrical conductivity of the glasses σ as a function of composition in the temperature range from room temperature to 280°C. By a number of parameters, a glass of the composition $(Sb_2S_3)_{0.4}(AgI)_{0.6}$ having a high ionic conductivity ($\sigma = 10^{-3}\ \Omega^{-1}\ cm^{-1}$) stands out. The impedance characteristics obtained in [5] showed that the electrical conductivity of this glass at 147°C changed jumpwise from 10^{-4} to $10^{-1}\ \Omega^{-1}\ cm^{-1}$. This behavior was attributed to the β-AgI–α-AgI phase transition.

The above system was also studied studied by Sun *et al*. [6]. In this system, the region of glass formation by hard quenching was 0.10–0.67 AgI (mole fraction scale), the remainder being Sb_2S_3. For certain compositions, the concentration dependence of the electrical conductivity was studied. An IR study suggested the occurrence of the exchange chemical reaction in the melts:

$$Sb_2S_3 + 2AgI \rightarrow Ag_2S + 2SbSI \qquad (1)$$

Formation of glassy alloys in the system Sb_2S_3–AgI was studied in the 1990s [7, 8]. This study was of practical significance for developing membranes of chemical sensors. A Mössbauer study with ^{129}I, ^{121}Sb, and ^{110}Ag isotopes ruled out the exchange reaction (1). It was established experimentally that silver is in the iodide rather than in the sulfide surrounding.

Thus, published data on the chemical interaction of components in the Sb_2S_3–AgI system are contradictory. In addition, the number of AgI modifications and their notations in different publications are inconsistent [9, 10, 15–20]. Therefore, we chose another approach. First we analyzed the possibility of occurrence of various chemical reactions by calculating the Gibbs energy ΔG^0 and then constructred the phase diagram and studied some optical properties (transparency in the IR region and refractive index).

To study the chemical interaction of components and assess the possibility of occurrence of exchange reactions in the Sb_2S_3–AgI system from ΔH_f^0 and ΔS_f^0 values [9, 10] (see table), we calculated the Gibbs energy ($\Delta G^0 \equiv \Delta H^0 - T\Delta S^0$) at T = 298 K for the reactions

$$Sb_2S_3 + 2AgI \rightleftarrows 2SbSI + Ag_2S, \qquad (2)$$

$$Sb_2S_3 + 6AgI \rightleftarrows 2SbI_3 + 3Ag_2S. \qquad (3)$$

The results obtained in calculating the isobaric–isothermal potential of the reaction ΔG^0 showed that reactions (2) and (3) cannot proceed, since $\Delta G^0 > 0$ [49.3 and 231.6 kJ mol^{-1} for reactions (2) and (3),

respectively]. Therefore, to solve properly the problem of chemical interaction of the system components, we constructed the phase diagram of the Sb_2S_3–AgI system. To do this, we performed the differential thermal (DTA) and X-ray phase (XPA) analyses.

EXPERIMENTAL

The glasses were synthesized in a horizontal electrical furnace at continuous agitation of the melt placed in preliminarily evacuated quartz ampules. The maximal temperature of the synthesis was 700°C and the synthesis time, 6 h. The ampules with the melt were cooled in air. The glasses were synthesized from antimony (SU-000 grade), sulfur (16-5 ultrapure grade), and AgI (chemically pure grade). Antimony trisulfide was synthesized in evacuated quartz ampules by the reaction $2Sb + 3S \rightarrow Sb_2S_3$ at $T_{max} = 700$°C. AgI was prepared by the reaction of $AgNO_3$ and KI solutions: $AgNO_3 + KI \longrightarrow AgI\downarrow + KNO_3$. All the reactants were of chemically pure grade. The yellow AgI precipitate was thoroughly washed many times with distilled water, filtered off, dried, and then heated in a vacuum ($P = 10^{-3}$ mm Hg) to 220°C for 3 h. After that, X-ray diffraction patterns (DRON-3 diffractometer, FeK_α radiation) were taken at room temperature. From these diagrams, Sb_2S_3 and AgI were identified and X-ray amorphous structure of the glassy compositions in the Sb_2S_3–AgI system was confirmed. The synthesis was performed no less than three times to obtain reproducible results.

The glass density ρ was determined by the method of hydrostatic weighing in toluene at room temperature. The density of toluene was checked by the density of a germanium single crystal. The refractive index n was determined on plane-parallel glass samples by a defocusing method with an MIK-1 microscope at $\lambda = 1.1$ μm. The IR transmission spectra were recorded on a UR-20 spectrophotometer.

The glass transition point T_g, the temperature of the glass–crystal transition (crystallization point) T_c, and the temperature of the end of the melting T_l were determined by the methods used in [12, 13]. To construct the phase diagram of the Sb_2S_3–AgI system, the alloys synthesized were annealed at a temperature below the crystallization point (200°C) for 100 h. The thermographic study of the samples was performed within 20–700°C on an installation described in [11]. The sample weight was 0.5 g.

The phase diagram of the Sb_2S_3–AgI system was constructed from the experimental data obtained by DTA and XPA of annealed crystalline samples

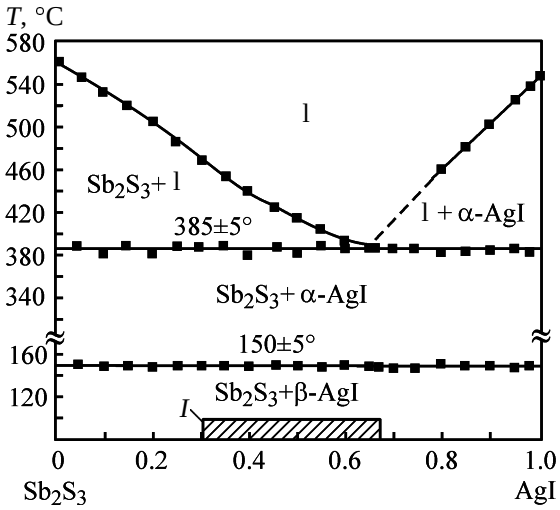

Fig. 1. Phase diagram of the system Sb_2S_3–AgI (mole fraction scale). (*T*) Temperature. (*I*) Glass formation range.

(Fig. 1). It was found that, upon spontaneous cooling of the melt in air, glassy alloys are formed in the composition range 0.30–0.67 AgI (mole fraction scale). Because the alloys tend to supercool, DTA curves were taken solely in the heating mode at a heating rate of 5 deg min^{-1}.

The glassy samples obtained were characterized by a shell-like fracture, X-ray amorphous structure, and existence of a glass transition point; they were transparent under an IR microscope. As illustration, we present X-ray diffraction patterns (Fig. 2) and thermograms (Fig. 3) of certain alloys in glassy and crystalline states.

The diffraction patterns of the glassy alloys exhibit no reflections (Fig. 2a), whereas the diffraction patterns of all the crystalline alloys contain reflections corresponding to Sb_2S_3 and AgI (Fig. 2b). This result agrees with the previous calculation of the Gibbs energy ΔG^0 of reactions of Sb_2S_3 and AgI and with the data of [7, 8].

The thermograms of the alloys studied exhibited peaks at T_g and T_c, along with the three thermal effects. The first effect corresponds to the temperature of the end of melting of the alloy T_l (liquidus line). The second is observed for all the alloys (except for the alloys of the initial components Sb_2S_3 and AgI) at 385 ± 5°C (solidus line T_s). Except for Sb_2S_3, the third thermal effect at 150 ± 5°C is observed in all the alloys and in AgI, with its value the lower, the smaller the AgI concentration (Fig. 3).

Our results suggest with confidence that (1) the constructed phase diagram of the Sb_2S_3–AgI system

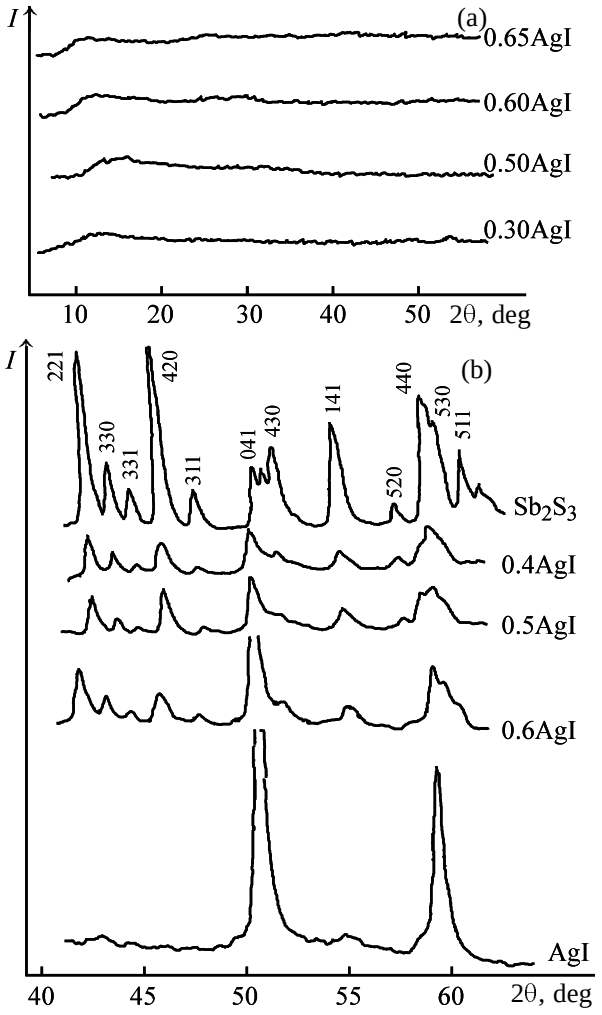

Fig. 2. X-ray diffraction patterns of (a) glassy and (b) crystalline alloys of the system Sb_2S_3–AgI (mole fraction scale). (*I*) Reflection intensity and (2θ) Bragg angle.

(Fig. 1) belongs to phase diagrams with nonvariant eutectic transformation ($l \rightleftarrows Sb_2S_3 + AgI$ at 385±5°C) and has an eutectic point at AgI mole fraction of 0.67; Sb_2S_3 crystallizes from the subeutectic alloys after a liquidus temperature T_l is attained, and AgI, from the supereutectic alloys; (2) at 145±5°C, β-AgI (hexagonal modification) undergoes a polymorphous transition into α-AgI (cubic modification), which is in line with the data of [15, 16]; below the line of the eutectic transformation (i.e., solidus line), there is a region in which two phases, Sb_2S_3 and AgI, are in equilibrium.

It should be noted that, in the range of AgI mole fractions of 0.7–0.8, the critical temperature T_l was not present in the thermograms. This is likely due to a small amount of heat released upon the crystallization of a small amount of the excess AgI phase, which

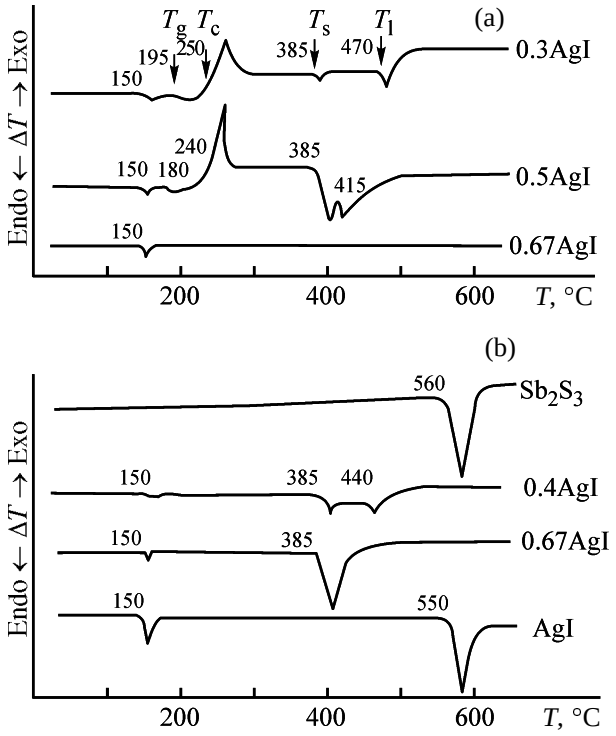

Fig. 3. DTA curves of (a) glassy and (b) crystalline samples in the Sb_2S_3–AgI system (mole fraction scale). (Δ*T*) Difference in temperatures between the sample and reference and (*T*) temperature.

is attributable to a regular decrease in the thermal effects with decreasing Sb_2S_3 concentration.

The dependences of T_g, T_c, and density ρ of the glassy samples on the composition are shown in Fig. 4a. With composition changing from 0.30 to 0.67 AgI (mole fraction scale), T_g and T_c decrease from 195 to 171°C and from 248 to 232°C, respectively, with the difference between them being about 50°C. In this case, the calculated criterion of the glass-forming ability, Hr, increases up to the AgI mole fraction of 0.67 and then decreases (Fig. 4b). As the AgI mole fraction is increased further above 0.67, the alloys are no longer amorphous. The density of the glasses regularly increases from 4.47 to 5.01 g cm^{-3} over the concentration range studied.

The Hruby criterion, Hr, is the ratio $Hr = (T_c - T_g)/(T_l - T_c)$. The larger $(T_c - T_g)$ and the smaller $(T_l - T_c)$, the larger the Hr value, and, consequently, the higher the glass-forming ability of the given melt. Published data show that, to compare the glass-forming abilities of different compositions, it is reasonable to calculate Hr. In this study, we made an attempt to find a correlation between Hr and an optical property, namely, the refractive index.

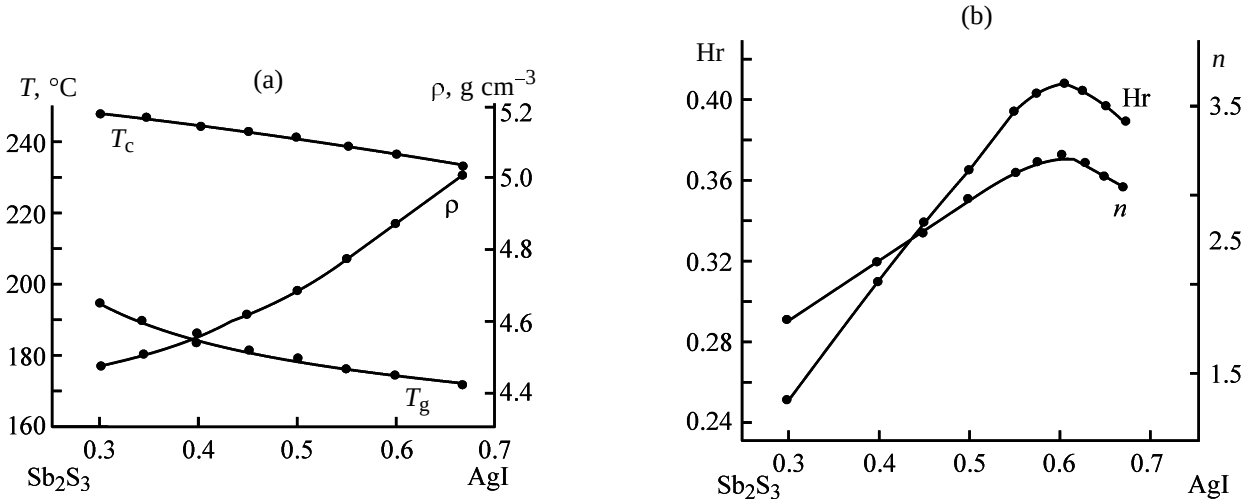

Fig. 4. (a) T_g, T_c, and ρ, and (b) refractive index n and Hr criterion vs. the composition of the Sb_2S_3–AgI glass (mole fraction scale).

The optical properties, refractive index n and transparency in the IR range, are important characteristics of iodine-containing chalcogenide glasses. Therefore, we studied how the composition affects these characteristics. The constructed dependence of the glass refractive index n on the AgI concentration in the alloy (Fig. 4b) shows that the refractive index from 1.90 to the maximum value n = 3.12 at AgI mole fraction of 0.60 and then decreases. The maximum n value is in the region of the eutectic composition. This is probably associated with higher homogeneity of the eutectic alloy in comparison with, e.g., subeutectic or supereutectic alloys.

The transmission spectra of two glassy compositions in the Sb_2S_3–AgI system are shown in Fig. 5.

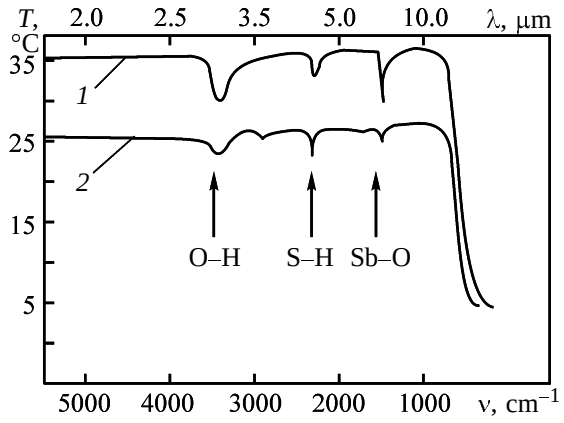

Fig. 5. IR transmission spectra of (*1*) $(AgI)_{0.4}(Sb_2S_3)_{0.6}$ and (*2*) $(AgI)_{0.6}(Sb_2S_3)_{0.4}$ glasses. Sample thickness 1.25 mm. (T_r) Transmission, (ν) wave number, and (λ) wavelength.

As seen, the glasses with the AgI mole fraction of 0.40 and 0.60 are transparent in the IR region up to a wavelength of 15 μm, and their optical transmission T (%) depends on the composition: the optical transmission of the glasses increases from 25 to 35% with increasing AgI content. At the same time, the intensity of the impurity absorption bands corresponding to O–H, S–H, and Sb–O in the transmission spectra increases. This fact shows that the initial AgI contains some water, which reacts with sulfur and antimony of the alloy. With changing composition, the absorption edge of the glasses studied does not noticeably shift to longer wavelengths.

CONCLUSIONS

(1) The phase diagram of the Sb_2S_3–AgI system with eutectic nonvariant transformation and polymorphous transition from the low-temperature β phase into the high-temperature α phase was constructed from data of differential thermal and X-ray phase analyses.

(2) The region of glass formation region in spontaneous cooling of the melts in air is within 0.30–0.67 AgI (mole fraction scale, remainder Sb_2S_3).

(3) In the region of the eutectic composition, the glasses studied have high, up to 3 and larger, refractive indices and are transparent in the IR range up to the wavelength λ = 15 μm.

(4) The glass with the AgI mole fraction of 0.60 can be used as a matrix for obtaining glasses with high ionic conductivity to produce on their basis

membranes for chemical sensors and a new class of biosensors to be used in medicine and biochemistry.

Abstract—Extraction of 1-methylnaphthalene, benzo[*b*]thiophene, and indole with *N*-methylpyrrolidone from their model mixtures with hexadecane in the absence and in the presence of lower-boiling *n*-alkanes (hexane, decane, dodecane) was studied.

The requirements to the environmental safety of motor and boiler fuels became considerably more stringent in the past 5–10 years. The permissible concentration of sulfur and aromatic hydrocarbons in automobile gasolines, diesel fuel, black oil for ships, and boiler fuel is restricted.

The content of nitrogen in fuels is not restricted. However, nitrogen compounds in fuels are catalytic poisons, and with an increase in their content the efficiency of hydrorefining decreases. Also decreases the yield of light petroleum products in catalytic cracking and hydrocracking of vacuum gas oils and black oils.

Exhaustive removal of sulfur and nitrogen compounds from fuels using traditional hydrogenation methods requires elevation of partial hydrogen pressures and upgrade of installations with inclusion of additional hydrorefining reactors because of low feed space velocities; this requires large investments and increases the power consumption. Hydrogenolysis of 4,6-dialkyl derivatives of dibenzothiophene is especially difficult because of steric hindrance [2].

In the alternative extraction procedure for fuel treatment, on the contrary, such heteroatomic aromatic or partially aromatic compounds should be readily removed, as suggested by higher, compared to arenes, stability constants of the complexes with polar solvents, low enthalpies of mixing, and low activity coefficients. In particular, the formation constants of complexes of *N*-methylpyrrolidone with benzo[*b*]thiophene and naphthalene at 20°C are 1.9 and 0.6 l mol^{-1}, respectively [3]. The activity coefficients of benzo[*b*]-thiophene and naphthalene at infinite dilution in diethylene glycol at 30°C are 6.6 and 11.2 [4]. The enthalpies of specific interaction of 1-methylnaphthalene, benzo[*b*]thiophene, and indole with *N*-methylpyrrolidone at 25°C are –33.5, –38.4, and –54.4 kJ mol^{-1}, respectively [5].

However, data on the extractive recovery of heteroatomic compounds and arenes are contradictory. For example, Podolyak *et al.* [6] report that benzothiophene is extracted better than naphthalene. At the same time, data obtained by Bikkulov *et al.* [7] indicate that naphthalene homologs are extracted from kerosene–gas oil fractions with *N*-methylpyrrolidone better than benzothiophene homologs.

Therefore, taking also into account problems with the determination of nitrogen compounds (whose content in petroleum fractions is by an order of magnitude lower than that of organosulfur compounds), it is urgent to examine the relative efficiency of extraction of arenes and aromatic sulfur and nitrogen compounds from model mixtures with saturated hydrocarbons.

The goals of this study were to compare the efficiency of the extraction of heterocyclic sulfur- and nitrogen-containing compounds and polycyclic arenes from model mixtures with *n*-alkanes and to elucidate the influence exerted by various nonpolar diluents on the efficiency of the extraction of heterocyclic compounds and arenes.

As a polar solvent for the extraction of heterocyclic compounds and arenes we chose *N*-methylpyrrolidone. This extractant is commercially used both for extraction of benzene, toluene, and xylene from reformer naphthas and for selective refining of oil fractions [8].

We found previously [9–11] that the separation factors of hydrocarbons substantially increase when the extraction of benzene and naphthalene homologs with polar extractants (acetonitrile, methyl Cellosolve,

dimethylformamide) from model mixtures with saturated hydrocarbons is performed in the presence of pentane or other low-boiling nonpolar diluents.

It seemed interesting to reveal how the molecular weight of *n*-alkanes affects the selectivity of the extractive recovery with *N*-methylpyrrolidone of not only arenes but also heterocyclic compounds. As nonpolar *n*-alkanes (diluents), we chose hexane, decane, and dodecane.

The model hydrocarbon system used as a feed contained (wt %) 49.67 hexadecane, 40.25 1-methylnaphthalene, 5.00 benzo[*b*]thiophene, and 5.08 indole. All the components of the model hydrocarbon system have relatively close boiling points (°C); the difference is, however, sufficient for separation on PFMS-4 nonpolar phase in GLC analysis: benzo[*b*]thiophene 221–222°C, 1-methylnaphthalene 245°C, indole 254°C, and hexadecane 286.5°C. Each of the heterocyclic and aromatic components contains two fused aromatic rings. With respect to the boiling point, these components belong to the diesel fraction.

It is known, however, that there are linear correlations between the selectivities of solvents to different arenes (e.g., to homologs of mono-, bi-, and tricyclic arenes), to indole and carbazole, or to benzo[*b*]thiophene and dibenzothiophene. This is due to a common mechanism of specific interactions of polar solvents with benzologs or homologs of arenes and heterocyclic compounds. Therefore, the relationships that will be revealed with the chosen model system will be applicable to higher-boiling components, e.g., to systems consisting of phenanthrene (or anthracene) homologs, dibenzothiophenes, and carbazole homologs (these compounds are present in vacuum gas oils and black oils).

EXPERIMENTAL

N-Methylpyrrolidone, benzo[*b*]thiophene, 1-methylnaphthalene, indole, *n*-hexadecane, *n*-dodecane, *n*-decane, and *n*-hexane were freshly distilled; the main substance content, according to GLC, was no less than 99.8 wt %. Experiments on one-step extraction were performed in a hermetically sealed vessel equipped with a magnetic stirrer. The raffinate and extract phases were sampled with a microsyringe after complete phase separation and were analyzed by GLC (column length 3 m, internal diameter 3 mm, stationary phase PFMS-4, solid support Chromaton N-AW-HMDS, carrier gas He, column temperature 160°C, vaporizer temperature 280°C, thermal conductivity detector, detector temperature 250°C). The compositions of the equilibrium phases were calculated using the calibration coefficients determined with reference mixtures: hexane 0.87, *N*-methylpyrrolidone 0.92, decane 0.94, benzo[*b*]thiophene 0.96, 1-methylnaphthalene 1.00, dodecane 1.10, hexadecane 1.16, and indole 1.22. With decane used as nonpolar diluent, an additional analysis on the Carbowax stationary phase was made.

We examined the influence exerted on the extraction efficiency by the following parameters (Table 1): water content in *N*-methylpyrrolidone (run nos. 1–3), extractant : feed ratio (run nos. 2, 4, 5), nonpolar diluent (decane) : feed ratio (run nos. 8–10), and molar weight of the nonpolar diluent, alkane (run nos. 6–8). Run no. 11 was performed with a different model mixture containing approximately equal amounts of the components to be extracted (wt %): benzo[*b*]thiophene 5.79, 1-methylnaphthalene 6.33, indole 4.74, and hexadecane 83.14. It is known that the distribution factors of components depend on their

* The values of K_d and β were calculated from the compositions of phases, without taking into account the nonpolar diluent.

content in the feed; in run no. 11, this factor is virtually eliminated.

As example, we present the material balance for one of extraction runs, calculated using the yields of the raffinate and extract phases and their compositions determined by GLC (Table 2).

As seen from Tables 3 and 4, the efficiency of the extraction of the components (with respect to all the parameters) increases in the order 1-methylnaphthalene < benzo[*b*]thiophene < indole. The degree of recovery and the distribution and separation factors increase in the same order.

At similar concentrations of the extractable components in the feed (Table 3, run no. 11), the distribution factors of benzo[*b*]thiophene and indole are higher than those of 1-methylnaphthalene by factors of 1.5 and 2.5, respectively.

The increased distribution factors of benzo[*b*]thiophene and separation factors are due to the higher electron-donor power of this compound compared to 1-methylnaphthalene. Still higher distribution and separation factors for indole are due to an additional kind of specific interaction, hydrogen bonding between *N*-methylpyrrolidone and labile N–H proton of indole.

With moist *N*-methylpyrrolidone used instead of the anhydrous extractant, the separation factors and concentrations in the extract of 1-methylnaphthalene, benzo[*b*]thiophene, and indole increase, but the degree of recovery and the distribution factors decrease. This is caused by the high selectivity of water to arenes and aromatic heterocyclic compounds and by the low solvency of water.

With an increase in the extractant : feed ratio from

1 : 1 to 2 : 1 (run nos. 5 and 2), the degrees of recovery of the extractable components increase (for benzo[*b*]thiophene and indole to a greater extent than for 1-methylnaphthalene), but the concentrations of the extractable components in the extract and the separation factors decrease. These results are attributable to greater transfer of hexadecane to the extract phase with an increase in the extractant : feed ratio and to an increase in the distribution factor of hexadecane from 0.04 (run no. 5) to 0.061 (run no. 2).

It is interesting to compare the data on the extraction of *N*-methylpyrrolidone without nonpolar diluent and in the presence of various alkanes of lower molecular weight compared to hexadecane. With an increase in the number of carbon atoms in alkane molecules, their activity coefficients in *N*-methylpyrrolidone increase and the mutual solubility decreases, as indicated by the critical solution temperatures (CSTs). For example, the CSTs of hexane and hexadecane with *N*-methylpyrrolidone are 51.85 and 94.45°C, respectively [12].

Therefore, the distribution factor of hexane, calculated from data in Table 2 (K_d = 0.112), is considerably higher than that of hexadecane (K_d = 0.042) in the same run no. 6. Relatively low-boiling nonpolar solvent can be readily distilled off from the extract phase, to obtain increased concentrations of the extractable components in the extract. The separation factors for the systems hexadecane–arene and hexadecane–heterocyclic compounds also increase appreciably. This trend may be due to the fact that *N*-methylpyrrolidone concentrating in the extract phase is selective to aromatic compounds, whereas the nonpolar diluent concentrating in the raffinate phase is selective to hexadecane and favors its transfer to the raffinate phase.

A drawback of the exctraction using systems polar extractant–nonpolar diluent is decreased recovery of the extractable components. This is caused by the fact that these components are readily soluble not only in *N*-methylpyrrolidone but also in the nonpolar diluent. Both the separation factors and the degrees of recovery of arenes and heterocyclic compounds can be increased by taking a higher ratio of the polar solvent to the feed.

With a higher-boiling alkane, decane or dodecane, used as a nonpolar diluent instead of hexane, the separation factors of the components increase to a still greater extent. This result can be accounted for as follows. With a decrease in the difference between the molar volumes of the saturated hydrocarbons of the feed (hexadecane in our case) and nonpolar diluent, the entropy constituent of the activity coefficient of, e.g., hexadecane decreases in accordance with the Flory–Huggins equation, which results in the growth of the selectivity to hexadecane in the order hexane < decane < dodecane.

With an increase in the ratio of the nonpolar diluent (decane) to feed, the separation factors and concentrations of the extractable components in the extract increase to a still greater extent, but this is accompanied by a decrease in the degree of recovery.

Table 5. Changes in the extraction parameters in run no. 7 relative to run no. 3

Parameter	1-Methyl-naphthalene	Benzo[*b*]-thiophene	Indole
Concentration, rel %:			
in raffinate	–3.7	–1.5	–7.9
in extract	+5.1	+3.8	+6.1
Recovery, rel %	–0.1	–1.6	+0.7
Distribution factor, rel %	+10.8	+11.7	+29.6
Separation factor, rel %	+45.1	+46.4	+69.8

Thus, there are two ways to increase the separation selectivity at a fixed temperature: (1) using the moist extractant and (2) using the extraction system polar extractant–nonpolar diluent. The efficiencies of these two approaches are compared in Table 5 (extraction run nos. 3 and 7). In run no. 3, the extractant contained two times more water, and run no. 7 was performed in the presence of dodecane. Table 5 shows that the recovery of 1-methylnaphthalene, benzo[*b*]-thiophene, and indole in run nos. 3 and 7 is virtually equal, and with respect to all the other parameters the extraction in the presence of dodecane is more efficient: the distribution and separation factors and the concentrations of the extractable components in the extract are higher, and their residual concentrations in the raffinate are lower. The yield of the raffinate in run no. 7 is also higher (by 2.25 wt %) than in run no. 3.

The advantages of the extraction system extractant–nonpolar diluent, compared to the moist extractant, should become more pronounced in going from one-step to multistep extraction.

CONCLUSIONS

(1) The efficiency of extraction of aromatic compounds with *N*-methylpyrrolidone from mixtures with saturated hydrocarbons increases in the order alkylnaphthalenes < benzo[*b*]thiophene < indole. The separation factors in the systems with benzo[*b*]thiophene and indole are higher than in the systems with 1-methylnaphthalene by factors of approximately 1.5 and 2.5, respectively.

(2) Extraction of arenes and heterocyclic compounds with a polar extractant in the presence of a nonpolar diluent is a more efficient way to increase the separation selectivity, compared to the use of the moist extractant.

(3) The separation factors in the systems hexadecane–1-methylnaphthalene, benzo[*b*]thiophene, or indole in the extraction with *N*-methylpyrrolidone in the presence of a nonpolar diluent (alkane) increase in the order of diluents hexane < decane < dodecane.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Solid-Phase Extraction of Aliphatic Amines from the Aqueous Phase with a Methacrylate Polymer

M. A. Gavrilenko, N. A. Gavrilenko, and M. G. Mokrousov

Tomsk State University, Tomsk, Russia

Received December 30, 2004; in final form, April 2005

Abstract—Solid-phase extraction of aliphatic amines from aqueous solutions with a methacrylate polymer was studied. The possibility of simultaneous sorption of amines considerably differing in the boiling point was examined.

Aliphatic amines widely occur in the nature. They act as secondary pollutants forming by biodegradation of nitrogen-containing compounds, including proteins and amino acids [1]. The necessity of monitoring amines is caused not only by an unpleasant odor of some of them, but also by the possibility of their transformation under certain conditions into considerably more hazardous nitrosamines [2].

Toxic amines are particularly hazardous in aquatic objects [3]. Owing to high polarity, amines are readily soluble in water, and their recovery is difficult. Amines are usually determined by capillary gas and liquid chromatography [4, 5]. Despite high sensitivity of these methods, determination of amines requires preconcentration. This is usually done by liquid [6, 7] and solid-phase [8, 9] extraction. A relatively new approach is solid-phase preconcentration of amines on the microlevel [10] involving the use of a detector highly selective to nitrogen. Also, Baltussen *et al.* [11, 12] suggested a combined approach involving solid-phase extraction with polydimethylsiloxane or poly(butyl acrylate) followed by thermal desorption into the chromatograph injector. However, nonpolar sorbents poorly extract polar amines, and polar poly(butyl acrylate) in the step of thermal desorption gives noise and false peaks in the chromatograms.

The use of styrene–divinylbenzene polymers, XAD, and cyclodextrins for solid-phase extraction of amines was described in numerous papers [13–16], but no acceptable procedure has been developed. Thus, studies in the field of sorption of polar substances from aqueous media remain very urgent.

In this study we examined solid-phase extraction of dimethylamine (DMA), ethylamine (EA), diethylamine (DEA), triethylamine (TEA), propylamine (PA), dipropylamine (DPA), and tripropylamine (TPA) from aqueous solutions with a polar hydrophobic methacrylate polymer (PM), followed by determination of the amines by capillary gas chromatography.

EXPERIMENTAL

The study was performed with a Shimadzu GC-9A gas chromatograph (Japan); a 25000 × 0.25-mm capillary column was coated with SE-30 (30 μm). The temperature of the detector and injector was 200°C. The column temperature program was as follows: 70°C, 1 min; heating to 200°C, 5 deg min^{-1}; 200°C, 3 min. The sample was pumped through the sorbent with a Gilson Minipuls-2 micropump (the United States).

Stock solutions of amines (1 g l^{-1}) were prepared in MILLI-Q water (Millipore, the United States) and were stored at 6°C. Working solutions (20–50 μg l^{-1}) were prepared just before the experiments in double-distilled water. Acidic solutions (pH < 4) were prepared with hydrochloric acid. The buffer solution with pH 9 was prepared by mixing 0.1 M solutions of potassium dihydrogen phosphate and sodium hydroxide.

The polymethacrylate sorbent was prepared by radical block copolymerization of methacrylate monomers, with benzoyl peroxide as initiator [17]. A 10 × 5-mm steel precolumn was packed with the sorbent of particle size 0.1–0.15 mm. Aqueous solutions of DMA, EA, DEA, TEA, PA, DPA, and TPA (50 μg l^{-1} each) were passed through the PM sorbent at pH 9. To evaluate the extractive power, we took 10 ml of the solution that passed through the sorbent and the same aliquot of the initial solution. Both samples were extracted with 1 ml of diethyl ether. The extracts were dried over anhydrous sodium sulfate and evaporated to 100 μl prior to the analysis. Before extraction of

1070-4272/05/7809-1408© 2005 Pleiades Publishing, Inc.

amines from aqueous solution, the column was dried with a nitrogen flow for 5 min. The amines were desorbed with diethyl ether (flow rate 0.1 ml min^{-1}). The resulting extract was drier over anhydrous sodium sulfate for 6 h and concentrated to a volume of 100 μl on a rotary evaporator under nitrogen.

The recovery of amines with the polymethacrylate at pH 9 was close to 100%, as judged from the absence of chromatographic peaks of the amines in the sample treated with the sorbent. However, at pH 7 and 3 the recovery was lower, ranging for various amines from 22 to 58 and from 11 to 28%, respectively (see table).

To determine the optimal conditions of the extraction of the amines with the PM sorbent, we examined how the recovery depends on the volume of the amine solution (20–400 ml) at a constant amount of the sorbent (200 mg) (Fig. 1) and on the sorbent amount at a constant volume of the amine solution (100 ml) (Fig. 2). We also studied the desorption with various amounts of diethyl ether (0.5–10 ml) at constant volume of the amine solution (100 ml) and constant amount of the sorbent (400 mg).

The extraction of DMA (which is washed out most readily) with 200 mg of PM is complete up to passing 80–100 ml of the amine solution; this volume can be increased by taking larger amounts of the sorbent. Further experiments were performed with 100-ml portions of the amine solution. No significant differences were observed in the experiments performed with different amounts of the sorbent. Further experiments were performed with 400-mg portions of PM. The optimal volume of diethyl ether was 2 ml per 400 mg of the sorbent.

The efficiency of the solid-phase extraction of amines with PM depends on the flow rate of the amine solution through the sorbent (Fig. 3). The best results in the group preconcentration of amines were obtained at a flow rate of 2 ml min^{-1}. For individual amines, the optimal flow rate is 1–2 ml min^{-1} for highly volatile DMA and 2–4 ml min^{-1} in the other cases. The narrow interval of the optimal flow rate in the extraction of amines is associated with the specific features of two-step preconcentration of polar substances on hydrophobic polar sorbents [18]. In the first step, the preconcentration occurs on the hydrophobic PM surface, after which the polar substances can diffuse into the bulk of the sorbent. Therefore, in the determination of amines, the flow rate should not be lower than 2 ml min^{-1}. However, the same effect allows PM to be used for solid-phase extraction of volatile polar compounds at low flow rates in the sorption and desorption steps. The chromatogram of a model solution containing all the examined amines (50 μg l^{-1} each) is shown in Fig. 4a.

Extraction of amines from aqueous solution (100 ml) at various pH

Amine	Recovery, %, at indicated pH		
	3.0	7.0	9.0
DMA	28.2	55.8	98.9
EA	22.8	35.5	95.6
DEA	15.5	49.7	100.0
TEA	18.4	68.4	94.0
PA	10.6	24.5	88.2
DPA	25.1	52.1	94.3
TPA	16.3	22.6	98.9

The detection limit of the amines in the procedure involving extraction with PM sorbent and detection by capillary gas chromatography was evaluated as the minimal detectable concentration at a signal-to-noise

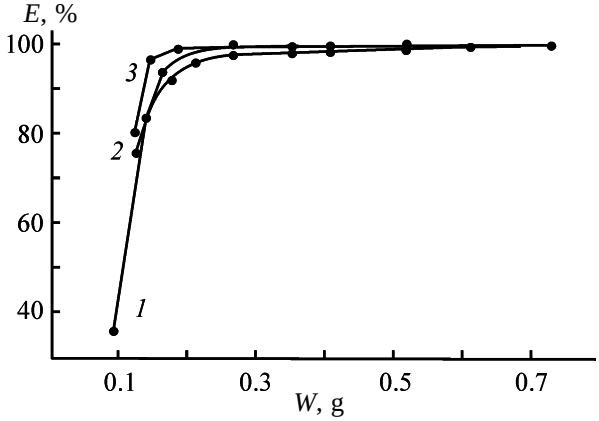

Fig. 2. Recovery *E* of (*1*) DMA, (*2*) DEA, and (*3*) DPA as a function of the sorbent weight *W* at a constant volume of the amine solution (100 ml).

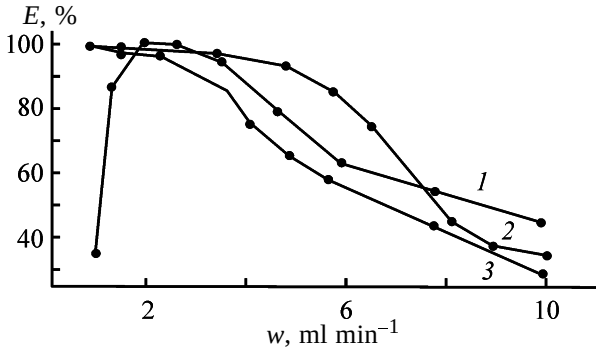

Fig. 3. Recovery *E* of (*1*) DEA, (*2*) DPA, and (*3*) DMA from aqueous solution as a function of the flow rate *w* of the amine solution through the sorbent.

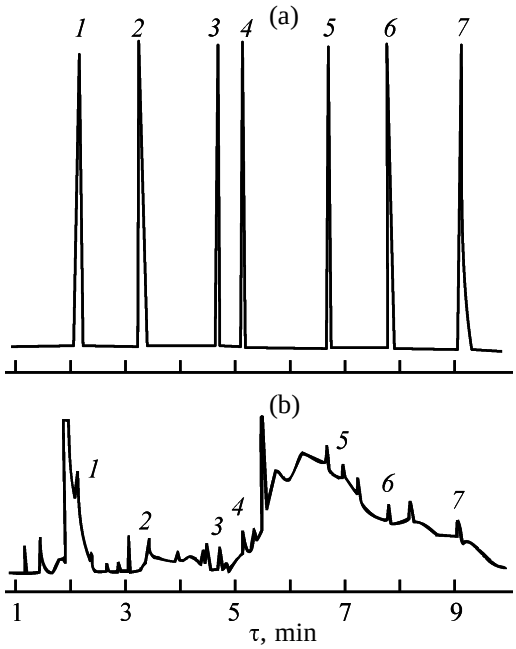

Fig. 4. Chromatograms: (a) reference solution of the amines (50 μg l^{-1} each) after solid-phase extraction with PM under optimal conditions and (b) river water sample (amine concentration 5 μg l^{-1}). (τ) Time. Amine: (*1*) DMA, (*2*) EA, (*3*) PA, (*4*) DEA, (*5*) TEA, (*6*) DPA, and (*7*) TPA.

ratio of 3 : 1. For the amines in question under the optimal conditions, the detection limit is 0.5–1.0 μg l^{-1}. At the sorbent weight increased to 600–800 mg and the sample volume, to 400 ml, the detection limit is 0.4–0.6 μg l^{-1} (Fig. 4b).

The suggested procedure of solid-phase extraction of amines was applied to analysis of river water samples. A 100-ml aliquot was filtered through a Nylon filter to remove solid particles and was adjusted to pH 9 with a buffer solution. No amines were detected by gas chromatography after preconcentration with the PM sorbent. Therefore, a solution of the amines used in our experiments was artificially added to the sample to obtain 5 μg l^{-1} concentration of each amine. The chromatogram of the resulting sample is shown in Fig. 4b.

CONCLUSION

Solid-phase extraction with a polymethacrylate sorbent allows efficient simultaneous preconcentration of amines with the boiling points varying in a wide range. Hydrophobic polar polymethacrylate sorbs polar amines and is chemically stable at various pH.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of Rhenium(VII) on Gel and Macroporous Anion Exchangers of Different Basicities from Solutions of Mineral Acids and Their Ammonium Salts

A. A. Blokhin, A. A. Amosov, Yu. V. Murashkin, S. A. Evdoshenko, M. A. Mikhailenko, and N. V. Nikitin

Received June 9, 2005

Abstract—Equilibrium sorption of rhenium on strongly basic gel-like anion exchanger Purolite A600, on weakly acidic anion exchangers Purolite A170 and A172 with macroporous and gel structures and on composite anion exchanger Purolite SIM202, which is a synthetic sorbent based on super-cross-linked polystyrene impregnated with trialkylamine Alamine 336, was studied in a wide range of concentrations of sulfuric, hydrochloric, and nitric acids and of their ammonium salts.

Rhenium belongs to elements that are the least abundant in the earth's crust. No proper rhenium deposits are found in the nature. Rhenium is obtained as by-product of refinement of copper–molybdenum ores, which are a primary rhenium source. Also, it is extracted from spent catalysts of petrochemical industry, among which platinum–rhenium catalysts are a major secondary source of rhenium. Depending on the raw material type and method of its reprocessing, rhenium can be extracted primarily from sulfuric acid solutions (washing sulfuric acid used in wet dust collection systems of molybdenum production or in gas-treatment systems of copper production), and also from nitric acid solutions (obtained in breakdown of molybdenite concentrates with nitric acid), hydrochloric acid solutions (obtained by leaching of rhenium compounds from spent platinum–rhenium catalysts), and from solutions of the corresponding salts, mainly of ammonium salts, formed by neutralization of the acids.

The ion-exchange sorption, along with liquid extraction, is the most efficient method for extracting rhenium from multicomponent solutions. Available data on the effect exerted by the macrocomponent on the Re(VII) sorption on various ion exchangers are scarce [1–4]. No systematic studies were performed in this field.

This study is concerned with the Re(VII) sorption on gel and macroporous ion exchangers differing in the basicity and on composite ion exchanger based on granulated polystyrene impregnated with technical-grade trialkylamine. The sorption was performed from solutions of sulfuric, hydrochloric, and nitric acids and from acidified solutions of the corresponding ammonium salts (sulfate, chloride, and nitrate, respectively) of various concentrations.

EXPERIMENTAL

The objects of this study were ion exchangers differing in the basicity and pore structure, manufactured by Purolite Company in the form of commercial resins that showed good performance in recovery of rhenium from various objects and of pilot samples, including (1) gel-like highly basic anion exchanger A600 functionalized with quaternary ammonium groups $-N^+R_3$, (2) macroporous weakly basic anion exchanger A170 containing secondary amino groups –NHR, (3) gel-like weakly basic anion exchanger A172 functionalized with the same groups as A170 anion exchanger (pilot sample), and (4) a composite anion exchanger SIM202 based on super-cross-linked polystyrene with a developed porosity (Hypersol-Macronet sorbent) impregnated with trialkylamine Alamine 336 (extractant content 0.9 mmol l^{-1} of sorbent) and thus containing functional tertiary amino groups $-NR_2$ [5].

The experiments were performed under static conditions. The ratio of the weighed portion of the ion exchanger in terms of the absolute dry mass (g) to

1070-4272/05/7809-1411 © 2005 Pleiades Publishing, Inc.

the solution volume (ml) was 1 : 100, and the contact time was 5–7 days. After this period, the solutions were separated from the ion exchangers and analyzed for the content of rhenium(VII).

The concentration of Re(VII) in the solutions was determined by the thiocyanate method using a KFK-2MP photoelectrocolorimeter [6].

From the change in the Re(VII) concentration, we calculated the sorption capacity of the ion exchangers [mg Re(VII)/g of dry ion exchanger], taking into account the weighed portion of the ion exchanger and the solution volume. Then, the values obtained were recalculated to the volume capacity [mg Re(VII)/ml of swollen ion exchanger], taking into account the specific volume of the ion exchangers. The distribution coefficients of Re(VII) D were calculated as the ratios of the volume capacity of the ion exchanger to the Re(VII) concentration in the equilibrium solution.

First we studied how the concentration of mineral acids (sulfuric, hydrochloric, and nitric) and their ammonium salts (at a constant solution acidity of 0.1 M) affects the Re(VII) sorption on the chosen ion exchangers. The Re(VII) concentration in the initial solutions was constant and equal to 0.5 g l^{-1} (0.00269 M). The data obtained were plotted in the form of the dependences of the distribution coefficients of Re(VII) on the concentration of the corresponding acids and salts (Figs. 1A–1C). As seen, as the concentration of the acids and corresponding salts, i.e., of ions of macrocomponents competing with the perrhenate ion, increases, the distribution coefficients in sorption of Re(VII) on all the ion exchangers decrease, though to a different extent. The presence of H_2SO_4 and $(NH_4)_2SO_4$ in the solutions affects the Re(VII) sorption to the least extent, and the presence of HCl and NH_4Cl, to a greater extent. The strongest suppressing effect on the Re(VII) sorption is exerted by HNO_3 and NH_4NO_3. At the similar total concentration of the macroanions, the ammonium salts of the corresponding acids affect the Re(VII) sorption to a lesser extent than the acids themselves, i.e., a so-called acid effect is observed.

With respect to the negative effect exerted on the Re(VII) sorption, the acids can be ranked in the order $H_2SO_4 < HCl \ll HNO_3$, corresponding to the order of the affinity of their anions for the ion exchanger: $HSO_4^- < Cl < NO_3^-$. The same order is observed with the ammonium salts of the acids.

In general, the anion-exchange selectivity is most adequately explained in terms of the Diamond–Whitney's theory [7], according to which the selectivity of anion exchangers with respect to the anions is the higher, the larger the anion size, the smaller its charge, and thus, the weaker its hydration. Under the action of water structure, large anions having small charge, which are weakly hydrated, are more readily displaced into the phase of the anion exchanger, where water has less ordered structure, and form there ion pairs with large hydrophobic cations that are functional groups of anion exchangers. In the process, small anions, which are hydrated more strongly, are displaced into the solution phase. Indeed, the thermochemical radius is 0.282, 0.230, 0.181, and 0.189 nm for ReO_4^-, SO_4^{2-}, Cl^-, and NO_3^-, respectively, and the Gibbs energy of hydration is –921, –330, and –289 kJ mol^{-1} for SO_4^{2-}, Cl^-, and NO_3^-, respectively [8]. For perrhenate ion, we found no data in the literature on the Gibbs energy of hydration. At the same time, the value reported for the MnO_4^- ion (–231 kJ mol^{-1}) suggests that it should be considerably lower than that for sulfate, nitrate, and chloride ions. Hence, single-charged ion ReO_4^- having the largest size and thus the lowest capability for hydration should be sorbed on anion exchangers more selectivity than the other ions mentioned above. In addition, sulfate ion has the highest (in the absolute value) hydration energy. Therefore, it exerts a weak competing effect on the Re(VII) sorption. The hydration energy of the ions decreases in the order sulfate > chloride > nitrate ion. Therefore, their competition with the perrhenate ion in sorption on anion exchangers increases in the same order.

The acid effect can be accounted for as follows. The higher distribution coefficients in the Re(VII) sorption from $(NH_4)_2SO_4$ solutions compared to H_2SO_4 solutions are due to the fact that in solutions of sulfuric acid the sulfate ion is in the form of single-charged protonated hydrosulfate ion HSO_4^-, whereas in $(NH_4)_2SO_4$ solutions it is in the form of deprotonated sulfate ion SO_4^{2-}. Apparently, single-charged hydrosulfate ion is less hydrated than double-charged sulfate ion. Therefore, it is competitive with perrhenate ion to a greater extent. For hydrochloric acid and ammonium chloride, or nitric acid and ammonium nitrate, the nature of the acid effect is difficult to understand. Hydrochloric and nitric acids are strong acids, and their anions show no tendency to protonate. At the same time, it was suggested in [7] that, e.g., HCl_2^--like associates, whose selectivity relative to anion exchangers should be higher than that of chloride ion Cl^-, can be formed in concentrated HCl. The same may be true for nitric acid.

It is important that, contrary to the published data, in the capability to sorb Re(VII) from solutions of

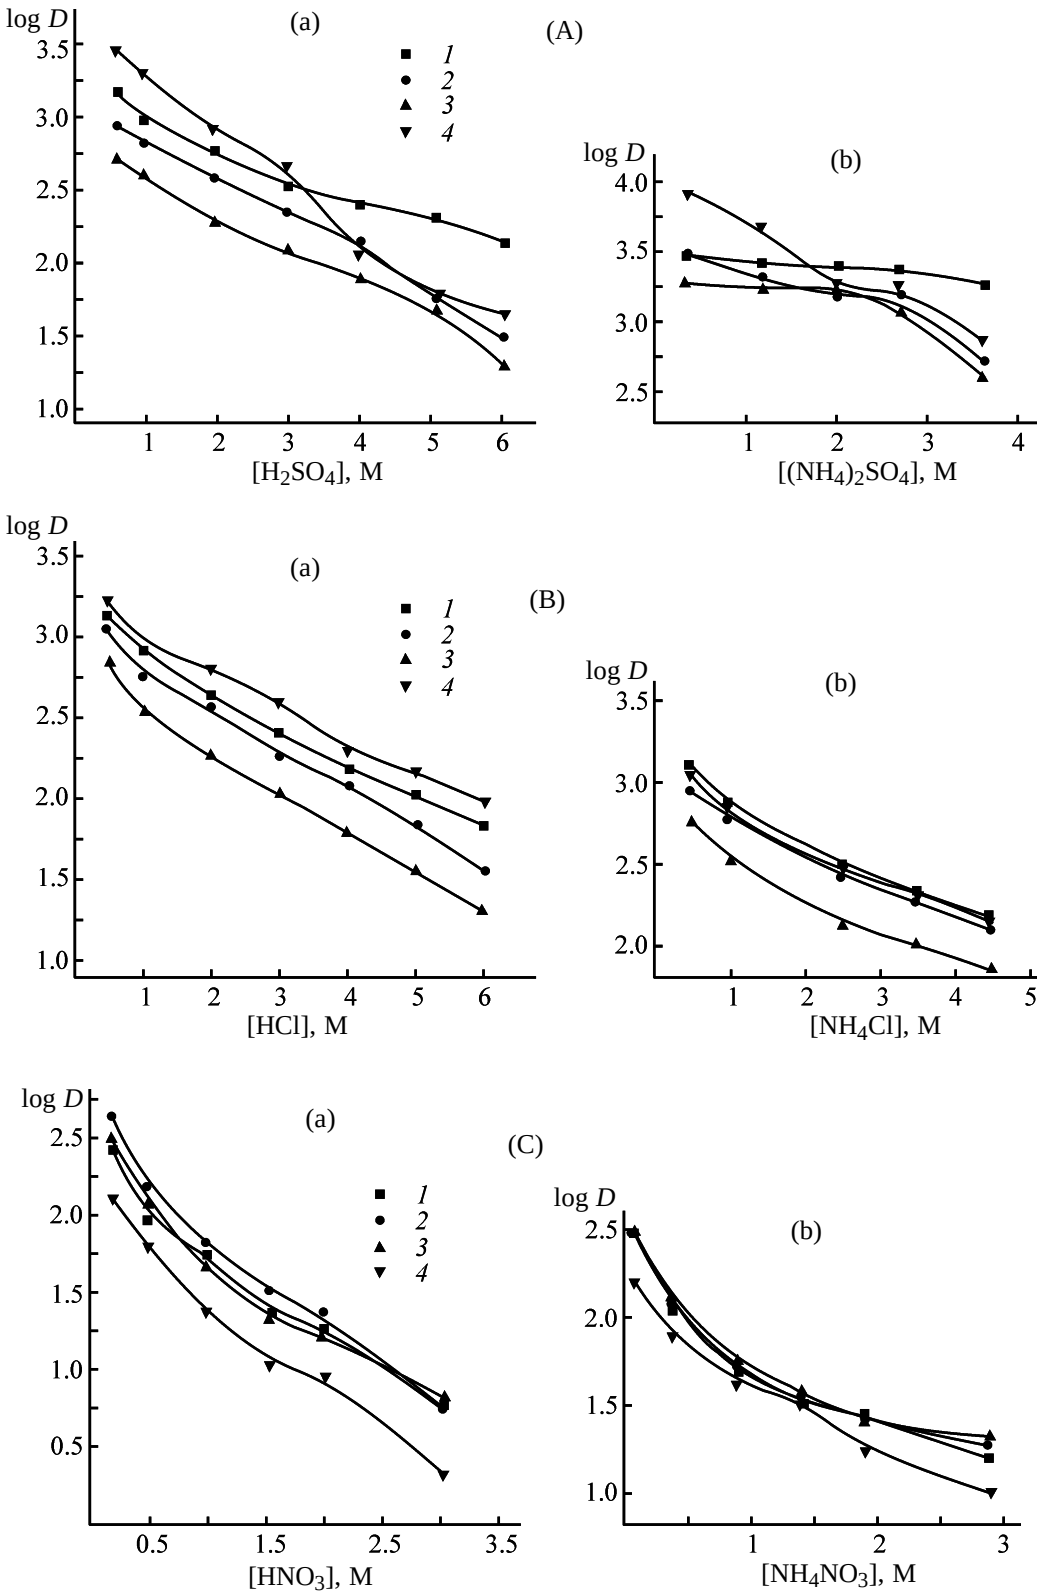

Fig. 1. Distribution coefficient of Re(VII) *D* vs. the concentration of (a) acid and (b) corresponding salt in sorption on Purolite anion exchangers. (A) H_2SO_4, $(NH_4)_2SO_4$; (B) HCl, NH_4Cl; and (C) HNO_3, NH_4NO_3. Ion exchanger: (*1*) A170, (*2*) A172, (*3*) A600, and (*4*) SIM202.

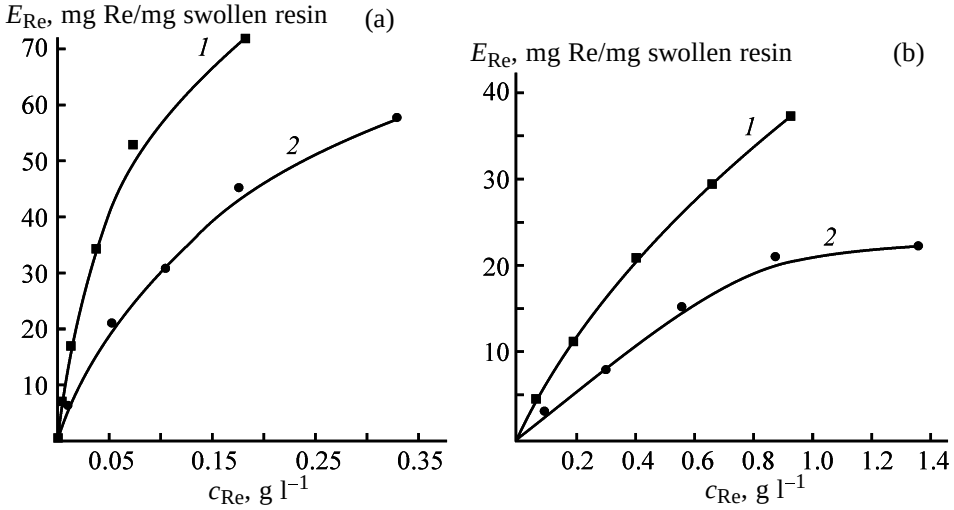

Fig. 2. Isotherms of Re(VII) sorption on A170 anion exchanger from (a) H_2SO_4 and (b) HNO_3 solutions. (E_{Re}) Sorption capacity of anion exchanger for Re(VII) and (C_{Re}) equilibrium rhenium concentration. Acid concentration, M: (a) (*1*) 1.0 and (*2*) 4.0; (b) (*1*) 1.0 and (*2*) 2.0.

different compositions with a high content of macrocomponents, the weakly basic anion exchangers tested here not only compete well with the strongly basic ion exchanger but also surpass it in sorption from solutions of sulfuric and hydrochloric acids and their ammonium salts. In HNO_3 and NH_4NO_3 solutions, the sorption on composite ion exchanger SIM202 is drastically deteriorated, whereas anion exchangers A170 and A172 show practically the same results as A600.

It seemed important to estimate the capacity characteristics of the ion exchangers for Re(VII) in a wide range of its concentrations at different concentrations of the macrocomponents in solutions. This was done by taking isotherms of Re(VII) sorption from H_2SO_4 solution, which suppresses the sorption to a minimal extent, and from HNO_3 solutions, whose negative effect on the Re(VII) sorption is especially strong, on A170 anion exchanger, which is a selective Re(VII) sorbent. The isotherms of Re(VII) sorption were taken from 1 and 4 M H_2SO_4 solutions and from 1 and 2 M HNO_3 solutions (Fig. 2).

The data obtained show that the Re(VII) sorption from sulfate solutions on anion exchangers is more efficient than from nitrate solutions over the entire range of its equilibrium concentrations. For example, the ion exchanger capacity relative to Re(VII) at its same equilibrium concentrations in sorption from 4 M H_2SO_4 is several times higher than in sorption from 1 M HNO_3. Thus, the selective weakly basic anion exchangers are suitable for efficient extraction of Re(VII) from concentrated H_2SO_4 solutions. At the same time, the ion-exchange method can hardly be recommended for Re(VII) extraction from nitrate solutions containing more than 1 M HNO_3.

CONCLUSIONS

(1) With respect to the negative effect exerted on the sorption of Re(VII) on strongly and weakly basic anion exchangers, mineral acids can be ranked in the order $H_2SO_4 < HCl \ll HNO_3$, in agreement with the order of the affinity of their anions for the anion exchangers ($HSO_4^- < Cl < NO_3^-$). The ammonium salts of the corresponding acids affect the Re(VII) sorption to a lesser extent.

(2) The weakly basic anion exchangers analyzed in this study surpass the highly basic anion exchanger in the capability to sorb Re(VII) from sulfate and chloride solutions.

(3) The sorption capacity of weakly basic anion exchanger A170 for Re(VII) from 4 M H_2SO_4 is several times higher than from 1 M HNO_3.

SORPTION AND ION-EXCHANGE PROCESSES

Synthesis and Properties of Organomineral Sorbents

Abstract—Composite sorbents including an active inorganic component and a polymeric binder were obtained. The effect of various factors on their sorption and strength properties was studied.

The high selectivity, heat resistance, and radiation stability of ion-exchange materials based on sparingly soluble inorganic compounds make such sorbents suitable for selective recovery of components from multicomponent solutions with the aim of utilization of these components or purification of process solutions and wastewater [1].

The possibility of effective use of inorganic ion-exchange materials is largely determined not only by their chemical properties, but also by the hydromechanical stability of granulates. As a rule, a sufficient hydromechanical stability of inorganic ion-exchange materials is achieved by creating composites [1], with inorganic materials commonly used as binders or supports.

Table 1 shows that a high mechanical stability of a material is, as a rule, provided by a significant decrease in the fraction of the active component in the sorption material.

An analysis of published evidence concerning the technology of polymeric materials and concepts of how stresses arise in granulated ion-exchange materials in their deformation [5] led to a conclusion that organic polymers can also be used as binders.

Here we describe fundamentals of a method for synthesis of organomineral sorbents, which yields granulates of inorganic sorbents with a content of the active component in a formulation exceeding 80 wt %, and report on certain properties of the ion-exchange materials obtained.

EXPERIMENTAL

The technique developed consists in the following. A suspension containing a polymer solution and a powdered inorganic sorbent is dispersed into a precipitant. The polymer is cured by washing-out the solvent from a drop of a suspension of the powdered inorganic component in a polymer solution, which is close to the known "wet" method for forming of synthetic and artificial fibers. The use of this method makes it possible to combine the processes of formulation curing and grain forming.

Some linear polymers, including perchlorovinyl (PCV), ABS plastics, and cellulose acetate, were tested as organic binders. These substances are well soluble in organic solvents, sufficiently wear-resistant, and nontoxic.

Water was used as a precipitant. This imposed certain requirements on the choice of a solvent for the polymer: this solvent should be fully miscible with water.

Acetone, dimethylformamide, and dimethylacetamide were tested as solvents meeting these requirements.

Hexacyanoferrates(II) and (III) of transition metals and hydrated titanium and aluminum oxides were used as active inorganic components.

The sorption properties of the organomineral

Table 1. Comparison of different techniques for production of granulates of inorganic ion-exchange materials

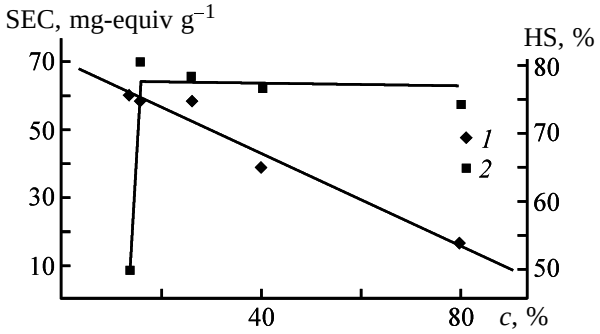
sorbents were studied with respect to different ions, to assess the selectivity of the materials studied.

The sorption of chloride ions was studied on AAT-0P sorbent (with hydrated Al_2O_3 as support). The experiments were carried out under static conditions by the method of separate samples, using a 0.1 M NaCl solution with pH 3 (adjusted with an HCl solution); weighed portion of the sorbent 1 g, ratio between the solution volume and sorbent mass 100 : 1, time of contact 0.5 h.

The sorption of Cs^+ on samples of ferrocyanide sorbents was carried out from solutions containing 0.56 g dm^{-3} cesium ions; weighed portion of the sorbent 0.5 g, l : s = 160 : 1.



Dynamic experiments were performed by filtration of electrolyte solutions at a rate of 4–6 cm^3 h^{-1} across a 20-cm sorbent bed in a glass column 5 mm in diameter.

In these experiments, the sorption of Li^+ on ISTZh-1P sorbent with hydrated TiO_2 as the active component was carried out, similarly to [6], from a solution containing (g dm^{-3}): Li_2SO_4 5.5, NaCl 56.0, and NaOH 3.0. Cesium ions were sorbed from a 0.01 M CsCl solution.

The concentration of metal ions in model solutions, solutions after sorption, and eluates was determined by atomic-adsorption analysis, and that of Cl^- ions, by titration.

To evaluate the hydromechanical stability (HS), 30 cm^3 of a working solution was poured into a plastic vessel with 5 g of a sorbent. To enhance the mechanical impact upon the sorbent, a 20-g fluoroplastic disc was placed in the vessel. The contents of the vessel were shaken for 3 h at a frequency of 4 Hz with an amplitude of 20 mm. The amount of grains that remained undestroyed was taken as their HS (wt %).

Of particular importance in optimization of the synthesis conditions is the composition of the suspension delivered to dispersion and, in particular, the concentration of the polymer and the ratio between the polymer and the inorganic sorbent. As shown by experiments, the suspension is cured in washing-out of the organic solvent without any significant change in volume. Therefore, to raise the capacity of the granulate per unit volume, more concentrated suspensions should be used when possible. However, this leads to a rise in viscosity, mainly because of an increase in the concentration of the polymer solution. The apparatus employed (pneumatic nozzles and disc

(*1*) SEC for Cs^+ and (*2*) HS vs. the fraction *c* of the polymeric binder (cellulose acetate) in the formulation.

atomizers) enabled working with solutions containing up to 11 wt % polymer.

The figure shows how the sorption exchange capacity (SEC) and HS of organomineral sorbents depend on the polymer content in a formulation.

It can be seen that an increase in the polymer content in the formulation leads to a virtually linear decrease in capacity. The dependence of the hydromechanical stability of the sorbent is of a clearly pronounced steplike type. For example, HS is virtually constant at a polymer concentration exceeding 16 wt %. This indicates, in our opinion, that a continuous polymeric skeleton of a grain is formed just at this concentration.

Our results show that the optimal content of cellulose acetate is 16–30% for sorbents based on hexacyanoferrates(II) and (III) of transition metals. For sorbents based on hydrated titanium and aluminum oxides, the concentration optimum of the polymer is 11–20% [6, 7].

In this range of the polymer content, the organomineral sorbents retain a high ion-exchange capacity for the target ion, and a sufficiently strong, deformation-resistant packing is ensured.

The kinetic parameters of the organomineral sorbents are fairly high. The effective inner diffusion coefficients *D* in Cs^+ sorption on organomineral sorbents based on copper potassium hexacyanoferrate $KCu_{1.5}[Fe(CN)_6]$ (FOC Cu) and cellulose acetate are given in Table 2.

Table 2 shows that the kinetic parameters are only slightly dependent on the polymer content in a formulation. It should be noted that the effective inner diffusion coefficients markedly exceed the diffusion coefficients of ions in an aqueous solution.

This phenomenon can be attributed to concentration of cesium ions on the surface of the pore space

Table 2. Diffusion coefficients and exchange capacities of FOC Cu sorbent at different fractions of the polymer

Cellulose acetate, %	E, (mg-equiv Cs) g^{-1}		D, $mg^2\ s^{-1}$
	per gram of sorbent	per gram of inorganic substrate	
25	1.30	1.78	0.1946×10^{-8}
40	0.92	1.54	0.1738×10^{-8}
60	0.69	1.73	0.173×10^{-8}
80	0.37	1.87	0.173×10^{-8}

[8] and also to a nonuniform distribution of the active component in a grain.

As the fraction of the polymer in the sorbent increases, the exchange capacity of the polymer becomes smaller, but it remains virtually the same when recalculated per gram of the inorganic phase.

In the course of curing of a grain, the suspension components are spatially redistributed. In particular, the outer surface of the grain is enriched with the most hydrophilic component, the inorganic constituent of the composite sorbent. The deformations accompanying this redistribution give rise to undesirable mechanical stresses. It was suggested to perform a hydrothermal treatment in order to intensify the relaxation of internal stresses and to modify the structure of the pore space. This is commonly done in the polymer technology. For example, it was shown in [9] that heating of cellulose acetate to 70–90°C in an aqueous medium leads to relaxation of internal stresses. The best results in hydrothermal treatment of organomineral sorbents were obtained with aqueous-salt solutions. For example, a certain rise in the exchange capacity and diffusion coefficient was observed for a sorbent based on copper potassium hexacyanoferrate and cellulose acetate as the content of acetic acid increased from 4 to 8%, and the concentration of NaCl, from 10 to 80 g cm^{-3}.

A stronger effect is produced by boiling ISTZh-1P sorbent in 0.05 M LiOH for 1.5–2 h. As a result, the exchange capacity increases by 8–12%, and the HS, by 36–39%. Boiling of grains of AAT-0P sorbent in a 0.05 M solution of Na_2SO_4 also leads to an increase in the HS by 5–8%, and in the capacity by 17–52%.

According to the data obtained, hydrothermal treatment leads to redistribution of components within a grain toward coarsening of polymeric fragments, which improves their sorption and strength properties. In conclusion, a number of known sorption materials are compared with the organomineral sorbents (Table 3).

Table 3 shows that introduction of an organic binder into the materials raises their HS by a factor of 1.3–4.4. The hydromechanical stability of ferrocyanide organomineral sorbents containing 16% cellulose acetate and 17% PVC (with copper potassium hexacyanoferrate the rest) exceeds by 6–20% the wear resistance of ferrocyanide–silica gel formulations (fraction of the active component 62%).

The organomineral sorbents ISTZh-1P and AAT-0P, based on hydrated TiO_2 and Al_2O_3, retain a high DEC and SEC for lithium ions and chloride ions. Their capacities recalculated per gram of the inorganic substrate (Table 3, in parentheses) exceed the corresponding values for samples containing no polymeric binder.

CONCLUSIONS

(1) Organomineral sorbents containing an active inorganic constituent and a polymeric binder were

Table 3. Comparative parameters of inorganic sorbents and their organomineral formulations

Parameter	Sorbent						
	FS-10 [1]	FOC Cu + PCV	FOC Cu + cellulose acetate	ISTZh-1 [6]	ISTZh-1P	AAT-0 [7]	AAT-0P
HS, %	75.0	80.0	95.0	21.1	93.0	49.2	85.4
Dynamic exchange capacity, DEC, (mg-equiv M) g^{-1}	185 (Cs^+)	240	286	4.1 (Li^+)	3.9(5.0)	–	–
Static exchange capacity, SEC, mg-equiv g^{-1}	–	–	–	3.3	3.2(4.0)	2.4 (Cl^-)	2.7 (Cl^-)
Separation factor $P_{Li,Na}$	–	–	–	70–90	80–100	–	–
Capacity to 1% breakthrough, (mg Cs^+) g^{-1}	133	196	213	–	–	–	–

synthesized. The sorbents can be recommended for multicycle use in recovery of valuable components from multicomponent solutions or for purification of wastewater to remove heavy metal ions. It was established that the content of a polymer in a grain in synthesis of sorbents should be within 11–20% for perchlorovinyl and 16–30% for cellulose acetate.

(2) The conditions of a hydrothermal treatment of the granulate ensuring the high strength and good sorption-kinetic characteristics were found.

(3) The dependence of the rate of the ion exchange on the fraction of a polymer in the sorbent was determined; granulation with an organic binder does not diminish the accessibility of the active inorganic constituent.

Received June 4, 2003; in final form, April 26, 2005

Abstract—Separation of large amounts (500 g) of ytterbium and lutetium by displacement complexing chromatography was studied. The optimal separation conditions were determined.

Detection of solar neutrinos is one of the most urgent problems of modern particle physics and astrophysics. Natural ytterbium can be used for preparing a solar neutrino detector. To detect ~100 events/year, the minimal weight of ytterbium contained in the detector should be 10–20 t. The lutetium concentration in ytterbium used for this purpose should not exceed 0.1 ppm (1×10^{-7} g lutetium per gram of ytterbium). To remove lutetium from ytterbium, we use displacement complexing chromatography [1]. Our preliminary experiments showed that the lutetium content can be decreased by a factor of 350 and ytterbium (1 g) with the lutetium concentration at a level of 0.05 ppm can be obtained by chromatographic separation of these elements on a series of columns packed with KU-2 × 8M cation exchanger (grain size 115 μm) at 70°C using 0.056 M solution of ethylenediaminetetraacetic acid (EDTA) as an eluent [2, 3]. The aim of this study was to develop a process for producing a large amount of pure ytterbium and to optimize the separation conditions of lutetium and ytterbium.

EXPERIMENTAL

Separation of ytterbium and lutetium was performed by displacement complexing chromatography (DCC) using a series of column one of which is a sorption column and the others are separating columns. Rare-earth elements (REEs) are sorbed as a uniform band on the sorption column and are separated on a series of columns packed with the resin in the form of retaining ion (Ni^{2+}, Cu^{2+}, H^+, etc.). The main role of the retaining ion is to decompose the REE complex during the whole separation time, which favors repeated sorption–desorption cycles. The complexes of the eluent with the retaining ion should be stronger than those with the ions being separated. The sorption of the retaining ion on the resin should be weaker than that of the ions being separated. To separate REEs, a complexing agent containing displacing ions, NH_4^+ or Na^+, is used. The sorption of this agent is stronger than that of REEs. When a column is washed with this agent, NH_4^+ cations substitute REE^{3+} cations. As a results, the resin is transformed into the NH_4^+ form and REE ions form complexes with the eluent (EDTA). These complexes are decomposed by reaction with the resin in the form of the retaining ion Ni^{2+}. The released REE ions are sorbed again and displace Ni^{2+}. Thus, separate REE bands are formed in the columns. The order of these bands corresponds to the strength of the REE complexes. As an eluent, we used 0.056 M aqueous solution of ethylenediaminetetraacetic acid (EDTA) neutralized to pH 7.0–7.5 with ammonia.

To remove small amounts of lutetium from a large amount of ytterbium (500 g), the optimal conditions of their chromatographic separation [number of chromatographic columns, their diameter (d) and height (h), height-to-diameter ratio, ratio of the cross sections of succeeding and preceding columns ($S_{n+1} : S_n$), order of attachment of the columns during the process] should be determined. In addition, the influence of the final step of the chromatographic process (complete elution with the complexing agent or partial elution followed by desorption of the residual ytterbium with the mineral acid to eliminate additional step of eluent separation in Yb_2O_3 recovery with the aim to accelerate the separation) on the ytterbium purity should also be studied. It was also necessary to check whether ytterbium was contaminated in the final separation steps. These preliminary estimations are required for preparation of ytterbium on a larger scale.

1070-4272/05/7809-1420 © 2005 Pleiades Publishing, Inc.

The ytterbium concentration was determined on an atomic absorption spectrometer (Perkin–Elmer 1100B) and an atomic emission spectrometer. The lutetium concentration was determined by γ-ray radiation of ^{176}Lu measured on a γ-ray spectrometer using 202 and 307 keV channels. The pH was measured on a pH211 pH-meter. An Ecoline VC-360 peristaltic pump was used to feed the solutions at the required rate. The elution rate was 4 ml min^{-1} cm^{-2}. Sulfonic acid cation exchangers in the hydrogen or nickel form were used as the sorbents.

To determine the optimal conditions of ytterbium recovery, we studied different factors affecting the chromatographic separation of ytterbium and lutetium on a series of columns. Among them are the ratio of the column height to its diameter ($h : d$) and the ratio of the cross sections of the succeeding and preceding columns ($S_{n+1} : S_n$).

Since under conditions of DCC the behavior of REEs is similar, the influence of these factors was studied with an example of separation of neodymium and europium labeled with ^{152}Eu, using 0.05 M ETDA as the element. The neodymium concentration was determined spectrophotometrically on an SF-16 spectrophotometer. The europium concentration was determined by the γ-activity of ^{152}Eu measured on an NRG-603 spectrometer (Czech Republic). The columns were packed with KU-2 sulfonic action exchanger in the H form. Nickel(II) (90 mg) was added to the solution along with europium and neodymium. Our preliminary experiments showed that in columns with $h : d < 10$ the elution front of the elements being separated is smeared. However, when the separation is performed on a series of columns attached in advance (i.e., the front of the REE band is at a distance of 5–7 cm from the end of the preceding column), with the elution rate set in accordance with the cross section of the attached column (4 ml min^{-1} cm^{-2}), the chromatographic separation becomes more efficient. If the cross sections of the adjacent columns differ by a factor of more than 4 (Fig. 2), the front of REEs gets distorted. As a result, the front and rear boundary of the europium band become smeared and the yield and purity of the element being separated are deteriorated. Hence, the ratio of the column cross sections should be no more than 2.

We compared two modes of the final step of ytterbium recovery: complete ytterbium elution with the complexing agent and partial ytterbium desorption from the terminal column with a mineral acid to eliminate the additional step of eluent removal in preparation of the final product, Yb_2O_3.

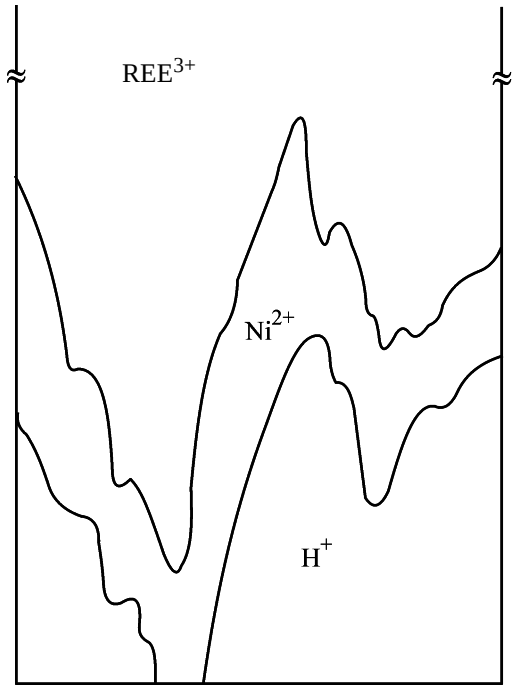

Fig. 1. Smearing of the front of the elements being separated on a column with a height-to-diameter ratio lower than 10.

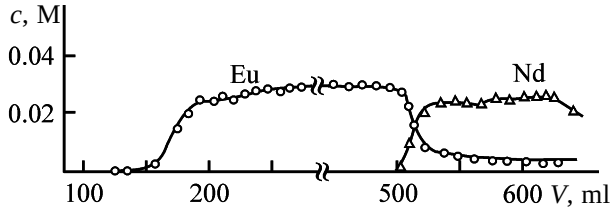

Fig. 2. Curves of elution of europium and neodymium with 0.05 M EDTA on columns with strongly different cross sections: (*c*) REE concentration and (*V*) eluent volume.

The results of these experiments are summarized in Tables 1 and 2. In each experiment we used 500 mg of lutetium and 374 mg of ytterbium.

Lutetium and ytterbium were separated on two columns with the following sizes: S_1 = 0.36 cm^2, h_1 = 80 cm and S_2 = 0.17 cm^2, h_2 = 80 cm. These elements were sorbed on the sorption column (S = 0.77 cm^2 and h = 11.3 cm). The columns were packed with KU-2 cation exchanger (industrial batch, 60–90 mesh) in the H form. Then the resin was converted into the Ni form. A 0.056 M EDTA solution neutralized with ammonia to pH 6.95 was used as the eluent. The elution rate was 4 ml min^{-1} cm^{-2}. The separation was performed at 70°C. The linear velocity of the REE band was 14 cm h^{-1}. Fractions (5–6 ml) were collected and analyzed for the lutetium content on

Table 1. Lutetium content in the samples (run no. 1)

17	3.9	0.43	1.7	2.25
18	3.3	<0.19	<0.62	2.25
19	4.6	<0.069	<0.31	2.25
H_2O	30	–	<0.15	
3 M HCl	44	–	<0.15	
3 M HCl	48	–	<0.15	

a Canberra γ-ray spectrometer with a 60 cm^3 germanium detector. The pH of the fractions was measured.

In the first experiment (Table 1), ytterbium was recovered by complete elution. As seen from Table 1, 50% of ytterbium eluted by the volume V = 21.6 ml (sample nos. 21–25) contains 1.1 mg of lutetium. Hence, the decontamination factor of ytterbium with respect to lutetium (the ratio of lutetium amount in the initial solution to that in the recovered ytterbium) is K_{dec} = 455.

In the second experiment (Table 2), lutetium and ytterbium were desorbed by the procedure of the first experiment. The elution was stopped when the distance from the rear of the ytterbium band and the lower part of the second separating column was 12 cm (50% elution). The column was washed with distilled water (V_1 = 30 ml) to remove EDTA and then with 0.5 M HCl to desorb ammonium ions (V_2 = 44 ml). After that ytterbium was desorbed with 3 M HCl (V_3 = 48 ml). The fractions were collected and analyzed for lutetium.

As seen from Tables 1 and 2, the last fractions before 50% elution of Yb in experiment nos. 1 and 2 contain similar lutetium amounts: $Lu_1 < 0.077$, $Lu_2 < 0.069$ mg ml^{-1}, respectively. In addition, 50% of Yb separated in the first and second experiments contains 1.1 and <0.15 mg of Lu, respectively. Thus, the purity of ytterbium recovered in the first experiment by elution with an EDTA solution is similar to that of ytterbium eluted with 3 M HCl after 50% separation of ytterbium with an EDTA solution. In the framework of LENS project, ultrapure ytterbium was recovered on a chromatographic unit with the productivity of 500 g of ytterbium in single sycle.[1]

The amount of the sorbent required for purification of 500 g of ytterbium was calculated from the number of separation bands by the equation

$$\nu = V/V_0 = [1 + (\alpha - 1)]/(\alpha - 1), \qquad (1)$$

where α is the separation coefficient of lutetium and ytterbium, equal to 2.09; N, fraction of the first component in the mixture (1.0); V_0, resin volume in the

Column no.	Column diameter d, cm	Column cross section S, cm^2	Height of sorbent bed h, cm	Sorbent volume in column, l	$d : h$ ratio	Ratio of column cross sections	Height of Yb band, cm
1	8.0	50	100	5.0	1 : 12.5	1.0	100
2	8.0	50	100	5.0	1 : 12.5	1.7	100
3	6.0	29	100	2.9	1 : 16.7	1.8	172
4	4.5	16	100	1.6	1 : 22.7	5.3	312
5	2.0	3	100	0.3	1 : 50.0	–	1667

sorption column; and V, resin volume in the separation column.

Substitution of these values in Eq. (1) gives ν = 2.0. V_0 depends on the amount of the initial lutetium–ytterbium mixture (500 g) and the sorbent capacity (1.7 mg-equiv ml^{-1} of the resin). Therefore, the required resin volume in the sorption column is 5.0 l. The resin volume in separating columns V is determined by the number of separation bands $V = V_0 \nu$, i.e., $V = 2 \times 5 = 10$ l of the resin distributed between several columns in proportions corresponding to the optimal ratios $h : d$ and $S_{n+1} : S_n$. The required height of the ytterbium band in the last column and hence the column diameter is determined from the equation

$$\log(c_a/c_b) = l \log \alpha_b^a / \mathrm{HETP}, \quad (2)$$

where c_a and c_b are the ytterbium and lutetium concentrations in the solution, respectively; HETP is the height equivalent to the theoretical plate; α_b^a, separation coefficient of ytterbium and lutetium; and l, height of the mixing zone.

Substitution of $\log \alpha_{Yb}^{Lu} = 0.32$ and HETP = 1 cm in Eq. (2) gives for required height of the ytterbium band with the lutetium content of 1 ppm at a 50% ytterbium yield the value of 180 cm. If 70% yield is required, the height of the ytterbium band should be 300 cm. The diameter of the last column is determined from these data.

The chromatographic unit is shown in Fig. 3. The parameters of ion-exchange columns with heating jackets are presented in Table 3.

The columns were packed with Amberlite JR-120 (16–45 mesh) and Dowex-50 × 8 (50–100 mesh) sulfonic cation exchangers in the H form in the amounts given in Table 4.

We used ytterbium oxide Yb_2O_3 (YbO-1 trademark) containing Er_2O_3 <0.005, Tm_2O_3 <0.005, Lu_2O_3 0.018, Ca <0.005, Fe 0.003, and Cu <0.005 wt %.

Table 4. Amount of H form of the cation exchanger in the columns

Column no.	Cation exchanger (mesh)	Volume of cation exchanger in the column, l
1	IR-120 (16–45)	5.0
2	IR-120 (16–45)	5.0
3	IR-120 (16–45)	1.0 (top)
	Dowex-50 × 8 (50–100)	1.9 (bottom)
4	Dowex-50 × 8 (50–100)	1.6
5	Dowex-50 × 8 (50–100)	0.3

Ytterbium oxide (Yb_2O_3) was analyzed by spark mass spectrometry on a JMS01-BM2 double-focusing mass spectrometer (laboratory of mass spectrometry and chromatography, Moscow, Russia).

Ytterbium oxide was dissolved in portions on heating by addition of 65% HNO_3 in a 1.5-fold excess. The ytterbium concentration in the resulting solution (V = 38.2 l) was 14 g l^{-1}, i.e., the solution contained 534.8 g of Yb. Analysis of the solution performed in Germany showed the presence of 267 mg of lutetium,

14	Yb desorption with 3 M HCl (columns 3–4)	11.5	24.40	280.6	18.8

i.e., the lutetium content was 499 μg g^{-1} Yb. Ytterbium was sorbed at room temperature from the solution on the first column. The amount of the adsorbed ytterbium was 456.7 g, i.e., 1.58 mg-equiv ml^{-1} of the resin. The resin in columns 2–5 was converted into the nickel form by passing 0.5 M $NiCl_2 \cdot 6H_2O$. Separation of ytterbium and lutetium was performed at 70°C by elution with 0.056 M EDTA (pH 7.17–7.63). The number of separation bands was $\nu = 1.96$.

After sorption of the REEs, the first column was washed with distilled water, and then the first and the second columns were washed with 0.056 M EDTA at 70°C. The elution rate was 4 ml min^{-1} cm^{-2}. The velocity of the REE band ranged from 11 to 14 cm h^{-1}. Separation was performed by connection of the columns in series. When the distance between the lower point of the second column and the rear boundary of the nickel(II) band was 10 cm, the third column was attached and elution was performed through the first three columns. When the distance between the lower point of the third column and the rear boundary of the nickel(II) band was 10 cm, the fourth column was attached and elution was performed through a series of the first four columns. When the distance between the lower point of the fourth column and the rear boundary of the nickel band was 10 cm, the fifth column was attached and the first column was detached.

Ten ytterbium fractions were taken from the fifth column. The total volume of these fractions was 18.5 l. The total amount of the recovered ytterbium was 161.9 g (35% of the sorbed amount). After these manipulations, columns 3–5 were washed with distilled water and the residual ytterbium was desorbed with 3 M HCl. The results of these experiments are summarized in Table 5.

After desorption of REEs from the third and the fourth columns, the ytterbium and lutetium amounts in the solution were 280.6 g and 18.8 ppm, respectively. The decontamination factor K_{dec} was 25.7. From the fifth column, 33.1 g of ytterbium and 43.2 μg of lutetium (K_{dec} = 11.6) were desorbed. Thus, 313.7 g of ytterbium (68.7% of the sorbed amount) was recovered.

Since ytterbium recovered in the first cycle contained 18.8 μg g^{-1} of lutetium (i.e., 18.8 ppm), it was repeatedly treated to remove excess lutetium. For this purpose we used columns 2–5 packed, as in the first cycle, with Amberlite YR-120 and Dowex-50 × 8 cation exchangers.

Combined fractions 13 (Yb–HCl, 33.1 of ytterbium) and 14 (Yb–HCl, 280.6 g of ytterbium) were used as the initial solution, i.e., the total ammount of ytterbium recovered in the first cycle and used in repeated separation was 313.7 g. Ytterbium and lutetium were sorbed on the second column. Separation was performed by washing column 2–5 connected in series with 0.056 M EDTA at 70°C. The results are given in Table 6.

The Yb–EDTA fractions were taken first from the fourth column (fraction 1, 1.5 l, 5.6 g of ytterbium) and then from the fifth column (fractions 2–6 contain-

Table 6. Parameters of ytterbium elution (experiment no. 2)

Solution no.	Ytterbium fraction	Fraction volume, l	Yb concentration, g l^{-1}	Yb amount g
1	Fraction 13 (HCl) (run no. 1)	2.9	11.40	33.1
2	Fraction 14 (HCl) (run no. 1)	11.5	24.40	280.6
3	Combined fraction from run no. 1 (initial solution, run no. 2)	14.4	21.78	313.7
4	Fraction 1: from column 4 (Yb–EDTA)	1.5	3.74	5.6
5	Fraction 2: from column 5 (Yb–EDTA)	1.5	6.18	9.3
6	Fraction 3: from column 5 (Yb–EDTA)	1.5	7.76	11.6
7	Fraction 4: from column 5 (Yb–EDTA)	1.5	7.89	11.8
8	Fraction 5: from column 5 (Yb–EDTA)	1.5	7.92	11.9
9	Fraction 6: from column 5 (Yb–EDTA)	2.5	8.01	20.0
10	Fraction 7: from column 4 (Yb–EDTA)	1.35	7.75	10.5
11	Fraction 8: from columns 3–5 (Yb–EDTA) and washing with H_2O	2.9	2.73	7.9
12	Fraction 9: desorption from column 3 (Yb–HCl)	8.2	26.94	220.9
13	Fraction 10: desorption from column 4 (Yb–HCl)	1.4	23.26	32.6
14	Fraction 11: desorption from column 5 (Yb–HCl)	0.5	20.20	10.1

ing 64.6 g of ytterbium). After that the columns were washed with distilled water (fractions 7 and 8 containing 18.4 g of ytterbium).

Then ytterbium was desorbed with 3 M HCl from the third (fraction 9, 220.9 g of ytterbium), fourth (fraction 10, 32.6 g of ytterbium), and fifth (fraction 11, 10.1 g of ytterbium) columns. Fractions 9 and 10 were combined. The ytterbium amount in the combined fraction was 253.5 g (70% of the initial ytterbium amount). Then ytterbium oxalate $Yb_2(C_2O_4)_3$ was precipitated (so-called pure fraction). The lutetium content in this fraction was 0.833 ppm. The decontamination factor in the second cycle was K_{dec_2} = 23.3. The total K_{dec} was 499/0.83 = 599. Fractions 3–8 and 11 were also combined (72.2 g of ytterbium). Ytterbium oxalate (tail fraction) was precipitated from the resulting solution.

Previously we found that the decontamination factor of ytterbium with respect to lutetium in separation of small amounts of lutetium and ytterbium (up to 10 g) under the optimal conditions ($h : d > 10$ and $S_1 : S_2 = 2$, HETP = 1 cm) on KU-2 × 8M sulfonic cation exchanger (115 μm grain size) was 350–450. The lutetium content in the sample was lower than 0.05 ppm.

When larger ytterbium amounts (500 g) are treated, the use of the fourth and fifth columns with substantially different cross sections ($S_4 : S_5 = 5.3$) and of Amberlite-IR-120 (16–45 mesh) and Dowex-50 (50–100 mesh) cation exchangers decreases the decontamination factor owing to both smearing of the rear boundary of the lutetium band and of stronger overlap of the lutetium and ytterbium bands. However, in the case of two-step ytterbium recovery, the lutetium content can be decreased to 0.833 ppm and the decontamination factor can be as high as 599.

CONCLUSIONS

(1) Optimal conditions of separation of ytterbium and lutetium were determined. The yield and purity of the recovered ytterbium decrease when the separation is performed on columns with the height-to-diameter ratio lower than 10 ($h : d < 10$) and the cross-section ratio larger than 2–3.

(2) Two modes of ytterbium recovery were studied: (*1*) complete elution with the complexing agent and (*2*) partial desorption with a mineral acid in the final step. The ytterbium purity is independent of the recovery mode.

(3) Separation of ytterbium and lutetium was performed on a large-scale level (500 g). 252.5 g of ytterbium with the lutetium content of 0.833 ppm was recovered with the decontamination factor K_{dec} = 599.

SORPTION AND ION-EXCHANGE PROCESSES

A New Procedure for Caffeine Determination

V. V. Khasanov, K. A. Dychko, T. T. Kuryaeva, G. L. Ryzhova, and E. V. Mal'tseva

Tomsk State University, Tomsk, Russia

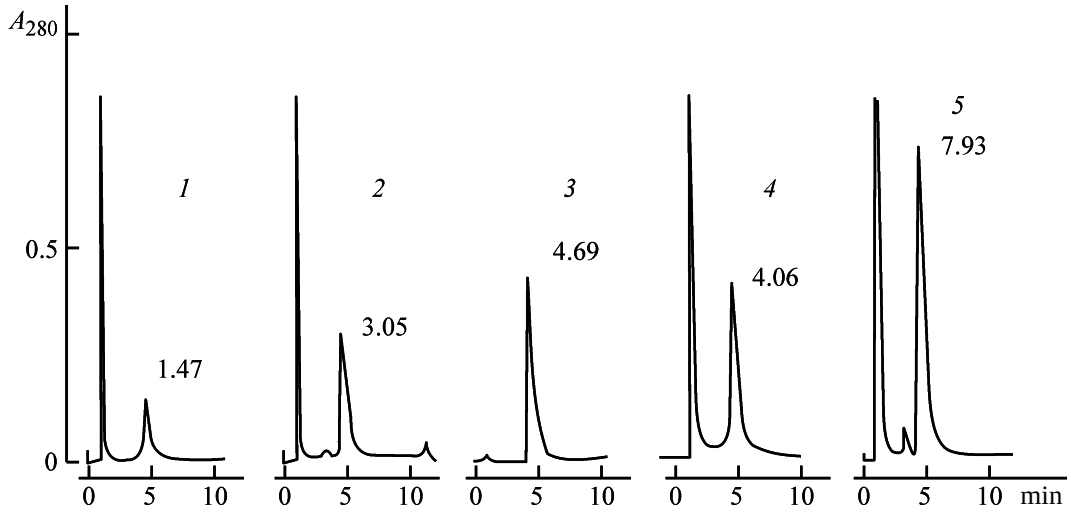
Received August 24, 2004; in final form, February 2005

Abstract—The content of caffeine in multicomponent natural objects (tea leaves, coffee beans, and instant coffee) and caffeine-containing beverage foods was determined by ion-exchange chromatography.

Since caffeine is an inherent component of some plants and foodstuffs produced from them [1], availability of the reliable procedures of its determination is important for various-purpose analyses (such as technological, umpire, etc.). In accordance with GOST (State Standard) [2], the main method of caffeine analysis is a photometric determination based on hydrolytic oxidation of caffeine into tetramethylpurpuric acid followed by photometric registration of the absorption density at λ 540 nm. The main disadvantage of this procedure is underestimation of the caffeine content in the samples [1].

The most general procedure of caffeine determination used in laboratories beyond Russia is reversed-phase high-performance liquid chromatography (RP HPLC). Kusch and Knupp [3] compared the analytical data on the content of caffeine in beverage foods determined by high-performance thin-layer chromatography and RP HPLC. They found that, despite some restrictions, each procedure provides reliable results with small measurement errors. As for caffeine determination in vegetable extracts of tea and coffee, the problem is more complex. The content of caffeine in tea and coffee is so high that no additional procedures of its preconcentration (such as solid-phase extraction often used in the analysis of caffeine in biological liquids [4]) are required. With solid-phase extraction and RP HPLC, the detection limit of the caffeine in protein-containing samples was determined as 200 ng cm^{-3}. However, wide assortment of compounds extracted with water from tea and coffee hinders direct determination of caffeine by RP HPLC, which is probably due to the short retention times of the polar caffeine molecules, especially in sorbents with small and intermediate content of grafted hydrocarbon chains. As a result, the caffeine peaks overlap with peaks of concomitant compounds even in the case of gradient elution. Another technique recently tested for determination is capillary electrophoresis [5]. Though this method provides very high separation efficiency, it is not widely used yet.

Nishitani and Sagesaka [6] performed an HPLC analysis of green tea components (catechins, phenolic glycosides, acids, and caffeine) on a C18 Wakosil-II 5C18 HG (3 × 150 mm) reversed-phase column (Wako Pure Chemical Industries, Ltd., Japan) using complex gradient profile with changes in the flow rate. The analysis time was 40 min. Smaller amount of components (8) can be separated with this system in 20 min. The detection limit of the components varied from 1.4 to 3.5 ng and the concentration dependence was linear up to charges of 1500 ng; the introduced/found ratio was 96–103%.



In this study we used a procedure more selective to caffeine, based on two separation mechanisms through ion-exchange and hydrophobic interactions.

EXPERIMENTAL

Analysis was performed on an FPLC liquid chromatograph (LKB Pharmacia, Sweden) equipped with a 50 × 5 mm column packed with Mono S sorbent (strong cation-exchanger with grafted sulfopropyl groups) produced by the same company. This sorbent is a hydrophilic polymer consisting of spherical particles (10 μm size) with a pore size of about 100 nm. A ready-to-use column was supplied by the company.

The elution was performed with a gradient in the organic modifier content. Two solutions were used: (A) 0.025 M sodium acetate (pH 6.8) and (B) 0.025 M sodium acetate (pH 6.8)–acetonitrile (70 : 30 volume ratio). The column was equilibrated for 4 min with a mixture A : B = 95 : 5; then the sample was injected, and after 4 min the gradient was switched on, up to the composition A : B = 15 : 85 in 10 min; the flow rate was 1 ml min^{-1} (300 cm h^{-1}).

Chromatographic patterns of the samples and caffeine reference; sample volume 100 μl, UV detector, λ 280 nm. (*1*) Georgian tea, (*2*) MK Gold tea, (*3*) reference, (*4*) Jacobs Meister coffee, and (*5*) Coca-Cola. Figures at peaks indicate the content of caffeine (in 100-μl sample volume).

The volume of the sample was varied from 100 to 500 μl (depending on the expected caffeine content); the process was monitored with a UV detector at λ 280 nm.

Before measurements, a weighed sample (100–200 mg) of tea or coffee was kept in solution A for 5–10 min at 90°C with stirring. Certain fraction of the extract was centrifuged for 5 min at 5000 rpm and filtered (0.45 μm).

The Coca-Cola and Pepsi caffeine-containing carbonated beverages were only filtered before analysis. Modern sorbents for ion-exchange HPLC exhibit pronounced hydrophobic properties of the hydrocarbon spacer retaining the ion-exchange group on the sorbent surface or even matrix material. The hydrophobic properties of the ion exchangers are weaker than those of reversed-phase sorbents. Thus, strongly ionized compounds will be retained on the ion exchangers predominantly by electrostatic interactions, and weakly ionized and nonionized compounds, by hydrophobic interactions. By varying the eluent pH, we can change the ratio of the ionized and nonionized caffeine molecules and, thus, control the contribution of one or another mechanism of retention in the column. At pH < 6, the electrostatic interactions of the caffeine molecules with a cation exchanger are so strong that they are poorly eluted from the column even by 1 M NaCl. Moreover, high concentrations of salt in the buffer solution enhance the hydrophobic interactions between caffeine and the sorbent. With changing pH from 6 to 7, the retention of caffeine decreases and it can be eluted with a gradient in the organic modifier concentration (as in the case of RP HPLC). The optimal pH value was determined experimentally. Under these conditions, polar and low-polar weakly ionized molecules of various compounds interfering with the caffeine determination on common reversed phases are not retained in the column and do not affect the analysis. After the gradient elution, the ion-exchange column is equilibrated with the initial eluent in less than 3 min and becomes ready for a new analysis. The chromatographic patterns of several samples are shown in the figure.

The main fraction of the concomitant compounds was eluted from the column immediately after the sample injection. The caffeine peak is easily separated from the peaks of concomitant compounds and thus is efficiently recorded. The absence of compounds simultaneously eluted with caffeine (peak purity) was tested using an RSD-2140 detector on diode matrices (Pharmacia-LKB, Sweden) by comparing the absorption spectra in the UV peak maxima of caffeine in the reference and samples studied.

The validation of the procedure suggested for the caffeine determination was performed in accordance with recommendation of the International Conference on Harmonisation (ICH Tripartite Guideline, CPMP/ICH/281/95), topic Q2B (Validation of Analytical Procedures: Methodology) [7]. The results are listed in Table 1. The accuracy of the procedure was evaluated at addition of the caffeine reference to the tea samples. For this purpose, the contents of caffeine added and determined from the experimental depen-

Instant coffee:		
Nescafe Classic, Brazil	4.00 ± 0.024	1.2
Jacobs Merido, Germany	3.83 ± 0.019	1.2
Maxwell House, Brazil	4.00 ± 0.022	1.3
Jacobs Meister Rostung, Canada	4.67 ± 0.024	1.3
Beverage:		
Coca-Cola, Russia	80.1 ± 0.464	1.2
Pepsi, Russia	95.4 ± 0.474	1.2

* For tea and coffee, the content of caffeine is given in percents of the dry weight of the sample (moisture content of the packed product), and for carbonated beverages, in mg l^{-1}; average values ± standard deviation are given.

CONCLUSIONS

(1) Combination of the ion-exchange and hydrophobic mechanisms of retention in the liquid chromatography allows development of a new express and reliable procedure of caffeine determination.

(2) The relative error in the caffeine determination does not exceed 1.5%; quantitative analysis is performed by an absolute calibration procedure.

(3) The calibration dependence at caffeine concentration from 1 to 100 mg ml^{-1} is linear with the correlation coefficient $r > 0.999$.

(4) By this procedure, the content of caffeine can be determined on a standard HPLC unit.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Effect of Lanthanide Additives to a Nickel Oxide Electrode of a Sealed Nickel–Zinc Battery on the Self-Discharge and Hydrogen Pressure

Z. P. Arkhangel'skaya, A. I. Demidov, M. M. Loginova, T. B. Kas'yan, and E. V. Apollonova

Abstract—The influence exerted by addition of a nickel-based alloy containing lanthanides (La, Ce, Nd, Pr) to the active paste of a nickel oxide electrode on the self-discharge and hydrogen pressure in a sealed nickel–zinc battery was studied.

Proceeding with studies of gas evolution and gas absorption in a sealed nickel–zinc (SNiZn) battery with a nickel oxide electrode (NOE) made of spherical nickel hydroxide [1], we examined the influence exerted by addition of a nickel-based alloy containing lanthanides (La, Ce, Nd, Pr) to the active paste of a nickel–oxide electrode on the self-discharge and hydrogen pressure in an SNiZn battery. Lanthanide oxides were introduced into the active paste of an NOE in order to raise the utilization coefficient of the active paste in the NOE and improve its preservation [2]. Erbium, thulium, ytterbium, and lutetium oxides were found to be the most effective additives at an elevated temperature (75°C).

Nickel-based lanthanide-containing alloys exhibit a high absorption capacity for hydrogen [3]. The replacement of a cadmium electrode with an electrode composed of a nickel alloy with lanthanides, which can absorb hydrogen and desorb it upon polarity reversal, gave rise to nickel–metal hydride batteries. As the interaction of nickel metahydroxide NiOOH with hydrogen is accompanied by reduction of the nickel ion Ni^{3+} and oxidation of hydrogen

$$2NiOOH + H_2 = 2Ni(OH)_2,$$

the influence of lanthanides on the self-discharge and hydrogen pressure in an SNiZn battery can be evaluated by a decrease in the NOE capacity and a change in the hydrogen pressure under cycling conditions.

EXPERIMENTAL

We introduced lanthanides into the active paste of an NOE in an amount of 1–2 wt % in the form of a nickel-based alloy containing La, Ce, Nd, and Pr. The study was performed on SNiZn batteries of the NTsG-25 type with an NOE composed of spherical nickel hydroxide [1]. The characteristics of the NOE studied in the batteries are listed in Table 1.

We determined the rated capacity of NOE by studying separate NOEs in prototype batteries. The electrodes were formed in two to three cycles, with a capacity equal to $1.1C_{th}$ of the positive electrode imparted in the first cycle, and $1.4C_{th}$, in the second and third cycles (C_{th} is the thermodynamic capacity). The zinc electrode contained 2 wt % CdO and 1 wt % PbO.

The open-circuit voltage U_{OC} of assembled batteries and the potential of NOE relative to a mercury

oxide electrode (Hg, HgO | OH^-) before the first forming charging depended on the content of the alloy in the active paste of the NOE (Table 2).

Table 2 shows that, before forming, the U_{OC} of the batteries decreases as the content of the additive in the active paste of NOE becomes higher. As the content of lanthanides increases, the potential of NOE shifts toward the negative direction and becomes more negative than the potential of the mercury oxide electrode. However, already after the first charging and during further discharge–charging cycles, the NOE potential becomes independent of the additive content and takes the characteristic value observed in the absence of an additive.

The open-circuit voltage and the charging-discharge characteristics of all the batteries under study become the same in the course of forming and cycling (Fig. 1).

The open-circuit voltage of batteries with NOE containing a lanthanide alloy (up to 2 wt %) and without additive varies in the course of storage in the same way (Fig. 2). However, the capacity in discharge after 29 days of storage of a battery containing 2 wt % alloy in the NOE is higher (Fig. 3). The loss of capacity in self-discharge is 30.6% for this battery and 36.0% for that containing no additive in its NOE. This result can be understood if we assume that the nickel-based lanthanide-containing alloy introduced into the active paste of the NOE is oxidized on its surface, but retains its ability to absorb hydrogen (Table 3).

Table 3 was compiled using data on self-discharge of ventilated nickel–zinc batteries, which is 10% in 30 days (2.5 A h) [4].

Calculation shows that the content of hydrogen in the alloy after 29-day storage of an SNiZn battery (0.32 A h) is close to the value characteristic of the alloy used as the active paste in the negative electrode of a nickel–metal hydride battery.

		total	in oxidation by hydrogen	
NOE:				
without alloy additive	24.5 (15.7)	8.8	6.3	–
with alloy additive	24.5 (17.0)	7.5	5.0	1.3

In the course of cycling of an SNiZn battery, the pressure first increases and then reaches a constant value (Fig. 4). The maximum total pressure in the battery corresponds to the pressure of hydrogen and oxygen in charging, and the minimum pressure, to that of hydrogen in discharge. In the absence of an alloy additive in the NOE, the hydrogen pressure in the battery was $(2.0–2.2) \times 10^2$ kPa, and the total pressure of hydrogen and oxygen, 2.8×10^2 kPa. In the case of an NOE containing the additive in an amount of 2 wt %, the hydrogen pressure in the battery was $(1.6–1.8) \times 10^2$ kPa, and the total pressure of hydrogen and oxygen, 2.2×10^2 kPa. Thus, the introduction of a nickel-based lanthanide-containing alloy in the active paste of an NOE made it possible to diminish the total pressure in an NTsG-25 sealed battery by 60 kPa, and the hydrogen pressure, by 40 kPa.

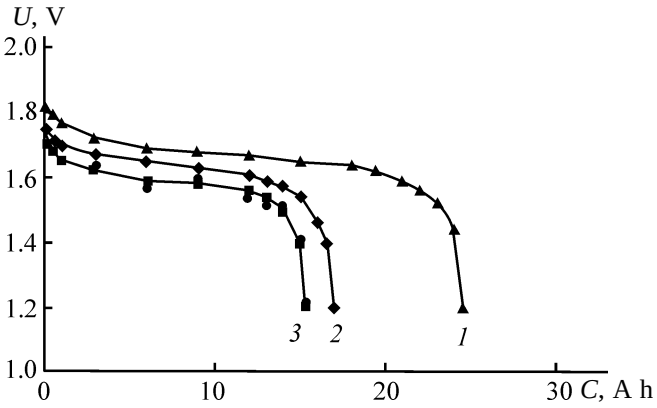

Fig. 3. Variation of the voltage *U* in discharge of NTsG-25 batteries (*1*, *2*) with addition of 2 wt % alloy of lanthanides to NOE and (*3*) without additive (*1*) before and (*2*, *3*) after storage for 29 days.

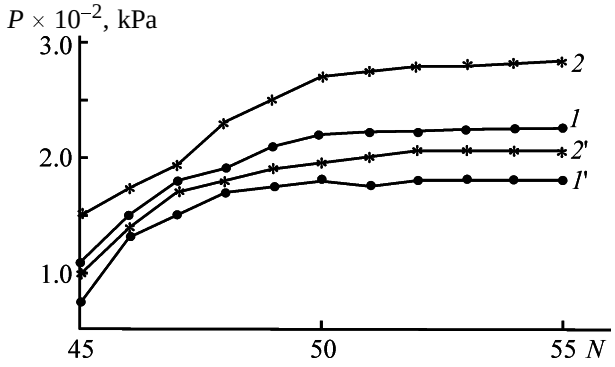

Fig. 4. Variation of (*1*, *2*) maximum and (*1*', *2*') minimum pressure *P* in an NTsG-25 battery (*1*, *1*') with addition of 2 wt % alloy of lanthanides and (*2*, *2*') without additive. (*N*) Number of cycles.

CONCLUSION

A nickel-based alloy containing lanthanides (La, Ce, Nd, Pr) introduced into a nickel oxide electrode retains its ability to absorb hydrogen. This leads to a decrease in the self-discharge of a sealed nickel–zinc battery in storage and makes lower the total pressure and hydrogen pressure in the battery in cycling.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Effect of the Electrolyte Concentration on the Reversibility of a Nickel Oxide Electrode in a Nickel–Zinc Battery

Abstract—The degree of charging of a nickel oxide electrode composed of spherical nickel hydroxide in a nickel–zinc battery was studied in anodic oxidation of the electrode in KOH solutions of different concentrations, containing hydroxozincate ions.

The use of a nickel oxide electrode composed of spherical nickel hydroxide on a foamed nickel support (FNi NOE), instead of a metal–ceramic (MC) electrode, in nickel–cadmium (NiCd) and nickel–metal hydride (NiMH) batteries made it possible to markedly simplify the production process and raise by 30–50% their electrochemical parameters. At the same time, as applied to a nickel–zinc battery, NOE of the same type made longer the service life of the battery compared to similar batteries with metal–ceramic NOE (MC NOE) but gave no noticeable advantages in the energy storage capacity.

The achievable degree of oxidation of an NOE composed of spherical nickel hydroxide in its operation in NiCd and NiMH batteries is 0.85–1.0 in terms of the $Ni(OH)_2 \rightarrow NiOOH$ transition [1], whereas in forming of NiZn batteries with the same NOE, this parameter does not exceed 0.7–0.8 [2]. In the previously developed NiZn batteries with an MC NOE, the degree of its charging was virtually the same as that obtained in NiZn batteries (0.85–0.9). If an NOE composed of spherical nickel hydroxide is used instead of MC NOE, its low degree of oxidation leads to a necessity for raising the amount of the active paste per unit capacity and, consequently, to a decrease in the capacity ratio of the negative and positive electrodes. This, in the end, reduces the specific energy of an NiZn battery with FNi NOE to 60 W h kg^{-1}, i.e., to a level provided by a similar battery with an MC NOE [3].

The aim of this study was to reveal what processes limit the chargeability of an NOE composed of spherical nickel hydroxide on a foamed nickel support both in forming of an NiZn battery and in its subsequent cycling under the conditions of varying concentrations of KOH and hydroxozincate ions in the electrolyte.

A preliminary analysis of our previous publications [2, 3] demonstrated that the hindrance to egress of a proton (and an electron) in charging of an NOE under the forming conditions may be due to simultaneous intercalation of zinc(II) contained in the electrolyte into the $Ni(OH)_2$ structure. The intercalated zinc is not an active component involved in electrochemical processes in the subsequent operation of the electrode. However, it can affect the distribution and interaction of the other components (H_2O; OH^-, K^+, and CO_3^{2-} ions) in forming of the NOE structure. Its own position in the layered structure of nickel hydroxides may vary [4], which is reflected in the degree of ordering of the nickel hydroxide structure and in its formability [5].

Another reason may be the electrolyte composition and, primarily, the KOH concentration both during the forming cycles and in the subsequent reversible operation, because an electrolyte of lowered concentration is used in NiZn batteries in order to diminish the solubility of zinc. In the course of cycling, this concentration decreases to even greater, and considerably so, extent [3] because of the small volume of the electrolyte and use of materials containing an admixture of carbonates and oxidizable organic additives.

A number of studies have been concerned with the influence exerted by zinc as a stabilizing additive on processes that occur in NOE, including that directly devoted to the issue in question [4]. In this study, we examined the influence exerted by zinc on processes occurring in forming of the $Ni(OH)_2$ structure and its

1070-4272/05/7809-1433© 2005 Pleiades Publishing, Inc.

stabilization under conditions of NOE cycling in KOH solutions of different concentrations.

It was shown that the achievable degree of charging of an NOE containing incorporated zinc is lower than that of an electrode containing no zinc, but is distinguished by high stability of its capacity under cycling conditions. As the KOH concentration in the electrolyte was raised from 2 to 8 M, the degree of charging increased from 0.7 to 1.0. However, these results were obtained on electrodes with a constant content of zinc [6% Zn/(Zn + Ni)], and, therefore, they do not reflect specific features of the processes that occur in an NiZn battery, with the content of zinc in the NOE steadily increasing and the KOH concentration in the electrolyte simultaneously decreasing.

In nickel hydroxide with a structure of the β-phase, zinc can be incorporated in amounts of up to 15% Zn/Ni or 10–12% $Zn/Ni(OH)_2$ [4, 6]. When zinc is accumulated in NOE in such amounts, the β-phase starts to decompose with the subsequent gradual transformation into the α-phase, and the interplanar spacing between $Ni(OH)_2$ layers grows from 4.6 to 7 Å [5], with simultaneous increase in the structural disorder [5, 6]. By contrast, the structure of nickel(II, III) oxides is more stable at a $Zn/Ni(OH)_2$ ratio less than 10%, compared with that in the absence of zinc, and provides a virtually constant degree of proton (electron) egress.

EXPERIMENTAL

We performed the study on NiZn batteries and prototypes of varied capacity with a nickel oxide electrode composed of spherical nickel hydroxide on a foamed nickel support.

FNi NOE was fabricated from nickel hydroxide with particles 10–30 μm in diameter. The starting active paste contained 53–53.5% nickel and admixtures of cobalt (5.4%) and zinc (3.4%), introduced in synthesis of nickel hydroxide.

As shown in [2], the degree of NOE charging obtained in forming cycles depends on the imparted charging capacity. Among the modes tested, the highest capacity was provided by that in which a capacity of 100–110% relative to the theoretical value for the $Ni^{2+} \rightarrow Ni^{3+}$ transition was imparted in the first cycle, and 120–140%, in the second.

Charging with an excess imparted capacity is accompanied by a change in the electrolyte composition, because nickel hydroxide is oxidized with consumption of hydroxide ions and release of water:

$$Ni(OH)_2 + OH^- \rightarrow NiOOH + H_2O + e. \quad (1)$$

In the subsequent discharge, hydroxide ions are returned into the electrolyte and water is consumed, but not completely, because the charging capacity C_{ch} exceeds the discharge capacity C_d. As a result, the KOH concentration in the electrolyte may decrease to a varied extent, depending on the mode of battery forming.

The degree of NOE charging in the battery varied with the ratio of charging to theoretical capacity, C_{ch}/C_{th} (0.8–1.5), only slightly, from 0.65 to 0.75 [2]. Therefore, in order to obtain a noticeable effect in comparative analysis, forming was performed in this study at different C_{ch}/C_{th} ratios.

The degree of Ni charging obtained in the case when the charging is limited by the final voltage, $C_{ch} < C_{th}$, was determined as the C_d/C_{ch} ratio (current utilization coefficient), and that in charging with $C_{ch} > C_{th}$ imparted in the transition $Ni^{2+} \rightarrow Ni^{3+}$, as the C_{ch}/C_{th} ratio (nickel utilization coefficient).

Table 1 shows that the degree of FNi NOE charging in prototypes with a cadmium counterelectrode exceeds by 15–20% that in prototypes with a zinc electrode. This fact confirms that hydroxozincate ions are involved in the formation of the NOE structure and affect the achievable degree of NOE charging.

Table 2 shows that two cycles are sufficient for forming of an FNi NOE. In the third and subsequent cycles, the capacity changes only slightly. It should be noted that the values obtained on prototypes are smaller than those for batteries, which is due to different electrolyte volumes per unit NOE capacity. Therefore, the results obtained in tests with prototypes are regarded as tentative.

To obtain the most contrasting, as regards the degree of charging, results, we carried out forming of prototypes with electrolyte of varied concentration under the most severe conditions with a C_{ch}/C_{th} ratio increased to 1.5 (Table 2). However, as the initial KOH concentration was raised from 7.0 to 8.5 M and forming was performed with a zinc counterelectrode, i.e., in the presence of $Zn(OH)_4^{2-}$ ions, the degree of charging increased by only 10%, and by only the 10th training cycle.

The variation of the electrolyte concentration in forming of FNi NOE during the forming cycles was determined for batteries with a capacity of 50 A h (C_{th} = 100 A h) at an initial KOH concentration in

* Charging/discharge capacity.

the electrolyte equal to 7 M and a C_{ch}/C_{th} ratio of 1.0 in the first and second cycles (Table 3). Even under these mild conditions, the electrolyte composition mainly changed during the forming cycles and varied only slightly in further cycling. In two forming cycles, the KOH concentration in the electrolyte decreased from 7 to 4 M in a charged battery, and to 5 M in a discharged one. In this case, the degree of NOE charging was 0.58–0.84. The high degree of charging obtained in these batteries is due to certain specific features of its operation.

The data in Tables 1–3 suggest that the impairment of the chargeability of FNi NOE in a NiZn battery is due to its forming directly in batteries and is associated with the influence exerted on the forming β-$Ni(OH)_2$ structure by zinc being intercalated from hydroxozincate ions at a decreasing KOH concentration in the electrolyte.

The data obtained in forming of FNi NOE were confirmed in determining the cyclic life of NiZn batteries with varied KOH concentration. The initial concentration of 7 M decreased in the forming cycles to 5 M and remained at a level of about 4 M in further cycling (Fig. 1). The degree of NOE charging was in this case in the range 0.65–0.60 and decreased to 0.45 after 200 cycles because of the accumulation of zinc in NOE in amounts leading to degradation of the active paste. The total cycling life of the batteries was 300–350 cycles.

Table 3. Variation of the KOH concentration in the electrolyte in the forming cycles and the achievable degree of NOE charging in a Ni/Zn battery. Rated capacity 50 A h, initial KOH concentration 7 M

Cycle	State	Capacity, A h	Current density, A dm^{-2}	C_{ch}/C_{th}	C_d/C_{th}	KOH concentration, M
Forming:						
first	Charged	100	0.23	1.0		4.4
	Discharged	58.5	0.27		0.585	5.0
second	Charged	100	0.23	1.0		4.0
	Discharged	84	1.8		0.84	
Training:						
fifth	Charged	84	0.32	0.9		3.8
	Discharged	80	1.8		0.80	4.0

At an initial value of 6 M, the KOH concentration was in the range 4.0–3.0 after the forming (Fig. 1). The degree of charging was in this case about 0.5 till 200th–250th cycle, but the total cycling life may start to decrease in earlier cycles because the zinc electrode may be passivated at the specified lower-limit KOH concentration.

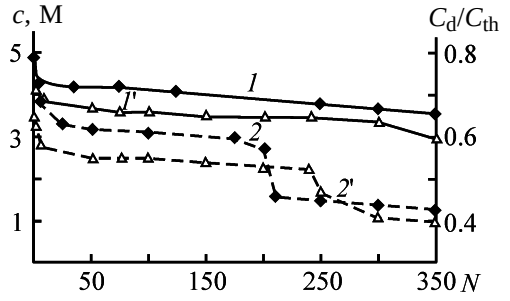

Fig. 1. Variation of (*1*, *1*') the KOH concentration in the electrolyte and (*2*, *2*') degree of charging of an NOE composed of spherical nickel hydroxide on an FNi support in the course of cycling of NTs-25 batteries. Initial KOH concentration, M: (*1*, *2*) 7 and (*1*', *2*') 6. (*N*) Number of cycles, (*c*) KOH concentration, and (C_d/C_{th}) degree of NOE charging; the same for Fig. 2.

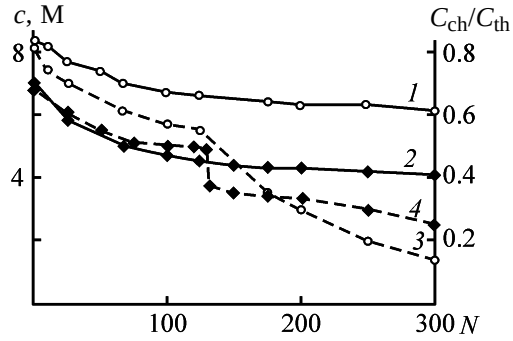

Fig. 2. Variation of (*1*, *1*') the KOH concentration in the electrolyte and (*2*, *2*') degree of charging of an MC NOE in the course of cycling of NTs-25 batteries. Initial KOH concentration, M: (*1*, *2*) 7 and (*1*', *2*') 6.

These results determine the lower limit to the KOH concentration in the electrolyte, at which the NOE retains its working efficiency.

To reveal specific features of the processes occurring in FNi NOE in electrolytes with different KOH concentrations, we compared the data considered above with the results obtained in testing under similar conditions batteries with MC positive electrodes (Fig. 2). It can be seen that the degree of charging of an MC NOE formed separately in an electrolyte containing no zincate ions in the initial cycles exceeds that of a compacted NOE composed of spherical nickel hydroxide on a foamed nickel support at any of the initial KOH concentrations used (8.5–7.0 M). However, it decreases in the course of cycling just as the KOH concentration does. This dependence reflects the extent to which the capacity of batteries with MC NOE is unstable with respect to service life.

The results obtained in cycling of batteries with MC NOE at a KOH concentration of 8.5 M indicate that it is inadvisable to use an electrolyte of this composition in batteries with FNi NOE, because its forming will occur at a high concentration of $Zn(OH)_4^{2-}$ ions, which will shorten the cycling life of the battery.

Thus, introduction of zinc into FNi NOE stabilizes its capacity by making weaker its dependence on the electrolyte concentration, but the achievable degree of charging decreases in this case. The actually achieved degree of charging of FNi NOE under the conditions of forming in a NiZn battery is lower than that possible for NiCd and NiMH batteries and in NiZn batteries with MC NOE. This is due to the presence in the electrolyte of zincate ions involved in the transformation of the active paste at a decreasing KOH concentration.

As shown in [4], the zinc-containing active paste is formed in an electrolyte with a low KOH concentra-

tion (6–4 M) in the solid phase with a direct transition β-$Ni(OH)_2 \rightarrow \beta$-NiOOH, for which the maximum degree of charging is 0.8. In this case, the specific capacity of FNi NOE is approximately equal to that of MC NOE because of the lower mass of the support of the former. A higher degree of charging is only achieved for a transition in forming via the γ-phase: $\beta_{(II)} \rightarrow \gamma \rightarrow \alpha \rightarrow \beta_{(III)} + \gamma$. For this phase to be formed in zinc-containing electrolytes, a higher KOH concentration is necessary, which is unacceptable for NiZn batteries.

CONCLUSIONS

(1) The degree of charging of a nickel oxide electrode on a foamed nickel support, obtained in forming in a nickel–zinc battery, does not exceed 0.7–0.85 of the calculated value corresponding to the transition $Ni^{2+} \rightarrow Ni^{3+}$, which is lower than the values obtained in nickel–cadmium and nickel–metal hydride batteries and in nickel–zinc batteries with a metal–ceramic nickel oxide electrode. This is due to the combined action of zinc introduced into the starting active paste of a nickel oxide electrode on a foamed nickel support and that contained in the electrolyte and to a decrease in the concentration of OH^- ions.

(2) The degree of charging of a nickel oxide electrode on a foamed nickel support obtained in subsequent cycling of nickel–zinc batteries is 0.6–0.5 and varies within this narrow range as the KOH concentration in the electrolyte decreases. In this case, the nickel oxide electrode on a foamed nickel support has about the same specific capacity as that of a metal–ceramic nickel oxide electrode because of the lighter support.

(3) Comparison of the degree of charging of the nickel oxide electrode on a foamed nickel support with that of the metal–ceramic nickel oxide electrode, obtained under similar conditions, shows that zinc intercalated into the electrode on a foamed nickel support stabilizes the capacity of the electrode and makes it less dependent on the varying electrolyte concentration, but simultaneously depresses the level at which this stabilization occurs.

Abstract—The composition and formation kinetics of erosion products of the metallic charge (aluminum, iron) in an electric-discharge reactor operating at an open-circuit voltage of 500–1000 V, peak pulse current of 250 A, and pulse energy of 0.5–1 J were studied. Dispersion products of the charge were subjected to electron-microscopic and X-ray phase analyses. The energy yield of erosion products was determined by chemical analysis to be hundreds of times the calculated yields of electrolysis. The erosion kinetics was studied and the mechanism of erosion was considered.

Electric-discharge methods for purification of wastewater, based on electroerosion of electrodes [1, 2], find use because a wider variety of chemical processes can be provided by substances constituting the electrode. If, however, the discharge occurs in water, the erosion yield of the electrodes is low, and the energy expenditure is high. For example, it was found in [3, 4] that the energy expenditure for erosion of metals in this mode is 2.8×10^6 to 5.6×10^6 kJ mol^{-1} (~104 kW h kg^{-1}).

In electric-discharge erosion treatment, the energy expenditure is 1.2–12 kW h kg^{-1} [5–10]. In this case, a reactor with bulky electrodes is used, with metal in the form of grains or shavings more or less insulated from one another by oxide films or having point contacts charged in between. When an electric current is passed through the reactor, a breakdown occurs in the multitude of insulating gaps, with electric explosions at these gaps or at conducting microcontacts.

In the opinion of Fominskii [5] and Zubenko and Yushchishina [6], the electroerosion of metals in water occurred via breakdown of the oxide layer at the electrode surface and the subsequent melting and spraying of the metal. The efficiency of such a process was rather high, 3–4 kW h kg^{-1}. Similar results were obtained in [9, 10]. In [7], a system with an active charge in the form of metal shavings was tested. In this case, the curvature of the contacting surfaces is markedly higher and each current pulse gives rise to multiple discharges at randomly arranged contacts. In this case, electroerosion occurs via disintegration of contacts by the current, and purification of water is associated not only with discharges in water, but also with chemical reactions involving the charge. Preliminary experiments demonstrated that the energy efficiency of erosion may be in this case as high as 1.2 kW h kg^{-1} [7]. This indicates that the method in question is promising both for purification of potable water and wastewater and for synthesis of various materials.

This study is concerned with the energetics, chemical mechanism, and formation kinetics of erosion products of the metallic (aluminum, iron) charge of an electric-discharge reactor.

EXPERIMENTAL

The experimental setup comprised a vessel into which 200 g of metal shavings used as a chemically active charge was placed. Electrodes were lowered into the vessel and 950 ml of distilled water was poured in. The electrodes were connected to a two-circuit source of pulsed current with the following parameters: pulse width ε_p = 10 μs; pulse repetition rate 100 Hz; voltage U 500–1000V; and current in the first half-period of the pulse, I = 250–400 A.

The concentration of iron ions was determined colorimetrically [11]: Fe^{2+}, with 2,2'-bipyridine; ΣFe, with sulfosalicylic acid in an alkaline medium; and Fe^{3+}, as the difference $c(Fe^{3+}) = c(\Sigma Fe) - c(Fe^{2+})$.

1070-4272/05/7809-1438© 2005 Pleiades Publishing, Inc.

The specific surface area of the forming precipitate was measured by BET from thermal desorption of argon.

Electron-microscopic studies were carried out on a JEM-100 CXII electron microscope, and X-ray phase analysis, on a Shimadzu XRD 6000 diffractometer.

The energy expenditure for water purification was determined by obtaining current and voltage pulse oscillograms with an S8-17 oscilloscope. The pulse energy was calculated by integrating current and voltage oscillograms, to give values E 0.5–1.0 J pulse^{-1}. In addition, we measured the temperature of water in which an iron charge is subjected to the action of an electric discharge: at E = 0.5 J pulse^{-1} its rise was 0.53 deg min^{-1}.

When electric pulses act upon a charge poured-over with water, electric discharges are observed in the form of sparks all over the visible volume. After the iron charge is treated for several tens of seconds, a black suspension becomes noticeable, which partly turns brown in storage. In the case of an aluminum charge, a light gray suspension is formed, which becomes white in storage.

Spectral studies and X-ray phase analysis of products formed in dispersion of the charge demonstrated that the reaction of metal particles with water yields both hydroxides and oxides, which have a developed surface and fibrous structure for aluminum (Fig. 1a), and are of different shapes (plates, needles, and isometric crystals; Fig. 1b) for iron. The diameter of fibers of aluminum erosion products is 5–10 nm, and the diagonal dimensions of iron plates, about 100 nm. These structures have a large specific surface area (105 ± 5 m^2 g^{-1} for an iron charge dried at 110°C, and 293 ± 5 m^2 g^{-1} for an aluminum charge).

An X-ray phase analysis of products formed in erosion of the electrodes demonstrated that the products obtained mainly contain a crystalline substance with a structure close to that of Fe_3O_4 in the case of an iron charge, and boehmite AlOOH in the case of the aluminum charge.

To study the dynamics of accumulation of erosion products of an iron charge in various forms in water, both the forming suspension as a whole and, separately, the filtrate were analyzed after a certain time of treatment with electric discharges. The data on iron accumulation in various forms in solid erosion products are listed in the table.

The experimental data obtained were processed and dependences were plotted in the log–log coordinates (Figs. 2, 3). The total amount of iron (mg s^{-1}) removed from the electrodes (charge) is described as a function of the time of action of the discharge by the following empirical relations:

$$\log c_{Fe} = 0.72 \log t + 1.1331 \text{ or } c_{Fe} = 13.6 t^{0.72}. \quad \text{(I)}$$

The relative amount of Fe^{3+} in the suspension is

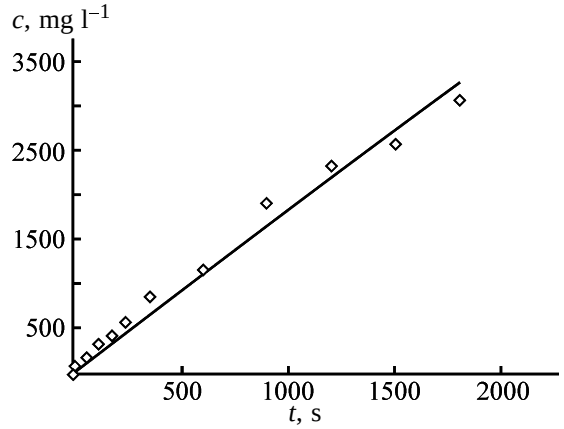

Fig. 4. Concentration c of aluminum ions in erosion products (in suspension) vs. the time *t* of action of an electric discharge.

shown in Fig. 3, whence follows that it passes through a minimum.

The variation of the concentration of Fe^{3+} and Fe^{2+} ions in the filtrate in electric-discharge treatment of water with an iron charge does not follow any regular pattern, and their concentration is approximately 1000 times less than that in the solid product, 0.187 to 2.347 mg l^{-1}.

The electroerosion kinetics of an aluminum charge was studied (Fig. 4). In contrast to the case of an iron charge, the dependence of the concentrations in the suspension and filtrate on the treatment time is linearized in the *c*–*t* coordinates [Al^{3+} concentration (mg l^{-1}) against the time of an electric-discharge treatment (s)].

The amount of aluminum removed from the electrodes (charge) is described as a function of the time of action of the discharge by the following empirical relation:

$$c_{Al^{3+}} = 1.82\,t. \qquad \text{(II)}$$

The installation used in the study shows a wide scatter of working characteristics, which is due to the structure and composition of the charge and to the dimensions and configuration of the reaction zone. Below, the results obtained in determining the energy expenditure in one of the runs are presented as an example.

In this run, the pulse repetition frequency was 100 Hz; energy released in a pulse, E = 0.5 J; mass of water, 950 g; mass of iron charge, 200 g; and mass of iron passing into suspension (in the form of oxide), 0.33 g min^{-1}. Hence, it can be calculated that the energy yield of iron was 7.0 mol (kW h)$^{-1}$, and the energy expenditure, 2.54 kW h kg^{-1} (0.142 kW h mol^{-1}) dispersed iron.

In this case, the balance of the electric and thermal energy has in this case the following form: with the loss of heat disregarded, a temperature rise by 0.714 deg min^{-1} corresponds to the experimentally determined uptake of electric energy equal to 3 kJ min^{-1}. In addition, chemical reaction may yield 16.5 kJ mol^{-1} in oxidation of iron with water, which may lead to a temperature rise by 0.01 deg min^{-1}, but more probable is oxidation of Fe with dissolved oxygen to give 376 kJ mol^{-1} (0.297 deg min^{-1}). The overall rise in temperature may constitute 1.0 deg min^{-1}. This value exceeds that found in the experiment (0.53 deg min^{-1}), which may be due both to thermal loss and to incomplete oxidation of iron to Fe^{3+}.

The energy expenditure obtained in this study markedly exceeds that reported previously (0.067 kW h mol^{-1} [7]), which is due to different geometric and other parameters of the experimental setup.

The energy expenditure in electroerosion of aluminum under comparable conditions was 0.046 kW h mol^{-1}. If the electroerosion mechanism consists in melting and spraying of the melt, the lower expenditure for heating to the melting point (30 and 9 kJ mol^{-1}) and for detachment of particles from the support (atomization heats 354 and 302 kJ mol^{-1})

may be responsible for the decrease in the energy expenditure.

It is of interest to compare the energy yield of the electroerosion product with the radiation-chemical and electrochemical yields of reactions in solutions and in an electric explosion of a wire [12–14].

For example, the energy yield of a product in nonchain radiation-chemical processes is commonly within 0.01–10 molecules per 100 eV. The above value of the yield for iron, 7.0 mol $(kW\ h)^{-1}$, corresponds to 19 molecules per 100 eV, and a value of 40 was obtained in [7].

In the case of a purely electrochemical oxidation of iron, the energy expenditure

$$W = znUF = 3 \times 1 \times 500 \times 97\,500 = 1.4 \times 10^8 \text{ J mol}^{-1} \text{ or}$$

$$714 \text{ kW h kh}^{-1}, \quad \text{(III)}$$

where z is the ion charge; n, number of metal equivalents; F, Faraday constant; and U, potential difference.

If 2.54 kW h is expended for oxidation of iron, only 3.6 g of the metal can be oxidized at a voltage of 500 V. As 1 kg is actually oxidized in this case, the amplification factor is more than 275, and even 550 according to [7].

A comparison with the process of metal dispersion by an electric explosion of a wire [12] can be made in the ratio of the supplied energy to the sublimation energy of the corresponding metal. In the given set of experiments, this value was 0.68 to 1.44 for electroerosion of iron, and 0.27 to 0.55 for aluminum. Commonly, metal powders are obtained by electric explosion of a wire at $E/E_c \approx 0.8$–2.5. If this procedure is carried out in the atmosphere of chemically active gases, the relative energy contribution may be ~0.6 and less.

Thus, the efficiency of electroerosion considerably exceeds that of processes in which each atom (molecule) of a reagent is subjected to an external action. This is evidence in favor of a collective or chain mechanism, in which energy is consumed for dispersion of the material via detachment of particles containing a large number of bound atoms, rather than by its evaporation. Alternatively, the process uses the energy of oxidation of the material with water or oxygen. The electroerosion resembles to the greatest extent the electric explosion of a metallic wire in an oxygen atmosphere [13, 14].

In the case when current pulses are passed through the metallic charge, the pulse energy probably mostly acts upon the metal, with the metal heated and small metal particles detached from the support. A particular detachment mechanism and the size of these particles will depend on the specific energy supplied and the rate of the energy supply. This may be evaporation of the metal, its melting and spraying, or mechanical detachment of nanoparticles. At the electric discharge parameters used in the study, the most probable in the primary process is formation of metal particles via spraying and detachment.

Apparently, the main stages of the process can be represented as the following scheme (M_c, compact metal; M_n, metal nanoparticles):

$$M_c \xrightarrow{\text{Electric-discharge erosion}} M_n, \quad (1)$$

reduction of water with the metal:

$$M_n + H_2O \longrightarrow M(OH)_n + H_2, \quad (2)$$

and oxidation of metallic particles with dissolved oxygen:

$$M_n + O_2 + H_2O \longrightarrow M(OH)_n. \quad (3)$$

The local temperature may be high because of the energy released by the electric discharge or by the exothermic oxidation [8]. Therefore, the resulting hydroxides may decompose partly (to oxohydroxides) or completely (to oxides). These are $Fe(OH)_2$, $Fe(OH)_3$, FeO, Fe_2O_3, Fe_3O_4, and FeO(OH) in the case of Fe, and $Al(OH)_3$, AlOOH, and Al_2O_3 for Al.

It is noteworthy that, in the mechanism described, the electric discharge acts upon the metallic electrode (charge), rather than upon water. In an alternative mechanism, the action of the electric discharge upon water is considered. This mechanism includes reactions in which O and OH radicals and H_2O_2 and O_3 molecules are formed in the electric discharge, with the subsequent oxidation of the compact material with these species. In this case, OH and O radicals presumably do not have enough time to react with M_n before their recombination to give H_2O_2, O_3, and O_2, and, therefore, the most probable pathway in this case is oxidation of the compact material with hydrogen peroxide and ozone, e.g., $Fe_c + H_2O_2 = Fe(OH)_2$.

The energy yield of reactions (1)–(3) under the action of an electric discharge on the metal should theoretically considerably exceed that for decomposition of water under the action of an electric discharge to give O_3 and H_2O_2 (without formation or involve-

ment of iron particles). This is due to the fact that, in the latter case, electric energy is expended for formation of each molecule of the product, whereas in the case of an electric discharge with electrode erosion, it is consumed for formation of a metal particle containing 107–108 atoms. At a particle size of 30–50 nm, only less than 1% of its bonds with the matrix are to be ruptured; further, nanoparticles react spontaneously to give the final product with energy release. The role of the electric discharge is reduced in this case to activation (depassivation) of the metal both via formation of nanoparticles and because of self-heating, with the amplification factor (per energy expended for detachment of a particle) exceeding 100. This estimate is made without regard for melting of the metal; taking this factor into account will make the amplification factor lower. The value calculated from the experimental data exceeds that expected on the basis of the above considerations by a factor of 2–3. This may be due to activation of the interaction between water and the metal matrix at the place of particle detachment or to a lower energy expenditure for dispersion of the metal by spraying.

The energy expenditure in electropulse erosion of iron, 0.067–0.142 kW h mol^{-1} (Fe), is markedly lower than that for electric-discharge synthesis of H_2O_2 molecules and OH radicals in water (0.12 molecule per 100 eV corresponds to 22.34 kW h mol^{-1} [15]), and, therefore, reactions of the type (1)–(3) are more probable; in the case of an iron charge, these reactions can be specified:

$$Fe_c \xrightarrow{\text{Electric-discharge erosion}} Fe_n, \quad (4)$$

$$Fe_n + H_2O \longrightarrow Fe(OH)_2 + H_2, \quad (5)$$

$$Fe(OH)_2 + O_2 + H_2O \longrightarrow Fe(OH)_3. \quad (6)$$

$$Fe_n + O_2 + H_2O \longrightarrow Fe(OH)_3 \text{ or } FeO(OH). \quad (7)$$

The fraction of completely oxidized iron passes through a minimum (Fig. 3), which may be due to consumption of dissolved oxygen by reactions (6) and (7), with the subsequent increase in this fraction through diffusion of oxygen to incompletely oxidized particles.

In the case of an aluminum charge, the occurring processes are simpler: aluminum particles formed in the electric discharge react with water and oxygen by reactions (2) and (3) to give a hydroxide, which can decompose to an oxohydroxide and oxide.

The main stages of the process for the aluminum charge can be represented as the following scheme:

$$Al_c \xrightarrow{\text{Electric-discharge erosion}} Al_n, \quad (8)$$

$$Al_n + H_2O \longrightarrow Al(OH)_3 + H_2, \text{ or } AlOOH + H_2, \quad (9)$$

$$Al_n + O_2 \longrightarrow Al_2O_3. \quad (10)$$

Complex ions, e.g., $[Al(H_2O)_5(OH)]^{2+}$ and $[Al(H_2O)_4(OH)_2]^{+}$, may be formed in solution.

Three mechanisms are possible for the erosion kinetics. The first consists in that erosion occurs via microscopic explosions of the material of the electrode (charge) at places of contacts, with the nature and number of these contacts remaining unchanged during erosion. This mechanism may become operative for a charge in the form of spheres or particles of other shapes, with surfaces of low curvature. This may be promoted by presence on the metal surface of thin dense films whose breakdown causes erosion, as well as by a low melting point of the metal and its low hardness. This is presumably the case for the aluminum charge, for which the erosion rate is constant (Fig. 4).

The second mechanism, which is characteristic of an iron charge, consists in that erosion occurs at irregularities with a high surface curvature (small radii of curvature). Electric discharge leads to a decrease in the height of projections and in the number of irregularities, and this decrease makes the resistance of breakdown gaps higher and the fraction of energy expended for spraying of the material lower.

The time dependence of the erosion rate can be represented in this case in the general form as

$$dc/dt = kc^{1/n}, \quad \text{(IV)}$$

where c is the concentration of the dispersed metal in the suspension, and n is the exponent dependent on the electrode configuration: $n = 3$ if the projections are eroded so that the volume of the metal being dispersed is proportional to the projection heights; $n = 2$ if the erosion products insulate or somehow diminish the active area of the electrodes; and $n = 1$ if the degree of erosion depends on the volume of the material removed in erosion (e.g., in the case of a decrease in the conductivity of the liquid, which is hardly probable).

Integration gives

$$c_{Fe} = \frac{n+1}{n} kt^{n/(n+1)} = k_n t^{\nu}. \quad \text{(V)}$$

Comparison of the experimentally obtained time dependences of the erosion yield [Fig. 2, formula (I)] shows that $\nu = 0.72$. This value corresponds to $1/n = 0.38$, which somewhat exceeds the theoretical value $1/n = 0.33$ for the case of erosion of projections.

The third mechanism consists in that, after primary erosion by, e.g., the second mechanism, a spontaneous topochemical reaction is initiated at damaged places. If this reaction is rapidly terminated (by fast formation of a protective film), the overall kinetics may correspond to formula (V). If, however, the specific rate of the reaction remains constant at the place of particle detachment, the kinetic equation becomes more complex:

$$dc/dt = k_1 c^{1/n} - k_2 c^m, \quad \text{(VI)}$$

where n is the configuration index for primary erosion; m, the index of the topochemical reaction, which is dependent on the configuration of the reaction zone; and k_1 and k_2, effective rate constants of the primary erosion and topochemical reaction, respectively.

Integration of this expression in the general form gives rather complex formulas inconvenient for analysis. However, rather simple expressions are obtained in certain particular cases, e.g., for $n = 3$ and $m = 1$:

$$t = 3(k_1 + k_2 c^{4/3})/4k_2. \quad \text{(VII)}$$

Such a mechanism is possible, e.g., in the presence of a catalyst.

CONCLUSIONS

(1) The action of pulsed electric discharges on a metallic charge causes its erosion with the subsequent oxidation of the forming micro- and nanoparticles. This gives precipitates with varied morphology: fibrous for Al and mixed (films, needles, nanocrystals) for Fe.

(2) The energy expenditure is 0.142 kW h mol^{-1} for Fe atoms, which is by a factor of 275 lower than that in electrolytic erosion. For the aluminum charge, the energy expenditure is approximately three times lower, which is due to the lower melting point of aluminum.

(3) A kinetic analysis demonstrated that, in electroerosion of a charge in the form of iron shavings, the erosion is hindered by dispersion of projections (points) and their resulting gradual smoothing. The electroerosion of aluminum occurs under similar conditions at a constant rate, at least during a time of about 30 min. This is probably due to higher plasticity and lower melting point of aluminum and to specific properties of the surface oxide film.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Regeneration by Membrane Electrolysis of an Etching Solution Based on Copper Chloride

D. Yu. Turaev, S. S. Kruglikov, and A. V. Parfenova

Mendeleev Russian University of Chemical Engineering, Moscow, Russia

Received March 24, 2005

Abstract—Regeneration of an acid solution for copper etching, based on copper(II) chloride, hydrochloric acid, and ammonium chloride, by membrane electrolysis was studied. The concentrations of copper(I, II) ions in the cathode and anode spaces, current efficiency, degree of copper recovery, and specific consumption of electric power at different quantities of electricity passed through the electrolyzer were measured. The influence exerted by the current density on the electric power expenditure for recovery of metallic copper was examined. The anode current efficiency by chlorine was determined with a spent etching solution and an H_2SO_4 solution used as anolyte.

One of the main procedures in manufacture of printed-circuit boards is copper etching, for which an acid solution based on Cu(II) chloride is frequently used. The working principle of this etching solution is based on the reaction

$$Cu^{2+} + Cu + 4Cl^- = 2[CuCl_2]^-, \quad (1)$$

whence follows that the etching solution should contain chloride ions in an amount sufficient for binding of the whole amount of copper(I) into a complex. The necessary excess of chloride ions is introduced into solution in the form of HCl, NH_4Cl, or NaCl. In the course of etching, the concentration of Cu(II) ions decreases through an increase in the concentration of Cu(I) ions, which makes slower the etching rate.

Under industrial conditions, such a spent etching solution can be regenerated [1] by oxidizing Cu(I) ions with atmospheric oxygen or hydrogen peroxide.

To maintain a constant, nearly optimal composition of the solution, all its components except Cu(II) ions should be added to it. As a result, each cycle of etching and chemical regeneration leads to a substantial increase in the volume of the etching solution and involves an additional expenditure of chemicals. Furthermore, the appearing excess amount of the solution requires an appropriate treatment, which consists at the majority of plants in the reagent method for production of metallic copper or of its sparingly soluble compounds (oxides, $CuO \cdot CuCl_2$).

Electrochemical regeneration of a spent etching solution in a two-chamber electrolyzer with cation-exchange membrane and circulation of the etching solution between the anode chamber and the etching machine was considered in [2]. It should be noted that the amount of ions of bivalent copper(II) formed at the anode in a process of this kind will always markedly exceed the amount of copper ions that passed across the membrane from the anode space into the cathode chamber. This mismatch leads to a decrease in the concentration of copper ions and increase in that of hydrogen ions in the catholyte. This, in turn, gives rise to a side reaction of hydrogen evolution at the cathode. Thus, circulation of the etching solution only between the anolyte and the etching machine leads to limitation of the rate of copper removal from the etching solution by the rate of its migration across the cation-exchange membrane from the anode space into the cathode space in the form of Cu^{2+} ions. In the steady state, the current efficiency by copper will be rather low, because it should be equal to the transport number of Cu^{2+} ions across the membrane. The additional supply of copper ions, which is necessary for maintaining their concentration in the catholyte at a prescribed level, can be provided by circulating the etching solution not only through the anode chamber, but also through the cathode chamber.

Copper is removed from the surface of printed-circuit boards in the etching machine by spraying of the etching solution over a printed-circuit board. Owing to the contact between the etching solution and atmospheric oxygen, copper(I) ions are partly oxidized to Cu(II) already in the etching machine. This reaction

1070-4272/05/7809-1444© 2005 Pleiades Publishing, Inc.

makes lower the concentration of copper(I) in the anolyte and thereby leads to a decrease in the quantity of electricity that should be passed through the anolyte before the onset of evolution of the toxic chlorine. This quantity of electricity is several times smaller than that necessary for removal of etched-off copper from the etching solution. Therefore, the scheme under consideration cannot balance the processes at the anode and cathode without formation of a chlorine–oxygen mixture at the anode.

Thus, a topical task is to modify the process of electrochemical regeneration to preclude formation of Cl_2 at the anode in considerable amounts. In this study, two possible ways to solve the problem are analyzed: (1) regeneration in two stages, with each portion of a spent etching solution electrochemically treated first in the cathode chamber and then in the anode chamber; and (2) electrochemical treatment of a spent etching solution only in the cathode chamber, with a sulfuric acid solution used as anolyte.

In the first version of the process, oxidation of $CuCl_2^-$ ions is the predominant anodic reaction, because nearly the whole amount of copper(II) contained in an etching solution during its residence in the cathode chamber will be converted either into the metal or into $CuCl_2^-$ ions.

In the second version, the rate of discharge of chloride ions at the anode will be limited by the rate of their transfer from the catholyte across the membrane, i.e., will be determined solely by the selectivity of the membrane.

EXPERIMENTAL

A two-chamber cell [3] with a Flemion cation-exchange membrane [4] was used in the study. The anode space was hermetically sealed in order to catch and absorb gases evolved at the anode. For a more effective removal of Joule heat, the cell was placed in a vessel with cold water. The current and voltage were monitored with a digital ammeter and an M-830B digital voltmeter. The cell was fed from a B5-48 dc power supply. A titanium plate with a working surface area of 0.25 dm^2 served as a cathode, and a platinum-plated niobium plate with the same working surface area, as an anode.

The electrolysis was carried out in accordance with the above-mentioned two schemes of the process. Scheme 1: an etching solution containing no Cu(I) ions in the 350-ml cathode chamber and a solution containing Cu(I) and Cu(II) ions in the 350-ml anode space; scheme 2: etching solution containing no Cu(I) ions in the cathode space and 1.0 N H_2SO_4 solution in the anode space.

Composition of the solutions used

Composition	Concentration, g l^{-1}		
	catholyte	anolyte	wash water
Cu^{2+}	39.3–41.2	24.1–34.6	2.54
NH_4Cl	150	150	9.46
HCl	50	50	3.15
Including Cu^+	0	23.8–33.5	0

Scheme 2 was also used in experiments simulating the recovery of copper ions from wash water in a trapping bath after etching. In these experiments, the catholyte simulated the wash water in the trapping bath and a 1 N H_2SO_4 solution served as the anolyte. The chlorine contained in the anode gas was absorbed with a 1 M solution of KI. The electrolysis was performed at current densities of 2 and 4 A dm^{-2}. The starting solution had the following composition (g l^{-1}): $CuCl_2 \cdot 2H_2O$ 106–111, NH_4Cl 150, and HCl 50. Metallic copper was dissolved to prepare the anolyte. The composition of the solutions poured into the cell before the experiments is listed in the table.

Cathodic and anodic polarization curves were obtained in the potentiodynamic mode at potential sweep rates of 0.5 and 1 mV s^{-1} with a PI-50-1.1 potentiostat. The content of Cu(I) and Cu(II) ions was determined in the starting solutions and in the anolyte in the course of electrolysis. In the experiments using an H_2SO_4 solution as the anolyte, the content of chloride ions was determined. The content of Cl_2 in the anode gas was found by titration of the iodine evolved in passing the anode gas through a KI solution.

Cathodic process. The scheme of processes occurring in the two-chamber electrolyzer in electrolysis of a chloride solution of copper is shown in Fig. 1.

The main cathodic reaction is reduction of Cu^{2+} ions, which occurs in two stages:

$$Cu^{2+} + 2Cl^- + e^- \rightarrow CuCl_2^-, \quad (2)$$

$$CuCl_2^- + e^- \rightarrow Cu + 2Cl^-. \quad (3)$$

In this case, it can be seen from curve *3* (Figs. 2a–2d) that, first, reaction (2) dominates, which is manifested in accumulation of Cu^+ ions in solution. Only after approximately 20 A h l^{-1} of electricity is passed, their concentration starts to decrease, i.e., the rate of further reduction becomes higher than the rate of their

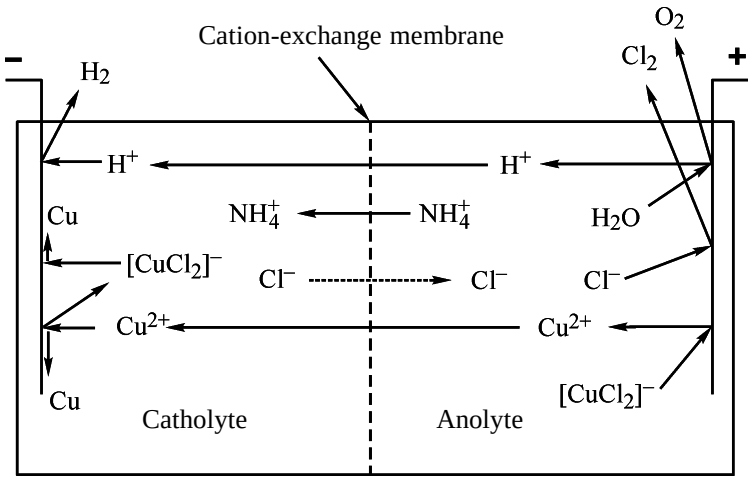

Fig. 1. Schematic of the processes occurring in a two-chamber cell.

formation. Presumably, the cathode potential is the main factor determining the predominance of a one- or two-electron process. This is indicated by the manner in which the current density affects the run of curve *3* (Figs. 2a–2d): at a current density of 2 A dm^{-2}, a higher concentration of Cu^+ ions is reached than that at a current density of 4 A dm^{-2}. This explanation is also supported by the faster decrease in the concentration of Cu^{2+} ions at a lower current density (Figs. 2a–2d, curves *2*). The cathode potential, naturally, depends on the current density and is steadily shifted in the course of electrolysis in the negative direction because of a change in the solution composition, which consists in that the total concentration of copper ions gradually decreases. At a lowered current density and, accordingly, at a more positive averaged cathode potential, it is possible to accumulate univalent copper in amounts exceeding the content of Cu^{2+} ions, which results in differential current efficiencies that exceed 100% (Figs. 3a–3d, curves *3*).

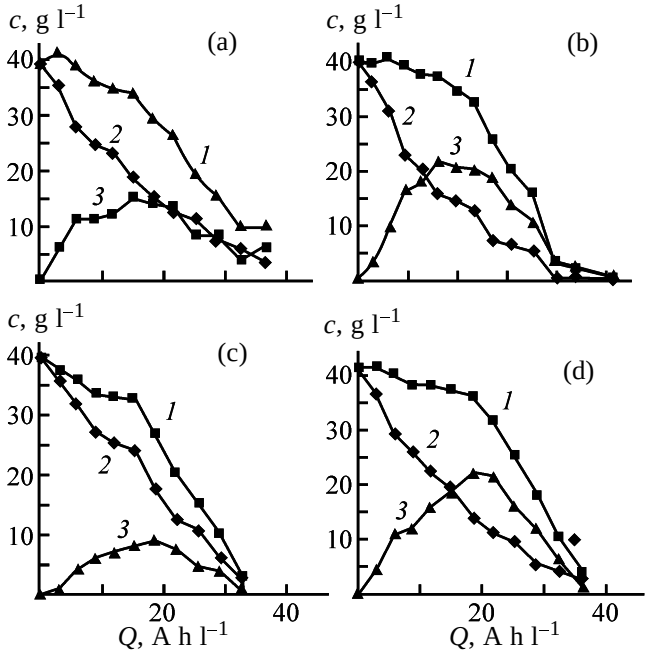

Fig. 2. Concentration *c* of copper ions in the catholyte vs. the amount *Q* of passed electricity. Anolyte: (a, b) Cu(I)-containing copper etching solution and (c, d) 1.0 N H_2SO_4 solution. Cathode current density, A dm^{-2}: (a, c) 4 and (b, d) 2. Concentration, g l^{-1}: (*1*) total, (*2*) Cu(II) ions, and (*3*) Cu(I) ions.

A considerable decrease in the concentration of Cu(I) and Cu(II) ions in the course of further electrolysis at an amount of passed electricity exceeding 30–40 A h l^{-1} will diminish the current efficiency by metallic copper and copper(I) to values that are markedly lower than 100%. With account of the fact that the concentrations of Cu(I) and Cu(II) are close, the decrease in the differential current efficiency can be only attributed to occurrence of a side process of hydrogen evolution. The results of polarization measurements confirm this conclusion (Fig. 4, curve *4*).

At a cathode current density of 4 A dm^{-2}, the average current efficiency by Cu^0 is, after the recovery of 62% of the whole amount of copper(I, II) present in the anolyte at the beginning of an experiment, 66%, and the average electric power consumption for recovery of Cu^0, 25.3 kW h kg^{-1}. At 2 A dm^{-2}, these values are strongly different: after the recovery of 77.1% of the whole amount of copper(I, II) contained in the catholyte at the beginning of an experiment, the average current efficiency by Cu^0 is 78.1%, and the average electric power expenditure for Cu^0 recovery,

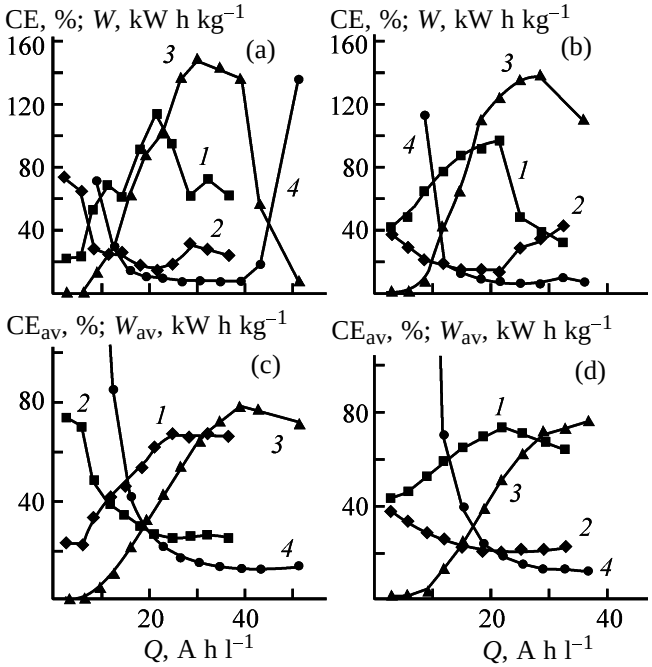

Fig. 3. Current efficiency CE by copper, specific electric power expenditure W, average current efficiency CE_{av}, and average specific electric power expenditure W_{av} vs. the amount Q of passed electricity at cathode current densities of (*1, 2*) 4 and (*3, 4*) 2 A dm^{-2}. Anolyte: (a, c) Cu(I)-containing copper etching solution and (b, d) 1.0 N H_2SO_4 solution. (a, b) (*1, 3*) CE and (*2, 4*) W; (c, d) (*1, 3*) CE_{av} and (*2, 4*) W_{av}.

11.7 kW h kg^{-1} (Fig. 3c). Use of a 1.0 N H_2SO_4 solution as anolyte at the same cathode current density does not lead to any significant changes in the dependence for the cathode space, compared with the anolyte in the form of a solution containing Cu(I, II) ions (Figs. 2, 3). Minor differences are, in all probability, due to transfer of Cu^{2+} ions from the anolyte into the catholyte, and also to different electrical conductivities of the anolytes compared.

Anodic processes. The total concentration of copper in the anode space decreases from 57.5 to 50.1 g l^{-1} (Figs. 5a, 5b; curves *1*) via migration of Cu(II) cations from the anode space into the cathode chamber. In the process, the concentration of copper(II) in the anode space increases (curve *2*), and that of Cu(I) decreases (curve *3*). To prevent evolution of the toxic Cl_2, the anode current density should not exceed the limiting current of diffusion of Cu(I) ions, which decreases with its concentration (Fig. 4, curves *1–3*). If a 1.0 N H_2SO_4 solution is used as anolyte, the anode current efficiency by chlorine (Figs. 5c, 5d; curves *4*) is limited by the concentration of chloride ions in the anolyte (Fig. 5, curves *5*), whose migration into the anolyte is governed by the

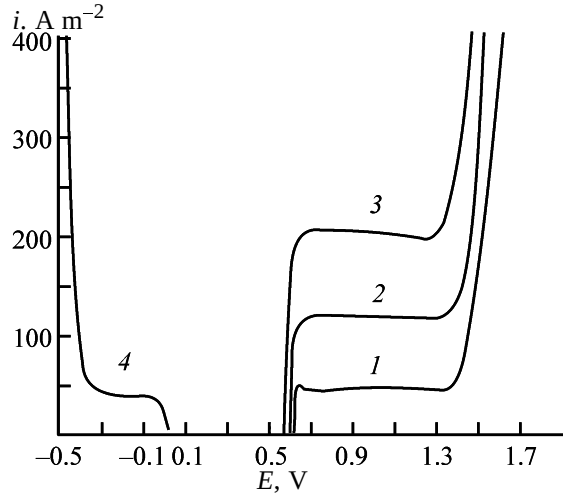

Fig. 4. (*1–3*) Anodic and (*4*) cathodic polarization curves. (*i*) Current density and (*E*) polarization. Curves *1–3* were measured with an anode made of platinum-plated niobium with a working surface area of 6.25 cm^2 (titanium as cathode) at a potential sweep rate of 0.5 mV s^{-1} in a solution of 50 g l^{-1} HCl and 150 g l^{-1} NH_4Cl. Content, g l^{-1}: (*1*) Cu^+ 7.62, Cu^{2+} 47.63; (*2*) Cu^+ 16.51, Cu^{2+} 43.18; and (*3*) Cu^+ 24.135, Cu^{2+} 40.00. Curve *4* was measured with a copper cathode with a working area of 5.72 mm^2 (platinum-plated niobium as anode) in a solution composed of 50 g l^{-1} HCl, 150 g l^{-1} NH_4Cl, and Cu_Σ 0.635 g l^{-1} at a potential sweep rate of 1 mV s^{-1}.

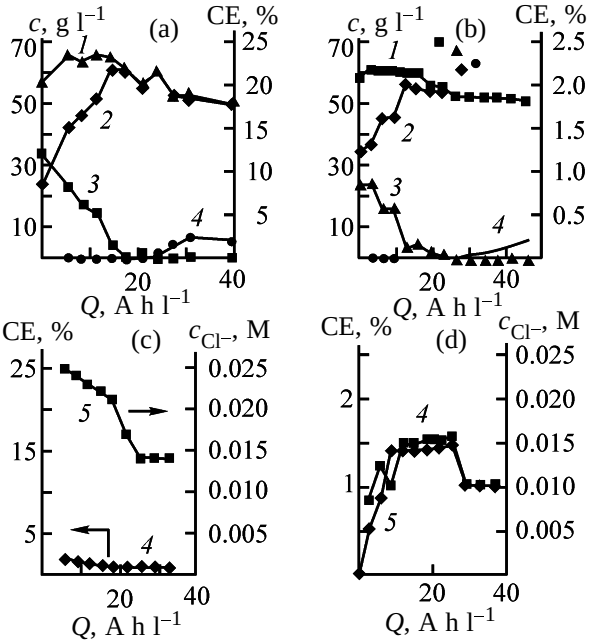

Fig. 5. Concentration of (a, b) copper ions c and (c, d) chloride ions c_{Cl^-} and (a–d) current efficiency CE by chlorine in the anolyte vs. the amount Q of electricity passed. Anolyte: (a, b) copper etching solution and (c, d) 1.0 N H_2SO_4 solution. Anode current density, A dm^{-2}: (a, c) 4 and (b, d) 2. Concentration, g l^{-1}: (*1*) total copper ions, (*2*) Cu(II) ions, and (*3*) Cu(I) ions; (*4*) current efficiency by chlorine; and (*5*) concentration of chloride ions.

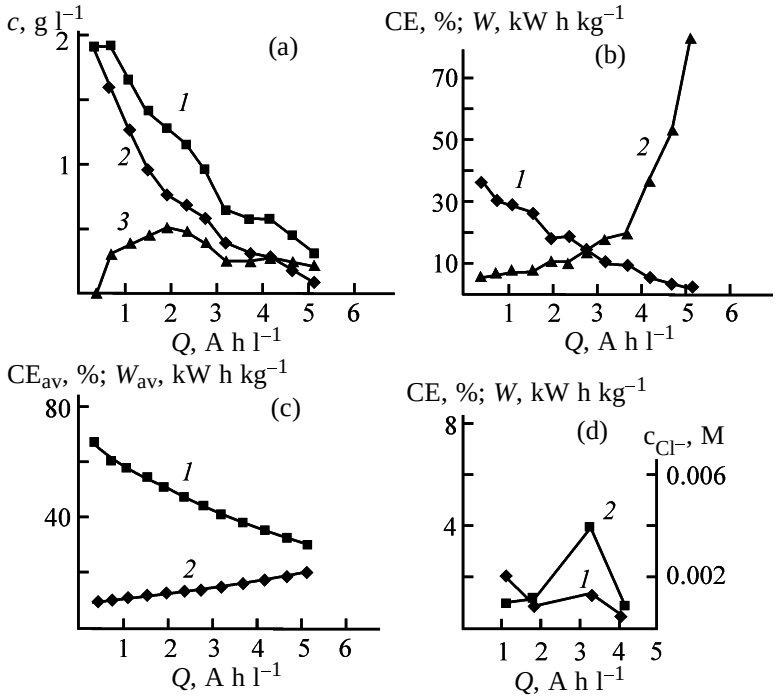

Fig. 6. Recovery of copper ions from the wash water from a trapping bath by membrane electrolysis. Two-chamber cell with a perfluorinated cation-exchange membrane; wash water from the trapping bath as catholyte and 1.0 N H_2SO_4 solution as anolyte; cathode and anode current density 1 A dm^{-2}. Dependence on the amount of passed electricity of (a) concentration *c* of copper ions in the catholyte: (*1*) total copper ions, (*2*) copper(II) ions, and (*3*) Cu(I) ions; (b) (*1*) current efficiency CE by copper and (*2*) electric power expenditure *W*; (c) (*1*) average current efficiency by copper and (*2*) average electric power expenditure; and (d) (*1*) concentration of chloride ions in the anolyte and (*2*) current efficiency by Cl.

selectivity of the cation-exchange membrane. It should be noted that, in the presence of chloride ions in the anolyte in a considerable concentration, the anode current efficiency does not exceed 2.5% at an anode current density of 4 A dm^{-2} and decreases with the current density (Figs. 5a, 5b; curves *4*). The regeneration by scheme (1) is particularly efficient if the concentration of Cu(I) ions in the solution being regenerated substantially exceeds that of Cu(II) ions. In this case, virtually complete oxidation of Cu(I) into Cu(II) is achieved at a simultaneous minor decrease in the total concentration of copper ions. If it is necessary to markedly diminish the total concentration of copper ions, Cl_2 inevitably evolves at the anode. The advantage of scheme (2) consists in the possibility of regeneration of copper etching solutions with any concentration ratio of Cu(I) and Cu(II) ions. Cl_2 evolved at the anode is completely absorbed via oxidation of Cu(I) into Cu(II). In both versions, it is advisable to use a low current density in order to make lower the electric power consumption.

The results obtained in a study of electrodeposition of Cu^0 from the wash water in the cathode space of the two-chamber electrolyzer with a hermetically sealed anode space are shown in Fig. 6. The curve describing the dependence of the concentration of copper ions in the catholyte on the amount of passed electricity show a run similar to that presented above. The current efficiency by Cu^0 decreases, which points to intense evolution of hydrogen during the entire experiment. This leads to an increase in the electric power consumption.

The electrochemical treatment of the wash water can decrease the concentration of copper ions in the trapping bath from 2.54 to 0.32 g l^{-1} on passing 5.1 A h l^{-1}, with the average current efficiency by copper equal to 30.5%, and the average electric power expenditure, to 20 kW h kg^{-1}.

CONCLUSIONS

(1) Separation of the cathode and anode spaces with a cation-exchange membrane makes it possible to prevent oxidation of copper(I) to Cu(II) at the anode, with its subsequent reduction to Cu(I) at the cathode, to raise the current efficiency by Cu^0, and to diminish the current efficiency by Cl_2.

(2) Use of low cathode and anode current densities

prevents or markedly diminishes the evolution of H_2 at the cathode and Cl_2 at the anode, and also reduces the electric power expenditure per kilogram of recovered Cu^0.

(3) Use of 1.0 N H_2SO_4 or a copper etching solution as anolyte enables regeneration of copper etching solutions with different Cu(I) and Cu(II) concentrations. However, this requires that the anode space should be hermetically sealed to trap the evolving chlorine and use it to oxidize Cu(I) ions.

(4) To decrease the loss of copper ions from the etching shop to wastewater, it is advisable to introduce a procedure of washing in the trapping bath, with a low concentration of copper ions maintained in the bath by means of membrane electrolysis.

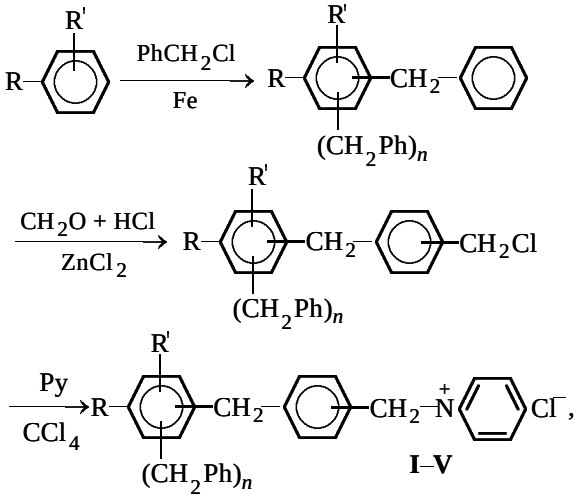
APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Corrosion-Preventing Properties of Benzyl-Substituted *N*-Benzylpyridinium Chlorides

D. A. Pisanenko, I. S. Pogrebova, V. O. Avilov, and K. V. Yantsevich



Kiev Polytechnic Institute, National Technical University of Ukraine, Kiev, Ukraine

Received May 4, 2005

Abstract—Benzyl-substituted *N*-benzylpyridinium chlorides were prepared by quaternization of pyridine with chloromethylated benzyl–substituted toluene, xylene, ethylbenzene, *o*-chlorotoluene, and phenetole. These compounds were studied as inhibitors of corrosion of 08 kp steel, 20 steel, and TsO zinc in solutions of sulfuric and hydrochloric acids at 20–80°C.

Quaternary ammonium salts are known [1] to be adsorption inhibitors of acid corrosion of metals. The inhibiting power of mixtures of these salts is frequently higher than that of the pure compounds [2]. Katapins used in industrial etching of ferrous and nonferrous metals with acids belong to this inhibitor type [3, 4]. The disadvantage of these inhibitors is irreproducibility of their protecting properties owing to the use in their synthesis of complex mixtures of alkylbenzens, nonaromatic hydrocarbons, and linear oligomer of benzyl chloride of uncontrolled composition. Therefore, preparation of inhibitors of this type from available compounds of known composition and study of their corrosion-preventing properties are urgent problems.

In this study we examined inhibition of acid corrosion of steels and zinc by benzyl-substituted *N*-benzylpyridinium chlorides prepared by the following scheme:

I–V

where n = 0–2; (**I**) R = Me, R'= H; (**II**) R = R' = Me; (**III**) R = Me, R' = 2–Cl; (**IV**) R = EtO, R'= H; (**V**) R = Et, R' = H.

To estimate the corrosion-protecting properties of salts **I**–**V** with respect to 08 kp steel, 20 steel, and TsO zinc, we measured the coefficient of corrosion deceleration γ, the degree of corrosion inhibition Z, and the shift of the corrosion potentials ΔE_c in the presence of these salts.

EXPERIMENTAL

The initial benzylarenes were prepared by the reaction of toluene, xylene, and ethylbenzene (technical grade) and of *o*-chlorobenzene and phenetole (reagent grade) with a threefold excess of benzyl chloride in the presence of iron chips [5] at 80–90°C for 5–6 h. The yield of benzylarenes was 61–89%. As determined by GLC, the ratio of mono-, di-, and trisubstituted benzylarenes in reactions with toluene, xylene, *o*-chlorobenzene, phenetole, and ethylbenzene was 62 : 26 : 12, 60 : 27 : 13, 65 : 25 : 10, 74 : 19 : 7, and 67 : 27 : 6, respectively. Benzylarenes of the known composition were chloromethylated in CCl_4 by the procedure described in [6]. Prior to the synthesis, a catalyst for this reaction was prepared. For this purpose, paraform and anhydrous $ZnCl_2$ were mixed in CCl_4 and dry HCl was bubbled through the mixture until complete dissolution of the components. To the freshly prepared catalyst, a solution of appropriate benzylarene in CCl_4 was added at simultaneous bubbling of dry HCl and stirring.

Monochloromethylation was performed for 4–6 h at the benzylarene : paraform : catalyst molar ratio

of 1 : 2 : 0.3 and 70°C. After reaction completion, a solution of chloromethylated benzylarene in CCl_4 was decanted from the lower bed of the spent catalyst and purged with nitrogen. The number of CH_2Cl groups was determined by the intensity of the ^1H NMR signals of methylene protons [7]. The solutions of chloromethylated benzylarenes in CCl_4 were used in pyridine quaternization under conditions of Katapin preparation [3]. The products of pyridine quaternization were dried on a rotary evaporator under a reduced pressure of 30–40 mm Hg. The residual water content was determined by refluxing a weighed portion of the salts in toluene using a Dean–Stark trap. The yields of salts **I**–**V** based on the initial benzylarenes were 76, 72, 76, 62, and 75%, respectively.

Chromatographic analysis of benzylarenes was performed on a Biokhrom chromatograph (5% SE-30 elastomer on Chromosorb W, helium carrier gas). The ^1H NMR spectra were recorded on a Tesla BS-487 spectrometer (80 MHz) using HMDS as an internal reference.

The corrosion experiments were performed in 0.5 and 3 M H_2SO_4 and in 1 and 6 M HCl at 20°C for 24 h, at 40 and 60°C for 2 h, and at 80°C for 0.25 h. The corrosion was monitored gravimetrically. The polarization curves of a steel plate with the working surface area of 1×10^{-4} m^2 were recorded in the acid solutions in the absence and in the presence of the inhibitors. The electrode potentials were given vs. a hydrogen electrode.

Our experiments showed that all the examined compounds strongly inhibit corrosion of 08 kp steel and TsO zinc in concentrated sulfuric and hydrochloric acids at 20–80°C (Table 1). On heating from 20 to 80°C, the corrosion inhibition coefficients of 08 kp steel in 3 M H_2SO_4 steadily increase, whereas in 6 M HCl they reach a maximum at 60°C and then sharply decrease. The strengthening of the inhibiting effect is probably due to an increase in the specific adsorption of the salts by interaction of π electrons of benzene rings with the steel surface. The decrease in the corrosion inhibition coefficient in 6 M HCl at 80°C is caused by desorption of the salts from the metal surface owing to fast dissolution of the metal [1]. The fact that the inhibition power of all the examined salts at 20–60°C in hydrochloric acid solutions is higher than in sulfuric acid solutions is consistent with the well-known influence of chloride ions on the protecting effect of cationic inhibitors of metal corrosion [1]. Comparison of the inhibiting power of

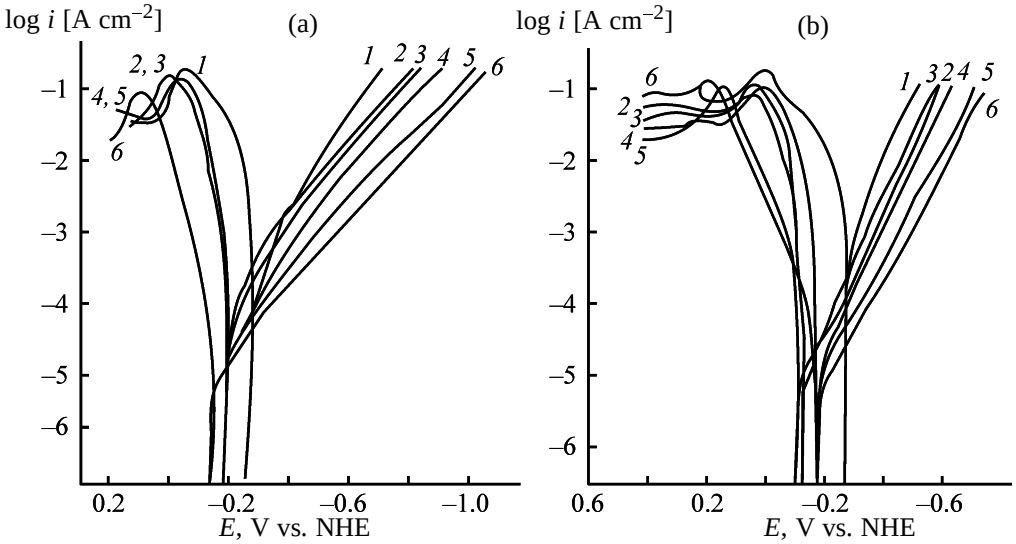

Fig. 1. Polarization curves of 20 steel in (a) 3 M H_2SO_4 and (b) 6 M HCl at 24°C in the presence of salts **I**–**V** (3 g l^{-1}). (*i*) Current density and (*E*) potential. (*1*) supporting electrolyte; (*2*) **II**, (*3*) **III**, (*4*) **IV**, (*5*) **V**, and (*6*) **I**.

salts **I**–**V** shows that both methyl (**II** and **III**) and bulky ethyl (**V**) substituents at the aryl fragment decrease the inhibiting power, probably due to steric hindrance in sorption of these compounds on the steel surface. The presence of the ethoxy groups in this fragment (compound **IV**) increases the protecting effect owing to specific interaction of the unshared electron pair of the oxygen atom of this group with the steel surface.

Adsorption on steel of salts **I**–**V** containing benzyl substituents directly bound to the aryl fragment is, on the whole, better than that of EPV, VPV and B-300 Katapins in which the sorption site, polybenzyl fragment, is remote from the pyridine ring [1, 8].

Table 2. Experimental (γ_{gm}) and calculated (γ_{pc}, $\gamma_{\Delta\psi1}$, and γ_θ) inhibition coefficient of 20 steel corrosion in 3 M H_2SO_4 and 6 M HCl at 24°C in the presence of salts **I**–**V**

V	0.070	56.64	31.62	44.67	1.26	0.21

* Calculated with b_c = –0.11 V, b_a = 0.029 V for **I** and **V** and b_a = 0.036 V for **II**–**IV**.

** Calculated with b_c = –0.11 V and b_a = 0.029 V.

The results of the voltammetric experiments in solutions of sulfuric and hydrochloric acids showed that compounds **I**–**V** inhibit both cathodic and anodic corrosion and shift the free corrosion potential E_c to the positive range. In most of experiments, the slopes of linear (Tafel) portions of the cathodic polarization curves b_c measured in the vicinity of steel potential E_c change slightly, and those of anodic polarization curves b_a change to a greater extent in the presence of these salts (Figs. 1a and 1b; Table 2). These changes, according to [1, 8], indicate that anions from the solution, sorbed on the metal surface and involved in its anodic dissolution, are displaced with the inhibitor. The anodic curved recorded in 6 M HCl in the presence of the most effective inhibitors **I**, **IV**, and **V** have two Tafel portions with different constants b_a. This is probably due to the fact that the adsorption of chloride ions increasing the efficiency of cationic inhibitors increases at anodic polarization [2]. The inhibition coefficients calculated from the polarization curves measured in hydrochloric acid solutions γ_{pc} differ from those calculated from the results of longer gravimetric monitoring γ_{gm} (Table 2). This difference can also be due to adsorption of chloride ions on the steel surface and decelerated formation of protecting inhibitor films containing organic cations and chloride anions.

To determine the inhibition mechanism, we studied the role of the energetic $\gamma_{\Delta\psi1}$ and blocking factors γ_0 in the course of steel corrosion inhibited by the exam-

ined salts. According to [9], the contribution of these factors into the inhibition coefficient γ_{gm} was estimated from the equation $\gamma_{gm} = \gamma_{\Delta\psi 1}\gamma_\theta = 10^{k\Delta\psi 1}(1 - \theta)^{-1}$. We assumed that $k = bk/b_0(b_a + b_c)$, $\Delta\psi_1 = \Delta E_c/[1 - b_a b_c/b_0(b_a + b_c)]$, where $\Delta\psi$ in the adsorption potential difference in the presence on an inhibitor; θ is the degree of coverage of the metal surface with the inhibitor; ΔE_c is the shift of the corrosion potential in the presence of the inhibitor; b_c and b_a are the Tafel slopes of the cathodic and anodic polarization curves; $b_0 = 2.3RT/F$.

The results of our calculations showed that most of the examined salts inhibit corrosion by the energy-blocking mechanism, with the energetic effect prevailing ($\gamma_{gm} > \gamma_{\Delta\psi 1} \gg \gamma_\theta$). The calculations for sulfuric acid solution containing salts **I** and **V** are complicated by the fact that $\gamma_{\Delta\psi 1}$ is higher than γ_{gm}. This difference is likely due to dependence of E_c on the following additional factors: coupled reduction of oxygen, adsorption of the inhibitors on the active sites of the metal surface, chemical reactions, etc. However, the linearity of $\log\gamma$–$\log c$ dependences (where c is the volume concentration of the inhibitor) for solutions of these compounds in sulfuric and hydrochloric acids suggests, in accordance with [1], that the energetic effect in the corrosion inhibition prevails.

CONCLUSIONS

(1) A procedure was developed for preparing benzyl-substituted *N*-benzylpyridinium chlorides by quaternization of pyridine with chloromethylated benzyl-substituted toluene, xylene, ethylbenzene, *o*-chlorotoluene, and phenetole (yield 62–76%).

(2) The benzyl-substituted *N*-benzylpyridinium chlorides are effective inhibitors of corrosion of carbon steels in solutions of sulfuric and hydrochloric acids.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Treatment of Highly Concentrated Wastewater with Spent Activated Carbon

V. I. Korchagin and E. V. Sklyadnev

Voronezh State Technological Academy, Voronezh, Russia

Received February 3, 2005; in final form, July 2005

Abstract—Sorption of the main polluting components of the wastewater from production of emulsion butadiene–styrene rubbers, soaps of synthetic and fatty acids and Leukanol, was studied on a preliminarily ground spent AG-3 activated carbon.

The world demand for adsorbents is expected to steadily grow in the future, since the amount of the water consumed tends to grow, and the quality of natural water is constantly deteriorated. Also, adsorbents are widely used in water and gas treatment. The use of adsorption processes suitable for exhaustive removal of organic compounds, in particular, surfactants, is hindered by complicated and expensive regeneration of adsorbents. For example, it is known [1] that regeneration of activated carbon costs approximately half as much as fresh carbon.

A peculiar way to solve the problem of sorption pretreatment of highly concentrated wastewater is the use of activated carbons from the main production. In particular, spent OU-A activated carbon from pharmaceutical production can remove 60–82% of organic pollutants from wastewater [2].

It is known [3] that sorption of technical surfactants involves no more than 1% of the surface area of SKT activated carbon, no more than 10–15% of that of KAD carbon, and no more than 20–25 of that of activated anthracite.

In sorption of surfactants, the surface of the sorbent macropores is of critical importance, as seen from characteristics of sorbents in [2]: SKT activated carbon has a macropore volume of 0.27, and KAD activated carbon, 0.52 $cm^3\ g^{-1}$. This can be confirmed by the data of Kisel'gof and Mikhailov [4] who reported that absorption of fairly hydrophilic Leukanol occurs on the sorbent surface.

It seems reasonable to use spent AG-3 activated carbon from the butadiene distillation stage of synthetic rubber production in treatment of highly concentrated wastewater from production of emulsion butadiene–styrene rubbers to remove surfactants, since AG-3 with a macropore volume of 0.41–0.52 $cm^3\ g^{-1}$ [2] belongs to macroporous sorbents, and the problem of its utilization still remains to be solved.

Specific pollutants in wastewater (serum) from the emulsion butadiene–styrene rubber coagulation stage are soaps of resin and synthetic fatty acids contained in the wastewater in amounts of ca. 500 mg dm^{-3}, as well as Leukanol, contained in amounts of 400 mg dm^{-3}. Leukanol belongs to "biologically hard" surfactants and occurs in water as individual molecules and associates, which complicates its sorption on granulated carbons.

The Leukanol concentration in solution was determined on an SF-46 spectrophotometer. In the UV region, the spectrum of Leukanol contains absorption bands with maxima near 227 and 235 nm. The Leukanol concentration was measured accurately to within 5.0 wt % [5].

Resin and synthetic fatty acid soaps were analyzed by direct titration with an alkali upon extraction from a model wastewater with an organic solvent, diethyl ether [6].

The total pollution indicator, chemical oxygen demand (COD), was determined titrimetrically [7]: Organic substances were oxidized with excess potassium dichromate in an H_2SO_4 solution under heating in the presence of a catalyst, silver sulfate. The residual potassium dichromate was determined by titration with a Mohr's salt solution, and the difference gave the amount of $K_2Cr_2O_7$ spent for oxidation of organic substances.

Testing preliminarily ground spent AG-3 activated carbon as sorbent in treatment of highly concentrated

wastewaters to remove surfactants, in particular, Leukanol, showed that the sorption capacity of AG-3 varies with the degree of grinding. Figure 1 shows that the isotherms of Leukanol sorption on spent carbons substantially depend on the activated carbon particle size. For example, spent AG-3 carbon with the particle size of 5–20 μm has a higher sorption power than that with the particle size of 60–100 μm.

Low capacity of all granulated activated carbons with respect to surfactants is due to a small proportion in their structure of fairly large adsorption pores [3]. Therefore, we preliminarily ground the spent activated carbon in a disintegrator and a ball mill, which caused pore opening and restoration of the sorption surface. This yielded a finely dispersed activated carbon with a developed external surface, on which the adsorption virtually was not complicated by internal diffusion, in contrast to granulated carbons.

Figure 2 shows that, during the wastewater treatment, the total pollution indicator, COD, varies with the content of the spent AG-3 activated carbon and its particle size. Introduction of spent AG-3 carbon with the particle size of 5–20 μm in amounts of over 10 g dm^{-3} sharply decreases the COD to 80–120 mg O_2 dm^{-3}, which is due to adsorption of resin and synthetic fatty acid soaps, as well as of Leukanol. Removal of surfactants and Leukanol from the wastewater can be confirmed by plots of the surface tension vs. the content of the spent carbon, obtained in treatment of real wastewater, serum from SKS-30ARK production. The decrease in COD reflects reduction in the content of organic pollutants, and the growth of the surface tension is due to an increase in the surface energy at the interface owing to a decrease in the content of surfactants in solution because of sorption.

It should be noted that treatment of highly concentrated wastewaters from emulsion rubber production with spent activated carbon is efficient, as this is favored by real parameters of wastewater: pH 2.2–3.5, temperature 50–60°C, and content of sodium chloride up to 5.0 wt %.

The sorption capacity of AG-3 activated carbon depends on pH of the wastewater and, in absorption of anionic surfactants, is at a maximum in an acid medium (Fig. 3) due to conversion of the salts of surfactants to acid form.

It is known [2] that the sorption capacity with respect to surfactants is at a maximum at 35–60°C, and the sorption in treatment of highly concentrated wastewater significantly accelerates with temperature. The reason is rearrangement of the molecules in solu-

tions, degradation of water–sorbate associates, and a decrease in the viscosity of the solution. At the same time, physical adsorption, like any exothermic process, becomes less efficient as a whole with temperature growth.

A similar influence is exerted by the temperature on adsorption of surfactants, in particular, Leukanol, on a ground spent AG-3 activated carbon (Fig. 3). The absorption power of the sorbent tends to increase upon washing with solutions of NaCl [3], which in our case is one of the wastewater components.

The above-mentioned factors in sorption from multicomponent systems, in particular, wastewater from synthetic rubber production, are manifested to a maximal extent at a certain temperature.

It is reasonable to concentrate the resulting aqueous dispersion of the spent activated carbon in order to make it suitable for subsequent utilization as a carbon-containing filler of polymeric systems in liquid-phase filling.

Upon treatment with preliminarily ground spent activated carbon to remove resin and synthetic fatty acid soaps, as well as a "biologically hard" NF dispersant, Leukanol, the wastewater from emulsion rubber production can be further supplied to the plant or municipal wastewater treatment facilities without preliminary dilution.

CONCLUSIONS

(1) Preliminarily ground spent activated carbon is suitable for local treatment of highly concentrated wastewater from emulsion rubber production.

(2) Soaps of resin and synthetic fatty acids, as well as Leukanol, are removed from the wastewater owing to pore opening and restoration of the sorption surface upon grinding of the spent activated carbon.

(3) Adsorption treatment of highly concentrated wastewater from emulsion rubber production is feasible, being the most efficient at the real values of the wastewater parameters: pH 2–3.5, T = 50–60°C, and salt content up to 5.0 wt %.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Use of a Carbonate-Containing Process Waste in Purification of Aqueous Solutions To Remove Zinc(II) Ions

T. G. Lupeiko, E. M. Bayan, and M. O. Gorbunova

Rostov State University, Rostov-on-Don, Russia

Received March 16, 2005

Abstract—A carbonate-containing waste from water-treatment installations of thermal power plants is tested as a sorbent for purifying aqueous solutions to remove zinc(II) ions. The effect of time, temperature, and other factors on sorption is evaluated.

The utilization of large-tonnage industrial wastes and, in particular, of the slurry formed in the flushing water of clarifying units at shops for chemical water treatment of thermal power plants is an important environmental problem. At present, most part of the forming waste is stockpiled on territories adjacent to power plants, occupies there an increasing space, and contaminates soil, as well as the surface and underground water. Therefore, development of methods for utilization of the water-treatment slurry, which will make it possible to convert this burdensome waste into "secondary resources," is a matter of current interest.

Previously, the composition and physicochemical properties of a waste formed in water treatment at Rostov Heat and Power Plant no. 2 has been studied [1], and it was shown that the slurry mainly contains calcium and magnesium carbonates, is homogeneous and finely dispersed, has a relatively constant composition, and is chemically and radiation safe. In [2, 3], we showed that the carbonate-containing waste (CCW) can be used for puryfing solutions to remove iron(III), copper(II), and chromium(III) ions.

Here we report the results obtained in studying the possibility of purification of aqueous solutions (real wastewater) to remove rather toxic zinc(II) ions with CCW.

According to the results of theoretical calculations, virtually complete recovery of zinc in the form of sparingly soluble $Zn(OH)_2$ requires that the precipitation should be performed at $8.0 \le pH \le 10.5$. In this case, it should be kept in mind that the precipitation of zinc(II) hydroxide onsets at pH 6.4, and at pH > 10.5 the precipitate starts to dissolve to form Zn(II) hydroxo ions, i.e., the recovery of zinc ceases to be complete [4]. The pH value of the CCW solution is ~9, which enables its use as a "mild" adaptive neutralizer precluding further dissolution of zinc(II) hydroxide. Also, in addition to the "hydrolysis" mechanism of the interaction of CCW with a zinc(II) solution, an exchange mechanism is possible, to give zinc carbonates in accordance with their solubility products: $SP_{MgCO_3} = 2.1 \times 10^{-5}$, $SP_{CaCO_3} = 3.8 \times 10^{-9}$, whereas $SP_{ZnCO_3} = 1.45 \times 10^{-11}$ [4].

In view of the aforesaid, removal of zinc(II) from solution can, theoretically, include the following processes.

(1) Partial dissolution of the carbonate components of a waste to form hydroxide anions, which leads to an increase in the solution pH:

$$CO_3^{2-} + H_2O \rightleftarrows HCO_3^- + OH^-,$$

$$HCO_3^- + H_2O \rightleftarrows OH^- + H_2CO_3,$$

$$H_2CO_3 \rightleftarrows H_2O + CO_2\uparrow.$$

(2) Shift of the equilibrium of zinc(II) hydrolysis toward formation of sparingly soluble hydroxo compounds and zinc hydroxide:

$$Zn^{2+} + HOH \rightleftarrows ZnOH^+ + H^+,$$

$$ZnOH^+ + HOH \rightleftarrows Zn(OH)_2\downarrow + H^+,$$

The addition of CCW to a solution of a zinc(II) salt will lead to mutual enhancement of the hydrolysis of the zinc salt and the carbonate component of the waste, leading in the end to precipitation of sparingly soluble hydroxo compounds or zinc hydroxide and to evolution of carbon dioxide.

c_{in} = 50 mg l^{-1}, pH_{in} = 5.70, CCW 5 g l^{-1}				
1	5	7.73	14.702	70.6
2	10	7.81	9.366	81.3
3	15	7.86	6.039	87.9
4	20	7.89	4.382	91.2

(3) Formation of sparingly soluble carbonate, hydroxocarbonate, and other compounds of zinc at and on the surface of solid $CaCO_3$:

$$CaCO_3(s) + Zn^{2+} \rightleftarrows ZnCO_3(s) + Ca^{2+},$$

$$CaCO_3(s) + 2Zn^{2+} + 2OH^- \rightleftarrows (ZnOH)_2CO_3(s) + Ca^{2+}.$$

It is noteworthy that the last stage is less probable, because solid phases are formed during a long time and hydrolysis processes are fast. Thus, hydrolysis is preferable as regards kinetic characteristics.

EXPERIMENTAL

The precipitation of zinc(II) from solutions with CCW was studied on model solutions with initial concentrations of zinc(II), c_{in}^{Zn}, of 50, 100, 200, and 500 mg l^{-1}, prepared from $ZnSO_4 \cdot 6H_2O$ with account of the content of zinc(II) in wastewater from elecotroplating shops of plants [5]. Zinc(II) compounds were precipitated under static conditions: to 100 ml of a solution to be purified, with a prescribed concentration c_{in}^{Zn} (mg l^{-1}), was added a weighed portion of CCW with a particle size of 0.25–0.50 mm, and the mixture was agitated for a time τ (min). Further, the solutions were filtered. The pH value and the concentration of Zn^{2+} in solution were monitored before and after the contact with the reagent; the degree of metal recovery, α (%), was calculated from the difference of the initial (c_{in}^{Zn}) and residual (c_{res}^{Zn}) concentrations. The concentration of Zn^{2+} was determined spectrophotometrically by the standard procedure [6]. The optical density was measured with a KFK-3 photometer (error ±5%); the solution pH was monitored potentiometrically with an I-120M pH meter (accuracy ±0.05). For solutions with c_{in}^{Zn} of 50, 200, and 500 mg l^{-1}, the optimal purification time of aqueous solutions was determined (Table 1).

It was established that the recovery of zinc(II) is fast. For example, recovery from solutions with a concentration of zinc(II) lower than 200 mg l^{-1} (at CCW expenditure of 40 g l^{-1}) occurs during the first 5 min. At higher concentrations of zinc(II) ions in solution or at a smaller amount of the reagent, a longer contact is necessary. For example, at a concentration of zinc(II) ions equal to 500 mg l^{-1} and 40 g l^{-1} of the reagent, the duration of contact increases to 120 min, with the degree of metal recovery of 85%. In purification of a solution with c_{in}^{Zn} = 50 mg l^{-1} and 5 g l^{-1} CCW, α = 91% after 20 min; at the same time, on raising the amount of CCW to 40 g l^{-1}, the recovery occurs virtually instantaneously. It is also apparent that making the contact time longer and the weighed portion of the reagent larger leads to an increase in the pH value of the filtrate, which also supports the above-suggested mechanism of the process.

The effect of the CCW expenditure on the completeness of recovery at a varied time of contact between a solution being purified and CCW was studied in a solution with c_{in}^{Zn} of 50 mg l^{-1} at pH_{in} 5.70. As can be seen in Fig. 1, 20 g l^{-1} CCW is sufficient for detoxication of the solution under study to the maximum permissible concentration (MPC_{Zn} = 0.5 mg l^{-1} [6]). In this case, the degree of recovery exceeding 99.5% is reached in 10 min, i.e., c_{res}^{Zn} in the purified solutions is lower than the maximum permissible concentration. If 10 g l^{-1} CCW is added to this solution, MPC_{Zn} is reached in 30 min. Figure 1 also shows that the difference in time is only important at relatively small additions of CCW, the effect of time being insignificant at larger amounts of the reagent. Presumably, this is due to the dissolution rate of CCW,

which is rate-determining factor only at relatively small amounts of CCW.

For practical purposes, it was necessary to determine how the dispersity of CCW particles affects the efficiency of zinc(II) recovery from solutions. The main fractions of the slurry, with grain sizes of 0.1–0.25, 0.25–0.5, and 0.5–1.0 mm were used. A solution with c_{in}^{Zn} of 50 mg l^{-1} was used in the experiment, the time of contact between CCW and the solution was 10 min. As expected, the degree of recovery at the same time of contact with the solution is higher, and the expenditure of CCW, lower if the finely dispersed 0.1–0.25-mm fraction is used (Fig. 2). Apparently, this is due to an increase in the active surface area and in the dissolution rate of finer particles in an aqueous solution. The latter was experimentally confirmed in determining the pH of aqueous solutions of various CCW fractions (Table 2). However, the optimal, in the authors' opinion, is the 0.25–0.50-mm fraction. First, its content in the waste is the highest (nearly 50% [3]), and, second, the finer fraction more rapidly leads to clogging of filters, which hinders separation of the purified water from spent CCW.

Another important issue is the effect of the anionic component of solutions on the degree of zinc recovery, because the composition of wastewater from electroplating shops is rather diverse in this regard. Solutions with c_{in}^{Zn} of 50 mg l^{-1} were used in experiments aimed to elucidate this question, at a time of contact between CCW and a solution equal to 10 min. It was found that the anionic component has virtually no effect on the recovery of zinc(II) ions, provided that the pH values of the starting solutions are sufficiently close. However, the degree of recovery of Zn(II) ions decreases in a more acidic starting solution (as in the case of a chloride solution no. 2, Table 3), and the CCW expenditure increases, which is quite understandable.

It would also be expected that the precipitation of zinc(II) from solutions should be strongly affected by their temperature. Indeed, zinc ions are virtually completely removed at 40°C from a solution with c_{in}^{Zn} of 50 mg l^{-1} in the presence of 10 g l^{-1} slurry in 10 min, whereas reaching the same degree of recovery in the same time at 20°C requires a doubled amount of CCW (Fig. 3). Thus, in recovery of metal ions from hot solutions, the expenditure of CCW dramatically decreases, precipitation of zinc(II) ions becomes considerably faster, and a higher degree of purification is reached more easily. Presumably, this is due to an increased solubility of the slurry and to an enhanced hydrolysis of the carbonates it contains and the zinc

salt itself, which favors a more intense evolution of carbon dioxide, rise in the solution pH, and more complete precipitation of zinc in the form of sparingly soluble zinc hydroxo compounds.

One more issue of high practical importance is how iron(III) ions affect the degree of zinc(II) recovery from solution, because iron-containing articles are most frequently zinc-plated. A model solution containing a varied amount of iron(III) and 50 mg l^{-1} zinc(II) was used in experiments aimed to elucidate this question; the time of contact between the solution and CCW was 5 min. It was noted that the precipitation of zinc(II) in the presence of iron(III) (Fig. 4,

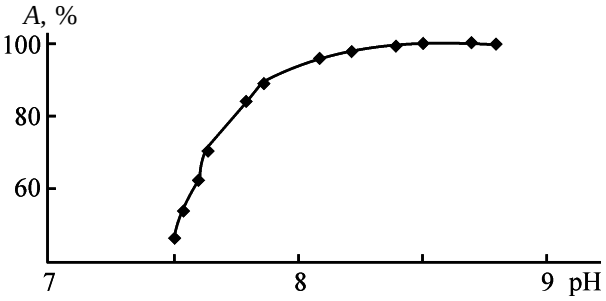

Fig. 5. Degree of Zn^{2+} recovery *A* vs. the pH of the medium.

curves *2–4*) is inferior to that from a pure solution (Fig. 4, curve *1*). Apparently, this is due to the fact that CCW is primarily consumed for precipitation of iron(III) ions. As shown previously [3], recovery of iron(III) is virtually instantaneous and the activity of CCW is in this case 200 mg Fe(III) per gram of the reagent. Therefore, only 0.75 g l^{-1} CCW is necessary for precipitation of iron(III) from the model solution being purified, with the rest of CCW consumed for recovery of zinc(II). In contrast to the case of iron(III), precipitation of zinc(II) requires a certain time and the expenditure of CCW for this process is considerably higher. Apparently, the reason is that precipitation of iron(III) is complete at a lower pH value (pH > 3) than that in removal of zinc(II). In addition, also different are the mechanisms of recovery of iron(III) and zinc(II). In the case of iron(III), the recovery mainly occurs via formation of a sparingly soluble hydroxide, whose solubility product is lower than those of the rest of phases. In removal of zinc(II), not only the hydroxide, but also hydroxo carbonate and carbonate can be formed by the exchange mechanism, and it is known that such a solid → solid conversion is slower than hydrolytic precipitation processes.

To determine how pH affects the recovery of zinc(II), we studied neutralization of a zinc solution with a slurry waste. Figure 5 shows that the degree of zinc(II) recovery exceeds 99%, which corresponds to the theoretically calculated value, on reaching pH 8.3. In addition, use of the CCW totally precludes dissolution of zinc(II) hydroxide caused by the overalkalization of the medium, because pH of a saturated slurry solution is 8.7. Thus, the slurry can serve as an effective and "mild" neutralizer of acid solutions, e.g., wastewater, because of the carbonate phases it contains.

The method suggested for purification of solutions to remove zinc(II) ions using CCW was successfully

tested on electroplating wastewater from the industrial plants of the city.

CONCLUSIONS

(1) Carbonate-containing waste formed in water treatment at electric power plants can be used for effective purification of acid aqueous solutions to remove zinc(II) ions to the MPC level. The expenditure of the carbonate-containing waste decreases, and the completeness of zinc(II) precipitation from a solution increases as the time of contact with the solution becomes longer, temperature increases, and the concentration of the solution being purified decreases.

(2) The 0.25–0.50-mm fraction of the carbonate-containing waste was chosen as the optimal for water purification.

(3) The anionic composition of the solution to be purified has virtually no effect on the interaction of zinc(II) ions with the carbonate-containing waste.

The results obtained in the study were confirmed by testing on wastewater from electroplating shops of various plants.

Abstract—Extraction of target components from porous particles is analyzed for the case when a solution is displaced from coarse pores at the particle surface into the bulk of the extracting agent under the action of pressure pulses. Elementary mathematical models are suggested for the initial (hydraulic) and final (diffusion) stages of the extraction process.

In the overwhelming majority of studies concerned with the theory of extraction in a system constituted by a liquid and a solid porous body, the process is considered in terms of the diffusion extraction model [1, 2]. At the same time, the contribution of the convective component of the mass-transfer process in porous particles is rather important for apparatus with a fast rabble, those of pulsatory and vibration types, and apparatus with ultrasonic treatment, electric discharge, vacuum boiling, vacuum oscillation, "explosive" boiling-up, etc. [1, 3–7]. Filtration of the extracting agent occurs in coarse capillaries through squeezing of the raw material, collisions of particles with the working members of the apparatus, periodic changes in the pressure in the system, intense boiling-up of the extracting agent, collapse of cavitation bubbles near particles, etc.

Most of researchers consider the convective mass transfer in terms of diffusion models by introducing effective diffusion coefficients [8–10]. The exception are studies in which the diffusion of a substance to be recovered from deep inside a porous particle to coarse pores and the convective transfer through these pores to the surface of particles are considered simultaneously [11, 12].

The extraction in apparatus with an active hydrodynamic action upon porous particles occurs in three stages. In the initial stage, the extracting agent penetrates under the action of capillary forces into coarse pores and dissolves the target (being recovered) component contained in the pores and around them. The rate of the process is determined by that of the filtration displacement of the solution from pores into the extracting agent surrounding the particles. In what follows, this stage will be named hydraulic. In the second, diffusion-convective, stage the rate of diffusion of the target component into transport pores is comparable with that of solution removal from the pores. The fundamental aspects of such a process in a porous body with a bidisperse structure were studied in [11, 12]. In the third, diffusion, stage, the rate of the process is determined by that of molecular diffusion of the target component from deep inside a porous particle to transport pores.

It is noteworthy that the observed kinetic pattern of an extraction process that occurs in an exclusively diffusion mode is formally similar to that of a process occurring in an apparatus with a strong hydrodynamic action upon porous particles. However, the time in which the same degree of extraction is reached in extraction in the diffusion mode markedly exceeds that in the mode of a convective mass transfer in porous particles.

Here we suggest the simplest models of the hydraulic and diffusion stages, whose analysis is the most important for practical purposes.

Mathematical model of the hydraulic stage. Let us consider a single pore that pierces a particle and is filled with a solution containing the target component (Fig. 1a; presence of the target component is denoted by hatching). The pore mouths open at the particle surface and are in contact with the extracting agent containing no target component.

After the action of the first separate pressure pulse (e.g., as a result of collapse of a cavitation bubble near the pore mouth), the liquid is "pushed" through the

1070-4272/05/7809-1462 © 2005 Pleiades Publishing, Inc.

pore, with a volume ε of the extracting agent with the target component being removed from the pore (Fig. 1b; part of the pore free of the target component is not hatched).

Further, we assume that all the pressure pulses are identical, equal to the statistical-average pressure pulse, the probability of their occurrence at the left- and right-hand mouths of a pore are the same, and the pulses are distributed in time.

A second pressure pulse may arise both at the right-hand and at the left-hand opening of a pore. Therefore, two "states" of the pore are possible (Fig. 1c). In the first case, a volume ε of the extracting agent with the target component is extracted from the pore, whereas in the second, nothing is extracted, with a column of the extracting agent only moving within the pore. Thus, the average amount of substance extracted under the action of a single pressure pulse is ε/2.

After a next, third pulse appears, four states of the pore are possible. Two of these lead to extraction of the target component, with the two others being ineffective (Fig. 1d). Thus, a volume ε/2 of the liquid with the target component is, on the average, extracted per pressure pulse.

Analysis of the state of a capillary under the subsequent actions shows that the same amounts of the extracting agent with the target component is extracted in the *m*th and (*m* + 1)th stages (*m* ≥ 2). Therefore, it is appropriate, in deriving a general formula, to numerate the pairs (2, 3), (4, 5), (6, 7) ... by the values *n* = 1, 2, 3, ..., respectively. It was calculated that the average volume of the extracting agent with the target component, extracted per pressure pulse in a state *m*, equal to *V*(*m*), has the following values:

$$n = 1,\ V(2,\ 3)/\varepsilon = 1/2;\ n = 2,\ V(4,\ 5)/\varepsilon = 3/8;$$

$$n = 3,\ V(6,\ 7)/\varepsilon = 5/16;\ n = 4,\ V(8,\ 9)/\varepsilon = 35/128,\ \ldots$$

This sequence is generalized by the formula

$$V(m)/\varepsilon = V(m + 1)/\varepsilon = (-1)^n \binom{-1/2}{n}$$

$$= \pi^{-1/2}[\Gamma(n + 1/2)]/[\Gamma(n + 1)], \quad (1)$$

where Γ is the gamma function, and *n* is the number of a pair.

The volume of the extracting agent with the target component, extracted upon the action of the nth pair, is two times greater. Therefore, from (1) we obtain

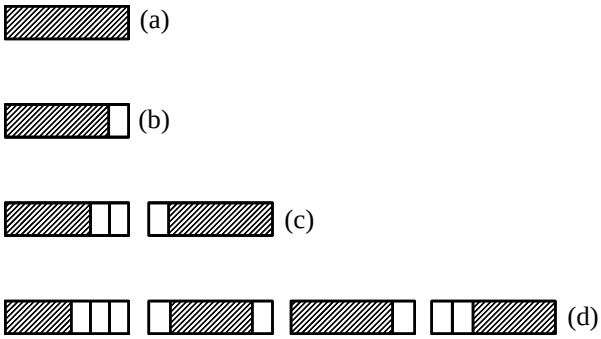

Fig. 1. Motion of the extracting agent within a pore under the action of pressure pulses. (a–d) For explanations, see text.

$$V(n)/\varepsilon = 2\pi^{-1/2}[\Gamma(n + 1/2)]/[\Gamma(n + 1)]. \quad (2)$$

The total volume of the extracting agent with the target component, *Q*(*N*), extracted upon the action of the first pulse and *N* following pairs of pressure pulses, is found by summation of expression (2):

$$Q(N)/\varepsilon = 1 + 2\pi^{-1/2}\sum_{n=1}^{N}[\Gamma(n + 1/2)]/[\Gamma(n + 1)]. \quad (3)$$

Formula (3) is remarkable in that the dependence on parameters of the system (pore size, pore tortuosity, viscosity of the extracting agent, etc.) and on those of the external action (pressure pulse intensity) are included in a single parameter ε, and the relative amount of the extracting agent with the target component is given by an algebraic expression.

This is an advantage of the model suggested, compared with the diffusion model, although the general type of the dependence is the same.

It should be mentioned, however, that the conclusion made implies that the pore has an infinite length. Therefore, formulas (1)–(3) are valid under real conditions only while the volume *Q* remains smaller than the capillary volume:

$$Q(N) < \pi d^2 l/4, \quad (4)$$

where *l* is the length of the capillary, and *d*, its diameter.

Let use convert expression (3) to a form convenient for practical use, keeping in mind the fact that *N* is rather large. In this case, the summation can be re-

placed with integration:

$$Q(N)/\varepsilon \approx 1 + 2\pi^{-1/2}\int_1^N \{[\Gamma(z + 1/2)]/[\Gamma(z + 1)]\}\mathrm{d}z, \quad N \gg 1. \tag{5}$$

Using an approximate expression for the gamma function [13]

$$\Gamma(z + 1) \approx (2\pi)^{1/2} z^{z+1/2}\exp[-z + \delta/(12z)],$$

$$z > 0,\ 0 < \delta < 1,\ z \to \infty$$

and neglecting the term $\delta/(12z)$, we rewrite (5) in the form

$$Q(N)/\varepsilon \approx 1 + 2(e/\pi)^{1/2}\int_1^N \{[(z + 1/2)^z]/z^{z+1/2}\}\mathrm{d}z \approx 1 + 2(e/\pi)^{1/2}$$

$$\times \int_1^N \{\exp z[\ln z + \ln(1 - 1/2z)]\}/\{\exp[(z + 1/2)\ln z]\}\mathrm{d}z.$$

Assuming, further, that $\ln[1 - 1/(2z)] \approx -1/2z$, we obtain

$$Q(N)/\varepsilon \approx 1 + 2\pi^{-1/2}\int_1^N z^{-1/2}\mathrm{d}z \approx 4\pi^{-1/2}(N^{1/2} - 1)$$

$$\approx 4\pi^{-1/2}N^{1/2}, \quad N \gg 1. \tag{6}$$

In practice, the number n of pressure pulse pairs is frequently small, with formula (6) inapplicable. The main error comes from the replacement of summation (3) with integration (5). The table lists the values of $V(n)$ and $Q(N)$, calculated by formulas (2) and (3) at $1 \le n \le 200$.

It was found that, at small n, dependence (2) is well approximated with a power function

$$V(n)/\varepsilon = An^{-\alpha}, \tag{7}$$

where $A = 0.505$ and $\alpha = 0.466$ at $1 \le n \le 10$; at $n \to 10\,000$, $\alpha \to 0.5$.

The rms deviation of the values of $V(n)/\varepsilon$, obtained using formula (7), from those given by formula (2) is $\sigma^2 = 1.21 \times 10^{-5}$.

Dependence (3) is rather well approximated by the expression

$$Q(N)/\varepsilon = 1 + \frac{A(n^{1-\alpha} - S^{1-\alpha})}{1 - \alpha} + \sum_{n=1}^{N} V(n)/\varepsilon. \tag{8}$$

For $N \le 100$, $S = 3$, $A = 0.505$, and $\alpha = 0.466$, the discrepancy between the values of $Q(N)/\varepsilon$, calculated by Eqs. (3) and (8), does not exceed 2%.

Use of power function of the type $Q(N)/\varepsilon = 1 + B_1N^{\beta}$ and $Q(N)/\varepsilon = B_2N^{\gamma}$ at $1 \le N \le 100$ gives an rms error $\sigma^2 = (0.5\text{–}7.3) \times 10^{-3}$, with the approximation error increasing with n; at $N \to 10\,000$, $\beta \to 0.5$ and $\gamma \to 0.5$.

The number of pairs of impacts, n, is a random function of time. In the stationary extraction mode, the average value of n (denoted by $\langle n\rangle$) is proportional to the process duration τ:

$$\langle n\rangle \sim \tau. \tag{9}$$

The dependence $V(n)/\varepsilon$ is, in fact, the rate of removal of the extracting agent from a pore at an instant of

time τ, corresponding to $\langle n \rangle$. It follows from the aforesaid that

$$V(\tau)/\varepsilon \sim 1/\tau^{1/2}. \quad (10)$$

It has been established in the diffusion theory of extraction [1] that the flux of the solute, q, from a single capillary and from a semiinfinite porous body can be calculated by dependences similar to (10):

$$q(\tau)/\varepsilon \sim 1/\tau^{1/2}. \quad (11)$$

However, the proportionality factor in expression (10) is determined by the hydrodynamic conditions of the process (via ε), and that in (11), by the molecular diffusion coefficient.

Equating the pore volume V_p to the volume of the extracting agent with the target component, removed from the pore [Eq. (6)], we can find the number of pairs of impacts, N^*, that provide complete replacement of the extracting agent in the pore with its "fresh" portion, coming from the bulk of the liquid:

$$N^* \approx \pi V_p^2/16\varepsilon^2. \quad (12)$$

In other words, the duration of extraction, $t \sim N^*$, to complete replacement of the extracting agent in pores is inversely proportional to the squared volume ε of the extracting agent, removed after the first pressure pulse:

$$t \sim 1/\varepsilon^2. \quad (13)$$

In the case of an intensive extraction ($\varepsilon/V_p \geq 0.01$, $N \leq 7840$), the dependence of the fraction φ of an unrenewed (not replaced with a "fresh" portion) extracting agent in a pore on the dimensionless time $\Theta = n/N^*$ can be conveniently approximated with the function

$$\omega = \Theta^k, \quad (14)$$

The exponent $k = 0.468–0.49$ for $\varepsilon/V_p = 0.01–0.25$, $k \to 0.5$, and $\varepsilon \to 0$.

Mathematical model of the diffusion stage. Let us assume that, after the diffusion-convective stage is complete, the content of the target component in transport pores is close to zero. In the third stage, there occurs a diffusion process not related to filtration motion of the extracting agent in pores. It is natural to choose the problem of diffusion in an infinite hollow circular cylinder as a model of this process. However, solution of a nonstationary problem for an annular region is exceedingly cumbersome [14]. Therefore, we replace the real medium with a model medium constituted by alternating planar layers of a solid body and planar pores. In Fig. 2, l is the average distance between the planar pores.

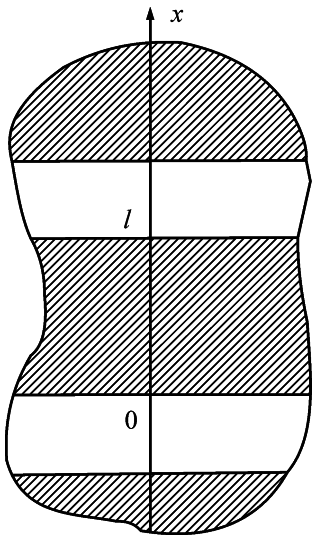

Fig. 2. Model of alternating planar layers of a solid body and planar pores.

In contrast to the cylindrical case, solution of the diffusion problem for a planar layer is rather simple [14]. Let us assume that at an instant of time $\tau = 0$ the concentration of the substance to be recovered in the layer is independent of the coordinate x and equal to c_0, and the concentration at the boundaries ($x = 0$, $x = l$) is zero. Then the local diffusion flux across the boundary $x = 0$ is given by

$$D\frac{\partial c}{\partial x}\Big|_{x=0} = \frac{4D}{l}c_0 \sum_{n=0}^{\infty} \exp\left[-\frac{4\pi^2 D}{l^2}(n + 1/2)^2\tau\right], \quad (15)$$

where D is the diffusion coefficient.

Qualitative analysis shows that the main amount of the substance being recovered leaves the layer at sufficiently large values of τ. Therefore, only the first term $n = 0$ can be kept in expression (15). Thus, we obtain the following approximate formula:

$$D\frac{\partial c}{\partial x}\Big|_{x=0} = \frac{4D}{l}c_0 \exp(-\pi^2 D\tau/l^2). \quad (16)$$

To find the full flux, it is necessary to multiply Eq. (16) by the surface area S of the pore, and to determine the total amount $Q(\tau)$ of the substance released by diffusion into the pore space, Eq. (16) should be integrated over the interval $[0, \tau]$:

$$Q = S\frac{4lc_0}{\pi^2}[1 - \exp(-\pi^2 D\tau/l^2)]. \quad (17)$$

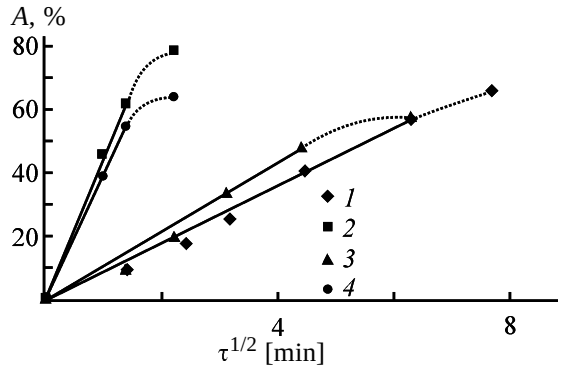

Fig. 3. Yield A of flavonoids from a vegetable raw material vs. $\tau^{1/2}$. (τ) Time. (*1*) Hawthorn, (*2*) licorice, (*3*) everlasting, and (*4*) galls; the same for Fig. 4.

Formula (17) overestimates the flux because the system of pores was replaced with a layer. Therefore, it is necessary to multiply expression (17) by a dimensionless factor $\chi < 1$, which characterizes the "filling" of the layer by pores:

$$Q = S\chi\frac{4lc_0}{\pi^2}[1 - \exp(-\pi^2 D\tau/l^2)]. \quad (18)$$

The factor before the square brackets in Eq. (18) is equal to the content of the target component in a particle before the beginning of the diffusion stage. The expression in the square brackets in formula (18) represents the time dependence of the fraction of the component recovered. Accordingly, the fraction of the unextracted component is given by

$$\bar{c}/c_0 = \exp(-\pi^2 D\tau/l^2), \quad (19)$$

where $\bar{c}$ is the average concentration of the target component in the solid after a time τ from the beginning of the diffusion stage.

The model of the hydraulic stage, suggested here, implies that the whole amount of the substance to be recovered is in the dissolved state and its content in the bulk of the extracting agent can be taken to be zero. In practice, the substance from the nearby lying layers of the porous material is permanently fed into pores via molecular diffusion and its content in the bulk of the extracting agent steadily increases. Therefore, the extraction yield may be proportional to a square root of τ only in the initial stage of the process, before the onset of the diffusion-convective stage. Nevertheless, a direct proportion to $\tau^{1/2}$ is observed during a long time in extraction from vegetable raw materials (Fig. 3).

Figure 3 shows experimental data on the kinetics of extraction of flavonoids (in terms of rutin) with an ethanol solution (40 vol %) from hawthorn fruits (70°C, s : l = 1 : 12) in the vacuum-oscillating mode (frequency of boiling-ups, 7.5 s^{-1}; amplitude of changes in the vapor space, 0.035 m), from licorice roots (25°C, s : l = 1 : 12) in a planetary apparatus (centrifugal acceleration at the drum circumference 28*g*, drum diameter 110 mm), and from everlasting flowers (70°C, s : l = 1 : 20) in the vacuum-boiling mode (temperature head 6.5°C). In addition, we used Balabudkin's data [15] on the kinetics of tannin extraction from galls in a rotary-pulsatory apparatus at a rotor rotation frequency of 2960 rpm. The rms deviation of the experimental data from the theoretical dependences (solid lines) in the initial stages of extraction of target components from licorice roots, everlasting flowers, and galls is 1.8%, and the maximum deviation, 2.9%. The rms deviation in extraction of flavonoids from hawthorn fruits is 2.9% at a maximum deviation of 5.3%.

Results similar to those presented in Fig. 3 were obtained in processing of experimental data on the kinetics of extraction of various kinds of vegetable raw materials in a pulsatory apparatus, apparatus with a fast rabble (3000 rpm), and in the case of an ultrasonic treatment of a suspension. The rms deviation of the experimental data from theoretical dependences was in the range 2.1–3.5% for various kinds of raw materials and extraction methods.

It is of interest to compare the model of the diffusion stage (15)–(19) with that of the final (the so-called regular) stage of a purely diffusion-type extraction [1, 2]. According to the latter, in the case of extraction of a target component from porous bodies of various shapes (sphere, infinite plate or cylinder), the dependence of the fraction of an unextracted component is described, beginning at a certain instant of time, by the formula [1, 2]

$$\bar{c}_D/c_{0D} = B_1\exp(-\mu_1^2 D\tau_D/R^2), \quad (20)$$

where $\bar{c}_0$ and c_{0D} are the average concentrations of the target component in a particle at, respectively the running and initial instants of time; B_1, coefficient dependent on the particle shape, Biot number, and root of the characteristic equation; R, radius of the sphere or cylinder or half plate thickness; and τ_D, total duration of the process.

Formulas (19) and (20) are formally similar, but the parameters appearing in these formulas are strongly different, with the exception of the diffusion coefficients D. Expression (19) contains the duration of the diffusion stage τ and the distance between pores l; the particle radius R (or half plate thickness) and total

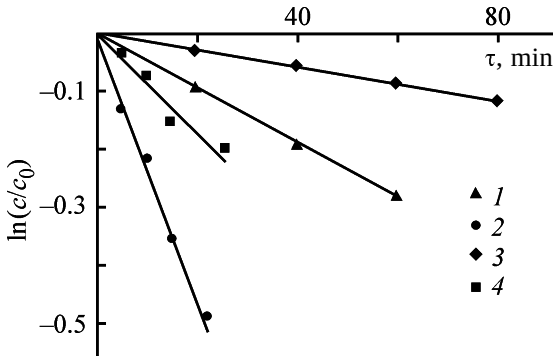

Fig. 4. $\ln(c/c_0)$ vs. the time τ of extraction in the diffusion stage.

duration of the process τ_D ($\tau_D \gg \tau$ and $R \gg 1$) appear in (20).

Experimental data on the extraction kinetics in the diffusion stage is well approximated (Fig. 4) with a dependence of the type (19). In extraction from hawthorn, the diffusion stage onsets approximately τ_{tot} = 60 min after the beginning of the process at a degree of extraction μ = 66%; for licorice, τ_{tot} = 10 min and μ = 69%; for everlasting, τ_{tot} = 80 min and μ = 64%; for galls, τ_{tot} = 10 min and μ = 72%. The rms deviation of the experimental data from the theoretical dependences is 1.2% at a maximum deviation of 3.3%.

Particles of the solid phase have rather diverse pore structures (pores may branch, have variable diameter, etc.), whereas the schemes considered are represented by the simplest models. Therefore, it should be emphasized that the adequacy of the accepted models was only established for those kinds of vegetable raw materials for which a comparison with experimental data was made. Formula (20) is frequently used to determine the effective diffusion coefficients, which presumably cannot be done with formula (19) because of the simplifying assumptions made in deriving Eqs. (18) and (19).

CONCLUSIONS

(1) The fundamental aspects of the extraction kinetics of target components from porous particles under the action of pressure pulses on their surface qualitatively coincide with those in diffusion extraction (Q–$\tau^{1/2}$). The extraction rate is only determined by the number of pulses in unit time and their power.

(2) The fundamental aspects of extraction in the final (diffusion) stage of the process can be described in terms of the simplest model in the form of a porous medium with alternation of planar layers of the solid and planar pores.

(3) Experimental data on the extraction kinetics of flavonoids from vegetable raw materials in apparatus with a strong hydrodynamic impact on porous particles are in good agreement with the theoretical models suggested.

Abstract—Homogeneous fullerene–polyphenylene oxide membranes containing up to 2 wt % C_{60} are synthesized and characterized by the density, electrical resistivity, and contact angle with water and ethanol. The effect of fullerene additive on the transport characteristics of the membranes in pervaporation of water mixtures with ethanol and ethyl acetate is studied.

Membrane processes find steadily growing use for purification, concentration, and fractionation of liquid and vapor mixtures. Pervaporation (separation of binary and multicomponent mixtures by evaporation through a membrane) appears to be an efficient process in those cases when the use of conventional methods such as distillation and rectification is impractical or inadvisable (for example, separation of azeotropic mixtures and substances with close physicochemical properties). In pervaporation under reduced pressure, the driving force of transmembrane transport is the pressure gradient controlling the fluxes across the membrane. It is commonly accepted that the model "dissolution–diffusion" most adequately reproduces the mechanism of this process [1–4].

The selectivity and efficiency of pervaporation is controlled by such factors as the structure, chemical nature, and composition of the membrane material. The spectrum of commercial pervaporation membranes is rather limited. Therefore, searching for novel high-performance membranes is, without question, of significant scientific and practical interest. In this relation, membranes based on hybrid polymeric materials containing various ultradispersed and nano particles show promise for advanced membrane processes. It is obvious that of primary interest are polymeric composites containing highly physicochemically active substances. In this study we examined thin-film membrabes based on poly(2,6-dimethyl-1,4-phenylene oxide) (PPO) modified with fullerene C_{60}.

The modification yields PPO–C_{60} donor–acceptor complex. Rheological and hydrodynamic study of its solutions revealed that the donor–acceptor bond is strong enough to remain stable upon dilution, despite small decrease in the intrinsic viscosity and broken symmetry of the PPO molecule [5]. It was demonstrated by TGA–MS and differential calorimetry that modification with fullerene improves the heat resistance of PPO [6]. Biryulin *et al*. [7] studied photoluminescence spectra of C_{60}–PPO films. Molecular complexes were found in the films containing up to 2 wt % C_{60}, while in the 4% C_{60}–PPO films, the major part of fullerene molecules is free.

Only a few publications are devoted to properties of fullerene-containing membranes based on poly(trimethylsilylpropyne), polystyrene, and Martimide [8–10]. It was demonstrated in our previous studies that the presence of fullerene strongly affects the transport characteristics of polystyrene and PPO in gas separation to enrich air with oxygen, increasing the selectivity and decreasing the permeability [11, 12]. In this study we examined the effect of modification with C_{60} on physical and pervaporation characteristics of homogeneous PPO membranes. The transport properties of the membranes were studied in separating aqueous-organic systems with ethyl acetate and ethanol.

EXPERIMENTAL

In the study we used PPO with MW 178 000. Fullerene containing more than 98% of C_{60} (Ioffe Physicotechnical Institute, Russian Academy of Sciences) was dried by heating to 100°C in a vacuum. Composites C_{60}–PPO containing up to 2 wt % C_{60} were

1070-4272/05/7809-1468© 2005 Pleiades Publishing, Inc.

prepared by mixing toluene solutions of the components.

Membranes 50–80 μm thick were produced by removal of toluene at 40°C from the mixed solution poured onto cellophane. The density ρ of the membranes was determined at 25°C in the sucrose solution by the flotation method. The free volume v_f was estimated by Eq. (1):

$$v_f = v_{sp} - 1.3v_w, \quad (1)$$

where $v_{sp} = 1/\rho$ is the specific volume and v_w, van der Waals volume determined by the Bondi method. The contribution of C_{60} to the occupied volume and molecular weight of PPO monomeric unit was taken into account in estimating v_w of the C_{60}–PPO composites.

Dielectric measurements were carried out in a hermetically sealed glass cell using chrome-plated brass contact electrodes at 0.1 kHz in a vacuum. Contact angles of the membrane surface with water and ethanol were determined by the Wilhelmy method on a KRUSS contact angle measuring system with computer-controlled sample immersion rate and data processing.

The pervaporation experiments were conducted using a laboratory cell with an effective membrane area of 14.8 cm^2 with stirring of the feed mixture at 50°C over the membrane at a residual pressure under the membrane of 0.2 mbar. The compositions of the feed mixture and permeate were determined refractometrically or chromatographically. The partition factor α was estimated as

$$\alpha = (X_A/X_B)/(Y_A/Y_B), \quad (2)$$

where Y_A and Y_B are the weight fractions of A and B in the initial (feed) mixture and X_A and X_B, in the permeate. The transport characteristics were determined to within 5%.

The equilibrium swellability (sorption) was determined gravimetrically. The equilibrium sorption S was estimated by Eq. (3):

$$S = (m_s - m_0) \times 100/m_0 \quad (3)$$

where m_s and m_0 are the weights of the swollen and dry membrane, respectively.

The formation of C_{60}–PPO donor–acceptor complex imparts typical brown color to the modified PPO membranes; the color intensity depends on the percentage of C_{60}. We examined some physical characteristics of the C_{60}–PPO membranes, which are relevant to understanding the features of the transport of small molecules across homogeneous membranes. In particular, we have determined the distribution of C_{60} in PPO films (from the dielcometric measurements) and also the density of the films and contact angles.

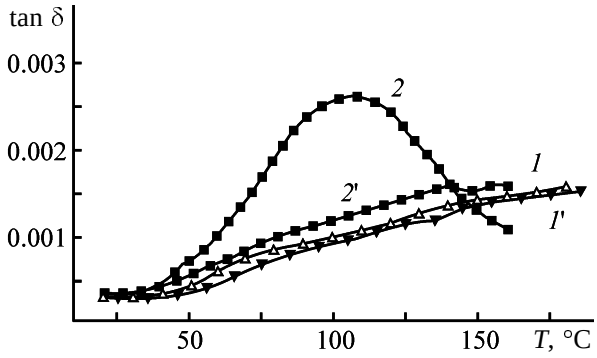

Fig. 1. Dielectric loss tangent tan δ as a function of the temperature *T*: (*1*, *1'*) PPO and (*2*, *2'*) 2% C_{60}–PPO. (*1*, *2*) Before heating and (*1'*, *2'*) after heating to 150°C without air access. Frequency 0.1 kHz.

Figure 1 shows the temperature dependences of the dielectric loss tangent tan δ of the initial PPO and 2% C_{60}–PPO membranes. At room temperature PPO occurs in the glassy state, demonstrating no dielectric relaxation range up to 180°C (Fig. 1, curve *1*). In the case of the C_{60}–PPO membranes we found a relaxation range at 80 to 120°C. Since $\tan\delta_{max}$ is observed only in the presence of C_{60}, it may be suggested that the occurrence of the relaxation range is associated with the mobility of the kinetic units of fullerene. Heat treatment of the C_{60}–PPO membrane suppresses the relaxation transition, and the temperature dependence of tan δ becomes similar to that of PPO.

It is known from the literature that fullerenes in solutions can form clusters [13]. It may be suggested that, as in the C_{60}–polystyrene system [12], the observed relaxation transition is associated with the mobility of the dipoles of fullerene clusters. However, in the C_{60}–PPO composite, the intensity of this transition is lower by an order of magnitude than that in the system with polystyrene, suggesting that only a small fraction of fullerene molecules in PPO films exist in the form of clusters. This is supported also by the lack of the $\tan\delta_{max}$ peak in the heat-treated sample (Fig. 1, curve *2'*). In preparing the composite films from solutions, the most of C_{60} molecules are more regularly distributed throughout the PPO film thanks to donor–acceptor interaction of C_{60} with the lone pair of the oxygen atom of PPO in addition to the interac-

tion of the phenyl ring with the π system of C_{60}. The fullerene molecules associated with PPO are capable of strong intermolecular interactions resulting in physical cross-linking of the PPO chains via fullerene bridges, which is reflected in considerable increase in the dielectric permittivity of the C_{60}–PPO composites (Table 1) and also can increase the density.

Introduction of foreign particles into polymer systems may result in both compaction and loosening of the polymer structure. To elucidate the effect of C_{60}, we measured the density of PPO films with various C_{60} content and estimated their free volume. Table 1 shows that addition of C_{60} increases the density of PPO, i.e., the PPO globules becomes more compact, and the free volume of the fullerene-containing composites decreases, thus reflecting the intercomponent interactions.

The contact angle is a parameter most commonly used to characterize the surface tension of solids [14]. We determined the contact angles of PPO and C_{60}–PPO membranes with water and ethanol using the Wilhelmy technique (Table 1). The results show that PPO is a hydrophobic polymer (contact angle with water is above 90°). Addition of C_{60} increases the contact angle, i.e., the hydrophobicity. Inversely, the PPO surface is readily wetted with ethanol, and addition of C_{60} decreases the contact angle with ethanol. These results appeared to be significant for interpretation of the effect of C_{60} on the sorption and pervaporation characteristics of PPO membranes.

Table 2. Equilibrium sorption *S* and interaction parameters of membrane materials with components of liquid mixtures

Solvent	*S*, wt %		Interaction parameter χ

Ethyl acetate	23	26	1.22	1.13
Ethanol	13	15	1.45	1.34
Water	0	0	–	–

In pervaporation, polymeric membranes operate as molecular sieves, but having active sites capable of dipole–dipole, ion–dipole interactions or hydrogen bonding with components of a liquid mixture to be separated [15]. The mass transfer depends to a considerable extent on the affinity of the membrane material for components of the mixture [2, 4]. Quantitatively, this affinity is characterized by the Flory–Huggins interaction factor χ (as known, χ directly characterizes the solubility of a polymer in a given solvent [16]). In the case of equilibrium sorption and a one-component solvent, χ can be estimated by Eq. (4) [17]:

$$\chi = \frac{-\ln \varphi_i - \varphi_p}{\varphi_p^2}, \quad (4)$$

where φ_i and φ_p are the volume fractions of the solvent and polymer, respectively.

Therefore, the fraction of the solvent in the polymer phase increases with decreasing χ, i.e., the lower χ, the better sorption. Equation (4) can be used for estimating parameters of interaction in binary solvents also on the condition that these parameters are composition-independent [17]. To estimate the interaction parameter, we studied the sorption of ethyl acetate, ethanol, and water vapors on the homogeneous membranes. The results obtained after establishment of the equilibrium show (Table 2) that the affinity of the PPO and C_{60}–PPO membranes for the solvent decreases in the order ethyl acetate > ethanol >> water (water appears to be absolutely inert solvent with respect to the polymers studied). The C_{60}-modified membranes better sorb both ethyl acetate and ethanol.

Pervaporation of aqueous-alcoholic mixtures represents a classical task for this membrane separation technique [18–20]. We studied the effect of C_{60} on the pervaporation characteristics of PPO membranes

in pervaporation of the H_2O–EtOH mixture. Figure 2 shows the dependences of the EtOH concentration in the permeate and selectivity on the EtOH concentration in the feed mixture in pervaporation of the H_2O–EtOH mixture through PPO and C_{60}–PPO membranes. The trend of the concentration dependence for pervaporation differs significantly from the equilibrium liquid–vapor diagram in the system water–ethanol (Fig. 2a). In pervaporation, at any concentration of the feed mixture, a water-enriched permeate is formed, i.e., the membranes in hand are selective with respect to water. Addition of C_{60} decreases the alcohol concentration in the permeate, i.e., the selectivity increases (Fig. 2b). This fact can be attributed to decreasing free volume of PPO with addition of C_{60} (Table 1), which could cause a decrease in the size of the transport channels in the modified PPO membranes, and, therefore, an increase in the selectivity with respect to water.

Figure 3 shows the permeability Jl as a function of the ethanol concentration in the initial mixture in pervaporation of the water–ethanol mixture. Since the penetrant flux J is inversely proportional to the membrane thickness l, which varied from 50 to 80 μm for different samples, we used the product Jl, to compare transport characteristics of the homogeneous membranes (the use of this product was demonstrated to be more correct [21]. As seen from Fig. 3, addition of C_{60} increases the penetrant flux across the membrane. Furthermore, increasing concentration of less penetrating component, ethanol, in the initial mixture also increases the permeability of the membranes, which seems to be surprising. This fact can be attributed to the specific sorption features of the investigated membranes with respect to water and ethanol.

Figure 4 shows the dependence of the equilibrium sorption on the EtOH concentration in the water–ethanol mixture for PPO and 2% C_{60}–PPO membranes. As seen, all the membranes studied are inert with respect to water, but readily sorb ethanol. Therefore, even small amounts of ethanol in water initiate swelling of PPO. In this case, addition of C_{60} increases the sorption capacity, which is consistent with data of Table 2 demonstrating that, in ethanol, the interaction parameter and contact angle of fullerene-containing membranes decrease. This is responsible for the fact that, with increasing EtOH concentration in water, the sorption on C_{60}–PPO composite increases to a larger extent than for PPO.

To interpret the observed preferential transport of water in pervaporation of water–ethanol mixtures through hydrophobic PPO-based membranes, we sug-

Fig. 2. gested the following mechanism. Initially only ethanol molecules are involved in the sorption through interaction with the lone electron pair of the oxygen atom of the PPO backbone with formation of hydrogen bonds; in such a way ethanol molecules are retained in the membrane phase, creating transport channels. Thanks to a considerable affinity for ethanol, water penetrates these channels whose size is well comparable with the kinetic diameter of the water molecule, the penetrability of water being higher because of smaller size of its molecules as compared to ethanol. Increasing ethanol concentration as a swelling agent in the feed mixture weakens the intra- and intermolecular interactions in the PPO membrane, i.e., placticizes the membrane, favoring increase in the permeate flux across the membrane. The sorption data confirm the increase in the degree of plasticization of the PPO matrix as well as of the number of mass-transfer channels with increasing ethanol concentration in water. These transformations result in increasing penetrability of water and selectivity, the tendency being more clearly pronounced for C_{60}–PPO membranes.

In studying pervaporation in the system water–ethyl acetate, the primary attention was paid to separation of ethyl acetate from homogeneous water-rich mixtures (<7 wt % ethyl acetate). The reason is that the phase separation in this system occurs over a wide composition range, and the homogeneity ranges are found at an ethyl acetate concentration below 7 and above 97 wt %. We studied the transport characteristics of PPO and C_{60}–PPO membranes in pervaporation of dilute aqueous ethyl acetate solutions. For all the membranes studied we obtained high selectivity with respect to ethyl acetate (Fig. 5), which can be attributed to hydrophobic nature of PPO. After formation of the transport channels as a result of sorption and swelling of the membrane in ethyl acetate, penetration of water into these channels is hindered because of high activity coefficients of the components, which results in phase separation in the mixture at an ethyl acetate concentration above 7 wt %. Figure 5 shows that addition of C_{60} further increases the selectivity. At the same time, addition of C_{60} only slightly changes the flux across the membranes: from 0.48 to 0.52 kg m^{-2} h^{-1} on passing from PPO to 2% C_{60}–PPO in pervaporation of 7% aqueous ethyl acetate. This can be a resultant of two oppositely directed factors: decreasing free volume, on the one hand, and increasing swellability of fullerene-containing membranes in ethyl acetate, on the other hand. Note, as a conclusion, that data on pervaporation of aqueous ethyl acetate solutions in combination with those on the system water–ethanol are important for developing a process for synthesis of ethyl acetate using pervaporation.

CONCLUSIONS

(1) Homogeneous PPO membranes modified with up to 2 wt % C_{60} demonstrate higher electrical resistivity and density as compared to unmodified membranes. Also the modification strongly affects the contact angle with water and ethanol.

(2) In pervaporation of water–ethanol mixture through fullerene-modified membranes, both the selectivity with respect to water and permeability increase with increasing ethanol concentration in the initial mixture. Modification of PPO membranes with fullerene makes them more organophilic (swellability in ethanol increases with increasing fullerene content). Increasing fullerene concentration increases both the

sorption capacity of the modified membranes and their efficiency in pervaporation of water–ethanol mixtures.

(3) PPO-based membranes demonstrate high selectivity with respect to ethyl acetate in pervaporation of water-rich mixtures; the selectivity grows with increasing C_{60} content.

Abstract—Atomic-force microscopy, reflectometry, and ellipsometry were applied to analysis of ultrathin films (3.3–13.6 nm) of a rigid-chain polyimide, formed on the surface of a silicon substrate by thermal imidization of Langmuir–Blodgett films of polyamido acid derived from 3,3',4,4'-diphenyltetracarboxylic acid and *ortho*-tolidine.

Formation of ultrathin films on the surface of solids and fabrication of nanolayer composites on their basis is an important part of modern micro- and nanotechnology. A particular place among polymeric dielectric materials used in microelectronics is occupied by polyimides (PI), because they possess a set of practically important properties, such as high thermal stability, mechanical and chemical stability, and radiation hardness [1]. The Langmuir–Blodgett method makes it possible to deposit onto the surface of solids PI films of thickness ranging from 0.5 to several hundreds of nanometers. The field of application of PI films produced by the Langmuir–Blodgett method is rapidly expanding. Introduction of functional groups into the polymer chain of polyimide makes it possible to obtain conducting films [2], as well as films possessing nonlinear optical [3], luminescent [4], and photoelectric properties [5]. These films can be used as antifriction [6] and water-proofing coatings [7] in microsystem devices. Deposition of Langmuir–Blodgett films (LBFs) of PI onto the surface of polymeric gas- and liquid-separating membranes markedly improves their selective properties [8, 9].

The most promising for practical use are LBFs of rigid-chain PI. For example, a rigid-chain PI obtained by imidization of a polyamido acid DP-*o*-TD synthesized from 3,3',4,4'-diphenyltetracarboxylic acid and *o*-tolidine has an exceedingly high thermal stability (the temperature of 5% weight loss is 560°C). In addition, this PI has a low thermal expansion coefficient (~0.5×10^{-5} K^{-1}) and exhibits a pronounced planarizing ability, high moisture resistance, and good adhesion to substrates used in the electronic industry.

PI LBFs are formed in two steps: first, monolayers of a diphilic prepolymer (ester or salt of a polyamido acid) are deposited by the Langmuir–Blodgett method on a solid substrate and then the film obtained is subjected to a chemical or thermal imidization. In the process, aliphatic radicals of the prepolymer molecule are removed, which leads to a significant decrease in the film thickness and to PI formation [10]. The homogeneity of the forming film and its surface roughness are largely determined by the structural organization of macromolecules in the PI film, which, in turn, depends on the structure of the prepolymer macromolecule, conditions in which LBFs are formed, and method of their imidization. Previous studies of PI films obtained by chemical and thermal imidization of the LBF prepolymer, alkylammonium salt of polyamido acid (PAA), DP-*o*-TD, with two multichains of tertiary amine, revealed the presence of a domain structure in the prepolymer LBF and in PI and showed that this structure depends on the pressure in the monolayer of a PAA salt and on the imidization method [11, 12].

The aim of this study was to examine PI films obtained through thermal imidization of an LBF of a PAA salt, with 7, 11, and 29 monolayers, by atomic-force microscopy, reflectometry, and ellipsometry.

EXPERIMENTAL

The synthesis of the alkylammonium PAA salt DP-*o*-TD with multichains of a tertiary amine, the isotherm of compression of a monolayer of a PAA salt, and conditions of its transfer to a silicon substrate were reported in [12]. In this study, the surface pressure in a monolayer in its transfer to a solid substrate was 25 mN m^{-1}. Monolayers of a PAA salt were deposited onto a (100)Si-KDB1.0 substrate preliminarily etched in a dilute solution of hydrofluoric acid to make thinner the oxide layer. The first layer was deposited by lifting the substrate from water at a velocity of 0.2 cm min^{-1}, and the rest of the layers, at 0.5 cm min^{-1}. After each lift of the substrate from water, the film was dried in air for 15 min. PI films (7, 11, and 29 layers) were obtained by step heating to 400°C in a vacuum of PAA salt LBF containing 7, 11, and 29 monolayers.

Surface micrographs of PI LBF were obtained in air with an atomic-force microscope manufactured by NT-MDT, Russia. A semicontact (tapping) mode was used in scanning the surface. This mode ensures a milder action of the probe upon a sample and makes it possible to preclude any damage to its surface. A rectangular cantilever with a tip curvature radius of 10 nm was used. The resonance frequency of the cantilever was 230 kHz.

The PI films were characterized by reflectance ellipsometry on an LEF-101 ellipsometer. The ellipsometric angles were measured in air at 632.8 nm. The thickness of PI films was calculated in terms of a single-layer model by the Holmes method.

Small-angle X-ray reflection patterns were obtained at room temperature by the θ–2θ scanning method (θ, angle of incidence of X-rays onto the sample surface; 2θ, angle of reflection) on a Seifert FPM HZG4 X-ray diffractometer (Germany). A characteristic K_β radiation of an X-ray tube with a Cu anode and thin focus (focus width ~0.04 mm), monochromatized with a primary (111)Si monochromator, was used. The structural parameters of the film (thickness *t*, density ρ of the constituent layers, and roughness σ of interfaces) were determined by fitting calculated model small-angle X-ray reflection curves to those obtained in the experiment. The calculations and fitting were made with a REFSIM software (Siemens AG, 1994, Germany) based on the recursive approach of Parrat [13] to calculation of the intensity of reflected beams and the model of Sinha *et al.* [14], which takes into account the roughness of interfaces between the layers.

Previous studies of the morphology of PI films (29 layers) by atomic-force microscopy have shown that the profile and roughness of the surface are due to presence of a domain structure in a film [11]. The AFM images of PI films (7 and 29 layers), obtained in this study, also demonstrate the presence of domains (Fig. 1), and it can be seen that both separate domains and their aggregates are present on the surface of the films. The surface profile obtained on those parts of a film which are composed of separate domains gives a notion of their dimensions (Figs. 1a, 1b; right-hand diagrams). For the PI films with 7 layers, the domain diameter is 30–50 nm. As the number of layers in a film increases to 29, the domain diameter grows to approximately 100 nm, and, accordingly, the surface roughness of the films, defined as an arithmetic mean of the absolute values of deviations from the average profile height on an area of 3000×3000 nm, increases from 1.34(5) to 2.80(5) nm. It can be seen in the AFM image of the PI film with 7 layers that, in its certain parts, similarly oriented domains form rows of different lengths (up to 1 μm). The domains constituting the rows are elongated.

The results obtained in studying the PI films by reflectometry are presented in Fig. 2 and in the table. The experimental reflection patterns shown in Fig. 2 have a shape typical of homogeneous films with density not modulated periodically in the direction perpendicular to the surface and a rather pronounced surface roughness, which is indicated by the absence of Bragg reflections and clearly pronounced Kiessig oscillations in the reflection patterns. Indeed, as can be seen in the table and Fig. 2, there is good agreement between the experimental reflection patterns and those calculated on the assumption of a single-layer PI film on a Si substrate. The quality of fitting of the experimental and calculated curves was significantly improved on assuming that there exists a thin (~2 nm) additional oxide (SiO_2) layer covering the Si substrate.

The density of the PI films containing 7 and 11 layers, found by reflectometry, was 1.39(5) and 1.23(5) g cm^{-3}, respectively. This is close to the calculated density of DP-*o*-TD PI ($C_{30}H_{18}N_2O_4$), equal to 1.40 g cm^{-3} [15]. For a thicker PI film (29 layers), the density was lower, 1.00(5) g cm^{-3}. The thickest film also has the maximum roughness of 2.6(3) nm. The roughness of the films with 7 and 11 layers was 1.6(2) and 2.0(1) nm, respectively. The roughness determined by reflectometry well coincides with that obtained by analysis of the AFM images of PI films.

According to the results of X-ray reflectometry, the thickness of the PI films (7, 11, and 29 layers) was

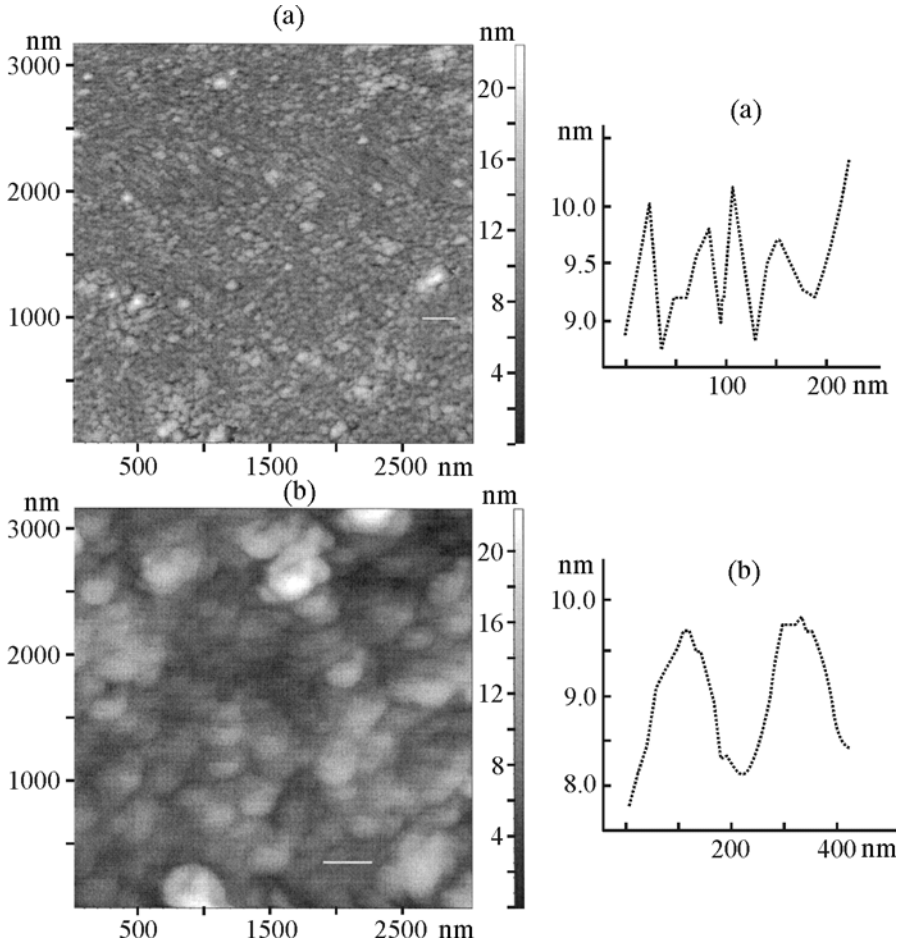

Fig. 1. AFM images of the surface of PI films and the profiles of regions (indicated by white lines) composed of separate domains. Number of layers: (a) 7 and (b) 29.

3.3(2), 5.3(3), and 13.6(5) nm, respectively (see table). The film thickness linearly depends on the number of monolayers in LBF of a PAA salt (Fig. 3). The calculated thickness of a PI layer is 0.474(7) nm (here the root-mean-square error characterizes the deviation of individual calculated thicknesses of a PI monolayer from the average value), which is in good agreement with model conformational calcula-

Parameters of the structural model of PI films

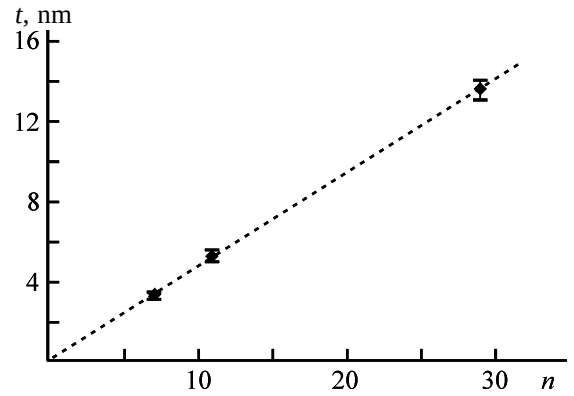

Fig. 3. Thickness *t* of a PI film vs. the number *n* of constituent layers.

tions of the structure of the PI macromolecule [11] and with published data on the thickness of a layer in PI LBF [16].

The ellipsometrically determined thickness of the film with 29 layers is 16.0(4) nm, which is close to that yielded by reflectometry. It was too difficult to determine by ellipsometry the thickness of thinner films.

Thus, as already noted, the reflection patterns obtained indicate that homogeneous PI films, without any pronounced layered structure, are formed on the surface of silicon. This fact is in agreement with the results previously obtained in a study of PI DP-*o*-TD LBF by electron diffraction analysis [11], which demonstrated that the packing of polymer chains in a film is mesomorphic. The presence of a mesomorphic and domain structure in a PI DP-*o*-TD film can be accounted for by specific structural features of the macromolecule of the prepolymer used, in which two molecules of tertiary amine are attached to a monomer unit of the polyamido acid, and each of these molecules contains three hydrocarbon chains with 17 methyl groups and one $-COO^-$ group. The interaction of the hydrocarbon chains within a molecule and that between neighboring molecules create a strong "contraction" effect, which favors aggregation of polymer chains both in the stage of formation of a monolayer and in its deposition onto a solid substrate. In addition, an ordered arrangement of polymer chains in a film is hindered by the presence of two methyl groups in the diamine moiety of the PAA macromolecule.

CONCLUSIONS

(1) Ultrathin Langmuir–Blodgett films of a DP-*o*-TD polymer, formed by thermal imidization of an alkylamine salt of polyamido acid with multichains of a tertiary amine, have a domain structure.

(2) The thickness of the polyimide film linearly depends on the number of layers in the Langmuir–Blodgett film of the prepolymer.

(3) As the film thickness increases from 3.3 to 13.6 nm, the domain size grows from 30–50 nm to approximately 100 nm, and the roughness, from 1.34 to 2.8 nm.

(4) The results obtained indicate that homogeneous films of the polyimide DP-*o*-TD, with a thickness of 3.3 to 16.0 nm, can be obtained on the surface of silicon, and the methods of X-ray reflectometry and atomic-force microscopy can be effectively used to evaluate their thickness, homogeneity, and roughness.

ACKNOWLEDGMENTS

The authors thank I.V. Gofman for carrying out the thermal imidization and to M.F. Panov for measuring the film thickness by ellipsometry. The study was in part supported by the Russian Foundation for Basic Research (project no. 05-03-33194) and by the grant NSh 1824.2003.3.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Preparation and Modification of Chitin-Based Fibers

G. M. Mikhailov and M. F. Lebedeva

Received April 21, 2003; in final form, July 2005

Abstract—Spinning solutions of chitin were modified with polyvinylpyrrolidone, methyl cellulose, and sulfite cellulose. The resulting systems were used for preparing fibers by the wet formation method. The deformation and strength characteristics of these fibers were determined, and their X-ray diffraction analysis was carried out. The influence of the modifying additives on the structure and characteristics of the systems prepared was explained.

Biological activity of a natural polysaccharide, chitin, makes it attractive for researchers in the context of preparation and use of materials thereof, in particular, fibers. Chitin accelerates 3–4 times healing of wounds, and chitin sutures give cosmetic seams [1–3]. Pilot sutures resolve in a patient's body within the period sufficient for complete healing of a wound. However, inadequate elasticity of chitin sutures precludes commercial production of resolving chitin-based surgical seam materials in world practice.

Sukhanova *et al*. [4] showed that brittle failure of chitin-based sutures is due to easy crystallizability of chitin. This property is exhibited by cellulose and a number of others polysaccharides. One of the ways to disturb the crystallinity of a chitin fiber is partial deacetylation of chitin, increasing the structural inhomogeneity of the suture.

An increase in the structural inhomogeneity of the system under partial heterogeneous deacetylation of chitin hinders crystallization of the polymer during preparation of the fiber and increases its elasticity [5]. At chitin deacetylation degree of ≤0.30, the fiber forms a knot and preserves 40% of its initial strength. Heterogeneous deacetylation involves a severe impact of a concentrated alkali (30–50%) at a high temperature on chitin and frequently yields products with difficultly reproducible characteristics. This makes unreasonable the use of such a step in the technology because of variable characteristics of the resulting copolymer (solubility, gel formation, possible formation of glucuronic acids, etc.), which not only complicates but frequently hinders preparation of spinning solutions and formation of a fiber.

Therefore, it is necessary to develop a method of structural modification suitable for hindering crystallization of the macromolecules of the polysaccharide, chitin, increasing the elasticity of fibers, and extending the application field of such a valuable polymer.

EXPERIMENTAL

We used the following chemicals: dimethylacetamide available from Vekton (it was dehydrated and vacuum-distilled, with collection of the fraction boiling at 42°C and a residual pressure of 7 mm Hg); lithium chloride crystal hydrate (dehydrated at 400°C); sulfite cellulose (Svetogorsk Paper and Pulp Combine), DP = 996; crab chitin (manufactured by Vostok-Bor Joint-Stock Company, Dal'negorsk), M = 170 kDa, without ash and proteins; chitin from the North Sea shrimp, M = 135 kDa, with ash and proteins removed; polyvinylpyrrolidone (PVP) (samples with different molecular weights were prepared by radiation-induced polymerization [6]); and methyl cellulose with DP = 980 and degree of substitution 0.94 (laboratory synthesis).

Spinning solutions were prepared by dissolving polymers in a dimethylacetamide + 5% LiCl mixture so that the total concentration of chitin and the modifying polymer was 3% [7, 8]. The desired systems were obtained by introducing into the chitin solution the required amount of the solution of the modifier, which was followed by thorough mixing and gas removal in a vacuum, whereupon the resulting mixture was used for formation of fibers.

Fibers were obtained on a PIFV-01 setup, using a dosing syringe and a 1/0.4 spinneret. For precipitation served an alcohol bath, and for plasticization, a water bath. The fibers were freed from LiCl by washing with hot water until complete absence of chloride ions

1070-4272/05/7809-1479 © 2005 Pleiades Publishing, Inc.

in the wash waters (test with $AgNO_3$). The fiber was dried at 105°C.

Mechanical tests were carried out on an Instron-110 universal tensile-testing machine. The stress–strain diagrams were obtained for a 50-mm sample at a loading speed of 5 mm min^{-1}. Before tests, the samples were kept for a day in a desiccator over a concentrated aqueous solution of magnesium acetate, i.e., at a relative humidity of 65%.

X-ray diffraction studies were carried out on a DRON-2 diffractometer and in an RKV-86 chamber using nickel-filtered CuK_α radiation.

To choose the main procedures for preparation and modification of chitin sutures, it is necessary to consider the physicochemical relationships in formation of fibers from polysaccharide solutions.

The mechanical properties of chemical fibers, in particular, synthetic fibers based on polysaccharides, chitin and cellulose, are governed by two major factors: (1) degree of orientation of the polymer macromolecules along the fiber axis and their stacking and (2) morphology of the fiber, character and presence of submicrodefects in its structure on the micro and macro levels.

Also, a specific feature of polysaccharides should be mentioned, namely, a strong crystal lattice due to high-energy hydrogen bonds and rigidity of the macromolecules due both to pyranose fragments of the polymer chain and intramolecular hydrogen bond between the hydroxy group at the C^3 atom in a pyranose fragment and the oxygen atom of the neighboring pyranose ring. This is specifically responsible for rigidity of the macromolecules of polysaccharides, chitin and cellulose, as well as for the specific features of their conversion into the dissolved state. Polysaccharides can be dissolved via preparation of labile low-substituted esters or ethers that are easily solvated or via dissolution of polymers in "straight" solvents, yielding addition compounds. The latter procedure seems preferable. Out of all systems able to dissolve cellulose and chitin, the most convenient is a complex solvent dimethylacetamide–lithium chloride [9–11] in which polysaccharides do not degrade. When protected from the impact of the environment, these solutions preserve their properties for years.

Dissolution of polysaccharides, e.g., cellulose, is commonly accelerated by treating successively with water and methanol, whereupon the latter is replaced by dimethylacetamide in order to make the reaction centers more accessible for solvation. Such a procedure, inclusion, allows transparent solutions of the polysaccharide with higher concentrations of the polymer in solution to be prepared in a shorter time. The time of preparation of the solution increases with an increase in the molecular weight of the polymer.

McCormick [11] prepared solutions of polysaccharides by heating the mixture to 150°C, followed by slow cooling under protection of the system with nitrogen against thermooxidative degradation, which yielded transparent solutions. In this study we took advantage of the given technique for preparing a solution of chitin to be used for forming fibers.

Fibers are formed by pouring the chitin solution into appropriate precipitating baths in which the addition compounds degrade with replacement of the solvent from the polymer solution jet with the precipitating agent. According to phase equilibrium laws, coagulation of the polymer occurs. The system separates into two phases, one of which is a concentrated solution of the polymer; a three-dimensional structure (gel) is formed. This phase has a high viscosity and imparts to the coagulated polymer the fiber-gel properties.

Subsequent processes occur simultaneously or in a certain sequence depending on the formation conditions chosen. Strengthening of the system is associated with orientation of the polymer macromolecules. It should be accomplished before the onset of crystallization, while the originally formed phase exhibits certain plasticity.

Thus, one of the prerequisites to preparation of high-strength polysaccharide fibers is prevention or deceleration of the polymer crystallization during formation of a suture. Above all, the water activity should be decreased. This can be done by using alcohols as precipitating agents for polysaccharides during fiber formation.

Also, crystallization during preparation of polysaccharide fibers can be decelerated by introducing into the system other polymeric substances capable of hindering crystallization of the polysaccharides by strong interchain interaction and yielding a highly oriented mesomorphic supramolecular organization and, as a result, a fine fibrillar structure making the fibers highly strong and elastic. These polymeric substances should be kinetically compatible with the polysaccharide, which will prevent phase segregation at high concentrations of the polymer in the spinning solution and ensure steric hindrance to premature crystallization of the polysaccharide macromolecules during formation of the fibers.

Table 1. Influence of the origin and concentration of chitin in solution on the deformation and strength characteristics of fibers

Sample no.	σ_t, MPa	ε_b, %	E, GPa	Origin	c, %	M, kDa
1	476	4.5	27.3	Crab	3.2	170
2	395	5.0	18.3	Shrimp	3.1	135
3	405	1.7	32.1	"	2.0	135

* σ_t is ultimate tensile strength of the fiber; ε_b, elongation at break; and E, initial modulus of elasticity (Young modulus).

Both the molecular weight of the polysaccharide and the concentration of the polymer in solution affect structure formation in the resulting sutures and, correspondingly, the deformation and strength characteristics of the fibers.

Table 1 presents the deformation and strength characteristics of the fibers obtained from crab chitin (sample no. 1) and chitin of the North Sea shrimp (sample nos. 2 and 3). At virtually identical concentrations of the polymers in the solutions (3.2 and 3.1%) and under identical conditions of formation, the fiber from crab chitin is characterized by higher strength and higher initial modulus of elasticity, while elongations at break are close. This can be due only to the difference in the molecular weight of the chitin samples (170 kDa for crab chitin and 135 kDa for shrimp chitin). At the same time, at different concentrations of the shrimp chitin in solutions (3.1 and 2.0%) but under identical formation conditions, the resulting fibers are close in the strength (395 and 405 MPa) but differ in the deformation properties: The elongation at break is 5 and 1.7%, respectively. Table 1 shows that, with decreasing concentration of the polymer in solution, the resulting sutures are more rigid (initial modulus of elasticity of sample nos. 3 and 2) and brittle (elongation at break is much lower, sample nos. 2 and 3).

Table 2 shows that, to achieve large elongations at break, formation should be carried out at negative spinneret extensions (when the solution is supplied from the spinneret at a velocity exceeding that of the fiber reception). The strength characteristics of the fibers are improved as well. This is presumably due to the conformational transformations of the glucopyranose rings of the polysaccharide macromolecules and, correspondingly, to the relaxation processes occurring during suture formation.

Table 3 presents the deformation and strength characteristics of the fibers obtained by modification of the chitin fibers with PVP. It is seen that the properties of the fibers are most strongly affected by minor (1–2.5%) PVP additions. PVP with molecular weight

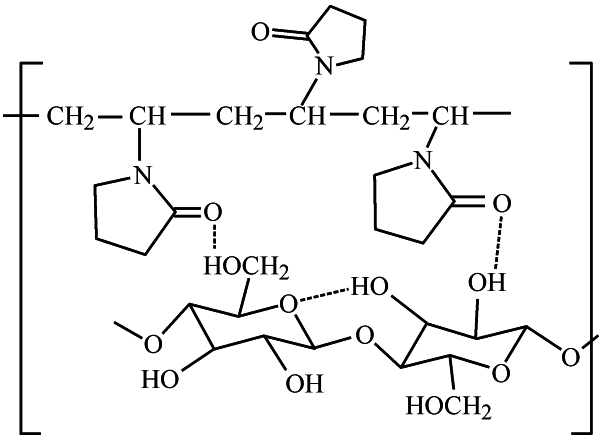
M of 12 and 35 kDa proved to be the best modifier. Upon introduction of 2.5% PVP with *M* = 12 kDa into a spinning solution, the strength of the fiber increased to 718 MPa, and the elongation at break was 6.8%. With increasing PVP concentration in the spinning solution to above 2.5%, all the mechanical characteristics of the fiber, also strongly influenced by the molecular weight of PVP, tended to decrease. The optimal characteristics were obtained at the molecular weight of 12.0 kDa.



With a low- (*M* = 8.0 kDa) and a high-molecular-weight PVP (*M* > 800 kDa), the strength and elongation at break markedly decrease; the modulus of elasticity remains virtually unchanged, but with PVP having *M* = 800 and 1500 kDa it tends to sharply decrease. Such a dependence of the mechanical properties of the fiber on the molecular weight of PVP is, evidently, due to formation of microheterogeneous structures already in the spinning solution.

By using PVP with *M* = 12 kDa as modifier, the elongation at break of the fiber can be increased to 6.8%. Such a fiber preserves in the knot up to 40% of its initial strength.

X-ray diffraction studies [7] of the fiber obtained from chitin and composite fibers containing 1% PVP with the molecular weight of 12.0 and 35.0 kDa show that the fiber preserves a highly ordered structure typical for the unmodified chitin fibers. The X-ray diffraction patterns taken along the fiber axis (meridian) contain reflections at 2θ of 17° and 26°, corresponding to interplanar spacings of 5.02 and 3.36 Å, respectively. In the X-ray diffraction patterns of the fibers containing over 2.5% PVP, the reflection at 2θ = 9° it slightly blurred. The X-ray diffraction patterns taken across the fiber (equator) exhibit clear reflections at 2θ of 9° and 19°36′, also corresponding to interplanar spacings of 9.8 and 4.45 Å, typical for chitin fiber.

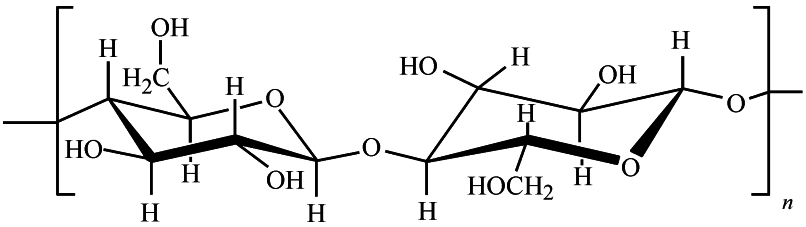
Thus, our X-ray diffraction studies show that, when introduced into a spinning solution in amounts up to 2.5% of those of chitin, PVP of varied molecular weights does not form a separate phase, and at a larger content of PVP the interplanar spacing in the system tends to increase.

Apparently, the macromolecules of the polysaccharide (chitin or cellulose) interact with PVP to form interchain hydrogen bonds:

This scheme shows that hydrogen bonding between the carbonyl oxygen from the pyrrolidone ring of PVP and hydroxy groups of the pyranose ring of the polysaccharide can involve the hydroxy group both at C^6 and at C^2 carbon atoms of the glucopyranose ring of the polysaccharide. The hydroxy group at C^3 forms an intramolecular hydrogen bond with the oxygen atom of the neighboring unit.

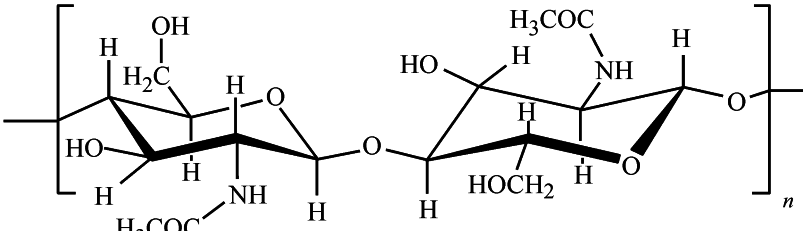
Also, the main chain of PVP is a hydrophobic element of the macromolecule and, when occurring in the interpolymer complex along with the modified system of hydrogen bonds of the polysaccharide, it decelerates crystallization of the polysaccharide macromolecules and modifies the supramolecular organization of the polysaccharide fibers. This improves the deformation characteristics of the fibers: They become more elastic, and their elongation at break increases. However, increases in the content of PVP and its molecular weight weaken the interchain interaction in polysaccharides and, consequently, deteriorate the deformation and strength characteristics of the fibers.

Introduction of up to 1.0% methyl cellulose into a solution of chitin [7] (Table 4) enhances the strength of a fiber to 834 MPa and increases its elongation at break to 4.5%. In the composition range studied (0.5–10.0%), the strength of the fiber shows a maximum at 1.0% content of methyl cellulose. Evidently, the methyl group of methyl cellulose hinders stacking of the macromolecules into crystal structures in the systems studied, decreases the density of the network of hydrogen bonds, as if plasticizing the system (as



manifested in the changes in the strength and elongation at break of the fiber), and favors its orientation strengthening.

When chitin is modified with cellulose, or cellulose with chitin [8], at a low content of the modifier in the system, there is a sharp extremum of the ultimate tensile strength: a maximum at 0.5% cellulose in chitin and a minimum at 0.5% chitin in cellulose. Introduction of only 0.5% cellulose into chitin increases the strength of the fiber by 23% of the initial value, and at the modifier content of 2.5% the strength is 457 MPa, i.e., it deceases almost to the initial level (436 MPa). This local maximum of the strength is accompanied by a minimum of the elongation at break (2.2%). At a low (0.5%) content of chitin in cellulose, the fibers have a similarly homogeneous, though less clearly expressed, structure.



Bochek *et al*. [12] note that minor amounts of chitin and cellulose produce oppositely directed changes of the structure both in solutions and in a solid phase (films). Also, they reported that introduction of chitin into cellulose yields a more heterogeneous structure than introduction of cellulose into chitin.

The X-ray diffraction analysis of the systems with a low content of the modifier does not reveal the factors responsible for this phenomenon. However, studies of the structures of solutions of these polysaccharides [12], as well as of D_2O sorption by nonoriented films obtained from these systems [13], showed that the amount of the vapor sorbed tends to decrease upon introduction of 0.5% cellulose into chitin and to increase upon introduction of the identical amount of chitin into cellulose. Small-angle neutron scattering studies of these films showed that the scattering inhomogeneities are the smallest in the case of films with a low content of any component of the mixture. The size of the scattering inhomogeneities exhibits a local jumpwise decrease. The number of these inhomogeneities increases at 0.5% content of cellulose in chitin, and the structure of the film becomes more homogeneous.

Analysis of the chemical structures of chitin and cellulose will reveal the driving forces governing the morphology of the modified fibers:

A

B

The schematically presented fragments of the cellulose (**A**) and chitin (**B**) macromolecules show that the only difference between them consists in that, in the pyranose ring of chitin, one hydroxy group is replaced by acetamide group. The latter will hinder the stacking of the macromolecules during crystallization in the polysaccharide mixture and affect the character of the hydrogen bonds in the system.

When introduced into chitin in small amounts, cellulose can create a surface layer on the surpamolecular structural formations of chitin, whose "additional" hydroxy groups will strengthen the interstructural (interelement) interaction. This will be specifically responsible for enhanced rigidity of the system and the ensuing decrease in the elongation at break of the fibers. Thus, when added to chitin in minor amounts, cellulose acts as an antiplasticizer.

By contrast, introduction of chitin into cellulose should weaken the intermolecular interactions at the boundary separating the structural elements, since the

acetamide groups of chitin will sterically hinder the mutual stacking of the cellulose macromolecules. Hence, minor additives of chitin will act as plasticizers of the system. This can be responsible for an increase in the elongation at break of the cellulose fibers containing small amounts of chitin.

Thus, the influence of minor additives introduced into the polymer and substantially affecting its properties is exerted via changing the supramolecular ordering of highly organized polymeric systems. Presumably, these phenomena have the following mechanism. Spread of the modifier over the surface of the boundary separating the structural supramolecular formations of the polymer in some cases decreases the surface energy of interelement interaction, thereby increasing the mobility of the structural elements. In these cases, the modified system undergoes structural plasticization. In other cases, the energy of interaction of the interstructural elements increases, and the modifying additive acts as a structural antiplasticizer of the polymer. However, the phenomena of interest can be interpreted in such a way only when the structural elements of a polymer body are separated by a boundary, that is, this is a heterophase system. This is in line with the conclusions made by Papkov [14]. These effects are manifested only in heterophase systems with structural formations corresponding to the "macroscopic level" of the structure.

The modifier is localized on the boundary separating the macroscopic elements of the supramolecular structure of the polymer. This yields a heterophase system with the boundary at the location site of the modifier.

However, the term "heterophase nature" in its traditional sense is hardly applicable to so closely related polymers as chitin and cellulose, whose polymer chains are formed by glucopyranose rings. Instead, we should discuss a substantial change of the concentration of the hydrogen bonds on the surface of the micro- or macrofibrils. When cellulose is modified by microamounts of chitin, this concentration decreases, and when chitin is modified by cellulose, increases. In these cases, when chitin fibers are modified by minor additions of cellulose, the latter acts as a structural antiplasticizer, probably forming an epitaxial layer on the boundary separating the supramolecular formations and increasing the total energy of the interstructural interactions via increasing the density of the network of hydrogen bonds.

When cellulose is modified with chitin, minor additives of chitin act as structural plasticizers of the cellulose fibers. The plasticizing effect is due to a decrease in the density of the network of hydrogen bonds of the interstructural supramolecular formations.

In nature, similar role is played by cellulose satellites, hemicelluloses. Being natural structural modifiers, they affect the deformation and strength properties of plant materials. This makes of special importance the history of preparation of the sample of the polysaccharide and the ways of its isolation and preliminary processing, governing its purity, molecular weight, and polydispersity and affecting formation of the supramolecular structure and thus the characteristics of fibers thereof.

CONCLUSIONS

(1) Factors influencing the structure and the deformation and strength characteristic of polysaccharide fibers were established. High deformation and strength characteristics of fibers can be achieved with a polysaccharide having a maximal possible molecular weight and a maximal concentration of the polymer in solution, and sutures should be formed at negative spinneret extensions.

(2) The structure of polysaccharide fibers can be modified both by another polysaccharide or its derivative (partly substituted ethers or esters) and hydrophilic carbon-chain polymers.

(3) The deformation and strength characteristics are improved when a minor addition of a modifier acts as structural plasticizer decreasing the total energy of the network of hydrogen bonds at the boundary separating the supramolecular formations. When the modifier increases the total energy of the network of interstructural hydrogen bonds, it acts as a structural antiplasticizer, increasing the rigidity of the system and deteriorating the deformation characteristics of the fibers.

ACKNOWLEDGMENTS

The authors are grateful to V.S. Bozhko ("Vostok-Bor" Joint-Stock Company, Dal'negorsk) for the submitted crab chitin and for the interest and assistance in carrying out this study; to V.A. Petrov for the submitted solutions of chitin with polyvinylpyrrolidone; and to V.N. Ushakov for the submitted polyvinylpyrrolidone samples.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

A Study of Structure Formation in Chitosan–Polyvinyl Alcohol Blends by Turbidity Spectroscopy

E. I. Kulish and S. V. Kolesov

Bashkir State University, Ufa, Bashkortostan, Russia

Received March 21, 2005

Abstract—The structure formation of film samples of chitosan, polyvinyl alcohol, and their blends was studied by turbidity spectroscopy.

A blend of water-soluble polymers, polyvinyl alcohol (PVA) and aminopolysacharide, chitosan (CS), shows promise for preparing films and fibers combining high strength, biodegradability, and high hydrophilicity [1]. Introduction of PVA into CS, which is characterized by physiological activity, increases the flexibility of fairly brittle chitosan films [2]. Film materials based on PVA are widely used as membranes, artificial leather, and packing. Chitosan is used for reinforcing PVA films. Many properties of the polymeric composition are set in the stage of its formation and are determined by the phase and supramolecular structure of the polymer blend. The possibility of controlling the structure and properties of polymeric films, on the one hand, and unique properties of CS, on the other hand, give grounds to expect that polymeric films based on PVA and chitosan can serve as polymeric support for systems with controllable release of a drug.

In this study, we examined the structure of film samples of PVA and CS blends prepared from the combined solution and the principal possibility of release of a drug (gentamicin) from such films.

EXPERIMENTAL

PVA of 16/1 grade [GOST (State Standard) 10 779–78)] with M_η = 25 000, CS sample [TU (Technical Specification) 6-09-05-296–76] prepared by base deacetylation of crab chitin (degree of deacetylation 75%, M_η = 120 000), and gentamicin antibiotic were used without additional purification. Films of the individual polymers and their blends were prepared by casting the initial solutions onto the glass surface. The polymer concentration was varied from 0.2 to 5 g dl^{-1}. The solvent quality with respect to CS was controlled by varying the solution acidity [dissolution of CS in 5% aqueous ultrapure grade acetic acid (hereinafter these solutions are denoted as 5-AA) or 1% acetic acid (1-AA)]. To determine the average dimensions of supramolecular particles r and their number N in 1 cm^3 in the films, we used turbidity spectroscopy [3, 4]. The measurements were performed within λ = 340–590 nm at 20°C on a KFK-2MP photocolorimeter. The kinetics of gentamicin release from films placed in alkaline solution (pH 10) to prevent dissolution of CS was studied spectrophotometrically at λ = 240 nm (the absorption band of the pentosan ring of gentamicin) on a UV-VIS Specord M-40 spectrophotometer. The gentamicin content in the film was 2 wt %.

The study of PVA and CS films showed that the average turbidity of the films prepared from dilute solutions is substantially higher than that of the films prepared from more concentrated solutions (Fig. 1). Figure 2 shows that, with increasing concentration of the initial solution, the dimensions of supramolecular particles decrease and their number increases. This non-trivial result can be explained as follows. Forma-

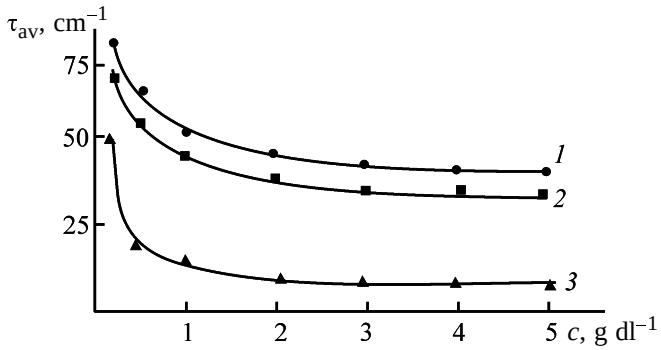

Fig. 1. Average turbidity τ_{av} of (*1, 2*) CS and (*3*) PVA films as a function of the polymer concentration c in the initial solution in (*1*) 5-AA and (*2, 3*) 1-AA.

tion of the film from dilute (0.2 g dl^{-1}) and concentrated (5.0 g dl^{-1}) solutions substantially differs in time. The initial 5% solution is viscous, and formation of the film proceeds very rapidly, within several hours. As a result, the film structure is similar to the structure of the initial solution. When the film is prepared from dilute solution, the solvent evaporation takes several days. The structure of the initial solution undergoes substantial transformation: supramolecular particles existing in the solution are consolidated, and, correspondingly, their number decreases.

It is of interest that the dimensions of supramolecular particles in CS films are substantially larger than in PVA films. This fact is consistent with the known tendency toward integration of CS crystallites in so-called clusters [5].

Apparently, films prepared from dilute and concentrated solutions should differ in their transport properties. It follows from Fig. 3 (curves *1*, *2*) that the release rate and degree of gentamicin release from the film prepared from the initially dilute solution are higher. This is apparently due to the fact that films prepared from the more concentrated solutions and hence having greater number of supramolecular particles with small dimensions will have denser packing and, correspondingly, reduced transport properties.

The films prepared from CS–PVA blends are microheterogeneous and contain crystalline areas of both CS and PVA [5]. At the same time, evident features of interpolymeric interaction appear in these blends. Figure 4 shows that, in the course of film formation from dilute solution, both more (5-AA) and less (1-AA) acidic, the trend in variation of the number and size of supramolecular particles with the CS to PVA ratio is the same. In both cases, the number of supramolecular particles in the blend is smaller and their size are larger than the corresponding additive values. Apparently, in this case we observe interpolymeric interaction, i.e., formation of CS–PVA heteroclusters, which, as known [6], are characterized by reduced packing density and larger size.

In the case of films prepared from concentrated solutions, the size of supramolecular particles in the region of small contents of CS in the mixture sharply increases (Fig. 5). It should be noted that just the blends with the prevalence of PVA (CS content 15–30 wt %) are characterized by elevated strength and the lowest crystallinity factor [7], which suggests the interpenetration of macromolecules.

This fact is indirectly confirmed by the data on the release of gentamicin from the films prepared from

CS–PVA blend and pure CS. As seen from Fig. 3 (curves *3*, *4*), gentamicin is released from the CS–PVA film at a higher rate and to a greater degree than from the CS film (curve *2*). Apparently, films prepared from CS–PVA blends have less dense packing and, correspondingly, better transport properties, which is possible only in the case of formation of heteroclusters.

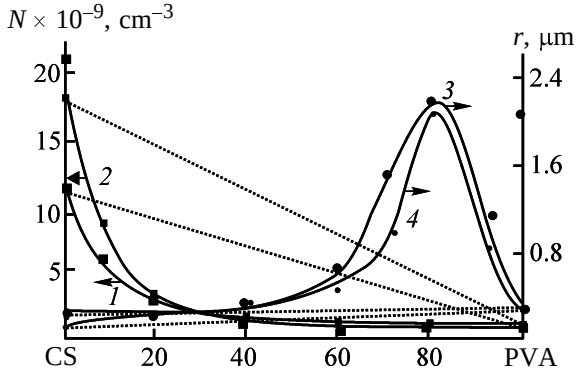

Fig. 5. (*1*, *2*) Number N and (*3*, *4*) size r of supramolecilar particles in films prepared from 5% solution in (*1*, *3*) 1-AA and (*2*, *4*) 5-AA as functions of CS + PVA blend composition.

CONCLUSIONS

(1) The conditions of formation of films from chitosan, polyvinyl alcohol, and their blends determine the number and size of supramolecular particles in the film. The number of supramolecular particles increases and their size, on the contrary, decreases with an increase in the concentration of the initial polymer solution. This fact is explained by consolidation of supramolecular particles at slow evaporation of the diluent in the course of film preparation from dilute solutions.

(2) A sharp increase in the size of supramolecular particles in films prepared from concentrated solutions with the prevalence of polyvinyl alcohol is attributed to formation of heteroclusters.

(3) The change in the structure of polymeric film due to change of the polymer concentration in the initial solution or introduction of the second polymer determines the film transport properties. The kinetics of gentamicin release from the films directly depends on the number and size of supramolecular particles formed in the film.

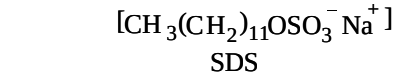
Received April 19, 2005



Abstract—Selenium nanoparticles were synthesized in aqueous solutions of polyelectrolyte complexes of sodium dodecyl sulfate, and the size and morphology of the forming nanostructures were determined.

Polyelecttrolyte complexes (PECs) of sodium dodecyl sulfate (SDS) with a cationic copolymer of *N*-vinylpyrrolidone and *N*,*N*,*N*,*N*-triethyl(methacryloyloxyethyl)ammonium iodide (VP–CC) are of particular interest as substances with a wide biological activity profile [1]:

PEC

VP–CC

SDS

Depending on the molar ratio γ of charged subunits in the complex (γ = SDS/CC), PECs exhibit a varied biological activity. The complex with γ = 0.5 is a strong competitive inhibitor of trypsin, whereas that with γ = 4.0 enhances the activity of this enzyme [2]. At γ = 0.5, PEC inhibits growth of animals, whereas at γ = 4.0 it possesses the highest growth-stimulating activity [1].

It has been established previously [3] that these complexes also differ in structural respect: at γ = 0.5, PEC has the form of micelles electrostatically bound to VP–CC; at γ = 4.0, a lamellar cluster of approximately 1000 SDS molecules is formed in a symmetric polymeric coil.

It is known that water-soluble polymers and anionic surfactants are effective stabilizers of silver [4] and palladium [5] particles. In an aqueous solution of SDS, palladium nanoparticles are stabilized via adsorption of SDS molecules on their surface and formation of a highly organized nanostructure of the 3D type "sphere around sphere" [5].

Of particular interest is the polymeric stabilization of nanoparticles of amorphous selenium, because, as established recently [6], nano-Se^0 stabilized with bovine serum albumin has a relatively low toxicity and retains a biological activity profile characteristic of ionic forms of selenium.

In view of the fact that the PECs mentioned above exhibit membranotropic properties and markedly raise the permeability of lipid bilayers [7], they can enhance the activity of selenium. Therefore, it seemed appropriate to synthesize nano-Se^0 in aqueous solutions of PECs and to determine the size and structural-morphological characteristics of the nanostructures formed in the process.

EXPERIMENTAL

We used a VP–CC copolymer with a molecular weight $M_w = 88 \times 10^3$, whose synthesis and purification have been described previously [3], and chemicals with a content of the main substance of no less than 99.9%. Polyelectrolyte complexes of various compositions were obtained by mixing aqueous solutions of VP–CC and SDS and then isolated in dry form by freeze drying. PEC with $M_w = 117 \times 10^3$ (γ = 0.5) and $M_w = 385 \times 10^4$ (γ = 4.0) were used. The reduction of ionic selenium was carried out at a 0.01% selenium

1070-4272/05/7809-1489© 2005 Pleiades Publishing, Inc.

concentration in the aqueous solution and a PEC : selenium mass ratio of 90 : 10, as in the case of the related selenium–polymer nanostructures [8]. The rate of Se(IV) reduction was evaluated in the thermostated mode (20°C) on a Specord M40 spectrophotometer by the rise with time in the optical density of a solution at a wavelength of 320 nm. The initial concentration of selenious acid was 1.0 mM (the pH of the reaction mass was 3.2 in both cases).

The molecular weights M_w and root-mean-square radii of inertia, R_g, of nanostructures were determined using the method of static light scattering [9], and their affinity for the solvent was found from the value of the second virial coefficient A_2. The ratio of the molecular weights of PECs and nanostructures formed by them was used to calculate the amount N of PECs adsorbed on the surface of nano-Se^0. The reduced intensity of scattering by solutions, R_θ, was measured with a Fica photogoniodiffusometer. The wavelength of the incident vertically polarized light was 546.1 nm. The measurements were performed at scattering angles in the range $\theta = 30°–150°$. The solutions and the solvent were purified by centrifugation at 15×10^3 rpm for 1–1.5 h. The increments of the refractive index, dn/dc, were determined by refractometric measurements on an IRF-23 instrument. For the system constituted by PEC, nano-Se^0, and water, $dn/dc = 0.244$ for $\gamma = 0.5$ and 0.198 for $\gamma = 4.0$.

The experimental data on light scattering by solutions of nanostructures were processed by the Zimm method by double extrapolation (to $c = 0$ and $\theta = 0$) of the plots of Kc/R_θ against $\sin^2(\theta/2) + kc$ (K, calibration constant; k, numerical constant).

The method of dynamic light scattering [10] was used to determine the average hydrodynamic dimensions of nanostructures, R_h. The ratio of the experimental values of R_g and R_h was used to find the value of the parameter ρ^* characterizing the structural-conformational state of the nanostructure [11–14]. The optical part of the installation for measuring the dynamic light scattering was equipped with an ALV-SP goniometer (Germany) (source of light: Spectra-Physics He–Ne laser, $\lambda = 632.8$ nm, power ~20 mW). The correlation function of the intensity of scattered light was determined using a Photo Cor-EC correlator with 288 channels (manufactured by Anteks Private Company, Russia). The correlation function was analyzed by Dynals software for processing of dynamic light scattering data (Gelios Company, Russia).

The data on M_w and root-mean-square radii of inertia were used to determine the average density of the nanostructures by the formula

$$\Phi^* = 3M_w/4\pi N_a R_{sph}^3, \quad (1)$$

where $R_{sph} = 1.29R_g$ [15].

The molecular dispersity of solutions of the nanostructures being formed was evaluated using the method of flow birefringence (FB) from the type of the gradient dependence of the magnitude of FB, Δn. In doing so, Δn was determined in relation to the gradient of the rate g of rotor rotation and to the PEC concentration c at a fixed concentration of selenium. We used a titanium dynamooptical caliper with an internal rotor of height 4 cm and a spacing of 0.03 cm between the rotor and stator. All the FB studies were performed with temperature-controlled solutions (21°C) in order to preclude changes in their viscosity and optical distortions caused by the temperature gradient. The installation was calibrated against phenylethyl alcohol, which exhibits a pronounced FB ($\Delta n/g = 17 \times 10^{-12}$), and the polystyrene–bromoform system. The error in determining the characteristic value of FB, $[n] = \lim_{g\to 0,\, c\to 0} (\Delta n/gc\eta_0)$ (η_0 is the solvent viscosity) did not exceed 10%. The measurements were performed at $g < g_k$, where g_k is the velocity gradient at which the flow becomes turbulent.

In the general case of $dn/dc \neq 0$, the experimental value of $[n]$ is constituted by three effects:

$$[n] = [n]_e + [n]_{fs} + [n]_f,$$

where $[n]_e$ is the intrinsic anisotropy; $[n]_{fs}$, microform effect; and $[n]_f$, macroform effect [16].

The quantity $[n]_f$ is related to the shape asymmetry of a particle, p, by the expression

$$[n]_f = [(n_s^2 + 2)/3]^2[M_w(dn/dc)^2 f(p)]/(30\pi RTn_s)$$

$$= \text{const}\, M_w(dn/dc)^2 f(p), \quad (2)$$

where n_s is the refractive index of the solvent; T, absolute temperature; R, universal gas constant; and $f(p)$, tabulated function of the ratio between the axes of a rigid (impermeable to the solvent) ellipsoid approximating a particle [16].

Electron micrographs of the forming nanostructures were obtained with a Philips CM300 FEG transmission electron microscope (accelerating voltage 300 kV). The samples had the form of thin films obtained upon drying of 100-fold diluted starting solutions on structureless carbon films of standard thickness. The dilution of the solutions was necessary to

prevent conglomeration of particles and formation of 3D agglomerates through drying.

In reduction of selenious acid in the presence of PEC, the rate constants of the process in which ascorbate is used as a reducing agent were 0.94×10^{-3} and 1.15×10^{-3} s^{-1} for γ = 0.5 and 4.0, respectively, i.e., the reaction rate was virtually independent of γ.

According to the data on static light scattering, M_w increased by a factor of 20 in going from γ = 0.5 ($M_w = 10^7$) to γ = 4.0 ($M_w = 20 \times 10^7$), i.e., 85 and 520 PEC particles, respectively, were adsorbed on the surface of nano-Se^0 (see table). In this case, the molecular-dispersed state of the solutions of nanostructures was preserved, which is indicated by the type of the $\Delta n = f(g)$ dependences: at $g < g_k$ they are well approximated by straight lines passing through the origin of coordinates for any c and γ [16].

The parameter p was estimated for the nanostructures under study in the approximation of $[n] \approx [n]_f$, using relation (2). It was found that a spherical nanostructure (p = 1) is formed at both values of γ. This is in full agreement with the data on the parameter ρ^* (see table): ρ^* = 1.0 (γ 0.5 and 4.0), which corresponds to a strictly spherical conformation of a particle.

However, experiments on static and dynamic light scattering revealed that nanostructures with different values of γ differ in R_g and R_h: $R_g = R_h$ = 40 nm (γ = 0.5) and $R_g = R_h$ = 100 nm (γ = 4.0) (see table), i.e., the nanostructure with a heavier molecular weight also has a large size (it is noteworthy that, in the absence of selenium in a solution, higher molecular weight and larger size are also observed for PEC with a higher content of SDS [3]).

A calculation of the average density Φ^* of a nanostructure by formula (1) demonstrated that a heavier particle (γ = 4.0) is also denser: Φ^* = 0.04 g cm^{-3} (Φ^* = 0.07 g cm^{-3} at γ = 0.5). This situation is different from that observed in [17], where a more compact nanostructure was denser. Apparently, these systems differ in the packing and distribution of organic molecules around selenium nuclei.

The second virial coefficient A_2 tends to zero for the nanostructure with γ = 0.5 ($A_2 = 0.5 \times 10^{-4}$ cm^2 mol g^{-2}), which characterizes the state of the solution as approaching the ideal. The value of A_2 for the nanostructure with γ = 4.0 is negative ($A_2 = -1.8 \times 10^{-4}$ cm^2 mol g^{-2}), which points to a poor thermodynamic quality of the solution. This results from orientation of hydrophobic alkyl chains of SDS toward the bulk phase of the solution. It should be emphasized that, at γ = 0.5, presence of selenium in a solution has virtually no effect on its thermodynamic state, whereas at γ = 4.0 transition from the PEC–water system to that constituted by PEC, nano-Se^0, and water is accompanied by a fundamental change in the thermodynamic state of the solution from good ($A_2 = 22 \times 10^{-4}$ cm^2 mol g^{-2}) to poor.

As is known [18], the Gibbs energy ΔG of the macromolecule–nanoparticle interaction, calculated per unit area of the particle surface, can be determined by the relation

$$\Delta G = kT \ln c / 4\pi R_{sph}^2, \quad (3)$$

where c is the initial concentration of the polymer (M).

It is noteworthy that relation (3) is valid for spherical nanostructures of arbitrary morphology in the range of formation of stable dispersions. Application of Eq. (3) to the nanostructures under study demonstrated that $\Delta G = -0.016 \times 10^{-5}$ J m^{-2} in the case of formation of a denser sphere (γ = 4.0). This value is considerably lower in magnitude than that in the case of a nanostructure with γ = 0.5, for which $\Delta G = -0.059 \times 10^{-5}$ J m^{-2}. The results we obtained are in qualitative agreement with the data on the parameter A_2 for the nanosystems studied.

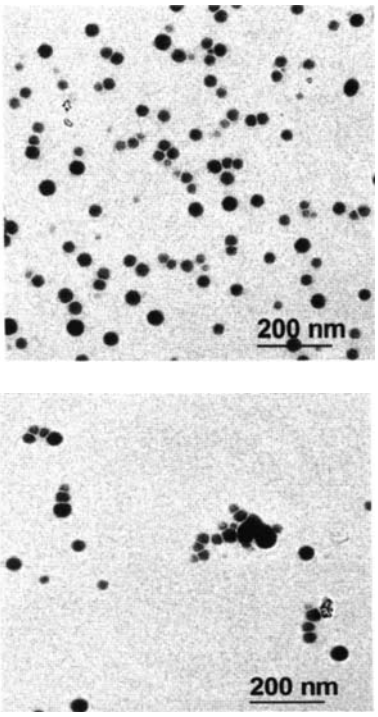

Fig. 1. Electron micrograph of a PEC–Se^0 film with γ = (a) 0.5 and (b) 4.0, formed by drying from an aqueous solution with a selenium concentration of 0.0001 wt %.

Thus, the energies and nature of interaction between nanoparticles and PEC in a complex multicomponent system constituted by PEC, nano-Se^0, and water strongly vary with γ (γ 0.5 and 4.0), which is reflected by the parameters ΔG and A_2. These nanostructures also strongly differ in the molecular weight, size, and density. Presumably, nanostructures with fundamentally different morphologies can be formed in the systems studied. Theoretically, their morphologies may be different for the polymer–nanoparticle systems [19].

This assumption is confirmed by the results obtained using high-resolution transmission electron microscopy for PEC films formed by drying from an aqueous solution with a selenium concentration of 0.0001 wt %. The nanosystem is mostly a mononuclear structure (Fig. 1a) for PEC with γ = 0.5, and mostly a polynuclear structure in the case of a PEC with γ = 4.0 (Fig. 1b).

In the physical parameters R_g, R_h, Φ^*, ΔG, and A_2 (see table), the PEC–Se^0 nanosystem with γ = 0.5 is close to the SDS–Se^0 nanosystem with the same selenium concentration and the same ratio of the components in solution [20]. This indicates that PEC mainly interacts with the selenium nucleus via SDS micelles.

CONCLUSIONS

(1) Hybrid selenium–polymer nanostructures fundamentally differing in their physical parameters and morphology were obtained for the first time by reduction of sodium selenite with ascorbate in aqueous solutions of polyelectrolyte complexes of a cationic copolymer and sodium dodecyl sulfate with various ratios of the charged subunits.

(2) The data obtained constitute a physicochemical basis for purposeful synthesis of potential selenium-based medicines with a lowered toxicity and high pharmacological activity.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Physicomechanical and Rheological Characteristics of Composite Materials with Organic and Inorganic Fillers

O. A. Legon'kova and A. A. Bokarev

State Institution of Higher Vocational Education, Moscow, Russia

Received September 13, 2004; in final form, May 2005

Abstract—The strength and rheological characteristics of polymer composite materials based on synthetic copolymers and various fillers were studied. The influence of the filler on the characteristics of composites was revealed.

Polymer composite materials (PCMs) consisting of polymer materials and inorganic or organic substances of various chemical natures and structures find expanding applications in the form of mixtures or alloys [1].

As a rule, the characteristics of PCM are not a sum of characteristics of its components and are governed by a variety of chemical and physical processes involving the components and occurring at the phase boundary [2].

Polymer blends used today as biodegradable polymers [3–7] contain biodegradable components: cellulose and its ethers and esters, starch, etc., resulting in biodegradation of the composition as a whole. These materials are of interest for practice.

The physicomechanical and rheological characteristics of highly filled materials consisting of a polymer matrix and a mixture of fillers imparting the biodegradability to the composite as a whole were not adequately studied.

In this study we examined the physicomechanical and rheological characteristics of composites with organic (wastes from threshing of grains of the third category, particle size 63–240 μm, bulk density 350 kg m^{-3}, moisture content 4%) and inorganic filler {water-soluble complex mineral NPK fertilizer Rastvorin A [OST (Branch Standard) 10-193–96], containing N, P, K, Mg, Mn, Cu, Zn, B, and Mo in the form of salts, necessary for growth and development of plants}.

As a polymer component we used a copolymer of ethylene and vinyl acetate, Sevilen (SEVA) of the 11306–070 and 11506–070 brands, copolyamide (coPA) prepared by copolycondensation of adipic and sebacic acids with hexamethylenediamine of the N-005 brand [glass transition point T_g 115–120°C, melt flow index MFI 15 g $(10\ min)^{-1}$], and acrylate–styrene carboxylated latex Lenteks A4 [TU (Technical Specifications) 2241-001-47923137–01]. The criterion of choice of these polymers is the presence of functional groups in their compositions. The other important factor is fairly low temperature of treatment of these polymers (130–150°C), which is important for preservation of the characteristics of fillers added to the composite.

The physicomechanical characteristics of the samples were determined in a wide range of the component ratios according to recommendations of GOST (State Standard) 14236–82, and rheological characteristics of filled composites, by capillary viscometry from MFI depending on the filler concentration.

EXPERIMENTAL

In addition of fillers to SEVA, irrespective of its brand, it was found that with increasing content of both wastes and mineral fertilizer in the binary polymer–filler system, the strength and relative elongation decrease (Figs. 1a–1c). In the case of filling with organic fillers (wastes from grain production), the samples become harder, and in filling with inorganic filler (mineral fertilizer), even at its high concentration, the samples preserve fairly high plasticity. This behavior can be caused not only by decreasing concentration of the matrix in the composite, but also by the plasticizing effect of the inorganic filler.

As for ternary systems SEVA–wastes–fertilizer (Fig. 1d), it should be noted that an increase in the

content of inorganic filler gives more plastic samples.

The variations of physicomechanical characteristics of the samples differing in the SEVA brand show similar trends.

Let us consider the behavior of the composite material based on coPA. The ratio of ultimate tensile strength of the filled sample to that of the initial nonfilled sample, $\sigma_{max}/\sigma_{t\,init}$, as a function of the concentration of the inorganic filler is shown in Fig. 2a. In addition of the fertilizer to the composite in the amount of up to 10% (Fig. 2a), the ultimate tensile

strength slightly decreases. This is apparently caused not only by decreasing content of the polymer per unit surface area, but also by the fact that at low degree of filling, even at a good adhesion between the polymer and filler, but in the absence of aggregation of powdered particles, the filler accumulates stresses and is a potential source of crack propagation [8]. With increasing concentration of the filler to 30%, the strength ratio $\sigma_{max}/\sigma_{t\,init}$ increases by a factor of more than 2. With increasing content of the filler, crack propagation becomes more hindered, and the amount of intermolecular interactions between components increases, which results in inhibition of the failure processes [9]. Further decrease in the strength is typical for highly filled polymers with a high content of inorganic filler and a low content of coPA. At a fertilizer concentration of approximately 75%, the sample becomes very brittle and has the strength by an order in magnitude lower than that of the initial sample. The relative elongation at break for all the samples decreases with increasing filling and finally becomes 2 times lower than that of the initial sample. With addition of wastes to coPA (Fig. 2b), the similar trend is observed, i.e., the system gets relatively strengthened; however, this effect is not so significant as in the two-component system with the inorganic filler.

The variations of the physicomechanical characteristics of the coPA–wastes–fertilizer system are shown in Fig. 3. The coPA content was constant, 50%. We varied the content of organic and inorganic fillers. At a high content of the filler, an increase in the content of wastes results in somewhat higher strength and rigidity of the composite. For the system with styrene acrylate–polymer matrix at 49% filling with inorganic filler, the ultimate tensile strength decreases by a factor of 0.9, and at filling with organic filler it increases by a factor of 2.7.

Addition of up to 10% inorganic filler to coPA results not only in insignificant decrease in the strength of the composite material but also in a decrease in MFI (Fig. 4a). With increasing content of inorganic filler to 60%, MFI increases significantly, which confirms the plasticizing effect of the fertilizer in the system. Then, MFI decreases, which is caused by saturation of the system with the filler, attainment of the filling limit, and decrease in the content of the thermoplastic component.

The revealed effect is governed by the total effect of components of the inorganic filler on the composite viscosity. Elucidation of this phenomenon is an important and sophisticated problem. Therefore, to understand the causes of extremal increase in the fluidity of systems filled with fertilizers, we filled the polymer with individual components of the complex mineral fertilizer. Filling was performed to a degree of 1–2%, taking into account that an increase in MFI was observed even at a fertilizer content of 25–30% (Fig. 4a) and the content of individual components in

MFI at various concentrations of salts

Sample	MFI, g (10 min)$^{-1}$, at indicated salt concentration, wt %	
	1	2
SEVA* + $MgCl_2$	7.5	7.1
SEVA + KCl	6.7	6.3
SEVA + P_2O_5	8.1	7.1
SEVA + KNO_3	2.9	Not determined because of
SEVA + NH_4NO_3	4.3	extremely high outflow rate

* MFI_{SEVA} = 7.8 g (10 min)$^{-1}$ (T_{test} 130°C).

complex fertilizer Rastvorin A was 5–15%. We added KCl, $MgCl_2$, P_2O_5, NH_4NO_3, and KNO_3 and found that specifically nitrogen-containing substances cause a significant decrease in MFI of the synthetic polymers (see table).

Addition of insignificant amounts of wastes from grain production increases the system viscosity, and on addition of 50 wt % of wastes the system practically loses the fluidity (Fig. 4b). The results obtained are typical for filled and highly filled systems in the absence of interaction between the filler and polymer matrix.

CONCLUSIONS

(1) Physicomechanical characteristics of polymer composites with inorganic filler depend on the kind of the polymer matrix: for SEVA, irrespective of its brand, and Lenteks A4, an increase in the fertilizer content results in a decrease in the ultimate tensile strength, and for the matrix based on coPA, in an increase in the strength by a factor of more than 2; for all polymer types, addition of the inorganic filler results in a decrease in the viscosity of the system.

(2) For all types of polymers, addition of the organic filler results in formation of a rigid system. In the case of using coPA and Lenteks A4 as a polymer matrix, the ultimate tensile strength increases.

(3) The order of addition of fillers into the system is of some importance for obtaining highly filled composites: first, highly filled two-component system polymer–fertilizer with the minimal viscosity should be prepared and then the organic filler should be added. In this case, the ternary system is homogeneous and compatible.

Abstract—Correlations between physicochemical properties and chromatographic retention parameters of adamantane derivatives were studied. The Kovats indices and contributions of hydrocarbon radicals and functional groups to the chromatographic retention were calculated from the experimental data.

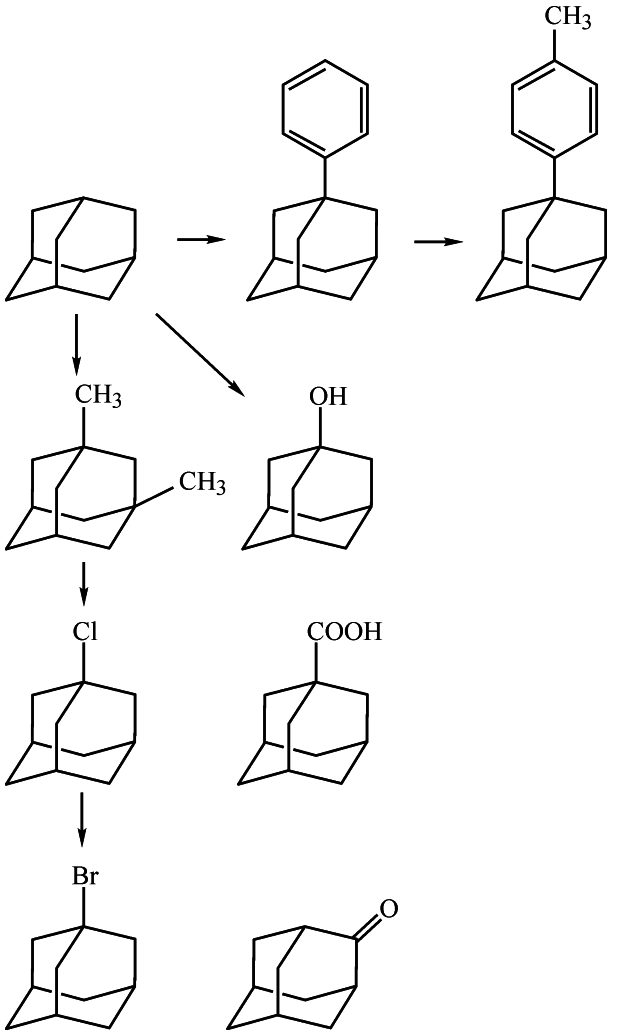
One of urgent problems of the modern chemistry is revealing quantitative relationships between the structures and physicochemical properties of compounds. This problem is solved within the framework of QSPR (Quantitative Structure–Property Relationships) studies [1]. One of promising lines in these studies is based on the use of chromatography as a powerful tool of organic chemistry used primarily for separating mixtures. Chromatography also finds increasing use as a method of structural analysis. The most widely used for this purpose is adsorption chromatography (chromatoscopy, according to A.V. Kiselev [2]), because it is commonly believed that, among macroscopic properties of molecular systems, adsorption on a uniform flat surface of an adsorbent at low fillings is the most strongly dependent on the geometric structure of molecules. Therefore, the QSRR (Quantitative Structure–Retention Relationships) approach is considered as a part of QSPR [1].

To reveal a correlation between the structure and chromatographic retention of organic molecules, it is necessary to understand what kinds of intermolecular interactions are characteristic of the given kind of molecules. It is assumed that the structure–property relationship for organic compounds is determined by the system of intermolecular interactions which, in turn, is governed by the energy of intermolecular bonds, internal rotation barriers of particular atomic groups, molecular symmetry, etc. [2]. At present, the problem of revealing correlations between the structure and chromatographic retention of organic compounds can be considered as solved for particular cases of homologous series [3]. The structure–retention relationships for wider taxonomic groups such as, e.g., structural analogs are studied to a lesser extent [4–6].

As investigation objects we chose structural analogs of adamantane, in view of the steadily growing interest in these derivatives. Data are available on the chromatographic behavior of alkyl, amino, hydroxy, and some other derivatives of adamantane [7–9]. Data on properties of adamantane-containing sorbents and stationary phases are virtually lacking. At the same time, it was shown that such sorbents can be efficient tools in studies of molecular structures of sorbates and intermolecular interactions [10, 11].

In construction of structure–chromatographic retention correlations for wide taxonomic groups, an effective approach is theoretical replacement of complex functional groups or structural fragments by simpler groups or vice versa. Therefore, the sample for revealing correlations includes either a large number of compounds with diverse structures or, on the contrary, a small number of structurally related compounds [9]. Previously [12, 13] we studied alkyl derivatives of adamantane and substances constituting a wide taxonomic group of cyclic compounds.

In this study we examined the chromatographic behavior of adamantane functional derivatives of various chemical nature on adamantylsilicone stationary phase.



EXPERIMENTAL

We used capillary chromatography with flow splitting. The experiment was performed with a Tsvet-100 chromatograph equipped with a flame-ionization

1070-4272/05/7809-1498 © 2005 Pleiades Publishing, Inc.

detector. The column temperature was 160°C, and the vaporizer temperature, 200°C. The carrier gas was nitrogen; the flow splitting ratio at the column inlet was 1 : 60. A 22 m × 0.22 mm capillary column was coated with cross-linked adamantylsilicone (film thickness d_f = 0.2 μm). The chromatographic properties of the adamantylsilicone stationary phase were reported previously [11].

As investigation objects we chose the compounds shown below.[1] The purity of the compounds was confirmed by elemental analysis and by IR and NMR spectroscopy.

To determine the relationships in the chromatographic retention within wide taxonomic groups, we also used the previously obtained characteristics of the chromatographic retention of some carbo- and heterocycles [13].

The retention indices (RIs) were calculated by the Kovats formula [3]. The RIs were reproducible within the limits of 1–2 units.

The differential molar free energy of sorption ΔG was calculated by the formula $\Delta G = -RT\ln k\beta$, where k is the retention factor, and β, phase ratio [14].

The experimental indices I averaged over 7–10 values and the quantites ΔG are given in the table.

Quantum-chemical calculations were performed with HyperChem program package, version 6.0, by AM1 and PM3 semiempirical methods and MM+ molecular mechanics method. The calculated molar volumes V and polarizabilities α of the compounds are given in the table.

The main principle of using physicochemical methods for determining the molecular structure is proof of the presence (or absence) of certain fragments, i.e., group identification, with different levels of detailing the structural features of a compound. This approach is largely based on the concept that the properties of organic substances are additive and the CH_2 group gives a constant increment in estimation of a physicochemical property. In determination of the chromatographic parameters, the additive schemes and their elements are primarily represented in the so-called homomorphism factors and other related criteria [3]. The use of chromatographic retention parameters is quite justified in this case, because the decisive factor in determining the structure of a compound from the chromatographic data is that variations of the thermodynamic characteristic of the sorption should be adequate to structural changes in the sorbate molecules.

The chromatographic retention is governed by three major factors: nature of the chromatographic system (mobile and stationary phases between which the sorbate molecules are distributed), chromatographic conditions, and molecular structure of the sorbate [3]. The properties of the adamantylsilicone stationary phase used in this study were described previously [11]. It was shown that adamantylsilicone is fairly selective in separation of structural isomers.

For structural analogs of adamantane, we observed regular, on the whole, variation of the retention characteristics in going from cyclanes to aromatic compounds, from carbocycles to heterocycles, and from mono- to polycyclic analogs [13].

Since the adamantane molecule is highly symmetrical with an extremely small external surface area

[1] The adamantane derivatives were prepared at the Chair of Organic Chemistry, Samara State Technical University and submitted by Prof. Moiseev.

and weak intermolecular interactions in the crystal lattice, introduction of various substituents decreases the molecular symmetry and affects the physicochemical characteristics, including the chromatographic retention [7]. In this case, simple additive schemes assuming the constancy of increments for a given kind of atoms are unsuitable because of the mutual influence of the atoms (or bonds between them).

The contribution of substituents to the retention indices depends on their structure and position in the molecule. Substituents strongly affect the electron density distribution in the molecule. This effect is not uniform usually; it is transferred by several mechanisms depending on the properties of the substituent itself and on the type of the reaction center, molecular core, and even surrounding (temperature, pressure). The effect of a substituent can correspond to the sum of several effects. Therefore, in complex molecular systems, additive schemes used for determining the retention characteristics should take into account various intramolecular effects associated with the nature and position of the substituent. For example, it is known that substituents at the bridgehead carbon atoms in the adamantane molecule make a considerably lower contribution to the retention than the same substituents at the bridging carbon atoms, because of the so-called "cage effect" (overlap of the rear sides of the atomic orbitals of the tertiary carbon atoms in the adamantane framework).

The table shows that the order of elution of the examined adamantane derivatives on the nonpolar adamantanylsilicone phase corresponds to the order of increasing molecular size. It is known [3] that such an elution order is characteristic of systems in which the intermolecular interactions between the sorbate and stationary phase are determined by dispersion forces. These forces, in turn, are determined by the molecular polarizability, which increases with the molecular size. Comparison of the retention data for adamantane derivatives and other cyclic compounds shows that, in aromatic and cyclic hydrocarbons, the main fragment determining the chromatographic retention is the benzene (or other) ring. Therefore, as seen from Figs. 1 and 2, for adamantane analogs of different structures the retention characteristics vary in parallel with the molecular volume and polarizability.

At the same time, it is known that specific interactions make a certain contribution to interaction of silicone stationary phases with compounds containing elements with lone electron pairs [14]. This fact may be responsible for differences in the retention characteristics of some sorbates with similar molecular weight, despite the nonpolar character of adamantylsilicone:

$I_{Ad-R} = 1171$, $M = 164$ | $I_{Ad-R} = 1268$, $M = 152$ | $I_{Ad-R} = 1332$, $M = 150$

Therefore, points corresponding to compounds with similar electronic structure (e.g., compounds containing several aromatic or saturated rings) are arranged in separate areas of the plots (Figs. 1, 2), exhibiting additional relationships within the general trend.

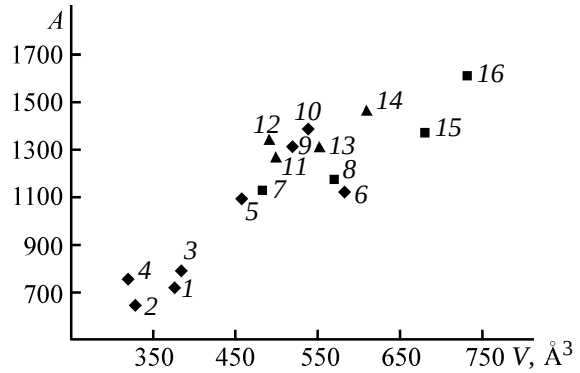

Fig. 1. Kovats indices *A* vs. molecular volumes *V*. (*1*) Cyclohexane, (*2*) benzene, (*3*) toluene, (*4*) pyridine, (*5*) naphthalene, (*6*) anthracene, (*7*) adamantane, (*8*) 1,3-dimethyladamantane, (*9*) 1-chloroadamantane, (*10*) 1-bromoadamantane, (*11*) adamantan-1-ol, (*12*) adamantanone, (*13*) adamantanecarboxylic acid, (*14*) acetyladamantane, (*15*) phenyladamantane, and (*16*) tolyladamantane; stationary phase adamantylsilicone; the same for Figs. 2 and 3.

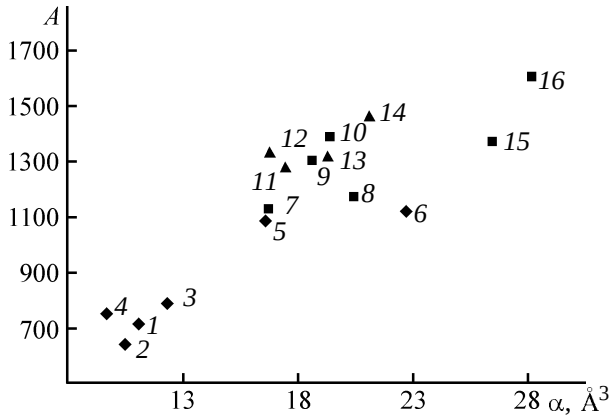

Fig. 2. Kovats indices *A* vs. molecular polarizabilities α.

On the whole, the retention characteristics of the examined compounds on adamantylsilicone are somewhat lower than on Apiezon L (ApL), which may be due to the steric effect of the adamantane core incorporated into the stationary phase.

Phenyl- and tolyladamantane having the largest molecular volume have also the largest retention indices. At the same time, the contribution of the phenyl (241) and tolyl (472) substituents to the retention of these compounds by adamantylsilicone in considerably lower than the retention indices of benzene (649) and toluene (796) molecules. This fact may be caused both by participation of the substituents in realization of the cage effect and by steric hindrance to interaction with the stationary phase.

The chromatographic retention of alkyladamantanes on stationary phases of various polarities was described in detail in [9]. It was showsn that the contribution of methyl radicals $\delta I(CH_3)$ in 1,3-dimethyladamantane is not additive because of their participation in realization of the cage effect and is as low as 31 units, whereas for *n*-alkanes this value is 100 units [3]. With the adamantylsilicone stationary phase, $\Delta I(CH_3)$ is 48 units. The suggested mechanism of the interaction of 1,3-dimethyladamantane with the stationary phase (with realization of the cage effect) is also confirmed by the fact that the retention index of this compound is considerably lower than it could be expected from its molecular volume.

It was determined previously [15] that, in going from adamantane to 1-fluoro-, 1-chloro-, and 1-bromoadamantane the retention index on nonpolar stationary phases increases by 100, 200, and 600 units, respectively [15]. This trend was attributed to an increase in the contribution of the induction interaction due to higher polarizability of the bromine atom compared to chlorine and fluorine. The contribution of the halogen to the retention is approximately the same as for haloalkanes on Apiezon L. On adamantylsilicone, the contribution of the Cl and Br atoms is 177 and 263 units, respectively. A significant decrease in the contribution of the Br atom on the adamantylsilicone stationary phase, compared to Apiezon L, is also attributable to steric hindrance caused by the presence of bulky adamantane fragments in both the sorbate and stationary phase.

It is known that ΔG is a quantitative characteristic of the structural and sorption properties of a substance being chromatographed and of the energy of its interaction with the stationary phase at a given temperature. The decisive factor in determining the structure of a compound from the chromatographic data is that variation of the thermodynamic characteristics of the sorption should be adequate to variation of the structure of the sorbate molecule. The differential molar free energy of sorption varies depending on the length of the alkyl chain and on the molecular structure as a whole. In many cases, the increment $\Delta G(CH_2)$ (with ΔH and ΔS, the pattern is similar) on certain sorbents is not constant within a homologous series. In such cases, ΔG does not always linearly correlate with the retention index. On the whole, if the dispersion component prevails in interactions between the sorbate and stationary phase, the free energy of sorption (and hence the retention characteristics) varies in parallel with the molecular weight [16]. Figure 3 shows that there is a good correlation between the retention indices of the examined compounds on adamantylsilicone and free energies of their sorption, indicating that ΔG in this series is an additive quantity.

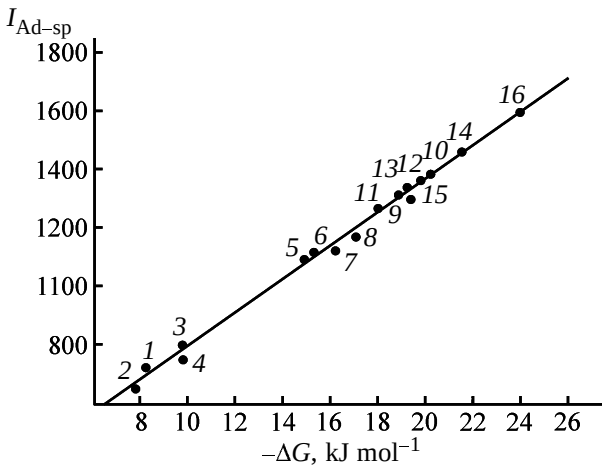

Fig. 3. Correlation between the Kovats indices I_{Ad-sp} and ΔG.

Thus, the chromatographic behavior of adamantane derivatives under the conditions of gas–liquid chromatography is determined by several factors. First, irrespective of the substituent at the adamantane core, the bulky adamantane fragment makes a major contribution to the retention on both polar and nonpolar stationary phases [9, 15]. Substituents cause redistribution of the electron density in the adamantane framework and correspondingly alter the retention characteristics. The contributions of substituents and functional groups to the retention on adamantylsilicone are somewhat smaller than on Apiezon L, which may be due to steric hindrance produced by the adamantane fragment of the stationary phase.

The relationships revealed can be used for predicting the retention and other physicochemical characteristics of adamantane derivatives and for developing identification procedures.

CONCLUSIONS

(1) Substituents cause redistribution of the electron density in the adamantane framework and the corresponding changes in the retention indices on the adamantylsilicone stationary phase.

(2) The steric hindrance produced by the adamantane core in the adamantylsilicone stationary phase causes a decrease, relative to Apiezon L, in the retention indices of adamantane derivatives.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of Copper on Oxidation of Polyethylene Containing Antioxidants

D. G. Lin, E. V. Vorob'eva, and N. V. Marchenko

Skorina Gomel State University, Gomel, Belarus

Received May 3, 2005

Abstract—Thermal oxidation of polyethylene containing amine and phenolic antioxidants during contact with copper (metal support, powder) and the trends in variation of the antioxidant performance were studied.

Oxidation of noninhibited polyethylene (PE) in contact with catalytically active metals (including copper) is accompanied by dissolution of the metal support and transfer of the metal into the polymer bulk [1–3]. It was shown in [1–5] that noticeable metal transfer starts since the end of the induction period of polymer oxidation (IPO) (the IPO duration was estimated from the content of carbonyl groups in PE). Egorenkov [6] confirmed the carboxylate mechanism of the metal transfer suggested in [7–9]. The absorption bands characteristic of metal salts of fatty acids were found in the range 1500–1650 cm^{-1} in the IR spectra of PE films containing the transferred metal. Egorenkov [6] also confirmed the existence of two types of carboxylates (anhydrous and hydrated) in PE. It follows from [10] that, in the course of contact oxidation of PE on a copper support, the most probable scheme of metal transfer is diffusion in PE of low-molecular-weight metal carboxylates (which are products of contact reactions).

The transferred metal compounds affect the development of redox transformations in PE. For instance, the copper compounds taken in small concentrations catalyze PE oxidation, but at higher concentrations they, on the contrary, inhibit it. Similarly, copper(II) stearate affects oxidation of noninhibited PE [11]. Therefore, it was suggested to consider the catalysis of PE oxidation on copper supports as homogeneous, effected by the transferred copper-containing compounds, the more so as, in the course of contact oxidation of PE on a copper support, IPO practically coincides with the time after which the metal transfer into the PE film becomes noticeable.

An antioxidant (AO) introduced into PE increases the IPO. Data on the influence of catalytically active metals and their compounds on the oxidation of inhibited PE are fragmentary [12–14]. It was shown in [13] that IPO becomes shorter when PE containing a phenolic AO contacts with copper, i.e., the AO becomes less effective. In the case of PE inhibited with amine AO Neozon D, contact with copper, on the contrary, increases the IPO [14]. We suggested that, upon contact with copper, the amine AO transforms into a product with a higher inhibiting power. However, it remained unclear why the performance of the phenolic AO drastically decreases in the presence of copper [13]. It is of interest to determine how transformations of AO (phenolic or amine) are connected with the copper transfer into the polymer being oxidized. This was the subject of our study.

EXPERIMENTAL

We used unstabilized, high-density PE prepared at low pressure on complex organometallic catalysts [GOST (State Standard) 16338–85, base trade mark 20308-005]. Amine (Neozon D, *N*-phenyl-2-naphtylamine, GOST 39–79) and phenolic (Irganox 1010, pentaerythriol ester of 4-hydroxy-3,5-di-*tert*-butylphenylpropionic acid) AO were taken as inhibitors. To prepare compositions with PE, an AO powder was dissolved in acetone (GOST 2603–79), and the solution was stirred on a magnetic stirrer for 3 min. The AOs were introduced by wetting of a PE powder with an AO solution, followed by solvent evaporation at room temperature. For certain samples of inhibited PE, we used fillers: a copper powder (trade mark M1), which was introduced into the polymer by mechanical mixing, or copper(II) stearate [TU (Technical Specifications) 6-09-12-152–75] introduced similarly to AO through the solvent. From PE blends with AO and other modifiers, we prepared films (100 μm) by hot pressing (150°C, 30 s) and used them in the study.

1070-4272/05/7809-1503© 2005 Pleiades Publishing, Inc.

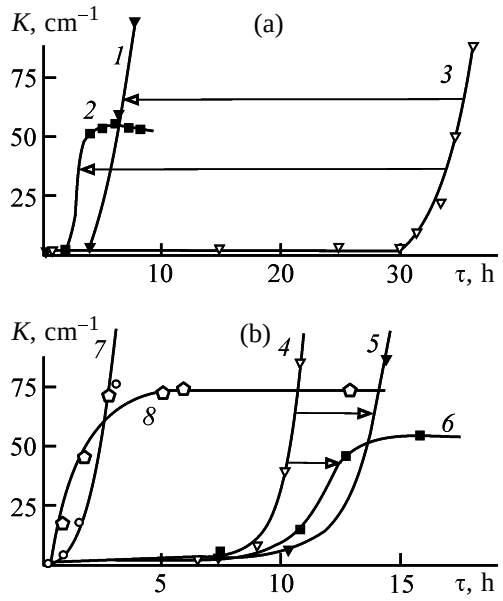

Fig. 1. Extinction index K of the absorption band at 1720 cm^{-1} in the IR spectra of PE films containing 0.1 wt % (a) Irganox 1010 and (b, curves *4–6*) Neozon D as a function of the time of their oxidation τ on (*1, 5, 8*) copper and (*2–4, 6, 7*) KBr supports. Oxidation temperature 150°C. (*2, 6*) Films contain 10 wt% copper powder.

The films were placed on a preliminarily purified copper (trade mark M1) foil. Simultaneously, these films were tested on inert supports (KBr plates).

The samples prepared were oxidized in air at 150°C in ovens. The degree of PE oxidation and the content of the transferred copper in PE were estimated.

The degree of PE oxidation was estimated from the IR spectra; the film was separated from the support when oxidation was performed on a copper foil and was not separated when the oxidation proceeded on a KBr plate transparent in the IR range. The IR spectra were recorded on an IR-75 double-beam spectrophotometer (Carl Zeiss, Jena) at 160 $cm^{-1}\,min^{-1}$ scanning speed. The extent of PE oxidation was evaluated by the extinction index (ratio of the optical density to the film thickness, cm) of the absorption band at 1720 cm^{-1} in the IR spectrum of the film. The band at 1460 cm^{-1} was used as an internal reference in determination of the optical density. The IPO duration we determined from the kinetic curves of carbonyl group accumulation; the IPO was considered to end when the extinction index reached 3–4 cm^{-1}.

The amount of the copper transferred into the PE film during the contact thermal treatment was determined by polarographic analysis [17]. To prepare working solutions for polarography, we used ash residue formed by two-step thermal treatment of the polymeric film [18] in an IR-20 muffle furnace [TU (Technical Specifications) 16-531.704–81]. The ash formed was dissolved in a supporting electrolyte (hydrochloric acid) prepared from reference solutions (TU 6-09-3780–74) using double-distilled water. The solutions were tested on a PU-1 device equipped with a mercury drop electrode; the metal content in the solution was determined with calibration graphs.

The data on oxidation of PE films inhibited with phenolic (Irganox 1010) and amine (Neozon D) AOs on the inert (KBr) and active (copper) supports are shown in Fig. 1. For comparison, the data on oxidation of noninhibited PE are also demonstrated. Noninhibited PE was oxidized on the inert support with a short (approximately 1 h) induction period, after which intense accumulation of oxygen-containing groups was observed (Fig. 1, curve *7*). The IPO decreased to several minutes when noninhibited PE was oxidized on the copper support (Fig. 1, curve *8*, initial portion). This is due to the catalytic effect of the metal compounds transferred. Then, after a time, the catalysis of PE oxidation on the copper support gives way to the inhibition due to accumulation of the critical amount of organometallic compounds, and the kinetic curve of the extinction index flattens out (Fig. 1, curve *8*, final portion).

Antioxidants (Neozon D, Irganox 1010) introduced into PE increase the stability of the polymer with respect to oxidation, and IPO increases (Fig. 1, curves *3*, *4*). At the same AO concentration (0.1 wt %), IPO increases to 8 (Neozon D) and 30 h (Irganox 1010). However, when the inhibited PO is oxidized on the copper support, the effects are opposite. Figure 1 shows that, for PE inhibited with Irganox 1010, IPO decreases from 30 to 4 h (curves *1, 3*), whereas for PE inhibited with Neozon D IPO increases from 8 to 11 h (curves *4, 5*). A similar pattern is observed for PE films filled with copper powder (10 wt %) (Fig. 1, curves *3, 2* and *4, 6*). In other words, the contact of inhibited PE with copper decreases the performance of phenolic AO, but increases the performance of the amine AO.

Let us consider the data on copper transfer into the inhibited PE heated on a copper support (Fig. 2, curves *2, 4*). Depending on AO type, the character of the kinetic curves of the metal accumulation in the film bulk differs in principle. With phenolic AO, the metal traces and metal transfer into the film are detected even during IPO (Fig. 2, curves *3, 4*). In the process, a well-defined absorption band at 1580–1620 cm^{-1} belonging to copper-containing com-

pounds appears in the IR spectrum of the polymer. By the end of IPO, the copper concentration in the polymer amounts to approximately 0.1 wt % according to polarography, which is fairly high metal concentration. In PE inhibited with Neozon D, there is no copper transfer during IPO. In this case, the metal and its complexes are detected in the PE film only when carbonyl-containing products of polymer oxidation appear. Therefore, we may conclude that, at the contact treatment of PE inhibited with amine AO, the IPO coincides with the induction period of the metal transfer.

The above features of copper transfer show that, at the contact oxidation of the inhibited PE, amine and phenolic AOs undergo different chemical transformations. As mentioned above, in the case of PE containing phenolic AO, the copper compounds are detected in the bulk of the polymer film before the appearance of the carbonyl-containing oxidation products. This fact means that, during the heat treatment, the redox transformations of the polymer with formation of organometallic compounds proceed in the copper-inhibited PE contact zone. These transformations cannot be monitored by transmission IR spectroscopy, since they proceed in a very fine boundary layer. The copper-containing compounds formed are transferred from the contact zone into the film bulk and catalyze there redox transformations. Since PE contains AO, the catalyzed process is terminated in the initial step, formation of the primary radicals. The phenolic AO is transferred into the zone containing the catalyst and deactivates the radicals formed. Such a mechanism of the AO consumption was described by Shlyapnikov *et al*. [19, 20]. They showed that, when oxidation zones are artificially organized in an inhibited polymer (e.g., by introducing oxidation catalysts), AO diffuses into these zones and is intensively consumed there. Similar process is observed in our case. As mentioned above, the copper-containing compounds diffuse into the film bulk from the contact zone and initiate formation of radical oxidation products. AO also migrates to this region from the whole film volume up to complete consumption. In this step of oxidation, the accumulation of copper-containing compounds and AO consumption proceed simultaneously. After AO consumption, IPO is ended, and the oxidation becomes autocatalytic. As a result, stable oxidation products (including carbonyl-containing compounds) are accumulated and may be monitored in the film.

Thus, the transfer of copper-containing compounds during IPO should accelerate the consumption of the phenolic AO in the whole film volume and, as a result, shorten IPO. To check this conclusion, we introduced into PE containing Irganox 1010 copper(II) stearate, which, as known [1, 11], is an analog of copper-containing compounds formed by the contact oxidation. In other words, we simulated accumulation of copper-containing compounds in the PE film in the step of IPO.

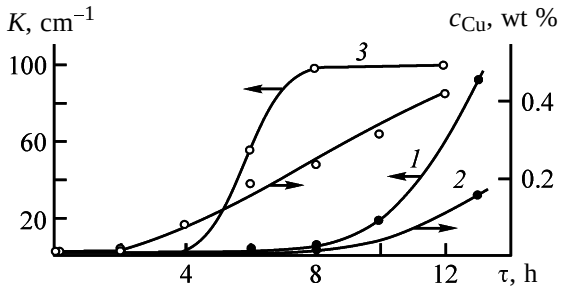

Fig. 2. (*1, 3*) Extinction index K of the absorption band at 1720 cm^{-1} in the IR spectra of PE films and (*2, 4*) concentration of the copper transferred into the film c_{Cu} as functions of the time of their oxidation τ at 150°C on the copper support. PE contains 0.1 wt % of (*1, 2*) Neozon G and (*3, 4*) Irganox 1010.

The concentration of copper introduced as copper(II) stearate was 0.05–0.4 wt %, i.e., this range covered the copper concentration accumulated in the film by the end of IPO (0.1 wt %).

The data on oxidation of PE inhibited with Irganox 1010 and containing various amounts of copper(II) stearate are shown in Fig. 3. As seen, copper(II) stearate catalyzes oxidation, since the IPO shortens, especially at 0.05 wt % copper (Fig. 3, curves *1, 2*). At higher copper concentrations, IPO increases, but remains shorter than IPO of the inhibited PE containing no copper(II) stearate (Fig. 3, curves *1, 5*). The data obtained undoubtedly indicate that the copper transfer into the PE bulk shortens IPO of the polymer. In turn, the IPO shortening is caused by accelerated consumption of AO during deactivation of the primary radicals whose formation is initiated by the copper compounds.

Oxidation of PE containing amine AO. It was mentioned above that, in oxidation of PE inhibited with amine AO, contact of the polymer with copper increases IPO. In the process, copper-containing compounds are not transferred into the polymer bulk during IPO (Fig. 2, curve *2*). Thus, in contrast to phenolic AO, amine AO suppresses the copper transfer into the film of the yet intact inhibited PE.

Presumably, in inhibition of PE oxidation with amine AO, the AO interaction with the copper support

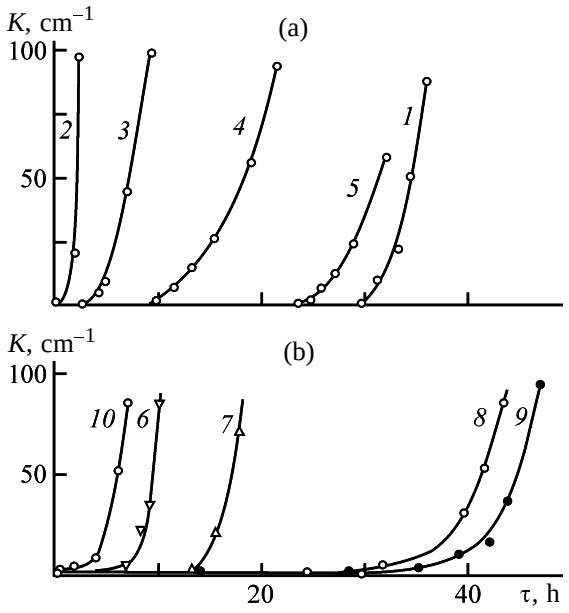

Fig. 3. Extinction index K of the absorption band at 1720 cm^{-1} in the IR spectra of PE films (a) containing 0.1 wt % Irganox 1010 and (*1*) 0, (*2*) 0.05, (*3*) 0.1, (*4*) 0.2, and (*5*) 0.4 wt % copper in form of copper(II) stearate as a function of the time of their oxidation τ at 150°C on KBr support, and (b) containing (*6*, *10*) initial Neozon D, (*7*) Neozon D thermally modified on copper support, (*10*) copper(II) stearate (0.111 wt %), and (*8*, *9*) thermally modified mixtures of copper(II) stearate and Neozon D as a function of the time of oxidation τ of the films at 150°C on (*6*) copper and (*7*–*10*) KBr supports. $(C_{17}H_{35}COO)_2Cu : C_{16}H_{12}NH$ (mol : mol): (*8*) 1 : 24 and (*9*) 1 : 246. (*2*) Heat treatment of blends and AO on the support for 10 h at 150°C; concentration of AO in the polymer 0.1 wt %.

or with copper-containing compounds is the main process, and it is localized in the contact zone. This reaction yields a new compound which is a more effective inhibitor as compared to the initial AO. This product of AO reaction with copper (or copper compounds) should be transferred back into the PE film and provide more efficient protection of the polymer against oxidation.

To check formation of this new compound, we performed the following experiment. A thin layer (approximately 1 mm) of Neozon D was placed on a copper support and heated at 150°C for 10 h in air. Then, the thus treated Neozon D (0.1 wt %) was introduced into the PE, and its inhibiting power was estimated from IPO (KBr support). We found that the thermal treatment substantially enhances the Neozon D inhibiting power: IPO increases by a factor of more than 2 (Fig. 3, curves *6*, *7*). The heat treatment of AO placed on the inert support (e.g., aluminum) does not change the AO properties: IPO of PE films containing such AO is approximately the same as IPO of films containing unmodified Neozon D.

A similar experiment was performed with two mixtures of AO with copper(II) stearate, in which the molar ratio of Neozon D to copper(II) stearate was 24 : 1 (blend A) and 242 : 1 (blend B), with the copper concentration of 1.0 and 0.1 wt %, respectively. In these mixtures, Neozon D was taken in a large excess relative to optimal ratio of 2 : 1 for formation of AO complexes with copper(II) stearate.

This statement requires comments. The enhancement of the inhibiting power of amine AO (Neozon D) in the presence of copper(II) stearate was observed previously with liquid hydrocarbons, in particular, *n*-decane [21–23]. Vetchinkina *et al*. [22] suggest two reactions converting AO into a more active product. In the first of them, *N*-phenyl-2-naphtylamine reacts with copper(II) stearate to form copper(I) complexes with the radical $C_{10}H_7N^{\bullet}C_6H_5$ and free stearic acid. In the second reaction, the stearic acid formed binds free AO and forms a salt that is incapable to react with copper(II) stearate. Vetchinkina *et al*. [22, 23] believe that just the copper(I) complexes are the effictive inhibitors that suppress PE oxidation after amine AO consumption. If we assume that in the system being oxidized AO is consumed only for the reaction with copper(II) stearate, in the mixture of Neozon D with copper(II) stearate the components should be taken in 2 : 1 molar ratio. Deviations from this ratio will result in preservation of either free AO or free copper(II) stearate.

After thermal treatment, the mixtures were introduced into PE in amounts corresponding to an AO concentration of 0.1 wt % in the polymer. It was found that the preliminary heat treatment of mixtures A and B substantially enhances the AO inhibiting pover: IPO increases by a factor 5 for A and 6 for B (Fig. 3, curves *8*, *9*). As seen, the inhibiting power of AO increases with a decrease in the copper content in the mixture. In the case of complex formation, we should expect an opposite trend, because increase in the copper concentration should increase the concentration of copper complexes and, as a result, increase IPO. However, this is not the case, i.e., another mechanism, differing from the mechanism acting in liquid low-molecular-weight hydrocarbons, is responsible for increasing inhibiting power of amine AO in the contact with copper and its compounds.

Hence, high performance in PE inhibition with Neozon D in contact with copper is caused by the catalytic influence of copper and its compounds on oxidation of Neozon-D molecules. As a result, stable

nitroxyl radicals are formed:

$$C_{10}H_7\text{–}NH\text{–}C_6H_5 \xrightarrow{Cu} C_{10}H_7\text{–}N^{\bullet}\text{–}C_6H_5$$

$$\xrightarrow{Cu} C_{10}H_7\text{–}NO^{\bullet}\text{–}C_6H_5.$$

These radicals (>NO$^{\bullet}$) repeatedly terminate chains in oxidative transformations of polymers [24]. This process ensures their high performance exceeding that of the initial AO.

CONCLUSION

When PE inhibited with phenolic AO is brought in contact with copper, the metal is actively transferred into the polymer bulk even during IPO. A decrease in the AO performance observed in this case is a result of accelerated consumption of AO for deactivation of free radicals formed in the local regions of the polymer under catalytic action of the transferred copper compounds. On the contrary, in contact with copper, Neozon D becomes more effective. In this case, the copper-containing compounds are actively transferred into the polymer inhibited with amine AO only after the end of IPO. An increase in the inhibiting power of Neozon D is caused by the catalytic effect of copper on AO oxidation.

Abstract—The plasticity of a composite based on epoxy polymer was studied as influenced by the concentration of the filler, nanosized powders containing aggregates of strongly bound ZrO_2 particles.

Composites based on epoxy polymers (EPs) are widely used as building and functional materials. The operation properties of composites can be efficiently controlled either by changing epoxy oligomer–curing agent system or by adding appropriate filler. It is known [1–3] that the properties of these systems are determined by various factors, i.e., nature and concentration of the filler, its morphology, particle size, adhesion power, procedure of addition into the polymer matrix, etc.

Ultradispersed fillers (nanosized particles) allowing formation of composites with unique physicomechanical properties are actively studied today [4–7]. However, preparation of polymeric nanocomposites is a complex procedure, because nanoparticles strongly tend to aggregation. The effect of the resulting aggregates on the properties of epoxy polymers is poorly understood.

In this study we examined the effect of aggregation of zirconium dioxide nanoparticles on the deformation and strength properties of an epoxy composite used for preparing thermally shrinkable adapter fittings [8, 9]. These fittings are used to obtain strong and hermetically sealed adhesive joints of tubes and rods of various, even dissimilar, materials [9, 11].

EXPERIMENTAL

As polymeric matrices we used the epoxy compound containing diglycidyl ester (DGE) of hydrophthalic acid, block oligomer (BO) of aliphatic epoxy resin and acidic oligoester, epoxy–diphenylolpropane resin (ED) with molecular weight of 390–430, *iso*-methyltetrahydrophthalic anhydride (IMTHPA), and tris(dimethylaminomethyl)phenol (TDAP) [8] with the following component ratio, weight fraction: 77.5 DGE, 20 BO, 2.5 ED, 68 IMTHPA, and 0.7 TDAP.

The filler powders were prepared by precipitation from zirconium oxychloride solutions: no. 1, from chemical reagents in laboratory; no. 2, from industrial intermediate product (hydroxide) with subsequent treatment in laboratory; and no. 3 was commercial product. The filler concentration was varied from 0 to 30 wt % (with EP content taken as 100%).

The experimental samples were prepared by mixing of the epoxy composite components with ZrO_2 powder in a given ratio at 60–70°C on a mechanical stirrer with subsequent curing in appropriate molds at 120°C for 4 h. Curing was performed with rotation of the molds to prevent sedimentation. Depending on the filler, three types of polymeric composites were obtained.

Thermally shrinkable fittings (couplers) were prepared by rolling of tubular billets. The initial size of fittings was as follows: 20 mm internal diameter d_0, 35 mm height, and 3.5 mm thickness. Curing was carried out in the hyperelastic state with subsequent cooling of the deformed billet on a mandrel to the temperature lower than the glass transition point T_g of the polymer matrix. The degree of deformation was determined from the expression $\varepsilon = (d - d_0)/d$, where d is the mandrel diameter.

In accordance with GOST (State Standard) 11262–80, the tensile strength tests were carried out with 37×5 mm plates with thickness of 2 mm on a tensile-testing machine equipped with a thermal chamber; the rate of a mobile clamp was 10 mm min^{-1}.

The microhardness H_μ was measured using samples cut off from the fittings after thermal shrink-age. The load on the indenter was 5 N; the average H_μ was calculated from 10–15 marks.

Differential scanning calorimetry (DSC) and thermomechanical analysis (TMA) were performed on

1070-4272/05/7809-1508© 2005 Pleiades Publishing, Inc.

a Du Pont 9900 thermomechanical installation using the samples cut off from the fittings; the heating rates were 10 and 5 deg min^{-1} for DSC and TMA procedures, respectively.

The fractional composition and morphology of ZrO_2 powders were studied by transmission electron microscopy (TEM); the samples were prepared by an ultrasonic dispersion procedure developed at the Physicotechnical Institute (Ukrainian National Academy of Sciences, Donetsk, Ukraine). The average size of the coherent scattering areas (CSA) were calculated from the Selyanov–Scherrer equation from the half-width $B_{0.5}$ of the diffraction peaks from the (111) plane. The failure surfaces in the composites were studied on a JEM 200A unit (JEOL) using a two-step replica procedure.

The dependences of the ultimate strain at rolling (without failure of the billet) on the content of ZrO_2, shown in Fig. 1, refer to three types of composites with the filler prepared by three different procedures. In the case of composite no. 1, the dependence ε(c) passes through a maximum at the filler concentration *c* 15–20 wt %. In the case of composite no. 3, there is also a maximum, but the curve starts to ascend only at a filler content higher than 10 wt %, whereas at small concentrations ε is independent of *c*. The behavior of composite no. 2 is essentially different; with increasing ZrO_2 content its ultimate strain decreases.

In all the cases, the tubular billets were broken during their deformation in the hyperelastic state. For comparison, the failure strains of the standard EP samples and composites based on them were measured under similar conditions at 100°C. It was found that the failure strain values correlate with the dependences shown in Fig. 1; for EP it comprised 35%, whereas for composite nos. 1, 2, and 3 (15 wt % filling) it was 50, 30, and 40%, respectively.

As seen from Fig. 1, changes in H_μ largely agree with the results of mechanical tests and data on the ultimate strain of the fittings ε(*c*), though H_μ was measured using the glassy material. In the case of composite no. 2, H_μ slightly increases with increasing filler content, whereas for composite nos. 1 and 3 the dependences pass through a minimum at *c* 15 wt %. Since H_μ is proportional to the yield point σ_T [12], composite nos. 1 and 3 are weakened to the greatest extent at a filler content of 15 wt %, whereas for composite no. 2 σ_T is nearly constant.

The calorimetric data show that the fillers studied are not inert to the polymeric matrix. This is confirmed by differences in glass transition point T_g,

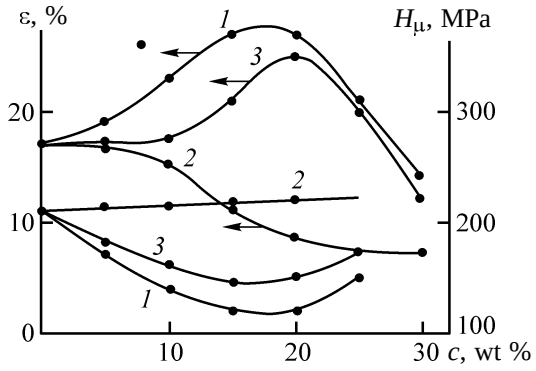

Fig. 1. Ultimate strain of the billet ε and microhardness H_μ as functions of the filler concentration *c*; curve nos. are composite nos.

glass transition width ΔT_g, and heat capacity change ΔC_p (Table 1). Higher values of T_g and ΔC_p for composites as compared to the polymeric matrix suggest a decrease in interstitial distances [13], which is due to the filling of the system with ZrO_2 particles acting as the points of the polymer network in the composite.

The DSC data well agree with TMA results, according to which the filler added to the polymer increases T_g and decreases the deformation changes at temperatures near T_g and the coefficient of thermal expansion in the hyperelastic state, i.e., it decreases the interstitial distances.

The XRD and electron microscopic data showed that ZrO_2 powders prepared under different conditions are characterized by CSA values typical for nanoparticles, but their morphology is different (Table 2).

Table 1. Thermal characteristics of composites based on EP

Composite formulation	T_g, °C	ΔT_g, °C	ΔC_p, J g^{-1} K^{-1}
EP	49	7	0.16
EP + 20% ZrO_2 no. 1	51	13	0.26
EP + 20% ZrO_2 no. 2	51	15	0.27
EP + 20% ZrO_2 no. 3	51	9	0.23

Table 2. Characteristics of the filler evaluated from XRD and TEM data

Filler	Size, nm			
	CSA	particles	aggregates	agglomerates
no. 1	37	40	200	500–1000
no. 2	35	20–40	300	300–2000
no. 3	24	20–100	300	2000–3000

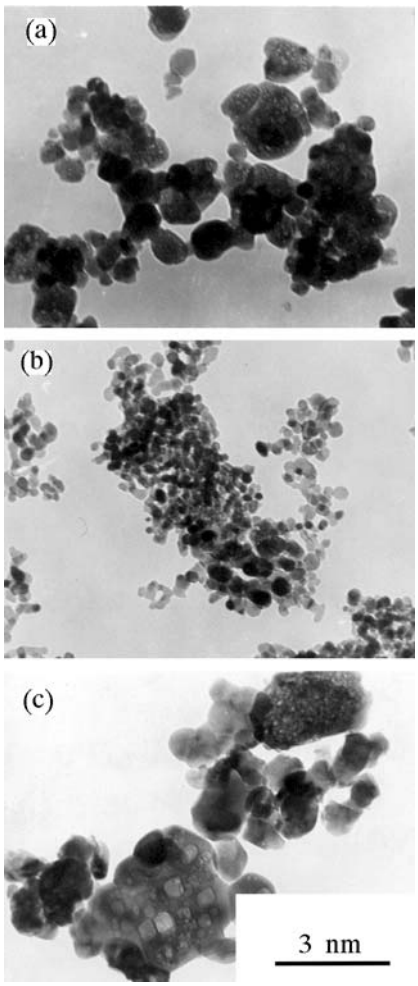

Fig. 2. Fractures of composite nos. (a) 1, (b) 2, and (c) 3 through the areas containing ZrO_2 particle aggregates.

Their features can be evaluated using TEM data on the size of the initial particles, aggregates (groups of initial particles), and agglomerates (groups of aggregates), and on the degree of particle binding in the aggregates. The degree of binding in the aggregates (i.e., aggregate density) can be evaluated from the dispersion of the particles in the electron-microscopic patterns taken after ultrasonic treatment (with power equal for all the samples) for breakdown of the aggregates and agglomerates.

As seen from Fig. 2, the particles in powder nos. 1 and 3 are characterized by strong bonds in the agglomerates and significant amount of pores, which suggests occurrence of the diffusion processes (sintering) in the powder system in the course of its annealing. Porous aggregate usually formed in the initial stages transforms into the polycrystalline particle at high-temperature treatment. In sample no. 2 (Fig. 2b), the interaction in the aggregates is rather weak.

As a rule, additives increase the strength and decrease the plasticity of polymer composites [14, 15]. In some cases, composites retain their plasticity at small charges of the filler [1, 16]. Thus, the increase in the composite plasticity with increasing filler content that we observed is unusual. The decrease in the plasticity of composite no. 2 and its increase in composite nos. 1 and 3 are still more surprising. The DSC, TEM, and XRD data do not provide unambiguous explanation of this difference in the mechanical properties of EPs and composites.

To reveal the other possible reasons of the unusual behavior of the composites under the load, we examined the fracture by electron microscopy. We found that the character of fractures in the samples is different. In composite nos. 1 and 2, the fracture passes through the aggregates (Figs. 2a, 2b). It should be noted that the density of particles in the aggregates of composite no. 1 is significantly greater than that in composite no. 2. In samples of composite no. 3, in which the particle density is comparable with that in composite no. 1, the crack passes through the boundary between the matrix and filler (Fig. 2c).

Analysis of the experimental and published data suggests that in our case the decisive role in the failure and, thus, in plasticity is played by the aggregates and degree of binding of the particles in them, rather than by the adhesion between the filler particles and matrix, as discussed in other papers. It should be noted that the phenomenon concerns nanoparticles. At present, our experimental data allow only qualitative explanation of the facts observed.

In the course of deformation, the structure of aggregates with strongly bound nanoparticles allows their turning and sliding [17], which consumes the energy of the growing crack and thus improves the material elasticity. The amount and distribution of the aggregates on the path of the growing crack are of particular importance. If their amount is small, the crack develops very rapidly, whereas when their amount is large, each aggregate acts as a barrier for the crack, exerting a certain strengthening affect. For example, with increasing content of ZrO_2 the plasticity of composite nos. 1 and 3 first increases and then decreases (Fig. 1). The shift of the maximum in the concentration dependence $\varepsilon(c)$ toward higher concentrations in the case of composite no. 3 is probably due to the fact that its aggregates are coarser, their amount is smaller, and porous ZrO_2 particles form polycrystalline aggregates. Turning and sliding of the particles in the above aggregates are hindered as

compared to composite no. 1; as a result, noticeable decrease in the plasticity is observed at higher concentrations of ZrO_2 as compared to composite no. 1. Owing to weak interaction of the particles in aggregates of composite no. 2, no turning and sliding between them is realized, causing the plasticity to decrease in the entire concentration range of the filler added; and the larger the number of particles in the aggregates, the greater the decrease in the plasticity.

It is known [18] that composites based on EPs may exhibit the plasticization effect, which is due to the selective sorption of components in the uncured polymer–filler system. Its appearance depends on various interrelated factors complicating specific interpretation of our experimental results. However, we can conclude that the complex effect of all the factors examined in this study causes an unusual change in the EP plasticity upon addition of ZrO_2 nanopowders.

CONCLUSIONS

(1) The morphology of aggregates and degree of binding of the filler particles (ZrO_2 nanopowder) strongly affect the deformation-strength characteristics of polymeric composites.

(2) The deformability of composites in the hyperelastic state increases by a factor of 1.5 on adding ZrO_2 nanopowders with significant porosity of aggregates formed by strongly bound primary particles.

(3) The plasticization of the polymeric composite was attributed to turning and sliding of the primary particles in the filler aggregates.

ACKNOWLEDGMENTS

The authors are grateful to G.Ya. Akimov and V.M. Timchenko for ZrO_2 powders and to M.K. Pakter for helpful discussion.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Effect of Active Fillers on Properties of Heat-Resistant Composites

A. V. Ishkov and A. M. Sagalakov

Altai State University, Barnaul, Russia

Received December 6, 2004

Abstract—The effect of active fillers such as titanium nitrides TiN_x, carbides TiC_x, and carbonitrides TiC_xN_y ($0.5 < x$ or $x + y \le 1.0$) on properties of polymeric composites based on thermostable binders PAIS-104, SFP-012 AK-30, and ED-20 is studied.

Active efforts are made today in developing new polymeric composites (PCs) representing both individual macromolecular compounds and polymer blends demonstrating not only additive, but also extraadditive properties [1].

Additives introduced into PCs to modify their physical and mechanical characteristics such as heat resistance, conductivity, strength, and plasticity are mostly referred to as active fillers.

The activity of one or another dispersed filler strongly depends on its specific surface area [1–3], since this characteristic controls the surface-modified fraction of the polymer. Additional contribution to the activity of the filler could be caused by the crystal-chemical defectiveness of its surface.

Introduction of many of the existing active fillers in a polymer matrix allows preparation of materials combining a number of useful performance characteristics. Such fillers are known as multifunctional [4].

Presently, one of the most widely spread techniques for preparation of active compounds is self-propagating high-temperature synthesis (SHS). The SHS technology allows simple and rapid synthesis of various classes of active compounds [5].

As active fillers for PCs, of some interest are inclusion compounds based on *d* elements of Groups IV–VI with nonmetals such as carbon, nitrogen, oxygen, boron, etc. In addition to high refractoriness (2800–3400 K), many of them are characterized by high strength and electrical conductivity. Therefore, their use allows preparation of novel advanced PCs.

In this study we examined the effect of active fillers on the properties of several heat-resistant composites.

EXPERIMENTAL

As multifunctional fillers we examined active Ti compounds with nitrogen and carbon, classified with inclusion phases.

Titanium nitrides TiN_x ($0.5 < x \le 1$) were prepared by the reaction of Ti powder (PTOM grade) with nitrogen gas in an autothermal flow reactor in the SHS mode at a controlled nitrogen consumption. Titanium carbides TiC_x ($0.5 < x \le 1$) were also prepared in the SHS mode by combustion of a mixture of Ti powder (PTK grade) with carbon black (PM-50 grade) under argon. Titanium carbonitrides TiC_xN_y ($x + y \le 1$) were synthesized by combustion of a mixture of Ti powder (PTK) with butadiene–acrylonitrile rubber of various grades under nitrogen. The composition of the products was determined by elemental and X-ray diffraction analyses. For synthesis of composites we used the <100-μm fraction of the active Ti compounds.

As a polymer matrix we used thermosetting polyaminoimide binder PAIS-104, rubber–resin binder SFP-012 AK-30, and epoxy–diphenylolpropane resin ED-20.

PAIS-104 binder (Karbolit Joint-Stock Company, Kemerovo, Russia) [TU (Technical Specifications) 6-05-231-192–79] is a powdered oligomer with a mean molecular weight of $(1–4) \times 10^3$, free amino group content ≤5%, dropping point 103°C, and gelation time 180 s. SFP-012 AK-30 binder was prepared at a pilot plant by combined coagulation of phenol–formaldehyde and rubber (SKN-26) latexes. ED-20 resin [GOST (State Standard) 10587–72] was cured with 2% polyethylenepolyamine (PEPA).

The composites were prepared by hot pressing of

1070-4272/05/7809-1512 © 2005 Pleiades Publishing, Inc.

a mixture of the filler and binder under the desired conditions.

The effects of active fillers on the polymerization of the binders as well as on the properties of the resulting heat-resistant composites were studied with an example of model binary mixtures.

As known, the presence of active fillers influences the parameters of the polymerization of a binder in PCs. For example, the curing of PAIS-104 occurs under heating through addition of free primary or secondary amino groups at the double bonds of the imide rings, which is accompanied by elongation of the chain and formation of a 3D polymer network. Cross-linking of SFP-012 AK-30 rubber–resin binder proceeds through the interaction of the reactive methylene, phenol, and nitrile groups, which is accompanied by liberation of low-molecular-weight by-products. Curing of epoxy–diphenylolpropane resins proceeds through opening of terminal epoxy groups under the action of PEPA with formation of cross-linked structures. Therefore, two former binders are cured through at least two competing processes, while a single reaction is responsible for polymerization of ED-20.

The lack of liberation of low-molecular-weight by-products in curing of PAIS-104 and ED-20 allows formation of compact monolithic structures with these binders, whose characteristics are controlled to a considerable extent by the kinetic parameters of the process. Introduction of the active filler increases the degree of polymerization (DP) of the binder in PCs, as demonstrated by sol–gel analysis and IR spectra.

Table 1 shows data on the degree of polymerization of PAIS-104 in the polymeric composite as influenced by the active filler ($TiC_{0.75}$ and $TiC_{0.5}N_{0.4}$) content.

Comparison of data from Table 1 with those on the conversion of free amino groups of PAIS in the course of polymerization, obtained photometrically upon azo couplingwith β-naphthol, reveals that the polymerization proceeds preferentially via the amino groups with formation of a 3D polymer network (Table 2), i.e., the filler has a specific effect on the process.

It is worth noting that this effect depends on the nature of filler and also on the stoichiometry of the process. Analysis of the rate constants of the competing reactions [polymerization–addition and autopolymerization (1)] in the absence and in the presence of active fillers $TiC_{0.75}$ and $TiC_{0.5}N_{0.4}$ shows that the fraction of structures formed by autopolymerization of dimaleimidodiphenylmethane (DMIDPM) increases

Table 1. Degree of polymerization of PAIS-104 in filled composites

Filler, %	DP		C=C bond conversion, %
	sol–gel analysis	IR spectroscopy	
$TiC_{0.75}$:			
0	77	73	29
50	80	77	42
60	89	86	55
70	91	93	70
80	94	94	75
90	95	94	79
$TiC_{0.5}N_{0.4}$:			
0	78	76	32

$TiC_{0.5}N_{0.4}$	6	16	26	36	44
$TiC_{0.3}N_{0.2}$	14	28	42	50	54

in the polymer:

$$K = \frac{k(\text{–NH})}{k(\text{C=C})}, \quad (1)$$

where k(–NH) is the rate constant of polymerization–addition of DMIDPM and diaminodiphenylmethane (DADPM) and k(C=C), that of autopolymerization of DMIDPM.

The K values for PAIS-104 cured in the absence of a active filler range from 2.3 to 4.0 (for the samples studied K = 3.0). Introduction of $TiC_{0.75}$ decreases K to 1.4 [K was estimated by Eq. (1) from data on conversion of C=C bonds and amino groups (Tables 1

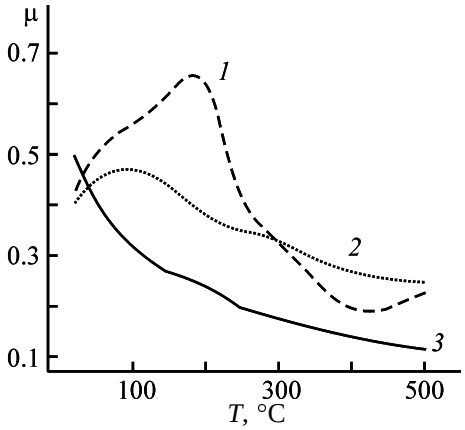

Fig. 1. Dry friction coefficient μ of PCs based on CFP-012 AK-30 as a function of the temperature *T*. Filler: (*1*) 5% $TiC_{0.75}$, (*2*) 5% $TiN_{0.5}$, and (*3*) no active filler.

and 2)]. In the presence of $TiC_{0.5}N_{0.4}$ *K* decreased to 1.3.

The decrease in *K* by more than a half in the presence of active fillers suggests increasing cross-link density and rigidity of the 3D network in the cured polymers.

The increase in the cross-link density in PAIS cured in the presence of active fillers is supported also by TGA data. The heat resistance in air of the resulting composite increases by 45–55°C.

Similar effect of active fillers on the curing of polymers was observed also for SFP-012 AK-30 binder. Figure 1 shows the temperature dependences of the friction coefficient for the model friction material prepared on the basis of the indicated binder and dispersed and fibrous fillers with addition of active fillers in amount of up to 25% of the polymer weight. The results show that, for the materials obtained with the active fillers, the temperature dependence of the friction coefficient passes through a maximum, which is typical of friction materials cured through copolymerization of phenol–formaldehyde resins and nitrile rubbers. The material obtained without active filler is characterized by a regularly declined curve (Fig. 1, curve *3*) typical of other friction materials obtained with resinous binders [6]. Addition of the active binders increases the heat resistance in air of the composite prepared with SFP-012 AK-30 by 65–80°C.

The results obtained in this study on the specific effect of the investigated fillers on the polymerization of thermoreactive binders PAIS-104 and SFP-012 AK-30 in combination with TGA data for the resulting composites clearly show that these compounds are quite suitable as active fillers for the indicated plastics.

Introduction of these compounds into polymeric composites allows directed modification of physicochemical characteristics such as the heat resistance, cross-link density, and conversion of functional groups, and, therefore, performance characteristics of the resulting materials.

Since the investigated fillers are conducting materials characterized by high chemical and heat resistance [4], their use as a component of PCs allows not only modification of the materials, but also preparation of conducting composites.

We examined electrophysical characteristics of some of the PCs prepared in this study. Figure 2 shows the dependence of the conductivity of the material based on ED-20 resin, prepared with addition of nonstoichiometric titanium nitrides, $TiC_{0.5}$ and $TiN_{0.95}$, on the volume fraction of the filler. The curves demonstrate typical S-shaped behavior [7].

The results show that the resistance of PCs regularly decreases with increasing filler content; ρ_v is above unity at low filler contents. On passing to the surface-modified structure of composites, the resistance drops. The second transition is observed at a filler content of about 75% (highly filled composites). Such a behavior suggests formation of ordered structures in the bulk of the composite.

It is known that the formation of ordered structures from the particles of active fillers in polymer matrices can start even at a filler content as low as 5–10 vol % [8]. However, this is realized only for carbonaceous fillers. The metallic powders starts to form structures only when taken in amounts above 50%. In the case of fillers examined in this study, structurization starts at their content of 24–25 vol %. Therefore, they take an intermediate position between carbonaceous and

Table 3. Characteristics of friction composites

Characteristic	Filler-free material	Filler content		
		2.0	3.0	5.0

B	Failed	1.9	1.2	1.9

* Tested up to (A) 500°C and (B) 700°C.

metallic fillers, imparting high conductivity to composites at low content.

At a filler content of 24 vol %, stable conducting structures are formed from its particles coated with a film of the surface-modified polymer and linked to each other through bridging bonds.

Due to the electronic conductivity mechanism in Ti nitride, the overall conductivity of low-filled PCs is a resultant of the intrinsic conductivity of the filler and the conductivity of the thin surface film of the polymer, realized most likely by the tunneling mechanism.

In studying the temperature dependence of the conductivity for the PCs based on PAIS-104, we recognized the self-regulation effect. The materials containing from 50 to 70 wt % of the filler demonstrate nonlinear temperature dependence of the conductivity over the experimental temperature range. In the range 75–85°C, an abrupt increase in the conductivity is observed, which is reproduced in repeated heating–cooling cycles. These samples are characterized by high positive temperature coefficient of the resistance. These results suggest the self-regulation effect in PCs based on PAIS-104 containing from 50 to 70 wt % of active Ti nitrides (Fig. 3).

This can attributed to the fact that, in the heating–cooling cycle, reversible thermal relaxation occurs in the layers of the surface-modified polymer, accompanied by rearrangement of the conducting structures.

In highly filled samples, in the course of curing, the thermal stresses in the polymer dissipate throughout the bulk of the sample, which is reflected in monotonic dependences of the conductivity.

In view of the fact that the investigated fillers affect the polymerization mechanism and characteristics of the polymeric matrix, being also capable of forming ordered structures in the composite even at low content, we examined the effect of the active filler on the mechanical characteristics of the polymeric friction composite based on SFP-012 AK-30 binder and fibrous and mineral fillers.

The results show (Table 3) that addition of the active filler decreases the attrition wear and increases the friction coefficient and bond resistance.

To conclude, reactive compounds such as Ti nitrides, carbides, and carbonitrides show promise as active fillers for polymeric composite materials.

CONCLUSIONS

(1) Active fillers such as titanium nitrides TiN_x, carbides TiC_x, and carbonitrides TiC_xN_y ($0.5 < x$ or $x + y \le 1.0$) influence the polymerization of thermostable binders and properties of the resulting polymeric composites (heat resistance and strength).

(2) In binders cured through polymerization of single-type functional groups, e.g., ED-20, the degree of polymerization increases, while in those cured through reactions involving different functional

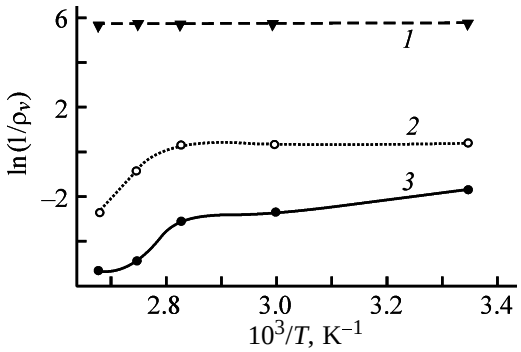

Fig. 3. Conductivity $\ln(1/\rho_v)$ of the PAIS-104-based composites containing (*1*) 90, (*2*) 70, and (*3*) 50 wt % of $TiN_{0.5}$ as a function of the temperature *T*.

groups (PAIS-104, SFP-012 AK-30), the active filler specifically influences the polymerization.

(3) In addition to the effects of reinforcing and increasing heat resistance, the reactive Ti compounds tend to structurization in the polymer matrix, allowing preparation of conducting polymeric composites.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Film-Forming Ability of Solutions Containing Products of Hydrolytic Polycondensation of Tetraethoxysilane

L. F. Chepik, E. P. Troshina, and V. V. Golubkov

Institute of Chemistry of Silicates, Russian Academy of Sciences, St. Petersburg, Russia

Received January 12, 2005

Abstract—Solutions containing products of hydrolytic polycondensation of tetraethoxysilane were studied by viscometry and small-angle X-ray scattering. The growth of polymer particles participating in formation of thin films was studied in relation to the solution composition and process conditions.

Processes with sol–gel transitions of the reaction mass are among the most intensively developed and promising methods of production of oxide materials. Variation of the conditions of sol–gel process opens up wide opportunities for preparation of oxide materials with given structure and characteristics [1–8]. One of the directions of using sol–gel synthesis, preparation of thin films on various surfaces, is based on the ability of oxygen-containing organoelemental compounds like metal alkoxides with the composition $M(OR)_n$ to undergo hydrolytic polycondensation to form polymers with M–O–M bonds. Deep hydrolytic polycondensation of oxygen-containing organoelemental compounds results in transition of a sol to a gel, i.e., in formation of inorganic polymer network structures, which transform to the oxide state on heating.

The hydrolytic polycondensation (HP) of tetraethoxysilane (TEOS) $Si(OC_2H_5)_4$ is used for preparing sols exhibiting film-forming characteristics. Thin silica films prepared from sols containing polymeric products of TEOS HP were used for production of antireflecting and beam-splitting coatings in optics [9] and as multifunctional coatings in microelectronics [10]. The noticeable drawback of these film-forming sols of TEOS is the instability of rheological characteristics. This is manifested in a regular increase in the viscosity of the initial low-viscous sol before its transformation to solid state, gel. The duration of the sol–gel transition and the time of manifestation of film-forming characteristics depend on the reaction conditions of TEOS HP. The increase in viscosity of sols is related to development of TEOS HP in time, and manifestation of film-forming characteristics, to the size of growing polymeric species formed from the initial TEOS. It was shown previously [11] that an increase in the viscosity of film-forming solutions is caused by an increase in the molecular weight of the polysiloxanes formed.

A wide use of sol–gel processes in preparation of oxide materials for industrial purpose stimulated active study of TEOS HP using various physical methods. In so doing, variations of physical characteristics and structure of sols are considered in relation to TEOS HP conditions. Among physical methods of studying sols and gels (^{29}Si NMR, DTA, X-ray fluorescence analysis), small-angle X-ray scattering (SAS) is one of the most informative methods. The use of this method for estimating changes in the size and shape of polymeric structures growing in the course of TEOS HP is described in numerous papers [12–19].

Here we made an attempt to study comprehensively using viscometry and SAS the dynamics of growth of polymer particles, whose presence governs the film-forming ability of TEOS sols in time.

The sols for preparing films were prepared by dissolving TEOS in aqueous alcohol at the molar ratio $TEOS : H_2O = 1 : 5.56$. The homogenizing medium was ethanol. The sol was acidified to pH 1–2.5 with HCl acting as acid catalyst. The amount of HCl (mol per mol of TEOS) in solutions was 5×10^{-4} (solution no. 2), 2×10^{-2} (solution no. 3), 0.14 (solution no. 4), or 0.7 (solution no. 5). In solution no. 1, no HCl was added. Variation of the amount of HCl affected the rate of increase in the solution viscosity and duration of film formation. HP of TEOS was performed at room temperature without stirring. The film-forming ability of TEOS sols was checked by casting of the solution onto plates of semiconductor-grade silicon with rotation on a centrifuge in the horizontal plane. With the expenditure of film-forming solution of

1070-4272/05/7809-1517 © 2005 Pleiades Publishing, Inc.

1–3 ml and the diameter of silicon plates from 70 to 90 mm, the thickness of films was 0.1–0.3 μm (n = 2000 rpm). We obtained a glassy film covering completely the plate, with no visual defects (cracks, fractures, uncovered areas, etc.) and standing thermal treatment at a temperature of 500–900°C without exfoliation from the support surface.

Preparation of oxide materials, including thin silica films, by sol–gel procedure involves TEOS HP. The TEOS HP proceeds in a solution under the action of acid catalyst in organic solvents in two steps:

(1) hydrolysis

$$\equiv Si{-}OC_2H_5 + HOH \xrightarrow{H^+,\ \text{organic medium}} \equiv Si{-}OH + C_2H_5OH;$$

(2) polycondensation

$$\equiv Si{-}OH + HO{-}Si\equiv \rightarrow \equiv Si{-}O{-}Si\equiv + H_2O,$$

$$\equiv Si{-}OC_2H_5 + HO{-}Si\equiv \rightarrow \equiv Si{-}O{-}Si\equiv + C_2H_5OH.$$

Thermal degradation of polyoxisilane results in formation of silica:

$$\equiv Si{-}O{-}Si\equiv \xrightarrow{\Delta} SiO_2.$$

In the course of TEOS HP, the molecular weight of polysiloxanes steadily increases owing to constantly arising siloxane bonds Si–O–Si. The inorganic structural network typical for the gel state is formed in the sol step, and then the sizes of the initial polymer particles increase. They are involved in side branching, cross-linking, and aggregation. The polymeric product of TEOS HP in the gel step is described by the formula

$$[Si(OC_2H_5)_a(OH)_bO_{0.5(4-a-b)}]_n,$$

with possible presence of certain amount of unchanged $-OC_2H_5$ and –OH groups in the final product [20].

The structural evolution of polymeric particles of TEOS sol, considered in relation to the synthesis conditions and aging time, is caused by variation of the sol rheology. Viscometry is one of the methods allowing estimation of the rate of TEOS HP. Here we used a Höppler viscometer with a falling ball rigidly connected to the balance beam.

In the initial step of existence of sol after combining all the components, the solution viscosity is an additive function of the viscosities of the initial substances and is approximately 2–3 cP (1 cP = 0.001 Pa s in the SI system). In this step called "ripening," film formation does not yet occur. With further development of TEOS HP in time, involving formation of polymers of more and more complicated structure up to three-dimensional skeleton of the gel, the solution viscosity increases. During aging of the solution in the range of viscosity from 3 to 7–8 cP, high-quality films can be produced. This period is termed the period of active film formation. At the viscosity above 7–8 cP, the film formation becomes practically impossible, although the solutions remain highly mobile and are far from transition into the gel state. These observations suggest that films can be prepared from sols at a certain size of polymeric products formed in the reactions involving TEOS.

Variation of the sizes of polymer formations in the course of TEOS HP was studied by small-angle X-ray scattering (SAS) on the installation described previously [21]. The SAS curves (dependence of X-ray scattering intensity on scattering angle) were measured at various ages of the solutions. The SAS data were compared with the viscosity data and manifestation of the film-forming characteristics of the solutions. Based on the SAS data, we determined the sizes of heterogeneity areas appearing as a result of development of TEOS HP in time. These sizes were determined in the approximation of scattering by spherical particles having a constant electron density by the Guinier method [22]. In the course of development of sol–gel process both in the initial steps and in the gel step up to its complete consolidation, a branched (fractal) structure is realized. The presence of a fractal structure results in appearance of a section in the SAS curves in which the angular dependence of the SAS intensity I can be presented in the form

$$I(\varphi) \sim \varphi^{-k},$$

where φ is the scattering angle. The parameter k depends on the structure type. For chain structures, k coincides with the fractal parameter (fractal dimension) D and relates the size and weight by

$$M \sim R^D,$$

where M is weight and R is radius.

It is well known that TEOS HP in acidic medium proceeds through formation of small (1.5–1.7 nm) polymer particles [7, 12]. This feature of the sol–gel process is of particular interest in design of materials with fine structure, such as thin-film coatings, mem-

branes, and microporous materials. The presence of these small particles in the sol in the early steps of TEOS HP should not noticeably affect the solution viscosity. Actually, irrespective of the amount of HCl per mole of TEOS, the viscosity of the solutions in this period is approximately 2–3 cP. This is equal to the additive value. The products of TEOS HP with gradually increasing the molecular weight do not noticeably contribute to this value (Fig. 1a). With development of TEOS HP, the viscosity of the solutions increases; in this case, aging of sols becomes dependent on the amount of HCl catalyzing TEOS HP. The variation of viscosity shown in Fig. 1a is restricted by the limiting viscosity equal to 15 cP, which can be measured on a Höppler viscometer with cell no. 0.01. The viscosities above 15 cP were not measured; the sol–gel transition was judged visually from the loss of the solution mobility.

In studying film-forming characteristics of sols, the range of viscosity variation from 2 to 7–8 cP, in which the solutions are able to form films, is of the most interest. The abrupt increase in viscosity for the solution without HCl and its transition to gel in 5 days did not allow us to evaluate the film-forming characteristics of this solution (Figs. 1a and 1b, curve *1*). For the other solutions, the period of film formation varied from 10 to 70 days, depending on the amount of HCl. The longest period of film formation (approximately 70 days) corresponded to the molar ratio HCl : TEOS = 0.03 : 1 (Figs. 1a and 1b, curve *3*). With increasing viscosity of the solutions, the film thickness tends to increase from 0.1 at the beginning of the process to 0.2–0.3 μm by the end of the film formation period. Increasing thickness of film applied from solutions with a viscosity higher than 8 cP makes these films not resistant to thermal treatment: they undergo fracture and exfoliate due to increasing mechanical stress. This period is associated with the loss of the film-forming ability of the sols. The viscometric method correlated with film-forming characteristics is quite reliable in indirect monitoring of TEOS HP and simplest estimation of the working life of the solutions.

The SAS method allows estimation of variations in the size of structural units in the course of TEOS HP, relating these variations to manifestation of the film-forming characteristics. From the X-ray scattering curves, we determined the size of heterogeneity areas appearing as a result of TEOS HP and confirming realization of the fractal structure in the step of the sol–gel transition. In the initial step, the heterogeneity size (radius), evaluated in the approximation of scattering with spherical particles with a constant electron density, is 4–5 Å. This value is close to the size of TEOS molecules entering into the process of chain growth. The variation of the size of polymer formations, obtained from SAS data, is shown in Fig. 2. For

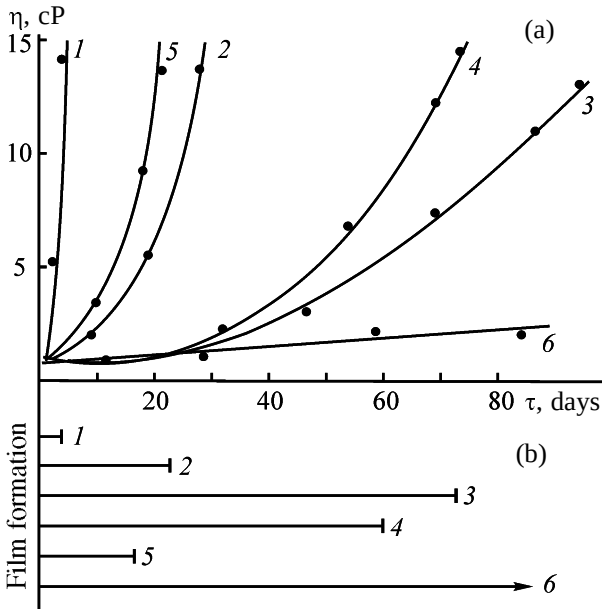

Fig. 1. (a) Variation of viscosity η and (b) film-forming ability of sols with time at various amounts of moles of HCl added. (τ) Process time. (*1*) Without acid; HCl content, mole per mole TEOS: (*2*) 0.0005, (*3*) 0.03, (*4*) 0.14, (*5*) 0.7, and (*6*) 0.7 (TEOS : TMEOS = 7 : 1 by volume); the same for Fig. 2.

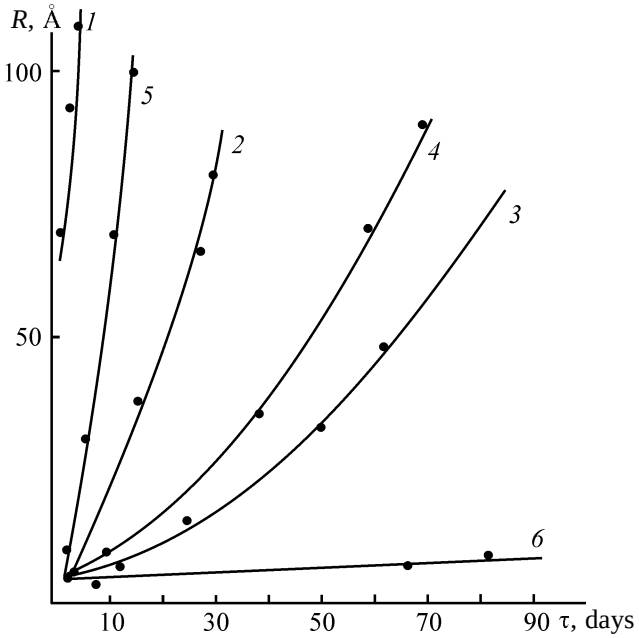

Fig. 2. Variation with time of the size of heterogeneity areas in sols at various amounts of HCl added (SAS data). (*R*) Radius of polymeric formation and (τ) time.

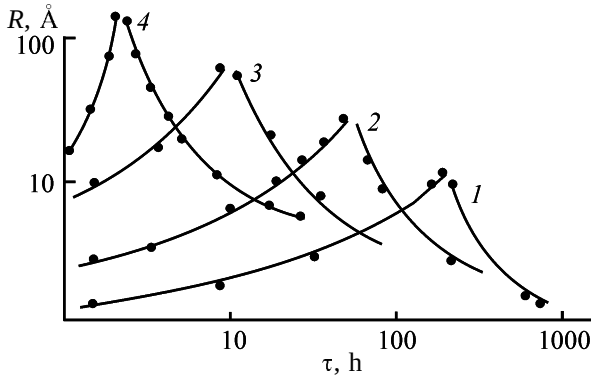

Fig. 3. Variation with time of the size of heterogeneity areas in sols at various temperatures (SAS data). (*R*) Radius of polymeric formation and (τ) process time. Temperature, °C: (*1*) 20, (*2*) 40, (*3*) 60, and (*4*) 80.

composition 1, in the absence of HCl, the SAS method revealed no variation in the scattering intensity in the first day, whereas for solutions containing HCl catalyst these variations were quite noticeable. Formally, this period can be considered as incubation period, as it is followed by abrupt increase in the sizes of polymer particles. On the fifth day, solution 1 transforms into a solid gel (Fig. 2, curve *1*). It can be suggested that, in composition 1, the areas of heterogeneity caused by more complete TEOS HP are denser. Comparison of the SAS data and film-forming characteristics suggests that the period of film formation corresponds to the presence of small particles in the solution with the size from 4–5 to 50–70 Å.

The duration of the film-forming period can be increased by adding trimethylethoxysilane (TMEOS) $(CH_3)_3Si(OC_2H_5)$. This monomer exerts a stabilizing effect on the polymeric reaction products. Cocondensation of TEOS and TMEOS results in termination of growing polysiloxanes chains due to blocking of the growth centers with methyl groups by the reaction

$$\equiv Si\text{–}OH + C_2H_5O\text{–}Si(CH_3)_3 \rightarrow \equiv Si\text{–}O\text{–}Si(CH_3)_3 + C_2H_5OH.$$

When cocondensation is performed at the volume ratio TEOS : TMEOS = 7 : 1 in a solution with the highest content of HCl, 0.7 mol per mol of TEOS, the lifetime of the solution can be increased from 5 days to 2 months and more (Figs. 1a and 1b, curve *6*). At a constant viscosity equal to approximately 3 cP within the observation period (more than 70 days), films of a constant thickness were obtained from the solution. The SAS data confirm constant size of heterogeneity areas in solution (Fig. 2, curve *6*).

Acceleration of aging of the sols and variations of the size of heterogeneity areas in the course of TEOS HP were studied by SAS (molar ratio HCl : TEOS = 0.03 : 1) at 80, 60, 40, and 20°C. As seen from Fig. 3, at each temperature the size of the scattering areas increases with time; at a certain instant of time, depending on temperature, the growth rate abruptly increases, the size becomes larger than the installation resolution, and then the size begins to decrease. The attainment of the largest size corresponds to formation of "infinite clusters" and sol–gel transition. It should be noted that the size grows in the step of polymerization. In this step, the size determined from the evidence of SAS data is an effective size of branched chains of silicon–oxygen tetrahedra randomly distributed in the liquid phase as matrix. After transition into the gel state, the silicon–oxygen skeleton becomes a matrix, and inclusions of the liquid phase become scattering areas. With further progress of the polymerization, the size of these inclusions decreases, i.e., the liquid phase is displaced. After evaporation of the liquid phase in the step of transition into the xerogel, the scattering areas are pores with the sizes of the order of 10–20 Å (radius in approximation of scattering with spherical particles with a constant density in the bulk).

The shapes of the dependences shown in Fig. 3 are typical of second-kind phase transitions and are in good agreement with the Flory–Stockmayer model [23, 24]. In this case, in deep steps of TEOS HP, an infinite cluster appears, which confirms irreversibility of the sol–gel transition. An increase in the temperature of TEOS HP results in acceleration of sol aging; with heating by 20°C, the time of attainment of a given particle size decreases by a factor of approximately 7. In this case, the SAS data also satisfactorily correlate with the period of manifestation of film formation properties. This fact suggests that the mechanisms of the influence of temperature and acid catalyst concentration on the TEOS HP are similar.

CONCLUSIONS

(1) Viscometric data give an insight into the rheology of hydrolytic polycondensation of tetraethoxysilane depending on the process conditions. The period of film formation corresponds to the variation of the sol viscosity from 2 to 8 cP.

(2) The results of analysis of sols by small-angle X-ray scattering allow the film-forming ability to be correlated with the presence of heterogeneity areas of the size from 4–5 to 50–70 Å in the solution.

(3) Data on the rheology of hydrolytic polycondensation of tetraethoxysilane, small-angle X-ray scattering, and film-forming ability reveal the similarity in the mechanism of development of hydrolytic polycondensation of tetraethoxysilane depending on the catalyst amount and temperature, consisting in gradual growth of the polymer from small primary particles to infinite cluster typical for sol–gel transition.

(4) Addition of trimethylethoxysilane as comonomer affects the rheology of tetraethoxysilane sols and their film-forming ability, with actually constant sizes of heterogeneity areas observed by small-angle X-rays scattering.

Abstract—Sorption of moisture on segmented poly(urethane–ureas) with flexible segments of various chemical structures and the effect of a humid atmosphere on the mechanical properties of these materials were studied. Poly(urethane–urea) prepared from mixtures of oligoethers shows advantages from the viewpoint of preservation of high strength in a humid atmosphere.

Block polyurethane elastomers, so-called segmented polyurethanes (SPUs), are widely used in various branches of industry thanks to their high strength, good deformation characteristics, and resistance to a number of solvents [1]. Depending on the destination, polyurethane items can operate in air or in direct contact with water (e.g., polyurethane coatings of squeeze rolls in paper-making industry).

Published data on the behavior of SPUs in moist media mainly concern the moisture transfer in these materials [2–5] and changes in the structure [2, 5, 6] and glass transition point [5, 6] of moistened polyurethanes. Experiments were performed with thin polyurethane films prepared from solution; in this case, correct estimation of changes in mechanical properties on moistening is complicated by intense moisture exchange with the surrounding medium. Data on the mechanical properties of the films are limited to the results of their mechanical tests before moistening [3]. Therefore, it is unclear to what extent the mechanical characteristics of various SPUs vary on moistening and how the extent of their variation depends on the polymer structure.

Studies in this direction are necessary for understanding how the mechanical characteristics of polyurethanes change on moistening and for choosing formulations of polyurethane materials suitable for operation in moist media.

In this study we examined the influence of the relative air humidity, varied in a wide range, on the mechanical properties of SPUs with various flexible segments. Our main goal was to reveal what structure of flexible blocks would provide the highest strength of the polyurethane material in a humid atmosphere.

EXPERIMENTAL

We used segmented poly(urethane–ureas) with poly(tetramethylene oxide) flexible blocks (SPUM-1), poly(propylene oxide) segments (SPUM-2), mixed polyether blocks (SPUM-3), and mixed polybutadiene–poly(tetramethylene oxide) flexible segments (SPUM-4). To prepare SPUMs, we took prepolymers based on oligo(tetramethylene oxide)diol (M ~1700), oligo(propylene oxide)diol Laprol 2102 (M ~1950), and polybutadienediol (M ~2100, SKU-DF-2 prepolymer). The molecular weight of the oligomeric diols was estimated from the content of hydroxy groups. The prepolymers were prepared by the reactions of appropriate diols with toluylene-2,4-diisocyanate. The prepolymers and their mixtures (in preparation of SPUMs with mixed flexible segments) were cured with 3,3'-dichloro-4,4'-diaminodiphenylmethane (Diamet Kh) by the procedure described in [7].

The molar ratio of the prepolymers (or their mixture) to Diamet Kh was 1.03, and the molar ratio of the NCO and OH groups in the synthesis of the prepolymers, 2.1.

The isotherms of the moisture sorption by SPUMs were obtained using the kinetic curves of the weight gain of the samples placed in atmospheres of different relative humidities φ (over appropriate solutions of

1070-4272/05/7809-1522 © 2005 Pleiades Publishing, Inc.

inorganic salts) at 22 ± 1.5°C. The control samples were kept over freshly calcined calcium chloride. As expected, the sample weights in this case were virtually the same as the initial weights of the samples taken from the molds. The weights of the dry and moistened samples were determined with an Ohaus AR-2140 analytical balance with an accuracy of $\pm 3 \times 10^{-7}$ kg.

For mechanical tests, SPUM samples were kept similarly in a dry or humid atmosphere to attain the equilibrium. The total time of the mechanical tests of a single sample did not exceed 120 s. In this time, the specific moisture content c changed by less than 4% relative to the equilibrium value.

The mechanical characteristics of SPUMs, strength f_b (breaking stress, or maximal stress calculated for actual sample cross section), relative critical strain ε_c, and nominal modulus E_{100} at 100% relative strain, were determined at 22 ± 1.5°C and an extension rate of 0.3 s^{-1}.

The molecular structures of the dry and moistened SPUM samples were studied by IR spectroscopy on a Bruker IFS-66/S Fourier spectrometer. Samples were prepared as films without solvents, by curing of the reaction mixture placed between two Teflon films. We checked that the Teflon film does not absorb in the range of carbonyl stretching vibrations (ν = 1620–1750 cm^{-1}). At moistening, one of the insulating Teflon films was removed. Before recording the spectrum, the sample surface was again covered with the Teflon film, and the sample was placed between KBr plates. The conversion of the isocyanate groups was also monitored by IR spectroscopy (disappearance of the absorption at ν = 2275 cm^{-1}). For the sake of convenient comparison, as in [8], the spectra of different samples were normalized with respect to the band at ν = 1575 cm^{-1}.

The results of the experiments showed that the equilibrium moisture content c of the samples was independent of whether it was reached from above (desorption from samples taken from a more humid atmosphere) or from below (sorption).

The reversibility of the moisture sorption and desorption and the shape of the curves in Fig. 1 indicate that the isotherms of the moisture sorption by the examined materials belong to type IV, according to the generally accepted classification. A significant difference in the moisture absorption by SPUM-1 and SPUM-2 (by a factor of 1.67–1.8) at $\varphi \geq 60\%$ may be caused not only by the different polarity of the flexible chains with different content of oxygen atoms.

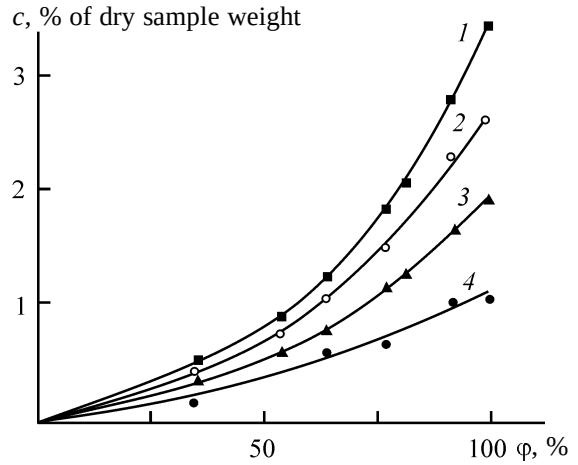

Fig. 1. Isotherms of moisture sorption by (*1*) SPUM-2, (*2*) SPUM-3, (*3*) SPUM-1, and (*4*) SPUM-4 at 22°C: (*c*) specific moisture content of the material and (φ) relative air humidity.

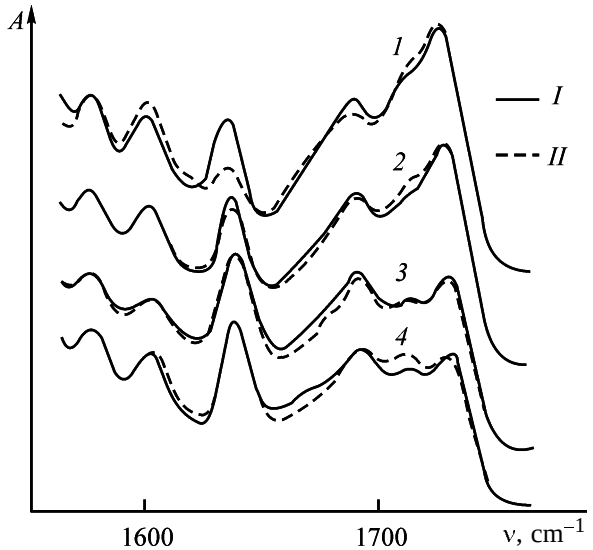

Fig. 2. IR spectra of (*I*) dry and (*II*) moistened (at φ = 92%) samples: (*1*) SPUM-2, (*2*) SPUM-3, (*3*) SPUM-1, and (*4*) SPUM-4. (*A*) Absorption and (ν) wave number.

On replacement of poly(tetramethylene oxide) flexible blocks by poly(propylene oxide) blocks, the degree of microphase segregation in poly(ether–urethane–urea) decreases; correspondingly, the amount of rigid polar blocks dissolved in the flexible phase of the polymer increases, and the volume of this phase grows [8]. Furthermore, the sorbed moisture breaks a part of self-associates of the urea groups localized in domains of rigid urethane–urea blocks. This is clearly seen from comparison of the intensities of the urea carbonyl absorption band (ν = 1640 cm^{-1}) in the IR spectra of the initial and moistened samples (Fig. 2, spectra *1*, dashed and solid lines). As shown in [2], an increase

in the volume accessible to water molecules and in the amount of polar groups capable of H bonding should increase the moisture absorption of the polyurethane material.

The structure of the rigid domains of the material with poly(tetramethylene oxide) flexible segments is less defective than that of SPUM-2 domains [8]. On moistening of SPUM-1, the amount of the strongest structural formations, self-associates of urea groups, remains essentially unchanged (Fig. 2, spectra *3*). As expected, the isotherm of moisture sorption by SPUM-3 containing mixed oligoether flexible blocks is intermediate between the isotherms of the moisture sorption by SPUM-1 and SPUM-2, and the specific moisture content of poly(urethane–urea) drastically decreases on partial replacement of polyether blocks by nonpolar polybutadiene flexible segments (Fig. 1, curve *4*).

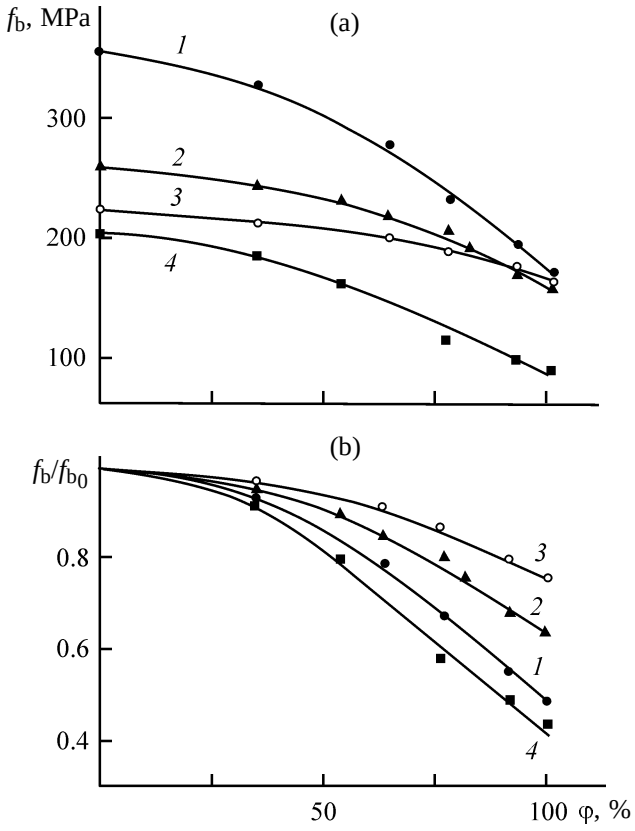

Fig. 3. (a) Strength f_b and (b) its relative change f_b/f_{b_0} on moistening of (*1*) SPUM-3, (*2*) SPUM-1, (*3*) SPUM-4, and (*4*) SPUM-2 samples, as functions of the relative air humidity φ.

The mechanical tests of SPUMs showed that the moistening exerted virtually no effect on the critical strain ε_c (see table). SPUM-2 sample with propylene oxide flexible segments is characterized by the lowest values of f_b and E_{100} and by their most pronounced decrease on moistening (by a factor of 2 at φ = 100%; Fig. 3, curves *4*). In the material containing 50% nonpolar flexible blocks, the decrease in the strength and nominal modulus was the least pronounced (Fig. 3, curves *3*). The curves of the relative change in the breaking stress upon SPUM moistening (Fig. 3b) are arranged in the order opposite to the sorption isotherms in Fig. 1.

The observed pattern of the mechanical behavior of SPUMs in a humid atmosphere is apparently caused by significant differences between the materials in the extent to which the domain structure and interchain interactions affect their density. The results of previous studies [8, 9] suggest that an increase in the intensity of the carbonyl absorption band belonging to urea self-associates (ν = 1640 cm^{-1}), observed in going from SPUM-2 to SPUM-3, SPUM-1, and SPUM-4, is indicative of an increase in the degree of segregation of rigid blocks in the same order. As the polarity of flexible chains decreases (and, as a result, the microphase segregation of rigid and flexible blocks in the polymer increases), the effect of the reinforcing filler

on the material strength (SPUM-1, SPUM-4) becomes stronger.

With an increase in the polarity of the flexible blocks and the corresponding increase in the solubility of the rigid segments in the SPUM flexible phase, the effect of the interchain interaction in the polymer matrix on the material strength is enhanced [1]. Correspondingly, weakening of this interaction upon water sorption should substantially decrease the strength of poly(ether–urethanes), which is the case. Partial break of urea self-associates in the presence of moisture also leads to a decrease in the elastomer strength (Fig. 3b, curve *4*).

It is noteworthy that, owing to high initial f_b of SPUM-3 (before moistening), the strength of the material with mixed flexible segments in a humid atmosphere is higher than f_b of the other materials, especially at moderate humidity ($\varphi = 50–75\%$) typical of industrial premises.

The fact that the strength properties of the SPUM containing nonpolar flexible segments are not significantly deteriorated in a humid atmosphere is of interest for developing materials preserving high strength in a moist medium.

CONCLUSIONS

(1) The dependence of the moisture absorption of poly(urethane–ureas) with various flexible blocks on the structural organization of the materials was elucidated.

(2) A correlation between the capability of poly(urethane–ureas) to sorb moisture and the decrease in their strength in a humid atmosphere was revealed.

(3) Moisture only weakly affects the mechanical characteristics of the material with mixed polyether and nonpolar polybutadiene flexible segments. The decisive effect on the properties of this material is exerted by the microdispersed rigid phase, which is not altered upon moistening of the polymer.

(4) To ensure high strength of poly(ether–urethane–urea) in a moist medium, it is appropriate to use for its synthesis a mixture or prepolymers derived from oligo(tetramethylene oxide)diol and oligo(propylene oxide)diol.

Abstract—Conditions for preparing boron-containing blocked diisocyanate in a melt of blocking agents at low temperatures in the absence of solvents were examined.

Variable-valence metal compounds, e.g., cobalt stearate and naphthenate, are effective promoters of rubber adhesion to brass-plated metal cord [1]. The main destination of promoters is to ensure not only the high initial adhesion strength in the rubber–brass-plated metal cord system, but also the stability of the strength under service conditions [1]. However, variable-valence metals catalyze oxidation of the rubber polymer [1] and therefore may decrease the durability of the items, e.g., of automobile tires. Also, these promoters are among the most expensive components of rubber stocks.

Various modifying systems, including blocked diisocyanates (BDs) [2], have been suggested as alternatives to cobalt-containing adhesion promoters. However, studies with BDs have not gone beyond laboratory trials. Probably, the advantages of BDs as adhesion promoters, as applied to a diversity of metal-reinforced elastomeric composites, require more evidences.

In this study, we proceed with the development of BDs ensuring high adhesion of rubber to brass-plated cord and the stability of the adhesion properties under the service conditions. We expect that an additional contribution to the adhesion properties will be made by high reactivity of diisocyanates regenerated by deblocking toward compounds containing labile hydrogen atoms.

EXPERIMENTAL

The source of labile hydrogen atoms in the brass coating of the metal cord can be zinc hydroxide. Its presence in the brass layer is very undesirable, because it not only causes formation of loose surface layers with a low mechanical strength, but also promotes excessive formation of copper and zinc sulfides [3]. Apparently, chemical bonds arising in the reaction of isocyanate groups with the OH groups of zinc hydroxide, on the one hand, and with rubber hydrogen, on the other hand, will prevent intense diffusion of copper and zinc ions toward the rubber–brass-plated layer contact zone. In turn, the density of the forming bonds will depend on the diffusion activity of BD. At a relatively low diffusion rate, the majority of the competing reactions of the diisocyanate with the rubber stock components and with rubber itself will occur beyond the adhesion contact zone. Therefore, to ensure fast supply of BDs to the boundary zones, these substances should have such specific properties as high dispersibility in the rubber bulk and high rate of diffusion to the adhesion zone.

To prepare such BDs, we proceeded from the process [4] involving synthesis in a melt of binary or ternary systems of blocking agents taken in an excess relative to the isocyanate groups and acting as a dispersion medium for BD particles proper. If the synthesis temperature does not exceed 90°C, the viscosity of the melt of the blocking agents, the melt with the added diisocyanate, and, finally, the reaction mixture up to complete conversion of the isocyanate groups is sufficiently low (at 80°C, 30–70 cP) to perform the process without solvent [5]. The products thus obtained are homogeneous compounds with a dropping point of 50–70°C and pronounced surface activity; they undergo no phase segregation in time [6]. In our case, to obtain a promoter of adhesion to brass-plated metal cord, we blocked a diisocyanate [brand D polyisocyanate, TU (Technical Specifications) 113-03-38-106–90, a (50–60) : (40–50) wt % mixture of diphenylmethane-4,4'-diisocyanate and its dimers] with

1070-4272/05/7809-1526© 2005 Pleiades Publishing, Inc.

the system ε-caprolactam–stearic acid, at the same component ratio as in [7].

A principally new approach to BD preparation is addition of boric acid (BA) to the BD formulation. It is noted [1] that boron-containing compounds favor preservation of the binding strength in the course of service, when the brass-plated metal cord is subjected to the action of water or sodium chloride diffusing to the surface of the metal cord in the tire belt through microcracks and cuts of the tread.

We found that BA added to BD in the step of the synthesis catalyzes the side reactions of branching and cross-linking which cause gelation of the reaction melt. Addition of BA to the BD melt after completion of the blocking reaction involves problems, as it becomes necessary to heat the reaction mixture to 120°C for melting of BA and homogenization of the formulation. Under these conditions, blocked diisocyanate catalyzes the deblocking–blocking reactions, which prevents obtaining a product with reproducible physicochemical properties and negatively affects the binding strength in the rubber–brass-plated cord system under the conditions of salt aging (Fig. 1).

Tests were performed with breaker rubbers based on SKI-3 polyisoprene rubber. Mother rubber stocks were prepared in a laboratory rubber mixer with a mixing chamber volume of 2 dm^3. The vulcanizing group and adhesion promoters were added to the mother stock on laboratory rollers. Vulcanization was effected with Kristeks polymeric sulfur in the presence of an accelerator, sulfenamide C, at 155°C for 25 min. The physicomechanical parameters of the vulcanized rubbers and samples of rubber with metal cord were determined in accordance with appropriate regulations: strength of vulcanized rubbers, according to GOST (State Standard) 270–75, and strength of binding of the rubber with 9L15/27 metal cord, according to GOST 23785.7–79 (H method). The salt aging of rubber samples with metal cord was performed in a boiling 5% NaCl solution, and exposure of the metal cord to a humid atmosphere, in a desiccator over water at 110°C.

It is known [8] that many substances form eutectic alloys. This phenomenon is typical both of substances whose alloys are mechanical mixtures of the individual components and of substances exhibiting limited mutual solubility of the components in the solid state. Therefore, we expected that the use of eutectic mixtures of BA with blocking agents would allow preparation of a boron-containing BD at temperatures as low as 80–90°C, thus eliminating gelation or premature deblocking–blocking reactions.

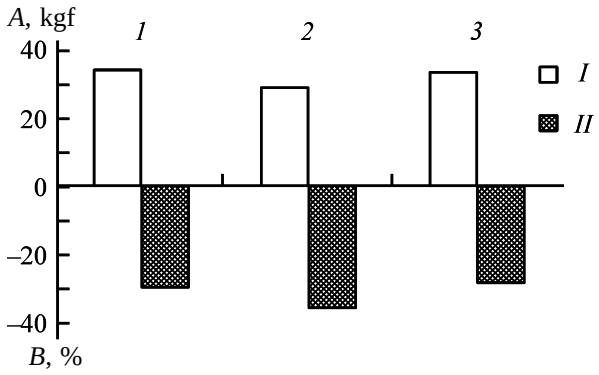

Fig. 1. (*I*) Initial strength *A* of binding of rubber with brass-plated metal cord (H method) as influenced by the kind of modifier and (*II*) change *B* in the binding strength after salt aging. (*1*) Cobalt stearate, (*2*) BD and BA (mechanical mixture), and (*3*) BD + BA in the form of an eutectic melt with ε-caprolactam.

We studied binary formulations of BA with ε-caprolactam and of BA with stearic acid. BA does not form an eutectic with stearic acid because of unlimited mutual solubility of the components in the solid state. A 8 : 2 (by weight) mixture of ε-caprolactam with BA forms an eutectic melt with a dropping point of 74°C.

Introduction of 2.0–2.5 wt % BA in the form of an eutectic alloy to the reaction mixture after complete conversion of isocyanate groups allows preparation of a BD compound with stable physical and colloidal properties. The properties of the compound in the initial state are, on the whole, virtually the same as in the absence of boron: It is highly soluble in toluene, the dropping point is 52 ± 2°C, and the surface tension isotherm obtained by the Kantor–Rebinder method coincides with that of an aqueous dispersion of BA–PIC [9]. The rubber–cord samples prepared with a boron-containing BD (BCBD) show relatively high strength in tests performed under normal conditions and in aggressive media (Fig. 1).

Thus, with BCBD used as adhesion promoter, zinc hydroxide in the brass layer exerts no negative effect on the binding strength in the rubber–metal cord system. Furthermore, preliminary exposure of the metal cord to a humid atmosphere, promoting formation of zinc hydroxide, decreases by 10% the strength of the adhesion contact when cobalt stearate is used as modifier and increases to the same extent the strength with the modifier we suggested.

The use of an ingredient with a relatively low dropping point in most cases involves problems because of possible agglutination of granules. To impart to the

products an acceptable technological shape, we used a previously developed procedure [10] involving capsulation of BD with colloidal silicic acid (white black, BS-100 or BS-120). The capsulation was performed in a ball mill. The BS-120 content in the examined modifiers was 35–38%.

It could be expected that a chemical reaction of the deblocked isocyanate groups with the silanol groups of white black and with adsorbed moisture would decrease the BD performance as adhesion promoter. Experiments on thermostating of the capsulated BDs at various temperatures and their subsequent extraction with toluene to remove the organic component show that the polyisocyanate reacts with the BS-120 surface only at 180°C. This is indicated by data shown in Fig. 2. From the samples that were not heat-treated or were heated at 155°C, the organic phase is extracted completely (52–55%), and from the samples heated at 180°C, only partially.

Hence, the adsorption interaction of BD with the surface of white black only slightly affects the modifying activity of the product heat-treated at 155°C (Fig. 3). The strength of rubber–metal cord samples obtained with this modifier is somewhat higher than that of the samples modified with cobalt stearate. It should be noted that, under the conditions of thermal oxidative aging, the rubber–metal cord samples modified with the heat-treated products show more stable binding strength parameters (Fig. 3). It is quite probable that, with non-heat-treated modifiers, the adsorbed moisture from silica causes hydrolytic degradation of the adhesion bonds in the contact zone. On the contrary, preliminary heat treatment of the products at 155°C results in removal of the adsorbed moisture and thus enhances the stability of the samples under the conditions of thermal oxidative aging. More severe heat treatment (180°C) causes not only removal of the adsorbed moisture, but also the reaction of the isocyanate groups with the silanol groups, as indicated by the results of the extraction of the organic component. As a result, the binding strength decreases.

It is interesting to compare the BDs that we suggested with the known BDs, in particular, with BKT-2 or BKT-3. The main differences in the physicochemical properties of these BDs are predetermined by the synthesis conditions. In the preparation of BKT-3, blocking of the diisocyanate is performed with a single blocking agent, ε-caprolactam, at relatively high temperatures, 145–150°C. The modifier is characterized by a branched structure owing to formation of biuret bonds and therefore has a relatively high dropping point (about 120°C).

Table 1. Interaction parameters and diffusion coefficients

Modifier	Interaction patameter χ	Diffusion coefficient $K_d \times 10^9$, $cm^2\ s^{-1}$
BKT-3	0.54	3.027
BCBD	0.51	6.005
BCBD capsulated with BS-120	–	5.490
Cobalt stearate	0.76	0.710

One of the conditions for formation of an adhesive joint is migration of the modifier to the rubber–cord boundary [11]. From the viewpoint of estimation of the distribution on the boundary, the boron-containing BD should be preferred because of its lower dropping point and better, compared to BKT-3, dispersibility in the rubber. These properties of the modifier are necessary but insufficient to ensure rapid modification of the boundary layer. Only the modifier with the high energy of egress to the surface [12] will be effective. Therefore, processes related to the diffusion of adhesion promoters to the polymer–brass-plated cord contact zone are of principal importance. The higher the diffusion rate, the more effective is the modifier [13].

We examined the diffusion activity of BCBD, BCBD capsulated with BS-120, BKT-3, and cobalt stearate. The diffusion processes were evaluated by the weight loss of rubber samples containing the modifiers being tested and stored between rubber samples containing no modifiers ("sandwich" system) [14]. We believed that the weight loss of the rubber samples was exclusively due to diffusion of the modifiers into the contacting rubber pieces. The diffusion coefficients were calculated by the procedure given in [14].

We found that BCBD and BCBD deposited onto BS-120 exhibit the highest diffusion rate in the initial period (24 h), as judged from the weight loss of the rubber samples (Fig. 4) and from the diffusion coefficients (Table 1).

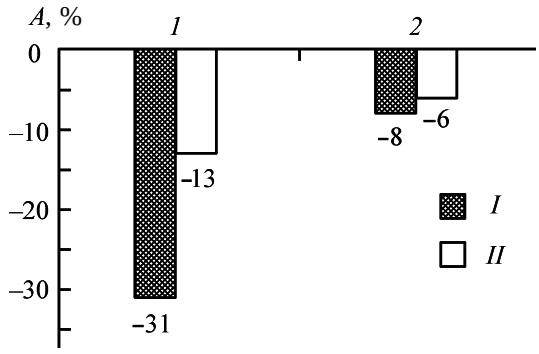

Fig. 5. Changes *A* in the strength of binding (H method) of rubber with 9L15/27 metal cord after (*I*) thermal oxidative aging (100°C, 72 h) and (*II*) salt aging (5% NaCl, 100°C, 6 h). Modifier: (*1*) BKT-3 and (*2*) BCBD capsulated with BS-120.

It should be noted that, despite close parameters of interaction with the polymer, the diffusion activity of BCBD is higher than that of BKT-3. The high diffusion coefficients of BCBD are most probably associated with its better dispersibility in the rubber matrix, which, in turn, is due to the fact that BD particles are surrounded with a surface-active dispersion medium. A BCBD particle capsulated with a silicic acid filler experiences no steric hindrance in migration toward the adhesive contact zone.

Under the conditions of thermal oxidative and salt aging (Fig. 5), BCBD compared to BKT-3 ensures more stable strength of the adhesive contact, which is consistent with the existing views [1] that the corrosion of brass-plated metal cord decelerates in the presence of boron compounds.

The physicomechanical properties of vulcanizates containing the modifiers under consideration are given in Table 2. The effect of BCBD on the strength of the vulcanizates is insignificant.

Table 2. Effect of modifiers on properties of vulcanizates

Parameter	Modifier* (1.00 wt % relative to rubber)			
	1	2	3	4
Nominal stress at 300% elongation, MPa	15.3	15.5	14.5	15.0
Nominal tensile strength, MPa	20.6	21.8	19.3	21.6
Relative elongation at break, %	407	445	397	446
Elongation set, %	27	31	24	28

* (1) Co stearate; (2–4) BCBD capsulated with BS-120, heat treatment: (2) none, (3) at 155°C, and (4) at 180°C.

CONCLUSIONS

(1) A boron-containing formulation imparting to rubber–metal cord samples high strength and stability under conditions of thermal oxidative and salt aging can be prepared by fusion of an eutectic alloy of boric acid and ε-caprolactam with blocked polyisocyanate having a dropping point of 50–70°C.

(2) Capsulation of the boron-containing blocked polyisocyanate with colloidal silicic acid, followed by heat treatment of the compounds at temperatures not exceeding 155°C, does not impair the strength of the rubber–metal cord samples.

(3) Good distribution in the rubber, low dropping point, and high diffusion activity ensure higher performance of the tested products as adhesion promoters, compared to the known blocked polyisocyanates.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Sulfur-Free Vulcanization of Modified Butadiene–Acrylonitrile Rubber SKN-40PVKh-30, Aimed To Obtain Elastomeric Materials Resistant to Aggressive Media

Sh. M. Mamedov

Institute of Radiation Problems, National Academy of Sciences of Azerbaijan, Baku, Azerbaijan

Received November 17, 2004; in final form, April 18, 2005

Abstract—A study was made of the thermal, peroxide, and radiation vulcanization of modified butadiene–acrylonitrile rubber SKN-40PVKh-30 in the presence of a polyhalomethyl compound, 1,4-bis[(4-trichloromethylphenyl)dichloromethyl]benzene, with epoxy and phenol–formaldehyde resins and 4,4'-dithiobis-*N*-phenylmaleimide (a sensitizer) additionally included in the formulation with the aim to improve the technical properties of the vulcanizates and elastomeric materials. The parameters of the three-dimensional network of the vulcanizates were studied by sol–gel analysis; the total number of active chains of the network ($1/M_c$), number of cross-linked molecules ($1/M_{n_\tau}$), and gel fraction content were determined for the thermal, peroxide, radiation, and thermoradiation vulcanizates.

Sulfur-free vulcanizing systems find growing use in industry for preparing thermally stable vulcanized rubbers resistant to thermal oxidative aging and other effects. The most widely used are vulcanizing systems based on organic peroxides, synthetic resins, and polyhalo and other active additives capable of reacting with macromolecules to form three-dimensional elastomer structures based on C–C cross-links [1–5].

Depending on the conditions of elastomer vulcanization with low-molecular-weight additives, the reactions occurring in the system result in formation of not only cross-links but also groups that are located beyond the network points subsequently transforming into cross-links. These processes are considered as formation of heterogeneous vulcanization structures [6–8].

Recently there has been much interest in the formation of vulcanization structures using new organic cross-linking agents, modifiers, and sensitizers for butadiene–acrylonitrile rubbers (BNRs) [9].

When stored or used in chemically and physically aggressive media in contact with water, oil, oil-bearing fluids, clay suspensions, and fuel, elastomeric materials (EMs) prepared from SKN-40 and SKN-40M rubbers vulcanized with sulfur-containing cross-linking agents degrade because of the cleavage of chemical bonds [4, 10].

One of the major factors affecting the resistance to aggressive media and mechanical characteristics of EMs is formation of chemical structures, i.e., vulcanization bonds, in elastomers. The use of different cross-linking agents and procedures results in formation in the elastomer of different types of three-dimensional bonds, which, in turn, affects the service life of EMs [1, 10].

Effective additives in preparation of vulcanization structures are polyhalomethyl compounds (PHMCs) such as 1,4-bis[(4-trichloromethylphenyl)dichloromethyl]benzene, epoxy (ERs) and phenol–formaldehyde (PFRs) resins, dicumyl peroxide (DCP), and 4,4'-dithiobis-*N*-phenylmaleimide (DTBPMI) accelerating radiation-induced vulcanization of elastomers [8, 11]. It was also found [12, 13] that the service life of EMs operating under various conditions can be prolonged by varying the vulcanization structures. However, the role of PHMCs, ERs, DCP, and DTBPMI as cross-linking agents and sensitizers in radiation-induced processes is poorly understood, and the available data are scarce.

In this study we examined the vulcanization of a modified BNR, SKN-40PVKh-30, induced by heating and γ-irradiation with simultaneous introduction of a PHMC, 1,4-bis[(4-trichloromethylphenyl)dichloromethyl]benzene, as cross-linking agent, of epoxy and phenol–formaldehyde resins as modifiers, and of

4,4'-dithiobis-*N*-phenylmaleimide (DTBPMI) as sensitizer. The formulation also contained dicumyl peroxide (DCP), zinc oxide, stearic acid, and P-324 carbon black, added to improve the technical properties of the vulcanizates and EMs.

EXPERIMENTAL

Elastomer stocks were prepared on rollers at 30–40°C and were vulcanized in a mold at 150–180°C (Table 1).

The radiation vulcanization was performed with a ^{60}Co γ-ray source [14]. The thermoradiation vulcanizates and elastomeric materials (EMs) were prepared by prebaking in a mold at 180°C for 5–7 min, followed by irradiation in air at 20°C to doses of 50–500 kGy at a dose rate of 6.9 Gy s^{-1}.

The sol–gel analysis was performed by the known procedure [13]. The degree of cross-linking was determined from the equilibrium swelling in toluene using the Flory–Renner equation.

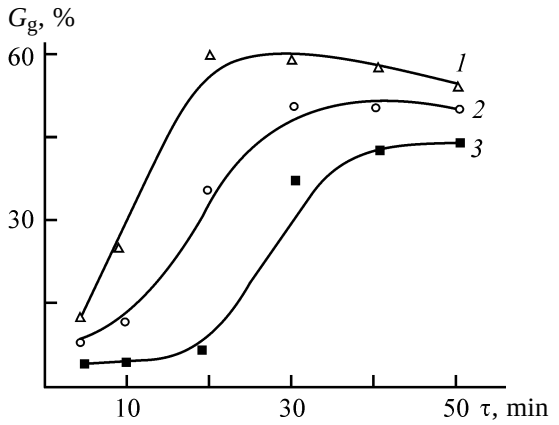

Fig. 1. Kinetic curves of gelation in elastomer mixtures based on SKN-40PVKh-30 and vulcanized by the (*1*) thermal, (*2*) sulfur, and (*3*) peroxide methods. (G_g) Gel fraction content and (τ) time.

The structural changes occurring in the rubber during vulcanization were estimated from the absorption spectra taken on an IKS-22 spectrometer.

Physicomechanical and rheological properties of the filled and unfilled rubbers were determined on samples vulcanized at elevated temperatures, by irradiation, and by combined thermoradiation treatment. The properties of the solutions were evaluated from the intrinsic viscosity, which was measured in benzene at 20°C on an Ubbelohde viscometer by the standard procedure. In calculations we used the Mark–Houwink equation with $K = 1.16 \times 10^5$ and $\alpha = 0.73$ [15].

The cross-links formed in the course of elastomer vulcanization consist of atomic groups of the vulcanizing system, or are simply the valence bonds between the atoms of the molecular chain of the elastomer. The structure of the vulcanization nodes depends on the composition of the vulcanizing system and the elementary reactions occurring between the cross-linking agent and elastomer.

The major vulcanization process is accompanied by chain degradation and internal addition of cross-linking agents and other reactive components. The formation of vulcanization networks depends on the relative reactivity of the elastomer in these processes.

The sol–gel analysis allows determination of the three-dimensional network parameters from the content of the gel (insoluble) fraction in the vulcanizate.

As expected, the gel content noticeably increases with the heating time (Fig. 1). The highest gel content in the model stocks indicates that the PHMC and ER

Peroxide (160°C, 25 min)	DCP + ZnO + SA + PFR + PHMC	1.58	5.0	5.9
Radiation (D = 300 kGy)	PHMC + ZnO + ER + SA + DTBPMI	1.45	5.7	6.8
Thermoradiation (180°C, 5 min, D = 400 kGy)	PHMC + ZnO + ER + SA + DTBPMI	1.69	3.5	4.2

* (τ_5) Time of vulcanization onset and ($\tau_{35} - \tau_5$) characteristic of the vulcanization rate.

participate in the cross-linking. As the measurements show, the gel fraction content in radiation and thermoradiation vulcanizates noticeably increases as the concentration of the vulcanizing systems in the elastomer bulk and the radiation dose are increased (Fig. 2). It should be noted that the initial gelation (100 kGy) corresponds to formation of one cross-linked polymeric unit per number-average rubber molecule. When insoluble fractions are formed at maximal doses (500 kGy), at a PHMC content of 4 wt % relative to the elastomer, the gel content in the radiation and thermoradiation vulcanizates reaches 58 and 80%, respectively.

One of the features of the elastomers is their high molecular weight, imparting to them unusual and valuable properties. Furthermore, the cross-linked elastomer consists of macromolecuels of different lengths, i.e., it is nonuniform in the molecular weight. The molecular weight of cross-linked elastomers was determined viscometrically. We evaluated the dependence of the viscosity of the unfilled vulcanizates on the heating time and irradiation dose.

The results of monitoring the intrinsic viscosity (Table 2) show that the molecular weights of the chemical and thermoradiation vulcanizates rapidly change. The elastomer stocks containing PHMC and ER give vulcanizates of higher molecular weights, compared to peroxide vulcanizates.

From the intrinsic viscosity we determined how the molecular weight of SKN-40PVKh-30 rubber varies in the course of vulcanization. In chemical vulcanization, it increases from 150.0 to 250.0 kDa within 25–35 min. With peroxide vulcanization, the pattern is different. Table 2 shows that the radiation vulcanization occurs more slowly than the thermal and peroxide vulcanization.

Interesting features are exhibited by thermoradiation vulcanizates in the presence of PHMC, ER, and DTBPMI. Additions of DTBPMI increase the degree of cross-linking by 15–20%. At a dose of 400 kGy, changes in the intrinsic viscosity of the thermoradiation vulcanizate are more pronounced compared to the thermal, peroxide, and radiation vulcanizates.

The rheological properties of vulcanizates are important service parameters of elastomers. We determined these properties viscometrically with a VR-2 Mooney viscometer. These properties are particularly sensitive to the molecular-weight distribution of a polymer.

The tendency of elastomer stocks to scorching was evaluated from the time in which the sample viscosity became higher than the initial value by 5 units.

The tendency to scorching is characterized by two parameters: (a) scorching onset time τ_5 in which the viscosity of the sample increased by unity and

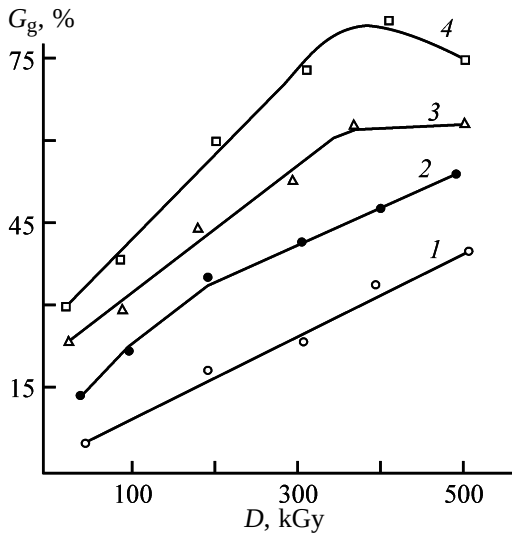

Fig. 2. Influence of the irradiation dose D on the gelation in (*1*, *2*) radiation and (*3*, *4*) thermoradiation vulcanizates based on SKN-40PVKh-30 rubber. (G_g) Gel fraction content. PHMC concentration, wt % relative to elastomer: (*1*, *3*) 2.0 and (*2*, *4*) 4.0.

Table 3. Influence of the vulcanization mode (thermal, peroxide, radiation, thermoradiation) on the total mumber of network chains $1/M_c$ and number of cross-linked molecules $1/M_{n_\tau}$ in SKN-40PVKh-30 vulcanizates

Vulcanization	Vulcanizing system	$1/M_c \times 10^5$	$1/M_{n_\tau} \times 10^5$
		mol cm^{-3}	
Sulfur (known)	Sulfur + Altax + SA + ZnO	11.2	4.7
Thermal	PHMC + ZnO + SA + ER	10.1	2.5
Peroxide (160°C, 25 min)	DCP + ZnO + SA + PFR + PHMC	11.5	2.2
Radiation (D = 300 kGy)	PHMC + ZnO + ER + SA + DTBPMI	6.7	0.92
Thermoradiation (180°C, 5 min, D = 400 kGy)	PHMC + ZnO + ER + SA + DTBPMI	12.3	4.0

(b) cross-linking rate evaluated as ($\tau_{35} - \tau_5$), where τ_{35} is the time in which the sample viscosity became higher than the initial value by 35 units. Both these quantities were taken as average values from tests of no less than two samples.

Examination of the influence of the PHMC, ER, DTBPMI, and PFR concentrations on the properties of rubber stocks and vulcanizates revealed an interesting trend. In contrast to common sulfur-containing cross-linking systems, on adding 3–4 wt % PHMC as cross-linking agent, 6.0 wt % epoxy compounds, and DTBPMI, the cross-linking induction period increased and not decreased, which reflects the higher resistance of these stocks to scorching.

At the same time, an increase in the PHMC content from 3.0 to 5.0 wt % relative to elastomer significantly affected the vulcanization activity of the system.

Also, an increase in the PHMC concentration in the peroxide and radiation vulcanizates does not noticeably affect the Mooney viscosity. All these results show that the vulcanizing group given in Table 1 should be considered as optimal for the stocks based on modified SKN-40PVKh-30.

As judged from the cross-linking rate, the thermoradiation and thermal vulcanization with the examined systems are the most efficient for SKN-40PVKh-30.

The calculation of structural parameters of unfilled rubbers from the results of sol–gel analysis is based on the use of quantitative relationships of the statistical theory of the structure of polymer networks, which does not take into account the physical state of molecular chains. According to this theory, the network structure is determined by the molecular weight of the elastomer, functionality of the forming network points, and molecular-weight distribution of the polymer.

The use of sol–gel analysis for determining structural parameters of the vulcanization network formed under the action of sulfur, PHMC, ER, and DCP allows more comprehensive characterization of the properties of the vulcanizates obtained using cross-linking agents.

Table 3 shows that the total number of active chains ($1/M_c$) in vulcanizates obtained with the examined system increases in accordance with the activity of the system. Higher concentration of these chains in thermoradiation and thermal vulcanizates obtained with the examined cross-linking systems, as compared to the traditional and peroxide vulcanizates, suggests more efficient cross-linking in the presence of PHMC and ER. In the radiation vulcanizates, on the contrary, the three-dimensional network is less thick than in peroxide and other examined vulcanizates.

To confirm the assumptions concerning the reactions of SKN-40PVKh-30 and PHMC in the course of cross-linking, we made a number of additional experiments.

After heating and irradiation for various times, we determined the content of total and bound chlorine in the vulcanizate and the content of chlorine in the form of $ZnCl_2$ (in both cases, relative to the amount added with the cross-linking agent). From these quantities, we calculated the number of incorporated PHMC molecules per cross-link. The results are given in Table 3.

With all the vulcanizing systems tested, the total content of chlorine somewhat decreases with increasing vulcanization time, and the content of bound chlorine increases. In particular, the amount of chlorine that has reacted with ZnO to form $ZnCl_2$ increases. This fact suggests simultaneous occurrence of the chlorine elimination from cross-linking agent molecules, evolution of volatile chlorine compounds, reaction with ZnO to form $ZnCl_2$, and addition of the organochlorine molecules to the rubber molecules, up

Table 4. Physicomechanical properties of vulcanizates based on modified SKN-40PVKh-30 rubber

to complete binding of the cross-linking agent with the elastomer, as indicated by a decrease in the PHMC content in the toluene extract. At longer heating and irradiation, the concentration of cross-links in the bulk of the vulcanizate increases and the number of incorporated PHMC molecules per cross-link decreases.

It should be noted, however, that calculation of this parameter, as we have done and as is done commonly, does not afford an informative result. Indeed, in our calculations we neglect the fact that, after partial elimination of chlorine, the molecular weight of the fragments bound to the elastomer becomes appreciably lower than that of the PHMC molecule as a whole. Also, PHMC molecules apparently decompose into two fragments, each capable of reacting with the elastomer; this fact is not taken into account either. Therefore, the number of cross-linking agent molecules per cross-link may be appreciably underestimated.

The molecular structure of the rubber changes similarly in the course of heating and irradiation. However, the background substantially increases under irradiation, which prevents quantitative determinations. Comparison of the IR spectra of the vulcanizates prepared by thermal and thermoradiation treatment in the presence of PHMC + ER + ZnO allows the following conclusions. Some trends are similar in both cases. The intensities of the bands at 1440 cm^{-1}, assignable to the C–H bending vibrations in $–CH_2–$ groups [7], and at 1340 cm^{-1}, assignable to the out-of-plane C–H bending vibrations in *trans*-CH=CH groups [6], decrease. A new band appearing at about 2240 cm^{-1} is assigned by some authors to complexes formed by metal chlorides with the –C≡N groups of the rubber [15]. The band at 740 cm^{-1} belonging to C–C vibrations noticeably decreases in the intensity [14]. This fact suggests that the cross-linking agent eliminates chlorine under the action of elevated temperatures and irradiation; this fact is apparently responsible for a decrease in the intensity of the band at 1230 cm^{-1}. Hence, addition of PHMC and ER to SKN-40PVKh-30-based stocks appreciably affects the cross-linking under various treatment modes.

It is known that the optimal structure of the vulcanization network of acrylonitrile rubbers, combining sufficient resistance to petroleum products, aggressive media, and thermal oxidation with the high performance under repeated strains and shear, should contain cross-links of different types, both polysulfide and those containing small amounts of sulfur or no sulfur, including C–C bonds [4].

Therefore, the physicomechanical properties of rubbers based on SKN-40PVKh-30 are of interest (Table 4). We found that PHMC and ER are reactive in all the vulcanization modes, especially in the presence of DTBPMI.

The radiation vulcanizates are inferior to thermoradiation vulcanizates in the strength but surpass thermal vulcanizates in the resistance to heat and solvents.

To elucidate the effect of temperature and service

III	72	66	62	54	50

* Medium: (I) seawater, (II) oil-bearing fluid, and (III) clay suspension.

conditions on the EM properties, we tested the EM samples at 150°C in aggressive media (Table 5). We found that the experimental EMs containing PHMC, ER, and DTBPMI, compared to the traditional (sulfur) vulcanizates, show lower swelling and residual compression strain and higher thermal aging coefficient in seawater and oil-bearing fluids. The tensile strength of the radiation vulcanizates after the contact with the aggressive medium decreased to a greater extent than that of the thermal and thermoradiation vulcanizates.

Thus, SKN-40PVKh-30-based thermal vulcanizates prepared by the radiation-chemical process in the presence of PHMC, ER, and DTBPMI surpass the vulcanizates prepared by the traditional procedures (sulfur, peroxide) in the resistance to thermal aging and in the dynamic endurance at repeated extension in aggressive media. All the examined stocks and cross-linking agents were recommended for use in EM formulations for fabricating sealing parts resistant to aggressive media for petroleum industry, using the radiation-chemical technology.

CONCLUSIONS

(1) The action of PHMC as a cross-linking agent in thermal, peroxide, radiation, and thermoradiation vulcanization of SKN-40PVKh-30 rubber in the presence of certain organic compounds (ER, PFR, DTBPMI) was studied.

(2) Structural changes occurring in SKN-40PVKh-30-based vulcanizates under the action of elevated temperatures and irradiation were examined.

(3) The IR spectra and data on the intrinsic viscosity, on the rates of reactions involving PHMC and the examined organic compounds, and on the structural parameters of the vulcanization networks allowed certain conclusions on the nature of the vulcanizing effect of the cross-linking systems tested and on their influence on the rheological and physicomechanical properties of the vulcanizates.

(4) The elastomeric materials prepared by the thermochemical and thermoradiation procedures are characterized by a medium ultimate strength and increased thermal aging coefficient, accumulation of residual strain, and weight gain; they surpass sulfur vulcanizates in the resistance to aggressive media.

(5) A formulation based on modified SKN-40PVKh-30 rubber and a procedure based on radiation-chemical technology were developed. The elastomeric materials resistant to aggressive media were recommended for use in oil well drilling.

Density and Viscosity of Sodium Phosphate Solutions

M. I. Nikandrov and Yu. I. Mikhailov

Dzerzhinsk Branch, Nizhni Novgorod State University, Dzerzhinsk, Nizhni Novgorod oblast, Russia

Received December 6, 2004

Abstract—The density and viscosity of sodium phosphate solutions with a concentration of 30–41.6 wt % at 70–100°C were determined.

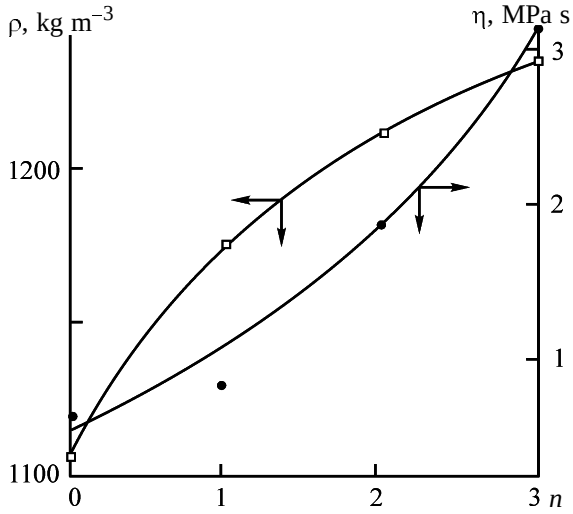
In preparation of $Na_2HPO_4 \cdot 7H_2O$ and $Na_3PO_4 \cdot 10H_2O$, the polythermal precipitation is performed from more concentrated solutions than in preparation of the dodecahydrates. Data on properties of sodium phosphate solutions are available for concentration of up to 26–30 wt % [1, 2]; data on the properties of more concentrated solutions, which are necessary for process calculations and choice of the equipment, are lacking.

In this study we determined pycnometrically the density of the binary solutions of sodium hydrophosphate and orthophosphate and of mutual solutions of sodium carbonate and hydrophosphate at 70–100°C and measured their viscosity with a VPZh-3 viscometer (see table). Solutions were prepared from the analytically pure grade salts.

The results obtained show that the density of the sodium phosphate solutions increases with the number of sodium atoms in the phosphate formula unit (see figure). For example, the density of the solution at 80°C changes from 1105 kg m^{-3} (phosphoric acid) to 1172 (NaH_2PO_4), 1220 (Na_2HPO_4), and 1427 kg m^{-3} (Na_3PO_4). This is due to the fact that increasing fraction of sodium ions, and, consequently, charge of the phosphate ions in the solution causes a corresponding decrease in the fraction of "free" water molecules and thus results in the ordering of the solution structure.

The fact that the rate of the density growth somewhat decreases as the number of substituted hydrogen ions in the phosphate increases is likely due to partial occurrence of the reactions

$$Na_3PO_4 + H_2O \rightleftarrows Na_2HPO_4 + NaOH,$$



$$Na_2HPO_4 + H_2O \rightleftarrows NaH_2PO_4 + NaOH,$$

altering the true composition of the solution.

Density ρ and viscosity η of the solutions at 80°C as functions of the number of sodium atoms in the phosphate formula unit *n*.

The viscosity of the phosphate solutions as a function of temperature in the coordinates $\log\eta - 1/T$ is a linear dependence, which allows determination of the entropy of viscous flow (94.6 J mol^{-1} K^{-1} for Na_2HPO_4 solution and 97.1 J mol^{-1} K^{-1} for Na_3PO_4 solution). The activation energies of the viscous flow are 16.7 and 16.1 kJ mol^{-1}, respectively.

The viscosity of the solutions with the same mole fractions of phosphates (2.4–2.6 kmol m^{-3}) increases also proportionally to the number of sodium atoms in the phosphate. It should be noted that the viscosities of NaH_2PO_4 solutions and phosphoric acid differ only slightly.

The results obtained will be useful for engineering calculations in the sodium phosphate technology.

Thermodynamics of Fuel Combustion at Tuyeres of a Blast Furnace

A. I. Demidov and I. A. Markelov

St. Petersburg State Polytechnic University, St. Petersburg, Russia

Received June 16, 2005

Abstract—A thermodynamic analysis of fuel (carbon and methane) combustion at tuyeres of a blast furnace is made.

As is known [1], coal coke and natural gas are used as fuel in manufacture of cast iron. The combustion of coke and natural gas in the tuyere zone of a blast furnace strongly affects the entire run of a melting in a blast furnace and is highly important for control over the operation of a blast furnace. Methane, the main component of natural gas, virtually completely decomposes at temperatures exceeding 1273 K into carbon and hydrogen [2]:

$$CH_4 = C + 2H_2. \quad (1)$$

The reaction space at tuyeres of a blast furnace can be conventionally divided into two zones, oxidative and reductive. In combustion of carbon and methane in the oxidative zone, the following reactions are possible [3, 4]:

$$2C + O_2 = 2CO, \quad (2)$$

$$C + O_2 = CO_2, \quad (3)$$

$$2CO + O_2 = 2CO_2, \quad (4)$$

$$CH_4 + 3/2O_2 = CO + 2H_2O, \quad (5)$$

$$CH_4 + 2O_2 = CO_2 + 2H_2O, \quad (6)$$

$$CH_4 + 1/2O_2 = CO + 2H_2, \quad (7)$$

$$CH_4 + O_2 = CO_2 + 2H_2, \quad (8)$$

$$H_2 + 1/2O_2 = H_2O. \quad (9)$$

The combustion of carbon and methane in the reductive zone is accompanied by reactions of carbon and methane with carbon(IV) oxide and water in a gaseous state:

$$C + CO_2 = 2CO, \quad (10)$$

$$CH_4 + CO_2 = 2CO + 2H_2, \quad (11)$$

$$C + H_2O = CO + H_2, \quad (12)$$

$$CH_4 + H_2O = CO + 3H_2. \quad (13)$$

The forming carbon(II) oxide undergoes conversion:

$$CO + H_2O = CO_2 + H_2. \quad (14)$$

Here we made a comparative analysis of the standard Gibbs energies of the reactions of fuel combustion at tuyeres of a blast furnace. The standard Gibbs energies of the reactions were calculated per mole of atoms of the starting substances, as it was done in [5]. The input data for calculating the standard Gibbs energies of the reactions were taken from the reference book [6]. The results of the calculations are presented in Tables 1, 2 and Figs. 1, 2.

As seen in Fig. 1, the largest negative changes in the standard Gibbs energy in the oxidative zone at

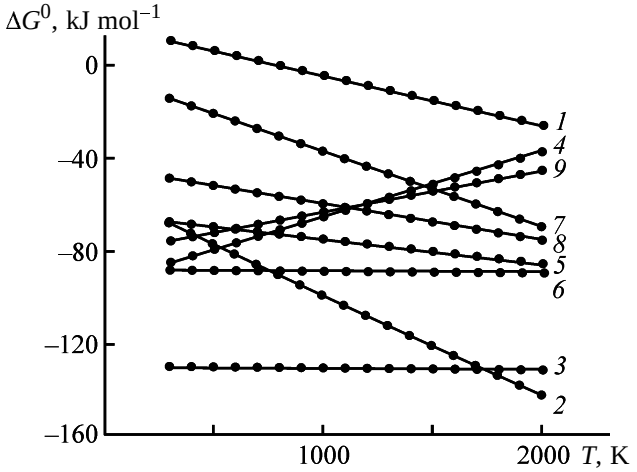

Fig. 1. Standard Gibbs energies ΔG^0 of reactions (1)–(9) vs. temperature T. Digits at curves are numbers of reactions; the same for Fig. 2.

high temperatures are characteristic of reactions (2) and (3). Straight line *2* [reaction (2)] intersects straight line *3* [reaction (3)] at 1750 K. To the right of the intersection point, straight line *2* runs lower than straight line *3*. This means that the chemical affinity of carbon for oxygen under the conditions of CO formation is the highest at high temperatures (above 1750 K). As temperature increases, the equilibria of reactions (4) and (9) are shifted toward formation of carbon(II) oxide and oxygen, and hydrogen and oxygen.

The standard Gibbs energy of the methane dissociation becomes negative at temperatures above 800 K, i.e., the equilibrium of reaction (1) increasingly shifts toward formation of carbon and hydrogen as temperature becomes higher. Of all the reactions of methane oxidation [reactions (5)–(8)], reaction (6), which yields carbon(IV) oxide and water, has the most negative values of the standard Gibbs energy. At low temperatures (< 700 K), the standard Gibbs energy of reaction (6) becomes even more negative than thate for reaction (2).

The results obtained in calculating the standard Gibbs energies of the reactions of carbon and methane combustion in the reductive zone of the furnace [reactions (10)–(13)] indicate that the values of ΔG^0 for

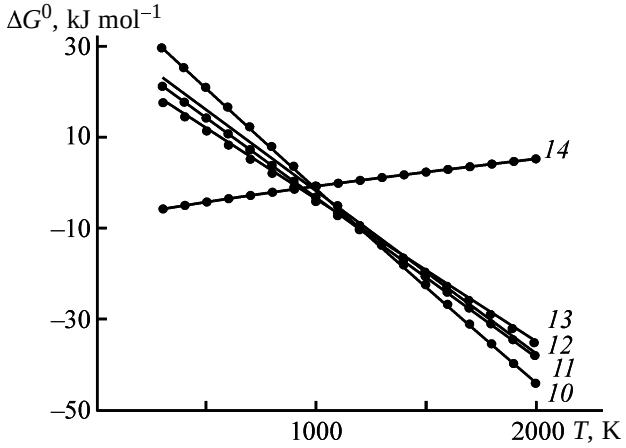

Fig. 2. Standard Gibbs energies ΔG^0 of reactions (10)–(14) vs. temperature T.

these reactions are close. At temperatures exceeding 1000 K, reactions (10)–(13) have negative standard Gibbs energies. As temperature becomes higher, the equilibria of these reactions increasingly shift toward formation of carbon(II) oxide and hydrogen. At high temperatures, reaction (14) of carbon(II) oxide conversion has positive standard Gibbs energy, i.e., gives a low yield of the reaction product [7].

Thus, thermodynamic analysis of fuel (carbon and methane) combustion at tuyeres of a blasting furnace shows that carbon(II) oxide and hydrogen must predominate in gases leaving the furnace. The experiments carried out in [8] confirm this conclusion. As a result of fuel combustion in the tuyere zone of the blasting furnace, the temperature of the gas reaches 2300 K. In this case, the content of methane and water vapor in the gas decreases nearly to zero. Carbon(II) oxide and hydrogen predominate in the reductive zone of the blasting furnace.

CONCLUSION

Thermodynamic analysis of fuel (carbon and methane) combustion at tuyeres of a blasting furnace and results of experimental studies show that carbon(II) oxide and hydrogen predominate in gases leaving the furnace.

Reaction of Calcium Hydroxide with the Oxide–Sulfate Fraction of Lead Battery Scrap

A. G. Morachevskii, Yu. S. Kuznetsova, and O. A. Kal'ko

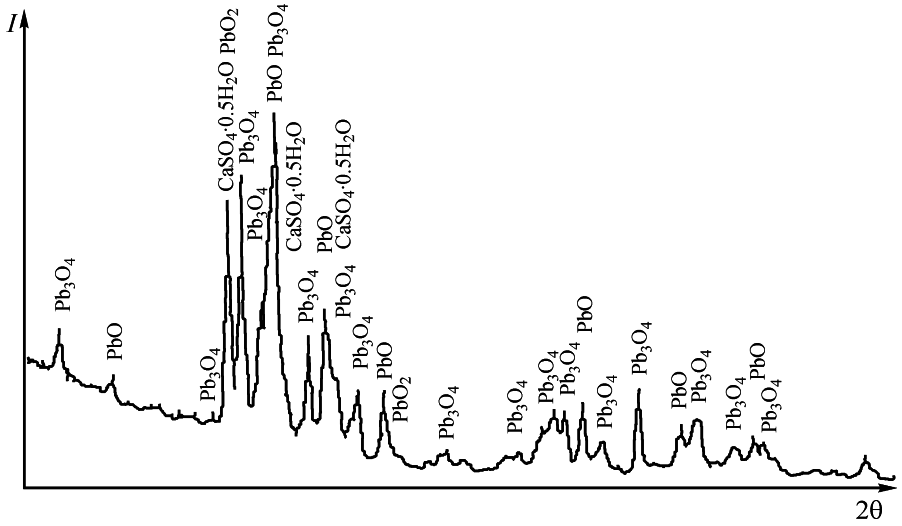
Abstract—The reaction of oxide–sulfate fraction of lead battery scrap with an aqueous suspension of calcium hydroxide was studied experimentally.

The up-to-date technologies intended for recycling lead battery scrap involve separation of scrap onto metallic, oxide–sulfate, and organic fractions and their subsequent reprocessing [1, 2]. In this utilization procedure, extraction of lead from the oxide–sulfate fraction into which the active masses of the positive and negative plates pass is an important problem. After washing with water and drying, the oxide–sulfate fraction contains, on the average, wt %: Pb 73.5, Sb up to 1.3, As up to 0.04, Cu 0.1, Fe 0.05, and SO_4^{2-} 16.7 (the remainder oxygen) [3]. A study of the mineralogical composition revealed PbO_2 and $PbSO_4$ as major components [3]. X-ray diffraction analysis also revealed the presence of PbO_2 (plattnerite, tetragonal modification) and $PbSO_4$ (anglesite) in comparable concentrations. According to the Rusin and Dasoyan's study [5], compounds of even more complex composition, $3PbO \cdot PbSO_4 \cdot H_2O$ and $4PbO \cdot PbSO_4$, can also be present in active masses.

Taking into account that lead oxides, unlike sulfates, are fairly easily reduced with carbon or carbon-containing materials at 720–740°C, it is reasonable to transform $PbSO_4$ into the carbonate, hydroxide, or hydrocarbonate, which decompose on heating with formation of lead monoxide PbO [6, 7]. The environmental advantages of this operation are doubtless. In a number of flowsheets at plants beyond Russia, sodium carbonate is mainly used for desulfation. As a result, cerussite $PbCO_3$ and relatively small amount of hydrocerussite $2PbCO_3 \cdot Pb(OH)_2$ are formed in the solid phase [4]. The possible materials for desulfation are also NaOH and K_2CO_3 [9].



The desulfation is based on different solubility products (SPs) of lead compounds. According to handbook [10], SP of $PbSO_4$ at 25°C is 1.58×10^{-8}. At the same time, the SPs of the desulfation products are considerably smaller: 7.41×10^{-14} for $PbCO_3$ and 1.99×10^{-20} for $Pb(OH)_2$. According to an approximate estimate, SP for $2PbCO_3 \cdot Pb(OH)_2$ is 3.5×10^{-46} [11].

Along with sodium or potassium carbonate and sodium hydrocarbonate, a considerably cheaper chemical, calcium hydroxide, can be used for converting lead into a compound more convenient for the reduction [12, 13]. In this study we examined the reaction of an aqueous suspension of $Ca(OH)_2$ (SP at

X-ray diffraction pattern of the products of reaction of oxide–sulfate fraction with aqueous suspension of calcium hydroxide, taken after keeping for 1 h at 480°C. (*I*) Reflection intensity and (2θ) Bragg angle.

25°C 7.94×10^{-6}) with the oxide–sulfate fraction from utilization of lead battery scrap. The solution was prepared from chemically pure grade CaO. The initial solution contained 0.025 g cm^{-3} CaO. pH of the initial solutions was within 12.2–12.4.

The necessary amount of CaO was calculated by the equation

$$PbSO_4 + Ca(OH)_2 + 2H_2O = Pb(OH)_2 + CaSO_4 \cdot H_2O.$$

In the experiments, CaO was in 10% excess relative to the calculated value.

The solid-to-liquid ratio (s : l) was 1 : 4 and temperature, 50°C. The pH was recorded continuously. The content of sulfate ions and antimony in the oxide–sulfate mass (50 g) was determined. After the experiment was complete, the precipitate was filtered off, washed, and dried at 130–140°C for 2 h. The reaction of the active mass with calcium hydroxide essentially differs from its desulfation with alkali metal carbonate or hydrocarbonate. The reaction products, $Pb(OH)_2$ and $CaSO_4 \cdot 2H_2O$, are in the solid phase, since SP of gypsum at 50°C is 3.89×10^{-5} [10]. The method is based on the fact that heating to the reduction temperature (720–740°C) yields PbO and $CaSO_4$ in the solid phase. With a NaCl–KCl mixture as flux, a rather readily fusible mixture is formed (equiv. %): KCl 38.5, $CaSO_4$ 19, $(NaCl)_2$ 42.5, melting point 605°C [15, 15]. The presence of a liquid flux facilitates the main reaction, reduction of lead(II) oxide.

A series of the experiments showed that the solution pH is stabilized at a level of 8.4–8.5 even within 20 min after the aqueous suspension starts to react with the solid phase, which indicates that the process is complete. Typical experimental results are presented in the table.

The presence of lead ions in the filtrate is associated with the relatively high pH values and amphoteric nature of lead hydroxide. The neutralization of the solution with sulfuric acid results in the precipitation of Pb^{2+} ions. In the process, antimony from the active mass is not noticeably dissolved. The X-ray diffraction analysis of the mass revealed the presence of $CaSO_4 \cdot 2H_2O$, PbO, and Pb_3O_4; $Pb(OH)_2$ being formed was amorphous. Only lead oxides, mainly Pb_3O_4, and $CaSO_4 \cdot 2H_2O$ were detected after keeping at 480°C for 1 h (see figure).

The reaction of CaO aqueous suspension with the oxide–sulfate fraction of lead battery scrap allows difficultly reducible lead(II) sulfate to be converted into lead hydroxide or lead monoxide PbO as the final product. PbO is reduced with carbon or carbon materials in the solid phase at 720–740°C.

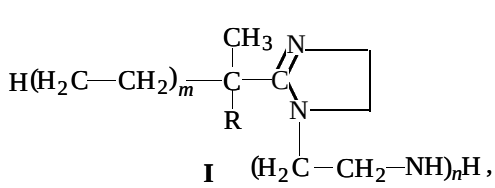
Effect of Substituents in 1,2-Disubstituted Imidazolines on Properties of Concrete Mixtures

V. V. Lisitskii, I. E. Alekhina, and N. A. Amineva

Bashkir State University, Ufa, Bashkortostan, Russia

Received March 30, 2005

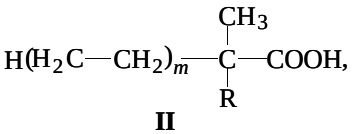
Abstract—Physicochemical properties of concrete mixtures and concretes was studied as influenced by the structure of salts of 1,2-disubstituted imidazolines with C_1–C_4 monocarboxylic saturated acids.



The products of condensation of higher carboxylic acids and polyethylenepolyamines are widely used in production of building materials. The hydrophobic properties of concrete mixtures are improved by modifying agents prepared by condensation of synthetic carboxylic acids with polyethylenepolyamines [1, 2]. The strength properties are enhanced by the products of reaction of 1-polyethylenepolyaminoethyl-2-alkyl-(C_6–C_{25})-2-imidazoline with orthophosphoric, sulfuric, or acetic acid [3–5]. *N*,*N*-Bis(2-hydroxyethyl)-2-alkyl-2-imidazoline [6] or polyamidoimidazoline resin [7] decrease water adsorption and permeability and increase the resistance of the concrete.

However, the products of cyclocondensation of linear carboxylic acids with polyethylenepolyamines are hydrolytically unstable (in contrast to 1,2-disubstituted imidazolines containing branched substituents in position 2 of the imidazoline ring [8–10]), and thus they are inefficient.

In this study we examined the mobility and water separation of concrete mixtures and strength properties of the concrete monolith as influenced by the nature of substituents in positions 1 and 2 of the imidazoline ring.



EXPERIMENTAL

1,2-Disubstituted imidazolines of the general formula

I

where R is ethyl, butyl; n = 1–3; m = 0–22, were prepared by heating in a nitrogen atmosphere of α,α'-branched monocarboxylic saturated acids of the general formula

II

where R is ethyl, butyl; n = 1–3; m = 0–22, with diethylenetriamine (DETA), triethylenetetramine (TETA), and polyethylenepolyamine (PEPA) at 280 ± 10°C for 10–12 h at the acid : polyamine molar ratio of 1 : 2 with subsequent vacuum treatment at 180–200°C. The salts of 1,2-disubstituted imidazolines (**I**) with formic, acetic, propionic, and butyric acids were prepared by heating of the equimolar amounts of imidazoline and acid in ethanol at 60–78°C for 1–2 h, followed by subsequent evaporation of solvents and vacuum drying of the salt at 80–90°C on a 350 R rotary evaporator (Poland).

The concrete mixture was prepared from a Portland cement and carbonate stone with coarseness of 5–10 and 10–20 mm (1 : 1.5 weight ratio). The salt was added to the concrete mixture with water. The concrete samples were hardened in the 4 + 3 + 6 + 2 mode (preliminary setting + heating + isothermal heating at 80 ± 3°C + cooling). The properties of the concrete mixtures and concrete monoliths were evaluated by the standard procedures.

In all the cases, addition of the salts of 1,2-disubstituted imidazolines with C_1–C_4 carboxylic acids increases their mobility and decreases the water separation (Table 1); the compression strength also increases.

It should be noted that the length of the C_1–C_4 alkyl substituent of saturated monocarboxylic acids does not affect the properties of the concrete mixtures. This indicates that the performance of the additive is determined by the structure of 1,2-disubstituted imidazoline. Our experimental results show that the increase in the length of the aminoethyl radical in position 1 of the imidazoline ring only slightly changes the mobility of concrete mixtures and water separation and does not noticeably affect the strength properties of the concrete monolith (Table 2).

With increasing length of alkyl substituents in position 2 of the imidazoline ring, the mobility of concrete mixtures sharply increases, whereas their water separation decreases (Table 2). The strength properties of the concrete also increase. Thus, the salts of 1,2-disubstituted imidazolines **I** with C_1–C_4 saturated monocarboxylic acids are efficient cationic surfactants, which, being adsorbed on the surface of Portland cement clinker, exert the plasticizing effect. Steaming of the concrete mixtures causes degradation of the concrete–additive complexes, but the rates of formation of hydroaluminates and hydrosilicates do not decrease, and the strength properties of the concrete are preserved.

It should be noted that addition of salts of 1,2-disubstituted imidazolines increases the resistance of concretes with respect to aggressive solutions that cause leach corrosion (Table 2).

CONCLUSION

(1) Salts of 1,2-disubstituted imidazolines with C_1–C_4 saturated monocarboxylic acids, when added to a concrete mixture, increase its mobility and decrease the water separation, which allows transportation of the concrete mixture at long distances without deterioration of its quality.

(2) Longer alkyl substituents in position 2 of the imidazoline ring strongly enhance the plasticizing effect of the salts of 1,2-disubstituted imidazolines.

Abstract—The influence of the initiator on the copolymerization of acrylic acid with a disubstituted derivative of monoethanolamine vinyl ether and chloranil was examined.

The structure and properties of copolymers depend on the synthesis conditions, in particular, on the initiator used [1]. Numerous studies concern the relative activity of various monomers in copolymerization, but the effect of initiator on these parameters is considered only in a few of them [2, 3]. In this connection, it is interesting to study the reactivity of a new monomer derived from monoethanolamine vinyl ether and chloranil (MEAVE–CA–MEAVE) [4] in the reaction with acrylic acid (AA) in the presence of various initiators. The copolymers thus obtained exhibit redox, complexing, and ion-exchange properties and show promise as ion exchangers.

In this study we examined how the initiator affects the relative activity of the monomers and the composition and microstructure of the copolymers in the copolymerization of MEAVE–CA–MEAVE with acrylic acid.

EXPERIMENTAL

MEAVE–CA–MEAVE was prepared as described in [4]. Dimethylformamide (DMF) was purified by the standard procedure [5]. The initiators, azobis(isobutyronitrile) (AIBN, mp 102–103°C) and potassium persulfate (PP), were recrystallized from absolute methanol and water, respectively [6].

The copolymerization was performed by an ampule method. The starting components were loaded in one portion. The mixture contained 6 wt % initiator (AIBN or PP) relative to the sum of the monomers. The reaction was performed at 78°C. The MEAVE–CA–MEAVE concentration was 20 g l^{-1}. The solvent was DMF in the case of AIBN and DMF : water (2 : 3 by volume) in the case of PP. The molar ratio of the monomers was varied from 20 : 80 to 80 : 20. The conversion was estimated from the concentrations of the unchanged monomers, which were determined polarographically (MEAVE–CA–MEAVE) and by titration (AA).

The polarograms were taken in 25% DMF, with phosphate buffer solution (pH 7.4) as supporting electrolyte, at 25 ± 0.5°C on a PU-1 polarograph with a mercury dropping electrode (open-circuit capillary characteristic $m^{2/3}t^{1/6}$ = 4.38 $mg^{2/3}\,s^{-1/2}$. As reference electrode we used saturated calomel electrode. The solutions were deoxygenated by bubbling with argon.

The polymer structure is primarily determined by the initiation procedure and by chain propagation and termination reactions [1]. The initiation affects the copolymer composition and the configuration of monomeric units. The choice of the initiator is most frequently governed by its solubility in the monomer or in the solvent and by the temperature at which the required rate of generation of free radicals can be attained. The initiators usually used for preparing copolymers of vinyl ethers with styrene and acrylic and other monomers are peroxides and azo compounds [7]. In copolymerization of MEAVE–CA–MEAVE with acrylic acid, we used AIBN and PP inducing the polymerization by the free-radical mechanism.

Using the Mayo–Lewis integral equation of the copolymer composition [1], we calculated the copoly-

Table 1. Copolymerization constants and Alfrey–Price parameters for the system MEAVE–CA–MEAVE (M_1) : AA (M_2) in the presence of various initiators

Constant, parameter	Initiator	
	AIBN	PP
P	–0.52	–0.53
r_1	0.58	1.34
r_2	1.80	0.36
r_1r_2	1.044	0.482
$1/r_1$	1.72	0.75
$1/r_2$	0.56	2.78
Q_1	0.59	1.65
e_1	0.56	–0.08
Δe	0.21	0.85

merization constants r_1 and r_2 (the coefficient p was determined by the Shtraikhman method [8]), and from these quantities we determined the Alfrey–Price parameters Q_1 and e_1 [2] for MEAVE–CA–MEAVE (for AA, Q_2 = 1.15, e_2 = 0.77). The results are given in Table 1.

Comparison of the copolymerization constants, $1/r_2$, and Q_1 shows that MEAVE–CA–MEAVE is more active in the presence of PP than with AIBN. With PP, the copolymers of the more regular structure are formed, as indicated by the value of r_1r_2 = 0.482.

The microstructure of the copolymers largely depends on the inital monomer ratio and their reactivity, as shown above, depends on the initiator used. From the copolymerization constants and data on the composition of the monomer mixture, we calculated the probabilities of formation of various diads $f_{M_1–M_1}$, $f_{M_1–M_2}$, $f_{M_2–M_2}$, the statistical mean block lengths in the copolymer chains L_{M_1} and L_{M_2}, and the Harwood parameter of the block structure R [9, 10] with both initiators (Table 2).

Table 2 shows that, at any MEAVE–CA–MEAVE content in the starting mixture, the copolymers obtained in the presence of PP are enriched in units of this monomer, and those obtained with AIBN, in units of acrylic acid. Copolymers with more regular alternation of the monomeric units in the macromolecular chain are formed at MEAVE–CA–MEAVE : AA molar ratios of 58 : 42 (AIBN) or 40 : 60 (PP). At these ratios, the Harwood parameter reaches a maximum, which corresponds to the presence of short monomer blocks in the copolymers.

One of the factors responsible for major differences in the behavior of MEAVE–CA–MEAVE in the presence of AIBN and PP may be formation of HSO_4^- ions [11], along with $OH^\bullet$ radicals, in decomposition of PP, as it is known that acids accelerate polymerization of vinyl ethers [12]. Another factor may be different rates of decomposition of AIBN and PP. In particular, it is known [13] that PP in solutions of quaternary ammonium salts decomposes even at room temperature.

CONCLUSIONS

(1) Copolymerization of a disubstituted derivative of monoethanolamine vinyl ether and chloranil with acrylic acid was studied in the presence of two differ-

ent initiators: azobis(isobutyronitrile) and potassium persulfate. In the presence of potassium persulfate initiator, the activity of the redox monomer is higher than with azobis(isobutyronitrile).

(2) The microstructure of the copolymers can be controlled not only by varying the monomer ratio in the initial mixture but also by using different initiators. Potassium persulfate not only enhances the reactivity of the disubstituted derivative of monoethanolamine vinyl ether and chloranil, but also ensures formation of more compositionally uniform copolymers.

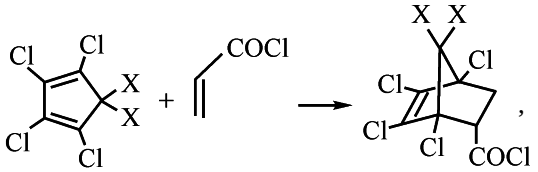
BRIEF COMMUNICATIONS

Acetylenic Esters of Polychlorobicyclo[2.2.1]hept-2-ene-5-carboxylic Acids

E. G. Mamedov



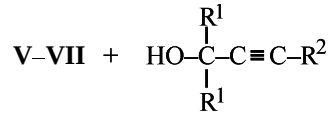
Institute of Petrochemical Processes, National Academy of Sciences of Azerbaijan, Baku, Azerbaijan

Received June 18, 2005

Abstract—Acetylenic esters of polychlorobicyclo[2.2.1]hept-2-ene-5-carboxylic acids were prepared from the corresponding acid chlorides and acetylenic alcohols.

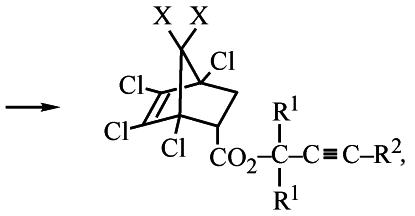
Polyhalonorbornenes are widely used in production of synthetic polyester resins with enhanced heat and flame resistance, epoxy resins, and additives to lubricating oils, and also as starting compounds in organic synthesis [1–3]. They exhibit fungicide, insecticide, and hebricide power and other kinds of biological activity. Modification with reactive acetylenic fragments enhances these properties. Interest in polyhalonorbornene derivatives is steadily growing, and new compounds of this class are being synthesized [4, 5]. The presence of heavy halogen atoms extends the possibilities of structural studies of these compounds by IR and NMR spectroscopy and X-ray diffraction analysis [6–8].

Acetylenic esters of bicyclo[2.2.1]hept-2-ene-5-carboxylic acids were studied in [9–11]. In this study we developed preparation procedures and examined the structures of acetylenic esters of polychlorinated norbornenecarboxylic acids. These esters are prepared by the reactions of polychlorobicyclo[2.2.1]hept-2-ene-5-carboxylic acid chlorides with acetylenic alcohols. The starting chlorides **V**–**VII** were prepared by [4+2]-cycloaddition of chlorinated cyclopentadienes **I**–**III** to acryloyl chloride **IV**:



I–**III** **IV** **V**–**VII**

where X = Cl (**I**, **V**), H (**II**, **VI**), OCH_3 (**III**, **VII**).



The condensation of **I**–**III** with **IV** was performed at 100–150°C for 10–15 h. The best results were obtained at 140°C, reaction time 10 h. Replacement of the geminal chlorine atoms by methoxy groups and hydrogen atoms favorably affects the reaction course; the yield of **V**–**VII** increases (see table).

The ^{1}H NMR spectra show that compounds **V**–**VII** prepared under these conditions are exclusively *endo* isomers.

Reactions of acid chlorides **V**–**VII** with alkynes **VIII**–**X** yielded the corresponding acetylenic esters of polychlorinated norbornenecarboxylic acids, **XI**–**XIX**:

VIII–**X**

XI–**XIX**

where $R^1 = R^2 = H$ (**VIII**); $R^1 = CH_3$, $R^2 = H$ (**IX**); $R^1 = CH_3$, $R^2 = CH{=}CH_2$ (**X**); $R^1 = R^2 = H$, X = Cl (**XI**); $R^1 = CH_3$, $R^2 = H$, X = Cl (**XII**); $R^1 = CH_3$, $R^2 = CH{=}CH_2$, X = Cl (**XIII**); $R^1 = R^2 = X = H$ (**XIV**); $R^1 = CH_3$, $R^2 = X = H$ (**XV**); $R^1 = CH_3$, $R^2 = CH{=}CH_2$, X = H (**XVI**); $R^1 = R^2 = H$, X = OCH_3 (**XVII**); $R^1 = CH_3$, $R^2 = H$, X = OCH_3 (**XVIII**); $R^1 = CH_3$, $R^2 = CH{=}CH_2$, X = OCH_3 (**XIX**).

The reaction was performed in organic solvents (diethyl ether, benzene) in the presence of tertiary amines (triethylamine, pyridine).

The use of chlorides **V**–**VII** as starting compounds allows preparation of esters **XI**–**XIX** of high purity

* **V**: d_4^{20} = 1.7974, n_D^{20} = 1.5620; **VI:** d_4^{20} = 1.6809, n_D^{20} = 1.5415; **VII**: d_4^{20} = 1.6989, n_D^{20} = 1.5460.

in almost quantitative yields. With propargyl alcohol **VIII**, the reaction occurs at room temperature with the heat release within 0.5 h; with alcohols **IX** and **X**, the reaction requires heating at 80°C for 5 h. In all the cases, the configuration of the starting acid chlorides **V**–**VII** remains unchanged, and the resulting esters are exclusively *endo* isomers. The structures of the compounds prepared were proved by IR and ^{1}H NMR spectroscopy and by elemental analysis (see table).

In the ^{1}H NMR spectra of **V**–**VII** and **XI**–**XIX**, the H^6_{endo} and H^6_{exo} protons give signals at 2.15–2.10 and 2.35–2.40 ppm, respectively, with the geminal coupling constant $J_{6,6}$ = –12–13 Hz and vicinal coupling constant $J_{5,6}$ = 4.50–4.60, $J_{5,6}$ = 6.10–6.20 Hz:

In the ^{1}H NMR spectra of **VII** and **XVII**–**XIX**, the protons of geminal OCH_3 groups give two singlets at 3.65–3.70 ppm.

The IR spectra of **V**–**VII** and **XI**–**XIX** contain characteristic bands at 1730 (C=O), 1620–1630 (C=C), and 750–760 cm^{-1} (C–Cl).

EXPERIMENTAL

The IR spectra were recorded on a UR-20 spectrometer, and the ^{1}H NMR spectra, on a Tesla BS-48 spectrometer (80 MHz) in CCl_4, internal reference TMS.

Hexachlorocyclopentadiene **I** was prepared according to [12], bp 109–111°C (11 mm Hg), n_D^{20} = 1.5654, d_4^{20} = 1.7210 {published data [12]: bp 110–111°C (11 mm Hg), n_D^{20} = 1.5652, d_4^{20} = 1.7213}. Tetrachlorocyclopentadiene **II** was prepared from hexachlorocyclopentadiene [13], mp 62–63°C (from petroleum ether). Dimethoxytetrachlorocyclopentadiene **III** was prepared from hexachlorocyclopentadiene [14], bp 109–111°C (11 mm Hg), n_D^{20} = 1.5268, d_4^{20} = 1.5012 {published data [14]: bp 108–110°C (11 mm Hg), n_D^{20} = 1.5288, d_4^{20} = 1.5010}. Acryloyl chloride **IV** was prepared according to [15], bp 75–76°C.

Polychlorobicyclo[2.2.1]hept-2-ene-5-carboxylic acid chlorides V–VII. A mixture of 0.05 mol of **I**–**III** and 0.05 mol of **IV**, containing 0.01 g of hydroquinone, was heated in a sealed ampule at 140°C for 10 h. The products were isolated by vacuum distillation.

Polychlorobicyclo[2.2.1]hept-2-ene-5-carboxylic acid propargyl esters XI, XIV, and XVII. To a stirred solution of 0.1 mol of propargyl alcohol **VIII** and 0.1 mol of triethylamine in 50 mol of absolute ether, we added dropwise with stirring 0.1 mol of **V**–**VII** at room temperature. An exothermic reaction was observed. After the reaction completion, the ammonium salt was filtered off, the solvent was distilled off, and the residue was recrystallized from *n*-heptane.

Polychlorobicyclo[2.2.1]hept-2-ene-5-carboxylic acid acetylenic esters XII, XIII, XV, XVI, XVIII, and XIX. A solution of 0.05 mol of **V**–**VII** in 15 ml

of benzene was added dropwise with stirring at 80°C to a solution of 0.05 mol of triethylamine in 15 ml of benzene. The mixture was stirred at 80°C for 5 h, after which it was worked up as described above.

CONCLUSIONS

(1) Acetylenic esters of polychlorinated bicyclo-[2.2.1]hept-2-ene-5-carboxylic acids were prepared in almost quantitative yields (87–92%) by reactions of acetylenic alcohols with the corresponding acid chlorides. The products are exclusively *endo* isomers.

(2) The primary alcohol reacts with the acid chlorides at 20°C within 0.5 h, and the tertiary alcohols, at 80°C.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

On the Dissolution Mechanism of Powdered Noble Metals in Cyanide Solutions under Aerobic and Anaerobic Conditions

Abstract—A possible mechanism of anaerobic dissolution of powdered palladium and gold is suggested.

At present, the main technique used to recover gold and silver from ores is their treatment with aqueous solutions of sodium cyanide in the presence of atmospheric oxygen. The world's output of gold recovered by this method in the early 1990s was as large as 70% [1]. This hydrometallurgical technique has been well developed and described in detail in the literature [1–6].

It is believed that silver and gold (M) dissolve in cyanide solutions in the presence of an oxidizing agent, atmospheric oxygen, in accordance with Elsner's equation

$$4M + 8CN^- + O_2 + 2H_2O = 4[M(CN)_2]^- + 4OH^-. \quad (1)$$

At the same time, the classical electrochemical mechanism of gold dissolution includes an anodic (2) and a cathodic (3) processes at the surface of a metallic particle and is described by the overall Bodlander equation (4):

$$Au + 2CN^- = [Au(CN)_2]^- + e, \quad (2)$$

$$O_2 + 2H_2O + 2e = H_2O_2 + 2OH^-, \quad (3)$$

$$2Au + 4CN^- + O_2 + 2H_2O = 2[Au(CN)_2]^- + H_2O_2 + 2OH^-. \quad (4)$$

It follows from Eqs. (1)–(4) that presence of oxygen in the reaction system is a necessary condition for dissolution of gold in cyanide solutions.

However, an important factor to be taken into account in studying the dissolution of gold is that its properties depend on particle size. A compact metal is chemically a very inert material, but, as its particles become smaller, not only the physical properties of the metal, but also its chemical activity start to change [7]. Metallic gold may be present in ores both in the form of rather large metallic particles and as colloid-dispersed particles, part of which have a size close to that of gold nanoclusters. Accordingly, it may be assumed that the conventional chemistry can somewhat change for gold particles of this kind.

Previously, the dissolution kinetics of powdered palladium and gold has been studied in relation to the concentration of sodium cyanide and composition of the gas atmosphere (oxygen, oxygen–argon, oxygen–hydrogen) [8].

As established in [8], the dissolution rate of powdered gold and palladium is first-order with respect to the concentration of a metal and cyanide ions, but zero-order with respect to the concentration of oxygen (partial pressure in the gas mixture). As the concentration of the cyanide ion increases, the dissolution rate of the metals grows and so does the amount of absorbed oxygen per mole of the metal. The dissolution rate of the metals also grows with temperature. However, the rate of oxygen uptake changes only slightly and even falls at comparatively high temperatures (40–60°C). In this case, the amount of deceases oxygen consumed for complete dissolution increases dramatically.

This communication reports on a study proceeding with these investigations in order to refine the possible pathways of dissolution of noble metals. On the whole, the experimental data obtained suggest that another oxidizing agent, water, is present in the system together with oxygen.

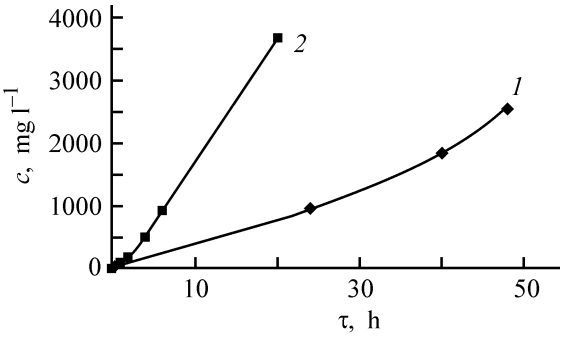

Fig. 1. Effect of the preparation procedure (dispersity) of gold on its solubility in aqueous cyanide solutions under anaerobic conditions. (*c*) Concentration of gold and (τ) time. (*1*) Gold produced by method 1 and (*2*) that produced by method 2.

EXPERIMENTAL

To study the influence exerted by the degree of dispersity on the solubility of gold under anaerobic conditions, it was obtained in two ways.

Method 1. A 2-g portion of metallic gold was dissolved in 200 ml of aqua regia, the excess of nitric acid was distilled off, the volume of the solution was brought to 100 ml by successive addition of hydrochloric acid and water, and it was cooled to room temperature. A 100-ml portion of an iron(II) sulfate solution with a concentration of 20 g l^{-1} was added to the resulting solution. The mixture obtained was allowed to stand until precipitation of metallic gold (for 24 h). The precipitate (finely dispersed brown powder) was filtered off, washed with distilled water to pH 6–7, and dried in a vacuum-desiccator over an alkali for 1 day.

Method 2. A 1-g portion of metallic gold was dissolved in 100 ml of aqua regia, the excess of nitric acid was distilled off, the volume of the solution was brought to 1000 ml by successive addition of hydrochloric acid and water and cooled to room temperature. A 50-ml portion of an iron(II) sulfate solution with a concentration of 20 g l^{-1} was added to the resulting solution. The mixture obtained was allowed to stand until precipitation of metallic gold (for 48 h). The precipitate (finely dispersed brown-violet powder) was filtered off, washed with distilled water to pH 6–7, and dried in a vacuum-desiccator over an alkali for 1 day.

Gold was dissolved at room temperature in a 150-ml three-necked round-bottom flask, into which 100 ml of a sodium cyanide solution with a concentration of 5 g l^{-1} (pH 11.5–11.8) was introduced. A 400-mg portion of gold was introduced into the extractor. After the system was purged with an inert gas of VCh grade (nitrogen, argon, helium) for 1 h, the weighed portion of gold was transferred into the solution. The dissolution was performed under continuous agitation and gas bubbling in order to prevent ingress of atmospheric oxygen into the system. To remove trace amounts of oxygen from the inert gas, it was preliminarily passed through a Drexel vessel filled with an alkaline solution of pyrogallol. To prevent loss of hydrogen cyanide, a Drexel vessel with a 10 wt % solution of an alkaline, was mounted at the outlet of the system. This made it possible to establish the balance for NaCN consumption.

Figure 1 shows kinetic curves for dissolution, under anaerobic conditions, of gold obtained in different ways. Approximately 50% of the gold produced by method 1 was dissolved in 2 days, whereas in the case of method 2, the metal virtually completely dissolved in 24 h. It can be seen from the results presented that, compared with method 1, gold produced by method 2 dissolves nearly five times faster. Apparently, this is due to its higher dispersity. The final concentration of NaCN was 3.3 g l^{-1} in the first case and 2.6 g l^{-1} in the second. This corresponds to consumption of 2.7 mol of sodium cyanide per mole of gold.

For explaining the results obtained, the authors made the following assumptions. As is known, the following equilibrium takes place at the interface between a powdered metal and water:

$$M + H_2O \rightleftarrows M_{aq}^{m+} + e_{aq}. \quad (5)$$

The equilibrium in reaction (5) is shifted toward the reverse reaction, for which $\log k_1 = 10$ [9] (where k_1 is the reaction rate constant) in the case of dissolution of gold. To shift the equilibrium toward the forward reaction, it is necessary to bind an electron. In the presence of oxygen in the reaction system, the following reaction must occur

$$O_2 + e_{aq} \rightleftarrows O_2^-. \quad (6)$$

For this reaction, $\log k$ is 10.3 at 23°C in an aqueous solution [9]. Indeed, a process of this kind does occur at the surface of gold nanoparticles [10].

The rates of the reverse reaction of (5) and forward reaction of (6) are comparable. However, compact noble metals virtually do not dissolve because $E^0_{O_2/O_2^-} = -0.563$ V [11] and there occurs the process

$$M_{aq}^{m+} + O_2^- \rightleftarrows M + O_2. \quad (7)$$

The presence of the CN^- ion, whose concentration in the solution commonly exceeds by several orders of magnitude the concentration of all other ingredients of the reaction system, leads to formation of the cyanide complexes $M(CN)_n^{m-n}$. This leads to dissolution of the corresponding noble metals.

Because powdered gold dissolves in the absence of oxygen in the reaction mixture under anaerobic conditions, the only compound that can act as an oxidizing agent in the reaction system is water:

$$e_{aq} + H_2O \rightleftarrows H^{\cdot} + OH^- \quad (8)$$

($\log k_3 = 1.2$, equilibrium constant $K_{eq} = 10^{-5}$ [9]).

A condition for a shift of the equilibrium (8) toward the reaction products and for the subsequent dissolution of the noble metal is that a high-power acceptor of atomic hydrogen should be present in the reaction system. This part can be played under anaerobic conditions by the cyanide ion only. It is known from the literature [9] that the rate constant of the reaction

$$H^{\cdot} + CN^- \rightarrow \text{(products not specified)} \quad (9)$$

is $10^{9.6}$. As mentioned above, the concentration of NaCN markedly exceeds that of all the other components of the reaction system. Therefore, process (9) can also shift reactions (5) and (8) toward forward reactions. However, even if this is the case, this occurs only to an exceedingly small extent.

In the presence of oxygen in an aqueous cyanide solution, it can be bound not only by reaction (6), but also by that with atomic hydrogen in accordance with the equations

$$H^{\cdot} + O_2 \rightarrow HO_2^{\cdot} \ (\log k_4 = 10.3 \ [9]), \quad (10)$$

$$H^{\cdot} + O_2^- \rightarrow HO_2^-. \quad (11)$$

Presumably, reactions (9)–(11) can proceed simultaneously. In this case, the products of reactions (10) and (11) can interact both with Au(0) and with the anion CN^-. If the fact that oxygen can also react with the cyanide ions and the products of reaction (9) is taken into account, it becomes clear why the consumption of oxygen grows with the concentration of the cyanide and the reaction order with respect to the concentration of oxygen is zero. In addition to reactions (9)–(11), hydrogen can also form H_2 molecules. An indirect evidence in favor of the mechanism suggested for dissolution of gold in aqueous cyanide solutions under anaerobic conditions is the well-known fact that dissolution of metallic copper is accompanied by vigorous evolution of hydrogen even if the process occurs in air. The rates of the processes considered here are the higher, the greater the reactivity of metallic gold, i.e., the closer the dimensions of its particles to nanoparticles.

It should be noted that the anion radical O_2^- formed can undergo disproportionation in aqueous solutions [12]:

$$2O_2^- + H_2O \rightleftarrows O_2 + OOH^- + OH^-. \quad (12)$$

Possibly, it is with the shift of equilibrium in Eq. (12) to the left that the above-described hindrance to dissolution of gold both at an excess of hydrogen peroxide and high concentrations of dissolved oxygen and at high pH values is associated [6].

It is known [13] that a qualitative reaction for the anion radical O_2^- in solution is the reduction by this anion of Nitro Blue Tetrazolium Chloride dye (Nitro BT), which is yellow in aqueous solutions, to red-brown diformazan, well soluble in chloroform. Indeed, introduction of several drops of chloroform into a solution that contains powdered gold being dissolved, sodium cyanide, and Nitro BT results in that the organic solvent first turns pink and then the color becomes more intense to the point of violet. This fact indicates that the solution contains O_2^- species, whose formation accompanies the dissolution of metallic gold. No coloration of this kind is observed in NaCN solutions in the absence of gold.

In order to confirm experimentally the possibility that noble metals can dissolve in aqueous cyanide solutions by the mechanism described by reactions (5) and (8)–(11), the kinetics of interaction between oxygen and hydrogen in the presence of a palladium black in an aqueous solution of sodium cyanide was studied.

Previously, the kinetics of this reaction in the absence of the cyanide ion was studied in [14–19]. It was established that, in the aqueous phase too, this reaction occurs by the radical-chain mechanism, with atomic hydrogen involved. It is important to note that the rates of the homolytic reactions between radicals in the gas phase or in water: $H^{\cdot} + H^{\cdot}$, $H^{\cdot} + OH^{\cdot}$, $H^{\cdot} + O_2$, $H^{\cdot} + HO_2^{\cdot}$, $H^{\cdot} + H_2O_2$, have second-order rate constants with values of about 10^{10} $M^{-1}\,s^{-1}$ [9, 20], which are comparable with the rate of reaction (9). Therefore, if the process goes via intermediate formation of the $H^{\cdot}$ radical, introduction of the cyanide ion into the system must lead to a sharp decrease in the rate of the reaction between hydrogen

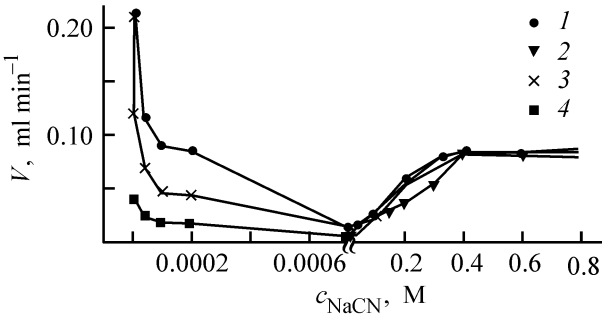

Fig. 2. Rate of uptake of oxygen or an oxygen–hydrogen mixture, *V*, vs. the concentration of sodium cyanide, c_{NaCN}, in the presence of a palladium black (m_{Pd} = *10 mg). (1)* 50% H_2 + 50% O_2, (*2*) 50% Ar + 50% O_2, (*3*) 25% O_2 + 50% H_2 + 25% Ar, and (*4*) 50% O_2 + 10% H_2 + 40% Ar.

and oxygen and must have no effect on the kinetics of palladium dissolution in aqueous cyanide solutions.

Figure 2 shows how the rate of uptake of an oxygen–hydrogen mixture in water depends on the concentration of sodium cyanide in the presence of a palladium black (the experimental procedure was described in [8]). Three regions can be distinguished in these dependences in going from low to higher concentrations of the cyanide ion: (1) steep decrease in the rate of uptake of the gas mixture at low concentrations of the cyanide ion (1×10^{-6}–1×10^{-3} M), (2) linear increase in the rate of uptake of the gas mixture at concentrations of the cyanide ion in the range 0.04–0.32 M, and (3) constant rate in the range 0.34–0.80 M. The steep decrease in the reaction rate in the first region, in which hydrogen reacts with oxygen, confirms experimentally that the cyanide ion is a kind of a trap for the $H^{\cdot}$ radical in the case of reactions that occur in water. The increase in the reaction rate in the second region is due to the dissolution of palladium and formation of a complex ion $[Pd(CN)_4]^{2-}$. In this region, only oxygen is absorbed from the gas phase and the reaction rate is first-order with respect to the concentration of the cyanide ion. In the third region, the reaction system is saturated with the cyanide ion and the reaction rate becomes independent of its concentration. At the same time, a decrease in the concentration of oxygen has no significant effect on the rate of oxygen uptake in portions 2 and 3 of the kinetic curves.

CONCLUSION

It was established that powdered palladium and gold can dissolve in aqueous solutions of sodium cyanide under anaerobic conditions.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Effect of Functionalization of Colloidal Gold on Controlled Flocculation by the Ligand–Receptor Mechanism

A. M. Kogut, A. S. Voronov, V. N. Kislenko, and W. Peukert

Abstract—Modification of colloidal gold particles with octadecanthiol and alkyl biotin, with the subsequent flocculation of these particles via introduction of a tetramer protein avidin, was studied.

Studies of the controlled organization of colloid nanoparticles into two- or three-dimensional (2*D* or 3*D*) structures open up wide prospects for their use in optics, electronics, and medicine. It has been shown that gold nanoclusters show high potentialities for use in nanoelectronics and for fabrication of biosensors [1, 2]. The surface functionalization of gold nanoparticles as objects of study and "building blocks" for organized structures is being studied extensively [3–5].

The surface of colloidal gold particles is commonly modified by self-organized monolayers of alkanethiols [6] and aromatic thiols [7]. All gold modifiers are chosen in these cases in view of the strong binding of the modifier to the surface by the Au–S bond. Biologically important molecules can also be fixed on the surface of colloidal gold particles, with nanoparticles of this kind finding use in development of ensembles of required size and configuration [8, 9], biodiagnostics, immunoassays [10], and manufacture of luminescent bioconjugates [11]. This approach is, as a rule, based on biomolecular recognition of the components of the known specific reaction model on the ligand–receptor principle. Nevertheless, the pattern of the surface functionalization of gold particles and the mechanism of aggregate formation in systems of this kind remain insufficiently studied.

This study is devoted to the fundamental aspects of the controlled organization of gold nanoparticles into 2*D* structures (aggregates) via successive modification of the surface of the particles with octadecanethiol (ODT) and alkyl biotin, with their subsequent flocculation with a tetramer protein, avidin, by the ligand–receptor mechanism.

In this case, the hydrophobic interaction between alkyl fragments of biotin with the hydrocarbon moiety of ODT apparently leads to biotinylation of colloidal gold particles. The thus modified gold particles can be bound with avidin via specific biomolecular recognition [12].

Commonly, colloid gold solutions have, depending on the particle size, a certain color and change their coloration as the dispersity increases [13, 14]. First, the size of nanoparticles of "citrate-reduced" gold and the absorption of visible light by these nanoparticles were studied in relation to a widely varying concentration of ODT molecules fixed on the surface of the particles (Figs. 1–3). It was found that the absorption spectra of the gold sol, measured immediately after synthesis of particles and four months later virtually, completely coincide. This points to a high stability of the gold sol stabilized by negatively charged ions of ketodicarboxylic acids, because, as follows from published data [15, 16], the process of gold sol formation apparently occurs in three stages.

In the first stage, in boiling of hydrogen tetrachloroaurate(III), it is partly hydrolyzed with the simultaneous partial removal of HCl from the reacting mixture:

$$H[AuCl_4] + H_2O \rightarrow H[Au(OH)_xCl_{4-x}] + HCl\downarrow,$$

where $x = 0-4$; {$[H(AuCl_4)]$, $H[AuCl_3OH]$, $H[Au(OH)_4]$, etc.}.

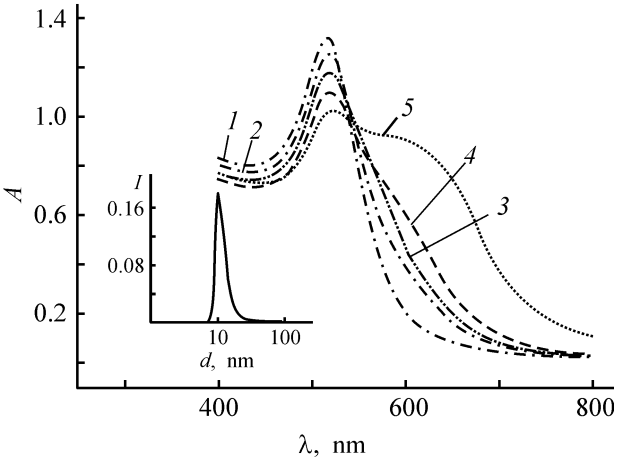

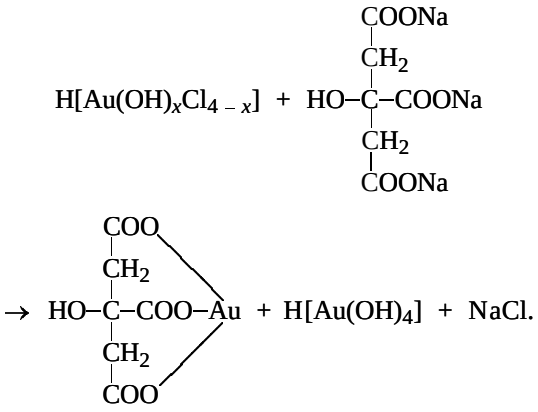

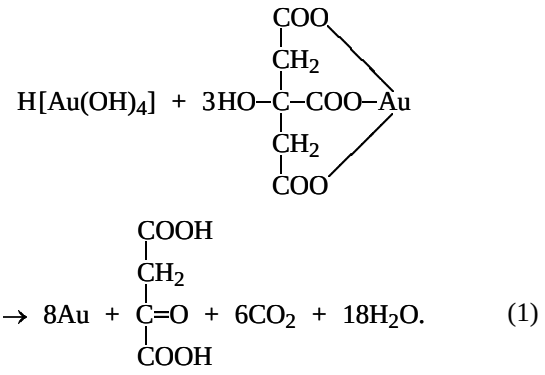

Fig. 1. (*1*) Spectrum of the initial gold sol and (*2*–*5*) its variation with time. Inset: particle size distribution of the initial gold sol. ODT concentration 1×10^{-5} M. (*A*) Optical density, (λ) wavelength, (*d*) particle diameter, and (*I*) signal intensity in measurements of dynamic light scattering. Time (min): (*2*) 15, (*3*) 3, (*4*) 6, and (*5*) 120.

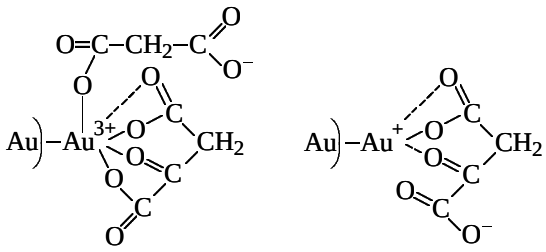
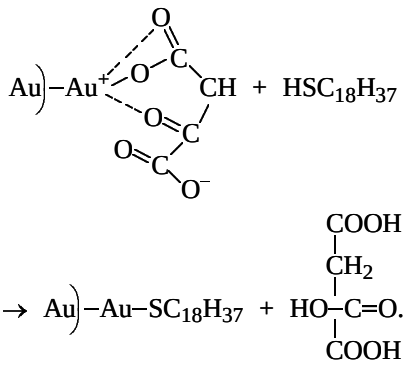


In the second stage, after a sodium citrate solution is added, $H[AuCl_4]$ rapidly hydrolyzes further to give NaCl and complexes of gold(III) with the ion of citric acid and hydroxy ions:



In the third stage, the Au(III) complexes obtained are reduced by citric acid to give gold particles and ketodicarboxylic acid:

The excess amount of A(III) and Au(I) ions bound into a complex with ketodicarboxylic acid is adsorbed on the surface of gold particles to form a double electric layer, which stabilizes the gold hydrosol by the scheme

If it is assumed that gold particles are formed by reaction (1), the residual concentration of gold complexes with ketodicarboxylic acids is $(0.5–1.5) \times 10^{-4}$ M. The average particle diameter of the gold sol obtained is 18 ± 2 nm, to which corresponds absorption at a wavelength of 519.3 nm (Fig. 1, inset). The particle size distribution is rather narrow. A particle contains, on the average, 2×10^5 gold atoms, on which $(2–5) \times 10^3$ gold ions bound into a complex with ketodicarboxylic acids are adsorbed. The number of particles in a unit volume of gold is 1.4×10^{16} l^{-1}. The sol has a bright red coloration. According to the data obtained by Mie [17], the effect of the particle size on the characteristic coloration of the gold sol is due both to the true absorption of light by the particles and to a "fictitious" absorption associated with light scattering. The gold sol, whose particles have a radius of 20 nm, absorbs in the green spectral range (~530 nm) and, therefore, has a bright red coloration enhanced by multiple scattering [13, 14]. The strongest coloration intensity of gold hydrosols corresponds to particles sizes in the range from 20 to 37 nm [14]. When light passes through a sol with different particle sizes, absorption peaks appear in the absorption spectra. The position of these peaks is determined by the particle size: as the particles become larger, the absorption peaks shift to longer wavelengths. Apparently, modification of the surface of gold particles with biotin molecules, with the subsequent addition of a tetramer protein avidin, will lead to particle aggregation and to changes in the absorption spectra. The concentrations of the reagents used to form an ODT coating on the particle surface were chosen so as to prevent their aggregation via substitution of ketodicarboxylic acids bound to gold ions on the surface of the particles by ODT molecules forming stronger bonds with gold ions by the reaction

As a result of the reaction, the surface charge of the particles decreases and their hydrophobicity becomes higher (Fig. 1). For example, a pronounced aggregation of gold particles occurs in the system at an ODT concentration of 1×10^{-5} M, which is indicated by a change in the absorption spectrum of the sol. The decrease in the height of the peak at 519 nm points to a fall in the concentration of primary particles in the sol, and its shift to longer wavelengths, to a gradual increase in the size of the aggregates. After 120 h, the absorption peak shifted into the range 600–630 nm, which can be attributed to a collective resonance of electrons in densely packed gold particles. It should be noted that, even at a sufficiently high concentration of aggregates, the concentration of the initial gold particles remains high, which is indicated by the peak in curve *5*. At a concentration of ODT in the system equal to 1×10^{-5} M, it binds up to 20% of gold ions adsorbed on the particle surface, which affects the total charge of the particles only slightly, but enhances the hydrophobicity of certain parts of a particle. With account of the fact that ODT is unevenly distributed over all the particles, only part of them, with the largest number of reacted gold ions, is capable of aggregation. It would be expected that a decrease in the ODT concentration in the system will only lead to a partial hydrophobization of the particles, without their subsequent aggregation. It is important for further studies that, at an ODT concentration of 1×10^{-7} M in the system, chemisorption does not lead to any significant disruption of the colloid stability of the gold sol (Fig. 2, curve *1*). The absorption spectrum of the mixture virtually coincides in the given case with that of the initial sample (Fig. 4). A study of how the gold particle size varies with time (Fig. 2) demonstrated that, at an ODT concentration of 1×10^{-7} M, their average size changes only slightly, whereas at 1×10^{-5} M, the average size of aggregates markedly increases already 15 min after the mixing of the reagents. In the latter case, aggregates containing up to several hundred primary gold particles can be formed. TEM

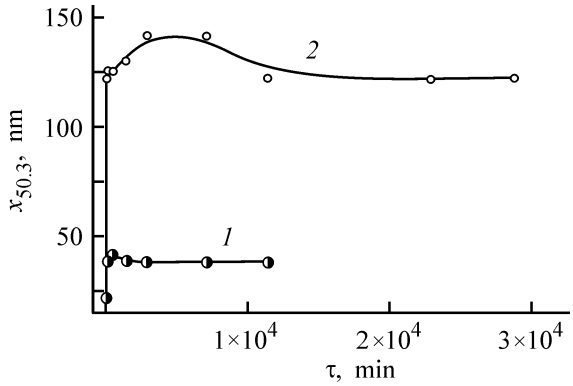


Fig. 2. Variation of the size $x_{50.3}$ of gold particles with time τ. ODT concentration (M): (*1*) 1×10^{-7} and (*2*) 1×10^{-5}.

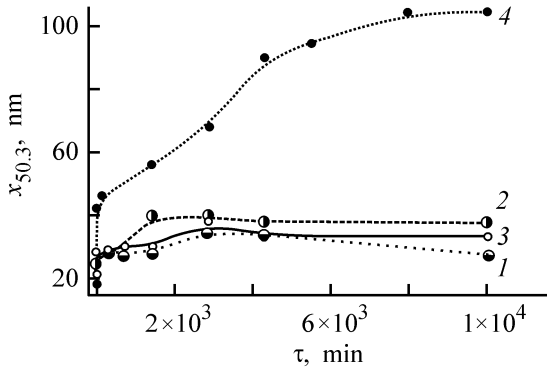

Fig. 3. Variation of the size $x_{50.3}$ of gold particles with time τ upon addition of (*1*) avidin, (*2*) alkyl biotin, (*3*) mixture of *1* and *2*, and (*4*) ODT, alkyl biotin, and avidin in accordance with the scheme. Concentration (M): (*1*, *2*, *4*) avidin, 1×10^{-8}; (*2*, *3*, *4*) alkyl biotin, 1×10^{-6}; and (*4*) ODT, 1×10^{-7}.

micrographs of a gold sol mixed with ODT demonstrated that, at an ODT concentration of 1×10^{-7} M, aggregates composed of three to five densely packed initial gold particles are formed, with a considerable fraction of the initial gold particles preserved.

Prior to studying the aggregation of gold particles in the system constituted by ODT, alkyl biotin, and avidin, it was appropriate to determine how addition of alkyl biotin or avidin molecules, or a mixture of these, affect the optical properties and particle size of the gold sol. As can be seen in Fig. 3, avidin and alkyl biotin present in the system in concentration of 1×10^{-8} and 1×10^{-6} M, respectively, lead to an only slight increase in the size of gold aggregates. This is apparently due to the fact that, under the experimental conditions, the adsorption of these reagents on gold particles stabilized with gold complexes with ketodicarboxylic acids is low. The absorption spectrum of

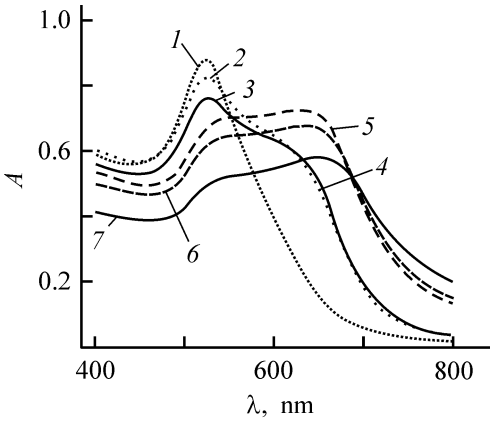

Fig. 4. Absorption spectra of (*1*) initial gold sol modified with ODT, (*2*, *3*) gold sol + ODT + alkyl biotin (*2*) 15 min and (*3*) 1 h after the introduction of alkyl biotin, and (*4*–*7*) gold sol + ODT + alkyl biotin + avidin (*4*) 5, (*5*) 5.5, (*6*) 9, and (*7*) 18 h after the introduction of avidin. (*A*) Optical density and (λ) wavelength. Concentration (M): (*1*–*7*) ODT, 1×10^{-7}; (*2*–*7*) alkyl biotin, 1×10^{-6}; and (*4*–*7*) avidin, 1×10^{-8}.

the gold sol remains virtually unchanged (Fig. 4). Successive introduction of alkyl biotin and avidin into the gold sol does not lead to its significant aggregation, either (Fig. 3, curve *3*), despite the reaction between alkyl biotin and avidin [11].

Introduction of alkyl biotin into a mixture containing the gold sol and 1×10^{-7} mol ODT leads to a slight decrease in the concentration of primary gold particles in the system and to formation of aggregates. This is indicated by a decrease in the height of the peak at 519 nm in the absorption spectrum of the gold sol and by the appearance of a new peak at 640 nm (Fig. 4, curves *1*–*3*). At an alkyl biotin concentration of 1×10^{-6} M, the spectrum of the mixture strongly varies during 1 h (Fig. 4, curves *1*–*3*) and then remains virtually unchanged. The last fact apparently indicates that alkyl biotin is adsorbed on hydrophobic parts of gold particles coated with ODT and there occurs partial aggregation of the particles via formation of bridge bonds between them. Apparently, the adsorption of alkyl biotin on the uncoated (with ODT) surface of gold particles is unimportant, which is indicated by only a slight change in the spectrum of the gold sol in the presence of alkyl biotin in the same concentration and by the insignificant increase in the number of aggregates in the system (Fig. 3, curve *2*). It may be assumed that alkyl biotin unbound to the surface of gold particles is present in the system in a considerable concentration.

Introduction of avidin, a tetramer protein with a molecular weight of 66 000, into a gold sol modified with ODT and alkyl biotin leads to an instantaneous change of the color of the gold sol in the system studied, which points to a noticeable flocculation of particles. The absorption spectrum of the gold sol markedly changes (Fig. 4, curves *4* and *5*). The height of the peak at 519 nm, associated with primary gold particles, dramatically decreases and a peak at 640 nm appears and grows in intensity during several hours. After 5–6 h, the heights of both peaks, at 519 and 640 nm, decrease. This indicates that coarse aggregates or floccules are formed. The conclusion is confirmed by measurements of the sizes of the aggregates (Fig. 3, curve *4*). During the first minutes after the mixture is formed, the particle size increases twice. After that the aggregates start to noticeably grow and reach the maximum size of 100–110 nm in 8×10^3 min. If the concentration of avidin is varied with the amount of the biotin "anchor" simultaneously raised, the rate of aggregate formation changes. This indicates that the aggregation rate can be controlled by varying the relative concentrations of the ligand and receptor. As already noted, the optical properties and size of gold particles modified with alkyl biotin apparently change upon the reaction with the protein because of the aggregation of gold particles, which results from "cross-linking" of the alkyl biotin adsorbed on their surface by the tetramer protein. In order to determine the efficiency of cross-linking and evaluate the change in the size and number of gold particle aggregates in a study of the absorption spectra of the sol in the visible range, a semiempirical spectroscopic flocculation parameter has been introduced [18], which can be used in evaluating the degree of aggregation of colloid particles. The flocculation parameter was defined as the integral area under the absorption curve in the range between 600 and 800 nm. In the course of flocculation and simultaneous aggregation of particles, the component determining the absorption at a longer wavelength grows in intensity. Thus, determining the area under the spectrum in the range between 600 and 800 nm must directly characterize the flocculation process. All the optical spectra presented in the figure (including that of unmodified gold) were normalized to the intensity of absorption at the wavelength of the surface resonance. The flocculation parameter was calculated for all the spectra obtained in the range between 600 and 800 nm. The calculations were carried out by subtracting spectrum of pure unmodified gold for the same range.

Figure 5 shows the plot of the flocculation parameter calculated for the experimental system against the time of experiment. It was found that the flocculation parameter can be neglected in experimental sys-

tems containing no avidin; the figure shows only the values calculated before and after the addition of the protein and in its presence. Apparently, aggregation occurs in the system after the addition of avidin, which is indicated by a steep rise in the flocculation parameter after the addition of the protein.

To obtain additional quantitative information about specific features of flocculation, the inset of Fig. 5 shows a typical curve describing the variation with time of the intensity of absorption by the initial particles at 519 nm (which is characteristic of pure gold particles). The decrease in the height of the peak at 519 nm in the absence of avidin from 1.3 to 1.0 points to an insignificant aggregation, which leads to disappearance of up to 20% of the initial particles to give aggregates constituted by 3–5 primary particles of the gold sol. This is demonstrated by the shift of the peak to longer wavelength. In the process, the flocculation parameter remains virtually constant.

Upon addition of an avidin solution to the system, the absorption peak substantially shifts to longer wavelengths (640 – 650 nm). Also, the height of the peak at 519 nm abruptly decreases, which points to a virtually instantaneous flocculation of primary particles to form aggregates.

In the first stage of flocculation, during the first minutes, primary gold particles are adsorbed on swollen globules of avidin macromolecules to give aggregates 45–50 nm in diameter (Fig. 3, curve *4*). In this case, there apparently occurs a reaction of specific addition of alkyl biotin adsorbed on the surface of primary gold particles to active groups on the surface of a swollen avidin globule. It should be noted that aggregates composed of 3–5 primary gold particles, which are formed upon addition of ADT and alkyl biotin, are also apparently adsorbed on avidin globules. The SEM micrographs in Fig. 6 clearly demonstrate rings of primary particles forming a shell on avidin globules. The number of aggregates composed of 3–5 primary particles in the SEM micrograph is insignificant, compared with chains of primary particles. This fact also points to an insignificant aggregation of primary particles upon their mixing with ODT and alkyl biotin. Apparently, the concentration of the avidin introduced affects the degree of adsorption saturation of the surface of globules of swollen avidin with primary gold particles and, accordingly, the flocculation rate. It should, however, be noted that dissolved alkyl biotin molecules favor cross-linking of avidin macromolecules and aggregation of its globules during the entire process. In the second, slow stage of flocculation, avidin globules undergo a slow aggregation because of the interaction of active groups

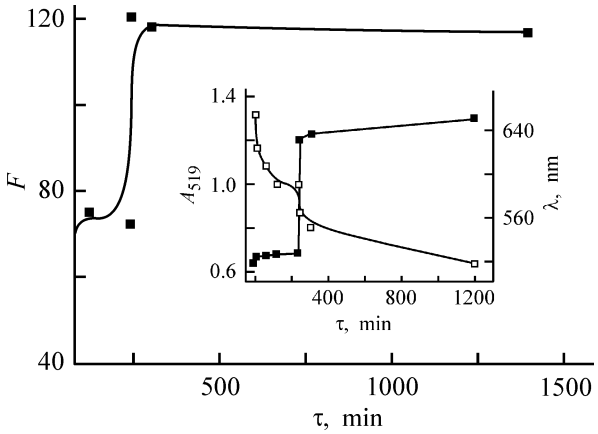

Fig. 5. Variation of the flocculation parameter *F* calculated for the experimental system described with time τ. Inset: variation of the light absorption at a wavelength of 519 nm, A_{519}, (synthesized colloid gold) and the shift of the absorption peak for a mixture of gold sol with ODT and biotin upon addition of avidin at 210th minute of the experiment.

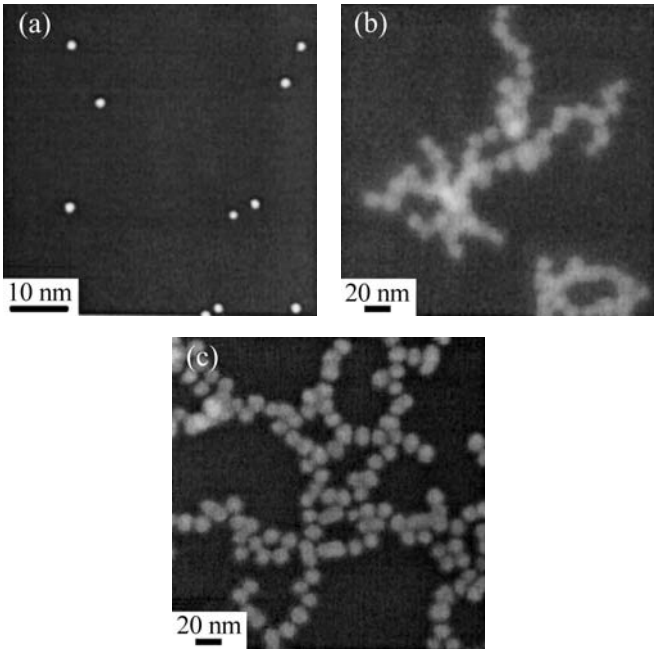

Fig. 6. SEM micrographs of (a) unmodified gold particles and of gold colloids containing alkyl biotin and 1×10^{-8} M avidin after (b) 1 and (c) 5 h of aggregation.

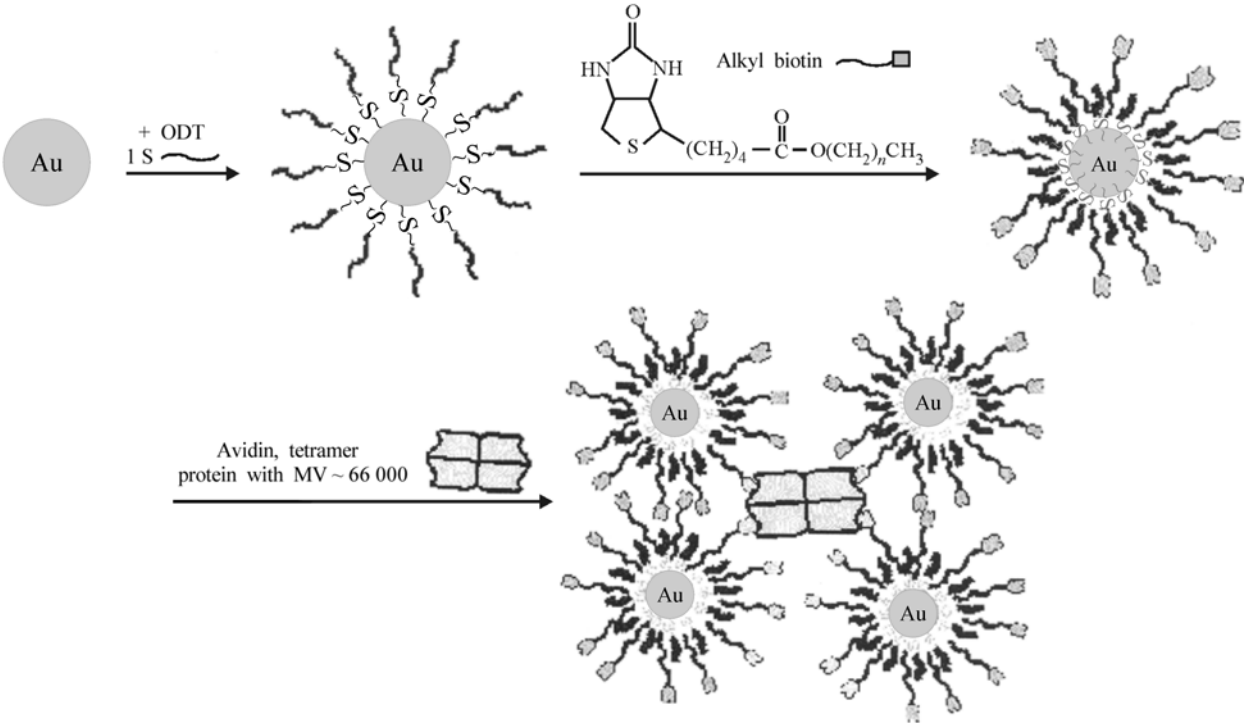
on the surface of avidin globules, which are not covered with primary gold particles, with free alkyl biotin molecules on gold particles adsorbed on avidin globules. This process yields aggregates more than 100 nm in diameter (Fig. 3, curve *4*). SEM micrographs (Fig. 6c) reveal the formation of a network constituted by chains of primary particles, with a pore size of 45–50 nm and more. Larger pores are appar-

ently formed by two or more avidin globules cross-linked by alkyl biotin molecules that were not adsorbed on gold particles before the introduction of avidin. It would be expected that the pore size will depend on the relative concentrations of avidin and primary gold particles and grow with the concentration of avidin and alkyl biotin in the system. The pore sizes will apparently be multiples of the size of the avidin globule, which is, to a certain extent, reflected by the SEM micrograph in Fig. 6c, obtained after 5 h of a specific interaction between biotin and avidin.

EXPERIMENTAL



Sodium citrate dihydrate, $HAuCl_4$, 1-octadecanethiol, ethanol, 1-hexadcanol, 1-propanol, avidin (egg protein), and biotin (Aldrich) were used without additional purification.

A colloid gold solution was synthesized by reduction of hydrogen tetrachloroaurate(III) with sodium citrate. Prior to use, all the glassware was thoroughly washed and rinsed with water purified by filtration through a Millipore-Q filter. A 120-ml portion of an $HAuCl_4$ solution was charged into a 250-ml vessel and brought to boiling, after which 12.5 ml of a 0.5% sodium citrate solution was rapidly added. The mixture was boiled for 3–5 min, until it turned red. The average diameter of colloidal gold particles was measured by the method of dynamic light scattering (Zetasizer Nano ZS) and by transmission electron microscopy.

Cetyl and propyl esters of biotin were synthesized by reacting, respectively, 1-hexadecanol and 1-propanol by the procedure described in [20]. The products were purified by flash chromatography with MeOH : CH_2Cl_2 = 5 : 95 as eluent. The yield of the target products was 40 and 70%, respectively.

The functionalization of colloid particles and the reaction with avidin were studied by spectroscopy in the visible range, using a Varian Cary 100 Scan spectrometer with a resolution of 2 nm, as well as by the method of dynamic light scattering on a Zetasizer Nano ZS instrument.

Self-organizing ODT monolayers were fixed on the surface of colloidal gold particles from 1×10^{-7} and 1×10^{-5} M solutions of 1-octadecanethiol in ethanol, after which alkyl biotin molecules were attached to these layers. In the following stage, addition of biotinylated gold particles to avidin molecules was performed by the scheme described in [19].

The stability of gold hydrosols was examined in the presence of alkyl biotin at concentrations used in the experiments described above, and in the presence of a mixture of both components. To analyze the interaction between gold sol particles with ODT and the consecutive reaction with alkyl biotin and avidin

in the first stage, 0.1 ml of a 1×10^{-4} or 1×10^{-6} solution of ODT in ethanol, respectively, was added to 1 ml of a gold sol synthesized. Thus, the content of ODT in the reaction solution was 1×10^{-5} and 1×10^{-7} M. The mixture obtained was allowed to stand for 2 h. To a sample with a total ODT concentration of 1×10^{-7} was added 0.1 ml of a 1×10^{-5} M solution of alkyl biotin in a 1 : 1 mixture of ethanol and water. The resulting solution was allowed to stand for 48 h, after which 0.1 ml of a 4.5×10^{-7} M solution of avidin was added and the kinetics of formation of gold aggregates was studied.

Self-organizing layers of gold particles were obtained on the surface of quartz plates by using an apparatus with a step motor, intended for deposition of coatings at a constant temperature and humidity by means of immersion. The motion velocity of the quartz plate was varied within the range 0.l–1 m min^{-1}. The plates were washed with water purified with a Millipore filter and with ethanol immediately before use, after which they were immersed in a gold sol aggregated for a certain time, kept there for 60 s, and then dried. The kinetics of aggregation of colloidal gold particles were compared by field-emission scanning electron microscopy on an LEO 1530 microscope with enhanced resolution (down to 5 nm).

CONCLUSIONS

(1) The changes observed in the absorption spectra of a gold sol mixed with octadecanethiol, alkyl biotin, and avidin indicate that gold particle aggregates with a controllable size are formed.

(2) The aggregation of god particles and their structure can be controlled by varying the concentrations of the reagents used in the mixture and the order of their introduction into the system.

(3) The adsorption of aggregates of gold particles bound to avidin makes it possible to obtain organized 2*D* structures.

Received March 28, 2005

Abstract—Recovery of thorium(IV) and radium(II) by precipitation methods in the chloride technology of perovskite processing was studied.

An efficient technique for breakdown of rare-metal raw materials is their decomposition with hydrochloric acid [1, 2]. Processing of concentrates containing radionuclides poses a problem of removal of these admixtures from chloride solutions. In this communication, we consider the recovery of thorium(IV) and radium (II) in the chloride technology of perovskite processing.

Perovskite from the Afrikanda deposit (best prepared for industrial processing) was used. The material contained (wt %): $(Nb + Ta)_2O_5$ 0.64–2.50, TiO_2 50.8–56.8, SiO_2 0.12–1.93, Al_2O_3 0.15–1.30, Fe_2O_3 0.43–2.00, FeO up to 1.44, Ln_2O_3 2.18–10.7 (here and hereinafter Ln_2O_3 is the sum of oxides of rare earth elements), CaO 26.3–38.1, Na_2O 0.10–2.35, ThO_2 0.07–0.14, and UO_3 ~0.01. Various alternative integrated technologies for perovskite processing to give tantalum and niobium pentaoxides, pigmentary titanium dioxide, and a rare-earth concentrate have been developed at the Institute of Chemistry, Kola Scientific Center, Russian Academy of Sciences. A promising variant is perovskite breakdown with hydrochloric acid, in which calcium(II), rare-earth elements(III), and thorium(IV) pass into a solution, and titanium(IV), niobium(V), and tantalum(V), into a precipitate, which is further processed into a commodity output by the known schemes [1, 2]. The chloride solutions obtained upon hydrolytic precipitation of titanium(IV), niobium(V), and tantalum(V) contained (g l^{-1}): HCl 100–200, $CaCl_2$ 100–150, ThO_2 0.1–0.2, Ln_2O_3 6–10, Fe_2O_3 [Fe(II) + Fe(III) in terms of Fe_2O_3], and TiO_2 1–10. In addition, sodium(I), aluminum(III), vanadium(V), manganese(II), and compounds of other elements were present in the solutions. The system has a complex multicomponent composition, with strongly different properties of chemical elements and a high salt content. It has been poorly investigated, which, on the whole, considerably complicates attacking the problem to be solved, specifically, the recovery of radionuclides from technological solutions.

Earlier [3, 4], we have studied the utilization of solutions produced in perovskite breakdown with hydrochloric acid, with thorium(IV) recovered by extraction with tributyl phosphate (TBP). The suggested variant of the technique enables efficient recovery of thorium(IV) from chloride solutions. A drawback of this procedure is a considerable flow rate of the extracting agent (1 : 1 volume ratio of organic and aqueous phases in the extraction process), which, in the end, adversely affects the economical characteristics of the technology. Furthermore, TBP is subjected to hydrolysis when brought in contact with acid (especially chloride) solutions, which requires that special operations should be introduced for removal of decomposition products from TBP and leads to an increased loss of the extracting agent [5].

This communication reports the results obtained in studying the purification of technological solutions to remove thorium(IV) and radium(II) by precipitation. In the experiments, we used solutions of the composition specified above and (for the most part) the same solutions concentrated by evaporation to a $CaCl_2$ concentration of 300 g l^{-1} and higher. The evaporation was performed to diminish the process flows and to regenerate (distill off) HCl, recycled into the stage of perovskite breakdown.

* With a NaOH solution (330 g l^{-1}) in run no. 3.

The purification of solutions to remove radionuclides was monitored by measuring the alpha and beta activities (α and β) and by chemical analysis for the ThO_2 content. The activity of the solutions is determined by the presence of natural thorium(IV) and uranium(IV) radionuclides and products of their decay, predominantly radium(II). To determine the values of α and β, a sample of a solution was evaporated to dryness; preliminarily it was found that radionuclides do not pass into the condensate in evaporation. The alpha and beta activities of a solid product were measured on a UMF 1500 D low-background installation, with the data obtained recalculated to the activity of a filtrate in becquerels per liter. A standard composed of the perovskite concentrate was used as reference. The values of α and β, presented in the paper, were calculated from the results of 5–10 (depending on the activity of solutions) parallel measurements of a sample and the background. The determination error was ±75 Bq l^{-1} for low-active samples and increased with a rise in the activity of the solutions studied to ±(500–1000) Bq l^{-1}. Other specific features of the experimental procedure and analytical monitoring technique were reported in [3].

Table 1 lists data on the extraction of thorium(IV) and rare earth elements(III) by neutralization of a solution containing (g l^{-1}): ThO_2 0.38, Ln_2O_3 20.2, Fe_2O_3 22.9, TiO_2 5.2, HCl 105, and $CaCl_2$ 314. It was assumed that precipitation of Th(IV) and U(VI) [6, 7] and coprecipitation of Ra(II) [8] on hydroxides of Ti(IV) and other elements will give filtrates containing no radionuclides. In run nos. 2–4, a two-stage neutralization gave a precipitate containing most of thorium(IV) (precipitation at pH 4.4–5.1) and a concentrate of rare earth elements(III) (neutralization to pH 8.0–9.3 [9]). Further processing of the precipitates could be carried out by the known techniques [3, 4, 10]. However, the activity of filtrates for all the variants of neutralization represented in Table 1 considerably exceeds sanitary norms for waste solutions. As Th(IV) and U(VI) are readily precipitated (see [6, 7] and Table 1: the ThO_2 content of the filtrates, found by chemical analysis, is less than 0.0001–0.001 g l^{-1}) we can conclude that the high activity of the filtrates is mainly determined by the presence of Ra(II) and products of its decay. In this context, we further paid the main attention to removal of radium(II) from solutions by its precipitation on $BaSO_4$. This method is successfully applied in both analytical [8] and industrial practice [13].

We used two starting solutions containing (g l^{-1}): ThO_2 0.06, Ln_2O_3 24.7, HCl 44, and $CaCl_2$ 290 with the α and β activity of 710 ± 90 and 1640 ± 80 Bq l^{-1}, respectively, (Figs. 1, 2) and ThO_2 0.08, Ln_2O_3 28.2, HCl 29, $CaCl_2$ 376 with the α and β activity of 10460 ± 1280 and 10560 ± 410 Bq l^{-1}, respectively,

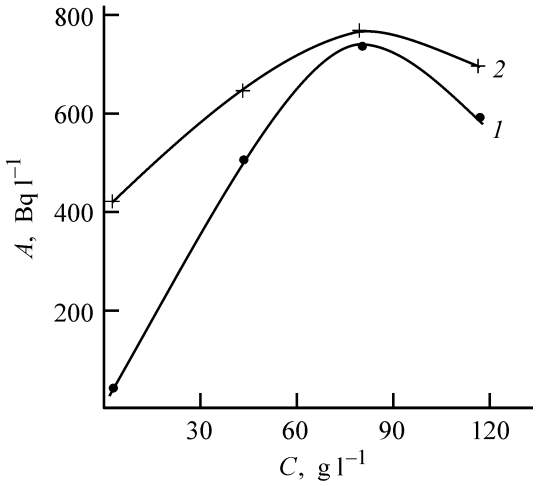

Fig. 1. (*1*) Alpha and (*2*) beta activities of filtrate vs. the concentration of BaCl in solution before recovery of radium(II). (*A*) Activity and (*C*) concentration of HCl.

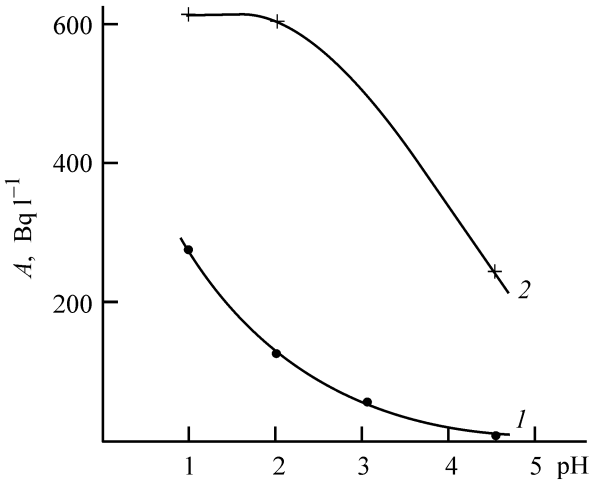

Fig. 2. (*1*) Alpha and (*2*) beta activities of the filtrate vs. the solution pH before recovery of radium(II). (*A*) Activity.

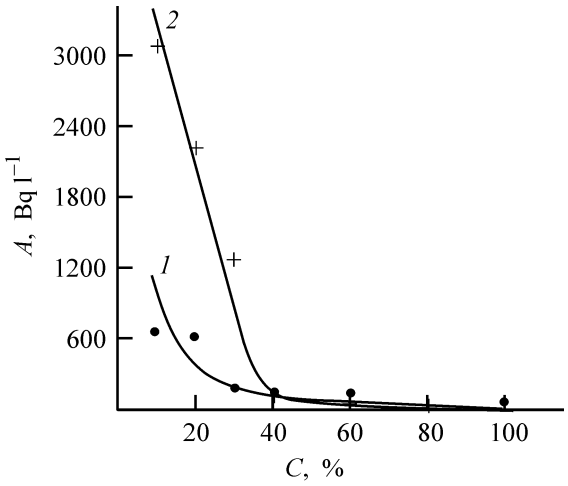

Fig. 3. (*1*) Alpha and (*2*) beta activities of the filtrate vs. the $BaCl_2$ expenditure. (*A*) activity and (*C*) $BaCl_2$ expenditure.

(Fig. 3, Table 2). The experimental results describing the influence of the acidity of a medium on the purification to remove radionuclides are presented in Figs. 1 and 2. Hydrochloric acid or lime milk was added to 25 ml of a solution of the above-mentioned composition to reach the required pH value or HCl content, and the solution was allowed to stay for at least 12 h. Further, a $BaCl_2$ solution (200 g l^{-1}) was added, the mixture was heated to a prescribed temperature (70°C), a Na_2SO_4 solution (180 g l^{-1}) was added, and the pulp was kept at a prescribed temperature for 60 min. After cooling to room temperature, the resulting precipitate was filtered off. A sample of the filtrate was evaporated to dryness and the alpha and beta activities were determined by the above-described technique. The amounts of $BaCl_2$ and Na_2SO_4, used in this set of experiments, were taken with regard to the experience of industrial processing of the loparite concentrate: 4 ml of the $BaCl_2$ solution per 25 ml of the technological solution (conditionally taken for 100%); the expenditure of the Na_2SO_4 solution was 400% relative to the stoichiometric amount required for $BaSO_4$ to be formed.

Table 2. Precipitation of radium(II) at the 100% $BaCl_2$ expenditure and varied solution pH values, Na_2SO_4 expenditure, and temperature

Solution pH before recovery of radium(II)	Na_2SO_4 expenditure, %	Temperature, °C	Filtrate activity, Bq l^{-1}	
			α	β
Effect of pH in the range 4.5–9.1				
4.5	400	70	150	429
5.5	〃	〃	118	334
6.5–9.1	〃	〃	<75	<75
Effect of Na_2SO_4 expenditure				
7.0	180–400	70	<75	<75
Effect of temperature				
7.0	180	20–70	<75	<75

It is known from the analytical practice [8] that Ra(II) is precipitated on $BaSO_4$ most completely from acid solutions. However, this is not confirmed for the system under study, which has a high calcium(II) content: by contrast, it is necessary to make lower the solution acidity to reach the minimum alpha and beta activities of solutions. It has been noted [8] that, in the case of joint crystallization of isomorphous compounds, the degree of precipitation of a microcomponent is the higher, the more completely it is precipitated. We can conclude that the solubility of $BaSO_4$ [and $CaSO_4$, on which Ra(II) is also partly coprecipitated in systems with a high $BaCl_2$ concentrations] is at a minimum at pH close to 7. Accordingly, a higher degree of Ra(II) removal is observed in this pH range. Additional studies of the mechanism of Ra(II) coprecipitation on $BaSO_4$ in systems with a high content of $BaCl_2$ and other salts are necessary.

The results of the experiments aimed to refine the conditions of Ra(II) precipitation are presented in Table 2 and Fig. 3. Raising the pH value further [before recovery of Ra(II)] improves the purification of the solution to remove radionuclides (Table 2) owing both to an increase in the degree of Ra(II) precipitation and to a more complete recovery of Th(IV) hydroxide.

However, carrying out the process at pH higher than 7 is inexpedient because of the precipitation of hydroxides of rare earth elements(III). We can also conclude that, in the technological range under study, a 180–400% variation of the Na_2SO_4 expenditure and a 20–70°C variation of temperature (Table 2) do not affect essentially the purification of solutions to remove radionuclides. Accordingly, the effect of $BaCl_2$ expenditure (Fig. 3) was studied at pH ~7, Na_2SO_4 expenditure of 180%, and temperature of ~20°C. It follows from the data obtained that the $BaCl_2$ expenditure can be lowered by at least a factor of 2. Calculations show that, with account of the decrease in the Na_2SO_4 expenditure from 400 to 180%, we can strongly (by a factor of 3.7) diminish the total weight of a $BaSO_4$ + $CaSO_4$ radioactive precipitate to be buried. In this case, the level of alpha and beta radiation from the solution (its composition is given above) decreased from ~10 000 to less than 75 Bq l^{-1} despite a decrease in the $BaCl_2$ and Na_2SO_4 expenditure. This means that the degree of removal of radiating elements was higher than 99%. It is necessary to note that not all the parameters affecting the purification of solutions to remove radium(II) in the complex system under study were investigated. For example, we found that keeping a pulp (before filtering-off the $BaSO_4$ precipitate) for no less than 12 h diminishes the alpha and beta activities in a filtrate by approximately factors of 9 and 3.8, respectively. This indicates that a further decrease in the activity of filtrates is possible. At present, we are carrying out investigations aimed to optimize the conditions at which technological solutions are purified to remove radionuclides and to improve the measurement accuracy, because nearly background values of α and β are to be determined.

The results obtained in testing the precipitating purification of a technological solution to remove radionuclides are listed in Table 3. Radium(II) was precipitated at 50 and 220% expenditures of $BaCl_2$ and Na_2SO_4, respectively, with the pulp allowed to stand before filtration for approximately 20 h. A high (> 99%) degree of purification to remove α- and β-radiating elements was reached; the content of ThO_2 and Ln_2O_3 in the filtrate after the recovery of a concentrate of rare earth elements(III) was less than 0.001 g l^{-1}. The precipitate obtained by neutralization with a lime milk to pH 2.5 is mainly composed of iron(III) hydroxide. After dissolution of the precipitate in HCl, iron(III) is readily removed by extraction with octanol at minimum process flows to give pure iron compounds [3, 4]; the aqueous solution purified to remove iron(III) and containing mainly titanum(IV) is directed to the operation of perovskite breakdown with hydrochloric acid to exclude loss of titanium(IV). The $BaSO_4$ + $CaSO_4$ precipitate obtained at pH 7 and containing Ra(II) and Th(IV) is buried, and the concentrate of rare earth elements(III) is processed by the known schemes (see [10] and G.V. Korpusov's works). The ways to process a solution freed from radionuclides and containing virtually only $CaCl_2$ were considered in [1–4].

Table 3. Precipitation of radionuclides from a solution containing (g l^{-1}): ThO_2 0.60, Ln_2O_3 29.2, Fe_2O_3 30.5, TiO_2 3.2, HCl 84, $CaCl_2$ 469 and having the activity α = 23 090 ± 2760 and β = 17 890 ± 670 (Bq l^{-1})

Solution	Activity, Bq l^{-1}	
	α	β
Filtrate upon precipitation of hydroxides (pH 2.5)	3610 ± 710	5110 ± 270
Filtrate upon recovery of Ra(II) (pH 7)	83 ± 200	120 ± 65
Filtrate upon precipitation of rare earth elements(III) (pH 9)	32 ± 180	52 ± 86

Thus, our studies revealed an efficient variant of utilization of chloride solutions in the perovskite technology. The variant is based on precipitating methods and has certain advantages over the recovery of thorium(IV) by extraction with tributyl phosphate (the procedure used is simpler and its technical and economic characteristics are improved).

CONCLUSIONS

(1) The precipitation of radium(II) on $BaSO_4$ was studied: namely, the influence exerted by the solution acidity [before Ra(II) isolation], $BaCl_2$ and Na_2SO_4 expenditure, and process temperature. It was found that radium(II) is most completely precipitated at pH ≥ 7. It was shown that, under the best conditions, the alpha and beta activities of the solutions studied decrease from approximately 10 000 to less than 75 Bq l^{-1}.

(2) A technological variant was suggested, which includes precipitation of hydroxides of Fe(III), Ti(IV), and other elements at pH ~2.5, precipitation of Ra(II) on $BaSO_4$ with the simultaneous precipitation of Th(IV) (pH ~7), and production of a concentrate of rare earth elements(III) (pH ~9).

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Reduction of Sulfates with Oil Coke in a Carnallite Melt

A. V. Litvinov and V. Z. Poilov

Perm State Technical University, Perm, Russia

Received April 7, 2005

Abstract—Purification of flotation carnallite to remove sulfates by their reduction in a melt was studied. The optimal parameters of the reduction and the effect of various factors on this process were determined. The mechanism of the process is suggested, and the results of industrial tests are given.

When passing to new raw materials for electrolytic production of metallic magnesium and, in particular, to flotation carnallite, brucite, or serpentinite, a necessity arises for additional purification of the molten magnesium electrolyte to remove sulfates. It is known that sulfate admixtures contained in the electrolyte substantially impair the current efficiency by magnesium and disrupt the operating mode [1, 2]. At a sulfate content in anhydrous carnallite exceeding 0.05 wt %, the current efficiency sharply decreases. A froth appears on the electrolyte surface and the electrolyte circulation is enhanced, which results in that the slime is stirred up and passivates the cathodes [3].

The procedures developed for purification of the molten magnesium electrolyte to remove sulfate admixtures by reduction with natural gas, carbon oxide, and magnesium [4–6] have been only implemented on laboratory installations. Their commercial use appeared to be unfeasible owing to the high fire and explosion hazard. In this study, we developed an efficient commercial procedure for removing sulfate admixtures from the melt of flotation carnallite.

We used as a raw material for laboratory studies four batches of flotation carnallite produced in laboratory by the flotation technique (VNIIG, St. Petersburg). They contained different amounts of calcium sulfate (0.07, 0.39, 0.55, and 0.68 wt %). We also used artificially contaminated halurgic carnallite containing 0.5–1.0 wt % sulfate ions.

When studying the removal of sulfate ions from an electrolyte melt, we simulated the processes occurring in the chambers of an industrial chlorinator: in the melting pot, in chlorinating chambers, and in the mixer (settling tank). We studied the removal of sulfate ions from the melt at 500–800°C (temperature profile of the chlorinator) in a reactor into which chlorine was fed to simulate the operation of chlorinating chambers, and argon, for a more complete mixing of the components. We determined the residual content of sulfate ions by photocolorimetry or gravimetry [7].

We used as reducing agents activated carbon and oil coke, and metallic magnesium for comparison. The data obtained for a model carnallite melt with various reducing additives are presented in Figs. 1 and 2.

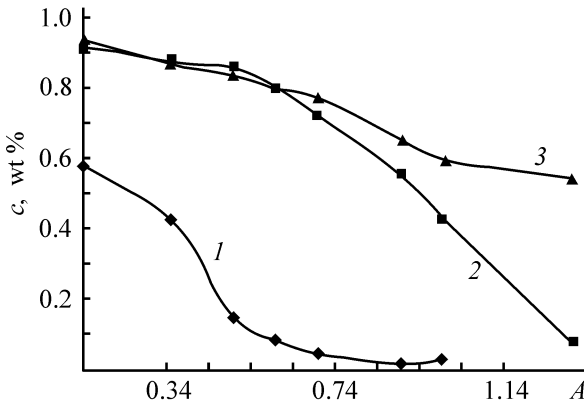

Fig. 1. Concentration c of sulfate ions in the carnallite melt vs. the weight ratio A between the amount of the reducing additive and $CaSO_4$. Process duration 1 h, T = 700°C, initial content of sulfate ions 1.0 wt %. Reducing agent: (*1*) oil coke, (*2*) metallic magnesium, (*3*) activated carbon; the same for Fig. 2.

Table 1. Degree of removal of sulfate ions from flotation carnallite, α, at a varied initial content of $CaSO_4$ in the carnallite melt

Content of $CaSO_4$ in carnallite, wt %		α, %
starting flotation-type	molten after removal of SO_4^{2-}	
0.070	0.020 ± 0.01	71.43
0.390	0.039 ± 0.01	90.00
0.550	0.049 ± 0.01	91.09
0.680	0.052 ± 0.01	92.35

Analysis of the curves in Figs. 1 and 2 shows that oil coke is the most effective additive. The maximum rate and degree of carnallite purification to remove sulfates are achieved with its help. In this case, the carnallite melt is not contaminated with carbon, whose content is strictly controlled in industry, because it is collected as a coke froth in the surface layer of the electrolyte melt. As can be seen, two other additives do not diminish the content of sulfate ions to the required value of 0.05 wt %. This fact predetermined the choice of oil coke as a reducing agent.

The effect of temperature on the reduction of sulfates with oil coke is shown in Fig. 3.

As can be seen from Fig. 3, the duration of purification of the electrolyte melt at 700–750°C to a residual concentration of sulfate ions of 0.02–0.05 wt % is 20–40 min. The obtained optimal parameters of the reduction of sulfate ions in the carnallite melt (700–750°C and process duration of 20–40 min) correspond to the working mode of the industrial chlorinator and to the residence time of the carnallite melt in the apparatus.

The procedure under study for removing sulfate ions was tested on four batches of dehydrated flotation carnallite with varied content of sulfates. The results obtained are listed in Table 1. The residual content of sulfate ions varied within the range 0.02–0.05 wt %. The content of sulfates in a dehydrated melt of halurgic carnallite at a working magnesium-manufacturing shop was 0.05–0.06 wt %. This suggests that the procedure developed for removal of sulfate ions from flotation carnallite can eliminate the main drawback of the flotation technology, the high content of sulfate ions.

The removal of sulfate ions from the carnallite melt was accompanied by vigorous gas evolution, which led to "boiling" of the melt. After the reduction was complete, the boiling stopped. At high initial concentrations of sulfates in carnallite, we observed blue tongues of flame on the surface of the "boiling" melt, which can be attributed to an additional oxidation of the products formed in the reduction of sulfate ions and in oil coke pyrolysis.

When bubbling methane, hydrogen, or propane through the melt, sulfate ions are reduced to give sulfur-containing gases [4]. The authors of [6] suggested that the products of pyrolysis of a hydrocarbon mixture make the greatest contribution to the reduction of sulfate admixtures in the carnallite melt.

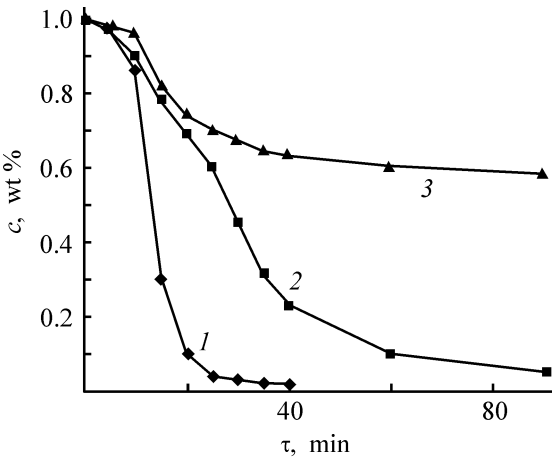

Fig. 2. Concentration c of sulfate ions in the carnallite melt vs. the process duration τ for different types of the reducing agent. The weight ratio between the amounts of the reducing agent and sulfate ions is 0.8.

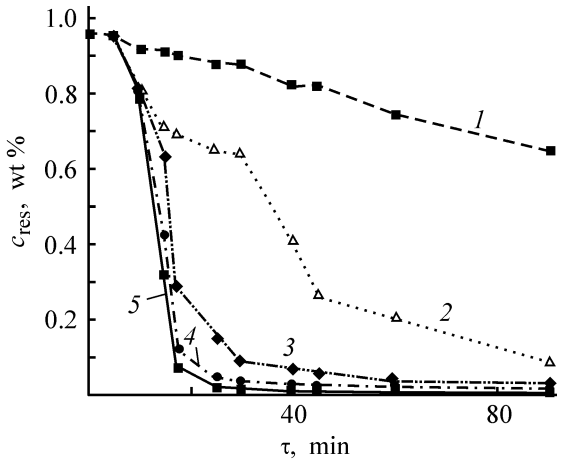

Fig. 3. Residual concentration c_{res} of sulfate ions in the carnallite melt vs. the duration of the reduction with oil coke, τ. Initial content of sulfate ions 1.0 wt %, weight ratio between the amounts of the reducing agent and sulfate ions 0.8; the same for Fig. 4. Reduction temperature (°C): (*1*) 550, (*2*) 675, (*3*) 710, (*4*) 750, (*5*) 790.

Experimental data obtained in the present study suggest that the reduction of sulfate ions in the carnallite melt has a more complicated character and cannot be accounted for exclusively by the reaction of sulfate ions with the reducing gases.

The mechanism of reduction of sulfate ions in a molten chloride medium can be represented as follows. Upon pyrolysis of the oil coke at 650–730°C, the bituminous part of the oil coke transforms into a carbonized solid and volatile substances H_2, CH_4, CO, CO_2, and H_2S [8]. At 670–730°C, the main part of the volatile products is evolved within the first 5 min of the process [9, 10]. Figure 4 shows the experimental time dependences of the rate of reduction of sulfate ions by oil coke in the carnallite melt.

Within the first 5 min of the process, sulfate ions are almost not removed from the melt (Figs. 3 and 4). Moreover, the total amount of gases evolved upon pyrolysis of the oil coke introduced as a reducing additive is substantially lower than that necessary for removing the admixtures from the melt [4]. We also emphasize that the oil coke is mostly distributed over the surface layer, and sulfate ions cannot be removed from the melt only via formation of volatile components of the oil coke and their reaction with sulfates, because the mixture of evolved gases passes through a minor upper part of the melt. The final evidence in favor of the "not-only-gaseous" mechanism of reduction of sulfate ions is that the oil coke calcined in the carnallite melt at 750°C and virtually freed of volatile components removes sulfate ions from the melt rather efficiently.

To determine the contribution of volatile reducing agents to the removal of sulfate ions from the melt, we carried out a thermal analysis of carnallite samples with fresh and calcined oil coke on an MOM Q-1500 derivatograph (Hungary). The sample weight was 200 mg, and the heating rate, 10 deg min^{-1}. The sample compositions are listed in Table 2.

The results of a differential thermal analysis of carnallite mixtures with oil coke (fresh and previously calcined in the carnallite melt) are presented in Fig. 5. In the range 550–750°C, a strong exothermic effect is observed for sample no. 1 (oil coke in the carnallite melt). This effect corresponds to oxidation of volatile components, primarily hydrogen and methane, by atmospheric oxygen [7, 8]. Owing to the superposition of this exothermic peak on the endothermic peak corresponding to reduction of sulfate ions by the oil coke (sample no. 2), the effect associated with the reduction is somewhat shifted and lies in the range 680–750°C, with the peak at 730°C.

Table 2. Compositions of samples for thermal analysis

Run no.	Sample composition, wt %			
	carnallite	oil coke		sulfate ions
		fresh	calcined	
1	97.5	2.5	–	–
2	95	2.5	–	2.5
3	97.5	–	2.5	–
4	95	–	2.5	2.5

In the case of pyrolysis of a calcined oil coke (sample no. 3), the peak of the endothermic effect is shifted to 630–720°C owing to changes in the composition of pyrolysis products and to an increase in the content of carbon monoxide and dioxide [7, 8]. Moreover, the total yield of volatile components decreases for

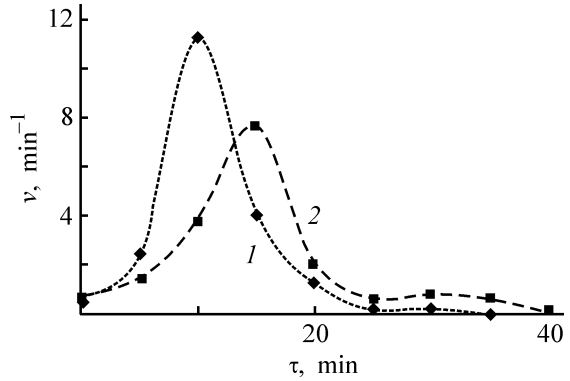

Fig. 4. Rate ν of removal of sulfate ions vs. time τ. T = 750°C. Reducing agent: (*1*) fresh oil coke; (*2*) oil coke calcined in the carnallite melt for 1 h.

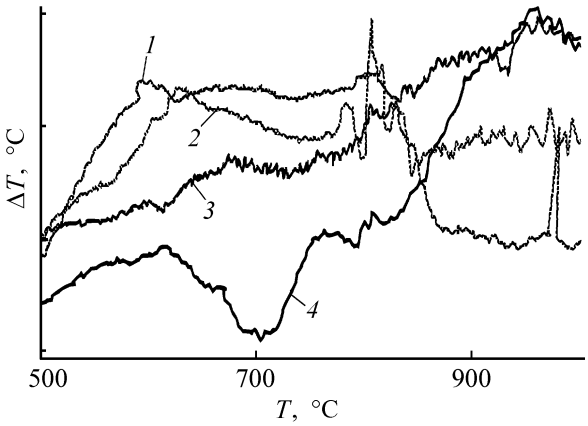

Fig. 5. DTA curves. (*T*) Temperature. (*1*) Pyrolysis of the oil coke in a carnallite melt containing no sulfates, (*2*) reduction of sulfates by a fresh oil coke, (*3*) pyrolysis of a calcined oil coke in the carnallite melt containing no sulfates, (*4*) reduction of sulfates by the calcined oil coke.

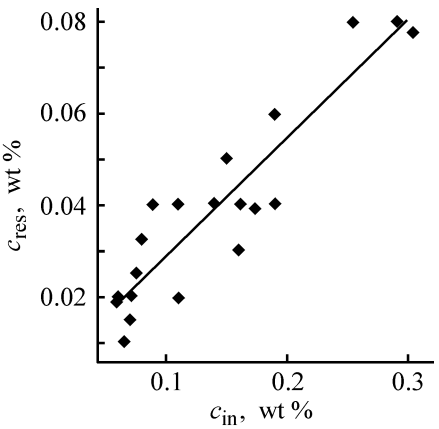

Fig. 6. Residual concentration c_{res} of sulfate ions in the carnallite melt in the mixer vs. the initial concentration c_{in} of sulfate ions in carnallite in the melting pot of the chlorinator.

this sample. For example, the loss of weight by sample no. 1 at 550–750°C was 3.6%, and that for the calcined sample, 1.7%. This fact is presumably responsible for the decrease in the rate of the process and for the shift of the peak of the maximum rate (Fig. 4). The reduction of sulfates in the carnallite melt by the calcined coke (Fig. 5, curve *4*) occurred in the range 660–750°C, with the maximum endothermic effect at 715°C. The difference between the peaks of endothermic effects in reduction with calcined and uncalcined coke is primarily due to the following: (i) pyrolysis of uncalcined oil coke releases a markedly greater amount of volatile components oxidized by atmospheric oxygen and (ii) the exothermic effect of oxidation of volatile products is superimposed on the endothermic effect of reduction of sulfate ions by carbon. In this case, the rate of reduction of sulfate ions by the preliminary calcined oil coke is significantly lower (Fig. 4) than that by the fresh coke. These data show that the reduction of sulfate ions by the oil coke also occurs via the reaction of oil coke components dispersed in the carnallite with sulfate ions.

Molecules of oil coke are a mixture of aromatic hydrocarbons with a π-electron system [9]. The high stability of molecular ions is a specific feature of aromatic hydrocarbons. When a C–C bond is formed, e.g., in the case when one macromolecule lies out of the plane of nearest neighbors, edge defects are formed. Foreign atoms, such as H, and groups like –OH, =O, –O–, =S, =N, and –N–, interact with the edge defects. On heating the oil coke, foreign atoms are removed from the carbon structure. For one or several carbon atoms, electrons appear to be unpaired near a defect. Such atoms have a trapped unpaired electron and rather stable C_M^-–C^+ groups are formed. As a result of evolution of a greater number of volatile components, the content of stable charged groups in a fresh oil coke is considerably higher, and, therefore, the rate of the reaction is higher in the case of a fresh oil coke (Fig. 4), compared with the oil coke calcined in the carnallite melt.

The reduction of sulfates, e.g., KSO_4^-, includes a primary act that consists in the attachment of a sulfate ion to certain points of the carbon network, in the first place to the edge defects, to give a transition complex C_M^-–C^+–O^-–SO_2–O^-–K^+. The stability of the complex and the composition of the products of its decomposition are determined by the temperature of the melt. At 650–750°C, the complex is unstable and decomposes.

Laboratory tests established that the oil coke can be used to reduce sulfates in the carnallite melt. It was shown that the reduction of sulfates by the oil coke also occurs via the reaction of oil coke components dispersed in the carnallite solution with sulfate ions.

Taking into account the requirements of cost saving and those of the current industrial scheme of magnesium production, we suggested to remove sulfates from the carnallite melt in a commercial chlorinator. The design of the chlorinator allows introduction of reducing additives of varied composition and enables purification to remove additionally introduced admixtures in a special chamber, the mixer.

We carried out tests on purification of a carnallite melt to remove sulfates in an indistrial chlorinator for magnesium production at the "Solikamsk magnesium plant" Joint-Stock Company. We tested the process of removal of sulfate ions from the carnallite melt for three ranges of sulfate ion concentrations in the carnallite melt (wt %): 0.07–0.16, 0.10–0.20, and 0.20–0.30. Sulfate ions were reduced in the chlorinator in the working mode in use at the electrolysis shop, with the only difference that a small amount of a reducing agent under study was introduced into the chlorinator mixer. We obtained a characteristic dependence of the residual content of sulfate ions in the carnallite melt at the chlorinator output on the content of sulfates in starting carnallite (Fig. 6).

It can be seen from Fig. 6 that the limiting content of sulfate ions in the starting carnallite, to which corresponds the permissible residual concentration of sulfate ions in the purified carnallite melt (0.05 wt %), is 0.15–0.18 wt %. The carnallite melt purified to this content of sulfate ions was further electrolyzed,

with no disturbance to the operation of electrolyzers observed.

CONCLUSIONS

(1) A procedure for purification of the flotation-type carnallite melt to remove sulfate admixtures was developed. The procedure ensures that the residual content of the admixtures decreases to 0.02–0.05 wt %.

(2) It was confirmed that a reducing agent dispersed in the carnallite melt, rather than that in the gaseous state, is involved in the reduction of sulfates by the oil coke.

(3) Industrial tests at an operating plant confirmed the high efficiency of the procedure developed for purification of the carnallite melt to remove sulfate ions.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Solubility of Polymethyl Methacrylate in Organic Solvents

I. Yu. Evchuk, R. I. Musii, R. G. Makitra, and R. E. Pristanskii

Litvinenko Institute of Physicoorganic and Coal Chemistry, National Academy of Sciences of Ukraine, Department of Physical Chemistry of Fuel Resources, Lviv, Ukraine

Received June 7, 2005

Abstract—Solubility of polymethyl methacrylate in 12 organic solvents at 30–70°C was studied.

The resistance of polymers to organic solvents is theoretically and practically important. At the same time, studies in this area are mainly concerned with swelling of polymers in various media. The dissolution process itself, despite its wide application in various technologies, has been studied to a considerably lesser extent.

According to the Nernst diffusion theory, the dissolution of low-molecular compounds in liquids occurs at the phase boundary rapidly and is limited by diffusion of components toward and away from the surface of a solid. The process rate v is determined by the diffusion coefficient D, boundary layer thickness l, and difference of the solute concentrations in the surface layer (c_0) and in the bulk (c):

$$v = \frac{D}{l}(c - c_0). \quad (1)$$

However, the process is considerably more complex in the case of polymers. Here, mention should be primarily made of studies by Ueberreiter *et al.* [1–4], who established for the example of polystyrene that the dissolution of a polymer is preceded by its swelling, with the subsequent formation of caoutchouc-like layer on the surface. Also, it was suggested that the overall rate of the process is determined by the rate of diffusion of a liquid into the polymer, in accordance with second Fick's law. It was found in [4] that the dissolution rate of polystyrene steadily decreases in the series of alkyl acetates as their molecular weight increases. However, attempts to relate the experimentally determined rate of polystyrene dissolution to the Einstein–Stokes coefficients

$$D = kT/6\pi\eta r \quad (2)$$

(D is the diffusion coefficient; η, viscosity; and r, radius of a solvent molecule) failed. This result is not surprising because no satisfactory correlation has been found until recently between the amount of adsorbed liquid S or the swelling rate and the physicochemical characteristics of solvents even for the first presumed stage of the dissolution, i.e., for swelling. The generally accepted Flory–Haggins theory, based on the Hildebrandt model of regular solutions, yields only semiquantitative relations and requires that an empirical correction interaction coefficient should be used [5]. Attempts to relate S to the electrophilicity E_T of solvents by Reichardt [6], their molal volume V_M [7], etc. have been no successful either.

At the same time, it was established in [8] that the only relationship between the limiting viscosity number of a polymer and the degree of its equilibrium swelling is that they behave in a similar way [8].

It was assumed that different types of interactions are involved in swelling of polymers and diffusion of solvents in these materials [9, 10]. Therefore, to obtain an adequate relation between S or D and solvent characteristics, it is necessary to take into account, in accordance with the linear free energies (LFE) principle, all mutually independent changes in the Gibbs energy of the components, associated with these parameters: $\Delta G = \Sigma \Delta g_i$.

To reveal the possible correlation between the physicochemical characteristics of organic solvents and the rate of polymer dissolution in them, we studied the dissolution of polymethyl methacrylate (PMMA) samples with an average molecular weight of 139 000 in 12 organic solvents. The dissolution rates at 30, 40, 50, and 70°C were determined gravimetrically.

The experimental results obtained are listed in Tables 1, 2. The data on the dissolution rate of PMMA at 30°C are analyzed in most detail (Table 1). As can be seen, there is no direct correlation between the dissolution rate and the structure or properties of a solvent, including its polarity. The best solvents for PMMA are partly substituted hydrocarbons, trichloromethane and trichloroethylene, in which polymer samples dissolve virtually completely in 30 min. At the same time, they nearly do not dissolve at all in trichloromethane. Good solvents are polar ethyl acetate and cyclohexanone. However, their ability to dissolve PMMA considerably decreases, as the molecular weight of esters increases, in agreement with the data of [4], and an even more polar dimethylformamide (DMF) dissolves PMMA even more slowly. Moreover, a strong difference in the dissolving power is even observed between aromatic hydrocarbons. At the same time, the curves describing the relative rate of the loss of mass by samples in the course of time, $Q = (w_0 - w_\tau)/w_0$, where w_0 is the initial mass of the sample and w_τ, its mass at an instant of time τ, are

always nearly linear, irrespective of the type of a solvent and temperature (Fig. 1).

Similarly to the rate of chemical reactions, the dissolution rate increases, on the average, twofold as the temperature is raised by 10°C (Table 2). A typical example of how the dissolution proceeds in the course of time at different temperatures is shown for dioxane in Fig. 2.

Attempts to describe the process in terms of the Einstein–Stokes dependence were unsuccessful. Figure 3 shows the relationship between the degree of PMMA dissolution (loss of mass in percent at 30°C in 20 min) and the parameter $1/\eta$ of this equation. It can be seen that these quantities exhibit to a certain extent opposite types of behavior: the degree of PMMA dissolution decreases as the solvent viscosity becomes higher, rather than a linear relationship. Especially strong deviations are observed for incompletely substituted hydrocarbons, trichloroethylene and chloroform.

Similar results were obtained for other time intervals (30, 40, and 60 min), with the deviations of experimental points from a straight line increasing with the extent of the process. This is not surprising, because the viscosity of the liquid phase gradually increases as it is saturated with the dissolved polymer. The deviations of the points also markedly increase with the temperature of the experiment, which can be attributed to dissimilar changes in viscosity with temperature for different solvents.

Somewhat better results were obtained with another parameter of the solvent, the molar volume V_M, which is directly related to the molecule radius r in formula (2). It was shown in [11] that the molar volume is an important parameter for generalization of data on the swelling rates for carbons in various solvents, with the process rate decreasing as this parameter becomes larger [11]. Similar results were obtained in the case in question. However, no clearly defined relationship could be obtained, either. Therefore, we attempted to find out whether the values obtained can be quantitatively generalized on the LFE principle by simultaneously taking into account the influence of both parameters in accordance with the dependence:

$$\log Q = a_0 + a_1\frac{1}{\eta} + a_2\frac{1}{V_M}, \qquad (3)$$

where Q is the relative loss of mass by the PMMA sample (%).

This attempt was unsuccessful too. Thus, the results obtained show that the dissolution kinetics of polymers is a complex process dependent on many

factors. Among them, mention should be made of the opposite directions of the following two processes. The first is the penetration (diffusion) of a solvent into the polymer, which is mainly determined by the size of its molecules. The second is that of a partial dissolution of a gel-like swollen surface layer of the polymer. This process is mainly dependent on the viscosity of the liquid phase, which, in addition, gradually increases in the course of its saturation with the polymer. Apparently, the second process will be also facilitated by agitation of the liquid, which makes its viscosity uniform throughout the polymer volume and prevents formation of highly viscous layers of a polymer solution on the surface of polymers.

Therefore, we attempted to generalize the data on the degree of polymer dissolution at different intervals of time (Tables 1, 2) by using the multiple-parameter Koppel–Palm equation [12], which takes into account different types of solvation, and supplementing this equation with terms that characterize self-association of solvents and their molar volume:

$$\log Q = a_0 + a_1\frac{n^2-1}{n^2-2} + a_2\frac{\varepsilon-1}{2\varepsilon+1} + a_3B + a_4E_T + a_5\delta^2 + a_6V_M. \quad (4)$$

Here n and ε are the refractive index and the dielectric constant of solvents, which determine the polarization and polarity and characterize the capacity of the solvents for nonspecific solvation; B and E_T, the Palm basicity and the Reichardt electrophilicity, which determine the specific solvation of the substrate; δ, Hildebrandt solubility, whose square is proportional to the cohesion energy of the medium; and V_M, molar volume of the solvent.

It was found that Eq. (4) adequately describes the dependence of the diffusion coefficients of solvents into the polymer on their physicochemical properties [9, 10]. Indeed, on excluding the most inconsistent data for trichloromethane, the degree of polymer dissolution attained at 30°C in 20 min (Table 1) is satisfactorily described by the following six-parameter equation

$$\log Q = 0.95 + (4.31 \pm 3.54)f(n) + (2.84 \pm 1.91)f(\varepsilon) - (0.95 \pm 0.93) \times 10^{-3}B + (0.088 \pm 0.107)E_T - (5.98 \pm 2.51) \times 10^{-3}\delta^2 - (26.1 \pm 4.32) \times 10^{-3}V_M, \quad (5)$$

$$N = 10,\ R = 0.987,\ S = 0.110.$$

On excluding the nonsignificant terms B and E_T, which characterize the specific solvation, we also obtain an adequate four-parameter equation:

$$\log Q = 3.35 + (4.11 \pm 1.48)f(n) + (4.41 \pm 0.63)f(\varepsilon) - (5.31 \pm 0.79) \times 10^{-3}\delta^2 - (26.2 \pm 2.59) \times 10^{-3}V_M, \quad (6)$$

$$R = 0.978,\ S = 0.109.$$

The above consideration shows that an increase in the size of solvent molecules (V_M) and in their self-association (δ^2) decelerates the dissolution of polymer in the solvents, which is presumably due to the hindrance to solvent diffusion into the polymer. At the same time, the nonspecific solvation of the chains of a polymer by the solvent favors its dissolution. However, particular interesting in this case is the conclusion that the possible specific solvation of PMMA is unimportant for the dissolution process, despite the presence of electron-donating carbonyl groups in its structure. Possibly, this is due to the fact that we studied nearly exclusively typical electron-donating solvents, and the electron-accepting trichloromethane is so active a solvent that it cannot be involved in the comparison.

It should be noted that Eq. (4) yields satisfactory results only for temperatures close to room temperature. Apparently, the effect of polymer diffusion into the liquid, which strongly depends both on the increase in viscosity upon saturation of the solution with the polymer and on the opposite effect of the decrease in the viscosity of the medium on raising the temperature, which is difficult to take into account, will be also the important factors under other conditions.

CONCLUSION

The dissolution rate of polymethyl methacrylate in various organic solvents cannot be described in terms of the Einshtein–Stokes dependence. Dissolution is a complex process dependent on the diffusion and solvation phenomena occurring in the system. The maximum dissolution rate is observed in trichloromethane and trichloroethylene. Dissolution in other solvents is determined, on the one hand, by the influence of their polarity and polarizability, which facilitate the process, and, on the other, by the energy density of cohesion and the molar volume, which act in the opposite direction.

SORPTION AND ION-EXCHANGE PROCESSES

Effect of Various Treatment Methods on Sorption Properties of Antimony(V)-based Simple and Mixed Oxohydrates

N. S. Grigorova and Yu. Yu. Semenova

St. Petersburg State University, St. Petersburg, Russia

Received June 29, 2005

Abstract—A comparative study of the sorption characteristics of crystalline antimonic acid and a silicon-phosphorus-antimony cationite subjected to thermal treatment in air and in a molten sodium nitrate was carried out. The possibility of regeneration of these sorbents, which are used in ion-exchange strengthening of glasses, was analyzed.

Owing to their thermal stability and clearly pronounced selectivity, inorganic ionites occupy a prominent place in the ion-exchange practice. An interesting application field of inorganic sorbents is ion-exchange strengthening of glasses [1].

The strengthening process consists in that Na^+ and Ca^{2+} ions in the surface layer of a glass are substituted with K^+ cations from a KNO_3 melt. The strengthening is performed in stainless steel baths. An inorganic cationite placed in the melt absorbs products formed in bath corrosion (Fe^{3+}), impurities contained in a molten technical-grade KNO_3, and ions of sodium and alkaline-earth metals, displaced from the glass by K^+ ions. The contact with a KNO_3 melt having a temperature of about 400°C requires that the sorbents used should be highly temperature resistant [2]. The strength characteristics of the glasses obtained could be markedly improved by using inorganic cationites based on oxygen compounds of antimony(V) for purification of molten potassium nitrate [1, 2].

Cationites in the form of mixed Sb(V), P, and Si oxohydrates have been obtained and studied at the laboratory of ion exchange at the chemical faculty of St. Petersburg State University. The polymeric matrix of these sorbents is based on crystalline antimonic acid (CAA) [structural type of pyrochlore, space group *Fd*3*m*]. The unit cell of CAA consists of 16 antimony-oxygen octahedra $[SbO_{6/2}]^-$ jointed at vertices [3]. The excess charge of the lattice is neutralized by cations capable of exchange (H^+, Na^+, K^+, etc.). The substitution of antimony atoms in the pyrochlore structure by phosphorus atoms leads to rupture of the polymer chain, and, therefore, phosphorus can be contained in silicon-phosphorus-antimony cationites only in certain amounts (not exceeding 2 mg-at g^{-1}). Silicon, which can isomorphically substitute Sb(V) in the sorbent matrix under certain conditions, is contained in the ionites in the form of silicon-oxygen octahedra $[SiO_{6/2}]^{2-}$. An increase in the excess charge of the crystal lattice of a sorbent enhances the sorption of multiple-charge cations [5, 6]. The selectivity of each silicon-phosphorus-antimony ionites is determined by the relative amounts of Sb, P, and Si in a sample. Selectivity to single-, double-, or triple- charged ions can be formed by varying the chemical composition of SiPSb samples. In addition, raising the content of silicon improves the chemical and thermal stability of the sorbents [4–8].

A CAA sample and that of a silicon-phosphorus-antimony cationite (SiPSb) with the highest content of silicon [Sb : P : Si = 1.80 : 0.62 : 6.69 mg-at g^{-1}], both synthesized at the laboratory of ion exchange at St. Petersburg State University, were chosen for examination.

The aim of this study was to analyze transformations of cationites in molten KNO_3. In addition, it was necessary to determine whether these transformations are reversible.

Results of a chemical analysis of the samples studied

Sample no.	Sample	Sb(V) content, mg-at g^{-1}	Absorption of indicated ions, mg-equiv g^{-1}			
			Ag^+	Ca^{2+}	Cd^{2+}	Fe^{3+}
1	CAA	4.93	4.63	2.36	5.43	1.25
2	SiPSb	1.84	2.68	1.10	1.45	2.95
3	CAA(KNO_3)	2.28	0.34	0.24	0.39	1.75
4	SiPSb(KNO_3)	0.95	1.16	0.70	0.90	0.94
5	CAA(t)	3.28	0.45	0.31	0.37	0.87
6	SiPSb(t)	1.85	2.73	0.55	0.88	1.22
7	CAA(KNO_3)-r	5.00	4.75	0.6	1.83	1.0
8	SiPSb(KNO3)-r	1.95	1.82	1.10	1.25	2.0
9	CAA(t)-r	4.27	4.88	0.34	2.08	1.15
10	SiPSb(t)-r	1.93	1.93	1.19	1.46	1.95

The results of a chemical analysis of the samples are listed in the table. The content of Sb(V) in the samples was determined iodometrically [9], with starch as indicator. The determination error was about 4%.

The starting CAA and SiPSb sorbents were brought in contact with a KNO_3 melt (with the reagents taken in a 1 : 100 ratio by weight) at 450–550°C for 6 days and then washed to remove the excess amount of KNO_3 [the sorbents subjected to treatment are designated as CAA(KNO_3) and SiPSb(KNO_3)]. The treatment time was chosen on the basis of specific features of the technological process of strengthening. For comparison, the initial samples were calcined in air under similar conditions [designated as CAA(t) and SiPSb(t)]. Further, all the samples were treated with a 0.1 N HNO_3 solution ($g : V = 1 : 100$) under quasi-dynamic conditions (the acid solution was periodically renewed during 14 days), washed with water to remove the excess amount of the electrolyte, and dried at 70°C for 24 h [CAA(t)-r, CAA(KNO_3)-r and SiPSb(t)-r, SiPSb(KNO_3)-r]. The letter r in the sample designations means that they were subjected to regeneration with nitric acid. HNO_3 was used in this case not only to convert the sorbents into the H^+ form, but, to a greater extent, as a strong oxidizing agent.

Finished samples were subjected to chemical and X-ray phase analyses.[1]

[1] The X-ray phase analysis of the samples was carried out at the laboratory of X-ray diffraction analysis (St. Petersburg State University) by the powder method on a URS-50 instrument with Cu_{K_α} radiation.

As already mentioned, CAA has a well-defined structure of the pyrochlore type (space group *Fd*3*m*). The anionic skeleton of CAA is constituted by $[SbO_{6/2}]^-$ octahedra jointed at vertices. The octahedra bear an excess negative charge neutralized by cations that are capable of exchange (counter ions). A comparison of the results of X-ray phase analyses of the initial CAA samples and those calcined in air [10] demonstrated that, upon calcination in air, the crystal structure of the pyrochlore type is preserved, but reflections with odd *hkl* indices become extinct. As is known, the latter characterizes substitution of a proton [10] H^+ or a hydroxonium ion H_3O^+ in positions 16*d* by Sb(III) ions, which appear in the course of calcination of the initial CAA sample via dehydration of the structure and thermal reduction Sb(V) → Sb(III). According to the results of a chemical analysis (see table), about 30% of the whole amount of antimony(V) contained in the initial CAA was transformed into a triple-charged state in the course of thermal treatment in air.

Calcination of CAA in a KNO_3 melt led to amorphization of the structure, which is manifested in reflection broadening (Fig. 1b). In addition to the pyrochlore phase, a new phase (*A*) was clearly seen in the X-ray diffraction pattern. This phase is similar to the hexagonal form of KNO_2 and has an empirical formula K_3NO_3. It is apparently a product of thermolysis of the starting KNO_3. Both the initial SiPSb sample and that calcined in air are X-ray-amorphous [4]. Calcination of SiPSb in the melt yielded phase *A*.

The results obtained in a chemical analysis of samples treated after calcination with a 0.1 N HNO_3 solution (table, sample nos. 7–10) point to a quantitative

transformation of Sb(III) to Sb(V). However, the pyrochlore structure could be regenerated only for the CAA(KNO_3) sample, whereas the structural transformations of the CAA(t) sample were irreversible, which is due, as shown in [10], to the irreversibility of the dehydration process (Fig. 1c). Regeneration of a SiPSb(KNO_3) sample returned it into the initial X-ray-amorphous state (Fig. 2c), and the amount of Sb(V) in the sample structure increased from 0.95 to 1.95 mg-at g^{-1}.

The sorption capacity of the samples was evaluated by the amounts of absorption of metal ions (Ag^+, Ca^{2+}, Cd^{2+}, Fe^{3+}) from 0.1 N solutions of the respective solutions (see table) under static conditions ($g : V = 1 : 100$, time of contact 7 days). The exchange capacity of the samples was calculated from the loss of concentration of metal ions in equilibrium solutions. The ion concentrations were determined by trilonometry. [11].

The initial cationites well sorbed Ag^+ ions and doubly charged ions Ca^{2+} and Cd^{2+}. The sorption of triple-charged Fe^{3+} ions by CAA was approximately four times lower, which is characteristic of this ionite [7]. The superequivalent sorption of Cd^{2+} ions, observed for CAA, is due to the fact that this ion tends to be hydrolyzed and can be absorbed in the form of polynuclear complexes. On passing to a mixed oxohydrate SiPSb, a pronounced enhancement of the sorption of triple-charged Fe^{3+} ions was observed (see table).

Thermal treatment of CAA both in air and in a melt led to a dramatic decrease in the absolute sample capacities to 7–14% of the initial value. The only exception was sorption of Fe^{3+} ions. Depending on the type of treatment, it either somewhat decreased or even increased to 140% relative to the initial value. This fact is apparently due to the specific behavior of this ion in aqueous solutions, and primarily to its high susceptibility to hydrolysis. In the opinion of the authors of [12], calcination of CAA in air (T = 500°C) leads to a complete dehydration of the structure. This creates favorable conditions for incorporation of the Fe^{3+} ion, which exists in the form of exceedingly stable hydroxo complexes with a charge of +2, +1, and even 0 [12]. The increase in the exchange capacity (to 140%) for Fe^{3+} ions, observed for the CAA(KNO_3) sample, is probably due to a certain extent of amorphization of the structure.

After regeneration of CAA samples with a 0.1 N HNO_3 solution, the initial capacity for Ag^+ ions was restored and the anomalously high absorption of Fe^{3+} ions disappeared (see table, sample nos. 7 and 9).

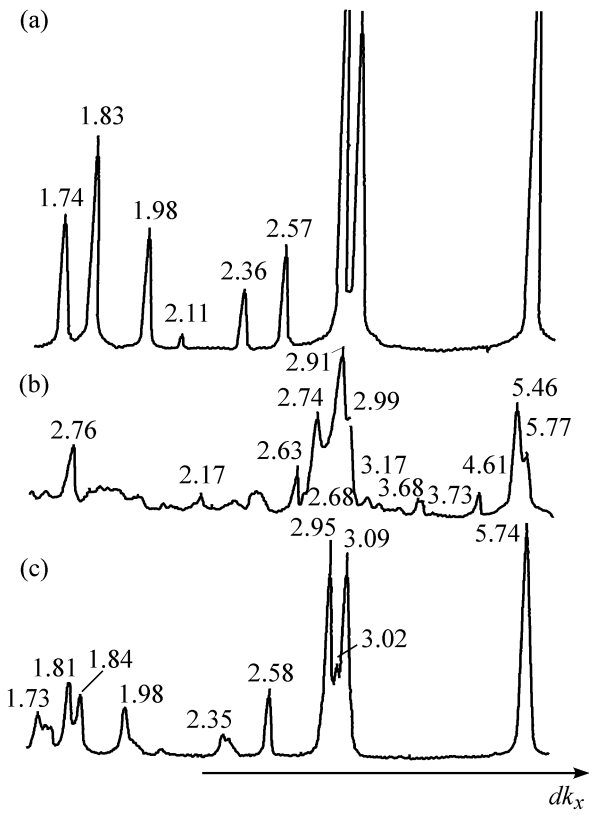

Fig. 1. X-ray diffraction patterns of CAA. (a) Initial CAA, (b) CAA(KNO_3), and (c) CAA(KNO_3)-r.

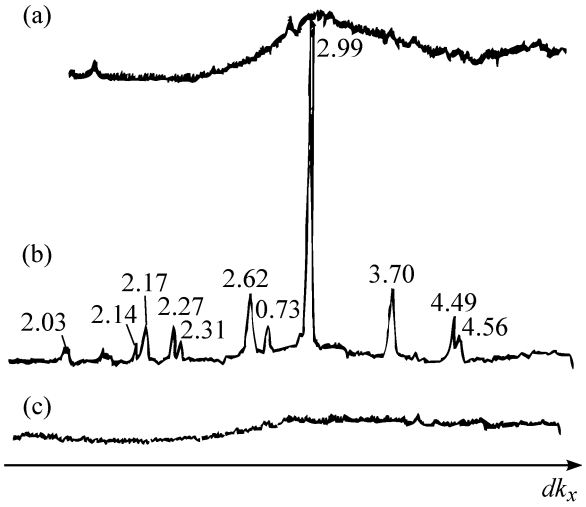

Fig. 2. X-ray diffraction patterns of SiPSb. (a) Initial SiPSb, (b) SiPSb(KNO_3), and (c) SiPSb(KNO_3)-r.

The sorption of doubly charged Ca^{2+} and Cd^{2+} ions remained virtually unchanged upon contact with HNO_3 and did not exceed 40% of the initial value.

Thermal treatment of SiPSb oxyhydrate did not lead to any pronounced fall in the sorption capacity of the ionites under study. In some cases, up to 100%

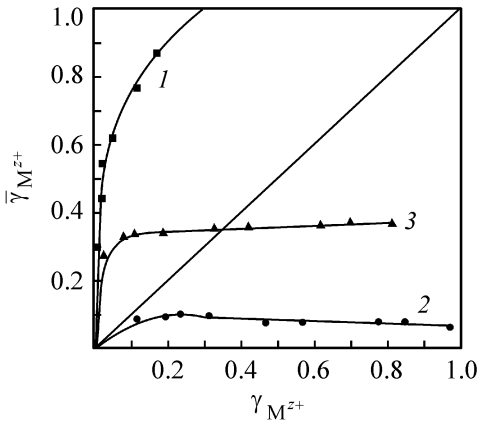

Fig. 3. Sorption isotherms for CAA(KNO_3). Sample: (*1*) CAA (init.), H^+ and Cd^{2+}; (*2*) CAA(KNO_3), K^+ and Cd^{2+}; and (*3*) CAA(KNO_3)-r, H^+ and Cd^{2+}. ($\bar{\gamma}_{M^{z+}}$, $\gamma_{M^{z+}}$) Equivalent fractions of the metal in the solid phase and in the equilibrium solution, respectively; the same for Figs. 4, 5.

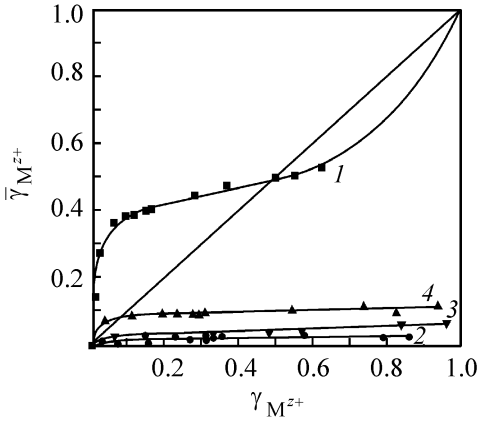

Fig. 4. Sorption isotherms for CAA(t). Sample: (*1*) CAA (init.), H^+ and Ca^{2+}; (*2*) CAA(t), H^+ and Ca^{2+}; (*3*) CAA(t)-r, H^+ and Ca^{2+}; and (*4*) CAA(KNO_3), H^+ and Ca^{2+}.

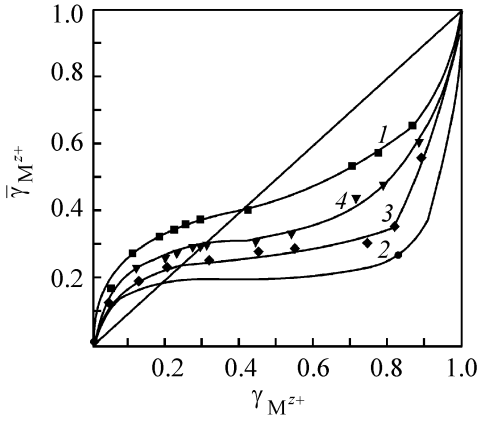

Fig. 5. Sorption isotherms for SiPSb. Sample: (*1*) SiPSb (init.), K^+ and Ca^{2+}; (*2*) SiPSb(KNO_3), K^+ and Ca^{2+}; (*3*) SiPSb(KNO_3)-r, K^+ and Ca^{2+}; and (*4*) SiPSb(t)-r, K^+ and Ca^{2+}.

of the exchange capacity was retained. SiPSb samples show a high degree of regeneration. After the regeneration, the capacity of the ionites for doubly charged ions was no less than 90% of the initial value, and that for Fe^{3+} and Ag^+ ions, about 70% (see table, sample nos. 8 and 10).

The sorption equilibrium on initial, calcined, and regenerated samples in mixed HCl–$CaCl_2$ and HNO_3–$Cd(NO_3)_2$ solutions was studied under static conditions by the method of separate samples (a weighed portion of a sample was poured over with a mixture of solutions of the acid and the corresponding salt of equal concentrations, taken in various ratios ($g : V$ = 1 : 100). Changes in the concentration of metal ions in equilibrium solutions were determined trilonometrically [11]. The results obtained in the form of exchange isotherms are represented as dependences of the equivalent fraction of a cation in the solid phase ($\bar{\gamma}_{M^{z+}}$) on the fraction of the same ion in the equilibrium solution ($\gamma_{M^{z+}}$) in Figs. 3–5. The determination error was 2–3%.

The initial CAA samples (Fig. 3, curve *1*) exhibited selectivity to the Cd^{2+} ion over the entire range of concentrations of the competing H^+ and Cd^{2+} ions in the equilibrium solution. As the solid phase was filled with Ca^{2+} ions, the selectivity of CAA was inverted (Fig. 4, curve *1*) in favor of H^+ ions, which is indicated by the S-like shape of the sorption isotherms.

For calcined CAA samples, all the isotherms (Fig. 3, curve *2*; Fig. 4, curves *2*, *3*) lie below the diagonal line K_{eq} = 1, which indicates that these samples have no selectivity to Ca^{2+} and Cd^{2+} ions. The general appearance of the isotherms points to a virtually complete loss of capacity by the sorbent. The regeneration of a CAA sample calcined in a melt was more complete than that for a sample calcined in air (Fig. 3, curve *3*; Fig. 4, curve *4*); however, it may be stated that the regeneration process leads to a minimum restoration of the sorption capacity of CAA.

The isotherms of sorption of Ca^{2+} ions on the initial SiPSb ionite are similar for thermally treated and regenerated samples, which indicates that, as the solid phase is filled, the selectivity to the metal ion is inverted in favor of H^+ ions (Fig. 5). The relative positions of the sorption isotherms demonstrate that thermal treatment affects the sorption characteristics of the SiPSb cationite to a considerably lesser extent, compared with the case of CAA, and regeneration is substantially more complete and efficient than that in CAA samples.

Some of the results of this study can be regarded as well expectable and coinciding with the available data.

This primarily refers to thermal transformations of CAA and SiPSb samples calcined in air. The data obtained confirm the conclusions [4] concerning the stabilizing effect of silicon on the thermal stability of the pyrochlore structure. The interaction between the sorbents studied and the melt is more complex. This process is accompanied by phase transformations, which lead to disintegration of the initial pyrochlore structure to give a new phase similar to the hexagonal lattice of the K_3NO_3 type.

The interaction of an amorphous mixed oxohydrate of SiPSb with a KNO_3 melt yields a clearly defined crystalline phase that does not belong to the pyrochlore type. The most interesting result obtained in regeneration with a HNO_3 solution of sorbents that were brought in contact with a KNO_3 melt is that the new phase disappears and the initial structure of pyrochlore is restored in CAA.

The data obtained in this study are practically important because they demonstrate the possibility of a complete restoration of the chemical composition, sorption properties, and initial structure of SiPSb oxohydrate after thermal treatment or exposure to a KNO_3 melt. The method developed can be suggested for regeneration of a valuable cationite that was used for a long time in ion-exchange strengthening of glasses.

CONCLUSIONS

(1) A comparative study of the behavior of a crystalline antimonic acid and silicon-phosphorus-antimony cationite in a KNO_3 melt revealed the following advantages of the silicon-containing sorbent: high thermal stability and increased selectivity to multiple-charge ions.

(2) Reversible phase transformations in an interaction between sorbents and a KNO_3 melt were found in an examination of the initial and modified sorbents based on oxygen compounds of Sb(V). These transformations lead to disintegration of the initial pyrochlore structure and give rise to a new crystalline phase.

(3) A new efficient method was suggested for regeneration of cationites based on oxygen compounds of antimony via a solid-phase transition Sb(III) $\rightarrow$ Sb(V). This method employs the oxidative capacity of nitric acid.

Abstract—The dependence of the microporous structure of activated carbon fibers on the carbonization temperature of hydrate-cellulose fibers was studied by BET, TVFMP, and Horvath and Kawazoe techniques and methods of the nonlocal density functional theory. The surface energy distribution function was obtained, together with the micropore size distribution curves. It was shown that the effective micropore sizes calculated by the TVFMP method are close to the maximum of the distribution function found in terms of the theory of the density functional.

Activated carbon fibers (ACF) differ from the conventional granulated adsorbents in that they make it possible to create adsorbents in the form of nonwoven structures, cardboard, fabrics, and other physical entities. The small geometric dimensions of elementary fibers lead to a substantial increase in the rate of internal mass transfer. Both the last parameter and the intensity of mass transfer in the course of adsorption depend on the size of micropores [1, 2]. At the same time, an objective analysis of the micropore volume distribution by pore size (MVDPS) is required in various areas of chemical technology, because this function determines the applicability fields and choice of an optimal adsorbent. Polymer precursors allow a sufficiently wide variation of the MVDPS. This study is concerned with one of ways to obtain ACF with various micropore volumes and sizes, which makes it possible to control the MVDPS in the existing industrial technology by somewhat modifying the carbonization mode of the starting precursor.

EXPERIMENTAL

As objects of study served samples of activated carbon fibers. A technical viscose thread was used as a precursor. Samples ACF-450, ACF-600, ACF-800, and ACF-1000 were obtained at different thermal treatment (carbonization) temperatures of 450, 600, 800, and 1000°C, respectively. The carbonization was performed in an industrial installation in nitrogen at the temperatures specified above for 36 min. Further, thermally treated carbon fibers were steam-activated at 800°C in an industrial furnace for 6 min. The resulting ACF had a mostly microporous structure with small-volume mesopores.

Isotherms of nitrogen adsorption were measured on a CAMO ERBA STRUMENTAZIONE MICROSTRUCTURE 85/02/04 instrument and SORTOMATIC-1900 installation. This was done at a temperature of –195.8°C at relative nitrogen pressures p/p_0 in the range from 1×10^{-4} to 0.85 (Fig. 1).

The adsorption isotherm reflects the porous structure of adsorbents and makes it possible to calculate

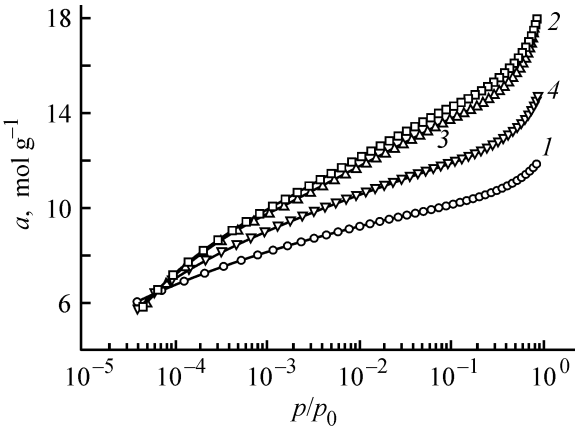

Fig. 1. Isotherms of nitrogen adsorption a (T = –195°C) on activated carbon fibers. (p/p_0) Relative pressure. (*1*) ACF-450, (*2*) ACF-600, (*3*) ACF-800, and (*4*) ACF-1000; the same for Fig. 2–4.

1000	$\frac{0.41}{0.04}$	0.06	$\frac{0.40}{3.4}$	0.30 – 0.32	0.35	$\frac{1035}{11}$	1023

some of its characteristics in terms of various model concepts. This study used methods for linearization of experimental data in accordance with the BET equation [5] and the equation of theory of volume filling of micropores (TVFMP) [3] and in terms of the molecular approaches of Horvath and Kawazoe (HK) [4] and nonlocal density functional theory (NLDFT) [5].

The porous structure parameters obtained are listed in the table: W_1 and W_2, specific micropore volumes found using the two-term TVFMP equation ($cm^3\ g^{-1}$); V_{me}, mesopore volume ($cm^3\ g^{-1}$); x, halfwidth of slit-like micropores (nm); and S_{sp}, specific surface area of the pores ($m^2\ g^{-1}$). The conventional pore classification by sizes, adopted by IUPAC, is as follows: micropores, <2 nm; mesopores, 2–50 nm.

It can be seen from the table that ACF samples contain only a small volume of mesopores, and, therefore, are mostly microporous adsorbents. Their specific surface area was evaluated by the BET and TVFMP methods. From the formal standpoint, the isotherms of nitrogen adsorption on the samples studied can be well approximated by the linear form of the BET equation at p/p_0 in the range from 5×10^{-3} to 0.15, with the straight lines emerging virtually from the origin of coordinates, i.e., the constant C of the BET equation tends to infinity.

A thermodynamic analysis of the BET equation in [6] demonstrated that, in this case ($C \gg 100$), the value of another constant of the equation, a_m, must correspond to the monolayer capacity. This statement is valid if there is no steric hindrance in micropores to formation of monomolecular layers of the adsorbate on opposite walls [7]. It can be seen from the table that raising the carbonization temperature to 600 – 800°C leads to a substantial increase in the specific surface area, and as this temperature becomes even higher, S_{sp} somewhat decreases. This can be explained as follows. In the low-temperature stage of carbonization of carbon fibers, mostly a macroporous structure is developed because of the evolution of gaseous products and transport porosity is formed. Such a carbon structure is favorable for penetration of the activating agent and formation of a developed porous structure. The change in the properties of carbon-containing materials on elevating the carbonization temperature is due to the onset of structural transformations and to shrinking, which consists in that the bending of carbon layers decreases and ultramicropores become narrower and pass to the turbostrate state, which closes the mouths of micropores. In addition, the transport porosity decreases. These phenomena make the specific surface area of ACF smaller.

The size of micropores was calculated using the TVFMP method. The theory of volume filling of micropores is based on the fact that, irrespective of the nature of sorbate and adsorbent, the distribution function of the Gibbs energy over the amount of adsorption is described by the equation for the Weibull distribution. For active carbons with a bidisperse microporous structure [3], this equation has the form

$$a = \frac{W_1}{V}\exp\left[-\left(\frac{\Delta\mu_1}{\beta E_{01}}\right)^2\right] + \frac{W_2}{V}\exp\left[-\left(\frac{\Delta\mu_1}{\beta E_{02}}\right)^2\right], \qquad (1)$$

where $\Delta\mu_1 = RT\ln p/p_0$; β, similarity coefficient equal to 0.33 for nitrogen; V, molar volume of the adsorbate; W_1 and W_2, specific volumes of micropores I and II in the microporous structure; and p and p_0, equilibrium pressure and saturated vapor pressure of the adsorbate, respectively.

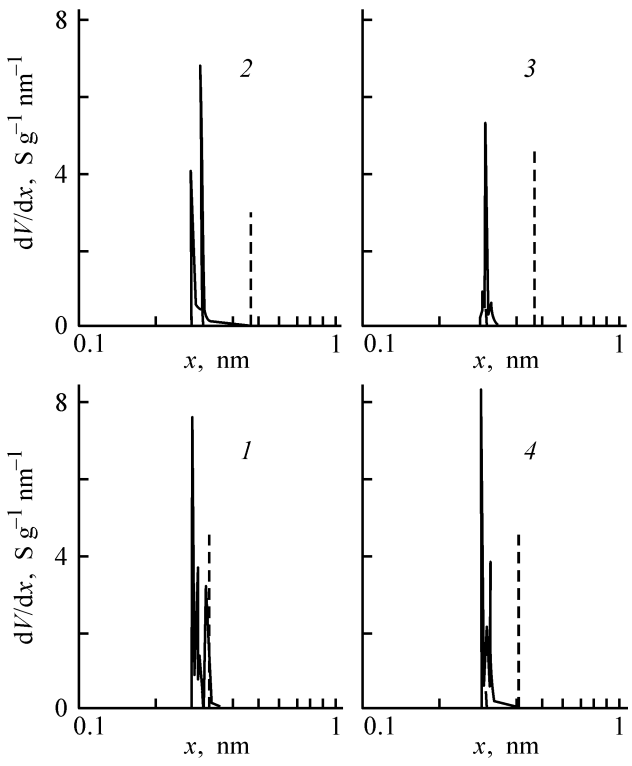

Fig. 2. Pore volume (V) distribution function by size x, calculated using the HK method.

The characteristic energy of benzene adsorption, E_0, is a function of the micropore size. The type of this function for active carbons was determined experimentally from small-angle X-ray scattering data and by the method of molecular probes [8]. It can be represented as

$$x = 5.4/(E_0 - 11.4), \quad (2)$$

where x is the micropore halfwidth (nm), and E_0 is the characteristic energy of benzene adsorption (kJ mol^{-1}). Simultaneously, a simpler expression $x = 12/E_0$ is used.

The following equation for calculating the specific surface area of micropores can be readily obtained in terms of the model of an infinite slitlike pore:

$$S = W/x. \quad (3)$$

In the given case, the experimental data are satisfactorily approximated by the two-term equation (1) in the range from $p/p_0 = 1 \times 10^{-4}$ [at lower pressures, the linear dependence $\ln a = f[\ln(p/p_0)]^2$ is not observed] to 0.04–0.05, which corresponded to the first basic microporous structure. To the second microporous structure corresponded a short linear portion that extended to $p/p_0 = 0.15$–0.2. The calculated values of W_1, W_2, x_1, x_2, and S_{sp} are listed in the table in the form of fractions, with the numerator corresponding to microporous structure I, and denominator, to structure II. Comparison of S_{sp} by TVFMP with that by BET shows that they are in a satisfactory agreement. However, TVFMP yields additional information about the porous structure: volume and size of micropores. The second porous structure has an order of magnitude smaller volume of micropores, and their size corresponds to the lower boundary of the range of mesopores (see table).

As the carbonization temperature is raised to 800°C (see table), the volumes of micro- and mesopores grow, with the size of micropores increasing simultaneously. Elevating the temperature further leads to a slight decrease in these parameters, which occurs in parallel with a similar change in the specific surface area of ACF for the reason described above.

Information about a finer structure of micropores is yielded by the HK and NLDTF methods. The starting point of the HK technique [4] is that the slitlike pore of the carbon adsorbent has only two states: empty or completely filled. A thermodynamic analysis and modeling of intermolecular interactions in a micropore led to steplike adsorption isotherms. To find the MVDPS, the authors of the HK technique calculated a set of local isotherms that could be used to describe any isotherm with a sufficiently high precision.

This analysis of the isotherms of nitrogen adsorption on ACF led to the distribution functions shown in Fig. 2. It can be seen that a rather uniform microporous structure is formed in ACF in the course of activation, with the TVFMP method (dashed line in Fig. 2) yielding closely similar results only for ACF-450 sample, and markedly overestimated results for the other samples.

The Nonlocal Density Functional Theory (NLDFT) was desribed in [5]. It starts from the fact that the adsorbate density varies across the width of a slit-like pore for the following two reasons. First, the intensity of intermolecular interactions varies under the conditions of superposition of the potentials of the opposite walls. Second, the energy of intermolecular interaction changes in formation of the second and subsequent layers, when the energies of the intermolecular interactions of an adsorbate molecule with the surface of the adsorbent and with the earlier adsorbed molecules are taken into account. In addition, the NLDFT theory can characterize the nonuniformity of the adsorbent sur-

face via the distribution function of the adsorbate–surface potential.

To determine the pore size ($dV/d\ln H$, where H is the width of micro- and mesopores) and surface energy distributions, the authors calculated a set of local isotherms at 70 values of ε_{sf}/k_B (20 to 90 K), 250 values of the pore width (up to 100 nm), and 500 values of the reduced pressure p/p_0 in the range 1×10^{-10}–1. The experimental isotherms were processed by Tikhonov's regularization method described in ample detail in [9]. In the NLDFT theory, the distribution function of the surface area of pores by energy is set in the form

$$\xi = \frac{dS/S_0}{d\varepsilon_{sf}/k_B}, \quad (4)$$

where S is the surface area of pores having a potential lower than ε_{sf}; S_0, total surface area of pores (thus, S/S_0 is the fraction of the surface area of the pores having a potential lower than ε_{sf}); ε_{sf}, potential of interaction between a carbon atom and a nitrogen molecule; and k_B, Boltzmann constant. The results obtained in the calculations are presented in Figs. 3, 4.

Comparison of the distribution curves produced by the HK and NLDFT methods shows that they are significantly different. This is a consequence of the nonrealistic steplike isotherm yielded by the HK technique. The NLDFT method seems to be more credible, because it postulates gradual filling of the adsorption volume, rather than a steplike filling of pores. Interestingly, the pore size by TVFMP falls in this case (if H is taken to be equal to $2x$) within the vicinity of the peaks in the pore distribution curves, even though do not coincide with these peaks.

As can be seen in Fig. 3, the carbonization temperature has virtually no effect on the distributions of mesopores (2.0–10 nm), but markedly shifts the peak for micropores to larger pore widths.

The surface energy distributions are shown in Fig. 4. It is of interest to compare them with the data of [5] for graphitized carbon black and activated kernel shell carbon, which have, similarly to ACF, a starting natural precursor based on cellulose.

The homogeneous graphitized carbon black studied in [5] shows a single peak at ε_{sf}/k_B = 58.01 K. ACF exhibit a strong scatter around this value, as also do the shell carbons Norit ROX and Ajax [5]. This can be attributed to a structural imperfection of the graphite lattice, especially for ACF, which are produced

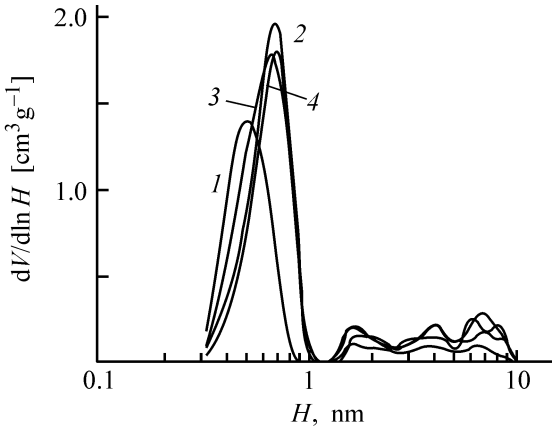

Fig. 3. Distribution function $dV/d\ln H$ of the volume V over pore width H by the NLDFT method.

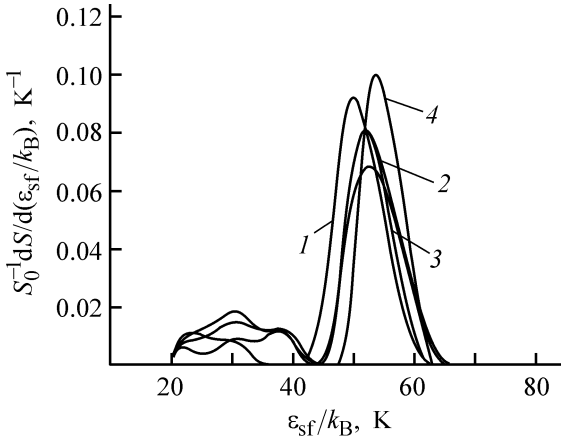

Fig. 4. Surface energy distributions $S_0^{-1}dS/d(\varepsilon_{sf}/k_B)$–$\varepsilon_{sf}/k_B$.

from an oriented precursor having no natural crystal structure.

Broadened peaks at lower energies are also present for kernel shell carbons. They can be attributed to a decrease in the interaction potential in blind pores (compared with the idealized infinite slitlike pores). It is interesting to note that the surface energy distribution curves for kernel shell carbons contain a peak at an energy exceeding 58.01 K. The authors of [5] attributed this peak to the presence of active centers of unsaturated carbon bonds at pore walls. Thus, ACF probably have a more energetically uniform surface than kernel shell carbons.

As the carbonization temperature increases, the structure of the ACF surface approaches that of graphite, because the peak of the curves is shifted toward 58 K, a value of ε_{sf}/k_B characteristic of pure graphitized carbon black.

CONCLUSIONS

(1) Activated carbon fibers have a mostly microporous structure, with the volume of mesopores not exceeding 0.1 $cm^3 g^{-1}$.

(2) As the carbonization temperature is elevated from 450 to 600–800°C, the volume of micropores increases from 0.37 to 0.51–0.53 $cm^3 g^{-1}$, with the pores simultaneously growing in size. At a carbonization temperature of 1000°C the volume of micropores somewhat decreases.

(3) The surface energy distribution curves were for the first time obtained for activated carbon fibers.

Development of Procedures for Synthesis of Carbon Materials with Molecular-Sieve Properties

S. S. Stavitskaya, V. E. Goba, A. N. Tomashevskaya, and N. T. Kartel'

Institute of Sorption and Endoecology Problems, National Academy of Sciences of Ukraine, Kiev, Ukraine

Received December 30, 2004; in final form, April 2005

Abstract—New methods for synthesis of uniformly porous carbon materials with sieve properties and small apparent density from phenol-formaldehyde resins were developed; the optimal conditions of their synthesis were determined. New types of finely dispersed carbon powders were prepared using various treatment procedures at different stages; the structural and sorption properties of the resulting materials were studied.

Synthesis of sorption-active carbon materials with developed pores of molecular size is being intensively studied using both common procedures [e.g., progressive activation, which increases the content of micro- and mesopores in the polydispersed system of carbon material (CMs)] and new methods, which yield carbon particles (nanotubes) with controlled size of pore openings [1–9], which may exhibit a molecular-sieve effect.

Solution of various scientific and technological problems (such as sorption and separation of macromolecular compounds and preparation of chemosorbents, carbon-based conducting materials, electronic nanodevices, and molecular sensors) requires development of new special-purpose materials. Therefore, a search for new ultramicroporous carbon materials a topical task.

In this study, we examined the procedures for preparing new carbon materials with sieve properties: low-density nanosize carbon powders.

Carbon molecular sieves can be prepared from various carbon-containing materials: lignite and coal (including anthracite), lignin, wood, peat, synthetic and natural polymers, and other organic compounds. Carbonization and activation of these materials under appropriate conditions yield sorbents with a rather uniform pore structure containing micropores whose size is comparable with that of adsorbed molecules. For example, such low-density materials were prepared by carbonization of polymeric compounds pretreated by various procedures, including modification with inorganic additives [10–14]. In particular, carbon sorbents with exactly the prescribed structure were prepared using NaCl [15] and silicon [1] additives.

EXPERIMENTAL

Oxidation and activation of carbon sorbents as influenced by additives of alkali metal (including potassium) salts were studied in [16]. In the present study, we examined various procedures for synthesis of carbon sorbents with molecular-sieve properties (required porosity) from phenol-formaldehyde resins, using a finely dispersed KCl additive.

The samples were prepared by two procedures.

(1) The initial polymer was boiled in a saturated aqueous solution of potassium chloride for 2 h. The sample was stored in solution for 8 h at room temperature, recovered from the solution, and dried at 120°C. Then, the sample was annealed in a furnace in an argon atmosphere at 200°C for 1 h, at 600°C for 0.5 h, and at 1000°C for 0.5 h. After thermal treatment, KCl was washed out with hot distilled water.

(2) The initial resin was treated with saturated KCl solution for 2.5 h at room temperature, the solution was decanted, and the sample was dried at 120°C and annealed at 600°C in an argon atmosphere for 1.5 h. After thermal treatment, KCl was washed out with hot distilled water.

The parameters of the pore structure determined from benzene sorption at various P/P_s [17] and the calculated apparent densities d of the resulting

* V_s is the limiting adsorption volume equal to $V_{mi} + V_{me}$; V_{mi}, V_{me}, and V_{ma} are the volumes of micro-, meso-, and macropores respectively; S_g is the geometric surface of micropores.

** The data for the initial polymer and sorbent treated with KCl are given in the numerator and denominator, respectively.

carbon sorbents before and after carbonization [18] are listed in Table 1. In this study, we used several samples of phenol-formaldehyde polymer [19], which were industrially prepared by polycondensation of various phenols and formaldehyde in the presence of catalysts. Both thermoplastic (novolak) and thermosetting (resol) resins [19] with a density of 40 to 250 mg cm^{-3} can be prepared, depending on the ratio of the initial compounds and their properties (e.g., the reactivities of mono- and bifunctional phenols are quite different), catalyst properties, solution pH, temperature and reaction time.

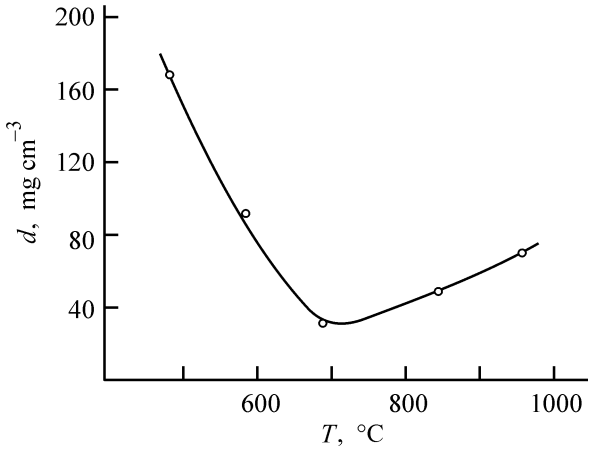

Fig. 1. Sample density d vs. temperature T of activation in a flow of carbon dioxide.

It can be seen from Table 1 that, after carbonization, the density of the samples treated with KCl by procedure 1 is significantly smaller as compared to the untreated samples. At the same time, the limiting adsorption volume V_s (equal to $V_{mi} + V_{me}$) is virtually independent of d and the ratio of micro- and mesopores varies in a relatively narrow range. Using procedure given in [18], we calculated the volume of macropores as the difference between the total pore volume determined from the moisture absorption capacity and the maximal volume of the adsorbed reference vapor (benzene). It should be noted that the structural parameters of the samples prepared by procedure 2 are significantly higher, which is probably due to worse removal of KCl from the pores in the samples prepared by procedure 1. However, both procedures yield uniformly microporous CMs.

We studied the reactivity and heat resistance of CMs under oxidation conditions (CO_2, O_2, HNO_3) at various temperatures to reveal the possibility of controlling the structure and chemical nature of the sorbent surface and imparting new properties to the resulting sorbents. To improve the microporosity and enhance the sorption capacity, the samples of various densities were exposed to high-temperature carbon dioxide activation [20]. The optimal activation parameters (namely, sample weight, time, temperature of thermal treatment and heating rate, and the flow rate of CO_2) were determined, and it was found how the density of CMs changes upon activation at 500–950°C (Fig. 1).

* (I) Strongly acidic carboxy, (II) weakly acidic carboxy, and (III) phenol groups.

As can be seen in Fig. 1, the density of the samples first decreases as the most reactive amorphous fraction of carbon burns out with the subsequent development of a pore structure; however, d starts to grow with further increase in the treatment temperature.

This is probably related to changes in the texture of the carbon samples studied. Up to activation temperatures of 800–950°C, the initial carbonized organic materials consists of both an ordered fraction (carbon crystallites packed relatively irregularly) and an amorphous fraction (high-carbon radicals) bound with carbon atoms at the prismatic faces of the crystallites [20–22]. The diffusion of gaseous oxidants into the carbon pores in the course of activation at 750–950°C is accompanied by chemical reactions. First, less compact amorphous carbon is burnt out, which yields micropores of irregular structure. In further activation, partial or complete burning out of separate crystallites leads to formation of the main structure of micro- and supermicropores; the development of meso- and macropores proceeds simultaneously. The reactivity of carbon atoms located at the edges of the graphitelike crystal lattice toward gases is the highest.

Thus, thermal activation at 750–950°C in the presence of carbon dioxide involves not only side radicals of the polymer carbon chains but also the main fraction of the aromatic layers. As a result, the structure of carbon samples becomes more ordered, i.e., the linear dimensions of polymerized aromatic carbon networks increase, the interplanar spacings decrease, and the true density of the resulting CMs also grows (Fig. 1). This is confirmed by X-ray diffraction patterns recorded on a DRON-2 unit (Fig. 2), indicative of the increased content of crystalline carbon in the structure (diffraction peak 002 [23]).

The structural parameters of CMs prepared at various temperatures in the course of carbon dioxide activation and calculated from the sorption isotherms of water and benzene vapors [17] are listed in Table 2 (geometric surface S_g of micropores; micropore half-width x; structural constants of the Dubinin–Radushkevich equation W_0 and B, which are significant characteristics of micropores [17]; and specific adsorption energy E_0). Small values of the structural constants W_0 and B indicate that the resulting CMs possess a developed micropore structure with a half-width varying within the range 0.5–0.8 nm, which is typical of molecular-sieve sorbents [9].

We also studied the CM samples treated with oxygen at 450–500°C and with HNO_3 in the liquid phase [20]; the results obtained are listed in Table 3. In

	720	156	17.7	122	15.1

the first case, the sample in a quartz reactor was placed in an electric furnace heated to a required temperature and treated with oxygen at a flow rate of 5 l min^{-1}. As for carbons prepared from phenol-formaldehyde resin, the weight loss by materials studied was 25–30%, depending on the time of thermal oxidation (burning).

The cation-exchange capacity (CEC) of the resulting oxidized samples and the acid strength distribution of the surface functional groups (SFGs) formed in the course of oxidation were determined by titration with bases of various strengths ($NaHCO_3$, Na_2CO_3, and NaOH [20]). The structural and sorption parameters of the oxidized CMs are listed in Table 3.

As can be seen from Table 3, the surface of oxidized CMs primarily contains carboxy (especially strongly acidic with pK ~ 2 [20]) and phenol groups. Both meso- and micropores are formed in the course of oxidation; the limiting sorption volume V_s (which strongly depends on the oxidation procedure) of the samples prepared by liquid-phase oxidation with HNO_3 exceeds by a factor of 2 that of the samples oxidized with atmospheric oxygen; in all the samples studied the micropores are predominant.

Along with intercalation (filling of the initial phenol-formaldehyde resins with potassium chloride and their subsequent carbonization at various temperatures for different times, thermal activation, and oxidation with various oxidants), we studied the preparation of new microporous CMs by fine dispersion. It was expected that fine dispersion would provide breakdown of macro- and partially mesopores to give carbon nanoparticles with a micropore structure.

Carbon sorbents for dispersion were prepared by two procedures: (I) resins were carbonized and then dispersed or (II) powdered resin sample was carbonized. The carbonization was carried out in a furnace at 600°C for 1.5 in an inert gas. Along with mechanical grinding, the samples were subjected to ultrasonic treatment for 15–720 min. Analyses were performed using samples taken at certain intervals in the course of a continuous carbonization. The results are listed in Tables 4 and 5.

As a result, we obtained new carbon materials ("carbon powders"), i.e., finely dispersed powdered (nanosize) materials with a low apparent density (Table 4), whose structure and microstructure strongly differ from those of the known carbon sorbents, e.g., carbon black and carbon dust [21]. With increasing time of thermal activation, the apparent density d of the resulting carbon powders decreases (Table 4). These powders have a fairly high micropore surface area (about 400 m^2 g^{-1}), and the small W_0 and B constants suggest a developed micropore structure of the samples [17].

The X-ray diffraction patterns (Fig. 2, Table 5) show that the initial carbon material (d = 139–217 mg cm^{-3}) consists of irregular amorphous carbon (smooth curve without any peaks). The other diffraction patterns, obtained for dispersed samples, exhibit more or less pronounced diffraction peaks typical of crystalline carbon. It should be noted that, after mechanical grinding, the apparent density either remains unchanged or slightly increases, being almost independent of the grinding time. The size of micropores increases after both mechanical (from 12.6 to 14.7 Å) and ultrasonic (from 10.0 to 17.7 Å) treatments; in

the latter case, the pore size exceeds that in the samples prepared by mechanical grinding.

CONCLUSIONS

(1) Carbon materials with molecular-sieve properties and predominant content of micropores of certain size were prepared from phenol-formaldehyde resine and KCl additive, using mechanical and ultrasonic treatment of the initial resin and sorbents carbonized at various temperatures.

(2) It is possible to control the structure and chemical nature of the surface and to impart new properties to carbon sorbents by high-temperature activation or oxidation (O_2 and HNO_3).

(3) Fine dispersion (mechanical and ultrasonic) yielded nanosize carbon materials with a low density (d 27–43 mg cm^{-3}), which surpass in structural parameters the known carbon materials, such as carbon black or carbon dust.

Abstract—The water-vapor sorption capacity of magnetite obtained by precipitation with solutions of NaOH, $NH_3 \cdot H_2O$, and urea in a single stage was studied. It was found that the type of a precipitating agent, thermal treatment temperature, concentration of the starting $FeSO_4$ solution, and order in which the reagents are poured together affect the water-vapor sorption capacity of the magnetite obtained.

Most widely used as a magnetic component in manufacture of magnetorheological fluids and magnetic paints, fibers, and tapes [1, 2] are ferromagnetic materials based on iron oxides: magnetite (Fe_3O_4) and γ-Fe_2O_3 [3, 4]. Modern ferromagnetic materials should satisfy a number of requirements: have high magnetic characteristics, good sorption capacity (in the cases when the surface is to be modified), and a certain specific surface area (10–50 $m^2\ g^{-1}$) for dispersion in a binder.

Synthesis of magnetite is a rather complicated task performed in four successive stages: synthesis of goethite α-FeOOH, thermal decomposition of goethite to hematite α-Fe_2O_3, and reduction of hematite to magnetite Fe_3O_4 [5].

It is known that magnetite can be obtained by single-stage precipitation [6]. However, the characteristics of such a material strongly depend on synthesis conditions (type of a precipitating agent and washing reagent, thermal treatment temperature, concentration of the starting $FeSO_4$ solution, and order in which the reagents are poured together).

In this study, the influence exerted by conditions of a single-stage precipitation of magnetite on its water-vapor sorption capacity is assessed.

EXPERIMENTAL

The single-stage precipitation of magnetite was performed from a 0.1–1.0 M $FeSO_4$ solution with a 20% NaOH solution at 85°C and pH 10–11 or with a 25% $NH_3 \cdot H_2O$ solution at pH 8–9, as well as with a 10% urea solution at 100°C and pH 5–6 under vigorous stirring for 3 h; a 20% solution of the oxidizing agent, NH_4NO_3, was added at a molar ratio $Fe^{2+}/NO_3^- = 3$.

After the synthesis, the magnetite obtained was allowed to stand for 1 day under a layer of the mother liquor for the necessary structure of its crystals to be formed. Then the precipitate was washed by decantation with hot distilled water to negative reaction for the SO_4^{2-} ion in the washing water and filtered off. The washing process was monitored with a 2% $BaCl_2$ solution. The precipitate obtained was additionally washed with ethanol or acetone. Samples dried at room temperature for 12 h were thermally treated in nitrogen at temperatures of 100 to 200°C for 3 h. The samples were stored in quartz weighing bottles with ground-glass covers.

An X-ray phase analysis was performed on a DRF-2.0 diffractometer (Fe_{K_α} radiation).

The shape and dimensions of particles of magnetic powders were studied with an LEO 1420 scanning electron microscope at a magnification of 37000. A gold layer was deposited onto the surface of the samples in a VUP-2K vacuum-evaporation installation.

The sorption of water vapor by magnetite was carried out by keeping samples for 20 days (time of the most intense moisture absorption) in desiccators at

1070-4272/05/7810-1596 © 2005 Pleiades Publishing, Inc.

a water-vapor pressure of 0.8, 9.8, and 17.2 mm Hg, set by appropriate sulfuric acid solutions [7], at room temperature. The content of water in a sample was judged from the difference between the masses of the initial sample calcined at 100°C and that kept in the desiccator.

Raising the concentration of $FeSO_4$ in the starting solution for synthesis of magnetite precipitated with, e.g., NaOH makes higher the water-vapor sorption capacity of the final product washed with water and thermally treated at 100°C for 3 h (Table 1).

As can be seen from Table 1, the maximum sorption capacity for water vapor is observed for magnetite obtained from a 1.0 M $FeSO_4$ solution.

In studying the influence exerted by the nature of a precipitating agent (NaOH, $NH_3 \cdot H_2O$, urea) and washing reagents (hot water, ethanol, acetone) on the sorption capacity of magnetite for water vapor, the conditions of its synthesis were the same in all the experiments: a 1.0 M $FeSO_4$ solution introduced into the precipitating agent, washing of the final product with water, its thermal treatment at 100°C for 3 h. The highest sorption capacity for water vapor [28% at a water-vapor pressure of 17.2 mm Hg (Table 2)] was obtained for a magnetite precipitated with a NaOH solution. The moisture content of samples obtained with $NH_3 \cdot H_2O$ and urea as precipitating agents is lower at the same water-vapor pressure: 20 and 12%, respectively.

One of the main reasons why the structure and properties of the sorbents obtained with different precipitating agents vary is that the final product contains impurities, e.g., chemisorbed cations or anions, whose amount in the samples obtained commonly depends on the precipitation pH [8]. In the case in question, the possible impurities are, in particular, SO_4^{2-} anions and sorbed molecules of ammonia.

The effect of an additional treatment with ethanol or acetone of a freshly precipitated magnetite preliminarily washed with water on its sorption capacity for water vapor is illustrated in Table 3. An additional washing with organic reagents makes its sorption capacity higher, which presumably results from desorption of impurities.

Magnetite samples washed with water and treated with acetone have a better sorption capacity for water vapor, compared with those washed with ethanol.

The sorption capacity of magnetite powders was changed by their thermal treatment at 150 and 200°C. Raising the thermal treatment temperature from 100 to

Table 1. Effect of the concentration of $FeSO_4$ in the starting solution on the sorption capacity of magnetite precipitated with NaOH

200°C leads to a pronounced increase in the sorption capacity of magnetite (Table 4).

As can be seen from Table 4, the sorption capacity of magnetite samples thermally treated at 200°C is considerably higher. An additional factor that affects the sorption capacity of magnetite is the order in which solutions are poured together in its synthesis.

Table 5. Sorption capacity of magnetite in relation to reagent mixing order (precipitating agent NaOH, additional treatment with acetone, thermal treatment temperature 200°C, treatment time 3 h)

1.485	33	1.484	1.485	1.484

The sorption capacity of magnetite obtained by adding a $FeSO_4$ solution to the precipitating agent NaOH exceeds that in the case when these solutions are poured together in the inverse order (Table 5).

According to [8], introduction of a precipitating agent into a salt solution at a low pH of the medium yields gels whose particles are strongly hydrated and have a high aggregative stability. Gels of this kind, as a rule, undergo a strong shrinking in drying, under the action of capillary contraction forces, to give finely porous adsorbents. As the pH value increases, the structure of the adsorbents obtained is enriched with coarser pores and reaches the limiting value at a given pH, i.e., at the pH of complete precipitation. As a result, the structure of a sample is constituted by a variety of components that differ in structural parameters. The difference in the case of an inverse order of reagent mixing, i.e., at a slow pouring of a salt solution into that of the precipitating agent, consists in that the pH of the latter solution is markedly higher than the value corresponding to the complete precipitation of the gel. Therefore, the gelation occurs instantaneously and the structure of the resulting sample is coarsely porous.

It should be noted that, according to the results of an X-ray phase analysis, samples of magnetite synthesized by single-stage precipitation under the optimal conditions (1.0 M $FeSO_4$ solution; washing with hot water and, additionally, with acetone; thermal treatment of the final product at 200°C for 3 h) were virtually phase-clean and their composition corresponded to the theoretical ratio of the concentrations of Fe^{2+} and Fe^{3+} cations in Fe_3O_4 (Table 6).

Electron micrographs of magnetite precipitated with solutions of (a) NaOH, (b) $NH_3 \cdot H_2O$, and (c) urea. Magnification 37000.

It can be seen in the micrographs of magnetite samples obtained with various precipitating agents that particles of magnetite are rhombohedral and lamellar–needle-like in the case of precipitation with NaOH, and mostly spherical-rhombohedral in the case of $NH_3 \cdot H_2O$ and urea.

The average size of magnetite particles is 500–1200 nm in the case of precipitation with NaOH, <300 nm for $NH_3 \cdot H_2O$, and 300–800 nm for urea. Thus, the comparatively high sorption capacities for water vapor, achieved in the study, and the simplicity of synthesis make it possible to regard magnetite precipitated with a NaOH solution as a promising material for manufacture and modification of fluid formulations on its base and, in particular, magnetic paints.

CONCLUSIONS

(1) The highest sorption capacity for water vapor is observed for magnetite precipitated with a NaOH solution, compared with that precipitated with ammonia or urea. For example, magnetite samples precipitated with NaOH, washed with water and acetone, and then thermally treated at 200°C have a better sorption capacity for water vapor (44% at a water-vapor pressure of 17.2 mm Hg).

(2) Variation of the synthesis conditions of magnetite enables subsequent modification of its properties: water-vapor sorption capacity, structure and dispersity of particles).

Abstract—Polyfunctional polyelectrolytes were synthesized by polycondensation of epichlorohydrin oligomer in the presence of allyl bromide. The polycondensation conditions were optimized, and composition and the properties of the resulting ion exchangers were studied.

Thanks to their high reactivity toward aliphatic and aromatic amines, epoxy compounds are widely used for preparation of various high-performance ion-exchange materials [1–3]. However, synthesis of thermally and chemically resistant ion exchangers with advanced sorption characteristics mostly involves many steps, requiring rigorous conditions.

With epichlorohydrin oligomer (ECHO) containing functional groups with close reactivities used as a starting reagent, it is possible to prepare ion exchangers with a more regular structure and advanced mechanical characteristics.

In this study, we synthesized and characterized ECHO-based polyelectrolytes.

EXPERIMENTAL

Epichlorohydrin oligomers were obtained in the presence of 1 wt % M-14 catalyst, activated aluminosilicate ($H^+ + Al^{3+}$). The reaction mixture was heated for 2 h at 30–50°C and for 5–6 h at 60–80°C under continuous stirring, and then cooled. The product was dissolved in benzene, the solution was filtered, and the product was precipitated by adding a 1 : 2 water–alcohol mixture. The resulting brown viscous mass was vacuum-dried at room temperature to constant weight.

The polycondensation of ECHO with polyamines was performed in various solvents. The mixture was stirred for 6 h at 60–80°C to the onset of gelation. The gel was transferred into a porcelain bottle and cured for 14–24 h at 80–100°C. The polyamines used were polyethylenimine (PEI), hexamethylenediamine (HMDA), and polyethylenepolyamine (PEPA). Also poly-2-methyl-5-vinylpyridine (PMVP) was used.

The polycondensation of ECHO with allyl bromide (AB) and amines was carried out in DMF at 40–70°C for 3 h. The prepolymerization was performed at various component ratios. The resulting gel was cured in an oven, crushed, and washed with distilled water. Finally, the product was converted from the OH form to the Cl form.

The static exchange capacity (SEC) and moisture content W were determined by the standard procedures [4].

The infrared spectra were registered on a Specord M-80/M85 spectrophotometer (in pellets with KBr + 1 mg of substance).

It is known that the properties of ion-exchange polymers depend on the ratio of the starting reactants, their concentration in the reaction mixture, solvent, temperature, and reaction time.

Performing polycondensation in a solvent enables synthesis of polymers under considerably milder conditions. Without solvent, the process is very fast and yields an inhomogeneous product. Therefore, a proper selection of a solvent in modification of ECHO with polyamines enables polycondensation under homogeneous conditions before gelation.

The effect of a solvent on the conversion of ECHO, judged from the exchange capacity and chlorine content, is illustrated in Table 1. This effect appeared to

Table 1. Effect of a solvent on the properties of the polymers (ECHO : PEPA : solvent = 1.0 : 2.0 : 1.0 weight parts; τ = 4 h; and T = 80°C)

be insignificant: SEC ranged from 7.4 to 8.1 mg-equiv g^{-1} and the chlorine content in the products, from 4.6 to 5.3%. However, the gelation rate waried with the solvent. A homogeneous gel was formed in DMF, as providing sufficient solubility for both the initial and intermediate compounds, and good swellability for the final products.

The amount of the solvent varied from 1.0 to 5.0 weight parts relative to the oligomer. The effect of the ECHO : DMF ratio on the SEC of the polyelectrolytes based on PEPA and ECHO is illustrated in Table 2.

As can be seen, changes in this ratio only slightly affect the characteristics of the final products. However, the chlorine content appeared to be at a minimum at ECHO : DMF = 1.0 : 2.0, and further experiments were carried out in this system.

A study of the effect of the reagent ratio showed that the amount of the polyamine added influences the conversion of ECHO and the density of cross-links in the resulting polyelectrolyte.

Table 3 shows that cross-linking occurs even at the minimal polyamine : ECHO ratio (0.2 : 1.0). However, in this case, the resulting products are characterized by a low SEC, as demonstrated by the high chlorine content (25–33%) and low nitrogen content in the copolymer (3–6%).

The use of a double excess of the polyamine provides a deep conversion and, accordingly, high SEC.

When ECH is used instead of ECHO, the reaction conditions only slightly influence the properties of the ion exchangers, which is due to its high reactivity. In this case, despite the high conversion and the resulting high SEC of the ion exchanger, the products show a considerable swellability and low mechanical strength (Table 4). Therefore, it is advisable to use ECHO in synthesis of polyfunctional ion exchangers.

At the optimal component ratio, we studied the effect of the reaction temperature on the properties of the polyelectrolytes (Table 5). With the temperature increasing from 60 to 110°C, the SEC of the samples grows, reaching a maximum at 80–100°C, and the gelation time decreases from 6 to 4 h. To minimize the thermal degradation, it is advisable to perform the polycondensation of ECH or ECHO with PMVP at 80°C.

It is well known that the properties of polyelectrolytes are strongly influenced by the mode of gel curing. A study of this stage demonstrated (Table 6) that,

at 80–100°C, its duration should be at least 24 h, to avoid formation of mechanically unstable polymers as a result of low conversion. The observed high swellability of the samples obtained at an insufficient curing time suggests a low cross-link density in the ion exchanger. The static exchange capacity of the ion exchangers reaches a maximum at 80–100°C and decreases with a further increase in the reaction temperature.

Infrared spectra of ion exchangers based on ECHO, AB, and amines (PEPA and PEI). (ν) Wave number.

Finally, the optimal conditions for the synthesis of the ECHO-based polyelectrolytes are as follows: temperature 80°C, ECHO : polyamine = 1.0 : (1.0–3.0) (depending on the polyamine), DMF content (2.0 weight parts), curing at 100°C for 24 h; and for ECH/PMVP: 80°C and ECH : PMVP = 1.0 : 1.0.

The IR spectra of the polymers (see figure) demonstrate no absorption bands associated with stretching and bending vibrations of CH_2–Cl at 672 and 1270 cm^{-1}. The band at 1420 cm^{-1} is assigned to bending vibrations of the methylene group bound to the electron-donating nitrogen atoms. The spectra show characteristic bands of amino groups at 3400, 1670, and 1600 cm^{-1}.

Introduction of allyl groups into the polymer structure improves the strength and heat and chemical resistance of the ion exchangers [5]. Therefore, we synthesized samples based on ECHO, AB, and the amines. Data on the effect of the prepolymerization temperature on certain physicochemical properties of these polyelectrolytes are listed in Table 7. With

the temperature increasing from 40 to 70°C, the SEC passes through a maximum at 50°C and then decreases to 3.5 mg-equiv g^{-1}, and the swellability steadily decreases from 5.6 to 2.1 ml g^{-1}.

A study of the effect of the reagent ratio on properties of the resulting ion exchangers showed that, at 70°C, an increase in the PEPA concentration from 1.0 to 3.0 wt parts results in that a soluble product is formed (Table 8). With the ECHO concentration increasing within the range 1.0–3.0 wt parts, the density of cross-links in the copolymer grows, which hinders the access to the functional groups and, accordingly, leads to a decrease in the SEC in 0.1 N HCl from 3.5 to 2.7 mg-equiv g^{-1}.

Condensation of AB, ECHO, and PEI was carried out at 60°C. With the PEI concentration raised from 1.0 to 3.0 wt parts, SEC in 0.1 N HCl increased to 12.6 mg-equiv g^{-1}. A further increase in the concentration made higher the swellability of the resulting polymers because of a decrease in the fraction of the cross-linking agent. In the case of HMDA, cross-linked polymers could be obtained only at AB : ECHO : HMDA = 1.0 : 1.0 : 2.0.

Experiments with varied order of reagent introduction showed that cross-linked polymers are only formed if, initially, PEPA is condensed with AB, and then ECHO is added at 20°C. However, the sorbents synthesized under these conditions have a low SEC (3.0 mg-equiv g^{-1}). Condensation of PEPA with AB at room temperature, followed by elevation of the temperature to 70°C in the presence of ECHO, results in only a slight increase in the SEC from 3.0 to 3.3 mg-equiv g^{-1}. The low exchange capacities obtained using the indicated procedure can be attributed to the fact that the interaction of AB with PEPA raises the basicity of the nitrogen atom, which, in turn, makes lower the reactivity of the amino group [6].

Finally, the optimal condensation conditions of ECHO with AB and various amines are as follows: 50°C, ECHO : amine : AB = 1.0 : 1.0 : 1.0 for PEPA and 60°C, 1.0 : 3.0 : 1.0 for PEI. The ion exchangers synthesized under the optimal conditions contain increased concentrations of weakly and strongly acidic functional groups, which extends their application area as selective sorbents for transition and noble metal ions.

The IR spectra of these polymers exhibit the absorption bands due to stretching and bending vibrations of the amino groups at 3400, 1670, and 1600 cm^{-1} and of the C–N bond at 1275 cm^{-1}, but not the bands at 550 and 600 cm^{-1} characteristic of the stretching vibrations of the C–Br and C–Cl bonds (see figure).

CONCLUSIONS

(1) The optimal conditions for synthesis of polyelectrolytes based on epichlorohydrin oligomer and amines are as follows: temperature 80°C; oligomer : polyamine weight ratio 1.0 : (1.0–3.0) depending on the polyamine; solvent (DMF) concentration 2.0 wt parts; and curing at 100°C for 24 h. For epichlorohydrin with poly-2-methyl-5-vinylpyridine: 80°C and weight ratio 1.0 : 1.0. In the presence of allyl bromide: 50°C and weight ratio 1.0 : 1.0 : 1.0. For polyethyleneimine: 60°C and weight ratio 1.0 : 3.0 : 1.0.

(2) The polymers obtained exhibit enhanced ion-exchange properties, as demonstrated by physicochemical methods and IR and elemental analyses.

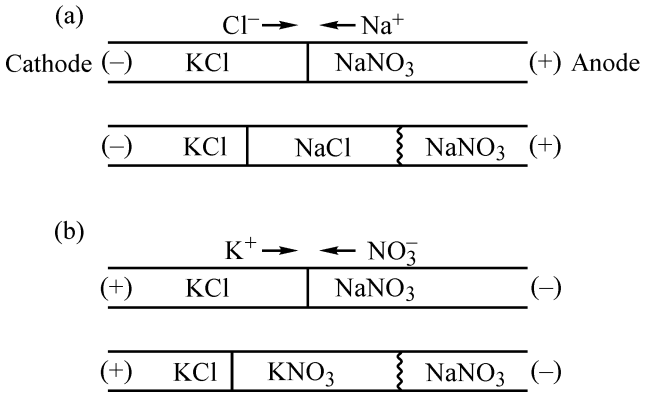
APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Synthesis of New Electrolytes in Solutions with dc Current

O. V. Oshurkova and V. P. Nesterov



Sechenov Institute of Evolutionary Physiology and Biochemistry, Russian Academy of Sciences, St. Petersburg, Russia

Received June 18, 2005

Abstract—Conditions under which new pure electrolyte solutions can be obtained by passing dc electric current through contacting solutions with four different ions were considered. Electrolytes were synthesized in capillary columns by various procedures.

The study is concerned with synthesis of electrolytes in which a new solution is obtained by passing dc electric current through electrolytes brought in contact. The possibility of such a synthesis was mentioned by Kohlrauch [1], who wrote that, if electric current is passed across the interface between contacting electrolytes, one more electrolyte is to be formed. A review devoted to isotachophoresis [2] reported, with reference to [1], that such a synthesis of new electrolytes is possible. However, conditions for synthesis of a pure solution were not formulated, procedures for synthesis of new electrolytes were not systematized, and the synthesis itself was not carried out experimentally in [2].

According to Kohlrauch's concept, a new electrolyte can be obtained in interaction of two solutions containing four different ions. This condition is necessary, but not sufficient for obtaining a new pure electrolyte. Let us illustrate this with the following example. In scheme 1a, two electrolytes are represented: KCl (catholyte) and $NaNO_3$ (anolyte). These solutions contain K^+, Na^+, NO_3^-, and Cl^- ions. On applying an electric field, K^+ and Na^+ ions will move toward the cathode, and NO_3^- and Cl^- ions, toward the anode. In the course of electrolysis, a new NaCl solution is formed at the place of contact between the solutions. Because the mobility of the potassium ion (u_{K^+}) exceeds that of the sodium ion (u_{Na^+}), a stable interface moving toward the cathode is formed between the KCl and NaCl solutions [3, 4]. No stable boundary is formed at the other end of the column of the NaCl solution, because the mobility of chloride ions (v_{Cl^-}) exceeds that of nitrate ions ($v_{NO_3^-}$), which will lead to mixing of NaCl and $NaNO_3$ solutions (Scheme 1a). The width of the mixing zone will increase with the time of electrolysis.

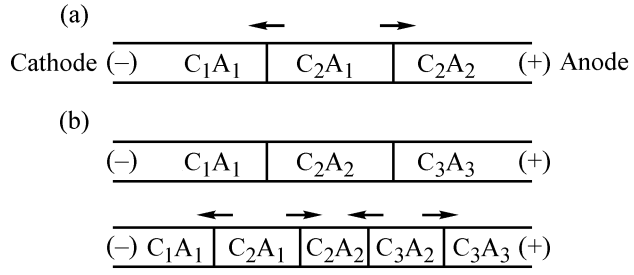
Scheme 1. Motion of ions: (a) in interaction of KCl (catholyte) and $NaNO_3$ (anolyte) solutions; (b) upon a change of the polarity across the electrodes (*wavy lines* correspond to mixing of solutions).

In the case of a change of polarity across the electrodes, a KNO_3 solution will form at the place of contact between the solutions (Scheme 1b). However, the KNO_3 and $NaNO_3$ solutions will mix because $u_{K^+} > u_{Na^+}$. To synthesize from two electrolytes, C_1A_1 and C_2A_2, containing four different ions a pure electrolyte C_2A_1 not mixed with the starting solutions in the column, it is necessary that the following inequalities should be observed:

$$u^C_{C_1} > u^S_{C_2}, \quad (1)$$

$$v^S_{A_2} < v^A_{A_2}, \quad (2)$$

where $u^C_{C_1}$ and $u^S_{C_2}$ are the mobilities of the cations of the catholyte and the electrolyte being synthesized, respectively; $v^C_{A_1}$ and $v^A_{A_2}$, mobilities of the anions of

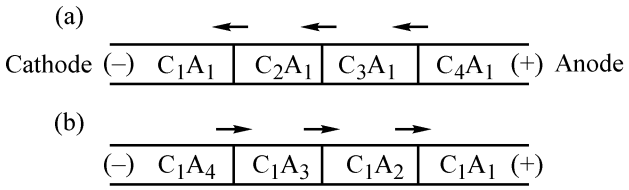


1070-4272/05/7810-1605 © 2005 Pleiades Publishing, Inc.

the anolyte and the electrolyte being synthesized, respectively.

The superscripts refer: *C* to the catholyte, *S* to the solution being synthesized, and *A* to the anolyte; the subscripts C_1, C_2, A_1, and A_2 denote the cations and anions of the respective solutions.

If inequalities (1) and (2) are observed, the boundaries between the solution being synthesized and the catholyte and anolyte are stable in an electric field and move in opposite directions. The boundary between the solution being synthesized and the catholyte will move toward the cathode, and that between the solution and the anolyte, toward the anode (Scheme 2a). The number of gram-equivalents of the substance being synthesized will be $I\tau$F, where I is the current (A); τ, time (s); and F, Faraday number (C g-equiv^{-1}). This formula follows from the fact that, if inequalities (1) and (2) are observed, only the anion passes across the boundary between the solution being synthesized and the catholyte, and only the cation, across the interface with the anolyte.



However, the potentialities of synthesis may markedly exceed that of the variant considered. Let us demonstrate this by the following example:

Scheme 2. (a) Synthesis of C_2A_1 solution from C_1A_1 (catholyte) and C_2A_2 (anolyte) in the case when inequalities (1) and (2) are observed; (b) simultaneous synthesis of two solutions, C_2A_1 and C_3A_2, from three solutions C_1A_1, C_2A_2, and C_3A_3. The *arrows* show the directions in which the boundaries of the electrolytes being synthesized move under the action of electric current.

Let us consider a column charged with three electrolytes. Let these be the following solutions: C_1A_1 (catholyte), C_2A_2 (middle solution), and C_3A_3 (anolyte) (Scheme 2b). If these solutions are chosen in such a way that, on passing an electric current, C_2A_1 solution is synthesized from the first pair of solutions (C_1A_1 and C_2A_2), and C_3A_2 solution from the second pair of solutions (C_2A_2 and C_3A_3), then two different substances will be simultaneously synthesized in the column. Such a synthesis is possible if inequalities (1) and (2) are observed for each pair of solutions (C_1A_1 and C_2A_2) and (C_2A_2 and C_3A_3) and for the solutions being synthesized (C_2A_1 and C_3A_2).

In this case, $I\tau$/F gram-equivalents of a new substance will be synthesized from each pair of solutions on passing $I\tau$ coulombs of electricity. The number of electrolyte pairs can be raised. In addition to the variants considered, replacement of one ion for another of the same sign in solution under the action of dc electric current should be regarded as synthesis of electrolytes. It is known that all the zones of the solutions acquire a common anion in the course of electrolyses in cationic isotachophoresis, and, by contrast, a common cation, in anionic isotachophoresis [3, 4]. The zones obtained in cationic and anionic isotachophoreses are shown schematically in Scheme 3. If C_2A_2 solution is placed instead of C_2A_1 solution in the column for cationic isotachophoresis, a stable zone of C_2A_1 solution will be obtained in the course of electrolysis. Thus, anion A_2 can be replaced with anion A_1 in the starting C_2A_2 solution. Similarly, one cation can be replaced with another in the starting solution by means of anionic isotachophoresis. One ion is frequently replaced with another in separation of electrolyte mixtures in practice of analytical capillary isotachophoresis [5, 6]. However, this method has not been regarded as synthetic and has not been used to synthesize new compounds.

Scheme 3. Distribution of zones in isotachophoresis. Variant: (a) capillary and (b) anionic.

To carry out this synthesis procedure experimentally, it is necessary to chose electrolytes and solution concentrations and to evaluate the ion mobilities. Let us describe a possible way to calculate the solution concentrations and ion mobilities for synthesizing a new electrolyte solution with the use of catholyte and anolyte (Scheme 2a).

This way can be put into effect only for the steady state (with the time-independent solution concentrations satisfying the controlling relation) [7]. To perform a calculation, it is necessary to know the catholyte concentration and have plots of the ion transference numbers with respect to the solvent against the solution concentrations for the catholyte, solution

being synthesized, and anolyte. With this information available, the calculation can be performed as follows.

(1) The cation transference number is found for the chosen catholyte concentration from the dependences of the ion transference numbers for the catholyte on its concentration.

(2) The concentration and the cation transference number of the electrolyte being synthesized are found graphically from the concentration dependence of the ion transference numbers of the catholyte and the electrolyte being synthesized [8].

(3) The anion transference number of this solution is found from the cation transference number of the catholyte being synthesized.

(4) The concentration and the anion transference number of the anolyte are found, also graphically, from the concentration and the anion transference number of the electrolyte being synthesized and from the concentration dependence of the ion transference numbers of the anolyte [8].

(5) The resulting solution concentrations and ion transference numbers can be used to find the mobilities appearing in relations (1) and (2).

(6) The ion mobility is calculated by the formula

$$u = T\chi/\mathrm{F}c, \tag{3}$$

where u is the ion mobility ($cm^2\ V^{-1}\ s^{-1}$); T, ion transference number; χ, electrical conductivity of the solution ($\Omega^{-1}\ cm^{-1}$); F, Faraday number ($C\ g\text{-}equiv^{-1}$); and c, solution concentration ($g\text{-}equiv\ l^{-1}$).

However, the above calculation procedure can be only used in very rare cases because of the complete lack of data on how the ion transference numbers depend on the solution concentration at high concentrations, for which such a synthesis is the most promising. In addition, the solution concentrations do not necessarily satisfy the steady-state conditions in syntheses of new substances.

Synthesis can be performed at equal solution concentrations. In this case, the choice of starting electrolytes is not difficult if the ion mobilities are only roughly estimated (higher or lower). The electrolytes are chosen by comparing the ion mobilities of solutions having equal concentrations ($g\text{-}equiv\ l^{-1}$) and a common ion. This evaluation method, suggested in [9], is worthwhile in practice in studying the separation of electrolyte mixtures in concentrated solutions by ion mobilities. Let us illustrate this technique by the following example.

Let there exist two electrolytes (C_1A_1 and C_2A_1) of equal concentrations. The equivalent electrical conductivity (λ) of C_1A_1 solution is given by

$$\lambda_{C_1A_1} = \mathrm{F}(u_{C_1} + v_{A_1}), \tag{4}$$

and that of C_2A_1 solution by

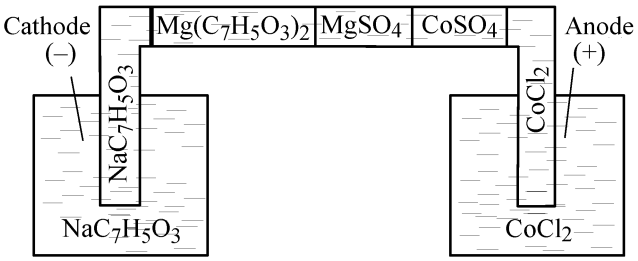
$$\lambda_{C_2A_1} = \mathrm{F}(u_{C_2} + v_{A_1}). \tag{5}$$

As the solutions have a common ion (anion) the mobility of the noncommon ion (cation) will be higher for that solution, which has a higher equivalent electrical conductivity. Therefore, a stable interface between the solutions will be formed if the electrolyte having a higher equivalent electrical conductivity is situated ahead of that with a lower electrical conductivity in the direction of motion of noncommon ions in the electric field. Hence follows that synthesis of a new solution on bringing in contact two solutions containing four different ions yields an electrolyte whose equivalent electrical conductivity is lower than that of each of these solutions at a concentration equal to that of the starting solutions. Let us consider, as an example, choice of electrolytes in interaction of two solutions containing four different ions: K^+, Na^+, Cl^-, and NO_3^-. Four different compounds can be formed from these ions: KCl, KNO_3, NaCl, and $NaNO_3$. The equivalent electrical conductivities of aqueous solutions of these compounds at a concentration of 2.0 $g\text{-}equiv\ l^{-1}$ and temperature of 18°C are as follows:

Substance	KCl	KNO_3	NaCl	$NaNO_3$
λ, $\Omega^{-1}\ g\text{-}equiv^{-1}\ cm^2$	92.3	69.0	66.6	54.4

It can be seen from the electrical conductivity data that the following compounds cannot be synthesized: (1) KCl, whose electrical conductivity is the highest; (2) KNO_3, whose electrical conductivity is lower than that of only a single solution; and (3) NaCl, whose electrical conductivity is lower than that of two solutions (KCl and KNO_3), but these solutions contain no sodium ions and, therefore, cannot be used in synthesis.

Only an $NaNO_3$ solution can be synthesized in pure form. As starting solutions for this synthesis can serve only KNO_3 and NaCl solutions containing four different ions and having an equivalent electrical conductivity exceeding that of the $NaNO_3$ solution. This principle of electrolyte selection was used when carrying out this synthesis in practice. In those cases when no data are available on the equivalent electrical conductivities of solution, the electrolytes can be chosen experimentally.



EXPERIMENTAL

Any of the synthesis variants considered above can be performed experimentally using devices for capillary isotachophoresis, described in [10, 11]. These devices have an extended detector that makes it possible to monitor the course of synthesis over a long part of the capillary column. ∏-shaped removable capillaries with an inner diameter of 0.05–0.8 mm can be used in the devices. The capillaries employed in this study had inner and outer diameters of 0.2–0.5 and 0.4–1 mm, respectively. The capillaries were 30 to 50 cm long, with a horizontal part of 20 to 30 cm. The ends of the capillaries were pointed as pipette tips, which made it possible to raise the hydrodynamic resistance of the capillaries and to virtually eliminate solution overflow. To carry out the synthesis, the capillaries were filled with the starting solutions and mounted in the device. This was done in such a way that like solutions at the capillary ends and in the electrode vessels came into contact. The synthesis was performed with aqueous electrolyte solutions. The following variants of synthesis were used.

(1) Synthesis of a solution (LiCNS) from a catholyte (2.0 N KCNS solution) and anolyte (2.0 N LiCl solution). The electrolysis was terminated when the solution being synthesized occupied a position in the horizontal part of the capillary between two marks. The marks were preliminarily deposited onto the capillary surface with a colored lacquer.

(2) Simultaneous synthesis of two new solutions. In this experiment, a 2.0 N solution of sodium salicylate ($NaC_7H_5O_3$) served as catholyte, and a 2.0 N $CoCl_2$ solution, as anolyte. A $MgSO_4$ solution was used as a middle solution. On passing an electric current, magnesium salicylate $Mg(C_7H_5O_3)$ was synthesized from $NaC_7H_5O_3$ and $MgSO_4$ solutions, and a $CoSO_4$ solution from $MgSO_4$ and $CoCl_2$ (Scheme 4). The electric current was switched off when the $MgSO_4$ solution completely disappeared. It should be noted that the interface between the $NaC_7H_5O_3$ and $Mg(C_7H_5O_3)$ solution, obtained in this case, was wider than those between other electrolytes. This is shown by a heavier line in Scheme 4.

(3) Replacement of the chloride ion for the rhodanide, acetate, and bromate ions in solutions of chlorides of rare-earth elements samarium(III), neodymium(III), and yttrium(III), respectively. $Sm(CNS)_3$ was synthesized from a 2.0 N KCNS solution (catholyte) and 1.5 N $NiCl_2$ solution (anolyte). In synthesis of $NdAc_3$, a 2.0 N KAc solution served as catholyte, and a 1.5 N $CdCl_2$ solution as anolyte. $Y(BrO_3)$ was obtained using a 2.0 N $KBrO_3$ solution as catholyte and a 1.5 N $CdCl_2$ solution as anolyte. In the cases mentioned in item 3, a steady state was attained in the capillary column. The lengths of the zones of the electrolytes synthesized were time-independent.

Scheme 4. Simultaneous synthesis of magnesium salicylate $Mg(C_7H_5O_3)$ and $CoSO_4$ solutions.

After an experiment was complete, the capillary in which synthesis was carried out was removed from the device and the zone of the solution synthesized was cut off at its boundaries. New electrolyte solutions with a prescribed chemical or isotopic composition can be synthesized in capillary columns not only in a free solution, but also in a transparent filler, e.g., agar-agar. It should be noted that the synthesis procedure under consideration can be easily made ecologically safe. However, only microscopic amounts of new electrolyte solutions can be synthesized in capillary columns. Special technological apparatus should be designed to synthesize larger amounts of electrolytes.

CONCLUSIONS

(1) Conditions for synthesis of a new electrolyte in interaction of two solutions containing four different ions were formulated.

(2) Various procedures for synthesis of new electrolytes were systematized.

(3) A rule for selection of starting electrolytes for syntheses was suggested.

(4) Various procedures for synthesis of electrolytes were carried out experimentally.

Abstract—The electroreduction of molybdate ions in the presence of hydrofluoric acid was studied. The effective activation energy of the electroreduction of molybdate ions was determined using the Arrhenius equation.

The electrochemical reduction of molybdate ions has been extensively studied. It has been confirmed once again most recently that the refinement of the existing electrolytes and creation of new efficient ones is a necessary and topical task both for synthesis of nonstoichiometric molybdenum oxide compounds [1, 2] and for deposition of metallic molybdenum coatings [3] that would satisfy current ecological requirements.

The necessary condition for electrodeposition of transition metals is that a bifunctional electrochemical system electrode/film/electrolyte should be formed on the cathode [4]. At the electrolyte/film interface, the film itself is formed from nonstoichiometric oxide compounds through reduction of discharging metal ions to an intermediate degree of oxidation, whereas at the electrode/film interface, the material of the film is consumed through further reduction of these compounds to metal. The simultaneous occurrence of these processes results in that the film is in a permanent dynamic equilibrium. The electrode processes at the phase boundaries of the system electrode/film/electrolyte can be rather easily controlled in aqueous solutions containing hydrofluoric acid.

The study is concerned with the electrochemical reduction of molybdate ions from electrolytes containing hydrofluoric acid. The voltammetry with a linear potential sweep served as the main method for studying the electroreduction of ions in the presence of hydrofluoric acid. The voltammograms were recorded in the galvanodynamic mode with a PI-50-1.1 pulsed potentiostat and a PDA1-004 laboratory *X*–*Y* compensation self-recorder at a potential sweep rate of $0.002–0.5$ V s^{-1} with compensation of the *IR* error. The recording error did not exceed $\pm 0.5\%$. We used in the experiments a three-electrode cell made of high-pressure polyethylene. A platinum plate (4 cm^2) served as the auxiliary electrode and the edge of a molybdenum rod (0.78 mm^2 area) pressed into Teflon, as the working microelectrode. The current density was related to the geometrical surface area of the electrode. Prior to each measurement, the working electrode was trimmed with a fine emery paper, polished, degreased with Vienna lime, and activated in a dilute hydrofluoric acid, which provided well reproducible results. The Luggin capillary of the reference electrode (0.1 cm in diameter) was brought from below to a distance of 0.2 cm from the surface of the working electrode. This configuration made it possible to minimize the ohmic loss [5] and to preclude screening of the electrode surface. A saturated calomel electrode was used as reference. The potentials are given relative to a standard hydrogen electrode. All the experiments were performed at 20 ± 0.1°C.

The solutions used in the study contained 5–10 g l^{-1} chemically pure ammonium molybdate (in terms of metal) and 1–100 g l^{-1} hydrofluoric acid (or an equimolar amount of sulfuric acid) of special purity grade. The current density of electrodeposition was varied from 0.5 to 400 A dm^{-2}. The rate of deposition (g/A h) of the solid phase onto the cathode was determined by the standard electrochemical procedure from the gain of mass by the deposit during the preparative electrolysis.

The voltammograms of electroreduction of MoO_4^{2-} ions in the presence of HF and H_2SO_4 are shown in Fig. 1. The fact that more electronegative cathode potentials are possible in electrolytes containing hydrofluoric acid is due to the stronger complexing agent of the F^- ion and, accordingly, to formation of more stable complex compounds, compared with those constituted by sulfates.

The rise in the electroreduction rate of molybdate ions with hydrofluoric acid concentration shows that the concentration of nonelectroactive species of polymolybdate ions in the electrolyte decreases, whereas that of fluorine-containing electroactive complexes formed upon the decomposition of polymolybdate ions under the action of fluoride ions increases [6]. For example, rather stable complex species containing three fluoride ions (conditional stability constant $\log \beta_3 = 3.8 \pm 0.6$) are formed at small concentrations of hydrofluoric acid in the electrolyte. At large concentrations of the acid, a complex ion containing four F^- ions (conditional stability constant $\log \beta_4 = 3.0 \pm 0.5$) is formed. Thus, the increase in the number of similar ligands incorporated into a discharging species upon formation of molybdenum fluoride complexes is responsible for the decrease in the activation energy of charge transfer to this particle. In addition to doing so, it also prevents polymerization of metal ions in a solution, the effect known not only for molybdenum, but also for tungsten, titanium, and niobium. An increase in the polarization accelerates the electrode process by making higher the dissociation rate of the complex compounds.

A study of the cathodic polarization in this process showed that its character is determined by the concentration of hydrofluoric acid in the electrolyte. For example, at small concentrations of the acid (less than 5 g l^{-1}), the total rate of electroreduction of the molybdate ion is low, which is confirmed by the small slope of the initial portion of the voltammogram (Fig. 1a, curves *1*, *2*). Raising the concentration of hydrofluoric acid in the electrolyte considerably accelerates the overall process of MoO_4^{2-} reduction (Fig. 1a, curves *3*, *4*). With the concentration of hydrofluoric acid raised to 50 g l^{-1}, the cathode potential at a current density of 25 A dm^{-2} is shifted by 2–2.5 V toward the region of electropositive values. It should be noted that elevating the temperature also shifts the cathode potential to electropositive values, but this shift is considerably smaller than that observed on changing the acid concentration.

The presence of several portions on the voltammograms recorded in solutions containing hydrofluoric

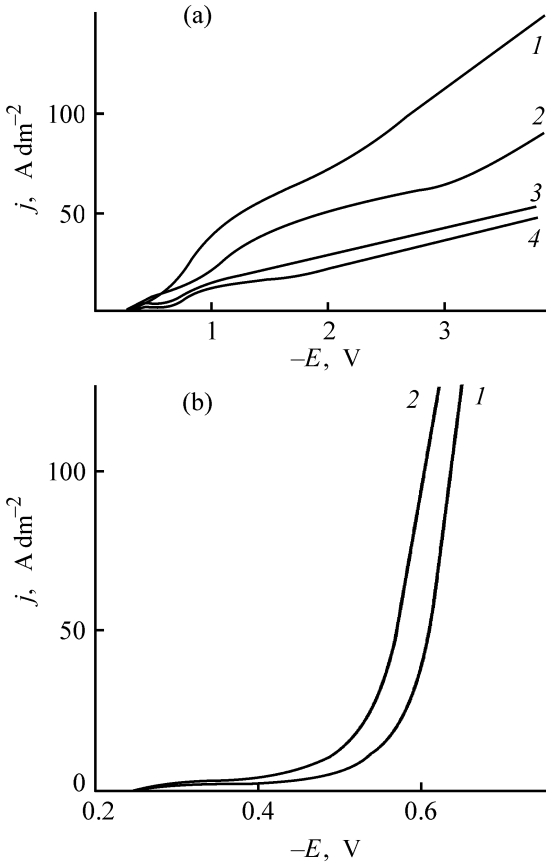

Fig. 1. Voltammograms of cathodic reduction of MoO_4^{2-} ions in electrolytes containing (a) HF and (b) H_2SO_4. (*j*) Current density, (*E*) potential; the same for Fig. 2.

acid confirms that different processes occur at the cathode. These data, along with the results of a microscopic study, suggest that each portion characterizes the formation of molybdenum oxide compounds with intermediate degrees of reduction, in which the average degree of oxidation of molybdenum decreases with increasing current density [3]. Colored films are formed on the cathode at a current density of 0.25–2.5 A dm^{-2}, dark deposits, at 2.5–15 A dm^{-2}, and black deposits, at current densities exceeding 25 A dm^{-2}. Light lustrous deposits of metallic molybdenum are formed at hydrofluoric acid concentrations higher than 25 g l^{-1} and current densities exceeding 50 A dm^{-2}.

The voltammograms characterizing the electroreduction of MoO_4^{2-} ions in a solution containing sulfuric acid are shown in Fig. 1b. The voltammograms have no extremal points and, compared with those recorded in solutions containing hydrofluoric acid, lie at more electropositive potentials. The deposits formed

at potentials of 0.7–0.8 V are sooty and strongly differ in structure from the black deposits formed from electrolytes containing hydrofluoric acid. It should be emphasized that we failed to obtain colored molybdenum-containing or metallic molybdenum coatings in H_2SO_4-containing electrolytes.

The voltammograms describing the reduction of molybdate ions in the solution containing hydrofluoric acid at various potential sweep rates are shown in Fig. 2. At potentials that precede the region of the limiting current, the electrode process depends on the potential sweep rate only slightly. All the voltammograms exhibit a characteristic delay up to a potential of approximately –0.45…–0.5 V, at which the current density is extremely low. As the polarization is raised further, the current density sharply increases up to a certain limiting value. Microscopic observations demonstrated that a film of molybdenum oxide compounds with intermediate degrees of reduction is formed on the cathode under these conditions. The plateau of this limiting current becomes narrower as the rate at which the polarization is varied increases.

At the highest variation rate of polarization, $|dE/d\tau|$, the ascending portion of the curve, which corresponds to reduction of molybdate ions, starts from less electronegative potentials. As the potential sweep rate decreases, the voltammogram shifts to the region of negative potentials, with the limiting current simultaneously decreasing. The dependences of the limiting current j_{lim} on the potential sweep rate V in the j_{lim}–$V^{1/2}$ coordinates are approximated by straight lines (Fig. 3), which confirms that these processes are diffusion-limited.

Raising the temperature makes considerably higher the rate of the above electrochemical process. The fact that the log j–1/T dependences (Fig. 4) are linear, i.e.,

formally similar to the Arrhenius equation, allows the effective activation energy to be determined from this equation. In this case, the behavior of the dependences obtained in the electrolytes containing more than 25 g l^{-1} hydrofluoric acid shows that the reduction of molybdate ion to metal is the diffusion-limited process (Fig. 4a). At low HF concentrations, when oxide compounds containing MoO_4^{2-} in an intermediate degree of reduction are formed, the process is limited by activated polarization (Fig. 4b) caused by the formation of a cathodic film [7]. The apparent disagreement between these results can be resolved on the assumption that the effective activation energy characterizes the diffusion limitation to the processes occurring in the film being formed on the electrode surface, because the polarization at the film/electrolyte phase boundary shows an activated behavior [8].

The effective activation energy of the electroreduction of molybdate ions in the presence of hydrofluoric acid strongly depends not only on the electrode potential (Fig. 5a), but also on the HF concentration in the electrolyte (Fig. 5b). This concentration determines the state of the metal surface in different portions of the polarization curve via redistribution of the rates of the processes occurring at the phase boundaries of a bifunctional electrochemical system electrode/film/electrolyte [9[. The effective activation energy of the MoO_4^{2-} electroreduction decreases in proportion to an increase in the potential, which electrostatically lowers the potential barrier for the reaction (Fig. 5a). This is especially clearly pronounced at low concentrations of hydrofluoric acid.

Thus, as the polarization potential and the rate of the electrode reaction increase, the contribution of the activated polarization gradually decreases, and that of the diffusion limitations grows. In the process, the effective activation energy gradually decreases to about 5 kJ mol^{-1}. Noteworthy is the fact that the effective activation energy remains virtually unchanged when the electrode potential is varied within 2–3 V at low HF concentrations in the electrolyte (Fig. 4a) and within 0.5–1.2 V at HF concentrations of 25–50 g l^{-1} (Fig. 5b). This may indicate that, not only the electrode process is diffusion-limited [7], but also the following two simultaneous processes cancel each other. The first is a decrease in the activation energy on raising the electrode potential, and the second, its increase with the derivative of current with respect to temperature in the Arrhenius equation. The second process is due to a rise in the diffusion permeability of the cathodic film, which acts as a kind of negative feedback. A similar effect

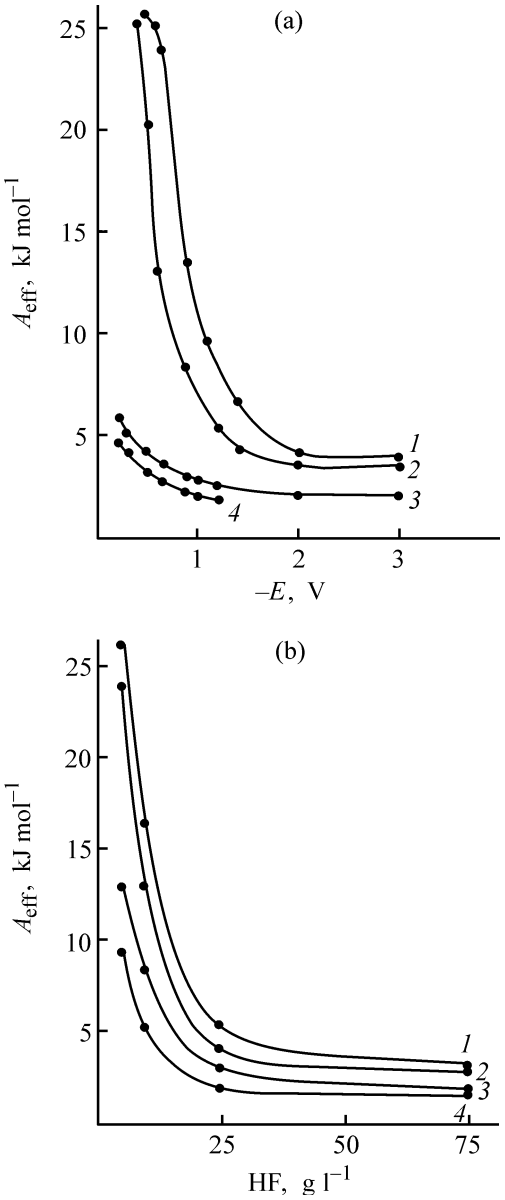

Fig. 5. Effective activation energy A_{eff} of cathodic reduction of MoO_4^{2-} ions in electrolytes vs. electrode potential E and HF concentration. (a) HF concentration (g l^{-1}): (*1*) 5, (*2*) 10, (*3*) 25, and (*4*) 50; (b) Electrode potential (V): (*1*) 0.5, (*2*) 0.6, (*3*) 0.9, and (*4*) 1.2. Mo(VI) concentration 10 g l^{-1}.

of a potential-independent effective activation energy has also been observed for the anodic dissolution of nickel [10, 11].

On the whole, the activation energy of the electroreduction of discharging molybdate ions considerably decreases as the concentration of hydrofluoric acid in the electrolyte becomes higher. This fact has been established previously in a study of how the activation energy varies with the ligand concentration and

the composition of the cathodic deposits formed in electroreduction of MoO_4^{2-} ion in the presence of hydrofluoric acid.

CONCLUSIONS

(1) A deeper electroreduction of molybdate ions occurs in electrolytes containing hydrofluoric acid, compared with those containing sulfuric acid. As a result, colored and black deposits of molybdenum oxide compounds containing molybdenum in a considerably lower degree of oxidation are formed at the cathode.

(2) Light lustrous deposits of metallic molybdenum can be obtained at current densities exceeding 50 A dm^{-2} and hydrofluoric acid concentrations higher than 25 g l^{-1}.

(3) The effective activation energy of the electroreduction of molybdate ions decreases as the polarization potential and rate of the electrode reaction become higher. This is accompanied by a decrease in the activation polarization and by enhancement of the diffusion limitations to the process occurring in a film composed of nonstoichiomertic molybdenum oxide compounds formed on the electrode surface.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Use of Ion-Exchange Membranes in Chemical Power Cells

D. Yu. Turaev

Mendeleev Russian University of Chemical Technology, Moscow, Russia

Received March 28, 2005

Abstract—A chemical power cell is suggested, in which the positive and negative electrodes are placed each in its own electrolyte. This makes it possible to obtain the highest absolute value of the electrode potential of each electrode. The electromotive force and the maximum theoretical specific energy are calculated for an acid-alkaline-salt battery of the zinc-dioxide–lead system.

Chemical power cells employing aqueous electrolyte solutions can be divided into three groups: with salt, acid, and alkaline electrolytes. The active pastes of the positive and negative electrodes are spatially separated with a porous separator.

The active pastes are also separated with ion-exchange membranes [1]. An electrochemical cell [2] is a variant of an air–zinc system, with a partition permeable to only OH^- and H^+ ions and water molecules. The negative Zn electrode is placed in an acid electrolyte, and the positive electrode, in KOH. The charging and discharge voltages are 1.8 and 1.2–1.3 V, respectively.

The possibility of using bipolar ion-exchange membranes to produce electric power by back electrodialysis was demonstrated in [3]. The electric power is generated by feeding HCl and NaOH solutions into adjacent chambers. An acid (alkali) solution is in contact with the cationic (anionic) side of a bipolar ion-exchange membrane. Nickel, on which water decomposes in discharge of the power cell through an active load, is used as a material of the anode and cathode. At a zero load current, the algebraic sum of the electrode and membrane potentials of the cationite and anionite membranes is directed against the sum of membrane potentials of MB-24 bipolar membranes.

Highly important is the chemical resistance of an ion-exchange membrane serving to separate electrolytes with a strongly oxidizing power. For example, a sulfonate-polysulfocarbonate cation-exchange membrane has been developed for separation of two electrolytes and use in batteries containing a strong oxidizing electrolyte, e.g., for a zinc–ferrocyanide battery [4].

The parameters of perfluorinated cation-exchange membranes of foreign and domestic manufacture were reported in [5].

An anion-exchange ion-selective membrane has been used in a fuel cell employing an aqueous acid solution of chromium(II) chloride as a reducing agent, and an acid solution of iron(III) chloride as an oxidizing agent [6].

Thus, use of ion-exchange membranes makes it possible to obtain various chemical power cells, including fuel cells.

EXPERIMENTAL

If ion-exchange membranes that favor motion of only a single kind of ions are used to separate active pastes, chemical power cells can be designed taking into account the operation of each of the half-cells. Most of half-cells containing an oxidizing or reducing agent lie outside the thermodynamic stability region of H_2O, equal to 1.23 V (Purbet diagram for water) [7], specified by two boundary equations derived using the Nernst equation for the reactions

$$2H^+ + 2e = H_2, \quad (1)$$

$$E_{p,\,H^+/H_2} = E^0_{H^+/H_2} + \frac{RT}{nF}\ln\frac{a^2_{H^+}}{a_{H_2}} = -0.059\text{pH}, \quad (1a)$$

$$4H^+ + O_2 + 4e = 2H_2O, \quad (2)$$

$$E_{p,\,O_2/H_2O} = E^0_{O_2/H_2O} + \frac{RT}{nF}\ln\frac{a^2_{O_2}a^4_{H^+}}{a^2_{H_2O}} = 1.23 - 0.059\text{pH}. \quad (2a)$$

1070-4272/05/7810-1615 © 2005 Pleiades Publishing, Inc.

The electromotive force of the hydrogen-oxygen cell is given by

$$\text{emf} = \Delta E = E_{\text{p, O}_2/\text{H}_2\text{O}} - E_{\text{p, H}^+/\text{H}_2}$$
$$= 1.23 - 0.059\,\text{pH} - (-0.059\,\text{pH}) = 1.23\ \text{V}. \quad (3)$$

It can be seen from Eq. (3) that the electromotive force of the hydrogen-oxygen cell is 1.23 V at any solution pH. An electromotive force exceeding 1.23 V for a cell containing aqueous electrolyte solutions can be obtained if the reaction of water decomposition into hydrogen and oxygen is hindered. The electromotive force of a hydrogen-oxygen cell can be raised if two electrolytes are used, one with pH –2, and the other with pH 16:

$$\text{emf} = 1.23 - 0.059(-2) - (-0.059 \times 16) = 2.29\ \text{V}. \quad (4)$$

It can be seen from Eq. (4) that, if solutions with different pH values are used, the electromotive force of a hydrogen-oxygen cell increases by approximately a factor of 1.86, compared with that of a hydrogen-oxygen cell with a single electrolyte having any pH. The electromotive force can be raised to an even greater extent if a pair of half-cells is chosen, in which the active pastes have the highest absolute value of the electrode potential in acid and alkaline media. In the electrochemical system

$$\text{Pb}\,|\,\text{PbO}_2\,|\,\text{H}_2\text{SO}_4\,||\,\text{NaOH},\ \text{ZnO}\,|\,\text{Zn},$$

the following conjugated electrochemical reactions occur.

Cathodic reaction [8]:

$$\text{PbO}_2 + 4\text{H}^+ + \text{SO}_4^{2-} + 2\text{e} = \text{PbSO}_4 + 2\text{H}_2\text{O},$$
$$E^0_{\text{PbO}_2/\text{PbSO}_4} = 1.68\ \text{V}. \quad (5)$$

The dependence of the electrode potential of the half-cell constituted by the dioxide-lead electrode on the concentration of the H_2SO_4 solution (5 M) will be calculated by the Nernst equation similarly to the known calculation for a lead battery [9], using data from reference books [10, 11]:

$$E_{\text{p, PbO}_2/\text{PbSO}_4} = E^0_{\text{PbO}_2/\text{PbSO}_4} + \frac{RT}{nF}\ln\frac{a_{\text{PbO}_2}a^4_{\text{H}^+}a_{\text{SO}_4^{2-}}}{a_{\text{PbSO}_4}a^2_{\text{H}_2\text{O}}}$$
$$= 1.68 + \frac{8.314 \times 298}{2 \times 96\,500}\ln\frac{1(0.273 \times 2 \times 5)^4 \times 0.273 \times 5}{1 \times 0.579^2}$$
$$= 1.75\ \text{V}. \quad (6)$$

In the lead battery, the true potential of the positive electrode is +1.76 V [12].

Anodic reaction for the zinc-alkaline half-cell [11]:

$$\text{ZnO}_2^{2-} + 2\text{H}_2\text{O} + 2\text{e} = \text{Zn} + 4\text{OH}^-,$$
$$E^0_{\text{ZnO}_2^{2-}/\text{ZnO}} = -1.21\ \text{V}. \quad (7)$$

The dependence of the electrode potential of reaction (7) on the alkali concentration equal to 10 M is given by

$$E_{\text{p, ZnO}_2^{2-}/\text{Zn}} = E^0_{\text{ZnO}_2^{2-}/\text{Zn}} + \frac{RT}{nF}\ln\frac{a_{\text{ZnO}_2^{2-}}a^2_{\text{H}_2\text{O}}}{a_{\text{Zn}}a^4_{\text{OH}^-}}$$
$$= -1.21 + \frac{8.314 \times 298}{2 \times 96500}\ln\frac{a_{\text{ZnO}_2^{2-}} \times 0.45^2}{1(3.88 \times 10)^2}$$
$$= -1.42 + 0.02956\log a_{\text{ZnO}_2^{2-}}. \quad (8)$$

The solubility of zinc oxide in a concentrated alkali solution does not exceed 0.5–1 M, and the true potential of the zinc electrode in a concentrated alkali solution is –1.30 V [12]. At $0.02956\log a_{\text{ZnO}_2^{2-}} = 0$, we have

$$E_{\text{p, ZnO}_2^{2-}} = -1.42\ \text{V}. \quad (8a)$$

The theoretical electromotive force of a cell constituted by two half-cells, acid ($c_{\text{H}_2\text{SO}_4} = 5$ M) and alkaline ($c_{\text{NaOH}} = 10$ M), is given by

$$E = E_{\text{p, PbO}_2/\text{PbSO}_4} - E_{\text{p, ZnO}_2^{2-}/\text{Zn}}$$
$$= 1.75 - (-1.42) = 3.17\ \text{V}. \quad (9)$$

According to the calculation presented, the theoretical electromotive force of the compound cell exceeds 3.0 V, which is comparable with the electromotive force of some lithium chemical power cells and exceeds that of a chemical power cell using a compositionally homogeneous acid, alkaline, or salt aqueous electrolyte. In discharge of a compound cell into an active load, the following reactions occur:

$$\text{Zn} + 4\text{OH}^- = \text{ZnO}_2^{2-} + 2\text{H}_2\text{O} + 2\text{e}, \quad (10)$$

at the zinc electrode (anode), and

$$\text{PbO}_2 + 2\text{H}_2\text{SO}_4 + 2\text{e} = \text{PbSO}_4 + 2\text{H}_2\text{O} + \text{SO}_4^{2-}, \quad (11)$$

at the lead electrode (cathode), with the overall current-forming reaction:

$$\text{Zn} + 4\text{NaOH} + \text{PbO}_2 + 2\text{H}_2\text{SO}_4 \overset{2\text{e}}{=} \text{Na}_2\text{ZnO}_2$$
$$+ \text{Na}_2\text{SO}_4 + 4\text{H}_2\text{O} + \text{PbSO}_4. \quad (12)$$

In both half-cells, the electrolyte is involved in the electrochemical reaction and is simultaneously consumed. Reactions (10), (11) can be performed from right to left, i.e., the compound cell can act as a secondary power cell (membrane battery [13]). Charging from the neutral Na_2SO_4 solution by membrane electrolysis yields H_2SO_4 and NaOH solutions. Simultaneously, reactions (10), (11) occur at the electrodes in the reverse directions and yield the active paste of a battery. The maximum theoretical specific energy of the membrane battery, W_{th} (W h kg^{-1}), calculated by Eq. (12) for a cell voltage of 3.17 V [see Eq. (9)] constant in the course of discharge is given by

$$W_{th} = \frac{U_{th} nF}{\sum_{i=1}^{n} \nu_i M_i}, \quad (13)$$

where U_{th} is the electromotive force of the cell or the open-circuit (OC) voltage (V); n, number of electrons involved in the overall electrochemical reaction, $n = 2$; F, Faraday number; and $\sum_{i=1}^{n} \nu_i M_i$, sum of products of the molar mass of substances involved in the overall electrochemical reaction by their stoichiometric coefficients.

$$W_{th} = \frac{3.17 \times 2 \times 96500}{65.4 \times 1 + 4 \times 40 + 239.2 \times 1 + 2 \times 98} = 257.2 \text{ W h kg}^{-1}. \quad (14)$$

The resulting value $W_{th} = 257.2$ W h kg^{-1} exceeds the known value of W_{th} for the lead battery (175 W h kg^{-1}), calculated using $U_{th} = 2.1$ V and $c_{H_2SO_4} = 100\%$ [12].

For practical purposes, with 10 M NaOH solution and 5 M H_2SO_4 solution used, it is necessary to primarily take into account the mass of water serving as a solvent:

$$W_{th,1} = \frac{3.17 \times 2 \times 96500}{6.54 \times 1 + 4 \times 40 + 371.7 + 239.2 \times 1 + 2 \times 98 + 318.5} = 125.8 \text{ W h kg}^{-1}. \quad (15)$$

The value (15) is the theoretical limit and, similarly to the value (14), disregards the design features of a battery and conditions of its discharge into an active load. The electromotive force of a chemical power cell and, accordingly, W_{th} and $W_{th,1}$ can be raised by using more concentrated electrolyte solutions [Eqs. (6), (8)].

If a cation- or anion-exchange membrane is used, a process in which the acid can be neutralized by the alkali without passing an electric current is possible and this should be taken into account in designing and operating a membrane battery. A rational variant of its use is a standby battery. Upon a complete neutralization of the acid by the alkali to pH 7, the active pastes of the electrodes remain unchanged, but the electromotive force of the chemical power cell decreases dramatically. The electrode potential of the negative zinc electrode is

$$E_{p,\,Zn^{2+}/Zn} = E^0_{p,\,Zn^{2+}/Zn} + \frac{RT}{nF} \ln \frac{a_{Zn^{2+}}}{a_{Zn}} = E^0_{p,\,Zn^{2+}/Zn} + \frac{2.3RT}{2F} \log \frac{SP_{Zn(OH)_2}}{a^2_{OH^-}} = -0.764 + 0.05905(14 - 7) + 0.029521 \log (1.2 \times 10^{-17}) = -0.85 \text{ V}. \quad (16)$$

The potential of the dioxide-lead half-cell, calculated using Eq. (6) and data from reference book [10], is given by

$$E_{p,\,PbO_2/PbSO_4} = E^0_{PbO_2/PbSO_4} + \frac{RT}{nF} \ln \frac{a_{PbO_2} a^4_{H^+} a_{SO_4^{2-}}}{a_{PbSO_2} a^2_{H_2O}} = 1.68 + \frac{8.314 \times 298}{2 \times 96500} \ln \frac{1(10^{-7})^4 (0.14 \times 2.63)}{1 \times 0.88^2} = 0.842 \text{ V}, \quad (17)$$

at pH 7 and $c_{Na_2SO_4} = 2.63$ M. Then the electromotive force of the cell

$$E = E_{p,\,PbO_2/PbSO_4} - E_{p,\,Zn^{2+}/Zn} = 0.842 - (-0.85) = 1.69 \text{ V}. \quad (17a)$$

The value obtained exceeds the electromotive force of iron–nickel, cadmium–nickel, and cadmium–silver batteries with an alkaline electrolyte and is comparable with, or somewhat exceeds that of primary chemical power cells with an alkaline electrolyte. Upon mutual neutralization of two electrolytes and reduction of PbO_2 from the positive electrode to $PbSO_4$, the chemical power cell allows further discharge, with the following reaction possible at the lead electrode:

$$PbSO_4 + 2e = Pb\downarrow + SO_4^{2-}, \quad (18)$$

whose electrode potential at pH 7 and $c_{Na_2SO_4} = 2.63$ M

$$E_{p,\,Pb^{2+}/Pb} = E^0_{p,\,Pb^{2+}/Pb} + \frac{RT}{nF} \ln \frac{a_{Pb^{2+}}}{a_{Pb}} = E^0_{p,\,Pb^{2+}/Pb} + \frac{2.3RT}{2F} \log \frac{SP_{PbSO_4}}{a_{SO_4^{2-}}} = -0.126 + \frac{2.3 \times 8.314 \times 298}{2 \times 96500} \log \frac{1.6 \times 10^{-8}}{0.14 \times 2.63} = -0.343\text{V}, \quad (19)$$

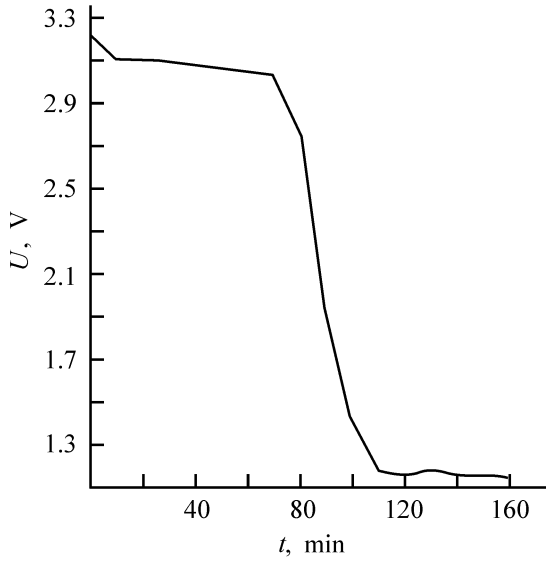

Fig. 1. Voltage U across the terminals of a chemical power cell vs. time t in discharge into an active load of 50 Ω at U_{OCin} = 3.25 V.

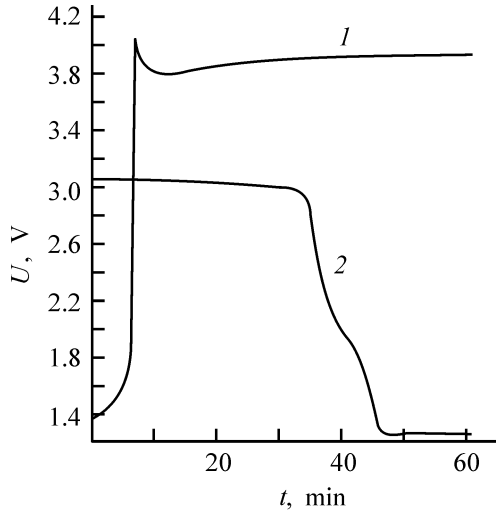

Fig. 2. Voltage U across the terminals of a chemical power cell vs. time t in (*1*) charging with a current of 0.25 A at U_{OCin} = 1.03 V and (*2*) discharge into an active load of 50 Ω at U_{OCin} = 3.13 V.

and then the electromotive force of the cell, found using Eqs. (19) and (16), is given by

$$E = E_{p,\,Pb^{2+}/Pb} - E_{p,\,Zn^{2+}/Zn} = -0.343 - (-0.85) = -0.507\ \text{V}. \quad (20)$$

Reaction (18) restores the working capacity of the dioxide-lead electrode, in contrast to the positive electrode in a lead battery, whose failure is due to disintegration of the Pb current lead of the positive electrode to $PbSO_4$.

The theoretical concepts were experimentally verified on a model chemical power cell, a two-chamber cell with a perfluorinated cation-exchange membrane of area 16 cm^2. A 25-ml portion of a 10 N NaOH solution was taken as a solution for the negative zinc electrode with S_{work} = 27 cm^2, and a 40-ml portion of a 10 N H_2SO_4 solution, for the positive electrode constituted by a PbO_2 layer on a smooth lead electrode with S_{work} = 35 cm^2. The potential difference across the electrodes was measured with an M830B digital multimeter. A PI-50-1.1 potentiostat served as a current source.

The results obtained in studying the time dependence of the voltage across the terminals of a chemical power cell are shown in Figs. 1, 2: discharge into an active load (Fig. 1), charging after 16 h in the idle state (with subsequent additional short-time discharge by short-circuiting) (Fig. 2, curve *1*), and subsequent discharge after 1.5 h (Fig. 2, curve *2*). The curve in Fig. 1 shows that the chemical power cell can be, in principle, used as a standby power source. The fact that a cell voltage exceeding 3.0 V is obtained confirms the theoretical calculations of the electromotive force, presented above. The decrease in the voltage is due to the complete reduction of the active paste of the positive electrode from PbO_2 to $PbSO_4$. In further discharge of the chemical power cell, the cell voltage is approximately 1.16 V and remains virtually unchanged, which can be attributed to occurrence of reduction reactions of lead sulfate to lead and of hydrogen ions to hydrogen gas. The possibility of using the chemical power cell as a battery is confirmed by its further charging (Fig. 2, curve *1*) and subsequent discharge (curve *2*). The rise in the voltage across the terminals of the cell to more than 4.0 V in its charging (Fig. 2, curve *1*) is due both to the formation of the active paste in the positive electrode (lead dioxide), with the corresponding shift of the electrode potential in the positive direction and its increasing contribution to the total electromotive force of the cell, and to a decrease in the voltage drop within the cell. The decrease in the voltage to 3.80 V is due both to an increase in the electrical conductivity of the solutions (via formation of additional amounts of the alkali and acid from Na_2SO_4) and to the formation of an electron-conducting PbO_2 film.

Further continuous rise in the cell voltage, which then tends to a constant value, is due to an increase in the concentrations of the alkali and acid and in the absolute value of the electrode potential of each of the electrodes. In the course of charging, sodium ions are species that carry the electric charge within the cell and do not change the intrinsic sign of the ion

charge on passing from the acid into the alkaline medium across the cation-exchange membrane. The subsequent discharge (Fig. 2, curve *2*) confirms the possibility of using the acid-alkaline-salt membrane battery as a secondary chemical power cell.

CONCLUSIONS

(1) Ion-exchange membranes can be used in various types of chemical power cells.

(2) The membrane chemical power cell has an electromotive force of more than 3.0 V, which exceeds that of cells using only a single aqueous electrolyte solution.

(3) The experimentally obtained charging-discharge curves demonstrate the possibility of using the membrane chemical power cell as an electric battery.

(4) Use of an ion-exchange membrane separating the electrolytes provides their regeneration in the course of electrolysis (cell charging).

Received July 20, 2005

Abstract—The effect of cathodic and anodic polarization of carbonized fibrous carbon materials of the KNM and NT-1 types in a Li_2SO_4 solution on their properties: electrical conductivity, steady-state electrode potential, electrical conductivity profile across the electrode thickness in relation to the electrolysis time, current density, Li_2SO_4 concentration, electrode thickness, and current reversal, was studied. The stability of the resulting electrical conductivity profile across the electrode thickness with time and in the course of the subsequent electrolysis was assessed. The reduction of Fe^{3+} in the ferri–ferrocyanide system on electrically iso- and nonisoconducting fibrous carbon electrode was considered.

The electrical conductivity of fibrous carbon materials (FCM) used in carrying out various redox processes in technical electrochemistry is an important parameter determining the efficiency of their use. The industrially manufactured FCM are electrically isoconducting across their thickness. At the same time, the efficiency of their use as flow-through 3*D* electrodes can be improved by creating a certain electrical conductivity profile across the electrode thickness. The possibility of fabrication of electrodes of this kind by cathodic and anodic polarization in solutions of acids and alkalis was first demonstrated in [1–3]. Of interest is to examine the possibility of obtaining electrodes with an electrical conductivity varying across their thickness in solutions of alkali metal salts whose dissolution does not change the solution pH.

The aim of this study was (i) to examine the influence exerted by conditions of electrode polarization of FCM in a Li_2SO_4 solution, Li_2SO_4 concentration, and electrode thickness on the electrical conductivity of FCM of the NT-1 and KNM types; (ii) to analyze the possibility of creating an electrical conductivity profile across the electrode thickness and its stability in storage of FCM and their use as electrodes; and (iii) to carry out comparative experiments in order to evaluate the efficiency of electroreduction processes for the example of Fe^{3+} reduction in the system $[Fe(CN)_6]^{3-}/[Fe(CN)_6]^{4-}$ on electrically iso- and nonisoconducting electrodes.

EXPERIMENTAL

The variation of the FCM properties was monitored by changes in the mass of samples, electrical conductivity, and steady-state electrode potential, determined by the procedures described in [1–3]. The study was carried out on carbonized low-electrical-conductivity materials of the NT-1 and KNM types, with electrical conductivities of 0.02–0.03 and 0.009 S cm^{-1}, respectively [4]. The choice of the materials was governed by the fact that the most pronounced changes upon polarization are observed for carbonized materials [1, 2], to which belong NT-1 and KNM. NT-1 is a combination of woven and nonwoven materials, which provides its mechanical strength and large reaction surface area. The experiments were performed with 2-cm^2 samples. The electrolysis was conducted with a B5-49 dc power source, with the solution circulated through the electrode volume at a rate of 0.2 ml s^{-1} cm^{-2} by a peristaltic pump in the installation described in [1]. After the electrode treatment, FCM samples were washed with distilled water and dried in air to constant mass. The electrical resistance of the samples was measured with a VM-509 ac bridge.

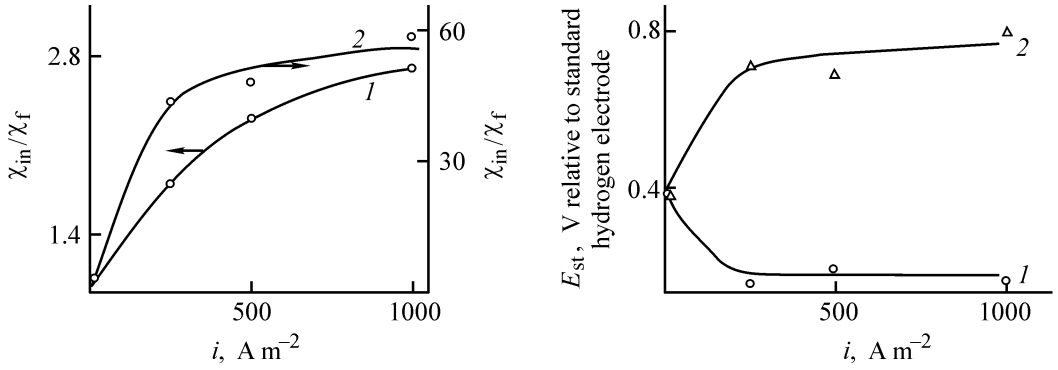

Fig. 1. (a) χ_{in}/χ_f and (b) steady-state electrode potential E_{st} of the NT-1 material vs. the polarization current density i. Polarization: (*1*) cathodic and (*2*) anodic. 0.1 M Li_2SO_4 solution, polarization time 1 h.

The electrical conductivity of FCM was calculated by the formula

$$\chi = l/RS, \quad (1)$$

where l is the sample thickness (cm); R, resistance (Ohm); and S geometric area of a sample (cm^2).

The steady-state electrode potential of FCM was measured relative to a silver chloride electrode and recalculated to the hydrogen scale. Dependences of the steady-state electrode potential of FCM ($E_{st.\ FCM}$) on the current density were plotted using potentials measured after keeping the FCM in solution for 1 h.

The working efficiencies of electrically iso- and nonisoconducting electrodes were compared for the example of electroreduction of iron(III) in the potassium ferri-ferrocyanide, with a 0.5 M KCl solution as a supporting electrolyte. The experiment was performed on the already mentioned installation in an electrochemical cell with electrode spaces separated by an MK-40 ion-exchange membrane. The cathodes were composed of several layers of the initial FCM and that subjected to an electrochemical pretreatment in such a way that a certain electrical conductivity profile was obtained. A solution of composition (M): $K_3[Fe(CN)_6]$ 0.02, $K_4[Fe(CN)_6]$ 0.02, KCl 0.5, was circulated in the cathode chamber; a 0.5 M K_2SO_4 solution served as anolyte. At regular intervals of time, 5-cm^3 samples were taken from the vessel with catholyte and analyzed for the content of Fe^{3+} by forward voltammetry with an electrode with surface renewed in solution [5].

Let us consider the influence exerted by some of the factored listed above (current density, anodic and cathodic polarization) on the electrical conductivity of a carbon material of the NT-1 type, because the effect of these factors has been studied in most detail just for this material. For convenience of comparison of the results obtained, the ratio of the electrical conductivities of NT-1 before (χ_{in}) and after (χ_f) its electrode polarization was plotted along the ordinate axis. Figure 1a shows how χ_{in}/χ_f depends on the current density. It can be seen that, first, the electrical conductivity of the material decreases as the current density grows, and, second, the anodic polarization leads to a more pronounced decrease in its value. For example, the electrical conductivity of FCM decreases at a current density of 1000 A m^{-2} by a factor of 55 in the case of anodic polarization (Fig. 1a, curve *2*) and only by a factor of 2.5 upon cathodic polarization (Fig. 1a, curve *1*).

The changes in the electrical conductivity in cathodic and anodic polarization are primarily due to modification of the surface chemical composition of fibers constituting an FCM and, in particular, to reduction (cathodic polarization) or formation of surface oxides (anodic polarization) [7]. This conclusion is also confirmed by the changes in the steady-state electrode potential of FCM ($E_{st.\ FCM}$). This potential shifts in the negative and positive directions upon cathodic and anodic polarization, respectively (Fig. 1b).

The results obtained in measuring the mass of FCM upon electrode polarization in a 0.1 M Li_2SO_4 solution are listed in the table.

It follows from the table that the mass of FCM changes only slightly upon cathodic polarization,

Change in the mass of NT-1, Δm, in relation to the current density i of electrode polarization (polarization time 1 h)

i, A m^{-2}	Δm, %	
	cathodic polarization	anodic polarization
250	+0.25	+11.5
500	–0.20	+15.4
1000	–0.70	+16.8

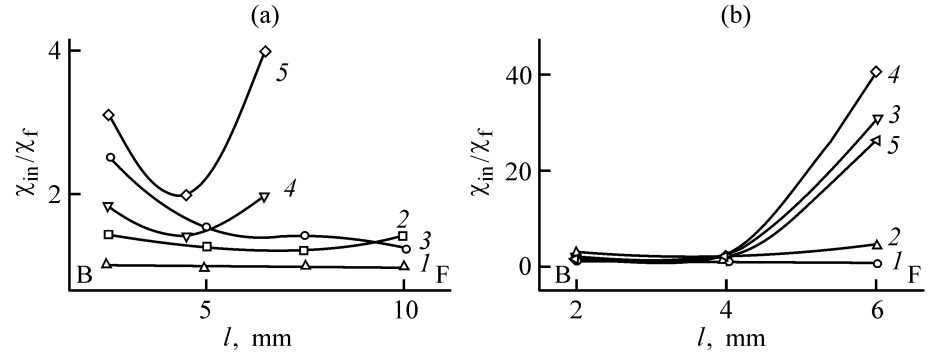

Fig. 2. χ_{in}/χ_f vs. the electrode thickness *l* after electrode polarization of NT-1 in a 0.1 M Li_2SO_4 solution. (a) cathodic polarization at current density (A m^{-2}): (*1*) 0.1, (*2*, *4*) 1000, and (*3*, *5*) 2500; polarization time (min): (*2*, *4*) 15 and (*3*, *5*) 5; (b) anodic polarization at current density (A m^{-2}): (*1*) 0, (*2*) 500, (*3*) 1000, (*4*) 1750, and (*5*) 2500; polarization time (min): (*5*) 5, (*4*) 10, and (*2*, *3*) 15.

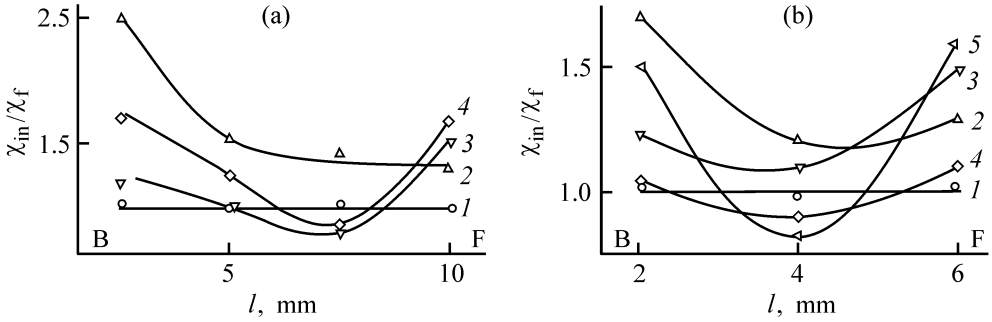

Fig. 3. χ_{in}/χ_f vs. the electrode thickness *l* after cathodic polarization of NT-1 at a current density of 2500 A m^{-2} at different (a) Li_2SO_4 solution concentrations and (b) polarization times. (a) Li_2SO_4 solution concentration (M): (*2*) 0.1, (*3*) 0.25, and (*4*) 5; polarization time (min): (*1*) 0 and (*2–5*) 5; (b) polarization time (min): (*1*) 0, (*2*) 2.5, (*3*) 5, (*4*) 10, and (*5*) 20; Li_2SO_4 solution concentration 0.1 M.

whereas that upon anodic polarization increases with the current density to reach a value of 17% at a current density of 1000 A m^{-2}. Such a significant increase in the FCM mass may be due to formation of oxide compounds and intercalation compounds of graphite [6, 7].

The results obtained served as a basis for a study of how electrolysis conditions affect the electrical conductivity profile across the electrode thickness. The possibility of formation of such a profile follows from the fact that the electrochemical process has a distributed nature and, consequently, the current density varies across the thickness of a 3*D* flow-through electrode, and from the data previously obtained for H_2SO_4 and NaOH (KOH) solutions [2].

The study revealed that an electrical conductivity profile across the electrode thickness is formed. The profile is dependent on the type of polarization, current mode, Li_2SO_4 concentration, and electrode thickness.

The results obtained are presented in the form of plots of the electrical conductivity distribution across the thickness of an FCM for different conditions of its polarization in a Li_2SO_4 solution; letters B and F designate the back (nearest to the current lead) and front (nearest to the anode) sides of the electrode, respectively (Figs. 2, 3).

The main factor that enables control over electrochemical processes is the current passed through the electrode. Therefore, the electrical conductivity profile across the electrode thickness can be strongly modified by changing the current (Figs. 2a, 2b). The experiments performed demonstrated that the type of polarization (cathodic or anodic) affects not only the quantitative characteristics of the electrical conductivity across the electrode thickness, but also the localization of regions with the minimum and maximum conductivity. In the case of a cathodic polarization in a 0.1 M Li_2SO_4 solution, the electrical conductivity decreases to the greatest extent at the backside of the electrode (Fig. 2a), and in the case of anodic polarization, at the front side (Fig. 2b). As the current density increases, the decrease in the electrical conductivity in the back and front surface layers of the electrode becomes more pronounced.

The electrical conductivity profile is noticeably affected by the electrode thickness. For a thinner electrode, a clearly defined profile with a minimum in the middle part of the electrode is observed. This leads to a more pronounced decrease in the electrical conductivity of FCM (Fig. 2a, curves *4*, *5*).

It was found that the Li_2SO_4 concentration affects the electrical conductivity profile across the electrode thickness (Fig. 3a). The electrical conductivity of the back and front sides of the electrode decreases. For solutions with a Li_2SO_4 concentration of ≥0.25 M, the electrical conductivity of the material increases upon cathodic polarization.

An increase in the electrical conductivity of FCM in the middle part of the electrode was also observed in the case of a cathodic polarization at a high current density (2500 A m^{-2}), depending on the electrolysis duration. At electrolysis times longer than 10 min, the electrical conductivity of FCM increases in the middle part of the electrode (Fig. 3b). A possible reason for this increase in the electrical conductivity of FCM is that intercalation compounds of graphite may be formed. Elucidation of why the electrical conductivity of FCM varies across the electrode thickness in this way requires an additional study, which is beyond the scope of this communication.

Interesting results were obtained in a study of the influence exerted by successive anodic and cathodic polarizations of FCM in a Li_2SO_4 solution on χ_{in}/χ_f (Figs. 4a, 4b). It can be seen from Fig. 4 that cathodic polarization of carbon materials (KNM and NT-1) preliminarily subjected to anodic polarization (curve *2*) restores the electrical conductivity of nearly all layers of the FCM electrode, with only the electrical conductivity of the front layer restored incompletely. The above results are in a good agreement with the data obtained in similar studies in H_2SO_4 and KOH solutions [3]. It may be assumed that oxide compounds formed on the surface of FCM fibers during anodic polarization are reduced in the subsequent cathodic polarization [7].

Further studies made it possible to compare the efficiencies of electrically nonisoconducting electrodes in reduction of Fe^{3+} to Fe^{2+} in the system $[Fe(CN)_6]^{3-}/[Fe(CN)_6]^{4-}$. The electrical conductivity of a potassium ferri-ferrocyanide solution (0.055 S cm^{-1}) exceeds $\chi_{NT\text{-}1}$ (0.02–0.03 S cm^{-1}). The distribution of the electrical conductivity across the electrode thickness will be the most favorable for the process of Fe^{3+} reduction in the case when the FCM conductivity is the highest at the backside, and the lowest at the front

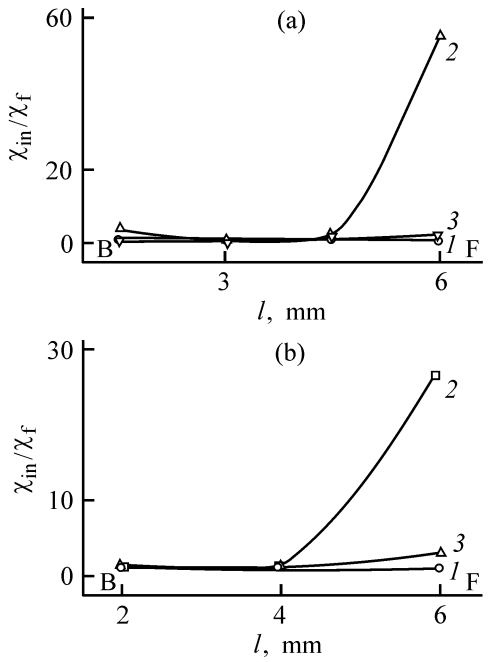

Fig. 4. χ_{in}/χ_f vs. the electrode thickness l after electrode treatment of (a) KNM and (b) NT-1 in a 0.1 M Li_2SO_4 solution. Current density 2500 A m^{-2}, polarization time 5 min. (*1*) Starting material, (*2*) anodic polarization, (*3*) anodic polarization followed by cathodic polarization.

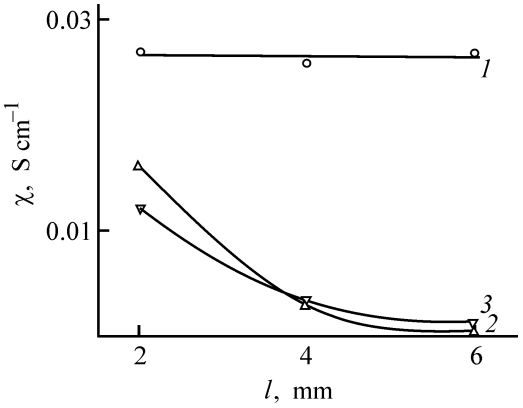

Fig. 5. Electrical conductivity χ vs. the electrode thickness l for NT-1. (*1*) Electrically isoconducting electrode made of the initial NT-1, (*2*) electrically nonisoconducting electrode composed of NT-1 subjected to electrode treatment in a 0.1 M Li_2SO_4 solution, and (*3*) electrode *2* upon reduction of Fe^{3+} to Fe^{2+}.

of the electrode. Therefore, two electrodes were chosen. The first was constituted by three layers of the starting material not subjected to any electrochemical pretreatment. The electrical conductivity profile of such an electrode is shown in Fig. 5 (curve *1*). The second was fabricated, to obtain the most favorable electrical conductivity profile (Fig. 5, curve *2*),

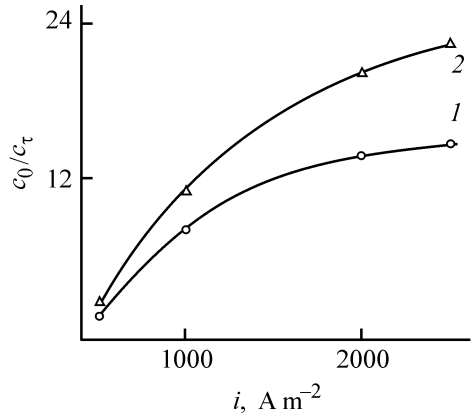

Fig. 6. Fe^{3+} to Fe^{2+} reduction ratio c_0/c_τ vs. the current density i. (*1*) Electrically isoconducting electrode and (*2*) electrically nonisoconducting electrode made of the NT-1 material.

from an FCM subjected to electrode pretreatment. The electrolysis was conducted, using the procedure described above, at different current densities for 30 min. After the electrolysis was complete, the solution was sampled and the concentration of Fe^{3+} was determined.

The data in Fig. 6 indicate that the Fe^{3+} reduction ratio c_0/c_τ increases with the current density for both the electrodes. At a current density of 500 A m^{-2} no significant difference in operation between the iso- and nonisoconducting electrodes is observed. At the same time, raising the current density to more than 500 A m^{-2} leads to a more efficient reduction of Fe^{3+} ions at the electrically nonisoconducting electrode. For example, at i = 2000 A m^{-2}, c_0/c_τ for the nonisoconducting electrode exceeds that for the isoconducting electrode by approximately a factor of 1.5.

A rather interesting and important result was that, if a target reaction not involving electrolysis of water occurs at the electrode, the electrical conductivity profile of a fibrous carbon electrode, produced by electrode treatment of FCM in a Li_2SO_4 solution, changes in the course of electrolysis only slightly (Fig. 5, curve *3*).

It should also be noted that the electrical conductivity of FCM, obtained by means of cathodic and anodic polarization, remains unchanged in storage for five to six months (measurements for longer periods of time were not performed).

CONCLUSIONS

(1) It was shown that cathodic or anodic polarization of carbonized FCM of the NT-1 and KNM types in a Li_2SO_4 solution can change their electrical conductivity, which depends on the current passed through the electrode.

(2) The most pronounced changes in the electrical conductivity of FCM were revealed upon anodic polarization. Successive anodic and cathodic polarizations can restore the electrical conductivity of FCM to nearly the initial value.

(3) The possibility of obtaining an FCM electrically nonisoconducting across its thickness by electrode polarization in a lithium sulfate solution was demonstrated. It was established that various electrical conductivity profiles across the electrode thickness can be obtained by varying such parameters as current density, electrode thickness, concentration of the Li_2SO_4 solution, and electrolysis time.

(4) It was demonstrated for the example of Fe^{3+} reduction in the $[Fe(CN)_6]^{3-}/[Fe(CN)_6]^{4-}$ system that electrically nonisoconducting electrodes produced by electrode treatment in a Li_2SO_4 solution enable a more efficient electroreduction, compared with the initial isoconducting FCM. The electrical conductivity profile of a fibrous carbon electrode remains unchanged in storage and upon its use in reduction of Fe^{3+} to Fe^{2+}.

Abstract—Intercalation compounds of GT-1 and GAK-3 graphites were electrically synthesized in concentrated sulfuric and nitric acids. Porous composite samples based on thermally expanded graphite produced from electrochemically synthesized GT-1 graphite hydrosulfate, chemically synthesized GSM-1 graphite nitrate, and fluoroplastic-4D (1–15 wt %), with a volume density of 650–1090 g l^{-2}, were fabricated and studied.

Studies concerned with power cells pay a considerable attention to development and testing of new materials for electrodes to be used, in particular, in fuel cells. It is known that thermally expanded graphite (TEG) and articles made of this material possess a number of unique properties: high porosity, electrical conductivity, corrosion resistance, and thermal stability; manufacturability and ductility; and possibility of fabrication of complex-shaped articles from this material [1–3]. This circumstance, combined with the comparatively low cost of TEG, makes it a promising material for electrochemical systems. For example, it has been suggested to use TEG for improving the distribution of gas reagents in electrodes of fuel cells [4]. It has been shown that making the current collector of TEG improves parameters of fuel cells [5]. Use of modified TEG in the electrodes of electrochemical sensors for methanol has been studied [6]. Oxidation of peroxide and glucose has been examined on an electrode made of TEG modified with cobalt phthalocyanine [7]. It has been demonstrated that the electrochemical parameters of TEG depend on whether or not oxygen functional groups are present on its surface [8]. The possibility of phenol electrooxidation on TEG has been analyzed [9].

Of interest in this context is to study a composite based on TEG and fluoroplastic, which shows a considerable hydrophobicity and chemical inertness at temperatures of up to 400°C. This composite can also be used to fabricate hydrophobized electrodes, which makes it possible to markedly raise the rate of electrochemical processes [10, 11].

The aim of the present study was to examine the influence exerted by the composition of a porous composite TEG–fluoroplastic on its electrical conductivity and electrochemical activity in oxygen reduction in aqueous electrolytes.

EXPERIMENTAL

Graphite intercalation compounds yielding TEG upon a thermal shock were obtained using electrochemical intercalation of acids. This method enables easy control over the degree of intercalation of acids into graphite and makes it possible to obtain intercalation compounds at lower acid concentrations without admixture of oxidizing agents [12]. For example, electrolysis in sulfuric [13–15], nitric [16], and formic [17] acids has been described.

The electrosynthesis was performed in a cylindrical glass electrolyzer with a thermostated jacket *1* and a horizontal position of the electrodes (Fig. 1). Onto the bottom electrode (anode) *2*, having the form of a fine-mesh platinum grid on a porous glass partition *3*, was placed a weighed portion *4* of graphite. A polypropylene diaphragm *5* made of a nonwoven material and then a fluoroplastic disc *6* with openings were placed on the graphite layer. A fluoroplastic cylinder *7* was put on the disc. A platinum

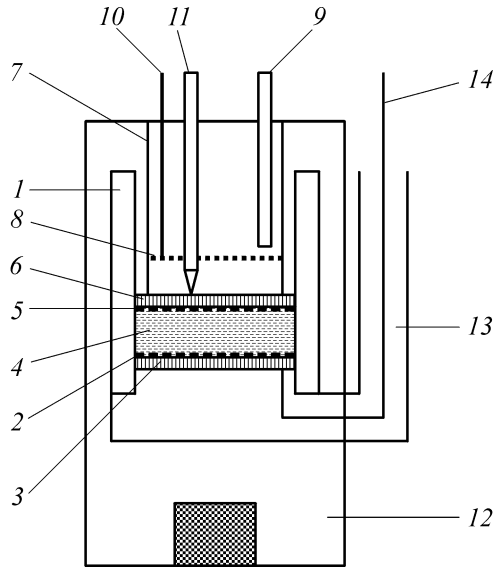

Fig. 1. Electrolyzer for synthesis of graphite intercalation compounds. For designations, see text.

cathode *8* was mounted in the middle of this cylinder, and a thermometer *9*, platinum current lead to the cathode *10*, and a capillary of the electrolytic switch *11* were fixed in its upper part. To improve the electric contact between graphite particles a load (20–30 g cm^{-2}) was applied to the cylinder by means of a rod *12*. An auxiliary vertical outlet *13*, through which the platinum current lead *14* to the anode passes and the electrolyte is poured-in (30 ml), was sealed-in in the lower part of the electrolyzer. The electrolysis was performed in the galvanostatic mode. The electrode potential was commonly varied within the range 1–3 V relative to a silver chloride reference electrode (EVL-1M1). The electrolysis conditions were as follows: weighed portion of graphite 4.5 g, area of the bulk electrode 7 cm^2 and its height 1.2 cm, electrolysis current 0.1 A per 1 g of graphite, temperature 20°C, electrolysis time 1.5–2.5 h, electrolytes 92% H_2SO_4 and 70% HNO_3. After electrolysis, graphite was washed to washing water pH 5–6 and dried in air at 100–120°C.

The possible influence exerted by the procedure used to prepare graphite intercalation compounds was examined using TEG obtained from graphite nitrate chemically synthesized from GSM-1 graphite and fuming HNO_3 [18]. Pd (2 wt %) was deposited onto this TEG by impregnation with an aqueous-alcoholic solution of H_2PdCl_2, with subsequent drying at 105°C and reduction in a flow of hydrogen at 100–250°C. The structural parameters of the resulting material and the size of Pd clusters on the graphite surface are similar to those for a G-Na TEG sample [19].

GT-1 and GAK-3 graphites manufactured by Uralgrafit Private Company, with bulk densities of 517 and 420 g l^{-1}, respectively, and particle size of 0.18–0.25 mm were used. The crucible graphite GT-1 contains 91.5 wt % graphite and ≤1.6 wt % Fe_2O_3 and has 90% of its particles more than 0.18 mm in size. The battery graphite GAK-3 contains 98 wt % graphite with 96% of its particles less than 0.25 mm in size and ≤0.5% Fe_2O_3. The special low-ash graphite GSM-1 has a bulk mass of 518 g l^{-1}, ash content of 0.08%, and 90% of its particles are 0.4–0.16 mm in size.

To obtain TEG, graphite compounds on a thin metallic tray were placed for several seconds in a furnace heated to 980°C and then transferred into a calibrated cylinder to measure the bulk density. The structural parameters of TEG were determined by measuring the nitrogen adsorption at 77 K [19].

The starting powder was obtained and articles were fabricated from it by the procedures used in [10, 11, 20]. Graphite was mixed with an aqueous suspension of fluoroplastic-4D (F-4D), which contained 2 wt % fluoroplastic, till complete coagulation of fluoroplastic on graphite particles. The resulting mass was transferred to a filter, washed with water and dried, first at 100–120°C and then at 310–320°C for 2.5 h. To make the powder loose, the mass was ground on a propeller-type mill and shaken in a closed space. To reveal the influence exerted by addition of two types of electrocatalysts, carbon blacks (of acetylene type, A437E, and of furnace type, P508E) and TEG with palladium were introduced into the electrode mass.

The samples were fabricated in the form of flat discs with a diameter of 3.5 cm, mass of 0.3–0.4 g, and thickness of 0.4–0.6 mm by compaction in a mold, and heated in air at 360°C for 5 min. When necessary, the samples were additionally compacted to a required thickness.

The electrical conductivity was measured by the four-probe potentiometric method [21]. The slope ratio of the dependence of voltage on current was used to find the resistance of a given sample, and then, using the known thickness and width of the sample, the electrical conductivity was calculated. The total porosity of the electrodes was measured by hydrostatic weighing; the electrolyte porosity was de-

Table 1. Parameters of products formed by electrochemical intercalation of sulfuric and nitric acids for different electrolysis times and graphite brands

termined in a NaOH solution after the experiments were complete [22].

The electrochemical activity of the samples in the reaction of oxygen electroreduction was measured at 20°C in a glass electrolyzer [11]. The current density was calculated per unit visible frontal surface area (5 cm^2). The catholyte volume was 0.023 l. Oxygen was fed into the electrode from its backside under atmospheric pressure. The electrode potential was measured relative to a silver chloride reference electrode. Polarization curves were measured at a potential sweep rate of 4 mV s^{-1}.

Table 1 lists the results obtained in electrosynthesis of graphite intercalation compounds and the bulk densities of TEG powders prepared from them.

It can be seen from Table 1 that the TEG with the lowest bulk density and largest specific surface area and micropore volume were obtained upon graphite intercalation with nitric acid. The greater increase in the mass of graphite upon intercalation with sulfuric acid, compared with nitric acid, can be attributed to the larger molecular weight of the former and a higher residual amount of this acid and water in graphite. As the amount of electricity passed through a sample increases, the mass of graphite grows and the bulk density of expanded graphite decreases because of the stronger expansion of graphite by gaseous substances evolving in thermal treatment. Compounds of graphite with H_2SO_4 partly expand already in the stages of washing with water and drying, and, therefore, they have a lower bulk density than graphite with HNO_3. The compound formed in H_2SO_4 has a blue color disappearing on bringing the compound in contact with water or air, which indicates that a stage-one intercalation compound is formed [15]. A black compound with a bluish tint is formed in HNO_3, i.e., a mixture of stage-one and -two compounds is obtained. It should be noted that TEG samples with parameters exceeding those of commercial graphite can be prepared on passing an appropriate amount of electricity.

Table 2 lists data on the electrical conductivity of composite samples fabricated from TEG powders obtained from GT-1 (H_2SO_4, 0.2 A h g^{-1}) and GSM-1 graphite. Prior to fabricating a hydrophobic mass, the starting TEG was ground in a propeller-type mill, which led to an increase in the bulk density.

It should be noted that articles fabricated from TEG commonly possess a closed porosity [23], and, therefore, the true porosity will be higher. It can be seen from Table 2 that both brands of expanded graphite have the same bulk density. Introduction of 5 wt % fluoroplastic leads to a dramatic increase in the bulk density of TEG. A further increase in the concentration of fluoroplastic leads to a decrease in the bulk density, which is due to a loosening action of fluoroplastic particles. A more pronounced increase in the bulk mass is observed upon introduction of palladium into the TEG structure.

Table 2. Electrical conductivity of composites based on TEG and fluoroplastic-4D

Sample no.	Mass used (TEG + F4D), wt %	Density, g l^{-1}		Porosity of a sample, vol %	Presence of additional components, mg cm^{-2}	Electrical conductivity, S cm^{-1}
		bulk density of the mass	volume density of a sample			
1	100% GT-1	17.9	664	66	0	257
2	GT-1 + 5% F4D	31.1	770	57	0	124
3	GT-1 + 10% F4D	26.1	785	56	0	87

10	1st layer: mixture [22% (GSM-1 + 5% F4D) + 22% (GSM-1 + 2% Pd)] 2nd layer: 56% (GSM-1 + 5% F4D)	–	1035	46	Pd 0.16	37.5
11	1st layer: mixture [40% (GSM-1 + 10% F4D) + 10% carbon black P805E] 2nd layer: [50% (GSM + 10% F4D)	–	845	56	Furnace-type carbon black P805E 4.1	197
12	1st layer: 52% (carbon black A437E + 8% F4D) 2nd layer: 48% (GSM-1 + 10% F4D)	–	654	67	Acetylene-type carbon black A437E 21.2	40.9
13	Carbon black A437E + 8% F4D	114	654	66	0	2.0

As can be seen from Table 2, the electrical conductivity of the materials strongly depends on their composition and porosity. Samples based on GSM-1 graphite have a higher electrical conductivity than those based on GT-1, which indicates that this parameter is affected by the synthesis procedure and nature of the starting graphite. The electrical conductivity of pure TEG samples has the same order of magnitude as that reported in the literature [21]: 150 S cm^{-1} at a density of 140 g l^{-2}. An increase in the concentration of fluoroplastic and in the porosity of the material makes its electrical conductivity lower, which is natural because the amount of the electrically conducting material decreases and the contact resistance between TEG particles increases through formation of nonconducting layers. The decrease in the conductivity of samples with Pd is presumably related to the procedure used to introduce Pd into the surface layer of TEG. Although the electrical conductivity decreases to 9 S cm^{-1}, it substantially exceeds that in materials with a carbon black. For example, the electrical conductivity is 1.28 S cm^{-1} for a material synthesized using a carbon black, with 12 wt % fluoroplastic, porosity of 58 vol %, and bulk density of 830 g l^{-1} [24], and 1.59 S cm^{-1} for a material with 30 wt % fluoroplastic and porosity of 55 vol % [20]. Approximately the same values have been obtained for materials containing a carbon black and high-pressure polyethylene and polyisobutylene [20]. Raising the content of the carbon black and Pd in the samples makes lower their electrical conductivity. Despite the high hydrophobicity of TEG [23], materials based on TEG exhibit a partial wettability with aqueous solutions (1.5–10.5 vol %), necessary for functioning of gas-diffusion electrodes.

Figure 2 shows polarization curves of oxygen electroreduction, obtained on electrodes fabricated from the materials listed in Table 2. In double-layer electrodes, the first layer was in contact with the electrolyte.

Hydrogen evolution occurs similarly to that on a carbon black with a high overvoltage. The evolution onsets at –1.6 V, i.e., the electroreduction of oxygen occurs till evolution of hydrogen. In the case of a vigorous gas evolution, there occurs relaxation of compacted TEG particles, they start to straighten, as if emerge to the surface, and regain their initial shape.

Addition of Pd and a carbon black enhances the activity of the electrodes. It should be noted that an increase in the Pd content by a factor of 2.8 (from 0.16 to 0.45 mg cm^{-2}) doubles the activity (at –0.45 V), whereas a further increase to 0.8 mg cm^{-2} has no effect on this parameter. This indicates that the internal surface of the electrodes is not equally accessible, which is also evidenced by the fact that the activities of electrodes with Pd and carbon black are virtually the same, although the activity of Pd in the reaction of oxygen electroreduction exceeds that of the carbon black. The electrode fabricated from a TEG electrochemically produced from GT-1 graphite has a higher activity than the electrode with TEG produced by the chemical method.

The best combination of an electrical conductivity and electric activity in reduction of oxygen was obtained for sample no. 11 (Table 2) with admixture of P805E carbon black. Electrode no. 12 has a lower activity than that of electrode no. 3, but exceeds the activity of a sample without admixture of carbon black. The increase in the activity of the electrode (Fig. 2, curves *2, 4*) on replacing the 0.5 M NaOH solution with 3 M KOH, i.e., on raising the electrical conductivity of the electrolyte, shows that the observed electrode polarization has a large ohmic component.

Curves *2* and *4* from Fig. 2 are plotted in the Tafel coordinates in Fig. 3. The slope of curve *2* varies from 0.33 to 1.52 V, and that of curve 4, from 0.082 to 1.0 V. It is known that, for porous electrodes, the slope of polarization curves measured in the kinetic mode and plotted in the Tafel coordinates is equal to a doubled slope of curves for an equally accessible electrode, and to a quadrupled slope for curves measured in the inner diffusion mode. An analysis of the polarization curves plotted in the Tafel coordinates demonstrated that, at noticeable current densities, the slope considerably exceeds a doubled slope (0.006 – 0.3 V [26]) of curves obtained in reduction of O_2 to H_2O_2 in alkaline solutions on electrodes

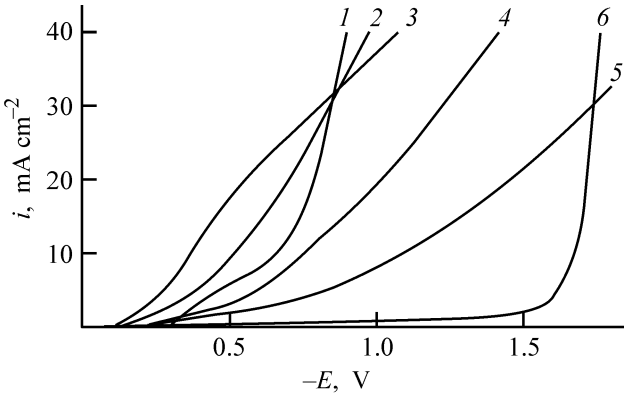

Fig. 2. Polarization curves for (*1–5*) electroreduction of oxygen and (*6*) hydrogen evolution on TEG-based electrodes in (*1*, *3–6*) a 5 M NaOH solution and (*2*) 3 M KOH solution. (*i*) Current density and (*E*) electrode potential. Electrodes from Table 2: (*1*) no. 11, (*2*, *4*, *6*) no. 3, (*3*) no. 8, and (*5*) no. 6.

fabricated from carbon graphite materials (no data on the kinetics of O_2 electroreduction on TEG can be found in the literature). This means that the electrodes probably operate in the inner-diffusion mode. Therefore, the rate of oxygen reduction on porous TEG-based electrodes can be raised if a three-phase boundary is developed and the diffusion and ohmic components of the process are diminished.

CONCLUSIONS

(1) Composites based on thermally expanded graphite and fluoroplastic-4D show a high electrical conductivity exceeding that of similar materials composed of carbon black.

(2) The rate of O_2 reduction in gas-diffusion electrodes fabricated from the materials under study is probably limited by inner diffusion.

(3) Deposition of palladium onto the surface of thermally expanded graphite enhances the activity of electrodes, but makes lower their electrical conductivity. A similar effect is produced by introduction of a carbon black into the electrode.

(4) Electrode fabricated from electrochemically produced thermally expanded graphite are more electrochemically active than electrodes fabricated from chemically obtained thermally expanded graphite, but have a lower electrical conductivity.

Abstract—Power expenditure for water purification to remove arsenic(V) was determined. The processes and kinetics of purification in an electric-discharge reactor with a metallic (aluminum or iron) charge were investigated. The purification mechanisms based on the adsorption of arsenic(V) on a fresh surface of hydroxides formed through dispersion and subsequent oxidation of a charged metal were suggested. Rate equations corresponding to the experimental data and to these mechanisms were given.

One of problems accompanying many commercial processes, especially those in the metallurgical industry, is effective removal of arsenic and other toxic elements from wastewater. Methods for arsenic removal from wastewater can be combined in two groups: those with and without reagents. The second group includes galvanocoagulation, electrocoagulation, and electropulse water purification.

The reagent methods are mainly based on coprecipitation with calcium phosphate [1] and carbonate [2] or on precipitation of arsenic(V) in the form of iron arsenates [3]. These simple and reliable methods have an essential drawback: they permanently use expendable materials, which complicates the scheme of water purification.

As the same time, no-reagent methods are free of this disadvantage.

The galvanocoagulation method [4] is based on the use of short-circuited iron–carbon galvanic cells. The galvanic processes yield iron hydroxides, which adsorb arsenate ions. As well as reagent methods, this method does not consume reagents and electric energy from the outside; however, its drawbacks consist in a low rate of the purification process and necessity for a permanent stirring of the solution to oxidize As(III) to As(V) by hydrogen peroxide or by air bubbling.

In the electrocoagulation method, the electrodes dissolve on passing a current and impurities are bound with a precipitate of the forming metal hydroxide. This no reagent method is readily controlled. The process is characterized by consumption of electric energy per unit mass or one mole of the dissolved electrode. According to the data of different authors [5, 6], the energy expenditure is 20–40 kW h kg^{-1} of a coagulant. The electrodes are passivated during the electrolysis, which requires their periodic replacement. Furthermore, this method is characterized by low purification rates.

Recently electropulse water purification has gained a wide recognition. Water purification by these methods is characterized by a very high rate and efficiency. The energy consumption depends on the type of discharge and mode of its application. Data on the energy consumption for water purification (per unit volume) to remove various organic impurities by electric discharges (ED) in the mode of an electric breakdown of a liquid were reported in the review [7]. Depending on the nature of an admixture and on purification conditions, 10–100 J cm^{-3} (2.8–28 kW h m^{-3}) are consumed. The purification of solutions containing cobalt and strontium ions required 3×10^3–2×10^4 J cm^{-3} (0.84×10^3–0.56×10^4 kW h m^{-3}).

Pulsed nanosecond barrier discharges have been applied to purification of drinking water to remove admixtures. They demonstrated a high efficiency: the energy consumption was as low as 0.2–0.04 kW h m^{-3} [8].

We have shown previously [9, 10] that a highly efficient electroerosion occurs upon pulsed action of

Concentrations of As(III) and As(V) in model solutions after an ED treatment in a reactor with aluminum and iron charge ($c_{in[As(V)]}$ = 300, $c_{in[As(III)]}$ = 380 mg l^{-1})

Run no.	Charge	Solution	Concentration after treatment, mg l^{-1}	
			As(V)	As(III)
1	Al	As(III)	28	52
2		As(V)	15	0
3	Fe	As(III)	0	0
4		As(V)	0	0

electric current on an iron charge: in this case, the energy consumption for transfer of iron to a suspension is 0.067–0.142 kW h mol^{-1}.

The aim of this study was to determine the energy consumption in the electropulse water purification to remove arsenic compounds with the use of a chemically active metallic charge and to analyze the chemical mechanism of this method.

EXPERIMENTAL

The experimental installation consisted of a container with 200 g of metallic shavings (iron and aluminum) used as a reactive charge. The electrodes were lowered into the charge, and 950 ml of a solution under study was poured in. The electrodes were connected to a double-circuit source of pulsed currents, with the following characteristics: pulse duration τ_p = 10 μs, pulse repetition rate 100 Hz, voltage U = 500–1000 V, and current of the first half-period of a pulse, I = 250–400 A.

Solutions of As(III) and As(V) salts of various concentrations in distilled water were used. We used GSO (State Standard Sample) 7264–96 to prepare As(III) solutions and analytically pure NaH_2AsO_4, for As(V).

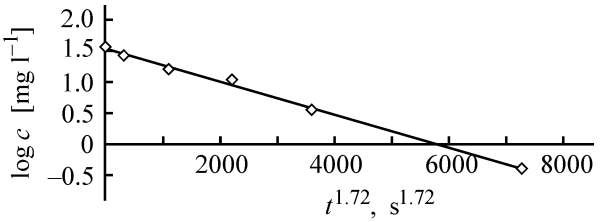

Fig. 1. Concentration of arsenic(V) ions, c, vs. the processing time t.

The concentration of As(III) was determined by inversion voltammetry with an STA-l instrument. The concentration of As(V) was found photometrically, in the form of arsenic-molybdenum blue [11] and also with the use of a QUICK As test-system (colorimetry on a sensitized paper by Gutzeit's technique) [12].

AsH_3 was qualitatively detected in the atmosphere over the surface of a solution treated with ED, using the QUICK As test-system at a sensitivity of 0.5 μg l^{-1}.

To compare the efficiencies of the aluminum and iron charges in water purification to remove arsenic compounds, we took equal volumes of solutions, with As(III) and As(V) concentrations of 380 and 300 mg l^{-1}, respectively, and treated them for 1.5 min with ED in the systems with iron and aluminum charges. Then the solutions were filtered ("blue-tape" filter) and the contents of both forms of arsenic were determined (see table).

It can be seen from the table that the efficiency of water purification with the iron charge is higher than that with the aluminum charge. Furthermore, As(III) is partially oxidized to As(V) in the case of an aluminum charge and incomplete water purification. In what follows, we studied in more detail the system with the iron charge, because it shows more promise for water purification to remove arsenic compounds.

To study the kinetics of arsenic(V) removal in an electric-discharge reactor with the iron charge, we carried out experiments on the kinetics of As(V) absorption. The concentration of the starting solution was 36.25 mg l^{-1}. In the course of the ED treatment, we sampled the filtrate at certain time intervals and determined its As(V) content:

t, s	$c_{As(V)}$, mg l^{-1}	t, s	$c_{As(V)}$, mg l^{-1}
0	36.25	120	3.958
30	27.395	180	0.521
60	16.18	240	0.208
90	11.31		

Processing of the experimental data demonstrated (Fig. 1) that the removal of arsenic(V) (mg s^{-1}) from water is described by equation(I).

$$\log c_{As(V)} = -0.0002 \log t^{1.72} + 1.5258, \quad (I)$$

The erosion of electrodes is described [10] by equation (II).

$$\log c_{Fe} = 0.72 \log t + 1.1331. \quad (II)$$

To study As(III) and As(V) adsorption on a solid erosion product after the ED treatment, we used As(III)

and As(V) solutions with the arsenic concentration of 51.92 and 38.01 mg l^{-1}, respectively. A solution was treated within 30 s in a reactor with an iron charge. The As(III) and As(V) contents of the treated solution (filtrate) were determined at certain time intervals. The results of the analyses are given in Fig. 2 in the coordinates: purification degree [$\alpha = (c_{in} - c)/c_{in}$]–logarithm of time.

It can be seen from Fig. 2 that, in both cases, the purification by ED is characterized by a very high rate and takes less than 30 s. Further, the concentrations of both As(III) and As(V) decrease insignificantly via the presumed adsorption.

In the course of the kinetic experiments, we made attempts to determine arsenic in the form of AsH_3 in the atmosphere over a solution with a charge. For this purpose, we tightly sealed a vessel with a polyethylene film and placed in it a strip of the QUICK test-system. The sensitivity of the test was 0.5 μg l^{-1}. At this sensitivity, the color of the strip remained unchanged upon complete purification of a solution with an As(V) concentration of 37 mg l^{-1}.

Mechanisms of water purification to remove admixtures of arsenic compounds. As(V) is present in water as $H_2AsO_4^-$ ions at pH 3–6 and as $HAsO_4^{2-}$ at pH 8–11; As(III) forms mainly H_3AsO_3 molecules at pH < 10 [13, 14]. As(III) and As(V) can be removed from water by an ED treatment through a reaction with iron(III) ions in solution and the subsequent precipitation of arsenates, e.g., by schemes (1) and (2).

$$Fe^{3+} + H_2AsO_4^- \rightarrow FeAsO_4\downarrow + 2H^+, \quad (1)$$

$$Fe^{3+} + H_3AsO_3 \rightarrow FeAsO_3\downarrow + 3H^+. \quad (2)$$

Such a scheme suggests that there is a functional relationship between the purification rate and the concentration of iron(III) ions in solution. As there is no relationship of this kind, these processes can be regarded as hardly probable.

A preliminary oxidation of As(III) by products of ED in water (OH, O_3, and H_2O_2) is also possible:

$$H_3AsO_3 + OH^- \rightarrow H_2AsO_4^- + 2H^+ \text{ etc.} \quad (3)$$

In the absence of oxygen or under oxygen-deficient conditions, oxidized arsenic can be also reduced to elementary arsenic or even to arsine by iron or atomic hydrogen [15]:

$$H_2AsO_4^- + Fe_H \text{ (or H)} + H_2O \rightarrow As\downarrow(AsH_3\uparrow) + Fe(OH)_2\downarrow + OH^-, \quad (4)$$

$$H_3AsO_3 + Fe_H \text{ (or H)} \rightarrow As\downarrow(AsH_3\uparrow) + (H_2O) + Fe(OH)_2\downarrow. \quad (5)$$

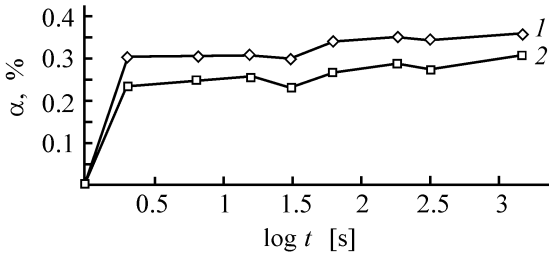

Fig. 2. Degree of extraction, α, of (*1*) As(III) and (*2*) As(V) from water (*1*) with the iron charge and (*2*) after the ED is switched off. (*t*) Treatment time.

The forming As^0 can be precipitated together with iron hydroxides, with arsine evolved as a gas. The possibility that this mechanism may be operative is supported by the data in Fig. 2: the degree of purification to remove As(III) is higher than that for As(V).

Our experiments did not confirm formation of arsine in water purification, i.e., reactions (4) and (5) yielding arsine do not take place. Furthermore, there are publications [15, 16] in which no elementary arsenic was detected on the surface of iron oxide and metal adsorbents by spectroscopic methods.

Therefore, the third mechanism is more probable, in which arsenic-containing ions are adsorbed on iron hydroxides (oxyhydroxides), e.g.,

$$=Fe(OH)_{solid} + H_2AsO_{4\,solution}^- \rightarrow (=Fe)_3AsO_{4\,solid} + H_2O + OH^-_{solution}, \quad (6)$$

$$=Fe(OH)_{solid} + H_3AsO_{3\,solution}^- \rightarrow (=Fe)_3AsO_{3\,solid} + H_2O. \quad (7)$$

Also possible is attachment of $H_2AsO_4^-$ anions to the surface [14].

We can assume that, under the action of ED, iron nanoparticles are removed from irregularities on the charge surface ("spikes") into solution, and dispersed particles of iron and a part of the metal in the resulting craters are partly or totally oxidized from the surface to give particles of Fe(II) hydroxides, which are rapidly oxidized further by dissolved oxygen. The resulting Fe(III) oxyhydroxide is the most efficient As(V) absorbent; as a result, the rate of its absorption is proportional to the total amount of corroded iron.

This method is rather efficient when ordinary iron-containing adsorbents are used [13]. In our case, its possibility is confirmed by the existence and type of functional *c*–*t* relationships for formation of iron hydroxide and water purification to remove arsenic (Figs. 1 and 2): the absolute values of the exponents

in these dependences differ by exactly unity. According to these data, the adsorption kinetics can be described as follows. The rate of absorption of arsenic compounds by the erosion product is given by

$$dc_1/dt = -k_i s c_{Fe} c_1, \quad \text{(III)}$$

Here c_1 is the concentration of the As impurity in water; s, specific surface area of the erosion product; and k_i, constant that accounts for the electric discharge characteristics and rate constants of chemical reactions.

As shown previously [10]:

$$c_{Fe} = (1 + m)kt^{1/(1+m)} = k_1 t^{1/(1+m)} = k_1 t^{\nu}, \quad \text{(IV)}$$

where $m = 1/3$ is the erosion index, which gives $\nu = 0.75$.

On substituting c_{Fe} into (III) and integrating, we obtain

$$\log c_i = \log c_{i,0} - \frac{k_1 k_i s}{2.3(1+\nu)} t^{\frac{m+2}{m+1}} = \log c_{i,0} - k_3 t^{1+\nu}, \quad \text{(V)}$$

where $c_{i,0}$ is the initial concentration of arsenic.

The experimental values $\nu = 0.72$ and $1 + \nu = 1.72$ are related to each other in complete correspondence with theoretical expressions (IV) and (V), being close to the theoretical value $\nu = 0.75$. Thus, the rate of the impurity absorption is proportional to the amount of dispersed metal.

It can be seen from Fig. 2 that the absorption proceeds very fast when the discharge is switched on, and nearly ceases when it is off. This means that absorption processes under ED conditions differ from the ordinary adsorption.

In this context, it is of interest to compare the experimental data on water purification to remove admixtures of arsenic compounds with the data on their adsorption on commercial adsorbents. Published data on the As(III) and As(V) adsorption on various adsorbents [17–19] are diverse, with the adsorption capacity for the most effective of them, $Fe(OH)_3$ and FeOOH, varying from 1 up to 250 mg g^{-1}. Such a wide scatter of the data is due to the dependence of the adsorption on numerous factors: dispersity and porosity of an adsorbent, adsorbate concentration, solution pH, adsorption duration, and stirring or the flow velocity of a solution relative to a layer. In the case of a complete (stoichiometric) reaction of iron oxyhydroxide with As(V), the capacity for As(V) would be 708 mg g^{-1}. Presumably, such a capacity is possible for a colloid solution of the hydroxide, but cannot be reached in the experiment because of the diffusion hindrances. Furthermore, practical use of colloids and suspensions presents serious difficulties associated with the necessity for separation of the dispersed phase from water.

The calculated capacity of an adsorbent monolayer for arsenic(V) is 0.004 mmol m^{-2} [14], i.e., 30 mg g^{-1} at a specific surface area of 100 m^2 g^{-1}.

For the process occurring under an electric discharge, the adsorption values were 96.1 and 156.7 mg g^{-1} for As(III) and As(V), respectively, at the specific surface area of the forming iron oxides equal to 105 m^2 g^{-1}. It is also important to note that these values were obtained under dynamic conditions within a very short time, which was considerably shorter than that required to obtain isotherms in [17, 18]. The capacity of the adsorbent in this case is 0.012 and 0.02 mmol m^2 for As(III) and As(V), respectively.

Thus, we see that the capacity in the electroerosion process approximately corresponds to the adsorption of three monolayers of As(III) and five monolayers of As(V). In all probability, this excess corresponds to a larger specific surface area at the instant of formation of a new phase, rater than to a multilayer adsorption (as it might be assumed). This specific surface area seems to be much larger than 105 m^2 g^{-1} at the beginning of the process, and then decreases to this value because of the cohesion and recrystallization of primary particles. If we assume that the surface is completely covered with arsenate ions, the specific surface area at the instant of adsorption will be 500 m^2 g^{-1} at the monolayer capacity of 0.004 mmol m^{-2} and As(V) adsorption of 156.7 mg g^{-1}. Such a surface area is physically well expected and corresponds to a size of FeO(OH) primary particles equal to 12 nm.

To gain insight into the purification mechanism, it is important to take into account the fact that the adsorption on a commercial adsorbent is limited by the diffusion of the adsorbate into micropores [18]. The capacity of the adsorbent formed in the ED purification exceeds by an order of magnitude that reached on commercial adsorbents (at a comparable sorption duration) and is close to the values corresponding to a complete monolayer on their surface. This indicates that, as expected, there is no diffusion hindrance in micro- and mesopores in adsorption at the instant when the adsorbent is produced, which ensures a higher rate and capacity.

CONCLUSIONS

(1) A study of the possibility of water purification to remove As(III) and As(V) by electric discharges with the use of an iron or aluminum charge demonstrated that the efficiency of the iron charge exceeds that of the aluminum charge. It was found in a study of the kinetics of arsenic(V) sorption that water is mostly purified during the electric discharge. The rate of water purification is proportional to the amount of dispersed iron; the subsequent adsorption on the erosion products is insignificant. The purification efficiency was 0.43 mol(As atoms) $(kW\ h)^{-1}$.

(2) Three possible mechanisms of water purification were considered. The results obtained in this study and published data made it possible to give preference to the mechanism in which an electric discharge acts upon the metal of the charge to form micro- and nanoparticles. Further, these particles are oxidized together with a part of the metal in the forming crater. At the instant when the oxides and hydroxides are formed, they sorb admixtures at a high rate, so that the adsorbent surface is completely filled.

Abstract—A pilot installation for catching of nitrogen oxides with water-condensation aerosols, with a throughput of 10 $m^3 h^{-1}$, was tested. A shell-and-tube industrial pilot installation for catching of nitrogen oxides with water-condensation aerosols, with a throughput of 1800 $m^3 h^{-1}$, was fabricated and tested.

Purification of gas flows to remove nitrogen oxides is an important issue of the environment protection. There exist various techniques for catching of nitrogen oxides: absorption by water or hydroxides, adsorption, catalytic reduction with ammonia, or thermal reduction with various reducing agents.

The conventional method of absorption by water is commonly used to catch nitrogen oxides of high concentration (approximately higher than 1 vol %), whereas catching of nitrogen oxides of lower concentrations by this technique requires a longer time of contact with the absorbing liquid. This, however, fails to ensure a high purification efficiency because of the low solubility of nitrogen oxide NO and low rate of its oxidation.

Absorption by aqueous solutions of alkali metal hydroxides is used for sanitary purification of exhaust gases; however, this does not solve the problem of NO catching, either, and, in addition, large volumes of salt-containing liquid waste are formed [1].

The more efficient adsorption methods of catching, which can also be used for sanitary purification to remove nitrogen oxides of low concentrations, operate in the batch mode, have a low sorbent capacity, involve a complex desorption procedure, and produce a large amount of liquid and solid wastes [2].

The selective catalytic method for detoxication of nitrogen oxides, with ammonia as a reducing agent [3], consumes ammonia, requires a careful adjustment of its feeding rate, fails to eliminate ammonia breakthrough, and is energy-intensive because the process occurs at 350°C with the use of expensive and deficient catalysts. It is appropriate to use this technique at low concentrations of nitrogen oxides (< 0.05 vol %, i.e., < 1 $g m^{-3}$).

A technique for reduction of nitrogen oxides without heating on carbamide supported by porous substrates (γ-Al_2O_3, zeolite, silica gel, activated carbon) has been developed [4]. The expenditure of carbamide is insignificant at low concentrations of nitrogen oxides in gases to be purified (<0.05 vol %, i.e., <1 $g m^{-3}$), but becomes unacceptably high as the concentration increases to 0.1–1.0 vol % (1–10 $g m^{-3}$) and more.

A method for catching of nitrogen oxides of these concentrations on water-condensation aerosols is suggested. Previously, it has been shown that the rate of absorption of nitrogen oxides by liquid aerosols is proportional to their surface area, i.e., substantially exceeds that in absorption by a film of a liquid [5]. Consequently, presence of liquid aerosols with a highly developed surface must accelerate the catching of nitrogen oxides and improve the efficiency of catching without use of expendable reagents. The results obtained in a laboratory study of the efficiency of purification of gas flows to remove nitrogen oxides by introduction of water-condensation aerosols have been published previously [6]. A patent on the corresponding technique for catching of nitrogen oxides has been obtained [7]. It was shown experimentally under laboratory conditions that the efficiency of catching of nitrogen oxides with concentrations of 0.2–30 $g m^{-3}$

1070-4272/05/7810-1636 © 2005 Pleiades Publishing, Inc.

increases upon introduction of water-condensation aerosols into a gas flow being purified. As gas flows with the above content of nitrogen oxides are commonly formed in dissolution of various products in nitric acid, the forming condensate of nitric acid should be returned to the dissolution reactor. The average volume of nitric acid is approximately 30–40 ml per gram of a caught nitrogen oxide. To reveal the potentialities of the method in more detail, tests were performed on pilot and pilot industrial installations.

EXPERIMENTAL

The pilot installation with a throughput of 10 $m^3 h^{-1}$ included a tube-in-tube cooler-condenser (diameter 120 mm, height 1000 mm) mounted over the cover of a working reactor in which wastes were dissolved in nitric acid. The installation was equipped with a rotameter and devices for gas sampling and was connected to the general ventilation system. To make larger the condensation surface area, a grating shelf comprising six discs placed one above another was introduced into the cooler-condenser.

NO_2 was determined by the accumulation method, which consisted in that nitrogen dioxide was reduced by passing the gas through an absorbing vessel filled with potassium iodide at a rate of 0.8 l min^{-1} and by titrating the forming iodine with sodium thiosulfate [8]. The determination of the sum NO + NO_2 was based on oxidation and absorption of nitrogen oxides by hydrogen peroxide to give nitric acid, whose amount was then found by titration with a sodium hydroxide solution [9].

Nitrogen oxide was determined by calculating the difference between the total content of NO and NO_2 and the content of NO_2.

The installation was tested under industrial conditions by passing through it a part of gases discharged from the reactor. The content of NO_2 in the exhaust gases was as high as 10 g m^{-3}, and that of NO, up to 1 g m^{-3} (maximum degree of oxidation 90%).

The efficiency of catching of nitrogen oxides was studied in relation to the time of gas passing and to the initial content of nitrogen oxides and water vapor. The last parameter was determined by the temperature maintained in the reactor. A study of the efficiency of NO and NO_2 catching in relation to the time of gas passing demonstrated that the efficiency remained virtually unchanged during 14 h.

The next set of experiments was concerned with the dependence of the efficiency of catching of nitrogen oxides on the amount of condensed water vapor, i.e., on the variation of the dissolution temperature. The efficiency of NO_2 catching increased from 63 to 83% as the temperature was raised from 40 to 70°C, i.e., as the content of water aerosols grew from 60 to 170 g m^{-3}, and remained unchanged (85%) in going from 80 to 90°C (content of aerosols 276 and 400 g m^{-3}, respectively). A similar pattern was observed for NO, with only the catching efficiency increasing to a lesser extent (Table 1).

Table 1. Efficiencies of NO_2 and NO catching in the condenser of the pilot installation in relation to the dissolution temperature (concentration of water aerosols) [initial concentration (g m^{-3}): NO_2 3, NO 0.55]

Reactor temperature, °C	Concentration of water aerosols, g m^{-3}	Catching efficiency, %	
		NO_2	NO
40	30	63	50
50	60	79	59
60	110	80	60
70	170	83	61
80	276	85	62
90	400	85	62

Table 2. Efficiencies of NO_2 and NO catching in the condenser of the pilot installation in relation to the initial concentration (reactor temperature 50°C)

Initial concentration, g m^{-3}		Catching efficiency, %		Residual concentration, g m^{-3}	
NO_2	NO	NO_2	NO	NO_2	NO
0.5	0.12	66	49	0.2	0.06
1.3	0.27	70	51	0.4	0.13
3.0	0.55	79	59	0.6	0.23
4.7	0.85	80	64	0.9	0.31
9.0	1.35	83	69	1.5	0.42

It was also established that the catching efficiency increases with the initial concentration of NO and NO_2 (Table 2).

The efficiency of NO_2 catching on the pilot installation is close to that previously published [6] for a laboratory installation.

Thus, it can be stated the process of water condensation can be used to catch NO_2 with a concentration in the range 0.5–9.0 g m^{-3} (and, possibly, higher) with

Table 3. Results obtained in testing the industrial pilot installation

Run no.	Throughput by gas, $m^3 h^{-1}$	NO_2 concentration at the inlet, $g m^{-3}$	NO_2 catching efficiency, %	Run no.	Throughput by gas, $m^3 h^{-1}$	NO_2 concentration at the inlet, $g m^{-3}$	NO_2 catching efficiency, %
1	1960	5.1	89	7	1960	6.0	93
2	1700	2.4	81	8	1960	4.0	89
3	1820	2.6	82	9	1700	1.5	73
4	1700	0.7	15	10	1820	3.1	85
5	1960	4.1	85	11	1960	4.3	91
6	1700	5.5	89	12	1700	1.6	74

a sufficiently high efficiency. Nitrogen oxide NO at degree of oxidation of about 90% is also caught under conditions in which condensed water aerosols are formed.

The results obtained in laboratory and pilot tests of the reagent-free method for purification of vent gases were used to design, fabricate, assemble, and test a industrial pilot installation with a gas flow throughput of 1800 $m^3 h^{-1}$. The installation has the form of a cooler-condenser (Fig. 1). A shell-and-tube variant is accepted for the design of the cooler-condenser, with 40 tubes 40 mm in diameter. The cooling water and the gas being cooled move in a counterflow. The cylindrical casing of the apparatus has two pipes on the side surface, which serve as inlet and outlet for cooling water *1*. The linear flow velocity of the gas is 2–4 $m s^{-1}$; calculated flow rate of cooling water, 45 $m^3 h^{-1}$; heat-exchange surface area, 2.2 m^2; apparatus height and diameter, 2500 and 950 mm, respectively; and the material of the apparatus, 12Kh18N10T steel. The apparatus is mounted directly onto the reactor in which the product is being dissolved.

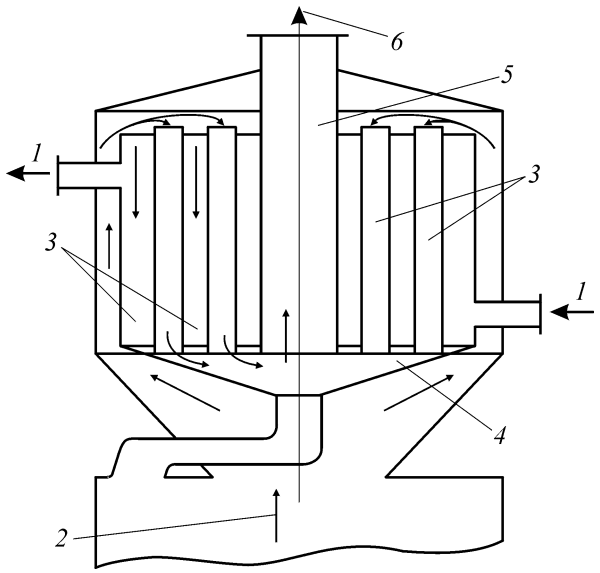

Fig. 1. 1 Schematic of the industrial pilot installation. (*1*) Cooling water, (*2*) inlet for vent gases, (*3*) tubes of the cooler-condenser, (*4*) condensate collector, (*5*) central tube, and (*6*) outlet for vent gases.

The gas flow is fed from the reactor into the cooler-condenser from below *2*, passes through the annular space between the outer wall and the shell-and-tube casing and turns down passing through the tube space *3*, where cooling mostly occurs. Swirling coils are inserted in each tube of the heat exchanger in order to improve the condensation. Arriving in the bottom part of the apparatus, where the condensate collector *4* is situated, the gas again changes its motion direction, passes through the central tube *5*, and is discharged into the atmosphere via the ventilation system *6*.

The condensate formed in film-type condensation and accumulated in the condensate collector flows down back into the reactor in which the waste is dissolved.

The industrial pilot installation was tested in waste processing. The tests were carried out in the following mode: the dissolution reactor was heated to 60–85°C, a portion of waste was introduced, the exhaust gases were passed through the cooled condenser, and the gas phase was sampled to determine the content of NO_2 (no analysis for NO was performed in the industrial tests) at the apparatus inlet and outlet. The results obtained are systematized and listed in Table 3.

It can be seen from Table 3 that the efficiency of nitrogen dioxide catching with water aerosols grows with the initial NO_2 concentration to reach 93–94% at an initial NO_2 concentration of 5.9–6.0 g m^{-3}. The low efficiency (15%) in run no. 4 is due to a decrease in the volume of cooling water, which resulted in that its temperature at the condenser outlet increased from 20 to 40°C and this made lower the concentration of condensation aerosols.

In addition, the poor efficiency is due to a lower initial concentration of NO_2. The dependence of

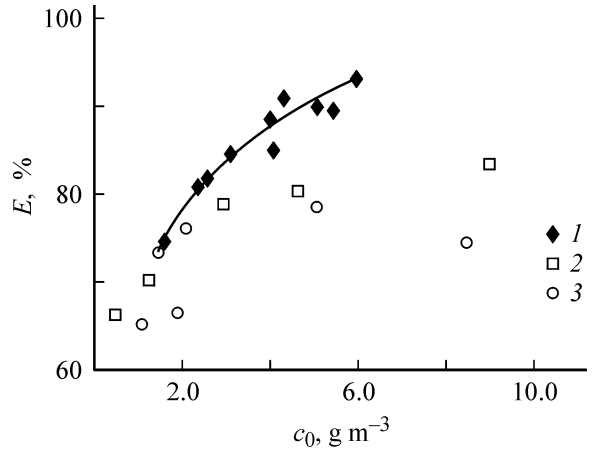

Fig. 2. Catching efficiency E vs. the initial NO_2 concentration c_0 in the gas flow being purified. Installation: (*1*) industrial pilot, (*2*) pilot, and (*3*) laboratory.

the efficiency on the initial NO_2 concentration is shown in Fig. 2, which also presents the results obtained on the pilot installation and in laboratory studies. Despite the different condensation conditions, a sufficiently good agreement is observed, with the higher efficiencies obtained on the industrial pilot installation.

CONCLUSIONS

(1) It was established in testing a pilot installation for catching of nitrogen oxides with water-condensation aerosols that the catching efficiency of NO_2 is 80% and more, and that of NO, 60% and more. The efficiency increases as the content of water aerosols is raised to 170 g m^{-3}. The catching efficiency remains constant within 14 h of operation.

(2) It was found in testing a shell-and-tube industrial pilot installation for catching of nitrogen oxides with water-condensation aerosols that the efficiency of NO_2 catching is 73–93% at a concentration of 1.5–6 g m^{-3}. It was demonstrated that the results obtained on the industrial pilot installation, pilot installation, and in laboratory studies coincide.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Pyrolytic Decarboxylation of Some Derivatives of Perfluorinated Mono- and Dicarboxylic Acids

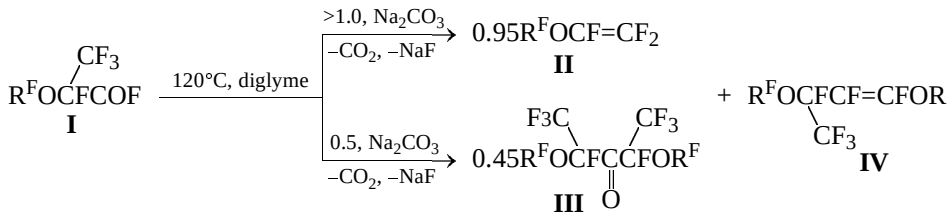
Received July 7, 2005

Abstract—Pathways of pyrolysis of perfluorinated carboxylic acids are considered in relation to the structure of the acids and reaction conditions. The reaction mechanism is discussed.

As shown in [1, 2], pyrolytic decarboxylation of salts of linear perfluorinated carboxylic acids gives terminal fluoroolefins in high yields, reaching 90 mol % in the case of sodium salts:

$$C_nF_{2n+1}CF_2CF_2CO_2M \xrightarrow{250-300^\circ C} C_nF_{2n+1}CF{=}CF_2 + CO_2 + MF;\ (M = Na^+,\ K^+,\ ...,\ Ca^{2+}...).$$



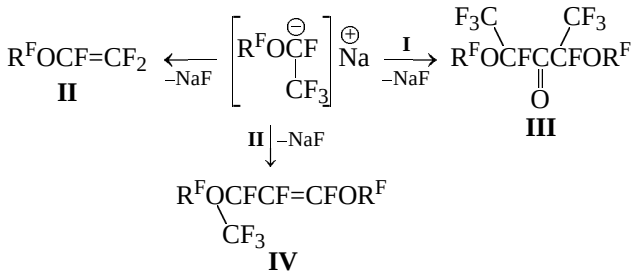
Similarly, terminal perfluoroalkoxyalkenes are formed in high yields by pyrolysis of sodium salts of perfluoro-ω-alkoxyalkanoic acids (from butyric to caproic) [3].

Perfluorinated alkyl vinyl ethers have also been obtained in high yields [4] by pyrolysis of solutions of perfluoro-2-alkoxypropionic acid salts in diglyme:

$$C_nF_{2n+1}OCF(CF_3)CO_2M \xrightarrow{120-160^\circ C,\ \text{diglyme}} C_nF_{2n+1}OCF{=}CF_2 + CO_2 + MF,$$

In this study, we examined in detail how the structure of perfluorinated carboxylic acid derivatives with various α- and β-substituents affects the pyrolysis pathway.

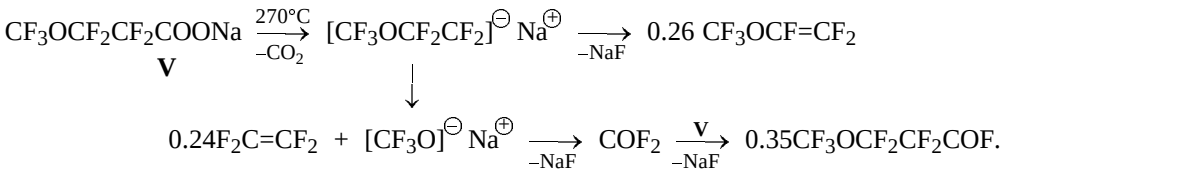
The pathway of pyrolysis of perfluoro-2-alkoxypropionyl fluorides in absolute diglyme at 120°C in the presence of anhydrous sodium carbonate depended on the ratio of perfluoroacyl fluoride and sodium carbonate:



R^F = CF_3– (**a**), $CF_3CF_2CF_2$– (**b**), $CF_3O(CF_2)_3$– (**c**), $C_3F_7OCF(CF_3)CF_2$– (**d**).

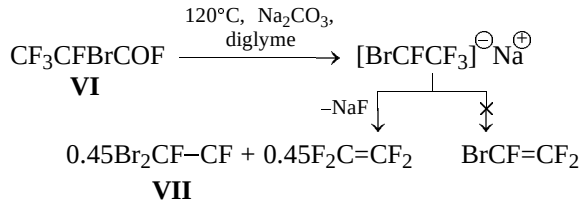
The figure shows how the yields of perfluorinated alkyl vinyl ethers, their linear dimers, and the corresponding bis(perfluoro-1-methyl-2-oxaalkyl) ketones depend on the molar ratio of sodium carbonate and acyl fluoride.

The first step of the reaction involves formation of sodium perfluoro-2-alkoxypropionate along with NaF and CO_2. The pyrolytic decarboxylation proper presumably involves formation of the reactive intermediate carbanion:



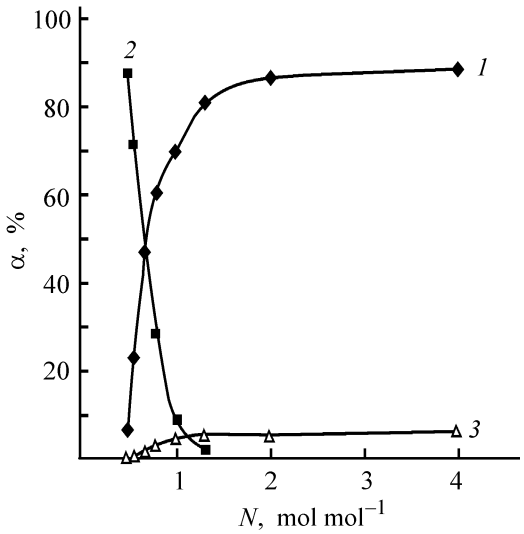
1070-4272/05/7810-1640 © 2005 Pleiades Publishing, Inc.

which, depending on the reactant ratio, can either eliminate the fluoride anion to form perfluorinated alkyl vinyl ether **II** or react with the initial substrate **I** to form ketone **III**. Also, we identified among the pyrolysis products small amounts of the dimers **IV** of perfluorinated alkyl vinyl ethers, which suggests the possibility of the reaction of the carbanion with **II**.



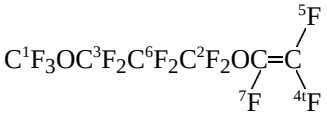
The structures of the products were confirmed by bromination across the double bond. The ^{19}F NMR data for the compounds identified are listed in the table.

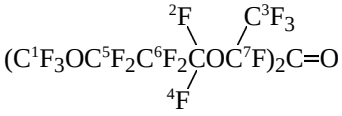
Gubanov *et al.* [5] showed that dry pyrolysis of sodium perfluoro-3-methoxypropionate follows the scheme

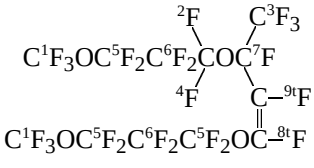


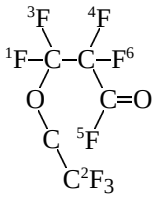
Experiments on pyrolysis of **V** in diglyme at 120°C showed that the perfluoro-3-oxaalkyl anion generated by decarboxylation can eliminate either the fluoride ion from the β-position or (major pathway) the perfluoromethoxide anion, with its subsequent transformation into carbonyl difluoride. The yields of perfluorinated methyl vinyl ether and tetrafluoroethylene were 30 and 60 mol %, respectively. With Na^+ replaced by K^+, the yield of tetrafluoroethylene increases from 60 to 95 mol %, suggesting stabilization of the trifluoromethoxide anion with the potassium ion, in agreement with the data of [5, 6].

An unexpected result was obtained in pyrolysis of 2-bromotetrafluoropropionyl fluoride **VI** in dry diglyme at 120°C in the presence of anhydrous sodium carbonate. Instead of the expected trifluorobromoethylene, we detected 1,1-dibromotetrafluoroethane **VII** in the reaction products by ^{19}F NMR (see table) and mass spectroscopy. Apparently, the bromotetrafluoroethyl anion generated by decarboxylation of the 2-bromotetrafluoropropionate anion is stabilized by abstraction of the bromine cation from the second substrate molecule, rather than by elimination of the fluoride or bromide anion:

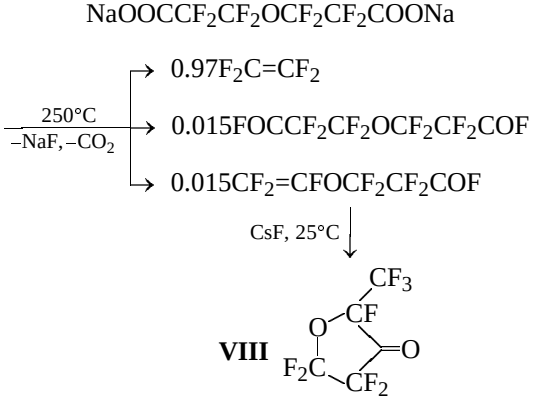








The formation of tetrafluoroethylene as the major product of pyrolysis of perfluoro-3-oxaalkanoic acid derivatives has been observed previously [7] in pyrolysis of sodium perfluoro-4-oxaheptanedioate at 250°C, when the monodecarboxylation product, perfluoro-3-vinyloxypropionyl fluoride, was obtained in a less than 2% yield. This product isomerized at room tem-



Yield α of pyrolysis products of perfluoro-2-alkoxypropionyl fluorides vs. the molar ratio *N* of sodium carbonate to acyl fluoride: (*1*) perfluorinated alkyl vinyl ether **II**, (*2*) perfluoro ketone **III**, and (*3*) dimer **IV** of perfluorinated alkyl vinyl ether.

perature under the action of CsF into a cyclic ketone, perfluoro-2-methyloxalan-3-one **VIII**:

Accordingly, we detected in the experiments on the pyrolysis of perfluoro-2-methyl-3-oxahexanedioic acid difluoride **IX** (its acyl moiety is isomeric to that of sodium perfluoro-4-oxaheptanedioate) in diglyme at 120°C in the presence of an equimolar amount of sodium carbonate, along with sodium trifluoroacetate and tetrafluoroethylene, also compound **VIII** formed in ~15 mol % yield:

The product was identified by the characteristic ^{19}F NMR signals of magnetically nonequivalent geminal fluorine atoms with coupling constants of 125 Hz for the CH_2O group and 280 Hz for the CF_2CO group. The ^{19}F NMR spectrum with the signals of the –OCF< and $–CF_3$ groups is given in the table; it is quite consistent with the data from [7].

EXPERIMENTAL

The pyrolysis products were analyzed chromatographically with an LKhM-8MD chromatograph [model 5, thermal conductivity detector, programmed heating from 30 to 200°C at a rate of 6 deg min^{-1}, 3000 × 3-mm columns, solid support Silokhrom-2 (0.16–0.2 mm, packing density 0.30 ± 0.01 g cm^{-3}), stationary phase 5F4E (15 wt %), carrier gas helium (40 ml min^{-1})].

The ^{19}F NMR spectra were recorded on a Bruker Spectrospin HX-90 spectrometer at a working frequency of 84.67 MHz; hexafluorobenzene or hexafluoro-*p*-xylene was used as internal reference. The ^{19}F chemical shifts were recalculated relative to CCl_3F.

The ^1H NMR spectra were recorded on the same device at 90 MHz, with hexamethyldisiloxane as external reference.

The mass spectra were recorded on a Chromass Varian CH-7M device.

Perfluoro-2-(4-oxaamyloxy)propionyl fluoride **Ic** was prepared by electrochemical fluorination of methyl 3-methoxypropionate [8], followed by condensation of the resulting perfluoro-3-methoxypropionyl fluoride with hexafluoropropene oxide on KF in diglyme.

The synthesis of perfluoro-2-methyl-3-oxahexanedioic acid difluoride **IX** has been described previously [9].

Perfluoro-2-methoxypropionyl fluoride **Ia** was prepared by condensation of COF_2 with hexafluoropropene oxide [10], and perfluoro-2-propoxypropionyl fluoride **Ib** and perfluoro-2-(2-methyl-3-oxahexyloxy)-propionyl fluoride **Id**, respectively, by dimerization and trimerization of hexafluoropropene oxide under similar conditions [11].

Perfluoro-2-bromopropionyl fluoride **VI** was prepared from 67 g (0.4 mol) of hexafluoropropene oxide and 43 g (0.42 mol) of dry NaBr in 75 ml of absolute diglyme at –30°C with stirring in a stainless steel autoclave. After warming up to room temperature, the lower organofluorine layer was separated, and 80 g of a product (yield 88 mol %) with bp ~20°C was obtained. It was identified as $CF_3CFBrCOOCH_3$ by the ^{19}F NMR [δ_F, ppm: 77.1 d (3F, CF_3, J 10 Hz), 134.1 q (1F, $CFBrCOOCH_3$, J 10 Hz] and mass spectra [m/z (I_{rel}, %): 209, 207 (5.4), $M^+ – OCH_3$; 181, 179 (30.5), $M^+ – 59$ (CF_3CFBr^+); 162, 160 (3.7), $C_2F_3Br^+$; 131, 129 (13.9), CF_2Br^+; 128 (4.8), $C_2F_4CO^+$; 109 (6.6), $C_2F_3CO^+$; 100 (7.2), $C_2F_4^+$; 81 (3.3), $C_2F_3^+$; 69 (119), CF_3; 59 (100) $COOCH_3^+$.

Pyrolysis of perfluoro-2-(4-oxaamyloxy)propionyl fluoride Ic. (a) A 250-ml four-necked round-bottomed glass flask equipped with a stirrer, thermometer, and water-cooled reflux condenser was charged with 31 g (0.3 mol) of dry Na_2CO_3 and 30 ml of diglyme dehydrated over CaH_2. The contents were heated on a water bath to 70°C, after which 50 g (0.15 mol) of **Ic** was added dropwise until the CO_2 evolution ceased. Then the reflux condenser was replaced with a descending condenser, the mixture [a suspension of Na_2CO_3 in a solution of sodium perfluoro-2-(4-oxaamyloxy)-propionate in diglyme] was heated to 120°C, and 40 g of the product was collected in the receiver. According to GLC, the product consisted of 97.5% per-fluorinated 4-oxaamyl vinyl ether **IIc** (92 mol %) and 2.5% perfluoro-4-oxaamyl 1,3,3,3-tetrafluoroethyl ether. The following products were isolated by fractional distillation and characterized: $CF_3OCF_2CF_2CF_2OCF=CF_2$, bp 64°C, d_4^{20} 1.636; mass spectrum, m/z (I_{rel}, %): 332 (0.37), $C_4F_{12}O_2^+ = M^+$; 169 (1.83), $C_3F_7^+$; 147 (1.92), $C_3F_5O^+$; 135 (1.39), $C_2F_5O^+$; 131 (0.9), $C_3F_5^+$; 119 (5.24), $C_2F_5^+$; 100 (2.2), $C_2F_4^+$; 97 (2.37), $C_2F_3O^+$; 81 (3.35), $C_2F_3^+$; 78 (4.29), $C_2F_2O^+$; 69 (100), CF_3^+; $CF_3OCF_2CF_2CF_2OCFHCF_3$, bp 71–72°C, d_4^{20} 1.622.

(b) Similarly, a mixture of 8 g (0.075 mol) of dry Na_2CO_3 and 30 ml of dry diglyme was heated to 60°C, and 50 g (0.15 mol) of **Ic** was added, after which the mixture was heated at 140–150°C for 2 h until the gas evolution ceased. Then the mixture was cooled to 80°C, the reflux condenser was replaced with the descending condenser, and the reaction products were distilled off in a vacuum (2–3 mm Hg). After the separation of the lower organofluorine layer, we obtained 43 g of the product containing, according to GLC, 93% bis(perfluoro-1-methyl-2,6-dioxaheptyl) ketone (90 mol %) and 7% of an impurity. We isolated by fractional distillation and characterized ketone **IIIc**, bp 74–75°C (18 mm Hg), d_4^{20} 1.757, n_D^{20} 1.2836. The impurity was identified by ^{19}F NMR as linear dimer **IVc** of perfluorinated 4-oxaamyl vinyl ether, $CF_3OCF_2CF_2CF_2OCFCF=CFOCF_2CF_2CF_2OCF_3$ (with CF_3 branch on the CF group).

bp 70–71°C (18 mm Hg), d_4^{20} 1.736, n_D^{20} 1.2805. Its structure was also confirmed by UV-induced bromination [characteristics of the dibromide: bp 73°C (2 mm Hg), d_4^{20} 1.9811, n_D^{20} 1.3443. The mass spectrum of the product was also consistent with the structure of the linear dimer, *m*/*z* (I_{rel}, %): 664 (6.4), $C_{12}F_{24}O_3$ = M^+; 595 (0.63), $M^+ - CF_3$; 579 (3.8), $M^+ - CF_3O$; 498 (0.6), $M^+ - C_3F_6O^+$; 479 (1.1), $M^+ - C_3F_7O$; 413 (7.7), 498 – CF_3O; 325 (2.4), $C_7F_{11}O_2^+$; 275 (2.3), $C_6F_9O_2^+$; 247 (2.7), $C_5F_9O^+$; 219 (1.1), $C_4F_9^+$; 178 (25.2), $C_4F_6O^+$; 169 (98.9), $C_3F_7^+$; 159 (33.0), $C_4F_5O^+$; 150 (5.9), $C_3F_6^+$; 147 (49.5), $C_3F_5O^+$; 135 (30.3), $C_2F_5O^+$; 119 (74.8), $C_2F_5^+$; 100 (37.3), $C_2F_4^+$; 69 (100), CF_3^+.

Similarly, we obtained by pyrolysis of perfluoro-2-methoxypropionyl fluoride **Ia**, perfluoro-2-propoxypropionyl fluoride **Ib**, and perfluoro-2-(2-methyl-3-oxahexyloxy)propionyl fluoride **Id** the corresponding symmetrical ketones **IIIa**, **IIIb**, and **IIId** with admixture of linear dimers **IV**.

Pyrolysis of perfluoro-3-methoxypropionyl fluoride. Similarly to the above-described procedure, a flask with the reflux condenser cooled by a dry ice/alcohol mixture was charged with 22.3 g (0.21 mol) of Na_2CO_3 and 40 ml of dry diglyme; 46 g (0.2 mol) of $CF_3OCF_2CF_2COF$ was fed through a siphon until the refluxing and CO_2 evolution ceased. The resulting suspension of NaF in a solution of sodium perfluoro-3-methoxypropionate **V** in diglyme was heated to 120°C, with fractional distillation of the pyrolysis products. Carbonyl fluoride was taken up by a sodium carbonate solution, perfluorinated methyl vinyl ether was condensed in a coil trap at –50°C, and tetrafluoroethylene was taken up by liquid bromine in a trap, with conversion into dibromotetrafluoroethane. We obtained 10 g of $CF_3OCF{=}CF_2$ (30 mol %) and 31 g of CF_2BrCF_2Br (60 mol %).

Pyrolysis of perfluoro-2-bromopropionyl fluoride VI. Similarly to the pyrolysis of perfluoro-3-methoxypropionyl fluoride, 45 g (0.2 mol) of **VI** was fed to a mixture of 22.3 g (0.21 mol) of Na_2CO_3 and 40 ml of dry diglyme, until the refluxing and CO_2 evolution ceased. Then the reflux condenser was replaced with a water-cooled descending condenser, the flask was heated to 120°C, and 23 g (45 mol %) of perfluoro-1,1-dibromoethane **VII** was distilled off; bp ~5°C, d_4^{20} 2.188, n_D^{20} 1.364; mass spectrum, *m*/*z* (I_{rel}, %): 262, 260, 258 (47.8), $C_2F_4^{79-81}Br_2^+ = M^+$; 193, 191, 189 (32.5), $M^+ - CF_3$; 181, 179 (100), $M^+ - Br$; 162, 160, 158 (17.5), $M^+ - C_2F_4 = Br_2^+$; 131, 129, $M^+ - CF_2Br$; 112, 110, $M^+ - CF_3Br = CFBr^+$. In low-boiling gases, after the uptake of CO_2 with an alkali, we identified tetrafluoroethylene and 1-hydro-1-bromotetrafluoroethane, which was also detected as impurity in the main product by ^{19}F NMR spectroscopy.

Pyrolysis of perfluoro-2-methyl-3-oxahexanedioic acid difluoride IX. A similar flask equipped with a water-cooled refluxed condenser was charged with 10.6 g (0.1 mol) of dry Na_2CO_3 and 50 ml of dehydrated diglyme. The mixture was heated on an oil bath to 60°C, and 31 g (0.1 mol) of **IX** was added dropwise from a dropping funnel over a period of 2 h. The mixture was stirred until the CO_2 evolution ceased. Then the mixture was gradually heated with stirring to 140°C, with collected the pyrolysis products in a trap cooled to –78°C. Low-boiling gases were passed through a trap with liquid bromine and then through an alkaline absorber. From the trap, we isolated 4 g (yield ~15%) of a product identified as perfluoro-2-methyloxolan-3-one **VIII** by comparison of the ^{19}F NMR and mass spectra with those reported in [6]; bp ~15°C. In the trap with bromine, 1,2-dibromotetrafluoroethane was obtained as a separate phase. The nonvolatile residue contained sodium trifluoroacetate.

CONCLUSIONS

(1) Depending on the pyrolysis conditions and structure of perfluorocarboxylic acid salts, the perfluoroalkyl carbanion generated by decarboxylation is stabilized not only by elimination of the fluoride anion to give the alkene, but also with that to give the corresponding ketones through both inter- and intramolecular attack at the acyl fluoride group.

(2) In the pyrolysis of potassium perfluoro-3-alkoxypropionates, the perfluorooxaalkyl anion is virtually quantitatively stabilized by elimination of the perfluoroalkoxide anion with the formation of tetrafluoroethylene.

(3) An attack of the bromotetrafluoroethyl anion at the bromine atom of another substrate molecule yields perfluoro-1,1-dibromoethane and tetrafluoroethylene.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis of Polyfluorinated Ethers

D. N. Bazhin, T. I. Gorbunova, A. Ya. Zapevalov, and V. I. Saloutin

Received November 10, 2004; in final form, June 2005

Abstract—Procedures for preparing polyfluorinated ethers $H(CF_2CF_2)_nCH_2OR$ by alkylation of the corresponding telomeric alcohols $H(CF_2CF_2)_nCH_2OH$ (n = 1–3) with alkyl halides and alkyl tosylates were examined.

The rising researchers' interest in synthesis of polyfluorinated ethers (PFEs) in the past decade is due to several factors. First, thanks to their physicochemical properties, compounds of this class are potential ozone-friendly substitutes of Freons [1]. Second, the majority of PFEs are inert low-freezing and, in some cases, relatively high-boiling liquids. These properties make them suitable as solvents, heat-transfer agents, and components of a new generation of power cells, improving the low-temperature characteristics of graphite electrodes [2]. An important property of PFEs is their adhesion to various materials, making these compounds promising as lubricants operating in a wide range of temperatures and loads.

Published procedures for PFE synthesis involve nucleophilic and radical addition of alcohols to polyfluoroalkenes, trifluoromethylation of polyfluorinated alcohols catalyzed by Lewis acids [3], alkylation of polyfluoroalkoxide anions with dimethyl sulfate [4] or polyfluoroalkyl chlorosulfites [5, 6], etc. Combinations of various reagents in PFE synthesis allow preparation of compounds of diverse structures. All the above-mentioned methods require anhydrous conditions, special equipment, and, frequently, difficultly available chemicals.

The classical route to ethers (Williamson reaction) involves the reaction of alcoholates with alkyl halides [7]. Among polyfluorinated alcohols commercially produced in Russia, telomeric alcohols of the general formula $H(CF_2CF_2)_nCH_2OH$ (n = 1–8) are the most readily available. However, conversion of telomeric alcohols into alcoholates for the Williamson reaction involves certain problems: reaction of these alcohols with alkali metals, developing with accumulation of the alcoholate or in the course of removal of excess alcohol, may cause self-ignition or even explosion of the reaction mixture; preparation of alcoholates using alkalis, followed by removal of water and excess alcohol, is not safe either [4]. At the same time, if the alcoholates are taken as solutions, the yields of the target compounds are low [8].

Within the framework of our study, the problem of raising the yields of PFEs derived from telomeric alcohols and alkyl halides is partially solved by performing the reaction in a DMSO + KOH mixture [see Experimental, method (a)] to enhance the basic and nucleophilic properties of the alcohol (n = 1):

$$HC_2CF_2CH_2OH + RX \xrightarrow{100^\circ C,\ 12\ h} HCF_2CF_2CH_2OR + HX,$$

I–**III**, 45–55%

where R = C_4H_9 (**I**), C_6H_{13} (**II**), $C_{10}H_{21}$ (**III**); X = Cl, Br.

However, even within the next telomeric alcohol (n = 2), this reaction yields no desired PFEs, apparently because of the formation of oligomeric products. The residue obtained after removing the excess KOH and solvent is undistillable in a rough vacuum.

Solov'ev *et al.* [9] reported on a one-step synthesis of fluorinated glycidol ethers under the conditions of phase-transfer catalysis. This method apparently facilitates the synthesis of a wide range of PFEs based on telomeric alcohols, but it is insufficiently versatile because of the different solubilities of the fluorine-containing components [10].

With the aim to raise the yields of PFEs, we chose appropriate solvent systems and prepared compound

IV–**IX** under relatively mild conditions [see Experimental, method (b)]:

$$H(CF_2CF_2)_nCH_2OH + RX \xrightarrow{A \text{ or } B,\ \text{catalyst, KOH}} H(CF_2CF_2)CH_2OR + HX,$$

IV–**IX**, 40–70%

conditions: (A) CH_2Cl, H_2O, 40°C, 5 h, n = 2; (B) THF, H_2O, 60°C, 5 h, n = 3. Catalyst: $[Et_3BzN]^+Cl^-$; X = Cl, Br; R = C_4H_9, n = 2 (**IV**); R = C_5H_{13}, n = 2 (**V**); R = $C_{10}H_{21}$, n = 2 (**VI**); R = C_4H_9, n = 3 (**VII**); R = C_6H_{13}, n = 3 (**VII**); R = $C_{10}H_{21}$, n = 3 (**IX**).

Comparative analysis of the two procedures for preparing PFEs **I**–**IX** shows that none of them ensures quantitative yields of the desired compounds, and no correlation can be revealed between the substrate structure and PFE yield.

The highest yields of PFEs (up to 90%) are attained when a two-step procedure is used: first a fluorinated alcohol is converted to a sulfonate (mesylate, tosylate, triflate) by the reaction with appropriate sulfonyl derivative [10], after which the sulfonate group is readily replaced by the alcoholate ion formed from a nonfluorinated alcohol *in situ*. According to [10], this two-step process can be schematically represented as follows:

$$R^fCH_2OH \xrightarrow{R'SO_2Cl,\ NEt_3} R^fCH_2OSO_2R' \xrightarrow{R''OH,\ NaH,\ 10\ h,\ 130^\circ C} R^fCH_2OR'',$$

where R^f = CF_3, C_6F_{13}; R' = CH_3, CF_3, *p*-$C_6H_4CH_3$; R'' = *p*-$C_6H_4NO_3$.

The key step in this reaction is nucleophilic replacement of the RSO_3^- group, which can be performed in a virtually quantitative yield. However, the reaction of sulfo derivatives with a fluorinated alcohol involves the loss of a valuable chemical in the first step. Furthermore, the use of NaH requires anhydrous conditions, and the reaction requires heating at 130°C for 10 h.

Among the examined routes to PFEs, the most promising is, apparently, introduction of a labile leaving group into the hydrocarbon component. The resulting derivative in the modified Williamson reaction is a more active alkylating agent than alkyl halides.

Comparison of the reactivity of mesylates, triflates, and tosylates, taking into account the reaction conditions, shows that tosylates are not inferior to the other reagents, but are preferable from the viewpoint of convenience in handling and availability.

Tosylation of common alcohols by the nucleophilic substitution mechanism occurs under relatively mild conditions; the subsequent reaction of the resulting derivatives with telomeric alcohols gives the desired compounds **IV**–**IX** in high yields and does not require any anhydrous medium [see Experimental, method (c)]:

$$ROH + TsCl \xrightarrow[-HCl]{KOH,\ H_2O} [ROTs]$$

$$\xrightarrow{H(CF_2CF_2)_nCH_2OH,\ KOH,\ THF,\ H_2O,\ \text{catalyst}} \textbf{IV}\text{–}\textbf{IX} + TsOK.$$

87–96%

It should be noted that isolation of the tosyl derivatives (ROTs) is not necessary for performing the second step of the synthesis successfully. Comparison of the yields of **IV**–**IX** in the processes whose second step was performed with isolated and crude ROTs shows that the difference in the yields is as small as 5–10%.

Thus, the latter procedure is the best from the viewpoint of conditions and results: reaction temperature 60°C, time (total of two steps) 8 h, and almost quantitative yields of the desired compounds.

The IR spectra of **I**–**IX** contain the following characteristic absorption bands, ν, cm^{-1}: 1111–1142 (C–F), 1200–1204 (C–O–C), and 2856–2879, 2927–2959, 2934–2966 (C–H).

The ^1H and ^{19}F spectra of all the PFEs prepared have common features.

EXPERIMENTAL

The IR spectra were recorded on a Perkin–Elmer Spectrum One Fourier spectrometer from thin films. The ^1H and ^{19}F NMR spectra were measured on a Bruker DRX-400 spectrometer in $CDCl_3$, internal references TMS and C_6F_6, respectively. The yields, boiling points, and elemental analyses of **I**–**IX** are given in Table 1, and the NMR data, in Table 2.

Synthesis of polyfluorinated ethers. Method (a). A mixture of 0.1 mol of alkyl halide, 0.25 mol of KOH, and 50 ml of DMSO was heated with vigorous stirring to 100°C to obtain a uniform mixture, and 0.1 mol of telomeric alcohol (n = 1) was added dropwise at this temperature over a period of 30 min. The mixture was stirred for 8 h at 100°C. Then 150 ml of water was added, and the mixture was neutralized with HCl. The resulting neutral solution was extracted with $CHCl_3$ (2 × 30 ml). The chloroform extracts were combined and dried over $CaCl_2$; the solvent was distilled off. The residue was subjected to fractional distillation to obtain 1-(1,1,3-trihydroperfluoroprop-

oxy)butane **I**, 1-(1,1,3-trihydroperfluoropropoxy)hexane **II**, and 1-(1,1,3-trihydroperfluoropropoxy)decane **III**.

Method (b). A mixture of 50 ml of CH_2Cl_2 and 50 ml of 40% KOH (conditions A) [or 60 ml of THF and 30 ml of 50% KOH (conditions B)], 0.1 mol of telomeric alcohol [n = 2 (conditions A) or n = 3 (conditions B)], and 1 g of triethylbenzylammonium chloride was heated with vigorous stirring to 40°C (conditions A) or 60°C (conditions B). At this temperature, 0.1 mol of alkyl halide was slowly added over a period of 30 min, and the mixture was kept for 5 h. Then, for conditions A, the upper organic layer was separated, washed with dilute HCl (2 × 100 ml), and dried over $CaCl_2$; the solvent was distilled off. For conditions B, 150 ml of water was added, and the oil thus formed was extracted with $CHCl_3$ (2 × 30 ml). The combined chloroform extracts were dried over $CaCl_2$, and the solvent was distilled off. In both cases, the residue was subjected to fractional distillation to obtain 1-(1,1,5-trihydroperfluoropentoxy)butane **IV**, 1-(1,1,5-trihydroperfluoropentoxy)hexane **V**, 1-(1,1,5-trihydroperfluoropentoxy)decane **VI**, 1-(1,1,7-trihydroperfluoroheptoxy)butane **VII**, 1-(1,1,7-trihydroperfluoroheptoxy)hexane **VIII**, and 1-(1,1,7-trihydroperfluoroheptoxy)decane **IX**.

Method (c). A mixture of 0.15 mol of *p*-toluenesulfonyl chloride and 0.15 ml of ethanol was heated to 35–40°C, and 50 ml of 40% KOH was added dropwise over a period of 1 h with vigorous stirring. The resulting mixture was stirred for 3 h at 35–40°C and cooled, after which 200 ml of water was added. The oil thus formed was separated and treated under conditions A [method (b)].

CONCLUSION

The most efficient route to polyfluorinated ethers is a two-step process involving preparation of tosyl derivatives of alcohols, followed by their reaction with telomeric alcohols $H(CF_2CF_2)_nCH_2OH$ under the conditions of phase-transfer catalysis, which allows preparation of ethers $H(CF_2CF_2)_nCH_2OR$ (n = 2, 3) in high yields (87–96%).

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Reaction of Urea with Citric Acid

R. Paleckiene, A. Sviklas, and R. Šlinkšiene

Kaunas Technological University, Kaunas, Lithuania

Received May 12, 2005

Abstract—Reaction of urea with citric acid in aqueous solutions at molar ratios of 1 : 1, 1 : 2, and 2 : 1 and the solubility of urea citrate were studied. The data obtained can serve to optimize use of citric acid as a physiologically active substance or nitrification inhibitor and in production of liquid fertilizers containing urea.

Urea is a frequent component of many liquid integrated fertilizers. Interaction of urea with citric acid can affect phase equilibria in the systems constituting liquid complex fertilizers.

Urea is highly reactive. Many urea compounds obtained in reactions with mineral or organic acids are known [1–5]. Citric acid is a necessary component in the system of biochemical reactions of the cellular respiration. Along with other tricarboxylic acids, citric acid is contained in small amounts in mitochondria of all the cells. Another function of citric acid is to support the acid–base equilibrium and ionic composition in a living body. Citric acid is a typical chelate forming agent in reactions with metal ions. It can also inhibit nitrification [6] and hence is of interest as a component of liquid complex fertilizers.

There is no reliable information on how urea reacts with citric acid. Fragmentary tentative results have been published previously [7].

In this study, we examined the reaction of urea with citric acid in aqueous solutions and determined the main physicochemical properties of the reaction product.

Urea $CO(NH_2)_2$ and citric acid $C_6H_8O_7 \cdot H_2O$ were of chemically pure grade. The compositions of the substances were determined by chemical and physicochemical analyses. The nitrogen content was found in solutions and in the solid phase [8–10].

A thermal analysis of solids was performed on a Du Pont Instruments 990 Thermal Analyzer at a heating rate of 10 deg min^{-1}.

The IR spectra were recorded on a Spectrum GX (Perkin Elmer) FT-IR spectrometer in KBr pellets. An X-ray phase analysis was performed on a DRON-6 diffractometer with copper radiation and nickel filter within the 0°–166.5° range of diffraction angles with a relative error at no more than 0.5%.

Mixtures of urea (Ur) and citric acid (HCit), taken in molar ratios of 1 : 1, 2 : 1, and 1 : 2, were dissolved in water taken in amounts corresponding to the weight ratio of the sum of the reactants to water of 1 : 0.25, 1 : 0.5, 1 : 0.75, and 1 : 1. The solutions were prepared at room temperature and, in a number of cases, were heated, if required, for complete dissolution of the initial substances. The results are listed in Table 1.

As can be seen, a precipitate is formed at a 1 : 1 molar ratio; its chemical composition corresponds to urea citrate with a nitrogen content of 11.1 wt %. Practically no nitrogen remains in solution. At Ur : HCit = 2 : 1, a substance with ~11 wt % nitrogen content precipitates, but nitrogen remains in solution in

Table 1. Chemical composition of aqueous solutions containing urea and citric acid and of precipitate

Ur/HCit molar ratio	Weight ratio of Ur + HCit to water	Nitrogen content, wt %	
		precipitate	solution

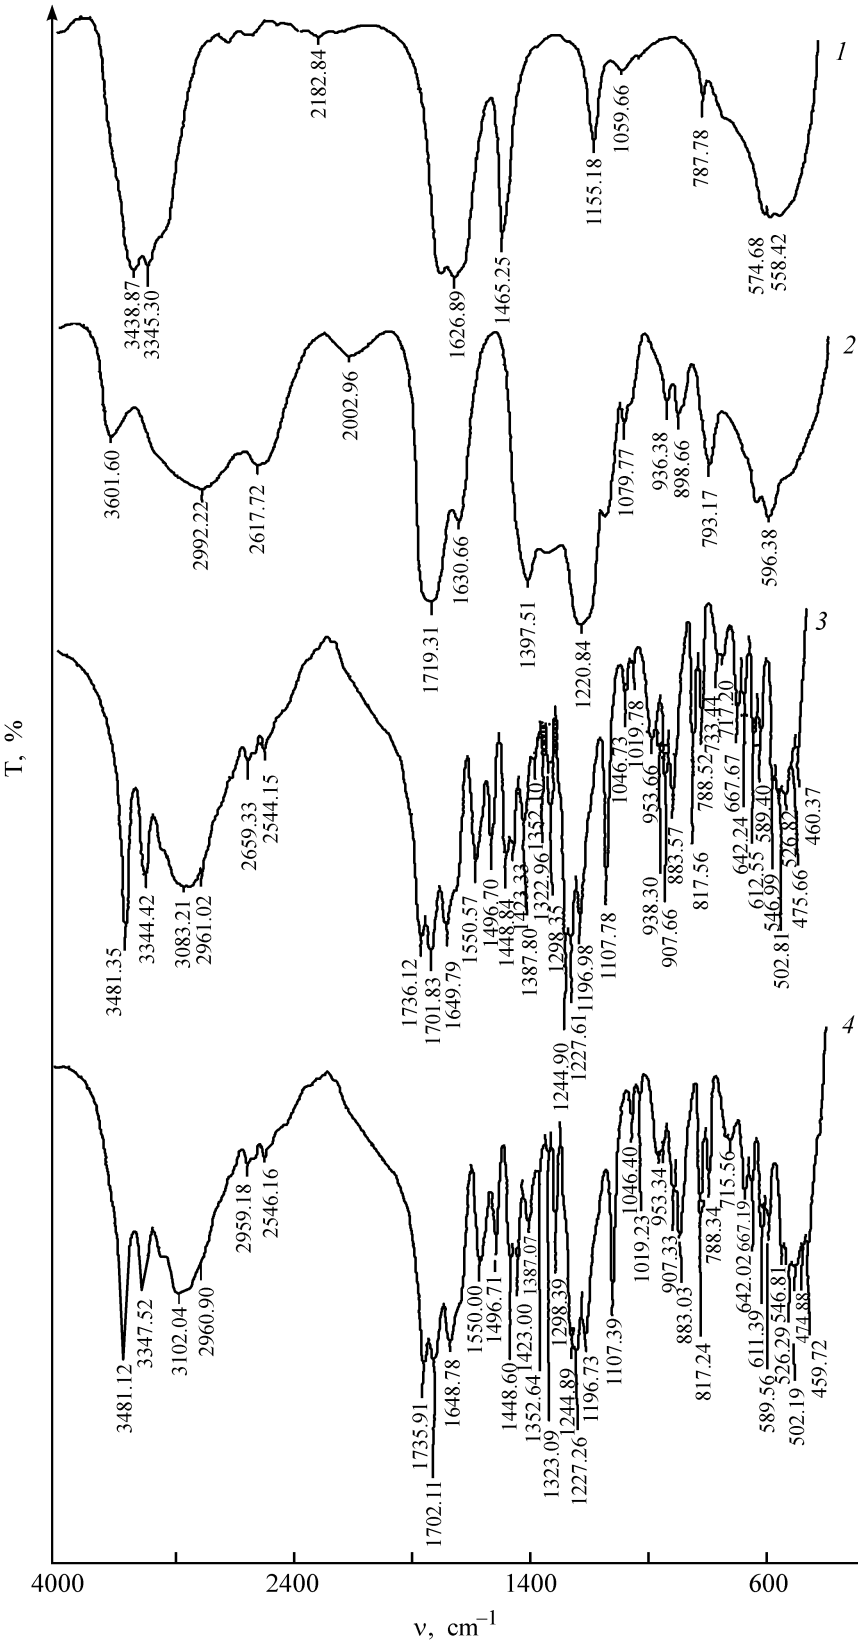

Fig. 1. IR spectra of (*1*) urea, (*2*) citric acid, and (*3*, *4*) Ur · HCit. Weight ratio of Ur + HCit to water: (*3*) 1 : 1 and (*4*) 1 : 0.5. (T) Transmission and (ν) wave number.

the amounts corresponding to 1 : 1 Ur : HCit molar ratio. All these facts suggest that urea citrate crystallizes.

In solutions with a Ur : HCit molar ratio of 1 : 2, no precipitate was formed within the range of weight ratios of the initial substances to water from 1 : 0.25 to 1 : 1. This shows that the compound Ur · HCit is not formed under the above conditions.

Interaction of urea with citric acid was studied by IR spectroscopy. Figure 1 shows the spectra of the starting urea (spectrum *1*) and citric acid (*2*) and of the 1 : 1 compound separated from the solutions with weight ratios of (Ur + HCit) to water of 1 : 1 (*3*) and 1 : 0.5 (*4*).

Changes in the spectrum of Ur · Hcit (Fig. 1, spectra *3*, *4*) relative to spectra of the starting urea (Fig. 1, spectrum *1*) and citric acid (Fig. 1, spectrum *2*) show that Ur reacts with HCit. The band of asymmetric stretching vibrations of the NH_2 group of Ur at 3480–3200 cm^{-1} is shifted to 3480–2500 cm^{-1} in the spectrum of the compound. In the spectrum of the compound, there is no well-defined band ν_{OH} within the range 3600–2500 cm^{-1}, in contrast to the spectrum of HCit.

In the region of bending vibrations of the urea amide group (1720, 1680, 1650 cm^{-1}), new narrow, well-defined bands, absent in the spectra of urea (Fig. 1, spectrum *1*) and HCit (Fig. 1, spectrum *2*), appear in the spectrum of the 1 : 1 compound (Fig. 1, spectra *3*, *4*). The bands of COO^- (1750–1600 cm^{-1}) and CH_2 (920–890, 855–735 cm^{-1}) groups and bands of the compound overlap with bands of urea CN (1604–1590 cm^{-1}) and CO (1700–1620 cm^{-1}) groups (Fig. 1, curve *1*). The presence of many new narrow, well-defined bands confirms that a compound of urea with citric acid is formed.

Figure 2 shows the curves obtained in differential thermal analysis (DTA) of urea (curve *1*), citric acid (*2*), and product of their reaction, prepared by crystallization from 1 : 1 aqueous solutions with a weight ratio of (Ur + HCit) to water of 1 : 1 (*3*) and 1 : 0.5 (*4*).

Well-defined endothermic effects are seen in the DTA curve of urea (Fig. 2, curve *1*). At 135°C, it melts and at 160–190°C, decomposes to give of biuret and cyanuric acid, which transforms at 220°C into cyanic acid with liberation of NH_3 and CO_2. At 370–470°C, cyanic acid undergoes a stepwise decomposition [1].

Under ordinary conditions, citric acid exists as a crystalline monohydrate, and the endothermic effect

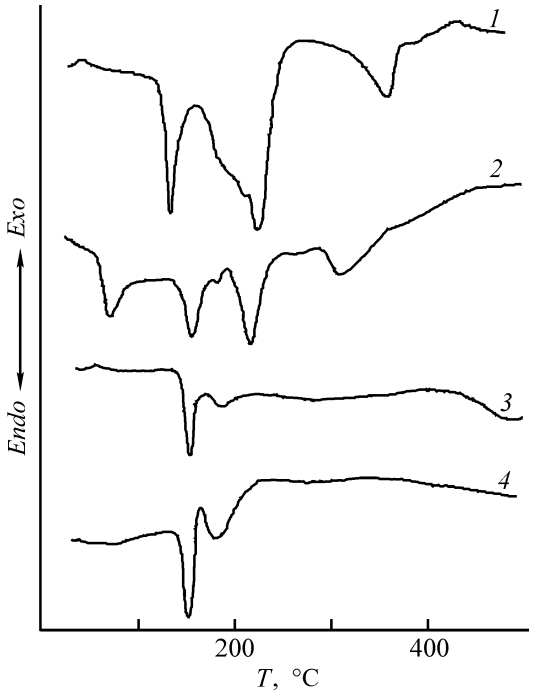

Fig. 2. DTA curves of (*1*) urea, (*2*) citric acid, and (*3*, *4*) Ur · HCit. Weight ratio of Ur + HCit to water: (*3*) 1 : 1 and (*4*) 1 : 0.5.

in the DTA curve at 60–93°C can be assigned to its dehydration (Fig. 2, curve *2*). At 148–160°C, anhydrous citric acid melts (this is in accordance with published data [11]). At temperatures higher than mp (180°C), citric acid transforms into an itaconic acid, which is reflected in the DTA curve by a large endothermic effect at 200°C. A diffuse endothermic effect at 310°C probably corresponds to itaconic acid decomposition [12].

Two endothermic effects are observed in DTA curves of the urea compound with citric acid (Fig. 2, curves *3*, *4*); a stronger effect at 160°c and a weaker effect at 200°C.

Comparison shows that urea, citric acid, and their compound have different DTA curves, and in the DTA curve of the compound, the effects characteristic of urea and citric acid are absent. This fact convincingly confirms that all the three compounds are individual. Thus, the DTA data confirm the existence of the Ur · HCit compound.

Figure 3 shows the X-ray powder patterns of urea (Fig. 1; *1*), citric acid (Fig. 1, *2*), and product of their reaction, prepared by crystallization from solutions with Ur to HCit molar ratio of 1 : 1 [Fig. 3, weight ratio of Ur + HCit to water: (*3*) 1 : 1 and (*4*) 1 : 0.5].

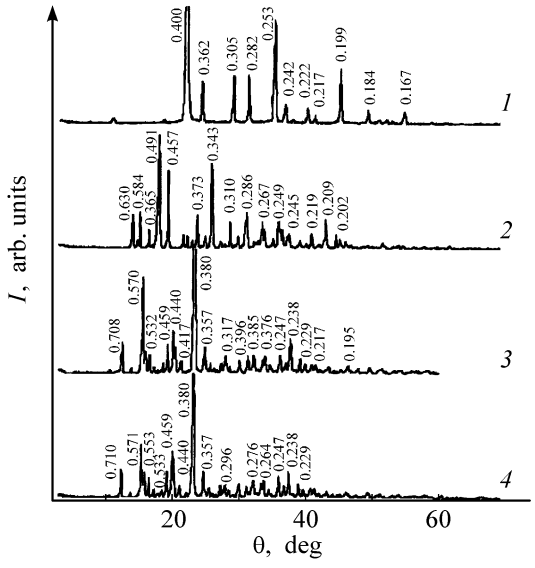

Fig. 3. X-ray powder patterns of (*1*) urea, (*2*) citric acid, and (*3*, *4*) Ur · HCit. Weight ratio of Ur + HCit to water: (*3*) 1 : 1 and (*4*) 1 : 0.5. (*I*) Intensity and (θ) Bragg angle.

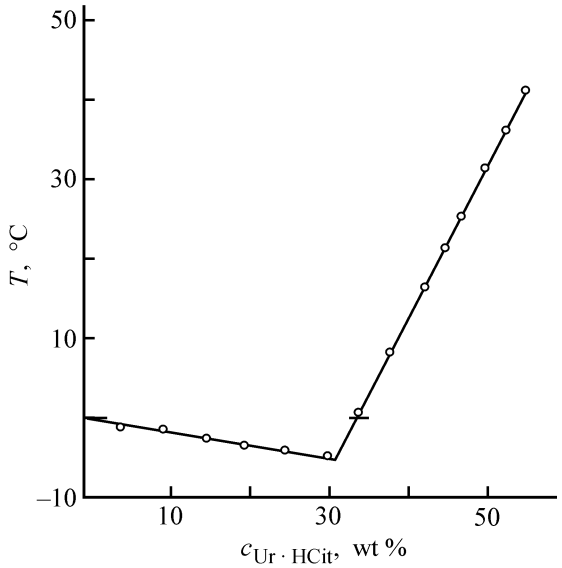

Fig. 4. Polytherm of Ur · HCit crystallization from water. (*T*) Temperature and ($c_{Ur \cdot HCit}$) Ur · HCit concentration.

The reflection intensities *I* and interplanar spacings *d* for Ur almost completely coincide with published data [13]. For HCit, certain discrepancies in *d* and *I* values between our and published data are observed, which may be caused by differences in methods of measurement and estimation of *I* and by the presence of an impurity of anhydrous HCit due to partial dehydration of $HCit \cdot H_2O$ in air.

A comparison of the powder patterns of the initial urea and citric acid and the product of their reaction showed that the product has an individual powder pattern, which contains no reflections belonging to Ur and $HCit \cdot H_2O$. This fact also convincingly confirms that the compound obtained is individual.

After recrystallization of Ur · HCit in ethanol and drying, we determined a solubility polytherm of the compound in water by the visual polythermal method [14] in the range from –5 to +40°C (Table 2, Fig. 4).

The solubility polytherm consists of two crystallization branches: those of ice (H_2O) and Ur · HCit. The eutonic point of the binary system corresponds to –5°C and to concentrations of the compound and water equal to 31.5 and 68.5%, respectively.

Thus, this study showed that urea reacts with citric acid to form a compound readily soluble in water.

Table 2. Physicochemical properties of the binary system Ur · HCit–H_2O

System composition, %		T_{cr}, °C	System composition, %		T_{cr}, °C	System composition, %		T_{cr}, °C

20.0	80.0	–3.2*						

* Solid phase ice (H_2O). ** Ur · HCit.

CONCLUSION

Urea reacts with citric acid in water at the 1 : 1 molar ratio to give urea citrate, which is readily soluble in water. Its solubility polytherm consists of two branches of crystallization: those of ice and urea citrate. The eutonic point of this binary system lies at –5°C and an urea citrate concentration of 31.5 wt %.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Reaction of 1-Amino-3-propoxy-2-propanol with Aldehydes

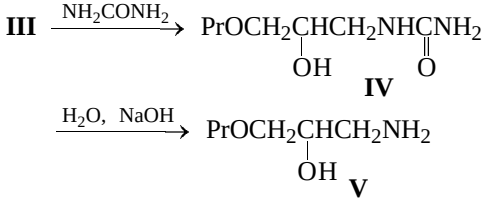
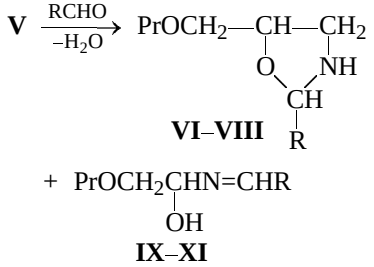
Abstract—The reaction of 1-amino-3-propoxy-2-propanol was examined as a route to the corresponding 1,3-oxazolidines.



Condensation of 1,3-amino alcohols with carbonyl compounds yields 1,3-oxazolidines [1–7], which exhibit a wide spectrum of biological activity. They are used as starting compounds for preparing drugs against arrythmia and stenocardia [8]. Some oxazolidine derivatives exhibit antitumor activity [9]. 1,3-Oxazolidine derivatives are frequently effective as antimicrobial agents [10].

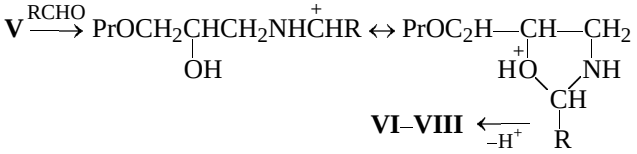
In this study, we examined the reaction of 1-amino-3-propoxy-2-propanol with aldehydes as a route to new substituted 1,3-oxazolidines.



In the synthesis of 1-amino-3-propoxy-2-propanol, we started from compound **I** formed by reaction of 1-propanol with epichlorohydrin **II** in the presence of $ZnCl_2$ catalyst. Compound **I** was converted to 3-propoxy-1,2-epoxypropane **III** by treatment with NaOH:

Nucleophilic opening of the oxirane ring in **III** with urea, followed by hydrolysis of the resulting amide **IV** with aqueous NaOH, yielded 1-amino-3-propoxy-2-propanol **V**:

Then we studied the condensation of amino alcohol **V** with various aldehydes and obtained the corresponding 1,3-oxazolidines **VI**–**VIII**:



where R = Me (**VI**, **IX**), Pr (**VII**, **X**), Ph (**VIII**, **XI**).

The yield of **VI**–**VIII** largely depends on the reactant ratio and reaction conditions. Usually the reaction starts at low temperatures (25–30°C). On adding an aldehyde to **V**, the temperature rises to 90–100°C. Above 90–100°C, by-products are formed. The 1 : 1.2 ratio between amino alcohol **V** and aldehyde **VI**–**VIII** is optimal. The yield of oxazolidines increases when the reaction is performed in benzene with azeotropic distillation of the released water.

The reaction of **V** with aldehydes yields, along with oxazolidines **VI**–**VIII**, also propoxy-substituted azomethines **IX**–**XI**.

The ratio of oxazolidines **VI**–**VIII** and azomethines **IX**–**XI** depends on the substituent at the carbonyl group. Apparently, bulky substituents R hinder the heterocyclization:

1070-4272/05/7810-1656 © 2005 Pleiades Publishing, Inc.

The structures of **VI**–**VIII** were confirmed by NMR and IR spectroscopy.

In the ^{1}H NMR spectrum of oxazlidine **VI**, the methyl group gives a triplet at 0.85 ppm. The methine proton bonded to the CH_3 group gives a multiplet at 4.2 ppm. The two CH_2N protons give a doublet at 2.9 ppm. The methine group in the CH_2CHCH_2 fragment appears as a quintet at 4.1–4.4 ppm. The ^{1}H NMR spectra of **VII** and **VIII** are similar to that of **VI** and differ only in the signals of R.

The IR spectra of 1,3-oxazolidines **VI**–**VIII** contain an absorption band of the five-membered ring at 1381, 1355, and 1240 cm^{-1}, respectively. The N–H stretching vibrations are manifested at about 3150 cm^{-1}.

Compounds **VI**–**XI** were tested as antimicrobial additives to DS-11 oil [GOST (State Standard) 9.052–75]. The antimicrobial activity of these compounds was assessed by the zone diffusion method using microorganisms (GOST 9.052–75). The procedure is described below.

A culture medium (20–25 ml) was placed in a Petri dish, cooled, and seeded with microorganisms. Then four holes (10 mm in diameter, 4–5 mm deep) were made with sterile tools on the surface of the culture medium, and 0.3–0.4 ml of a 5% solution of a test compound in T-46 oil was introduced into these holes. The Petri dishes with bacteria were kept in a thermostat for 2 days at 28–30°C, and those with fungi, at the required humidity for 4 days.

We found that the compounds synthesized are readily soluble in oil, exhibit pronounced antimicrobial effect at low concentrations (0.5–1.0 mol %), and do not stimulate corrosion. With 0.5–1.0 mol % of **V**, the width of the suppression zone is 0.9–1.6 cm for bacteria and 1.1–1.3 cm for fungi. As a reference we chose the widely used sodium pentachlorophenolate; at its concentration of 0.5–1.0 mol %, the width of the suppression zone is 0.7–1.3 cm for bacteria and 0.7–1.4 cm for fungi.

The antimicrobial activities of oxazolidines **VI**–**VIII** and azomethines **IX**–**XI** are lower than that of amino alcohol **V**.

EXPERIMENTAL

1-Chloro-3-propoxy-2-propanol I. A three-necked flask equipped with a thermometer was charged with 10 g of 1-propanol, 18.5 g of epichlorohydrin **II**, and 0.5 g of $ZnCl_2$. The mixture was heated at 60–70°C for 4 h and then cooled to 20°C in a vacuum. Compound **I** was isolated by distillation; yield 25.6 g (90%), bp 93–94°C (20 mm Hg), n_D^{20} = 1.4398. Published data [11]: bp 97–98°C (20 mm Hg), n_D^{20} = 1.4378.

3-Propoxy-1,2-epoxypropane III. A three-necked flask was charged with 15.3 g of **I** and 50 ml of dry diethyl ether, after which 11.2 g of finely divided KOH was added in portions, and the mixture was heated on a water bath at 50°C for 1 h. After cooling, the precipitate was separated and washed with three portions of diethyl ether. The solvent was removed, and the product was distilled. Yield 7 g (60%), bp 147–148°C, n_D^{20} = 1.4716. Published data [12]: bp 63°C (11 mm Hg), n_D^{20} = 1.4691.

***N*-(3-Propoxy-2-hydroxypropyl)urea IV.** Compound **III** (23.2 g) was added dropwise to 12 g of molten (135–140°C) urea, and the mixture was heated at 135–140°C for 3 h, after which it was cooled and extracted with hot chloroform. The white crystalline substance that precipitated from chloroform was filtered off. Yield 5 g (14%), mp 121–122°C.
