1-Amino-3-propoxy-2-propanol V. A flask equipped with a thermometer and a reflux condenser was charged with 8.8 g of **IV** and 2 g of 20% NaOH. The mixture was refluxed for 15 h, cooled, dried over KOH, and distilled in a vacuum. Yield 4 g (60%), bp 85–86°C (1 mm Hg), n_D^{20} = 1.4520.

2-Methyl-5-propoxymethyl-1,3-oxazolidine VI and 1-methylimino-3-propoxy-2-propanol IX. A three-necked flask equipped with a thermometer and a dropping funnel was charged with 13.3 g of **V** and 50 ml of benzene. Then 3.4 g of acetaldehyde was added with vigorous stirring from the dropping funnel. The stirring was continued for 1 h at room temperature and then for 2 h at 65–70°C. The solvent was distilled off on a water bath, and the residue was distilled in a vacuum. Two fractions were isolated: (i) 5.9 g (37%) of **VI** and (ii) 7.5 g (47%) of **IX**.

Compounds **VII**, **VIII**, **X**, and **XI** were obtained similarly. The physicochemical constants of **VI**–**XI** are listed in the table.

Yields, constants, and elemental analyses of **VI**–**XI**

CONCLUSIONS

(1) A procedure was developed for preparing 1-amino-3-propoxy-2-propanol, from which the corresponding 1,3-oxazolidines were obtained in reasonable yields.

(2) 1-Amino-3-propoxy-2-propanol, when used as an additive to DS-11 oil, exhibits antimicrobial and fungicidal activity, exceeding that of sodium pentachlorophenolate.

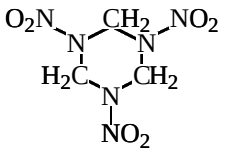
ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Energy and Acid–Base Characteristics of the Surface of Nitramine Fillers for Polymeric Composites

N. V. Baranova, S. A. Bogdanova, V. G. Bandorin, and A. V. Kostochko

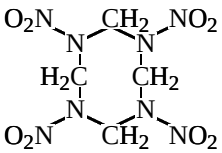
Kazan State Technological University, Kazan, Tatarstan, Russia

Received March 25, 2005



Abstract—Single crystals of nitramine fillers for special-purpose polymeric composites are characterized by the surface energy and its constituents and also by the acidity of their surface.

It is well known that mechanical properties of filled polymeric composites are governed by interactions at the interface between the polymer matrix and the filler. The structure and properties of the interfacial layers depend not only on the physicochemical characteristics of the polymer, but also on the surface properties of the filler. The major contribution to the development of the concepts of the interfacial interactions as the key factor governing the properties of filled polymers was made by Lipatov [1, 2], Fowkes [3], Berger [4], and Kinloch [5]. They have clearly demonstrated the necessity for studying the donor–acceptor and dispersion interactions at the polymer/filler interface. At the same time, the morphology of fillers, as a factor strongly affecting the surface energy and acid–base characteristics, has been considered insufficiently.



In preparation of energetic cellulose nitrate composites, it is necessary to ensure the adhesion of the polymer to crystalline nitramine fillers. We have determined previously the surface energy and its constituents in softened cellulose nitrates [6, 7]. In studying mechanism of interaction between the polymer and filler in order to improve the performance characteristics of such systems, it appeared advisable to estimate the surface energy and its constituents and also the surface acidity of crystalline fillers, nitro derivatives of heterocyclic amines.

EXPERIMENTAL

As objects of this study served single crystals of cyclotrimethylenetrinitramine (N3) and cyclotetramethylenetetranitramine (N4), prepared by the temperature drop method under free convection conditions in solution.

N3

N4

In this method, supersaturation was set by the temperature difference between the zone of dissolution of the polydisperse crystals and the zone of single-crystal growth.

As initial solutions we used the solution of N3 in an acetone–DMF mixture and the solution of N4 in an acetone–DMSO mixture, saturated at room temperature. The solvents were purified prior to use.

The surface energy (SE) of various faces of the samples (γ_S) and its polar (γ_S^p) and dispersion (γ_S^d) terms were determined from the contact angles with probe liquids whose surface tensions are listed in Table 1.

Table 1. Surface tension of probe liquids and its polar and dispersion terms

Liquid	γ_L^p	γ_L^d	γ_L
	mN m^{-1}		
Water	50.2	22.0	72.2
Glycerol	30.0	34.0	64.0
Formamide	26.0	32.3	58.3
5% Aqueous ammonia	33.8	31.9	65.7
Ethylene glycol	29.3	19.0	48.3
Methylene iodide	2.3	48.5	50.8

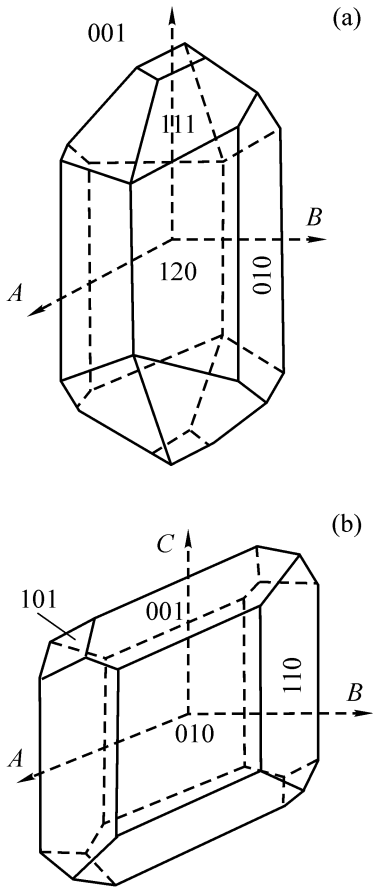

Fig. 1. Crystallographic orientation of single crystals of (a) cyclotrimethylenetrinitramine and (b) cyclotetramethylenetetranitramine.

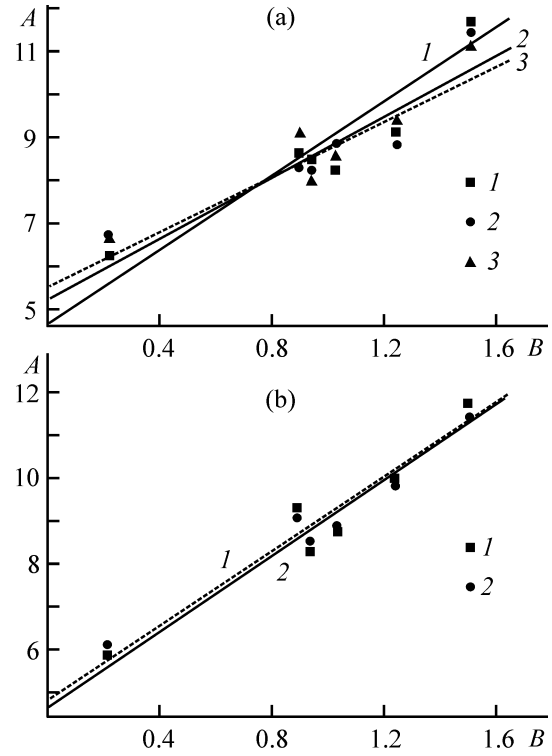

Fig. 2. Fowkes plots for determining the surface energy of (*1*) cyclotrimethylenetrinitramine and (*2*) cyclotetramethylenetetranitramine from data obtained with six probe liquids. Fowkes coordinates: (*A*) $W/(\gamma_L^d)^{0.5}$ and (*B*) $(\gamma_L^p/\gamma_L^d)^{0.5}$. (a) Face: (*1*) (120), (*2*) (010), and (*3*) (001). Fit parameters: (*1*) $Y = 4.68 + 4.29X$, (*2*) $Y = 5.24 + 3.53X$, and (*3*) $Y = 5.54 + 3.18X$. (b) Face: (*1*) (010) and (*2*) (110). Fit parameters: (*1*) $Y = 4.70 + 4.36X$ and (*2*) $Y = 4.84 + 4.31X$.

The contact angle was determined by the sessile drop method at 29 ± 1 K. The measurements were carried out in a cell with a water seal, using a KM-8 cathetometer equipped with a micrometer gauge. At least 10 drops of equal volume were placed onto the surface with a microsyringe. Preliminarily, the spread kinetics was studied, to determine the equilibrium value of $\cos\theta$.

Following to the Fowkes concept [3], the free surface energy was estimated graphically from the experimental contact angles using the Owens–Wendt equation. The dependence plotted in the coordinates $(\gamma_L^p/\gamma_L^d)^{0.5} - 0.5\gamma_L(1 + \cos\theta)/(\gamma_L^d)^{0.5}$ was represented by a straight line (correlation factor $r \geq 0.93$). Data were processed by the least-squares method.

The surface acidity parameter D was determined by Berger's method [4] from the polar and dispersion terms of the surface energy and contact angles with Lewis acids (ethylene glycol and glycerol) and Lewis bases (5% aqueous ammonia and formamide). For the surfaces bearing essentially acidic groups (proton donors), $D > 0$, and for proton-acceptor surfaces, $D < 0$.

The elementary fragments forming the single crystal of cyclotrimethylenetrinitramine are rhombic prism (120), bipyramid (111), and pinacoids (010) and (001) (Fig. 1a), and those in the cyclotetramethylenetetranitramine are rhombic prism (110), dihedrons (011), and pinacoids (010) and $(\bar{1}01)$ (Fig. 1b).

Contact angle measurements were carried out on the most developed faces of the single crystals. For N3 these are (120), (010), and (001); and for N4, (010) and (110). The surfaces to be studied were 1.0×0.7 cm.

Since the surface energy is mostly different for different faces [8], it was necessary to determine the energy characteristics of all the most developed surfaces in the crystals.

The dependences plotted in the Fowkes coordinates are shown in Figs. 2a and 2b. The experimental sur-

Table 2. Energy parameters of different faces in single crystals of the nitramine fillers

Filler	Face index	γ_S^p	γ_S^d	γ_S
		mN m^{-1}		
N3	(120)	18.40	21.90	40.30
	(010)	12.50	27.40	39.90
	(001)	10.10	30.70	40.80
N4	(010)	19.00	22.00	41.00
	(110)	18.60	23.40	42.00

face energy γ_S and its polar (γ_S^p) and dispersion (γ_S^d) terms are listed in Table 2.

The surface energy of the N4 crystal is somewhat higher than that of N3 (Table 2), which can be attributed to the presence of short intra- and intermolecular bonds in the structure of N4. Despite that the crystals of the nitramines studied are built up from polar molecules, they demonstrate orientation polarization in the solid state. The N4 molecules have some rotational freedom and, in the crystal, they demonstrate capacity for polarization, which is more clearly pronounced as compared to N3.

The results obtained show that, in the organic crystals studied, the dispersion term of the surface energy prevails over the polar term.

Presently, the adsorption (molecular) theory of adhesion is considered to be the most preferable tool for understanding of processes occurring in formation of polymer-based materials [5]. In the framework of this theory, an important part is played by the concept of acid–base interactions, since it is the acidity or basicity of polar molecules in the surface layer between the contacting condensed phases that controls the adhesion interaction (the effect of acidity or basicity on the adhesion contact is more significant than that of the surface energy). The Fowkes opinion [3] is that the work of adhesion could be considerably increased through acid–base interaction on the surface. Therefore, it is important to determine the acidity factor of both the polymer and surface centers of the filler.

The acidity factors of the nitramine fillers in hand, determined by Berger's method, are given in Table 3.

Analysis of these data shows that acid sites dominate on the surface of the fillers ($D > 0$). This is not surprising, since N3 and N4 molecules contain electropositive nitrogen of the nitro groups, which is a typical Lewis acid. It is noteworthy that the maximal D values correspond to the pinacoidal faces.

Table 3. Acid–base characteristics of the surfaces of single crystals of the nitramine fillers

Filler	Face index	Acidity factor D, (mN m^{-1})$^{0.5}$
N3	(120)	1.10
	(010)	3.64
	(001)	1.49
N4	(010)	2.88
	(110)	1.82

The results obtained show that the acidity factor depends on the type of the crystal surface, more so for N3, which is probably due to its more pronounced anisotropy.

To conclude, the surface energy and acid–base characteristics of the fillers should be necessarily taken into account in developing filled polymeric composites with advanced mechanical properties.

CONCLUSIONS

(1) The surface energy and its constituents were determined for various faces of the single crystals of nitramine fillers. It was shown that the surface energy characteristics depend on the crystal morphology.

(2) It was demonstrated Lewis acid groups dominate in the surface layer of the cyclotrimethylenetrinitramine and cyclotetramethylenetetranitramine crystals.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

A Spectrophotometric Study of Solid-Phase Topochemical Polymerization of Diyne Arylcarbamates and Logistic Representation of Results

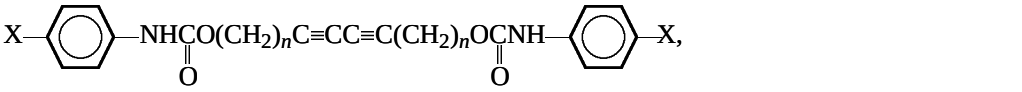
A. N. Marinichev, S. Yu. Vyaz'min, and I. N. Domnin

St. Petersburg State University, St. Petersburg, Russia

Received April 27, 2005

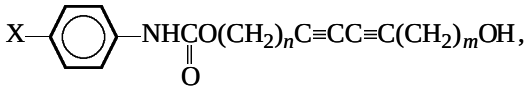
Abstract—Application of a logistic regression to interpretation of results is illustrated by spectrophotometric data on solid-state polymerization of symmetric and asymmetric diyne carbamates.

Use of organic solvents in modern large-tonnage chemical industry may be a source of ecological problems because of the possible uncontrolled development of chemical processes performed. Therefore, chemical transformations in the solid phase have a clear advantage and development of methods for carrying out processes of this kind is a task of a rapidly developing, ecologically safe "green chemistry" [1]. The reaction of solid-state topochemical polymerization (STP) has been discovered by Wegner for the example of 2,4-hexadiyne-1,6-diol $HOCH_2C{\equiv}CC{\equiv}CCH_2OH$ [2]. STP of functionally substituted diacetylenes (DA) belongs to one of classes of topochemical reactions and consists in a diffusionless transition of monomer crystals into polymer crystals, with the centers of mass of monomer units retaining their crystallographic position. Such a stereospecific polymerization, governed by the monomer packing in the crystal lattice, yields a stereoregular polymer with a linear arrangement of molecules and small number of structural defects [3]. As is known, a key influence on the course of such STP is exerted by the long-range order in the crystal lattice of a monomer. STP to give polydiacetylenes (PDA) can be initiated by ultraviolet or gamma-ray irradiation, as well as by X-rays or a flow of beta-decay electrons. In some cases, STP is also possible upon heating of the starting monomers [4].



PDA find increasingly wide use as a chromatic element in biosensors [5–7]. However, of particular interest to researchers are their unique optical properties, because their third-order optical susceptibility coefficients $\chi^{(3)}$ reach, for this class, the most optimal values among all the known organic compounds. In this context, a study of PDA has become, from a particular area of the chemistry of polymers, an interdisciplinary field of intensive research including synthesis of new DA and PDA, analysis of the STP mechanism, spectroscopy, materials science, and even chemistry of biomimetics [8].

One of the most important tasks in studies of STP is to establish relationships between structural features of monomer DA and their activity in STP. The best studied, in this regard, monomer is bis(*p*-tolyl) hexa-2,4-diyne-1,6-diol sulfonate [9], for which an induction period and an autocatalytic stage have been observed in UV- and radiation-initiated STP. In the first case (UV irradiation), the rate of TPS markedly decreases as the conversion becomes higher, which can be attributed to transfer of the energy of the excited state of the monomer to the polymer chain [10]. As a rule, STP is only observed in those DA whose substituents contain groups that can form hydrogen bonds or be involved in a dipole–dipole interaction. In this context, DA that contain urethane groups as substituents in the side chain and can form intermolecular hydrogen bonds in neighboring stacks of diacetylene monomers are of particular interest [11]. As a continuation of the previous research in this field [12], 5 new symmetric diacetylene arylcarbamates and 27 new phenyl- and arylcarbamates of asymmetric structure were synthesized.



No detailed systematic data on the reactivity of diynes in relation to the number of methylene groups (*n*) between the system of conjugated triple carbon–carbon bonds and the carbamate function can be found in the literature. There are no data, either, on the influence exerted by a substituent in the aryl ring of diyne carbamates. This influence must apparently af-

1070-4272/05/7810-1662 © 2005 Pleiades Publishing, Inc.

fect the strength of the hydrogen bond and, consequently, the specific features of packing of diyne molecules in the crystal. For these reasons, the carbamate group was chosen as a functional group, and the following bis-arylcarbamates were selected among the simplest model compounds:

[X = H: n = 2 (**Ia**), n = 3 (**Ib**), n = 4 (**Ic**), n = 5 (**Id**). n = 6 (**Ie**), n = 7 (**If**), and n = 9 (**Ig**); X = OMe: n = 3 (**Ih**), n = 4 (**Ii**), and n = 5 (**Ij**)] and a number of diyne *N*-arylcarbamates of asymmetric structure, previously not described in the literature:

[X = H: n = 2, m = 2 (**IIa**); n = 2, m = 4 (**IIb**); n = 4, m = 4 (**IIc**); n = 5, m = 4 (**IId**); n = 6, m = 4 (**IIe**); and n = 9, m = 4 (**IIf**); X = OMe: n = 2, m = 2 (**IIg**); and n = 4, m = 4 (**IIh**)].

EXPERIMENTAL

The PMR and ^{13}C NMR spectra were measured on a Bruker DPX-300 instrument (300.13 MHz), with TMS as internal standard and $CDCl_3$, DMCO-d_6, and CD_3COCD_3 as solvents. The IR spectra were recorded on a Specord IR-75 spectrometer in $CHCl_3$ or KBr pellets. The electronic spectra were obtained on a Specord M40 UV-VIS spectrometer in DMF and CH_3CN. Analytical thin-layer chromatography was performed on Sulifol UV-254 plates, with development with UV light (λ_{max} = 254 nm) or a potassium permanganate solution. Preparative thin-layer chromatography was carried out on Silpearl silica gel with development with UV light, and column chromatography, on an M60 silica gel (manufactured by Merck). STP was performed under irradiation with UV light from BUV-15 low-pressure mercury lamps (λ_{max} = 254 nm). The polymerization was done under the standard conditions for all the diynes. A 5- to 20-mg portion of a diyne, dependent on the mass of the weighed portion necessary for recording the electronic spectrum, 3–5 ml of *n*-hexane, and a magnetic rabble were placed in a weighing bottle 21 mm in diameter. The bottle with the suspension was placed at a distance of 10 cm from the lamps. The irradiation was carried out with agitation at a constant rate at room temperature for a varied time recorded with a stopwatch. After that, the reaction mixture was allowed to stay for 1.5–2 h in an exhaust hood to remove *n*-hexane and then placed in a vacuum-desiccator for 24 h. Two samples were taken from each weighing bottle for a study of the STP by electron spectroscopy.

Changes in the system, caused by the STP of diyne arylcarbamates, are well recorded spectrophotometrically by measuring the analytical signal (AS), whose role can be played by the extinction coefficient ε (M^{-1} cm^{-1}), at different instants of time t. Tables 1, 2 list the experimental extinction coefficients obtained in this study for 10 symmetric and 8 asymmetric dyine carbamates.

The kinetic curves $\varepsilon(t)$ are monotonic lines bounded by the limiting value $\varepsilon(\infty)$, which can show a slowed-down variation of the extinction coefficient at the initial instants of time (so-called induction period).

Such dependences, both with an induction period and without it, are well described by logistic regression curves of the type:

$$\varepsilon(t) = c/[1 + a\exp(-bt)], \quad (1)$$

where a and c are constants relating the initial and final (limiting) values of AS:

$$\varepsilon(0) = c/(1 + a) \text{ and } \varepsilon(\infty) = c. \quad (2)$$

In addition, it can be readily shown that expression (1) is a solution to the differential equation

$$dy/dt = bt(1 - y), \quad (3)$$

in which $y = \varepsilon(t)/c$ is a dimensionless AS. Similarly to the rate constant of a first- or pseudo-first-order, the parameter b has dimension of a reverse time (min^{-1}). Thus, the single-parameter kinetic equation (3) can be accepted as a simplified description of the kinetics of a multistage chemical process, with the formation and accumulation of the product (poly-

diacetylene in the case in question) recorded via the AS. It is noteworthy that a nonzero value of ε(0) may, apparently, be due to the instrumental background of the AS being measured.

Previously [13], a logistic regression has been applied to description of a reversible decomposition of a substance into products, with direct monitoring of how the reagent concentration varies. The present com-

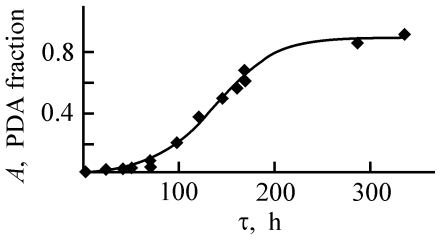

Fig. 1. Kinetic curve for polymerization of diyne at 75°C [15]. (*A*) PDA fraction and (τ) time. Here and in Fig. 2, the experimental data are represented by points, and the calculated dependence, by lines.

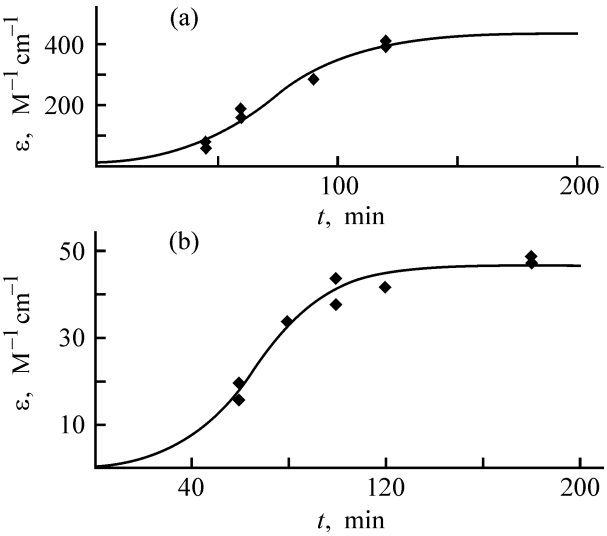

Fig. 2. Kinetic curve for STP of (a) 7,9-hexadecadiyne-1,16-diyl-bis-*N*-phenylcarbamate (**Ie**, n = 6, X = H) and (b) 13-hydroxy-6,8-tridecadiyne-1-yl-*N*-phenylcarbamate (**IId**, n = 5, m = 4, X = H). (ε) Extinction coefficient and (*t*) time.

munication discusses the cases when this monitoring is done with AS.

The parameters *a*, *b*, and *c* were calculated from the experimental data obtained, using the Logist 83 program from the freely accessible software package Statistics with List Editor (http://text.staticfree.info/statsle.pdf), which was transferred to a Texas Instruments TI-89 graphic calculator [14].

An equation of type (1) was tested for published data on [15] the STP of diyne to give PDA. Here, the PDA fraction x was regarded as the AS. The equation for calculating $x(t)$, obtained by processing of experimental data, has the form:

$$x(t) = \frac{0.900}{1 + 81.5\exp(-0.0323t)}.$$

The results obtained in the calculation (line) and the experimental points are shown in Fig. 1.

In a similar way, an expression of type (1) was used to describe the experimental data [ε(*t*)] obtained in this study (Tables 1, 2). The same tables list values of the parameters *a*, *b*, and *c*. To characterize the agreement between the calculated results and the experiment, the average value of Δε, the absolute value of the differences of the experimentally determined ε and ε_{calc} calculated by an equation of type (1), was determined. It can be seen from the values of Δε in Tables 1, 2 that the nonlinear equation (1), which reflects the logistic time dependence of the extinction, rather adequately reproduces the fundamental aspects of the STP: existence of a limiting value, and S-shaped time dependence. It should be noted that no *a priori* information (initial values) is necessary for finding the parameters of the nonlinear equation (1). The relative error of the parameter *b*, which is, in fact, the rate constant of STP in the brief kinetic description suggested here, did not exceed 10%, as a rule.

The error of *a* and *c*, which did not exceed five units of the last digit, was found by variation to obtain, wherever possible, stable smallest values of Δε.

Figure 2a shows calculated lines (kinetic curves of STP) and experimental points for a symmetric (**Ie**) and asymmetric (**IId**) diynes.

CONCLUSION

The data obtained make it possible to formulate some semiquantitative conclusions concerning the relative reactivities of diyne arylcarbamates. In particular, the rate of STP decreases in proportion to the increasing number n of methylene groups in series with both even and odd n. The rate of STP increases by approximately a factor of 3 on introducing a methoxy group into the aryl ring.

Abstract—The solvent effect on the kinetic parameters of synthesis and molecular characteristics of copolymers formed by homogeneous radical copolymerization of sodium 2-acrylamido-2-methylpropane-1-sulfonate with *N*-vinylpyrrolidone in aqueous-ethanol solutions at pH 9 and 60°C in the presence of potassium persulfate as an initiator was studied.

The reaction medium strongly affects the radical polymerization of water-soluble monomers [1, 2], which allows variation of the kinetic parameters and characteristics of the resulting polymers by changing the nature of a solvent. Here, we consider the influence of the composition of water–ethanol mixtures on homogeneous radical copolymerization of sodium 2-acrylamido-2-methylpropane-1-sulfonate (Na-AMS) with *N*-vinylpyrrolidone (VP), which has not been studied previously. The interest in these studies is caused by the features of radical polymerization of ionic monomers [1, 3] and VP [4, 5] and also by the practical significance of copolymers of Na-AMS with VP, which have valuable characteristics and show promise for industry and medicine.

EXPERIMENTAL

We used Na-AMS prepared by neutralization of H-AMS solutions [Lubrizol-2404 manufactured by the Lubrizol Corporation (UK), mp 185°C, main substance content more than 99%] with NaOH to pH 9. VP manufactured by Merck (Germany) was twice distilled in a vacuum in the presence of 0.1% KOH (63°C, 3 mm Hg), n_D^{20} = 1.5117, main substance content (GLC) more than 99%. Potassium persulfate (PP) was twice recrystallized from aqueous solution; the main substance content found by the redox method was 98.7%. Ethanol was purified by distillation, bp 78.3°C. All the solutions were prepared using distilled water; the other reagents were of chemically pure grade.

The procedures of copolymerization and dilatometric analysis and the experimental procedure have been described previously [6]. After copolymerization, the copolymers were recovered from the reaction mixture by precipitation in a large excess of acetone, washed with acetone, and dried in a vacuum at 50°C to constant weight. The yield of the copolymer was determined gravimetrically. The composition of copolymers of Na-AMS with VP was determined by elemental analysis for sulfur [7]. The molecular weight (MW) of the copolymer was judged from the intrinsic viscosity of the solutions [η], which was measured in 0.5 N NaCl at 30°C in a VPZh-3 capillary viscometer with d_c = 0.43 mm.

The copolymerization of Na-AMS (M_1) with VP (M_2) was carried out in 20% aqueous solutions and in water–ethanol mixtures (volume ratios 70 : 30, 50 : 50, and 30 : 70). The reaction was initiated by thermal decomposition of PP ([PP] = 7.4×10^{-4} M) at 60°C. To exclude phase separation, the content of ethanol in the solvent did not exceed 75 vol %. All the copolymerization runs were performed at pH 9 to prevent hydrolysis of VP [8] and to provide the efficiency of initiation with PP [9] and the constancy of the initiation rate with variation of the ionic strength of the solution (due to variation of Na-AMS concentration in the initial monomer mixture and in the course of copolymerization) [10]. In the absence of PP, no copolymers were formed under the experimental conditions. The process rate was monitored dilatometrically. The initial portions of the kinetic curves ob-

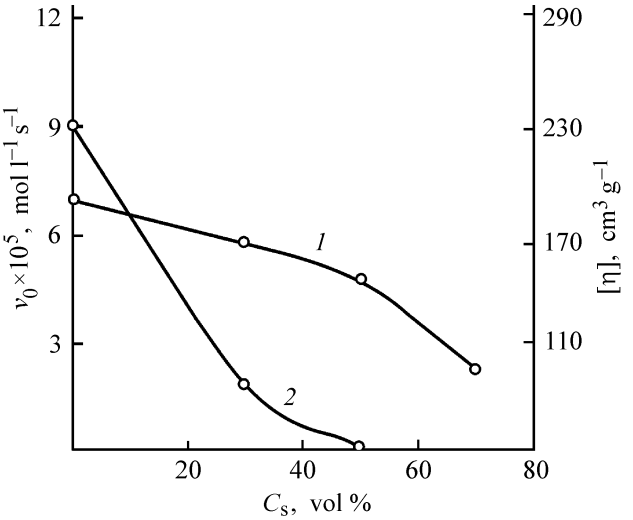

Fig. 2. (*1*) Initial rate of copolymerization of Na-AMS with VP v_0 and (*2*) [η] of copolymers vs. the content of ethanol in aqueous–ethanol mixture C_s. $[M_1] + [M_2] = 30\%$, $[M_1]/[M_2] = 1 : 1$.

tained from the dilatometric data were linear, and we found from their slopes the initial rates of copolymerization v_0 at low degrees of conversion ($\chi < 3\%$).

The dependence of v_0 on the mole fraction of Na-AMS in the initial monomer mixture (M_1) in copolymerization of Na-AMS with VP in water and in water–ethanol mixture (1 : 1) is shown in Fig. 1. The dependence $v_0 = f(M_1)$ passes through a maximum. As can be seen, the MWs of the resulting copolymers vary in parallel with v_0. The maximum values of v_0 and MWs of copolymers correspond to the equimolar ratio of the comonomers in the initial mixture ($M_1 = 0.5$). The IR data [11] showed that the maxima in the dependences $v_0 = f(M_1)$ and MW = (M_1) are caused by the donor–acceptor interaction between the comonomers (Na-AMS has a medium electron-acceptor power and VP, a medium electron-donor power).

The yields of the copolymer in copolymerization in water and in water–ethanol (1 : 1) mixture are listed in Table 1. It can be seen that the yield of the copolymer in these solvents increases with the content of Na-AMS in the initial monomer mixture.

The influence of the solvent composition on copolymerization of Na-AMS with VP is shown in Fig. 2. With increasing polarity of the solvents and with increasing water content in the water–ethanol mixture, v_0 grows. The MW of the copolymer increases in parallel with v_0 because of increasing influence of the chain transfer to alcohol molecules owing to labile hydroxyl hydrogen atoms. These trends can also be traced in Fig. 1 (curves *1*, *2* and *2*, *4* at M_1 = const). According to data on radical polymerization of other water-soluble monomers and, in particular, acrylamide [4] and VP [12], formation of hydrogen bonds between water molecules and C=O groups of both monomers is enhanced with increasing water content in the solvent, which lowers the electron density at the double bonds of the comonomers and raises their reactivity. As a result, v_0 values increase.

The running composition of the copolymer of Na-AMS with VP as a function of the composition of the initial monomer mixture at low conversions ($\chi < 3\%$) is shown in Fig. 3. The dependences $m_1 = f(M_1)$ in copolymerization in water and in a water–ethanol mixture (1 : 1 by volume) are S-shaped with

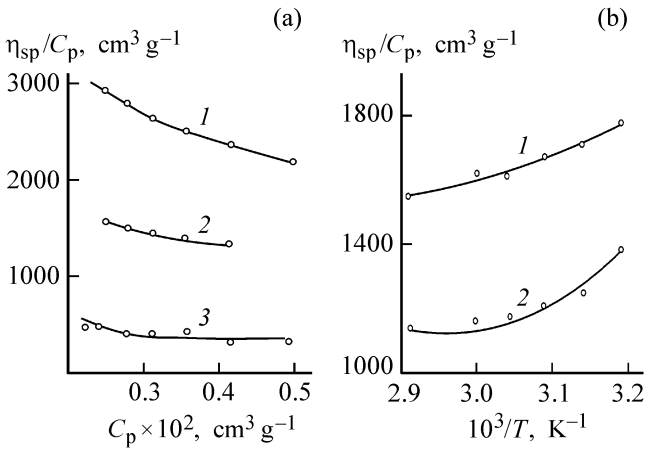

Fig. 4. Reduced viscosity of Na-AMS–VP copolymer η_{sp}/C_p ([η] = 265 cm^3 g^{-1}, content of Na-AMS units 42 mol %) (a) vs. copolymer concentration C_p at 30°C and (b) vs. temperature (T, K) (*1*) in water and (*2*, *3*) in a water–ethanol mixture, (*2*) 1 : 1 and (*3*) 1 : 3. C_p = 0.5 wt %.

an azeotropic point. The effective relative activities of the monomers in copolymerization, evaluated from data in Fig. 3, $r_1 = k_{11}/k_{12}$ (for Na-AMS) and $r_2 = k_{22}/k_{21}$ (for VP), are summarized in Table 2. It can be seen that that the r_1 and r_2 values determined by the Mayo–Lewis and Kelen–Tudos methods are in a good agreement with each other: In the solvents studied, $r_1 < 1$ and $r_2 < 1$, which suggests preferable reaction of macroradicals with the "foreign" monomer in comparison with the "own" monomer. In this case, $r_2 > r_1$, which confirms the higher reactivity of VP in comparison with Na-AMS. The product $r_1 r_2$ suggests formation of alternating copolymers of regular composition in the solvents studied.

Figure 3 shows that, in a wide range of compositions of the initial monomer mixture, the polymer is enriched with VP units on passing from the mixed solvent to water (from curve *1* to curve *2*). The above variation of the composition of the Na-AMS–VP copolymer is caused by an increase in r_2 (Table 2).

The copolymerization of Na-AMS with VP in the media under consideration is influenced not only by the solvation effect but also by ionization of the ionic groups of Na-AMS and its units in macroradicals. The latter factor governs the electrostatic interactions between the reacting particles and the conformation state of the macroradicals, which, in tern, affect the reactivity of Na-AMS and its macroradical in copolymerization. The significant role of electrostatic interactions in the system studied is indirectly suggested by the polyelectrolytic character of the concentration dependence of the reduced viscosity η_{sp}/C_p of the Na-AMS–VP copolymer of (Fig. 4a) in water (curve *1*) and in water–ethanol mixtures (curves *2* and *3*). With increasing polarity of the solvent, the ionization of the ionic groups of the macromolecules and the electrostatic repulsion between like fixed charges along the chain become stronger. As a result, the sizes of macromolecular globules and η_{sp}/C_p values at C_p = const increase (Fig. 4a). In copolymerization, an increase in the water content enhances the elec-

trostatic repulsion between Na-AMS and macroradical with terminal Na-AMS unit, which decreases the elementary constant of chain prolongation k_{11}. It can be assumed that a decrease in the activity of Na-AMS as a result of electrostatic interactions prevails over an increase in its activity as a result of hydrogen bonding with the solvent. This resulted in low r_1 values and their constancy in the solvents studied. An increase in the solvation power of the medium in substitution of water for a water–ethanol mixture (1 : 1 by volume) resulted in an increase in r_2 and caused enrichment of the copolymer with VP units, observed in Fig. 3 (passing from curve *1* to curve *2*).

The influence of conversion on the characteristics of the resulting copolymers was estimated in copolymerization of Na-AMS with VP in a water–ethanol mixture (1 : 1 by volume) for various compositions of the initial monomer mixture; the results are summarized in Table 3. As can be seen, the composition and MW of the copolymer do not noticeably vary in the course of the reaction. Similar data have been obtained in copolymerization of other water-soluble monomers in solutions [13, 14]. Gromov *et al.* [13, 14] believe that the constancy in the copolymer composition with variation of the degree of conversion is caused by the constancy of the comonomer ratio in the vicinity of the macroradicals due to formation of micellar associates selectively adsorbing monomers from aqueous solutions. In our case, penetration of Na-AMS molecules having bulky side substituent [–C(O)–N(H)–C$(CH_3)_2$–CH_2–SO_3Na] is more hampered, compared to VP, by steric hindrance. Therefore, the VP concentration in the vicinity of the macroradical will differ from its average concentration in the reaction mixture.

To determine the equations for the overall rate of copolymerization of Na-AMS with VP in the solvent studied, we performed experiments at varied concentrations of the monomers and initiator, with the other reaction conditions being constant. The log–log dependences of v_0 on the concentrations of Na-AMS, VP, and PP in copolymerization in the water–ethanol mixture (1 : 1 by volume) are shown in Fig. 5. In all cases, v_0 grows with increasing concentrations of comonomers and initiator. Data presented in Fig. 5 are well fitted by straight lines; from their slopes we determined the kinetic reaction orders with respect to the monomers and initiator and obtained the empiric equation for the total rate of copolymerization of Na-AMS with VP in water:

$$V = k_c[\text{Na-AMS}]_{0.9}[\text{VP}]_{0.6}[\text{PP}]_{0.8}, \qquad (1)$$

where k_c is the copolymerization rate constant.

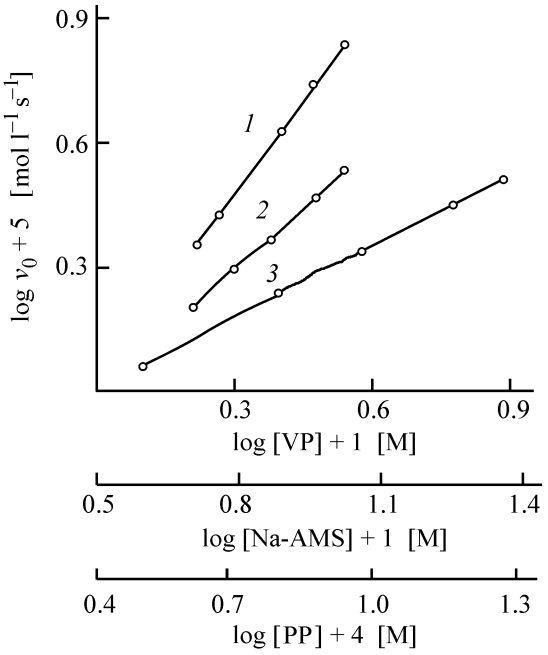

Fig. 5. Initial rate of copolymerization v_0 of (*1*) Na-AMS with VP in a water–ethanol mixture (1 : 1) vs. concentration of (*1*) Na-AMS, (*2*) VP, and (*3*) PP in log–log coordinates. (*1*) [VP] = 0.587, [PP] = 7.4×10^{-4} M; (*2*) [Na-AMS] = 0.587, [PP] = 7.4×10^{-4} M; and (*3*) [Na-AMS] = [VP] = 0.587 M.

For copolymerization of Na-AMS with VP in a water–ethanol mixture (1 : 1 by volume), the equation is as follows:

$$V = k_c[\text{Na-AMS}]_{1.5}[\text{VP}]_{0.6}[\text{AIBN}]_{1.0}. \qquad (2)$$

Comparison of Eqs. (1) and (2) shows that, in the case when ethanol is added to water, the reaction

orders with respect to Na-AMS and PP somewhat increase. The above rise in the reaction order with respect to the initiator is apparently caused by increased contribution of monomolecular chain termination to the total chain termination in copolymerization in concentrated solutions. Low reaction orders with respect to VP are in a good agreement with published data [15, 16] and are usually observed in polymerization of this monomer in concentrated aqueous solutions.

The MW and copolymer yield in copolymerization of Na-AMS with VP in water–ethanol mixture (1 : 1 by volume) are plotted in Fig. 6 as functions of concentration of Na-AMS and PP. It can be seen that, the yield of the copolymer increases with the concentrations of Na-AMS and PP and MW grows with increasing concentration of Na-AMS and decreasing concentration of initiator, which agrees with the general pattern of radical polymerization.

The influence of temperature on the copolymerization of Na-AMS with VP in water and in a water–ethanol mixture (1 : 1 by volume) was studied in the range 40–70°C. The experimental results are plotted in the Arrhenius coordinates in Fig. 7. These data show that v_0 increases with temperature. The effective overall activation energies of copolymerization in the solvents studied are the same and equal to 99.6 kJ mol^{-1}. With variation of temperature, v_0 is affected by the conformational state of macroradicals, as suggested by data presented in Fig. 4. An increase in temperature results in a decrease in the sizes of macromolecular globules and in η_{sp}/C_p values at C_p = const (Fig. 4b) as a result of weakening of electrostatic repulsion between sulfonate anions along the chain, caused by a decrease in the degree of ionization of Na-AMS units. Therefore, a decrease in the chain charge makes higher local concentration of Na-AMS in the vicinity of macroradicals and causes v_0 to increase.

CONCLUSIONS

(1) With increasing water content in a water–ethanol mixture, v_0, MW, and the content of VP units in copolymer grow due to an increase in r_2 (at constant r_1). The composition and MW of the copolymer do not vary with conversion.

(2) The v_0 values increase with the concentrations of Na-AMS, VP, and PP and temperature and pass through a maximum (similar to MW of copolymer) with as the composition of the initial monomer mixture is varied (the maximum is reached at the molar ratio $[M_1]/[M_2] = 1 : 1$) due to complexation between the comonomers.

Abstract—The strength of photocured composites as influenced by the concentration and specific surface area of a silica filler was studied.

Photocured composites used in various branches of industry are promising materials owing to their high quality and relatively simple curing procedures. Filling is the main procedure for integrated control over the polymer properties. Filled photocured composites are of particular interest in view of their expanding use in stomatology and microelectronics [1–8] and prospects for their use in other branches of industry (e.g., in automobile and aircraft building). Applicability of filled photocured composites is primarily determined by their strength. The compression strength, microhardness, and abrasion resistance are the main parameters characterizing photocured composites for stomatology [4]. The strength parameters also furnish certain information on the composite structure [9, 10].

In this study, we examined the strength of filled photocured composites as influenced by the concentration and specific surface area of the silica filler.

EXPERIMENTAL

The following chemicals were used: α,ω-bis(methacryloxyethyleneoxycarbonyloxy)ethylene-oxyethylene (OKM-2), triethylene glycol α,ω-dimethacrylate (TGM-3), and ethoxybisphenol α-dimethacrylate (EPO) [Dzerzhinsk, Russia] oligomers; Aerosils A-100, A-175, A-300, and A-455 [Kalush, Ukraine] (additionally calcined at 400°C for 1 h), silica gels were modified using K-2 and A-174 silane acrylates [Red'kino, Russia]; benzyl dimethyl ketal (BDK) [Ciba (Switzerland)] photoinitiating agent; and tris(dimethylaminomethyl)phenol (TMP), *N*,*N*,*N*,*N*-tetramethylehexamethylenediamine (THA), and *N*,*N*,*N*,*N*-tetramethylenethylenediamine (TMEDA) activators.

Oligomer OKM-2 containing 0.6 wt % DBK and 0.1–0.2 wt % TMP, THA, or TMEDA was used as a polymeric matrix for filled photocurable composites. This composition was filled with various amounts of A-175, A-300, A-380, and A-455 Aerosils. As a rule, we used in our experiments the composition consisting of OKM-2 + 0.6 wt % BDK + 0.1wt % TMP (hereinafter named as matrix).

The compositions were photocured using a DRUFZ-125 lamp (17.3 W m^{-2}, λ 300–400 nm) placed at distance of 10–20 cm from the sample. The physicomechanical propertiesof the resulting photopolymers were measured in conformity with the following GOSTs (State Standards): compression resistance σ_c (MPa), GOST 232026–78, 4651–82; abrasion wear $d = 1/\sigma_a$ (m mm^{-3}), GOST 110127–69; microhardness σ_m (MPa), GOST 4670–71; flexural strength σ_f (MPa), GOST 25604–82; and impact resilience F_i (MPa, GOST 9454–78).

In filling of oligomers, the limiting concentrations of silica can be attained, namely, the limiting filler concentration c_l and concentration of the fluidity loss, c_f. At silica concentration higher than c_l the composite loses stability (self-dispersion) and its strength properties decrease to zero, and at $c > c_f$ the viscous flow of the composite is terminated. Apparently, c_l and c_f should show an inverse correlation with the specific surface area *S* of silica. Indeed, as can be seen

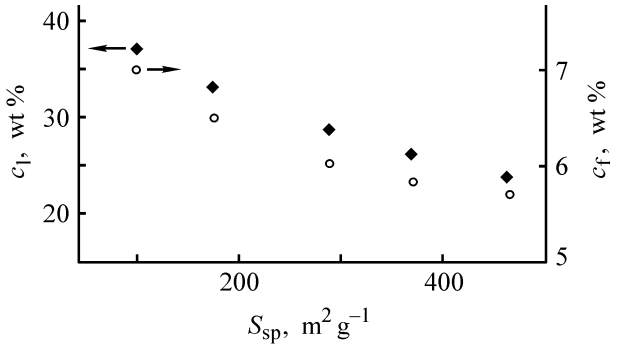

Fig. 1. Limiting concentration of the filler c_l and concentration of the fluidity loss, c_f, for OKM-2 oligomer vs. the silica specific surface area S_{sp}.

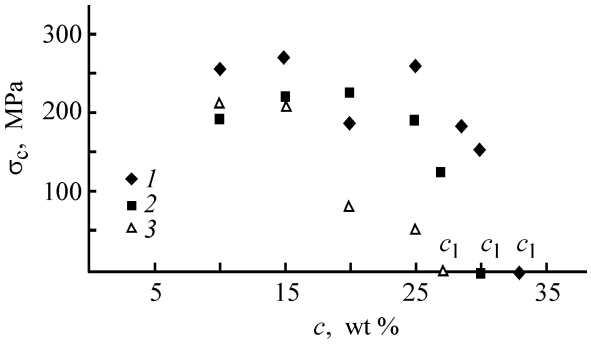

Fig. 2. Compression strength σ_c of the matrix [OKM-2 + 0.6 wt % BDK + 0.1 wt % TMP] vs. the concentration c of unmodified (*1*) A-175, (*2*) A-300, and (*3*) A-380 fillers.

from Fig. 1, c_l and c_f of OKM-2, TGM-3, and EPO oligomers nonlinearly decrease with increasing content and specific surface area of A-100, A-175, A-300, and A-455 fillers (numbers indicate the increasing specific surface area of Aerosils). It should be noted that the modification of the filler surface can affect these dependences and c_l can be raised by a factor of 1.2–1.5, using K-2 and A-174 modifying agents. For example, c_l = 28 wt % in the case of unchanged A-300, and c_l of the same filler modified with A-174 (10 wt %) reaches 45 wt %.

We also found that the strength properties (σ_c, σ_m, and d) are improved, with a decrease in the specific surface area of unmodified silica (Table 1).

For each silica we found the concentration range in which the compression strength σ_c of the photocured composites is higher as compared to the unfilled matrix. The typical dependences of σ_c on the silica content are shown in Fig. 2. It cab be seen that these dependences can be divided into two types. The dependences for highly dispersed A-300 and A-380 fillers pass a single maximum, after which the composites completely lose their strength. This maximum is indicative of the formation of the optimal three-dimensional silica skeleton (Shklovskiy-de Gennes model). As c_l is approached, the strength drastically decreases (Fig. 2) causing degradation of the system (overfilling).

In filling with A-175 silica, the dependences $\sigma_c = f(c)$, $F_i = f(c)$, $\sigma_f = f(c)$, and $\sigma_m = f(c)$ pass through two maxima (Figs. 2, 3; Table 2), which are preserved even upon replacement of the activator. This phenomenon can be explained as follows. The first maximum (which is absent with A-300 and A-350 fillers) is probably due to the maximum in the degree of conversion at an A-175 filler concentration of 10–12 wt % [11, 12], because σ_c directly depends on the conversion [13, 14]. As in the case of highly dispersed fillers, the second maximum indicates the formation of the optimal silica skeleton, because, with further increase in the filler content, the composite strength drastically decreases with its self-dispersion.

Table 1. Strength properties as influenced by the degree of filling with Aerosils of various particle size

Aerosil	Degree of filling, wt %				
	15	20	25	20	
	σ_c, MPa			σ_m, MPa	d, m mm^{-3}
–	(176)*	(176)	(176)	(382)	(0.2)

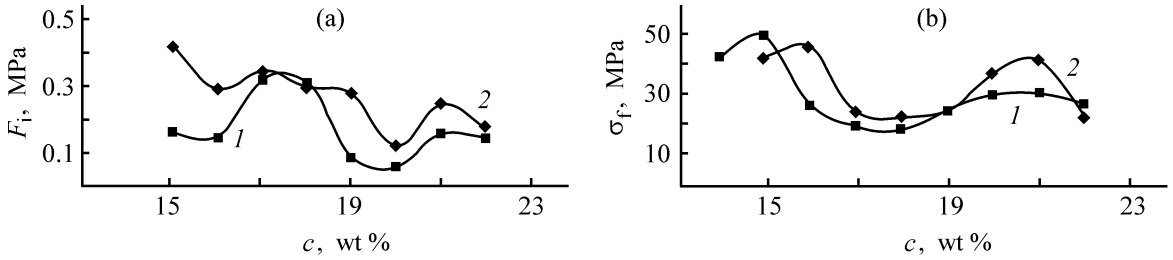

Fig. 3. (a) Impact resilience F_i and (b) flexural strength σ_f vs. the content of A-175 silica in OKM-2 + 0.6 wt % BDK + 0.1 TMEDA upon irradiation for (*1*) 8 and (*2*) 12 min.

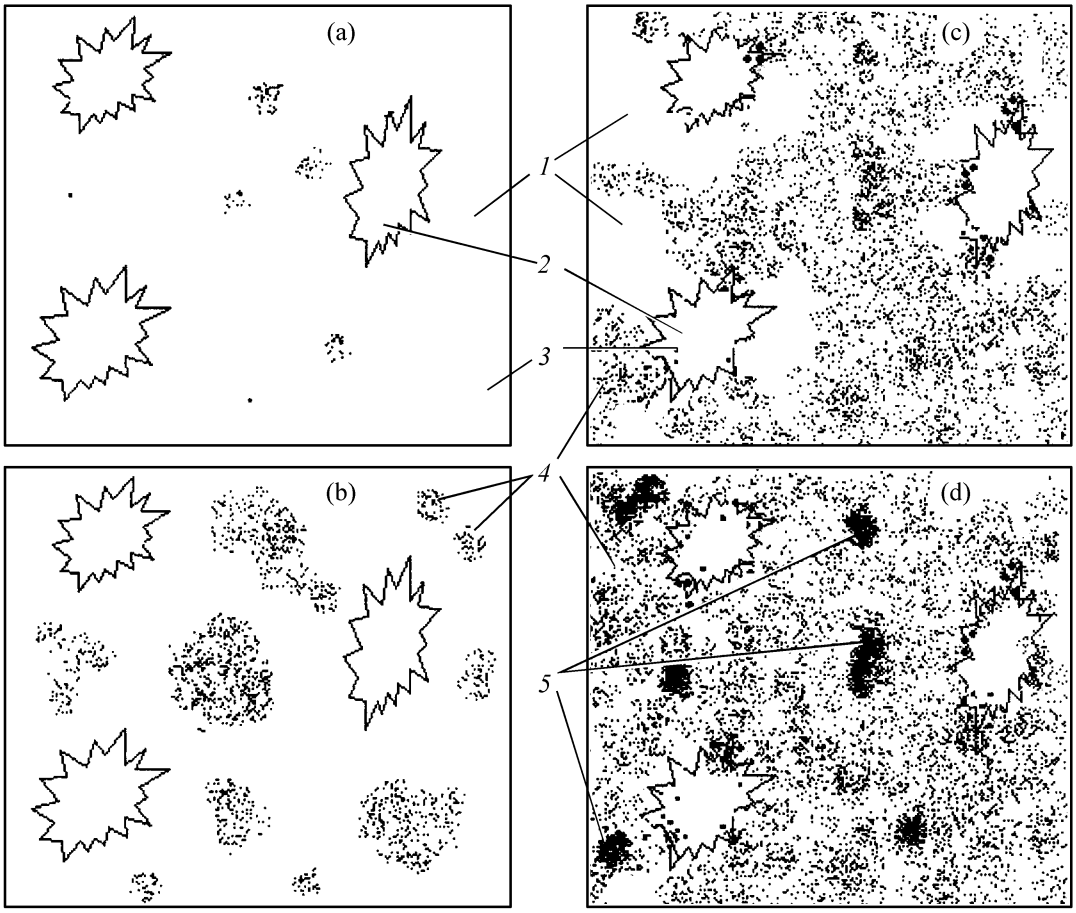

Fig. 4. Arrangement of silica particles and heterogeneous areas at different degrees of filling: (a) low filler concentrations, (b) moderate filler concentrations, (c) high and near-limiting filler concentrations, and (d) overfilled composites. (*1*) Free polymer, (*2*) heterogeneous areas, (*3*) separate filler particles, (*4*) particles and aggregates of filler surrounded by near-surface polymer layers, and (*5*) areas of degradation of the polymer structure and "dry" aggregates of silica filler.

To account for the maxima observed, we suggest the following scheme of changes in the polymer structure with increasing silica content, which is based on the tetra-component model of the filled polymer, suggested by Solomko [9] and Shklovskii-de Gennes model [15]. At low and moderate concentrations of the filler (e.g., up to 5–10 wt %), its particles are displaced in the course of polymerization to the less compact and poorly ordered areas of the polymer (Figs. 4a, 4b). With increasing concentration, these silica-structured areas expand, which raised up to a certain filler concentration increases the conversion [11, 12] and improves the polymer strength (Fig. 2, first maximum). With a further increase in the filler concentration, the silica-free polymer volume decreases (Fig. 4c, *1*). As a rule, these polymer areas are preserved near dense heterogeneous polymer areas, into which no silica particles can enter. The formation of

such heterogeneities was reported in [13, 16]. As a result, the polymer structure is reinforced by the silica particles. This accounts for the appearance of the second extremum in the dependences of the strength on the degree of filling (Fig. 2, Table 2). As of the limiting filler concentration is attained, separate silica particles are probably displaced into the dense heterogeneous areas of the polymer, causing their deformation and degradation (Fig. 4d). At the same time, the amount of the polymer phase with a broken structure and high internal stresses increases (Fig. 4d, *5*). As a result, the strength of the composite sharply decreases (Fig. 2).

CONCLUSIONS

(1) In c_l filling of oligomers with silica, the limiting concentration c_l of the filler, above which the composite undergoes mechanical breakdown (self-dispersion), should be taken into account. The values of c_l nonlinearly decrease with increasing specific surface area of silica and can be raised by modification of the filled surface.

(2) As a rule, addition of silica (A-175, A-300, and A-380 Aerosil) at concentrations of up to $c << c_l$ (10–20 wt %) significantly improves the compression strength, microhardness, and abrasion wear of the polymer. With decreasing specific surface area of silica, the strength properties of the resulting polymers are enhanced.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Epoxidation of Soybean Oil in the Course of Cooxidation with Hydrogen Peroxide in the Presence of Propanoic Acid and Chlorinated KU-2 × 8 Cation Exchanger

M. Sh. Gurbanov, Ch. A. Chalabiev, B. A. Mamedov, and A. A. Efendiev

Institute of Polymeric Materials, National Academy of Sciences of Azerbaijan, Sumgait, Azerbaijan

Received February 22, 2005; in final form, June 2005

Abstract—Pattern of soybean oil epoxidation catalyzed by chlorinated KU-2 × 8 cation exchanger in the presence of H_2O_2 and propanoic acid was studied. The epoxidation rate and the selectivity of formation and yield of the epoxidation product were studied as influenced by the concentration of H_2O_2, C_2H_5COOH, and the catalyst. Some kinetic and activation parameters of soybean oil epoxidation were determined.

Epoxidized unsaturated oils are used in paint-and-varnish industry and as a plasticizer-stabilizer of polyvinyl chloride [1]. Unsaturated compounds, including higher unsaturated acids are epoxidized by peroxy acids in organic solvents [2–6]. The process can be performed with peroxy acids generated *in situ* from the corresponding carboxylic acid and hydrogen peroxide in the presence of mineral (H_2SO_4, HNO_3, and H_3PO_4) and organic (*p*-toluenesulfonic acid and trichloroacetic acid) acids, transition metal salts [cerium(IV) sulfate and zirconium(IV) sulfate], KU-2 cation exchanger, and Mn(IV) complexes. Strong water-soluble acids can be readily converted into peroxy acids. However, cooxidation of carboxylic acid and epoxidation of unsaturated compounds in the presence of these catalysts is ineffective because of the difficult recovery of the catalysts from the final reaction products. At the same time, epoxidation of unsaturated compounds with peroxy acids prepared in advance is unfeasible, because peroxy acids are explosive and the process is performed in two steps. Ion-exchange catalysts are the most suitable both for preparation of peroxy acids [7, 8] and for epoxidation of unsaturated compounds with peroxy acids formed *in situ* [9, 10].

In this study we examined the pattern of epoxidation of soybean oil (SO) with peroxypropanoic acid formed *in situ* in the presence of a chlorinated KU-2 × 8 cation exchanger (CCE).

EXPERIMENTAL

Epoxidation was performed in a 250-ml three-necked flask equipped with a hydroseal, mechanical stirrer, and reflux condenser. The required amounts of propanoic acid, hydrogen peroxide, CCE, and toluene solution of SO were placed in the flask. The reaction was performed in the course of 8 h. Then the catalyst was filtered off on a Schott filter. The aqueous layer of the filtrate was separated from the organic layer. The organic solution was diluted with toluene and washed with distilled water to absence of H_2O_2 in the aqueous phase. Toluene was removed (323–328 K, 13.3 kPa) and the epoxidized oil was recovered. The physicochemical parameters of the epoxidized soybean oil (ESO) were determined.

The catalysts, chlorinated KU-2 × 8 cation exchanger with a 9.5 wt % chlorine content and an exchange capacity of 3.54 mg-equiv g^{-1}, was prepared by treatment of KU-2 × 8 cation exchanger with a mixture of HCl and H_2O_2 [11]. The efficiency and stability of this catalyst in synthesis of peroxy acids was shown in [12].

We used a 30 wt % solution of H_2O_2, freshly distilled propanoic acid (chemically pure grade, bp = 414.4 K, d = 0.9934 g cm^{-3}, n_D^{20} = 1.3865), and SO with an iodine number of 129. The content of epoxy groups and the iodine number were determined by the procedure described in [13]; the content of H_2O_2

* (1) Qualitative parameters were determined for the final products epoxidized for 8 h.
(2) Some epoxidation parameters: $A = 5.02 \times 10^5$ M^{-1} s^{-1}, E = 57.4 kJ mol^{-1}, ΔH^0 = 52.0 kJ mol^{-1}, $\Delta S^{\neq}$ = –152.5 J mol^{-1} K^{-1}, $\Delta G^{\neq}$ = 47.1 kJ mol^{-1}, k_1 (M^{-1} s^{-1}): 0.243×10^{-4} (313 K), 0.575×10^{-4} (323 K), 1.1×10^{-4} (333 K), 2.43×10^{-4} (343 K).

and peroxypropanoic acid, by the procedure in described [14]; and the viscosity of ESO, by the procedure in described [15]. Toluene (analytically pure grade, bp = 383.6 K, d = 0.8669 g cm^{-3}, n_D^{20} = 1.4969) was used as a solvent.

Samples of ESO are transparent green-yellow viscous liquids without mechanical impurities. The viscosity of these samples at 293 K is 0.0865–0.0890 N s cm^{-2}, and the acid number ranges from 0.3 to 0.4 mg (KOH), depending on the preparation conditions (see table). These parameters did not change after storage of these samples at room temperature for a year and after heating on an oil bath at 473 K for 20 min.

The selectivity of the CCE catalyst was estimated as the molar ratio of the epoxy groups in the products to the total number of SO double bonds that had reacted with H_2O_2 in the presence of PA.

Cooxidation of SO in the presence of PA, H_2O_2, and CCE is a consecutive two-step process. The first step is the reaction of PA with H_2O_2 in the presence of CCE to form peroxypropionic acid (PPA); the second step is oxidation of SO, with PPA being formed. It is known [16] that oxidation of carboxylic acids to peroxycarboxylic acids in the presence of acidic catalysts is reversible; both forward and reverse reaction are second-order. However, as PPA is consumed for SO oxidation, the overall process may be irreversible, depending on the ratio of the rate constants of the first and the second steps. Clearly, the epoxidation is the most efficient when the rate of the second step is equal to, or higher than, that of the first step. Hence, to provide simultaneous efficient generation of PPA and SO epoxidation and to prepare the target product with a high content of epoxy groups, the optimal range of the process parameters should be determined.

For this purpose, we studied the rate of H_2O_2 consumption and a change in the PPA concentration as influenced by the temperature and CCE amount. The kinetic curves of H_2O_2 consumption in SO oxidation in the presence of PA and CCE are shown in Fig. 1. It can be seen that the H_2O_2 consumption is accelerated on heating from 313 to 343 K (see table), and hence the time of SO oxidation decreases. For

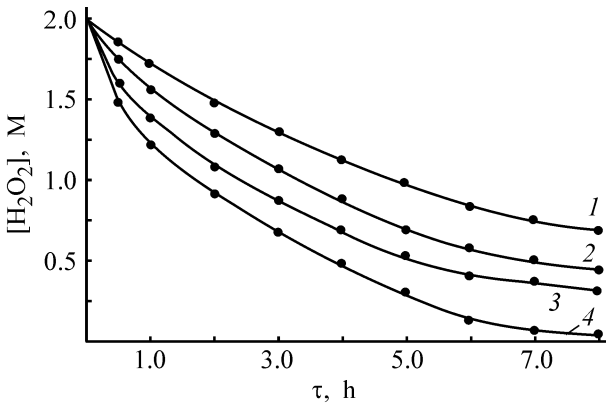

Fig. 1. Kinetic curves of $[H_2O_2]$ consumption in SO epoxidation at (*1*) 313, (*2*) 323 (*3*) 333, and (*4*) 343. Amount of CCE 10 wt % relative to the total amount of H_2O_2 and PA. $[H_2O_2]_0 = [PA]_0 = [SO]_0$ = 2 M. (τ) Time; the same for Figs. 2–4.

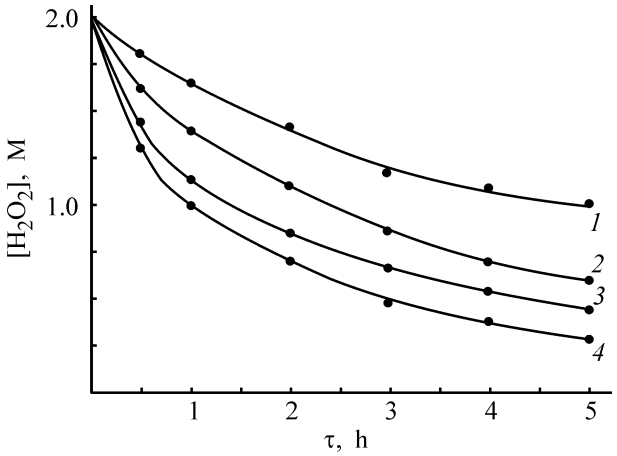

Fig. 2. Kinetic curves of $[H_2O_2]$ consumption in SO epoxidation in the presence of CCE. CCE amount, wt % relative to H_2O_2 + PA: (*1*) 5, (*2*) 10 (*3*) 15, and (*4*) 20. $[H_2O_2]_0 = [PA]_0 = [SO]_0 = 2$ M, T 333 K.

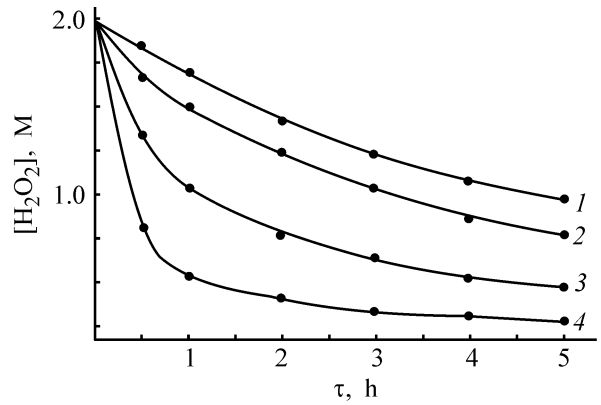

Fig. 4. Kinetic curves of $[H_2O_2]$ consumption in SO epoxidation at $[H_2O_2]_0 : [PA]_0 : [SO]_0$ (*1*) 1 : 0.25 : 1, (*2*) 1 : 0.5 : 1, (*3*) 1 : 1 : 1, and (*4*) 1 : 2 : 1. Amount of KU-2 × 8 cation exchanger 10 wt % relative to H_2O_2 + PA, T = 333 K, $[H_2O_2]$ = 2 M.

example, 50% of the H_2O_2 amount required for SO epoxidation is consumed at 343 K within 114 min, whereas at 313 K, thus takes 290 min. The first portions of the kinetic curves are well described by the kinetic equation of a second-order irreversible reaction, i.e., in this temperature range, the second step is faster than the first step and the SO oxidation becomes irreversible.

The kinetic curves of H_2O_2 consumption in SO oxidation in the presence of PA and different amounts of CCE are shown in Fig. 2. It can be seen that the H_2O_2 consumption is accelerated as the CCE content increases from 5 to 20%. The reaction is of the first order with respect to the catalysts at the CCE content of 15%. Previously, we have shown [3] that acid catalysts including KU-2 × 8 accelerate only the first step of cooxidation of unsaturated compounds in the presence of carboxylic acids and H_2O_2 and do not accelerate epoxidation of the double bond. To confirm the absence of the catalytic effect of CCE on SO epoxidation, we studied the oxidation of SO with PPA in the absence and in the presence (10 wt %) of CCE. No effect of CEE on the epoxidation rate was detected.

Hence, the effects of temperature and the CCE content on the rate of formation and consumption of the peroxy acid differ. The acceleration of the process with increasing catalyst content is due to a rise in the current PPA concentration. On heating, both the formation of peroxy acid and the oxidation of the double bond are accelerated (Fig. 1, 3).

The kinetic curves of H_2O_2 consumption in cooxidation of SO in the presence PA and CCE at different $[H_2O_2] : [PA] : [SO]$ molar ratios are shown in Fig. 4. The qualitative parameters of SO epoxidation are summarized in the table. These data show that the optimal are the equimolar $[H_2O_2] : [PA] : [SO]$ ratio, and CCE amount equal to 15% of the total weight of H_2O_2 and PA. When the molar ratio changes from 1 : 0.25 : 1 to 1 : 2 : 1 (an increase in the PA amount), the process is significantly accelerated but the quality of the target product is impaired, probably bacause of acceleration of side reactions, including the opening of the epoxy ring of PA. Hence, the reaction should be performed at 333 K, despite that the H_2O_2 consumption in the epoxidation at 343 K is faster.

It should be noted that SO oxidation is accelerated with increasing H_2O_2 content. However, the use of large amounts of hydrogen peroxide is inefficient owing to the high consumption of the oxidizing agent. In addition, the epoxy number of the target product increases insignificantly in this case. Some kinetic parameters of cooxidation of SO with H_2O_2 in the pres-

ence of PA and CCE are also listed in the table. It is seen that the rate and the rate constant of the first step are fairly high, the activation energy is low, and the negative activation entropy is fairly high.

Thus, SO epoxidation with hydrogen peroxide in the presence of PA and CCE is a complex process including consecutive and parallel steps. The first step is PA oxidation with hydrogen peroxide to PPA:

$$H_2O_2 + C_2H_5COOH \underset{k_2}{\overset{k_1,\ CCE}{\rightleftarrows}} C_2H_5COOOH + H_2O. \quad (1)$$

As PPA is formed in the aqueous phase (aq.ph) and the epoxidation occurs in the organic phase (org.ph), PPA is distributed between these phases

$$[C_2H_5COOOH]_{aq.ph} \rightleftarrows [C_2H_5COOOH]_{org.ph}, \quad (2)$$

$$\gamma_1 = [CH_3COOOH]_{org.ph}/[CH_3COOOH]_{aq.ph}. \quad (3)$$

The distribution of PA between the aqueous and organic phases occurs in a similar way

$$[C_2H_5COOH]_{aq.ph} \rightleftarrows [C_2H_5COOH]_{org.ph}, \quad (4)$$

$$\gamma_1 = [CH_3COOH]_{org.ph}/[CH_3COOH]_{aq.ph}. \quad (5)$$

The double bonds of SO are epoxidized mainly in the organic phase

$$\rangle C{=}C\langle + [C_2H_5COOOH]_{org.ph} \xrightarrow{k_3} \rangle C\text{--}C\langle\ (O) + [CH_3COOH]_{org.ph} \quad (6)$$

It should be noted that side reactions are possible. Propionic acid dissolved in the organic phase promotes opening of the epoxy ring to form ester:

$$\rangle C\text{--}C\langle\ (O) + [C_2H_5COOH]_{org.ph} \xrightarrow{k_4} \underset{HO\ \ OCOC_2H_5}{\rangle C(OH)\text{–}C(OCOC_2H_5)\langle} \quad (7)$$

The epoxidation kinetics can be described by the following set of differential equations:

$$-\frac{d[H_2O_2]}{dt} = \{k_1[C_2H_5COOH][H_2O_2] - k_2[C_2H_5COOOH][H_2O]\}[CCE], \quad (8)$$

$$-\frac{d[SO]}{dt} = k_3[SO][C_2H_5COOOH]_{org.ph}, \quad (9)$$

$$\frac{d[SOE]}{dt} = k_3[SO][C_2H_5COOOH]_{aq.ph}\gamma_1 - k_4[SOE][C_2H_5COOH]_{aq.ph}\gamma_2, \quad (10)$$

$$\frac{d[SOEst]}{dt} = k_4[SOE][C_2H_5COOH]_{aq.ph}\gamma_2. \quad (11)$$

In accordance with the mass balance, the components of the reaction mixture are related by the following equations

$$[H_2O_2]_t = [H_2O_2]_0 - [H_2O_2]_{cons.}, \quad (12)$$

$$[SO]_t = [SO]_0 - [SOE] - [SOEst], \quad (13)$$

$$[C_2H_5COOH]_t = [C_2H_5COOH]_0 - [C_2H_5COOOH] - [SOEst], \quad (14)$$

where $[H_2O_2]_0$ and $[H_2O_2]_t$ are the initial and current concentrations of H_2O_2, respectively; $[SO]_0$ and $[SO]_t$, initial and current concentrations of SO (or the double bond of SO), respectively; [SOE] and [SOEst], current concentrations of epoxidized SO and SO ester, respectively; $[C_2H_5COOH]_0$ and $[C_2H_5COOH]_t$, initial and current concentrations of PA, respectively.

The distribution coefficients of PA and PPA between the aqueous and organic phases at different temperatures are determined experimentally.

CONCLUSIONS

(1) Chlorinated KU-2 × 8 cation exchanger is highly active and stable catalyst for SO epoxidation in the presence of H_2O_2 and C_2H_5COOH.

(2) Chlorinated KU-2 × 8 cation exchanger catalyzes only the formation of peroxypropionic acid and has no effect on the rates of oxidation of the double bond of soybean oil and of the opening of the epoxy ring of the target product, which increases the selectivity and efficiency of epoxidation and improves the quality of the target product.

Abstract—The possibility of controlling the composition, microstructure, and molecular weight of copoly(arylene phthalides) was examined.

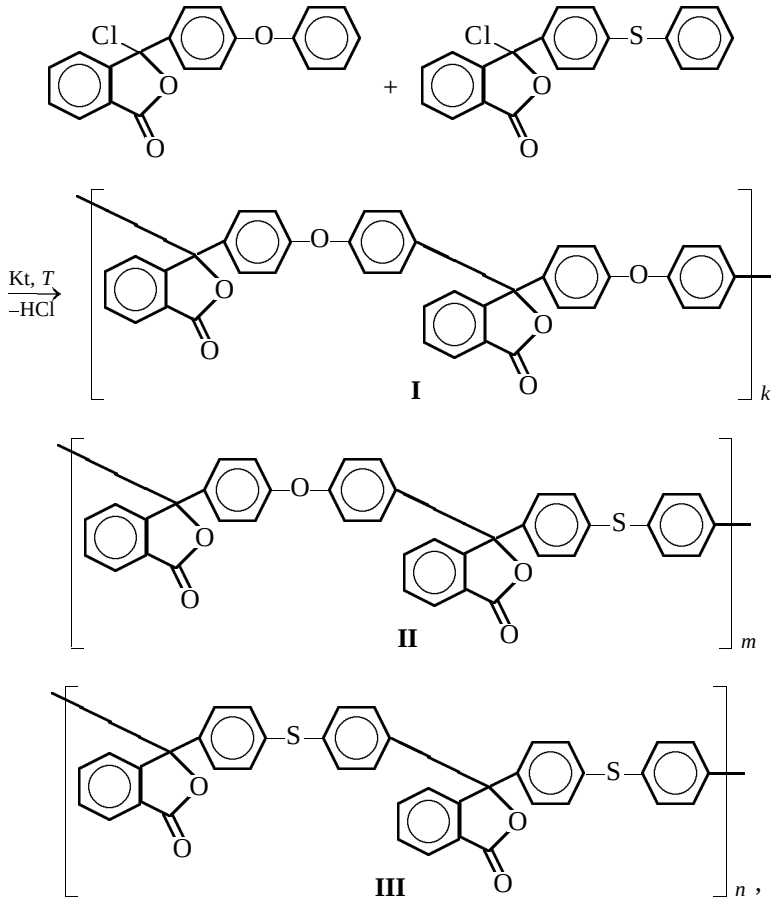
One of promising lines in modern polymer chemistry is synthesis of heat-resistant polymers and materials based on them, [in particular, poly(arylene phthalides)], which exhibit, along with high heat resistance and high softening points, other valuable properties, such as solubility, film-forming ability, and chemical resistance [1–3]. Poly(arylene phthalides) possess not only a unique combination of physicomechanical characteristics, but also unusual electrical properties.

Understanding of the fundamental aspects of synthesis of copoly(arylene phthalides) would allow preparation of copolymers with a required composition, microstructure, and molecular weight.

Under the conditions of nonequilibrium binary copolycondensation, the microstructure and composition of the forming copoly(arylene phthalides) can be affected by such factors as the reactivity of the comonomers, order of introduction of the starting monomers and catalyst, concentration and ratio of the monomers, type and amount of the catalyst, and temperature and time of synthesis. We have shown previously that acid pseudomonochlorides *p*-(3-chloro-3-phthalidyl)diphenyl oxide and *p*-(3-chloro-3-phthalidyl)diphenyl sulfide are highly reactive, form the corresponding homopolymers [2, 3], and enter into copolycondensation to give macromolecular copoly(arylene phthalides) [4].

In this study, we examined how the kind and amount of the catalyst affect the microstructure, composition, and reduced viscosity of the forming copoly(arylene phthalides) and estimated the relative reactivities of the comonomers.

EXPERIMENTAL



The starting compounds and solvents were purified according to [5–7]; their constants were consistent with published data [6, 7]. *p*-(3-Chloro-3-phthalidyl)diphenyl oxide and *p*-(3-chloro-3-phthalidyl)diphenyl sulfide were prepared according to [2]. The copolymerization was performed in the one-step mode; the comonomers were loaded in a single portion at the beginning of the process. An example of the procedure for preparing copoly(arylene phthalide) is given below. A four-necked flask equipped with a mechanical stirrer, an air-cooled reflux condenser, and a gas (Ar) bubble counter was charged with 4.206 g of *p*-(3-chloro-3-phthalidyl)diphenyl oxide and 4.406 g of *p*-(3-chloro-3-phthalidyl)diphenyl sulfide, after which 12.5 ml of nitrobenzene and 0.055 g of anhydrous $InCl_3$ were added. The synthesis was performed at 110°C for 10 h. Samples of the reaction mixture were taken at definite intervals (5, 10, 20, 40, 60, 90 min). The polymer from the samples and the final product were precipitated into methanol, reprecipitated from chloroform into methanol, washed with methanol and acetone, and dried in air at 180°C for 24 h.

The reduced viscosities η_r of the copolymers were measured in chloroform at 25°C and a polymer concentration of 0.5 g in 100 ml of the solvent.

The electronic absorption spectra of the solutions of copoly(arylene phthalides) were measured on a Shimadzu UV-3100 spectrophotometer at 20°C; the substrates were taken as $(0.1–1) \times 10^{-4}$ M solutions in 96 wt % sulfuric acid.

1070-4272/05/7810-1683 © 2005 Pleiades Publishing, Inc.

The reaction of equimolar amounts of *p*-(3-chloro-3-phthalidyl)diphenyl oxide and *p*-(3-chloro-3-phthalidyl)diphenyl sulfide in nitrobenzene in the presence of Lewis acids yields structures **I**–**III**;

where **I** is the diphenyl oxide phthalide (OO) homodiad; **II**, diphenyl oxide phthalide–diphenyl sulfide phthalide (OS) heterodiad; and **III**, diphenyl sulfide phthalide (SS) heterodiad; *k*, *m*, and *n* are the mole fractions of the OO, OS, and SS diads, respectively.

The mole fractions of the homo- (OO, SS) and heterodiads (OS) and the composition and microstructure of the copoly(arylene phthalides) were determined from the UV spectra (sulfuric acid solutions) of the copolymer samples taken in the course of the synthesis [8]. As catalysts for binary copolycondensation of the chloro phthalides we tested Lewis acids $InCl_3$, $GaCl_3$, and $SbCl_5$, which were taken in concentrations of 0.5–10 mol %. Figures 1a–1c show how the content of diads **I**–**III** in the copolymers varies in the course of the synthesis at various concentrations of $InCl_3$, $GaCl_3$, and $SbCl_5$. It is seen that, irrespective of the kind and concentration of the catalyst, OO diads are formed in the first minutes of the synthesis in larger amounts than SS diads. Only with 10 mol % $SbCl_5$, OO and SS diads are formed in the first minutes of the synthesis in equal amounts (Fig. 1c, curves *1*‴ and *3*‴). At $InCl_3$ and $GaCl_3$ concentrations of 0.5 mol %, the content of OO diads in the course of the synthesis exceeds that of SS diads by a factor of 25–50. The activity of $SbCl_5$ at its concentration of 0.5 mol % is low, and the copolymer is not formed. With an increase in the concentration of any of the catalysts tested and in the synthesis time, the amount of OO diads decreases, and that of SS diads increases. The content of heterodiads rapidly grows with the catalyst concentration, and their mole fraction approaches 0.55. Within 1 h, all the kinetic curves flatten out, and, in the subsequent process, the content of homo- and heterodiads varies insignificantly. The content

of OO and SS homodiads by the end of the synthesis varies with the catalyst used, whereas the content of heterodiads is about the same. With $InCl_3$, copoly(arylene phthalides) with almost equal content of OO and SS homodiads can be obtained. With $GaCl_3$, the resulting copolymers contain an appreciably larger amount of OO homodiads than that of SS homodiads, with the difference being the larger, the lower the $GaCl_3$ concentration. With $SbCl_5$ taken in concentrations of 1.0 mol % and higher, copolymers with the mole fraction of the heterodiads in the range 0.5–0.55 can be obtained, and the content of the homodiads depends on the catalyst concentration. With 1.0 mol % $SbCl_5$, the content of OO homodiads is higher than that of SS homodiads (mole fraction 0.35 and 0.12, respectively); the mean length of diphenyl oxide phthalide blocks, L_O, is 1.6, and that of diphenyl sulfide phthalide blocks, L_S, is 0. With 5 mol % $SbCl_5$, the content of OO and SS diads becomes close within 10 min (mole fraction 0.24 and 0.22, respectively; L_O = 1.9, L_S = 1.8). With 10 mol % $SbCl_5$, the content of the homodiads is the same in the first minutes of the synthesis, but then the content of OO diads tends to decrease, and that of SS diads, to increase. As a result, the polymer formed by the end of the synthesis is enriched in SS diads (mole fractions: OO 0.18 and SS 0.3; L_O = 1.6, L_S = 2.1).

The polymer chain structure can be quantitatively characterized by the microheterogeneity coefficient K_m and mean lengths of the oxide and sulfide blocks, L_O and L_S, which were calculated from the mole fractions of the homo- and heterodiads of copoly(arylene phthalides) [9]. With an increase in the concentration of any of the catalysts tested and in the synthesis time, K_m decreased from 1.27 at the beginning of the synthesis to 1.0 by its end (10 h). This means that, in the first minutes of the synthesis at low concentrations of the catalyst, the more active oxide comonomer forms oxide sequences which fairly regularly alternate with a single sulfide fragment (the most probable structure is ~OOSOOSOOOSOOO~, K_m = 1.27, L_O = 3.0, L_S = 1.0), with no sulfide homodiads. *p*-(3-Chloro-3-phthalidyl)diphenyl sulfide is incorporated exclusively in OS heterodiads **II**. With an increase in the catalyst concentration and synthesis time, the microheterogeneity coefficient tends to unity, which is indicative of the formation of random microblock copolymers enriched in oxide or sulfide fragments, depending on the kind and concentration of the catalyst.

The kind and concentration of the catalyst exert no significant influence on the molecular weight of copoly(arylene phthalides). This is illustrated by

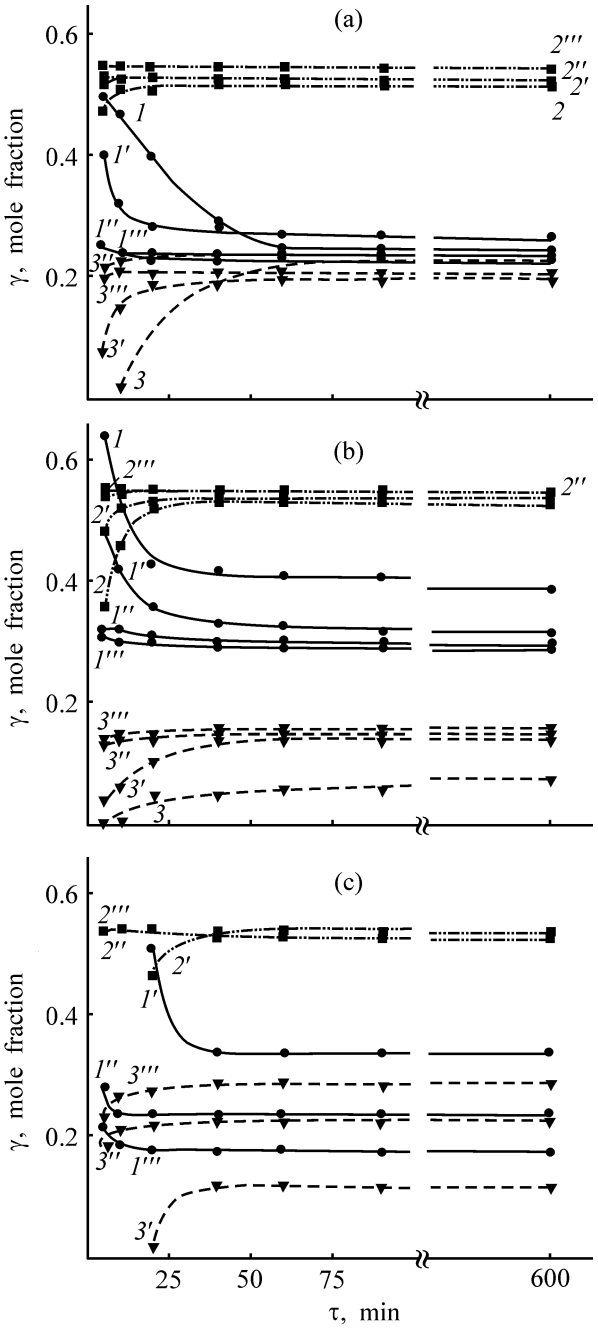


Fig. 1. Variation of the content of (*1*) OO, (*2*) OS, and (*3*) SS diads in the course of copolycondensation of *p*-(3-chloro-3-phthalidyl)diphenyl oxide and *p*-(3-chloro-3-phthalidyl)diphenyl sulfide in the presence of catalysts (a) $InCl_3$, (b) $GaCl_3$, and (c) $SbCl_5$. (γ) Mole fraction of diads and (τ) time. Catalyst concentration, mol %: (*1*–*3*) 0.5, (*1*′–*3*′) 1.0, (*1*″–*3*″) 5.0, and (*1*‴–*3*‴) 10.0.

Figs. 2a–2c. With an increase in the $GaCl_3$ concentration, the reduced viscosities of the copolymers steadily increase in the course of the synthesis. The highest reduced viscosity (0.75 dl g^{-1}) was obtained with 10 mol % $GaCl_3$ at a reaction time of 10 h (Fig. 2b).

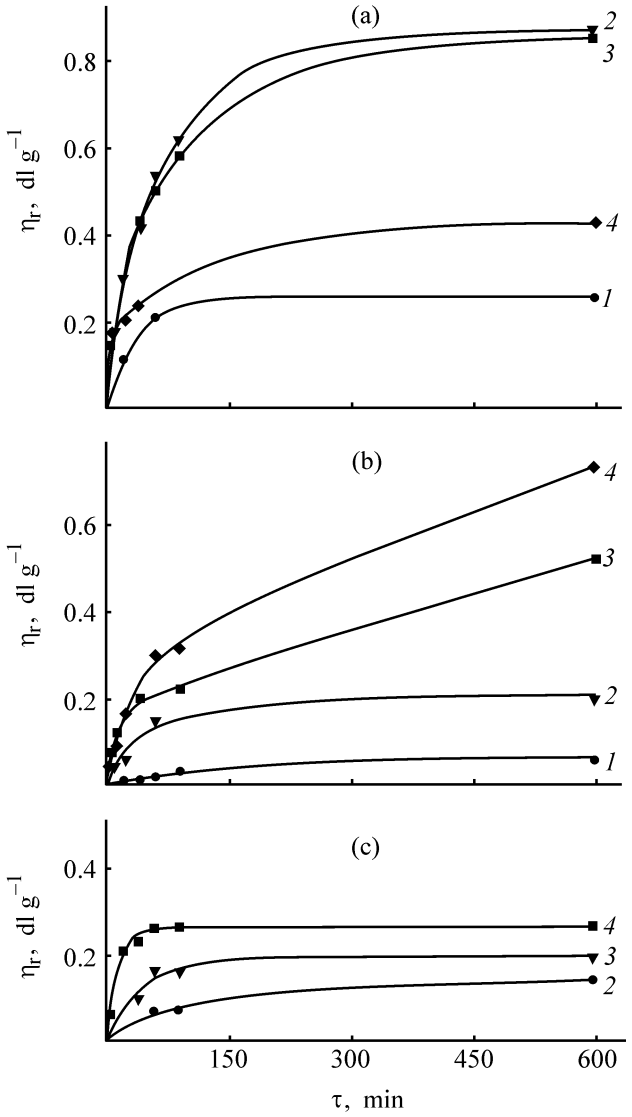

Fig. 2. Influence of the concentration of (a) $InCl_3$, (b) $GaCl_3$, and (c) $SbCl_3$ on the reduced viscosity η_r of copoly(arylidene phthalide) in the course of its synthesis. Catalyst concentration, mol %: (*1*) 0.5, (*2*) 1.0, (*3*) 5.0, and (*4*) 10.

With $InCl_3$, the copolymer with the highest reduced viscosity, 0.87 dl g^{-1}, was obtained at a 10 times lower catalyst concentration, compared to $GaCl_3$ (Fig. 2a). As can be seen from Fig. 2a, the optimal $InCl_3$ concentration is in the range 0.5–1.0 mol %. $SbCl_5$ is the least active among the catalysts tested. At an $SbCl_5$ concentration of 0.5 mol %, no copolymer is formed, and even at its concentration of 10 mol % the reduced viscosity of the copolymer is as low as 0.2 dl g^{-1}.

CONCLUSIONS

(1) A UV study of sulfuric acid solutions of copoly(arylene phthalides) formed by binary copolycondensation of equimolar amounts of *p*-(3-chloro-3-phthalidyl)diphenyl oxide and *p*-(3-chloro-3-phthalidyl)diphenyl sulfide revealed the influence of the kind and concentration of the catalyst on the composition, microstructure parameters (mole fractions of diads, microheterogeneity coefficient, mean block lengths), and molecular weight of the copolymers.

(2) The composition, microstructure, and molecular weight of the copoly(arylene phthalides) can be controlled by varying the kind and concentration of the catalyst.

(3) The catalysts tested allow preparation of both random copolymers and copolymers enriched in oxide or sulfide sequences of various lengths.

Received May 3, 2005

Abstract—Synthesis of cross-linked polyfunctional polyelectrolytes based on polyglycidyl aromatic amines is optimized, and the composition and physicochemical properties of the products are studied.

The three-membered ring in epoxy monomers is reactive toward both electrophilic and nucleophilic reagents. Similarly to compounds with unsaturated bonds, α-oxides are typically involved in reactions of addition and polymerization, and they are widely used in synthesis of soluble and solid polyelectrolytes [1–4].

Polyglycidyl aromatic compounds show the greatest promise for preparation of ion exchangers by polycondensation. These compounds exibit high reactivity and enhanced heat and chemical resistance. Furthermore, it is possible to control the density of cross-links in the resulting ion exchanger by varying the distance between the three-membered rings in the monomers.

The goal of this study was to develop procedures for synthesis of highly permeable polyelectrolytes on the basis of polyglycidyl aromatic diamines and to characterize their properties.

EXPERIMENTAL

Polyglycidyl diamines were synthesized according to the procedure described in [5].

Condensation of the resulting epoxy compounds with amines was carried out in the presence of acetone, DMF, toluene, or cyclohexanone (CH) for 0.5–2 h. Then the homogeneous mass was transferred into a porcelain bottle and cured in an oven for 14 h at 80–110°C. The gel was crushed and screened, to obtain the 0.25–1.0-mm fraction.

Pretreatment of the resulting products and determination of the relevant physicochemical characteristics were performed using the procedures described in [6].

The infrared spectra of the initial, intermediate, and final products were recorded on a Specord M-80/M85 spectrophotometer in KBr (1 mg of substance per 200 mg of KBr) and in a thin layer.

As starting reagents in synthesis of the polyelectrolytes we used polyglycidyl aromatic compounds obtained by condensation of epichlorohydrin with aromatic diamines [4,4'-diaminodiphenyl (DADP), 4,4'-diaminodiphenylmethane (DADPM), 4,4'-diaminodiphenyl oxide (DADPO), 4,4'-diaminodiphenyl sulfide (DADPS), and 4,4'-diamino-3,3'-dimethyldiphenyl (DADMDP)] (Table 1) or aliphatic di- and polyamines

* (s) Soluble product.

[hexamethylenediamine (HMDA), polyethylenepolyamine (PEPA), and polyethyleneimine (PEI)].

It is known [5–7] that properties of ion exchangers are primarily characterized by the static exchange capacity (SEC), which, in turn, depends on such factors as the nature of a solvent, proportion of the initial components, temperature, and curing time.

The effect of a solvent on SEC of the ion exchangers was examined with acetone, DMF, toluene, and cyclohexanone (Table 2). DMF and acetone were found to be the most appropriate solvents providing a sufficient solubility of the starting reagents and good swellability of the final products. The static exchange capacity of PEI/DADPM copolymers prepared in acetone and DMF is 11.8 and 10.9 mg-equiv g^{-1}, respectively, while that in cyclohexanone, only 7.7 mg-equiv g^{-1}. Similar trends were observed for the other amines. In the absence of a solvent, the condensation is too fast, producing an inhomogeneous gel. Additionally, the use of a solvent eliminates a local overheating which could occur as a result of exothermic opening of the epoxy groups. Therefore, we used as a reaction medium DMF or acetone (50 wt % solutions).

Previously, we have shown [8] that the SEC of the polymers based on polyglycidyl aromatic diamines (PGAs) and aliphatic diand polyamines increases in the order HMDA < PEPA < PEI. Table 2 demonstrates that high-molecular-weight amines are more efficient in synthesis of ion exchangers with a high SEC as compared to the monomeric diamines. Use of PEPA and PEI enables preparation of ion exchangers with an SEC of 8–12 mg-equiv g^{-1}.

In the synthesis of polyfunctional compounds by polycondensation, unchanged active groups could remain in the product, which is caused by differences in their reactivity and also by steric and concentration factors. Therefore, it is necessary to determine the optimal curing temperature, at which all the functional groups of the initial monomer are involved in the reaction.

The results obtained in a study of how the curing temperature and the composition of the starting mixture affect the SEC of the resulting HMDA-based ion exchangers are listed in Table 3. An increase in tem-

perature from 60 to 120°C makes the SEC smaller, which can be attributed to a considerable compaction of the polyelectrolyte structure and to its possible deamination and degradation under these conditions. At temperatures below 60°C the prepolymer is not cured because of the formation of soluble products.

A study of the effect of the reagent ratio revealed that the amount of amine introduced into the copolymer strongly affects the properties of the final products. A significant increase in the SEC was observed as the amine content in the reaction mass was raised up to a two-fold excess of the polyamine by weight (Table 3), and further increase only slightly changed the SEC. In the case of HMDA, essentially soluble products are formed.

As for the effect of the curing time, the SEC increases significantly in the first 1.5–2.0 h and then slightly decreases. For DADPM/HMDA ion exchangers, the SEC decreased from 6.3 to 6.1 mg-equiv g^{-1} as the curing time increased from 2 to 8 h. A similar trend was observed for the rest of the aromatic diamines studied.

The IR spectra of PGAs demonstrate characteristic absorption bands due to symmetric (1260 and 1280 cm^{-1}) and antisymmetric (745, 865, 935, and 970 cm^{-1}) stretching vibrations of the C–O bonds in the epoxy ring. The bands at 1650–1550 m^{-1} confirm the presence of the amino groups. The bands at 1300–1350 m^{-1} are assigned to stretching vibrations of the C–N bonds in the aromatic amines. No characteristic absorption bands of the epoxy rings are found in the spectra of the final products.

The acid–base behavior of the solid polyelectrolytes was studied by potentiometric titration. The shape of the potentiometric curves is controlled by the nature of di- and polyamines, and also by the set of functional groups of the ion exchanger. For the PEI- and PEPA-based products, the shape of the curves is more distinct as compared to that for the HMDA-based copolymer. From the potentiometric curves we estimated the dissociation constants pK_a and empirical coefficients m reflecting the strength of electrostatic interaction between the functional groups in the polymer (Table 4).

Data on the chemical resistance of the ion exchangers are summarized in Table 5. The ion exchangers studied demonstrate a high stability in alkaline and acid solutions, but are less resistant to strong oxidizing agents. Analysis of the chemical resistance data in relation of the nature of a polyamine shows that the PEI-based samples are relatively more stable in aggressive media.

* Initial SEC.

The heat resistance of polyelectrolytes is governed not only by the nature of functional groups, but also by the network structure. However, thermal degradation of the ion exchangers first involves the active groups, being primarily reflected in a decrease in the SEC. Heat resistance tests were carried out by boiling the products in distilled water for a long time. The maximal decrease in the SEC was 4.33, 3.64, and 4.29% for PEI-, PEPA-, and HMDA-based polyelectrolytes, respectively.

Such a high heat resistance (Table 6) is probably due to the cross-linked structure of the polymers and also to the presence of thermally stable aromatic fragments in them. Depending on the structure of the starting amines used, the heat resistance of the products increases in the order tetraglycidyl derivatives of aromatic diamines < DADPS < DADP <DADPM, and decreases in the series of aliphatic polyamines HMDA > PEI > PEPA.

CONCLUSIONS

(1) The optimal synthesis conditions of polyfunctional anion exchangers by condensation of polyglycidyl aromatic diamines with aliphatic di- and polyamines are as follows: curing temperature 80–100°C, curing time 1.5–2.0 h, solvents: DMF and acetone, and glycidyl amine : hexamethylenediamine weight ratio 1.0 : 1.0; glycidyl amine : polyethylenepolyamine = 1.0 : (1.5–2.0); and glycidyl amine : polyethyleneimine = 1.0 : (2.0–3.0).

(2) The acid–base dissociation constants of the functional groups of the polymer and the empirical coefficient characterizing the interchain interaction suggest that weakly basic anion exchangers with high chemical resistance are formed.

ACKNOVLEDGMENTS

Received June 2, 2005

Abstract—Modification of arabinogalactan of Siberian larch and of its oxidized oligomers with 5-aminosalicylic acid was studied. The chemical composition, some physicochemical properties of the modification products, and the optimal modification conditions were determined.

Modification of macromolecular compounds (MMCs) with pharmaceuticals is a promising approach to improvement of the pharmaceutical properties of drugs [1].

Macromolecular pharmaceuticals should meet the following requirements: (i) the molecular weight of water-soluble MMCs should be optimal, (ii) a polymer (or oligomer) should contain functional groups binding drugs, and (iii) elimination of the polymeric or oligomeric matrix from the body after completion of the drug action should occur readily. Natural polysaccharide, arabinogalactan (AG), prepared by extraction of Siberian larch (*Larix sibirica L*) with water, meets these requirements [2–4]. This water-soluble polymer exhibits membrane-acting, gastroprotecting, and immunomodulatory properties and undergoes receptor intermediate endocytosis [4–6], which makes it promising as a nontoxic carrier of molecular and ionic drugs in preparation of biologically active compounds of prolonged action. In this study, we modified polymeric (AG_{pol}) and oligomeric (AG_{ol}) fractions of AG prepared by oxidative functionalization and degradation of AG under the action of $H_2O_2 + O_2$.

Polysaccharides form complexes with various metal ions [7–9]. Data on complexation of AG with compounds exhibiting therapeutic properties are scarce [10].

In this study, we examined modification of AG and its oxidized fractions with 5-aminosalicylic acid (5-ASA), which inhibits prostaglandin synthesis [11].

EXPERIMENTAL

We used natural AG (M 40 000) recovered from Siberian larch by extraction with water [12]. Water-soluble phenols including dihydroquercetin were removed from AG on a polyamide sorbent. The resulting aqueous solutions contained trace amounts of flavonoids. The weight ratio of the galactose and arabinose residues was 5.6 : 1 [13]. Oxidative functionlization of natural AG and synthesis of its oxidized oligomers were performed by oxidation of aqueous hydrogen peroxide solutions of AG with molecular oxygen in a glass bubbling reactor. The volume of the reaction mixture was 10 ml. After the reaction was complete, the fraction of oxidized AG polymers was separated from the oligomer fraction by precipitation with acetone at a reaction mixture to acetone volume ratio of 1 : 5. To recover the oligomer fraction from the supernatant, acetone and water were removed and the residue was dried in a vacuum. The functional groups of natural AG and the polymer and oligomer fractions were analyzed in our previous study [14]. The IR spectra of the samples (Nujol mulls) were recorded on a UR-20 spectrophotometer. The UV spectra of 0.1% aqueous solutions of the compounds were recorded on a Specord M-40 spectrophotometer. The pH of aqueous solutions was measured on a ANION-4100 pH meter and adjusted with 0.1 M NaOH. The optical rotatory power was measured on a Perkin-Elmer-141 polarimeter. The intrinsic viscosity of solutions of

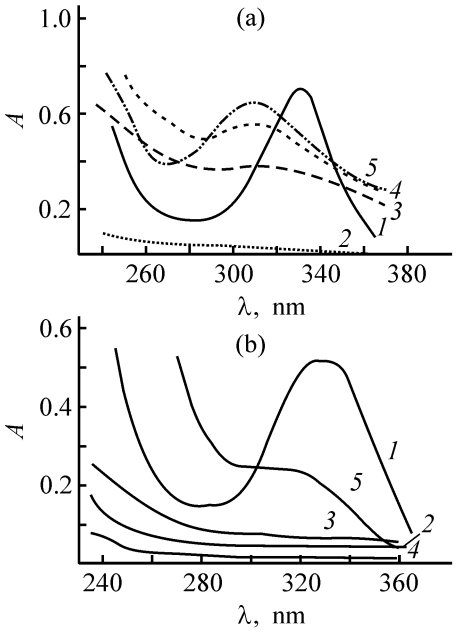

Fig. 1. UV spectra of aqueous solutions of (a) (*1*) 5-ASA, (*2*) AG, (*3*) AG–5-ASA, (*4*) AG_{pol}–5-ASA, and (*5*) AG_{ol}–5-ASA, and of (b) (*1*) 5-ASA (*2*) PVA, (*3*) PVA–5-ASA, (*4*) GA, and (*5*) GA–5-ASA. Concentration (g l^{-1}): (*1*) 0.01 and (*2–5*) 1; *l* = 1 cm.

AG, its oxidized fractions, and modified compounds was measured at 30 ± 1°C on an Ubbelode viscometer with a suspended level [15].

To remove unchanged 5-aminosalicylic acid (5-ASA), the products were twice precipitated from an aqueous solution with ethanol. As determined by TLC, the resulting product did not contain 5-ASA. A thin-layer chromatographic analysis of the compounds was performed on Silufol plates using a 1-butanol–pyridine–water mixture (6 : 4 : 5) as an eluent. The chromatograms were developed with ninhydrin.

The main functional groups of AG macromolecules are hydroxy groups and ether bonds. Natural AG also contains a small amount of carboxy groups of uronic acids. Arabinogalactan can be modified by reaction of these functional groups with drugs. Arabinogalactan macromolecules undergo oxidative functionalization and degradation during treatment of AG with hydrogen peroxide [16]. The oxidized polymers and oligomers contain additional carboxy and carbonyl groups, offering an additional potential for the chemical modification.

Natural AG and AG_{pol} and AG_{ol} fractions of oxidized AG were modified with 5-ASA containing carboxy, hydroxy, and amino groups. 5-Aminosalicylic acid, as well as salicylic acid, is weak and partially dissociates in water. We determined what form of 5-ASA (molecular or ionic) reacts with AG. The dissociation constants of carboxy and hydroxy groups of salicylic acid are 10^{-3} and 1.5×10^{-14}, respectively [17]. Probably, these functional groups of 5-ASA also weakly dissociate. The amino groups of 5-ASA can bind protons formed in dissociation, thus increasing the degree of dissociation of the carboxy groups. Hence, not only acid molecules, but also zwitterions $^{+}H_3NC_6H_3(OH)COO^{-}$ should be present in aqueous solutions of 5-ASA. In neutral solutions of the sodium salt of this acid prepared by neutralization with NaOH, $H_2NC_6H_3(OH)COO^{-}$ also exists. In an acidic solution, $^{+}H_3NC_6H_3(OH)COOH$ ions prevail, whereas in a basic solution, the main species is $H_2NC_6H_3(OH)COO^{-}$. The electronic absorption spectrum of a 5×10^{-4} M aqueous solution of 5-ASA with pH 7 contains a single band at 333 nm. At pH < 7, the sorption peak is shifted to 304 nm. Modification products of arabinogalactan and its oxidized species AG_{pol} and AG_{ol} containing 5-ASA absorb at 315–317 nm (Fig. 1a). Since polysaccharide solutions do not absorb in this range, the band with λ_{max} = 315–317 nm can be assigned to the reaction product of 5-ASA with the examined biopolymers. This product is not formed in acidic solutions. Therefore, all the subsequent reactions of AG, AG_{pol}, and AG_{ol} were performed at pH 7.0–7.1.

To determine the type of functional groups of 5-ASA reacting with AG and AG_{pol} and AG_{ol}, we performed a model experiment with polyvinyl alcohol (PVA) and hyaluronic acid, instead of the biopolymer. The product of the reaction of PVA with an equimolar amount of 5-ASA does not absorb in the range 220–350 nm (Fig. 1b). Hence, the hydroxy groups of PVA (and hence those of AG and AG_{pol} and AG_{ol}) do not react with 5-ASA. Since sodium salts of AG and AG_{pol} and AG_{ol}, formed in neutral solutions, dissociate into carboxylate anions, modification of the polymers and oligomers involves these functional groups. Indeed, the reaction product of 5-ASA and GA absorbs at λ_{max} = 317 nm (Fig. 1b). Thus, our model experiments showed that the most possible modification mechanism is the reaction of the protonated amino group of 5-ASA with the carboxy groups of GA, AG and AG_{pol} and AG_{ol} by the following scheme:

$$\text{AG–COOH} + \text{H}_2\text{N–C}_7\text{O}_3\text{H}_5 \rightarrow \text{AG–COO}^{-}\,^{+}\text{H}_3\text{N–C}_7\text{O}_3\text{H}_5,$$

where AG–COOH is AG, AG_{pol}, or AG_{ol} and $H_2N–C_7O_3H_5$ is 5-ASA.

The 5-ASA content of the modified product decreased by 0.15 wt % after treatment with hydrochlor-

ic acid (pH 2) for 48 h. Hence, this product is fairly stable in acidic solutions.

The reaction products of 5-ASA with AG and AG_{pol} and AG_{ol} were isolated, purified, and characterized by IR and UV spectroscopy and TLC. The optical rotatory power of these products was determined. All these compounds are water-soluble, but insoluble in acetone, alcohol, and diethyl ether. Their intrinsic viscosity η is close to that of the initial polysaccharide fractions, suggesting that the biopolymer chains do not degrade during modification. After addition of 5-ASA to the initial and oxidized AG, the rotatory power increases: $[\alpha]_D^{25}$: +11.9 (AG), +8.4 (AG_{pol}), +5.3 (AG_{ol}), and +12.0 (AG–5-ASA), +13.0 (AG_{pol}–5-ASA), and +16.0 (AG_{ol}–5-ASA). The maximal change in $[\alpha]_D^{25}$ is observed after modification of the oligomeric and polymeric fractions of oxidized AG.

The IR spectra of the modified samples of initial and oxidized AG contain and additional band at 1580 cm^{-1}, which is due to stretching vibrations of the benzene ring of the 5-ASA residue. This fact also suggests that the modified samples contain 5-ASA. The compositions of the modification products prepared under different conditions are listed in the table.

These data allow the following conclusions. The 5-ASA content of the products prepared at 20°C in 24 h increases as the [5-ASA] : [AG] molar ratio is raised by a factor of 10. An increase in the reaction time at 20°C and [5-ASA] : [AG] molar ratio = 1 : 1 has a similar effect. The 5-ASA content of the reaction products prepared in 3 h at the [5-ASA] : [AG] molar ratio of 1 : 1 increases with temperature. The relative increase in the 5-ASA content in the modified compounds in going from AG to AG_{pol} and AG_{ol} is clearly due to the higher content of carboxy groups in the oxidized samples. The content of carboxy groups per 100 polysaccharide molecules in AG is 4.7, whereas in AG_{pol} and AG_{ol} it is 12 and 76, respectively. Hence, the content of carboxy groups in the oligomeric and polymeric fraction exceeds that in the initial AG by a factor of 15 and 3, respectively, which agrees well with the 5-ASA content of these compounds.

The acute toxicity of the examined compounds is more than 5000 mg kg^{-1}. Hence, these compounds are moderately and low-toxic.

COMCLUSIONS

(1) Arabinogalactan and its oxidized polymeric and oligomeric fractions were modified with 5-aminosalicylic acid. Modified compounds with the drug content ranging from 1 to 29%, depending on the type of the polysaccharide fraction, were prepared. The modification involves reaction of the protonated amino groups of 5-aminosalicylic acid with carboxylate anions.

(2) The modified compounds are low-toxic, with the polymers and oligomers being synergists of 5-aminosalicylic acid.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis and Properties of Functionally Substituted Unsaturated Polysulfones

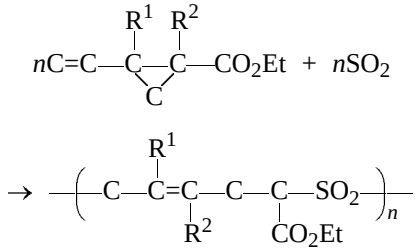
Abstract—High-temperature copolymerization of ethyl esters of vinyl- or isopropenylcyclopropanecarboxylic acids with SO_2 was studied as a route to functionally substituted unsaturated polysulfones. The composition, structure, and some properties of the polysulfones obtained were studied. The copolymerization mechanism was considered.



Copolymers of olefins with SO_2, polysulfones (PSs), show much promise for practice [1–3]. In particular, they can be used as plastics, materials for concentrating sulfuric acid solutions [1], and coatings for fabrics, paper, and wood [2]. Polysulfone materials are used for insulation and soundproofing. Polysulfones prepared from SO_2 and higher olefins improve the viscosity index of hydrocarbon lubricants [3].

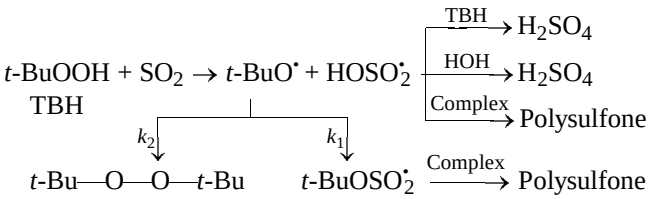
One of the main application fields of PSs is microelectronics. The fact that PSs degrade to monomers under high-energy irradiation allows their use as sensitive components in positive resists [4]. At the same time, it is known that the properties of resists largely depend on the conditions of their synthesis and on the structure of an olefin used [5].

The physicochemical characteristics of the existing polysulfones do not meet the growing requirements to polymers used in photolithographic processes. Therefore, it is necessary to develop new high-performance reactive materials of this type.

In this study, we examined copolymerization of SO_2 with functionally substituted vinylcyclopropanes (VCPs). Copolymerization of VCPs with SO_2 was performed at low temperatures in the presence of *tert*-butyl hydroperoxide (TBH). To examine the reaction features, the reaction was performed at different temperatures.

Experiments showed that VCPs react with SO_2 in the presence of TBH according to the scheme

where R^1, R^2 = H, Me.



The reaction occurs spontaneously and is complete in a short time. However, after thorough purification of the components, the spontaneous copolymerization of VCPs with SO_2 does not occur. The yield of the polysulfones does not exceed 5% in 1 h, being essentially independent of the copolymerization temperature.

Introduction of O_2 substantially raises the final yield of the polysulfone. Similar effect was observed in copolymerization of cyclopentene with SO_2 in the bulk [6].

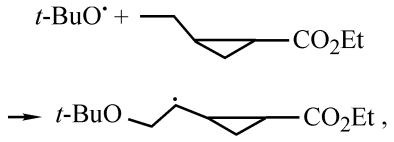
Further experiments showed that the VCP activity in the copolymerization depends on the time of its contact with air: The longer the contact with air (or oxygen), the higher the activity. Hence, the copolymerization is initiated by a substance formed from VCP and O_2, i.e., by a hydroperoxide. In the presence of a hydroperoxide, the copolymerization rate is high and the transformation of VCP to PS can be apparently brought to completion. Upon contact with O_2, VCP copolymerizes with SO_2 in the absence of TBH.

1070-4272/05/7810-1695 © 2005 Pleiades Publishing, Inc.

Thus, the copolymerization occurs in the redox system TBH–SO_2 [7]. The reaction of the two components of the redox system generates free radicals:

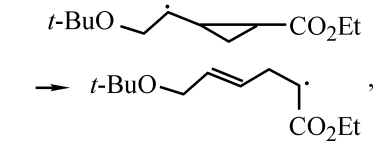
where $k_1 >> k_2$.

According to elemental analysis, the VCP : SO_2 ratio in the repeating unit of the copolymer is 1 : 1. When the copolymerization is performed in solution, the reaction rate is the highest at the equimolar ratio of the monomers. The yield of PS considerably decreases with increasing temperature.



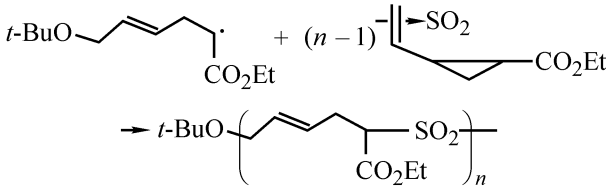
The copolymerization is fast and occurs without an induction period typical of radical reactions. The highest yield of PS is attained in 10–15 min. A longer reaction does not result in a higher yield. The structure of PSs was determined by spectroscopic methods. The IR spectra suggest that VCP is incorporated into the polymer chain, with simultaneous opening of the double bond and three-membered ring, as indicated by the presence of a medium-intensity band at 1630 cm^{-1} (stretching vibrations of internal C=C bond), two strong bands at 1320 and 1130 cm^{-1} assignable to the antisymmetric and symmetric stretching vibrations of SO_2, and a weak band at 3020 cm^{-1} (C–H stretching vibrations of VCP molecule). Also, bands corresponding to the *cis* (730 cm^{-1}) and *trans* (970 cm^{-1}) configurations of the C=C bond are present. Thus, we can conclude that VCP reacts at the 1,5-positions, i.e., with simultaneous opening of the double bond and three-membered ring. The ^1H NMR spectra are also indicative of the formation of a linear PS.

The copolymerization apparently involves intermediate formation of a π complex of SO_2 with the C=C bond of the VCP molecule [8]. This follows from changes in the chemical shift of olefinic protons in the ^1H NMR spectra, from the shift of the absorption peak in the UV spectra, and from the facts that the copolymer composition is independent of the composition of the starting mixture and that the reaction virtually does not occur in some solvents. Both the free and complexed VCP molecules may be involved in the process, although the complexation should enhance the susceptibility of VCP to attack by free radicals. The complexation of VCP and SO_2 follows from a downfield shift of the olefinic proton signals in the ^1H NMR spectra in the presence of SO_2.



The copolymerization mechanism involves homolytic cleavage of TBH into free radicals, induced by SO_2:

$$t\text{-BuOOH} + SO_2 \rightarrow t\text{-BuO}^{\bullet} + HOSO_2^{\bullet}.$$



These radicals initiate the copolymerization, which consists of the following elementary steps [9]: initiation to give intermediate cyclopropylcarbinyl radicals

rearrangement of these radicals into allylcarbinyl radicals

and chain propagation on allylcarbinyl radicals, involving the donor–acceptor complexes:

The copolymerization occurs at a high rate even at low temperatures. Hence, the initiator is rapidly consumed. The radicals are generated in a large amount, which results in their recombination and formation of low-molecular-weight products. To obtain high-molecular-weight copolymers in high yield, it is necessary to prolong the effect of the initiator. This can be done by performing the copolymerization under heterogeneous conditions (in the bulk, so as to exclude dissolution of the forming PS). Another alternative is to perform homogeneous copolymerization at low temperatures (so as to raise the viscosity of the system, thus complicating the diffusion of macroradicals and lowering the termination rate).

The thermal stability of the PSs obtained was evaluated by differential thermal analysis. We found that the polysulfones are stable up to 200°C. Analysis of the gas phase shows that intense degradation of PS

starts above 200°C and is accompanied by SO_2 evolution. Kinetic analysis shows that the degradation occurs in a single step. The calculated activation energy (E_a = 34.3–76.2 kJ mol^{-1}) and reaction order (n = 1.1–1.3) suggest the chain mechanism of PS degradation [10].

A GPC analysis of PSs showed that, despite relatively low polydispersity, they are nonuniform in molecular weight (the chromatograms are bimodal). The number-average and weight-average molecular weights of the synthesized PSs, determined with PEG as reference, are as follows: $\overline{M}_n \sim (350-470) \times 10^3$ and $\overline{M}_w \sim (500-760) \times 10^3$. A characteristic feature of PS is the presence of active functional groups. Therefore, irradiation of thin PS films causes structural changes. The prevalent process is photodegradation, as indicated by a decrease in the intrinsic viscosity [η] of solutions of the irradiated PSs, by an increase in the precipitation threshold in their turbidimetric titration due to decreased content of high-molecular-weight fractions, by a decrease in the slope of the integral curve (and the resulting broadening of the peak in the differential curve), and by a decrease in the quantum yield of degradation.

Thus, the copolymerization of VCPs with SO_2 can be regarded as spontaneous copolymerization of donor–acceptor complexes formed by the comonomers in the initial mixture. After thorough removal of hydroperoxides and instantaneous degassing of all the components, the copolymerization of VCP with SO_2 is insignificant. To obtain high-molecular-weight PSs suitable for use in microelectronics, it is necessary to perform the process at low temperatures in the presence of TBH.

EXPERIMENTAL

The IR spectra of PSs were recorded on a Specord M80 spectrometer, and the ^{1}H NMR spectra, on a Tesla BS-487B spectrometer (80 MHz, reference HMDS). The thermograms were measured on an MOM derivatograph (Hungary) in air at a heating rate of 5 deg min^{-1}.

The molecular weight was determined by gel permeation chromatography (GPC) and viscometry. Chromatographic analysis of PSs was performed on Covo (Czechia) and KhZh-1309 high-performace liquid chromatographs. The columns were packed, respectively, with microspherical silica gel Separon SGX and microspherical macroporous silica gel with grafted octadecyl groups Separon C-18; eluent DMF.

Turbidimetric titration of PSs was performed on an FEK-56M photoelectron colorimeter.

VCPs were prepared as described in [6] and were distilled before use from freshly calcined $CaCl_2$; SO_2 was dried by passing through a column packed with $CaCl_2$ and bubbling through H_2SO_4.

The monomers were washed first with 10% NaOH and then with 3% $FeSO_4$ to remove hydroperoxides, after which they were treated with water, dried over $CaCl_2$, and vacuum-distilled.

Copolymerization was performed in the bulk and in toluene or acetone by the following procedure. The required amount of SO_2 was condensed in a flask cooled with a dry ice–acetone mixture. Then the required amount of VCP containing the required amount of TBH was added to the cooled flask. The copolymerization was performed at temperatures of –10 to 0°C; the VCP : SO_2 molar ratio was 1 : 1.2.

After a certain time, the copolymers were precipitated, purified by reprecipitation from acetone into diethyl ether, and dried at 30–40°C in air.

The compositions of the copolymers were determined from the sulfur content, and the structures, by IR and ^{1}H NMR spectroscopy.

The viscosity of PSs was measured on an Ubbelohde viscometer at 25°C in cyclohexanone. All the PSs were tested for solubility in acetone, DMF, DMSO, cyclohexanone, 1,2-dichloroethane, toluene, and dioxane.

CONCLUSIONS

(1) Reactions of ethyl esters of vinylcyclopropanecarboxylic acids with SO_2 in the presence of tert-butyl hydroperoxide yield unsaturated polysulfones with equimolar ratio of the comonomer units. In the course of the copolymerization, both the double bond and the cyclopropane ring in vinylcyclopropane monomers are opened simultaneously; the copolymerization involves formation of a complex by the comonomers.

(2) The polysulfones prepared are thermally stable up to 200°C. Above this temperature, they decompose with evolution of SO_2. The polysulfones can be used as resists in microelectronics.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Fat-Polymeric Fillers: Synthesis, Properties, and Application

V. I. Chursin

Central Research Institute of Leather-Shoe Industry, Federal State Unitary Enterprise, Moscow, Russia

Received March 24, 2005

Abstract—Properties of the copolymerization products of acrylic monomers and esters of polyethylene glycol and unsaturated fatty acids were studied. The complexing power and leather-technological properties of fat-polymeric systems were analyzed as influenced by the acidity of the medium and the type of the monomer.

Polymeric products modified with fat-liquoring materials find increasingly growing application in leather production [1]. One of the methods for preparing these products is mixing of individual components yielded by dispersion into aqueous medium of fat-polymeric compositions. Among the drawbacks of such products are different resistances of the system components to changes in pH, rise in temperature, and exposure to chemicals. Depending on the treatment conditions, chemical compounds entering into the fat-polymeric composition are sorbed by the structural elements of the derma to different extents, which gives no way attaining uniform properties across the thickness and over the area of the ready-for-use leather. In our opinion, the greatest promise is offered by synthesis of the polymers in the presence of fats containing unsaturated groups that can be involved in copolymerization.

In this study, we examined the properties of fat-polymeric filling materials (Fetan) synthesized from acrylic monomers and esters of polyethylene glycol and unsaturated acids (OPEGs) with a high degree of unsaturation.

EXPERIMENTAL

We studied how the amount of the acid catalyst affects the properties of the products synthesized from acrylamide (AA) (Fetan 8, Fetan 16, and Fetan 30; the figures indicate the amount of sulfuric acid in units of 0.1% of the mass of the reaction system), as well as those based on glycidyl methacrylate (GMA), Fetan GMA. The copolymerization was done at 25°C at the monomer : OPEG : water volume ratio of 1 : 1 : 4.

The resulting products are viscous light yellow systems with the following characteristics: content of the base substance and substances extractable with organic solvents 24–26 and 7–9 wt %, respectively, and pH of the 5% (by weight) solution 3.0–4.0.

The fat-polymeric filler Fetan was examined spectrophotometrically, viscometrically, and turbidimetrically. The viscometric measurements were made on a capillary viscometer (d = 0.56 mm) at 20°C. The viscosity-average molecular weight $\bar{M}_\eta$ was calculated from the intrinsic viscosity [η] by the formula $[\eta] = 0.63 \times 10^{-4} M_\eta^{0.8}$, suggested for aqueous solutions of polyacrylamide (PAA) [2], since in both cases the initial monomer is AA.

We found that polymerization yields macromolecular compounds with $\bar{M}_\eta = (250-400) \times 10^3$. When Fetan is prepared in the presence of a large amount of H_2SO_4, the parameters [η] and $\bar{M}_\eta$ increase. Kritskaya and Ponomarev [3] reported that an increase in $\bar{M}_\eta$ during nonisothermal polymerization of AA may be due to enhanced activation in the presence of H_2SO_4. The $H^\bullet$ atoms, which are free radicals, can add at the double bond of the monomer molecule, thereby initiating copolymerization. Such initiation is not associated with decomposition of peroxides, since they were not used in the polymerization. The $\bar{M}_\eta$ of the fat-polymeric fillers under study increases in the order: Fetan 8 < Fetan 16 < Fetan 30. These results were confirmed by the turbidimetric data. We showed that the precipitation threshold for Fetan 8 is 1.5 times that of Fetan 30.

The structure and molecular-weight distribution (MWD) of the polymer are strongly affected by its ability to penetrate deep inside the derma and get bound to the functional groups of collagen. In the presence of a large amount of an acid catalyst, the polymer chain propagates more actively, which yields

fillers with high $\bar{M}_\eta$. It should be remembered that diffusion of the polymeric filler with a high $\bar{M}_\eta$ deep into the leather will be hindered, and Fetan 30 will be mostly deposited in loose layers and on the surface of the semifinished product. The particle size of the polymeric filler was estimated from the absorption intensity of the Fetan solution at various wavelengths, i.e., from the turbidity spectrum [4]. We found that the particle size is the largest for Fetan 30 (160–170 nm), and the smallest, for Fetan GMA (110 nm). The particle size for Fetan 8 and Fetan 16 lies within 140–160 nm.

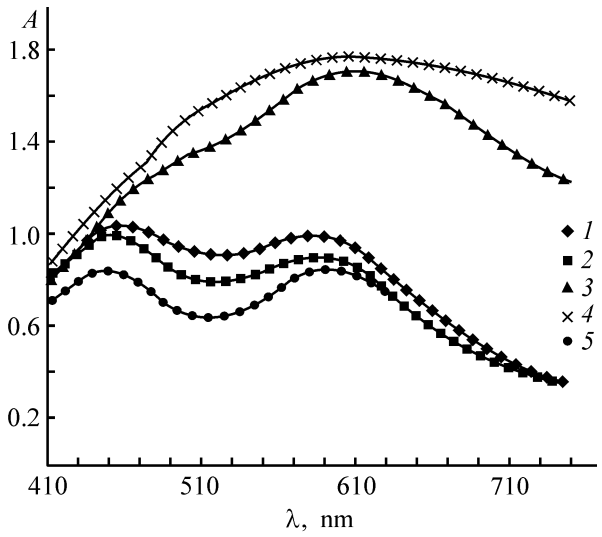

Fig. 1. Electronic absorption spectra of the solutions of the filler in the presence of CTA. (*A*) Optical density and (λ) wavelength. (*1*) CTA, (*2*) Fetan 8, (*3*) Fetan 16, (*4*) Fetan 30, and (*5*) Fetan GMA.

Additional information about copolymerization was derived from the absorption spectra of the initial components and end products. Table 1 shows that OPEG is characterized by an intense absorption band corresponding to stretching vibrations of the C=O bond of the ester group at 1738 cm^{-1}, as well as a band at 952 cm^{-1} corresponding to out-of-plane bending vibrations of the C–H bond in the >C=CH– group of oleic acid. It can be stated that the copolymerization is rather fast, because already 15 min after mixing of the initial components the spectra contain no absorption bands characteristic of the double bonds of AA and OPEG. Polymerization goes to high conversions of the initial components and is mostly complete within 1 h. In the spectra of the polymerization products, the intensity of absorption near 1650–1670 cm^{-1}, characteristic of the COO– groups, is enhanced, and a new band corresponding to sulfurcontaining groups of H_2SO_4 appears at 600–680 cm^{-1}. The absorption bands at 1095 and 1197 cm^{-1}, characteristic of the ester moieties, become more prominent. Thus, the absorption spectrum of the resulting products is similar to that of PAA (1110, 1340, 1450, 1670 cm^{-1}) [5], except for the presence of a broad band at 670 and the lack of a band at 1340 cm^{-1}.

In view of the fact that fat-polymeric fillers are used in the stage of the dye-fat liquoring processes, following the chrome aftertanning, it was of interest to study their interaction with the chrome tanning agent (CTA). Technologically, our results should be taken into account in substantiating the expediture of the CTA for fixing of fats and dyes in the final stage of fat liquoring. The interaction of Fetan with CTA was studied photometrically [6]. The absorption spectrum of the CTA solution contains two bands with characteristic peaks at 420 and 580 nm. Figure 1 shows the absorption spectra of the solutions containing Fetan and CTA in certain proportions. It is seen that, upon introduction of the CTA into a solution of fat-polymeric fillers Fetan 16 and Fetan 30, the optical density *A* strongly increases. The spectrometric curves do not contain the peak at 420 nm, characteristic of the CTA. This suggests that, upon increasing molecular weight of the filler in the presence of a larger amount of H_2SO_4, CTA can react with the carboxy groups of the polymer, yielded by acid hy-

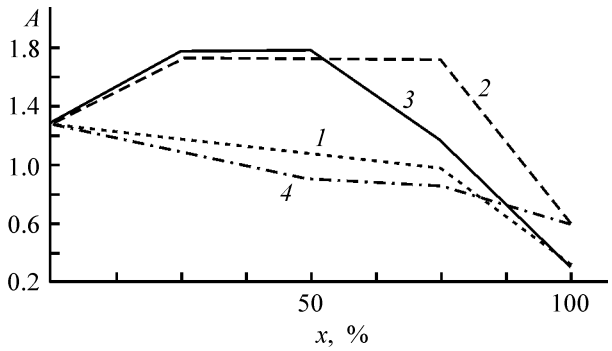

Fig. 2. Optical density A of the solution vs. the weight fraction of Fetan x, %: (*1*) Fetan 8, (*2*) Fetan 16, (*3*) Fetan 30, and (*4*) Fetan GMA.

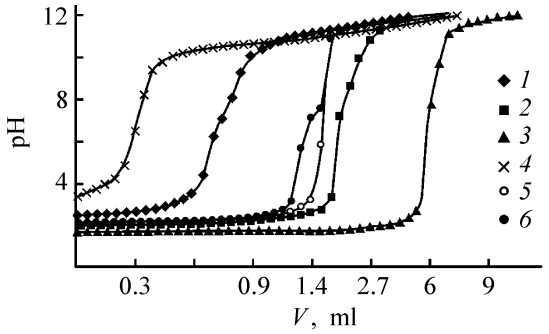

Fig. 3. Potentiometric titration of the initial components and copolymerization products. (V) Volume of the 0.5 N NaOH solution added. (*1*) Fetan 8, (*2*) Fetan 16, (*3*) Fetan 30, (*4*) Fetan GMA, (*5*) OPEG, and (*6*) AA.

drolysis of Fetan. Figure 2 shows that there is no complexing in the case of Fetan GMA. For Fetan 8, complexing can be observed even at the filler : CTA weight ratio of 75 : 25. Introduction of CTA into a Fetan 16 solution yields fairly stable complexes at the identical ratio of the components. This conclusion is of technological importance, as this allows optimization of the amount of CTA required for fixing of Fetan in leather. As the content of the carboxy groups increases due to acid hydrolysis, stable complexes are formed in the case when the weight fraction of Fetan 30 is 50%.

The potentiomatric titration curves of the initial components and copolymerization products (Fig. 3) show that, with increasing amount of the H_2SO_4 spent, the alkaline capacity of Fetan tends to grow. The identical runs of the curves suggest that polymerization of Fetan proceeds at the double bonds of AA and OPEG, without involving the functional groups of the initial components. A similar effect has been revealed earlier by Averina *et al.* [7] in a study of copolymers of MMA and triglycerides.

Thus, we confirmed the feasibility of preparation of fat-polymeric fillers based on acryl monomers and polyethylene glycol esters of unsaturated acids. With increasing acidity of the reaction system, the molecular weight and particle size of the polymer tend to grow, which suggests that this factor can be used in preparation of polymerization products with desired molecular weights. We carried out technological tests of the filler with a semifinished product intended for manufacturing of leathers for shoe top. With the Fetan fat-polymeric filler used in dye and fat liquoring processes in amount of 3% relative to the mass of the semifinished product, the amount of the CTA was, in accordance with the previously revealed relationships, 1% for Fetan 8 and Fetan 16 and 1.5% for Fetan 30. The technological tests of the new fat-polymeric filler in production of leathers for the shoe top (Table 2) showed that treatment with Fetan filler yields filled elastic leathers and affords a growth of the leather sample area relative to the reference sample. The largest gain in the thickness and area of the leather samples was exhibited by the samples filled with Fetan GMA and Fetan 30. The use of the fat-polymeric fillers in dye and fat liquoring processes decreases the amounts of the corresponding filling and fat liquoring materials by 20–30%, favors uniform distribution of fats, and ensures manufacture of high-quality competitive leathers.

Table 2. Characteristics of the leathers manufactured with the use of Fetan fat-polymeric fillers

Characteristic	Reference sample	Fetan 8	Fetan GMA	Fetan 16	Fetan 30
Gain, %:					
thickness	4.5	6.8	7.7	7.0	7.6
area	0.65	1.0	1.22	1.0	1.4
Elongation at a stress of 9.8 MPa, %	22.0	19.0	24.0	17.5	18.4
Elongation at break, %	48.0	39.0	39.0	42.0	41.0
Ultimate strength, MPa	28.0	23.5	25.5	26.5	26.0

CONCLUSIONS

(1) Raising in the amount of H_2SO_4 spent for polymerization during synthesis of fat-polymeric tanning agents based on acrylic monomers and esters of polyethylene glycol and unsaturated acids leads to an increase in the viscosity-average molecular weight of the polymer.

(2) Spectral studies showed that the expenditure of H_2SO_4 affects the ratio of the components during complexing in the copolymer–chrome tanning agent system.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Binding in Paper-Like Composites Based on Mineral Fibers

V. K. Dubovyi

St. Petersburg State Forestry Engineering Academy, St. Petersburg, Russia

Received May 24, 2005

Abstract—The structural and physical parameters of paper-like composites based on mineral fibers with aluminum polyhydroxo complexes as binders were determined and analyzed. Samples of the composites based on mineral fibers differing in the content of binders were analyzed by IR spectroscopy and electron microscopy. Formation of interfiber bonds in the materials studied was hypothesized.

The use of inorganic, mainly artificially prepared, mineral fibers as the base component of composites is one of the most intensively developed lines in modern paper technology. Paper-like composites based on mineral fibers exhibit a set of properties unachievable in principle for conventional paper and pressboard types based on plant fibers. Specifically, they are characterized by high thermal, chemo-, and biostability and resistance to various, in particular, hard radiations, as well as high filtration power, which allows a low aerodynamic resistance to be combined with a high coefficient of entrapment of submicron particles [1, 2].

However, despite these properties, applications of materials based on mineral fibers are yet limited. Mineral fibers are used in noticeable amounts in production of insulation materials and, to a lesser extent, of filtration materials. The reason is that, unlike plant fibers, mineral fibers cannot form interfiber bonds in paper sheets. Thus, the conventional paper production technology should be supplemented with introduction of special binders in order to obtain materials combining the advantages offered by the sheet form with unique properties of mineral fibers. The use of organic binders limits application of materials based on mineral fibers, since, at high temperatures and under exposure to aggressive media, binding additives degrade, which leads to degradation of the material as a whole. The properties of composites based on mineral fibers are manifested to the full extent when inorganic substances, in particular, aluminum compounds, are introduced as binders.

Theoretical concepts of how aluminum compounds exert their reinforcing effect on cellulose-based materials suggest that similar mechanisms are applicable to certain kinds of mineral fibers as well. In this study, we used $Al_2(SO_4)_3$ as a compound of this kind. This chemical is readily available and is widely used in paper production [3]. Aluminum sulfate proper is not a binder; rather, reinforcing effect is exerted by the products of its hydrolysis at a pH adjusted by a NaOH solution. Presumably, the resulting polynuclear acido complexes of aluminum can attract into their structure various ligands and, in particular, hydroxy ions occurring on the mineral fiber surface [4].

We examined glass fibers with average diameters of 0.2 and 0.7 μm, as well as kaolin and basalt fibers with diameters of 1.9 and 1.1 μm, respectively. A paper casting apparatus produced laboratory paper sheets (sheet-cast paper) from mineral fibers without and with $Al_2(SO_4)_3$. In the latter case, $Al_2(SO_4)_3$ was added in amounts of 20, 40, 60, and 80% relative to the fiber mass (recalculated for Al_2O_3). Casting was conducted at pH 7.0–7.5. The surface density of the cast paper varied from 15 to 80 g m^{-2}.

The strength and deformation properties of the cast paper were derived from the results of mathematical processing of the stress (σ)-vs.-strain (ε) curves.

The stress–strain curve obtained by processing the load (F)-vs.-elongation (ΔL) indicator diagram demonstrating the results of the static tensile tests allows analysis of the deformation process and is widely used in materials science as an integrated characteristic of the mechanical properties. Such a diagram was obtained for sheet paper-like materials based on mineral fibers, tested on tensile-testing machines equipped with a unit recording variations of the load and strain for the sample during the tests.

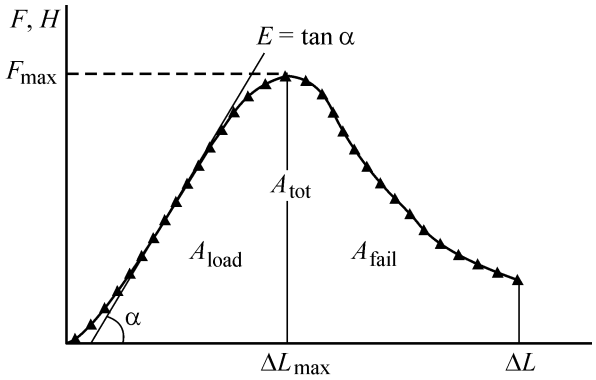

Fig. 1. Technique for calculation of the deformation characteristics.

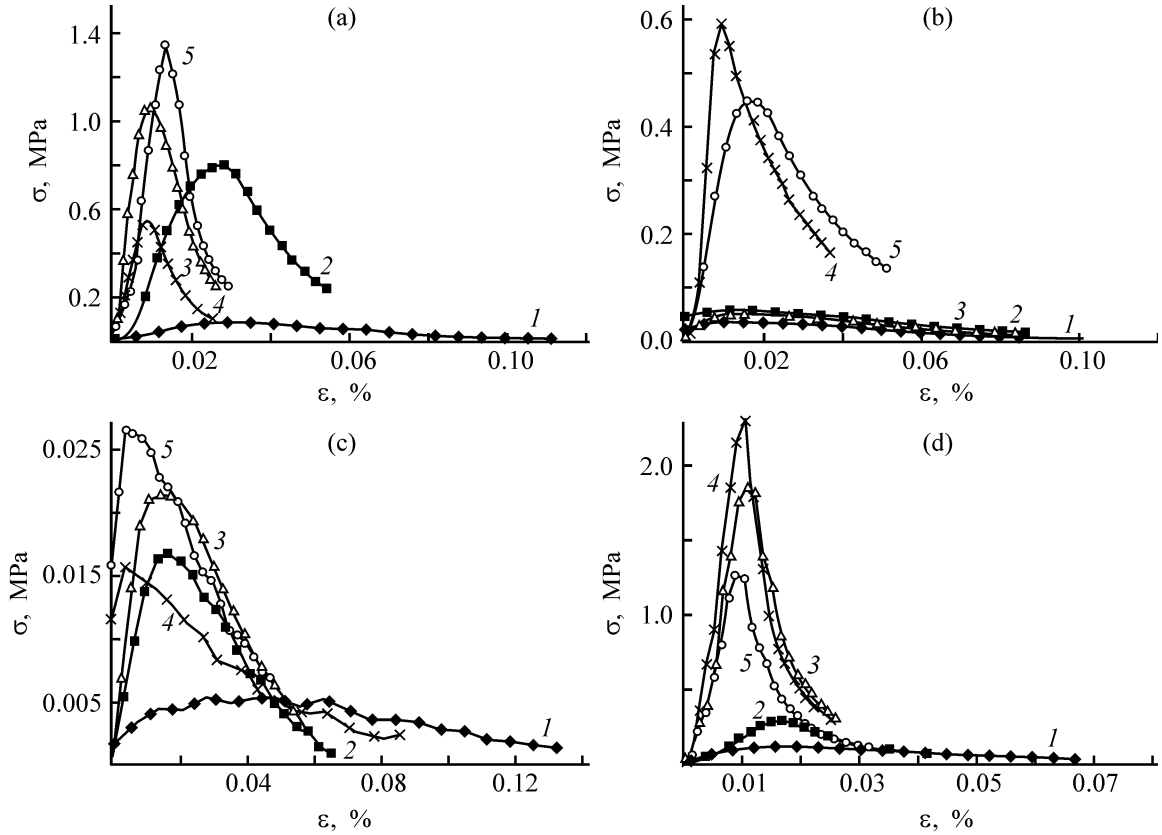

Fig. 2. Stress (σ) vs. strain (ε) curves for samples of the sheet materials from mineral fibers with a surface density of 50 g m^{-2}, differing in the content of aluminum sulfate (recalculated for Al_2O_3). $Al_2(SO_4)_3$ content, wt %: (*1*) 0, (*2*) 20, (*3*) 40, (*4*) 80, and (*5*) 100. Sample: (*1*) glass fiber 0.2 μm in diameter, (b) glass fiber 0.7 μm in diameter, (c) kaolin, and (d) basalt; the same for Figs. 6, 7.

In this study, we carried out measurements on a laboratory test complex comprising a Testosistema-105 tensile-testing machine and a PC.

Each sample tested was characterized by the length *L*, width *b*, and thickness δ, averaged over the measurements taken at several points. After testing each sample, the information about the characteristics of the sample and the testing results were transferred from the Testosistema-105 machine to the PC.

Mathematical processing of the results was carried out using the MS Excel table processor by a specially developed routine according to the scheme shown in Fig. 1. Mathematical processing on the PC of the experimental load–elongation curves, obtained in replicate runs, yielded an average curve consisting of 21 points, for each of which the following characteristics are calculated: force *F*; *H*; elongation Δ*L*, mm; stress σ, MPa,

$$\sigma = F/b\delta;$$

and strain ε, %,

$$\varepsilon = \Delta L/L.$$

The curve in Fig. 1 clearly exhibits two portions: up to the point corresponding to the maximal load (F_{max}, ΔL_{max}), when the sample preserves integrity, and after applying the maximal load, when the sample fails. There is no instantaneous failure; rather, the fibers are pulled apart, which requires applying certain force to overcome the friction forces [5].

Figure 2 shows the strain dynamics of the materials in the form of the stress–strain curves.

The rigidity in extension of a sheet material is estimated from the modulus of elasticity (E) characterizing the slope of the initial section of the stress–strain curve, i.e., the response of the material to the force applied.

Without binder, all the samples under study exhibit an extremely low strength, which could be enhanced by increasing the mass per square meter, which will yield more reliable results. The poorest strength and strain characteristics were exhibited by a sheet material prepared from kaolin fibers, and the best strength and rigidity, by basalt fiber materials and small-diameter glass fibers. An increase in the diameter of glass fibers deteriorates the properties by decreasing the number of the fibers per unit volume and, accordingly, that of interfiber contacts.

The σ–ε curves of the kaolin fiber samples and of the glass fiber samples with the diameter of 0.7 μm are flat near the peak, i.e., a very weak structure breaks very smoothly, and the fibers virtually do not resist pulling apart.

By contrast to paper and pulp materials, the σ–ε curves of the mineral fiber sample exhibit a pronounced reverse branch after passing the peak. This suggests that the material does not fail instantaneously, and the fibers being pulled apart exhibit a certain resistance by virtue of the friction forces. The relative fraction of the total area under the curve for the area after failure is about the same.

The binder not only improves the deformation and strength characteristics, but also affects the character of deformation of the sheet material under extension (Fig. 2). We showed that the material gets not only stronger but also more rigid, which is accompanied by a decrease in the extensibility of the material: the peak in the curves shifts toward the ordinate.

In extension of a fibrous material containing a binder, interfiber binding forces are specifically responsible for the increasing rigidity of the structure and its response to the force applied. This follows from the stress–strain curves: a steeper portion of the curves in the loading branch corresponds to the samples containing a larger amount of the binder. The reverse runs of the curves after the peak are similar in length and slope for most of the samples; they characterize the resistance of the fibers to pulling apart, when the interfiber contacts are broken.

The reinforcing effect in the presence of the binder varies between different materials. For example, for paper cast from the glass fiber with the diameter of 0.2 μm, the reinforcing effect is manifested even with 20% $Al_2(SO_4)_3$ (recalculated to Al_2O_3), and for the paper cast from glass fiber with a diameter of 0.7 μm, a comparable effect requires introduction of 60–80% additive.

The nature of the mineral fibers also affects the deformation and strength characteristics of the samples prepared using a binder. Even with the binder, the kaolin fiber material remains very weak. The strength of the samples increases in the order kaolin < glass fiber 0.7 μm in diameter < glass fiber 0.2 μm in diameter < basalt.

The deformation characteristics of the materials based on mineral fibers suggest that the strength and rigidity of the samples increase upon introduction of $Al_2(SO_4)_3$ and adjustment of pH to 7.0–7.5. This confirms formation of interfiber bonds, which are stronger than the permanently acting friction forces and intermolecular interaction forces.

To elucidate the nature of the interfiber bonds formed, we carried out an IR study of the samples. They were prepared from a formulation similar to that used for studying the deformation characteristics, though with a surface density of 5–15 g m^{-2} to ensure the required IR transmission.

The transmission spectra of the samples were measured on a Specord IR spectrometer in the range 2700–3800 cm^{-1}, corresponding to the vibrational frequencies of the hydrogen-bonded OH groups. The spectra were recorded with a resolution of 2 cm^{-1}.

The characteristic lengths of the hydrogen bond in the samples under study were estimated by the band shape analysis.

The analysis of the shape of the OH absorption band was based on the previously used [6] ratio of the hydrogen bond length d to the OH absorption

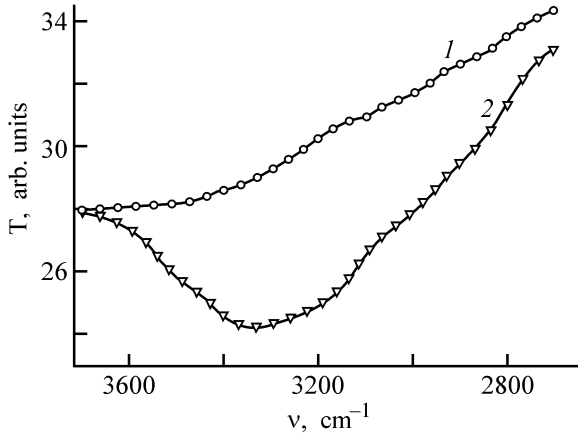

Fig. 3. Fragments of the IR spectra of the samples in the region of the OH vibrational frequencies. (*1*) with binder and (*2*) without binder. (T) Transmission, and (ν) wave number.

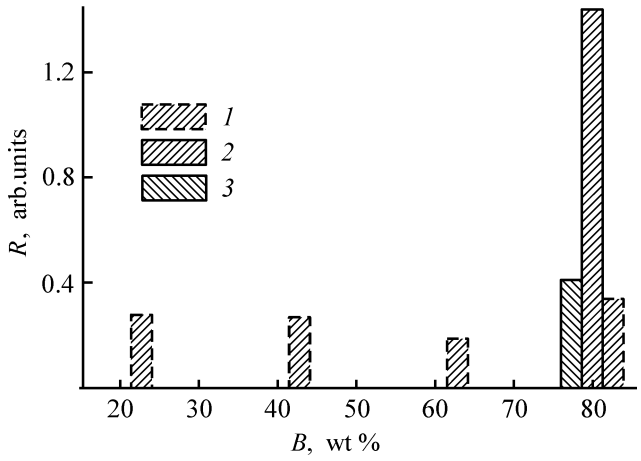

Fig. 5. Ratio of strong to weak H bonds, *R*, vs. the amount of the binder *B* (recalculated to Al_2O_3). (*1*) Fiber glass 0.2 μm in diameter, (*2*) kaolin fiber, and (*3*) basalt fiber.

frequency. Using this approach, we studied formation of the composites based on mineral fibers and aluminum hydroxo complexes as influenced by the hydrogen bond.

The shape of the OH absorption band was analyzed using the empirical ratio of the frequency ν of vibrations of the proton in the OH groups to the distance *d*, Å, separating the proton from the nearest oxygen atom.

$$\nu = A - B\exp(-d/C).$$

Here, *A*, *B*, and *C* are numerical coefficients calculated using published data [7], $A = 3590$ cm^{-1}, $B = 3.04 \times 10^{11}$ cm^{-1}, and $C = 0.13$ Å.

Figure 3 shows fragments of the IR transmission spectra of the basalt fiber samples in the range corresponding to stretching vibrations of the OH group. It is seen that 80% of the $Al_2(SO_4)_3$ binder introduced (recalculated to Al_2O_3) gives rise to a broad asymmetric absorption band. To analyze the shape of the absorption band, it was decomposed into Gaussians (see an example of decomposition into two Gaussians in Fig. 4). It is seen that such a decomposition fairly satisfactorily describes the experimental absorption band for the basalt fiber. The Gaussian with a maximum at 2950 cm^{-1} corresponds to a stronger hydrogen bond [a smaller distance to the nearest oxygen atom (d = 2.65 Å)], and the Gaussian with a maximum at 3320 cm^{-1}, to a weaker hydrogen bond [(d = 2.77 Å)]. The accuracy of resolution over the curve area was ca. 1%. In the frequency range under study, the shape of the absorption band varied with the kind of the mineral fibers and with the percentage of the $Al_2(SO_4)_3$ introduced, which can be interpreted in terms of the change in the strength of the hydrogen bond. To quantitatively estimate the ratio of the strong to weak hydrogen bonds, we determined the ratio of the areas of the corresponding Gaussians. Figure 5 demonstrates how the ratios of the strong to weak hydrogen bonds are influenced by the amount of $Al_2(SO_4)_3$ introduced.

Our results show that the samples under study contain interfiber bonds which, according to their nature, can be categorized as hydrogen bonds, i.e., those involving OH groups.

The strength of the hydrogen bond as determined by the distance between the hydrogen and oxygen atoms does not fully characterize the efficiency of the interfiber binding, since integrated assessment requires information about the area of the contacts. It should also be noted that the materials prepared for

IR spectroscopy had a low mass per square meter. The degree of retention of the binder in them is very low. Moreover, it is necessary to take into account the possibility of incorporation into the sphere of aluminum polyhydroxo complexes of other ligands in addition to the surface OH groups entering into the composition of mineral fibers. Thus, the IR data can be regarded as a qualitative confirmation of the occurrence of bonding via OH groups.

To understand more clearly the nature of binding in the presence of binders, we carried out optical- and electron-microscopic studies of the samples based on mineral fibers.

The surface and the internal structure of the samples were examined on an MBB-1 microscope in the ordinary white transmitted light using ×20 lenses and ×40 and ×70 water-emulsion lenses, as well as in the phase contrast mode with ×10f, ×20f, and ×40f lenses. The micrographs of the samples were obtained with an optical microscope using an MFNE-1U4,2 automatic microphotographic attachment.

The surface of the samples was examined at ×620 to ×7200 magnifications in a JSM-32C (Jeol) scanning electron microscope.

The samples were preliminarily mounted on stages and then coated with a Pd + Au alloy film on a JFC-100 (Jeol) ion sputtering setup. Stereo images were obtained with a Mantya 6 × 7-cm photo camera.

It is seen from the micrographs that the glass fibers 0.2 μm in diameter (Fig. 6a) have a smooth surface and a uniform internal structure. In the sheet, fibers are bent and curved, and thinner fibers are roundly bent into loops 5–6 μm in diameter. The glass fibers 0.7 μm in diameter are more linear, though slightly curved (Fig. 6b). The basalt fibers have a smooth surface, and their diameter varies along their length. The internal structure of the fibers is uniform (Fig. 6c). The kaolin fibers have a smooth, clean surface; they occur in a bent state over a wide thickness range. They have a uniform internal structure and are virtually transparent (Fig. 6d). The smooth surface of the mineral fibers suggests insignificant influence of the friction forces on the interfiber binding in the paper-like materials under study.

With increasing amount of the $Al_2(SO_4)_3$ introduced, the binder starts to deposit in the form of "lumps" growing in size (Figs. 7a–7d). At the maximal amount of $Al_2(SO_4)_3$ (80% relative to the mass of the fiber) (recalculated to Al_2O_3), the interfiber contacts are covered with the binder, which creates structures typical of the paper-like composites with the nodal

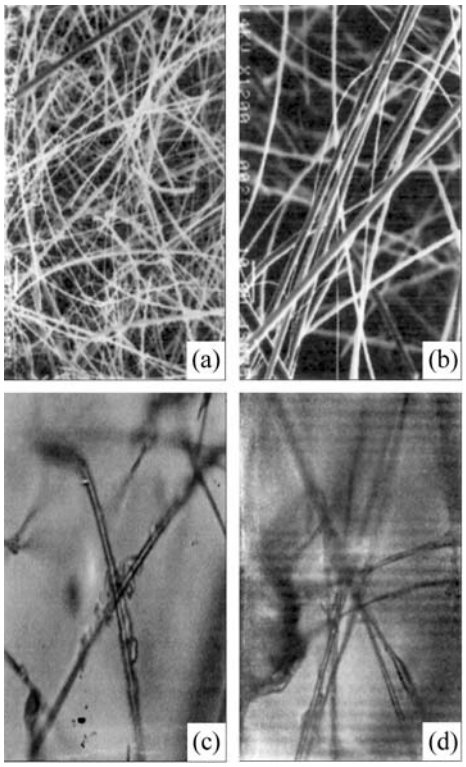

Fig. 7. Electron micrographs of the samples based on the mineral fibers with the binder (80% relative to the fiber mass, recalculated to Al_2O_3).

localization of the binder and fairly large pores [8]. The stress–strain curves (Fig. 2) correspond specifically to this type of the structure.

CONCLUSIONS

(1) A comprehensive study of the binding in materials based on mineral fibers containing inorganic binder, such as aluminum polyhydroxo complexes, showed that, upon introduction of this binder into a formulation based on mineral fibers, the strength of the paper-like composites prepared by wet molding increases.

(2) Formation of hydrogen bonds (presumably, via incorporation of the surface OH groups of the mineral fibers into the sphere of aluminum polyhydroxo complexes) was confirmed.

(3) It was demonstrated that the structure of the materials based on the mineral fibers studied can be characterized as a porous composite with the binder occurring at the interfiber contact sites.

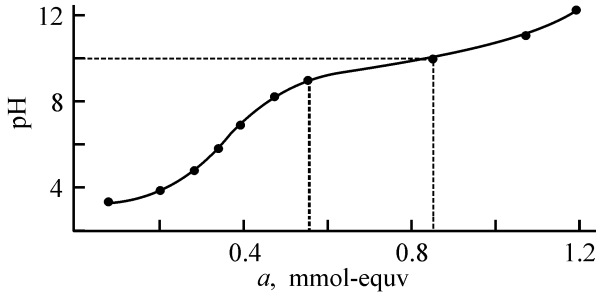
Abstract—A technique was developed for desorption of gold(I) from a strongly basic resin containing guanidinium sorption sites with aqueous-organic alkalis.

Strongly basic resins containing quaternary ammonium cations as sorption sites are widely used for industrial recovery of gold(I) from cyanide-containing aqueous alkalis. Gold(I) is desorbed from these resins with acidic aqueous thiourea. This procedure is hazardous and expensive. Furthermore, these resins must be treated before sorption with acid to remove cyanide complexes of nonferrous metals and iron [1].

Anion exchangers containing basic nitrogen sorption sites, among them guanidine derivatives, sorb gold(I) from cyanide-containing aqueous alkalis. However, desorption of Au(I) from these sorbents with aqueous alkali is inefficient. For example, in eluting Au(I) from a resin containing *N*-(6-aminohexyl)-*N*′-butylguanidinium sorption sites ($pK_a \sim 12$) with 10% aqueous alkali, only 40% of gold passes into the eluate. Under the same conditions, the degree of gold desorption from a resin containing 1,5,7-triazabicyclo-[4.4.0]decene-5 sorbing groups ($pK_a \sim 16$) is only 1%. From resins with different sorbing amino groups separated by di- and triatomic hydrocarbon bridges containing alcoholic groups, 35–65% of gold is desorbed with 0.01–4 M aqueous alkali [2].



These data show that a significant fraction of gold(I) sorbed on resins under consideration cannot be eluted from them with aqueous alkali.

It is known that the acid ionization constants of organic compounds depend on the solvent. For example, pK_a of ammonium salts in water–alcohol mixtures decreases linearly with increasing alcohol concentration and sharply decreases (by two pK_a units) at alcohol concentrations of 60–70% [3]. Assuming that similar correlations occur for resins containing guanidinium cations, we can expect that, in going from aqueous alkali to solutions of alkali in water–alcohol mixtures or other appropriate aqueous-organic solvent with relatively low permittivity, the pK_a of the resin sorption sites decreases and, as a result, the desorption of gold(I) from the resins is facilitated.

EXPERIMENTAL

In our experiments, we used a strongly basic anion exchanger Purolite A-180 widely accepted in the hydrometallurgy of gold. This resin has the form of a poly(styrene–divinylbenzene) matrix modified with guanidinium cation as sorbing groups. To elucidate the acid–base behavior of Purolite in aqueous alkali, we carried out its potentiometric titration with aqueous NaOH.

The potentiometric titration curve (see figure) shows that, in alkaline medium, guanidinium cations

in Purolite are formed at pH up to 12. This means that the resin can sorb anions from aqueous alkali. The total anion-exchange capacity of Purolite is 1.2 mg-equiv g^{-1}. The inflection point in the potentiometric titration curve is due to the presence of foreign protonated species in the resin. The sorption capacity of the resin, calculated from the portion of the potentiometric titration curve in the pH range 9–12 corresponding to deprotonation of guanidinium cations, is 0.65 mg-equiv g^{-1}. This value shows that guanidinium groups in Purolite can efficiently recover anions from aqueous alkali.

Gold was recovered from the pulp in an counterflow device consisting of 10 series-connected pulp agitators. The resin was fed into the tenth and discharged from the fourth agitator. As pulp passed through agitator nos. 1–3, gold was leached from the ore with aqueous sodium cyanide. The results of these experiments are listed in Table 1.

Table 1 shows that after seven successive stages of sorptive leaching of gold with Purolite A-180, tailings containing 0.07–0.13 g Au/t are formed. Under these conditions, the resin capacity for gold recovery is 1%, which is sufficient for preparing a commercially acceptable final eluate.

As can be seen from Table 2, desorption of gold with 10% aqueous NaOH is inefficient, since more then 30% of gold remains on the resin.

We also studied desorption of gold from Purolite A-180 anion exchanger with 0.1 M NaOH solution in an aqueous–organic mixture. In these experiments, a weighed portion of the resin was contacted with the desorbing solution for 24 h at 45°C without stirring. After the first desorption stage was complete, the liquid phase was separated from the resin and analyzed for gold. The desorption procedure was repeated four times. After the fourth desorption treatment was complete, the resin was analyzed for gold. The results of these experiments are listed in Table 2.

Table 2 shows that solutions of alkali in aqueous–organic mixtures efficiently desorb gold(I) from the resin. After four successive desorption stages the residual gold content in the resin was 0.007–0.05%. Under these conditions, the gold content in the first eluate fractions was sufficiently high to use them for recovery of gold by electrolysis. The gold content in the final eluate was 1–2 g l^{-1}. After desorption of gold with aqueous alkali, the resin can be reused without regeneration.

CONCLUSIONS

(1) In recovery of gold from cyanide-containing leachates with Purolite A-180 anion exchanger, the tailings contain 0.07–0.13 g Au/t.

(2) Desorption of gold from Purolite A-180 containing approximately 1% dicyanoaurate(I) complex with solutions of alkali in aqueous–organic mixtures allows preparation of eluates with a gold content as high as 1–2 g l^{-1}.

Abstract—Extractive recovery of gold(I) from cyanide-containing aqueous alkali with guanidine dialkyl and diaryl derivatives was studied.

According to recent studies, alkyl guanidines show promise for extraction and sorption of dicyanoaurate(I) anions from aqueous solutions [1, 2]. To elucidate how the guanidine structure affects the efficiency of extractive recovery of gold(I) from aqueous cyanide solutions, we prepared and tested several guanidine derivatives

where R is isopropyl, isobutyl, octyl, cyclohexyl, phenyl, or benzyl.

Taking into account that alkylguanidines are poorly soluble in the solvents commonly used in extraction (benzene, toluene, xylene, hexane, kerosene), we tested some other solvents. We found that the best solvent for guanidine derivatives are aromatic and aliphatic amines.

EXPERIMENTAL

In our experiments, gold(I) was recovered from aqueous solutions containing dicyanoaurate(I) $[Au(CN)_2]^-$ (50 mg l^{-1}, 0.01 M) with solutions of dialkyl- and diphenylguanidines in both dichloroethane and 0.02 M amine–dichloroethane mixture. Gold was determined by atomic absorption technique on an AAS-30 device.

Disubstituted guanidines used in our experiments were as follows:

Guanidine	Yield, %	mp, °C
N,*N*'-dioctyl	53	98–160
N,*N*'-dicyclohexyl	62	157–158
N,*N*'-dibenzyl	94	176–178
N,*N*'-diisopropyl	99	62–64
N,*N*'-diisobutyl	99	153–154
N,*N*'-diphenyl	chemical pure	148–148.5

It is known that amines, among them aromatic amines, are capable of extracting gold(I) from cyanide solutions [3]. For example, on bringing 2,4-xylidine in contact with aqueous $[Au(CN)_2]^-$ at pH 8, approximately 20% of gold passes into the organic phase. On contact of 0.01 M *N*,*N*'-diisoropylguanidine in dichloroethane with Au(I) cyanide complexes in aqueous alkali at pH 9, 10.5, 11.4 and 12.5, gold is recovered to 99, 80, 43 and 20%, respectively. The extraction of gold from cyanide-containing aqueous alkali with alkylguanidine slightly increases with lengthening of alkyl substituents. For example, on contact of *N*,*N*'-diisobutyl- and *N*,*N*'-dioctylguaniine in dichloroethane with a solution of gold(I) in cyanide-containing aqueous alkali at pH 9, 10.6 and 12.3, the percentage of gold that passes into the organic phase is 93, 78, 41 and 96, 87 and 51 for the former and latter guanidine derivatives, respectively.

In going from 0.01 M *N*,*N*'-diisobutylguanidine in dichloroethane to its solution in 2,4-xylidine, the degree of gold recovery is 99% up to pH 12.5 at the contact time shorter than 5 min. A similar pattern is observed in extraction of Au(I) with *N*,*N*'-diisobutyl

1070-4272/05/7810-1712 © 2005 Pleiades Publishing, Inc.

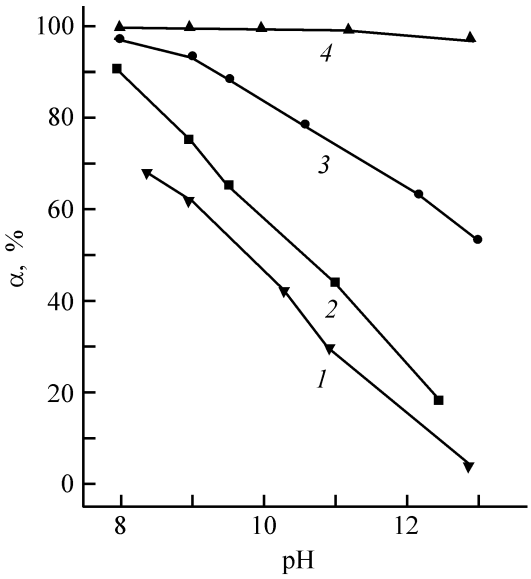
and *N,N'*-dioctylguanidine in 2,4-xylidine. The results obtained in extraction of gold(I) with solution of *N,N'*-dicyclohexylguanidine in multicomponent organic solvents are listed in Table 1.

We believe that the synergistic effect in extraction of Au(I) with guanidine–amine mixtures is caused by the fact that the guanidinium cation–$[Au(CN)_2]^-$ ion pairs dissolve in the amine. In the presence of an amine, the guanidine basicity significantly increases, and, as a result, so does the stability of the ion pairs in the alkaline media (up to pH 12). Under these conditions amine molecules solvate dicyanoaurate complexes.

Taking into account the fact that the addition of amines to guanidines improves the extraction of gold(I) from alkaline solutions, it was of interest to elucidate how the amine structure influences the recovery of gold(I) from cyanide-containing aqueous alkali. For this purpose, we studied the extraction of $[Au(CN)_2]^-$ with *N,N'*-diisobutylguanidine in the presence of both aliphatic and aromatic amines.

The figure shows the curves of gold(I) extraction from cyanide-containing aqueous alkali with *N,N'*-diisobutylguanidine–amine mixtures.

It is seen that, depending on their structure, amines either enhance or suppress extraction of gold with alkylguanidine. For example, in the presence of di- and tributylamines, the extraction of gold with *N,N'*-diisobutylguanidine decreases (curves *1*, *2*). This negative effect can be attributed to dissolution of guanidinium cation–$[Au(CN)_2]^-$ ion pairs in the aqueous phase. This assumption is confirmed by the fact that, on adding trioctylamine instead of tributylamine, gold(I) is completely extracted even at pH 13 (curve *4*).



We found that, in extraction of gold with guanidine derivatives in the presence of amines, the phase separation is decelerated in going from lower to higher amines. Thus, the organic phase composition can be chosen so as to ensure both the efficient extraction of gold(I) from cyanide-containing aqueous alkali and fast phase separation. One of extractants meeting these requirements is a solution of *N,N'*-diisobutylguanidine in trioctyamine–xylene mixture.

It was noted above that alkylguanidines with long-chain substituents show limited solubility even in amines. We found that, as opposed to alkylguanidines, their aromatic derivatives are readily soluble in amines.

Table 1. Extraction of gold(I) with 0.01 M *N,N'*-dicyclohexylguanidine in multicomponent solvent (50% 2,4-xylidine, 30% decanol, and 18% xylene

pH	Gold content, mg l^{-1}		Degree of gold recovery, %
	aqueous phase	organic phase	
8.0	0.5	68.2	99.3
9.4	0.6	68.1	99.1
10.2	0.6	68.1	99.1
11.7	0.6	68.1	99.1
13.0	0.6	63.1	91.8

Aromatic *N,N'*-diphenyl- and *N,N'*-dibenzylguanidines are fairly readily soluble in aromatic hydrocarbons and, in particular, in xylene. Therefore, we studied the extraction of gold(I) with solutions of aromatic guanidines in amine–xylene mixtures. Although 0.01 M *N,N'*-diphenylguanidine in aniline efficiently extracts gold(I) from aqueous alkali (pH 10–11), a significant fraction of the extractant dissolves in the aqueous phase. This drawback is absent in extraction with mixture of *N,N'*-dibenzylguanidine with higher amines, which are poorly soluble in water. The data on extraction of gold(I) from cyanide-containing aqueous alkali at different pH with *N,N'*-dibenzylguanidine in vari-

Table 2. Extraction of gold(I) with 0.01 M *N,N'*-dibenzylguanidine in multicomponent organic solvents

Amine	Solvent	Degree of gold(I) recovery, %, at indicated pH				
		8.4	10.5	11.8	12.6	13
	$C_2H_4Cl_2$	99	72	43	24	–
Aniline	Aniline	99	98	97	95	–
2,4-Xylidine	2,4-Xylidine	99	99	99	99	97
Trioctylamine*	Xylene	99	99	99	98	97
N-Hexylaniline*	"	99	99	99	99	98
N-Octylaniline*	"	99	99	99	99	99
N-Decyl-2,4-xylidine	"	99	99	99	99	99

* In the presence of trioctylamine (0.02 M).

ous solvents are listed in Table 2. These results show that gold(I) is quantitatively extracted with a solution of *N,N'*-dibenzylguanidine in 2,4-xylidine and trioctylamine–xylene mixture.

These data also show that *N*-alkyl aromatic amines can be used instead of trioctylamine as additives ensuring virtually complete extractive recovery of gold(I).

CONCLUSIONS

(1) Disubstituted guanidines efficiently extract gold(I) dicyanide complexes from aqueous alkali.

(2) Gold(I) is quantitatively extracted from cyanide-containing aqueous alkali with guanidine derivatives in combination with aliphatic and aromatic amines at widely varied alkali concentration.

Catalysis of the Reaction between 4-Nitrobenzoic Acid and Ammonia by Boric Acid + Polyehylene Glycol-400

L. Ya. Shteinberg

Institute of Chemical Technology and Industrial Ecology, Rubezhanskii Krasitel' Limited Liability Company, Rubezhnoe, Lugansk oblast, Ukraine

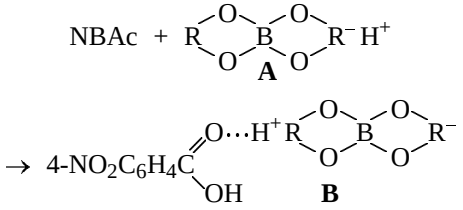
Received April 13, 2005

Abstract—Solvent effect on the synthesis of 4-nitrobenzamide by the reaction of 4-nitrobenzoic acid with ammonia in the presence of the catalytic system constituted by boric acid and polyethylene glycol-400 was studied.

4-Nitrobenzamide is the synthetic precursor of 4-aminobenzamide used for preparing a numbers of dyes [1].

In [2], we showed that the system constituted by boric acid and polyethylene glycol (PEG-400) effectively catalyzes the synthesis of 4-nitrobenzamide (NBA) by the reaction of 4-nitrobenzoic acid (NBAc) with ammonia in a mixture of 1,2,4-trichlorobenzene with *o*-xylene. It was noted that PEG-400 favors dissolution of boric acid and homogenization of the reaction mixture. In this study, we examined this catalytic reaction in various media:

$$\underset{\text{NBAc}}{4\text{-}NO_2C_6H_4COOH} + NH_3 \xrightarrow{H_3BO_3 + \text{PEG-400}} \underset{\text{NBA}}{4\text{-}NO_2C_6H_4CONH_2} + H_2O.$$



Catalysis by boron compounds of amidation reactions performed in aromatic and aliphatic hydrocarbons, including hexane, benzene, toluene, cumene, isomeric xylenes, and trichlorobenzene, was considered in [3–5]. To carry out the reaction of NBA with ammonia, we took protic and aprotic solvents differing in the polarity and boiling point. The results obtained and dielectric constants of the solvents ε are listed in the table.

As seen, the reaction readily proceeds in various aromatic and aliphatic aprotic solvents and their mixtures. With an increase in the reaction time and catalyst amount, the NBA yield grows becoming almost quantitative (run nos. 4, 7, 8).

In the series of solvents with low (and similar) polarity, the yield of the target product varies in parallel with the reaction temperature (run nos. 1–3, 5, 12): *p*-cymene (177°C) > decane (174°C) > white spirit (155–162°C) > *o*-chlorotoluene (155°C) > *o*-xylene (145°C). At close temperatures, the NBA yield varies in parallel with the solvent polarity in the order (run nos. 6, 7, 9) *o*-dichlorobenzene > 1,2,4-trichlorobenzene > decane. The same influence of the solvent polarity on the NBA yield is observed in amidation under similar conditions in binary mixtures *p*-cymene–nitrobenzene (run nos. 13–17). As can be seen, the NBA yield steadily grows with increasing nitrobenzene content, and accordingly, solvent polarity.

The highest NBA yields were attained in *o*-dichlorobenzene and 1,2,4-thichlorobenzene even without refluxing of the reaction mixture and distillation of the water released, which is evidently removed from the reaction zone with excess ammonia (previously, in catalysis by titanium and boron compounds, intense azeotropic distillation of the released water was necessary for obtaining benzanilide [9]).

As known [10], boric acid readily reacts with various alcohols, including glycols, and polyethylene glycols (HOROH), to give complexes **A** exhibiting elevated acidity. Such compounds can serve as acid catalysts in amidation. An increase in solvent polarity can favor stabilization of transition state **B** and acid catalysis:

B + NH_3 → NBAm + H_2O + **A**.

20	Triethylene glycol	23.19	175–180	6.0	33	0

* In all the experiments, the PEG-400 amount was taken as a half (in moles) of that of boric acid.

** The values of ε were taken from [6, 7]; for the mixture of *n*-cumene with nitrobenzene, the ε values were calculated using an additive scheme from the volume fractions of the components [8] (listed in table).

*** Filtrate from run no. 6 was taken as a solvent.

**** Filtrate from run no. 8 was taken as a solvent.

However, an attempt to obtain NBA in more polar solvents, glycols, failed (run nos. 18–20). A TLC analysis of the reaction mixture showed that NBAc rapidly (during 1 h) disappeared, but there was no NBA among the reaction products. Probably, in glycols, NBAc in the presence of boric acid forms glycol esters, which then do not react with ammonia.

A high polarity of the solvent may also favor homogenization of the reaction mixture. We found that, in amidation in low-polar decane (run nos. 5, 6), crystalline NBA precipitates already within 2 h. In more polar *o*-dichlorobenzene and 1,2,4-trichlorobenzene, the reaction mixture is homogeneous, amidation proceeds faster, and crystalline NBA precipitates only after cooling the reaction mixture to room temperature after the reaction is complete (run nos. 7–9).

Thus, with decane as a solvent, the reaction proceeds in the heterogeneous system gas–liquid–solid, formed within 2 h after the beginning of the reaction. Probably, the crystalline NBA precipitate is bound with a part of the catalyst, which may hinder its interaction with the reactants and the catalytic reaction as a whole.

To study the catalyst distribution in the reaction mixture, we performed experiment nos. 10 and 11, using as solvents the filtrates from separation of the solid target product in experiment nos. 6 and 8, respectively, without adding the catalytic system. It was found that the filtrate showed no catalytic power in decane (run no. 10), i.e., the whole amount of the catalyst was probably removed from the filtrate with NBA. In 1,2,4-trichlorobenzene, the filtrate showed fairly high catalytic power (run no. 11), thus confirming the uniform distribution of the catalyst. The degree of NBAc binding with ammonia can vary with the solvent polarity. As known, carboxylic acids form salts with amines. The reactivity of carboxylate anions and protonated amines in nucleophilic substitution at

the carbonyl carbon atom may be substantially lowered [11, 12].

Since NBA is not formed from NBAc ammonium salt in the presence of the catalytic system [2], it was of interest to test the stability of this salt under the reaction conditions.

We found that the NBAC ammonium salt undergoes no changes on heating to 120°C for 20 h without solvents or on washing with *o*-xylene or *o*-chlorobenzene at room temperature, followed by filtration and drying: its melting point remains unchanged. However, on heating of the suspension of NBAc ammonium salt in these solvents to 60–80°C, it decomposes with liberation of ammonia. Heating of such a suspension in *o*-xylene at 145°C for 10 min causes complete decomposition of the ammonium salt: after cooling, only NBAc is recovered from the reaction mixture. Probably, NBAc reacts in the free state but not as ammonium salt under the reaction conditions, even in the presence of a large excess of ammonia.

EXPERIMENTAL

Boric acid, NBAC, PEG-400, *o*-xylene, decane, 1,2,4-trichlorobenzene, *o*-dichlorobenzene, and nitrobenzene were of the same quality as in [2, 9, 13]. *o*-Chlorotoluene and white spirit were vacuum-distilled. Ethylene glycol, diethylene glycol, and triethylene glycol were dried over sodium sulfate and vacuum-distilled. *n*-Cymene was washed with sulfuric acid, water, solutions of potassium permanganate, sodium hydroxide, and again water, dried over sodium sulfate, and vacuum-distilled. NBA and ammonium salt of NBAc were prepared, the mixtures were analyzed, and the purity of the products was determined as in [2] with separation of an additional amount of the target product and vacuum distillation of the solvent from the reaction mixture.

CONCLUSIONS

(1) The catalytic system constituted by boric acid and polyethylene glycol-400 is the most efficient in synthesis of 4-nitrobenzamide from 4-nitrobenzoic acid and ammonia in aprotic solvents at 145–177°C. Under the reaction conditions, ammonium salt of 4-nitrobenzoic acid rapidly decomposes, with ammonia liberated and no 4-nitrobenzamide formed.

(2) In polar proton-donor glycols, 4-nitrobenzoic acid rapidly transforms into unidentified products without formation of 4-nitrobenzamide.

Acylation of Aspen Wood and Cellulose with *p*-Aminobenzoic Acid in Trifluoroacetic Acid and Thionyl Chloride

A. V. Protopopov, V. V. Kon'shin, and M. M. Chemeris

Polzunov Altai State Technical University, Barnaul, Russia

Received November 15, 2004; in final form, September 2005

Abstract—Cellulose esters with *p*-aminobenzoic acid were prepared.

Cellulose esters find growing use in industry due to their characteristics (e.g., light and weather resistance, hydrophobicity, and low processing temperature) and the renewability of raw materials for their production [1]. Esters of cellulose with aromatic amino acids (e.g., *p*-aminobenzoic acid) may exhibit biological activity; it is well known that all amino acids and their derivatives are biologically active substances. Cellulose by itself, as a matrix-carrier, is biologically inert and has sorption characteristics [2]. Therefore, new methods for synthesis of cellulose esters are of interest.

Synthesis and characteristics of cellulose esters containing aromatic substitutes have not been systematically studied, although some representatives (cellulose benzoate and phenylacetate) have been synthesized using chlorides of the corresponding acids [3] and trifluroacetic anhydride [4] as acylating agents.

Here, we suggest a method for preparing cellulose derivatives with the use of *p*-aminobenzoic acid (*p*-ABA), starting directly from pretreated aspen wood [lignocellulose material (LCM)], and describe the procedures of analysis for the content of the bound amino acid.

EXPERIMENTAL

Acylated derivatives of LCM (ALCM) were formed by the reaction of LCM with an acylating mixture containing *p*-ABA, trifluoroacetic acid (TFAA), and thionyl chloride (TC), with continuous stirring at constant temperature. Synthesis of ALCM can be represented by the scheme

$$p\text{-}NH_2C_6H_4CO_2H + CF_3COOH + SOCl_2 \rightarrow [p\text{-}NH_3C_6H_4COCl]^+CF_3CHCOO^- + ROH \xrightarrow[-CF_3CO_2H]{} p\text{-}NH_2C_6H_4CO_2R,$$

where ROH is cellulose or LCM.

ALCM was synthesized in a round-bottomed flask, into which *p*-ABA and TFAA were introduced. The mixture was kept at a required temperature, after that TC was added and the mixture was kept at the same temperature *p*-ABA chloride was formed. To the resulting acylating mixture we added air-dry aspen wood (content of α-cellulose 64.8, lignin 35.2 wt %), which was preliminarily extracted and prehydrolyzed to remove extractive substances and hemicelluloses. The reaction product, ALCM, was precipitated into ethanol, washed, and dried to air-dry state. Cellulose produced by the Priozersk Paper and Pulp Plant (content of α-cellulose 96 wt %) was acylated under the similar conditions to obtain acylated cellulose (AC).

Bound *p*-ABA was determined by the Kjeldahl method [5].

The degree of substitution of hydroxyls by *p*-ABA in the resulting products was evaluated by chemical analysis for nitrogen in percent relative to the cellulose weight; the amount of converted hydroxy groups of cellulose c_a was also evaluated:

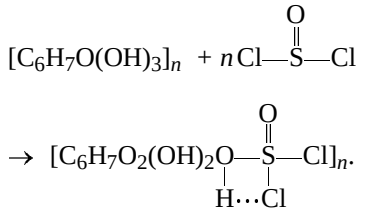
$$c_a = \frac{N \times 8.571n \times 100}{M}, \quad (1)$$

$$c_{OH} = \frac{17n \times 100}{M - 1.19n}, \quad (2)$$

where N is the content of bound nitrogen (wt %); $c_a = 8.571N$, content of *p*-aminobenzoate groups (wt %); 8.571, coefficient equal to the ratio of molecular weight of *p*-aminobenzoate group to the atomic weight of nitrogen; n, number of acyl groups in *p*-ABA, $n = 1$; c_{OH}, amount of acylated hydroxyl groups (wt %); and M, molecular weight of LCM or cellulose.

1070-4272/05/7810-1718 © 2005 Pleiades Publishing, Inc.

Content of bound nitrogen N in ALCM and AC (the amount of converted OH groups c_{OH} is given in parentheses)



Synthesis duration, h	Content of N (c_{OH}, wt %) at indicated synthesis temperature, °C				
	25	35	45	55	65
ALCM:					
1	3.82 (7.01)	3.95 (7.22)	3.34 (5.66)	3.66 (6.45)	2.34 (3.55)
2	5.57 (12.84)	4.70 (9.50)	3.56 (6.20)	3.31 (5.59)	3.02 (4.93)
3	5.93 (14.52)	5.42 (12.20)	5.01 (10.59)	5.36 (11.95)	5.24 (11.47)
5	6.86 (19.98)	6.14 (15.59)	6.10 (15.38)	5.18 (11.24)	–
AC:					
1	1.65 (2.32)	1.52 (2.12)	0.98 (1.30)	0.15 (1.18)	–
2	2.44 (3.75)	2.06 (3.05)	1.02 (2.36)	0.28 (1.35)	–
3	2.52 (3.87)	2.31 (3.51)	1.75 (2.50)	0.88 (2.15)	–
5	4.50 (5.81)	3.20 (5.32)	3.16 (5.26)	3.07 (5.04)	–

Solving jointly Eqs. (1) and (2), we find c_{OH}:

$$c_{OH} = \frac{17n \times 8.571/120}{1 - 1.19N \times 8.571/120}. \quad (3)$$

The analytical data for acylation products are listed in the table.

The data obtained show that acylation of *p*-ACA proceeds better at room temperature. With increasing synthesis duration, the content of bound nitrogen in the acylation products grows. The data suggest that acylation of LCM with the above mixture proceeds more completely than the similar acylation of cellulose. In this case, acylation of LCM proceeds predominantly at the OH groups of cellulose, since lignin contains 9–11% hydroxy groups, among which 3–4% are phenolic hydroxyls, which are not acetylated under these conditions. As shown previously [6, 7], TC forms a stable adduct with OH groups of cellulose at the crystallite surface, thus hampering the catalytic function of the solvent, TFAA. The presence of branched network of lignin in LCM retards the formation of the adduct with TC:

An IR analysis of ALCM and AC revealed the absorption bands in the ranges 3500–3000 (stretching vibrations of OH and NH_2 groups and the C–H bond of aromatic ring), 1730–1750 (stretching vibrations of CO groups in esters), and 1610–1450 cm^{-1} (weak bands caused by vibrations of aromatic ring).

CONCLUSION

In acylation of a lignocellulose material and cellulose with *p*-aminobenzoic acid in trifluoroacetic acid in the presence of thionyl chloride, the process is more complete with the lignocellulose material at 25°C.

Influence of the Caprolactam Quality on the Characteristics of Polycaproamide Thereof

N. P. Gankov, D. P. Nenov, and F. D. Radenkov

Ekomedbio EAD Business-Innovation Center, Sofia, Bulgaria
Technical University, Sofia, Bulgaria

Received March 2, 2005

Abstract—The influence of the caprolactam quality on the characteristics of polycaproamide thereof was elucidated.

Among the main factors governing the quality of polycaproamide (PCA) is the quality of the raw material, caprolactam (CL) [1].

We have found earlier [2] that caprolactam undergoes major changes during preparation for polymerization. Accumulation of the oxidation products begins even during transportation of liquid CL, as well as during melting of crystalline CL and storage of CL in the liquid state [3].

It was of interest to elucidate how the quality of commercial CL[1] satisfying the requirements imposed by the appropriate standard affects the characteristics of PCA thereof, using high-sensitive instrumental methods of analysis along with the conventional techniques.

First, we examined samples of commercial crystalline caprolactam, CL-1, prepared using phenol[2]: reference CL-2 sample prepared by recrystallization of CL-1 from dilute aqueous solution at room temperature; and sample of preoxidized caprolactam, CL-3, prepared by heat treatment of CL-1 in air at 90°C for 24 h.

The CL samples were polymerized at 260 ± 1°C in sealed glass ampules heated in an aluminum unit for 24 h. This time is sufficient equilibrium in molecular weight to be attained. Before being sealed the ampules containing CL were purged with nitrogen for a long time. The AG salt (3%) was added to the samples as a polymerization activator. No H_2O was introduced as activator and no acid, as chain-terminating agent, since they create superpressure and cause ampules to break. After polymerization was the complete, the ampules were cooled, and the polymer was crushed manually.

The CL samples under study were characterized by such parameters as compliance with the BDS 10780–88 requirements, content of carbonyl compounds (CCs) [4], and fluorescence intensity. The PCA samples werecharacterized by relative viscosity, Huggins constant K_H [5] characterizing the content of branched and cross-linked PCA structures, content of the abnormal acylation product (1,11-diamino-6-ketoundecane, DAKU) [6] and of carbonyl compounds, optical density [7], fluorescence intensity, and content of terminal carboxy groups.

We measured the relative viscosity of a 1% (by weight) PCA solution in H_2SO_4 (95.6 wt %) at 25°C using an Ubbelohde viscometer at the solvent outflow time of over 100 s. The CC and DAKU content in CL and PCA was determined polarographically [7]. The optical density of the solutions was measured on an SF-16 spectrophotometer (according to BDS 10780–88), and the fluorescence intensity, on a KFL-2-1 instrument. The optical density of the sulfuric acid solutions of PCA was measured by the modified Sbrolli technique [7] (300 mg PCA per 25 ml of 60 wt % H_2SO_4, wavelength 245 nm, rectangular cell with the absorbing layer thickness of 10 mm). The results obtained are listed in the table.

The table shows that the samples of commercial and additionally crystallized CL contain no carbonyl compounds. The freshly prepared CL should not contain oxidation products [8]. If these compounds are

CL-2	〃	〃	0.005	0.045	14.2	15.8	0.22	2.39	63.6	0.25
CL-3	0.44	0.36	0.034	0.130	21.2	28.9	0.18	2.26	68.6	0.36

formed during synthesis of CL, they are removed in the course of the final purification by rectification and distillation.

We have reported earlier [1, 9] that the oxidation products and, in particular, carbonyl compounds are accumulated in commercial CL only during its transportation and storage, especially in the molten state in the presence of atmospheric oxygen.

We found that special preoxidation of the initial caprolactam (CL-3) modifies its properties and the properties of the resulting PCA: the content of the carbonyl compounds increases to 0.44 in CL-3 and to 0.36 mg-equiv g^{-1} in PCA, and the fluorescence intensity and optical density become higher.

Interestingly, the content of CC in PCA is lower than that in the initial oxidized CL. This is consistent with the previously revealed relationship: The CC content in the polymer is independent of the degree of oxidation of CL, while the fluorescence intensity of the polymer correlates well with the degree of oxidation of the initial caprolactam. This is presumably due to the fact that the fluorescence of the polymer solution is associated with compounds that possess conjugated double bonds [10], which are formed by polyamidation of the oxidized CL. In polyamidation at high temperatures, hydroperoxides and their decomposition products contained in CL decompose to compounds having no aldehyde groups [11], which prevents their polarographic detection. This led to a conclusion that only a combination of the fluorescence and polarographic analysis can furnish true information about the thermooxidative processes in PCA.

We also found that oxidation of CL is essential for synthesis of polymers and deteriorates the quality of PCA, except for such a parameter as the DAKU content. By contrast, the DAKU content in the PCA obtained from oxidized CL-3 is lower than that in the PCA prepared from recrystallized CL-2. This may be due to the inhibiting effect exerted on the abnormal acylation by water released in side reactions that occur during the synthesis of PCA. The table shows that, with oxidized CL, the relative viscosity of the polymer solution decreases, and the content of the terminal carboxy groups increases, which suggests a decrease in the molecular weight. This is accompanied by a major increase in the Huggins constant (K_H = 0.36), which suggests the presence of branched and cross-linked structures in the polymer. For the PCA samples prepared from the oxidized caprolactam (CL-3) the Huggins constants exceed 0.25. This specific value of the Huggins constant in the absence of DAKU is due to the disturbance of the chemical homogeneity of PCA by side thermooxidative reactions proceeding during synthesis [12, 13].

Apparently, there is a complex correlation between the characteristics of the initial caprolactam and the quality of the resulting PCA. Undoubtedly, a major role is played by the degree of oxidation of the initial CL, but this parameter is not stipulated by the BDS 10 780 – 88 and, thus, is not monitored manufacture of Vidlon fibers.

CONCLUSIONS

(1) There exists a complex correlation between the characteristics of the initial caprolactam and polycaproamide thereof, on the one hand, and the degree of oxidation of caprolactam, on the other. This correlation is governed, above all, by the polyamidation conditions.

(2) True information about the thermooxidative processes occurring during synthesis of polycarpoamide can be furnished by combined fluorescence and polarographic analyses only.

(3) The content of 1,11-diamino-6-ketoundecane in polycaproamide prepared from oxidized caprolactam is lower than that in the polycaproamide prepared from recrystallized caprolactam. This is due to the in-

hibiting effect exerted on the abnormal acylation by water released in the side reactions that occur during synthesis of polycaproamide.

Professor Petr Petrovich Budnikov (To 120th Anniversary of His Birthday)

Petr Petrovich Budnikov, a prominent scientist and pedagogue, made an outstanding contribution to the development of chemistry and technology of silicates, binders, and construction materials. During many years, he had been a member of the Editorial Board of *Zhurnal Prikladnoi Khimii* (Russian Journal of Applied Chemistry) and was actively involved in its work.

P.P. Budnikov was born on October 21, 1885, in Smolensk. In 1906, he finished Smolensk secondary school and entered the chemical department of Riga Polytechnic Institute (RPI). This institute, founded in 1862, was the first polytechnic institute in Russia. The teaching level of chemical disciplines at the institute and its research activities were strongly affected by the already well-known, by that time, physical chemist W. Ostwald (1853–1932, 1909 Nobel Prize in Chemistry), who was a professor at Riga Polytechnicum in 1881–1887 [1]. In 1903, Ostwald was elected the first honorary member of Riga Polytechnic Institute. Budnikov mentioned, among his teachers, professor of inorganic and physical chemistry and department dean P.I. Walden (1863–1957), professor of organic chemistry K.A. Bischoff (1855–1908), and talented physical chemist M.G. Centnerschwer (1874–1944). Technological disciplines were taught by professors M. Witlich (1866–1933), E.W. Britzke (1877–1953), M. Glasenapp (1845–1923), and S.G. Shimanskii (1867–1931) [1–3].

In May 1911, Budnikov graduated with excellence from RPI and worked during a certain time at the dye-and-paint laboratory of the Institute under the supervision of professor Shimanskii. In 1912, Budnikov became an engineer at the electrocarbon plant at Kudinovo (Moscow Province), but soon moved to Lodz (Poland), where he started teaching chemistry and chemical technology at Lodz textile industrial college. At the beginning of World War I, in 1914, the college was evacuated to Moscow. In 1915–1918, together with teaching at the college, he headed a shop at a chemical plant in Moscow. In 1915, RPI was also evacuated to Moscow. After having graduated from this institute, Budnikov continued to maintain close relationships with a number of professors from RPI. The Brest peace treaty (March 1918) envisaged re-evacuation of RPI with the entire teaching staff, equipment, and library. However, a part of teachers and students decided not to return to Riga occupied by German troops. The remaining part of RPI served as a basis for organization of Polytechnic Institute in the town of Ivanovo-Voskresensk (now Ivanovo). The decree on founding the Institute was signed by V.I. Lenin on August 10, 1918. Budnikov was actively involved in the organization of the new institute and was elected first a docent, and in 1919, a professor of Ivanovo-Voznesensk Polytechnic Institute and headed the chair of chemical technology of mineral substances.

In 1926, Budnikov moved to Kharkov and was elected a professor of the chair of technology of mineral substances and technology of silicates at Kharkov Technological Institute. In 1927–1932, he also held a professorship at the chair of chemical technology of inorganic substances at Kharkov Engineering-Economical Institute. Budnikov was dean of the faculty of chemical engineering at Kharkov Technological Institute in 1934–1938, and dean of the faculty of silicate technology at the same institute in 1938–1941). In 1936–1939, Budnikov headed the chair of silicate technology at the Industrial Academy (Kharkov).

1070-4272/05/7810-1723 © 2005 Pleiades Publishing, Inc.

Together with being involved in intensive pedagogical and research activities at higher-school institutions of Kharkov (in 1926–1941), Budnikov paid a considerable attention to engineering, scientific-organizational, and public issues. In 1926–1928, he was chief engineer of the silicate plants ?managed by Kharkov City Council; in 1932–1941, he headed the department of chemically resistant ceramic materials at the Reasearch Institute of Silicates (Kharkov). In 1932–1941, he was chairman of the Kharkov branches of the Mendeleev All-Union Chemical Society and All-Union Scientific, Engineering, and Technological Society of the silicate industry. Beginning in 1935, Budnikov had long been a member of the Expert commission on chemical technology at the Higher Qualification Commission of the USSR.

In 1934, the degree of a doctor of technical science was conferred on Budnikov; in 1939, he was elected an academician of the Department of physicomathematical, chemical, and geological sciences, Academy of Sciences of the Ukrainian Soviet Socialist Republic. In the same year, Budnikov was elected a corresponding member of the Department of chemical sciences, Academy of Sciences of the USSR.

In 1941–1943, Budnikov lived in Ufa (Bashkir Autonomous SSR), where institutions of the Academy of Sciences of the Ukrainian SSR were evacuated. During this period of time, he was chairman of the Department of physicomathematical, chemical, and geological sciences, Academy of Sciences of the Ukrainian SSR.

Beginning in the autumn of 1943 and till the end of his life, Budnikov was a professor at Mendeleev Institute of Chemical Engineering in Moscow and headed the chair of general silicate technology.

Budnikov's scientific legacy is vast. The evidence concerning his published works and numerous inventor's certificates can be found in a publication from the series "Materials on Biobibliographies of Scientists from the USSR," devoted to Budnikov [5]. The same book, as well as other publications [6–8], makes a brief analysis of his scientific, pedagogical, and public activities. Budnikov has been the subject of numerous journal publications, listed (till 1965 inclusive) in [5].

The following principal areas of scientist's research can be distinguished: physicochemical properties of oxide and silicate systems, refractory and highly refractory materials and compounds, ceramic materials, binders and cement, methodological issues.

In the first of the areas mentioned, Budnikov paid a considerable attention to analysis of reactions in liquid and solid phases; mechanism, thermodynamics, and kinetics of reactions in solids; and control over reaction rates. Investigations of this kind are important for solving a large number of problems in inorganic materials science. These studies were partly summarized in the monograph *Reaktsii v smesyakh tverdykh veshchestv* (Reactions in Solid Mixtures), in coauthorship with A.M. Gistling, Moscow: Gostroizdat, 1961, 423 pp.). Budnikov with co-workers studied, using various methods, phase diagrams of a large number of oxide systems, including those containing oxides of rare and rare-earth metals, and refined to a substantial extent the state diagrams of systems that are the most important for the technology of silicate systems. The scientist performed extensive studies of high-temperature sintering of systems of interest for nuclear power engineering.

Widely known and highly practically important were Budnikov's studies of the physicochemical properties of gypsum and its varieties. His monograph, *K issledovaniyu gipsa* (To a Study of Gypsum, Leningrad: Akad. Nauk SSSR, 1930, 180 pp.), was reprinted with supplements in 1933 and 1943. These studies served as basis for the development of quite a number of cement brands with various properties.

Numerous studies of refractories, including their new types, were concerned with thermal apparatus for widely diverse fields of industry: metallurgy, power engineering, and cement, glass, and chemical industries. Budnikov was the first to obtain and study new highly refractory materials, made an important contribution to the development of scientific foundations for manufacture of articles with an mp > 2000°C from pure beryllium, zirconium, and aluminum oxides, and developed the technology of hot compaction of metal oxides to obtain complex-shaped articles.

Budnikov paid a considerable attention to the most important ceramic material, porcelain. He demonstrated the possibility of improving the working parameters of insulating porcelain by introduction of various additives. His studies devoted to use of zirconium dioxide favored the improvement of domestic brands of ceramic materials. His works in the field of ceramics (including those chemically resistant), glasses, and enamels led to a pronounced improvement of the technology of their manufacture and to expansion of their application fields. The book published by a group of authors headed by Budnikov, *Tekhnologiya keramiki i ogneuporov* (Technology of Ceramics and Refractories), Moscow: Izd. Lit.

Stroit. Mater., 1950, 575 pp., was later reprinted and strongly affected the training of specialists in this field.

Studies of the physicochemical foundations and manufacture technology of binders and cement were widely represented among Budnikov's works. According to the available data [8], the number of his printed publications exceeds 1600. Budnikov was the author of a number of monographs, textbooks, manuals, original studies, and 80 inventions. He was many times a participant of international congresses and conferences, studied the organization of higher education in countries of Western Europe and in the United States, and visited a large number of foreign plants. Budnikov was elected a member of the American Ceramic Society (1924), member of the German Ceramic Society (1929), honorary member of the Czechoslovak Ceramic and Glass Society (1934), and academician of the Polish Academy of Sciences (1956).

Budnikov was awarded honorary titles of the Honored Scientist and Technologist of the Ukrainian SSR (1943) and Russian Soviet Federative Socialist Republic (1961), and, three times, the State Prize of the USSR. Budnikov's scientific, pedagogical, and public activities were honored with the highest State awards.

Petr Petrovich Budnikov died on December 6, 1968, at the age of 83.

REVIEWS

Electron–Proton Effect in Catalysis

K. K. Kalnin'sh

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received October 24, 2005

Abstract—The essence of the electron–proton effect is described with donor–acceptor complexes of quinones with hydroquinones as example. It is shown that this effect frequently occurs in organic chemistry and plays an important role in noncatalytic and catalytic reactions.

INTRODUCTION

Catalytic processes play an enormous role in organic and bioorganic chemistry. The essence of the catalytic effect is a decrease in the energy barrier of a chemical reaction, resulting in acceleration of the reaction. Thanks to the catalysis, many reactions can be carried out at common temperatures and pressures. Particularly high performance and striking specificity are shown by natural catalysts, enzymes, ensuring concerted occurrence of numerous biochemical reactions at very high rates.

In this review we discuss a new phenomenon that we discovered, the electron–proton effect underlying the acid–base catalysis. It is impossible to adequately account for a catalytic decrease in the energy barrier of chemical reactions without considering this effect. The electron–proton effect is a physical phenomenon arising from concerted interaction of the fast motion of electrons and slow motion of protons. The effect is manifested in a considerable decrease in the energy of the excited levels of an electron donor–acceptor (EDA), or charge-transfer, complex under the action of an intra- or intermolecular hydrogen bond.

The EDA interactions and H bonds are so-called specific intermolecular interactions. Their energy is usually low compared to the energy of chemical bonds (~100 kcal mol^{-1}), being as low as 3–5 kcal mol^{-1}. The EDA interactions are associated with an overlap of the electronic shells of molecules (frontier orbitals) and are characterized in the ground state by a small shift of the electron density from the donor molecule to the electron-acceptor molecule. Under thermal, electrical, or photochemical excitation of sufficient energy, EDA complexes can pass to an electronically excited state in which an electron is fully transferred from the donor to acceptor. A characteristic feature of EDA complexes is that their electronic spectra contain absorption bands corresponding to the intermolecular electron transfer. The frequency of this band is unambiguously determined by the ionization potential of the donor I_D and electron affinity of the acceptor E_A.

In the excited state, an EDA complex transforms into a neutral or charged chemically active radical pair (or biradical), which subsequently undergoes radiative (luminescence) or nonradiative (chemical reaction or energy dissipation) deactivation. From the chemical viewpoint, EDA interactions are redox reactions, also characterized as electron transfer reactions.

In a hydrogen bond, a proton donor DH interacts with electron-donor groups of a proton acceptor A; depending in the extent of this interaction, the proton H^+ is either localized at the donor molecule DH and only slightly shifted along the hydrogen bond D–H···A toward the acceptor A, or fully transferred to the acceptor A: $D^-\cdots H-A^+$. The latter case is a proton transfer reaction occurring in the vibrationally excited state of a hydrogen bond. Hydrogen bonding is a kind of acid–base interactions.

Charge-transfer complexes and hydrogen bonds are traditionally studied independently from each other and not in connection with each other, although it is quite obvious that these two kinds of intermolecular interactions should exert a certain influence on each other, and their effect on physical and chemical processes should be combined. In terms of the electronic states, the effect of an H bond on EDA complexes consists in a decrease in the energy and lifetime of the lowest excited levels corresponding to charge (electron) transfer; however, only in a few separate papers we can find experimental evidence for this conclusion. Published facts of the mutual influence of charge-transfer complexation and H bonding are not summarized and correlated, and they give no grounds for any far-reaching conclusions. No attempts were made to evaluate this influence quantitatively, which could

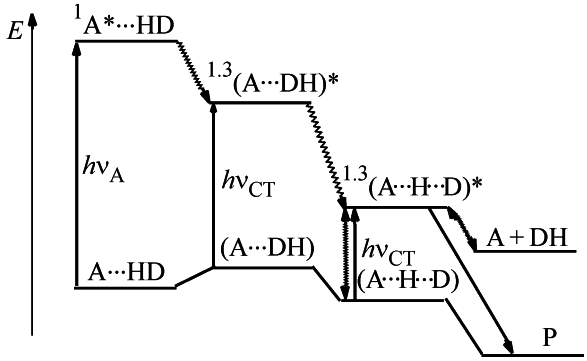

Fig. 1. Scheme of energy levels for photochemical and thermal processes.

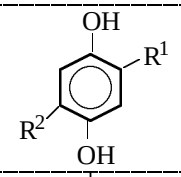
impart predictive power to reasoning about the role of hydrogen bond in electron-transfer processes.

In this connection, discovery of the electron–proton effect [1–10] is of principal importance. This discovery reveals a fundamental relationship between the electron donor–acceptor and proton donor–acceptor (PDA) interactions of molecules. The spectral manifestation of the effect is an appreciable (by 1.5 eV and more) decrease in the energy of excited levels of an EDA complex upon H bonding. This effect underlies such physical phenomena as luminescence quenching with hydrogen bond or paramagnetism of hydrogen-bonded compounds; it accounts for the occurrence of numerous and diverse reactions involving transfer of an electron and a proton (a hydrogen atom in total). The electron–proton effect plays an extremely important role in acid–base enzymatic catalysis.

1. ENERGY DIAGRAM FOR PHOTOCHEMICAL AND THERMAL PROCESSES

Several types of catalysis are considered in the literature: acid and base (usually termed acid–base), bifunctional, coordination, organometallic, etc. In each case, the corresponding specific interactions (e.g., hydrogen bonding, interactions involving donor and vacant orbitals of a transition metal catalyst) ensure the main and the most important catalytic effect (in accordance with our concept [1]): a decrease in the energy of the electronically excited state of the catalytic reaction complex to the level corresponding to thermal energy.

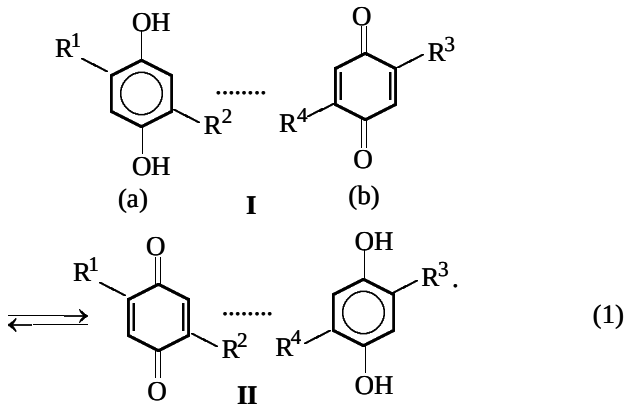
Since the probability of occurrence or the rate of a chemical process is determined by the energy of the excited complex, the lower this level lies (Fig. 1), the higher its population and the larger the number of elementary reaction events occurring in unit time, and hence the higher the reaction rate. The vertical straight lines in Fig. 1 show transitions from the ground state to an excited level of an H-bonded complex A···HD and to electronically excited levels of an electron donor–acceptor complex (A···DH)* and $^{1.3}$(A···H···D)*, shifted toward lower energies. The energy gap between the latter level characterizing an EDA complex with a hydrogen bond and the level of the free reactants in solution A + DH is narrow and can be readily overcome in the course of thermal excitation of molecules under common conditions.



The scheme in Fig. 1 illustrates the simplest case of catalysis by a hydrogen bond in an excited state of an EDA complex. It is important that here we deal with the excitation of an electron donor–acceptor complex and not of a hydrogen-bonded complex. If the labile hydrogen atom in the electron-donor molecule DH will be replaced by the CH_3 group, the hydrogen bond between the donor D–CH_3 and acceptor A will not be formed, and the catalytic decrease in the energy levels in this system will not take place. Within the traditional concept, the two above-considered cases (with a hydrogen bond between the electron donor and acceptor and without it) are considered as different classes of chemical compounds, so that the relationship between the above example (when hydrogen bonding decreases the energy levels) and acid–base catalysis is lost. At the same time, acid–base catalysis is essentially based on the effects of a hydrogen bond in an excited state of a catalytic reaction complex.

Let us consider a simple but frequent case of interaction of two molecules one of which (DH) is an electron and proton donor and the other (A), an electron and proton acceptor. The electron transfer (electronic excitation) between the electron donor and acceptor in the case when the components contain labile hydrogen atoms should be considered in combination with the proton transfer.

2. ELECTRON DONOR–ACCEPTOR AND PROTON DONOR–ACCEPTOR PROPERTIES OF QUINONES AND HYDROQUINONES



Convenient objects for experimental studies of the electron–proton effect are crystalline complexes of quinones with hydroquinones, so-called quinhydrones, which are a particular case of π complexes with a hydrogen bond. The excited states of such complexes are responsible for the thermal transfer of the hydrogen atom [5], an elementary step of many organic reactions. The specific crystal structure of quinhydrones is constructed by the donor–acceptor bond and a chain

Table 1. Electron-donor and proton-donor power of substituted hydroquinones

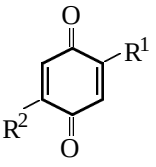
6a	Cl	Cl	8.16		7.90	3553	375
7a	C_6H_5	H		8.10			

system of hydrogen bonds [11–13]. Unusual spectral and chemical properties of quinhydrones are caused by the stabilizing effect of the hydrogen bond on the excited states of the complexes. No more than 30 quinhydrones are known; in most cases, these are complexes of 1,4-naphthoquinone and *p*-benzoquinone derivatives with the corresponding reduced species [13, 14].

In our studies we used *p*-benzoquinone and its derivatives, differing in the electron-acceptor and proton-acceptor power. The electron- and proton-donor power of the corresponding hydroquinones can be changed by varying the substituents. For any quinhydrone complex **I**, there exists the conjugated complex **II** arising from the transfer of two hydrogen atoms:

(1)



Four characteristics are decisive in the formation of a quinhydrone: electron-donor and proton-donor power of hydroquinone derivatives and electron-acceptor and proton-acceptor power of the corresponding quinone derivatives; the steric effects of substituents are also significant. To understand the nature of the electron–proton effect, it is necessary to reveal the relationship between these four EDA and PDA characteristics; to do this, it is appropriate to use a series of hydroquinones and the corresponding oxidized species as example.

The proton-donor power of substituted hydroquinones can be evaluated by the shift of the OH stretching vibration frequency, $\Delta\nu_{OH}$, upon formation of a hydrogen bond with a reference proton acceptor, tetrahydrofuran (Table 1). The IR spectra of hydroquinone **1a** and methylhydroquinone **2a** in the isolated (monomeric) form contain single OH bands whose frequencies ν_{OH} are close to those of the corresponding phenols [15]. In methoxy, chloro, and bromo derivatives of hydroquinone (**3a**–**5a**), the hydroxy group vicinal to the substituent forms an intramolecular hydrogen bond (IHB), which results in a low-frequency shift of ν_{OH} (Table 1). The vibration frequencies of these groups in the free state are unknown and were assumed to be equal to those of the corresponding *meta*-substituted phenols.

In tetrahydrofuran, all the examined hydroquinone derivatives in a concentration less than 0.05 M give single bands corresponding to the hydrogen-bonded species O–H···O. The spectral shifts relative to the band of the corresponding monomeric form, $\Delta\nu_{OH}$, linearly correlate with the acidity constants pK_a; with respect to the acidity, the hydroquinone derivatives can be ranked in the following order: **2a** ≈ **3a** < **1a** < **5a** < **4a** ≈ **6a**.

The proton-acceptor power of quinones is characterized by the shift $\Delta\nu_{OH}$ of the OH stretching frequency of a reference proton donor ROH upon formation of a hydrogen bond C=O···H–OR. The spectral shifts $\Delta\nu_{OH}$ (Tables 1, 2) show that substituents oppositely affect the proton-donor power of hydroquinones

Table 2. Electron- and proton-acceptor power of quinones

Compound			E_A	E_A^{calc}	$\Delta\nu_{OH}$, cm^{-1}
	R^1	R^2	eV		
2b	CH_3	H	1.79	2.03	109
3b	OCH_3	H	1.60	2.04	96
1b	H	H	1.88	2.06	93
4b	Cl	H	2.10	2.29	69
5b	Br	H	2.15	2.34	
6b	Cl	Cl	2.26	2.50	54
7b	C_6H_5	H		2.58	

1a–**6a** and the proton-acceptor power of the corresponding oxidized species **1b**–**6b**. In particular, methylhydroquinone is the weakest proton donor in the examined series, whereas the corresponding oxidized species, methylbenzoquinone, is a good proton acceptor. The electron-withdrawing Cl substituent enhances the proton-donor power of hydroquinones but decreases the proton-acceptor power of the oxidized species.

The electron-donor power of **1a**–**6a**, characterized by the ionization potential I_D, can be evaluated either theoretically or from the charge-transfer (CT) bands of the complexes of these compounds with a reference electron acceptor, 1,3,5-trinitrobenzene (Table 1). For a group of electron donors with known ionization potentials [16] and energies E_{CT}, a linear correlation

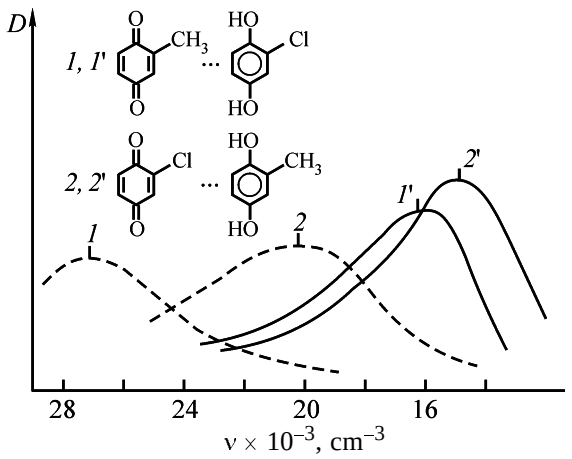


Fig. 2. Absorption spectra of complexes (*1*, *1*') methylbenzoquinone (MBQ)–chlorohydroquinone (CHQ) and (*2*, *2*') chlorobenzoquinone (CBQ)–methylhydroquinone (MHQ) in (*1*, *2*) acetonitrile and (*1*', *2*') KBr. (*D*) Optical density and (ν) wave number; the same for Figs. 4–6 and 18.

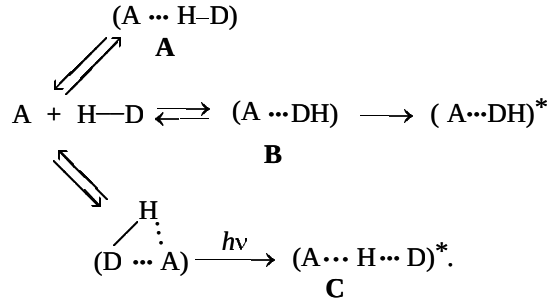


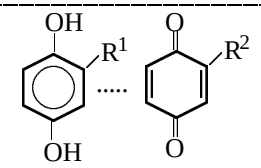
is observed:

$$I_D = 1.31 \times 10^{-4} E_{CT} + 4.49 \text{ eV}. \quad (2)$$

Equation (2) was used to find the ionization potentials of substituted hydroquinones **1a**–**6a**; for **1a**, the value we obtained, I_D = 7.83 eV, is close to that reported previously, I_D = 7.86 eV [16]. The electron affinities E_A of **1b**–**6b** were determined by Briegleb [17] and later refined by Farragher and Page [18]. The E_A values slightly corrected using the CT energies for various compounds are listed in Table 2.

On the whole, it can be concluded that the enhancement of the electron-donor power of hydroquinones is accompanied by weakening of their proton-donor power. The similar conclusion is valid for the electron-acceptor and proton-acceptor power of quinones. The experimental dependences obtained express the universal inverse correlation between the electron and proton affinities of molecules.

The interaction of a quinone (electron and proton acceptor) A and hydroquinone (electron and proton donor) H–D involves the following steps:



where (A···H–D) is a hydrogen-bonded complex; (A···DH), π complex; and  , a hydrogen-bonded π complex.

Structures **A** and **B** can be formed both in solution and in the crystal, whereas structure **C** in the ground electronic state predominantly exists only in the crystal.

A compromise between the donor–acceptor interaction requiring the planar orientation of the molecules and the hydrogen bond O–H···O=C results in a specific structure of the crystal; for example, in the complex **1a**–**1b**, the distance between the molecular planes is 3.16 Å, at a hydrogen bond length of 2.72 Å [11].

The most significant feature of quinhydrone complexes is a considerable decrease in the CT energy in going from a solution to a crystal (Fig. 2, Table 3), depending on the kind of substituent and procedure for preparing the complex and the sample. For exam-

Table 3. Spectral and thermochemical characteristics of quinhydrones

Complex			E_{CT}, cm^{-1}		ΔE_{CT}	$\Delta\nu_{OH}$	E_a	Preexponential term
	R^1	R^2	solution	crystal, in KBr	cm^{-1}			
1a–**1b**	H	H	24000	16800	7200	390	17400	31 [19]

4a–**2b**	Cl	CH_3	26800	17400	9400	360		

ple, trituration of the crystalline complex with mineral oil results in lower E_{CT} (by 1000–1500 cm^{-1}) than pelletizing with KBr. These factors ultimately affect the state of the hydrogen bond whose effect on E_{CT} is the most significant. The major contribution to this spectral shift is made, along with the effects associated with the phase transition, by stabilization of the excited state of the π complex (A···DH)* due to hydrogen bonding; therefore, the difference E_{CT}(soln) – E_{CT}(cr) is the measure of participation of the hydrogen bond in the formation of a quinhydrone.

Quinhydrones are characterized by large shifts of the OH stretching vibration frequencies, $\Delta\nu_{OH}$, in the crystal compared to solution; for example, for complex **4a**–**4b** in the crystal $\Delta\nu_{OH}$ = 360 cm^{-1}, whereas in solution $\Delta\nu_{OH}$ is as small as 90 cm^{-1}. This fact indicates that the hydrogen bond in the crystal is considerably stronger. At the same time, the relative shift in going from one complex to another, $\Delta(\Delta\nu_{OH})/\Delta\nu_{OH}$, in the crystal is several times smaller than in solution. For example, for the pair of complexes **2a**–**4b** (weak proton donor and strong electron acceptor) and **4a**–**2b** (strong proton donor and weak electron acceptor), the relative shift is 0.2 in the crystal and 1.0 in solution. These features of quinhydrones are caused by the fact that in the crystal the hydrogen bond coexists with the donor–acceptor bond.

The IR spectrum of complex **1a**–**2b** contains several relatively narrow OH stretching vibration bands, suggesting the presence of several hydrogen bonds of different energy in the unit cell. Also, the strength of hydrogen bonds in the crystal is subject to the steric effect of bulky substituents. For example, the methyl group in the acceptor fragment of the complex produces steric hindrance in formation of crystalline quinhydrone. This fact may be responsible for weaker H bonding in complex **1a**–**2b** compared to **1a**–**1b** (Table 3), despite the fact that methylbenzoquinone **2b** is a stronger proton acceptor than *p*-benzoquinone **1b**.

3. COMPENSATION EFFECT

Pair complexes of quinones with hydroquinones in solution are common EDA complexes without hydrogen bonds, as indicated by a linear correlation between the CT energy and the difference $I_D - E_A$, with a slope close to unity (Fig. 3, straight line *A*). Similar correlations were obtained for a large number of EDA complexes without hydrogen bond in solution [20, 21]; passing to the solid phase causes only a slight decrease in E_{CT} (by no more than 0.3 eV). On the contrary, the CT bands of complexes of quinones with hydroquinones undergo a considerable bathochromic shift, depending on the structure of the components, in going from solution to the solid phase. For a group of structurally related complexes we obtain straight line *B* with a slope of 0.6 (Fig. 3), and the lowest values of E_{CT} are approximated by straight line *C*.

The largest shift, ΔE_{CT} = 9400 cm^{-1}, is observed for a complex of a weak electron acceptor, methyl-*p*-benzoquinone **2b**, with a relatively weak electron donor, chlorohydroquinone **4a**, whereas for the conjugated complex **4b**–**2a** the shift is as small as 5600 cm^{-1}. In the other complexes, the shifts range from 5000 to 10000 cm^{-1} (Table 3), with the following regular trend: In a pair of conjugated complexes,

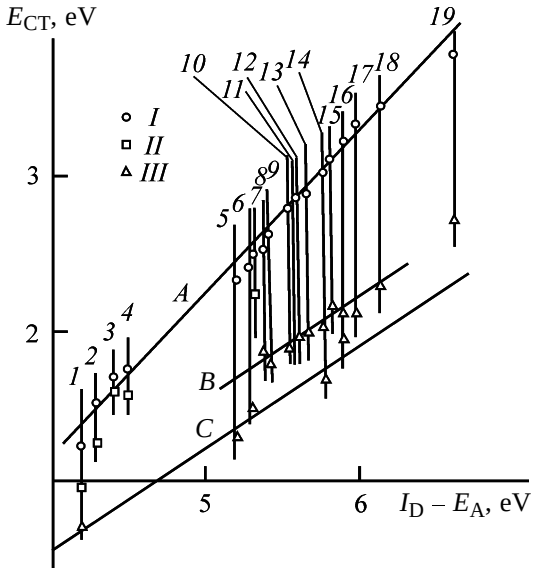

Fig. 3. Correlation of the charge-transfer energy E_{CT} with the difference $I_D - E_A$ for (*I*) complexes in solution, (*II*) crystals without hydrogen bond, and (*III*) crystals with hydrogen bond. (*1*) Tetracyanoquinodimethane–benzidine, (*2*) dichloro-PM–TMPD, (*3*) chloro-BQ–TMPD, (*4*) PM–TMPD, (*5*) BQ–*p*-PD, (*6*) BQ–bromo-*p*-PD, (*7*) 1,3,5-trinitrobenzene–*p*-PD, (*8*) BQ–2,6-dichloro-*p*-PD, (*9*) bromo-BQ–methyl-HQ, (*10*) bromo-BQ–HQ, (*11*) chloro-BQ–HQ, (*12*) BQ–methyl-HQ, (*13*) methyl-BQ–methyl-HQ, (*14*) BQ–HQ, (*15*) methyl-BQ–HQ, (*16*) BQ–chloro-HQ, (*17*) methyl-BQ–chloro-HQ, (*18*) methyl-BQ–2,5-dichloro-HQ, and (*19*) BQ–phenol, where PM is pyromellitic anhydride; TMPD, *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine; *p*-PD, *p*-phenylenediamine; BQ, *p*-benzoquinone; and HQ, hydroquinone.

the complex exhibiting weaker EDA characteristics is characterized by the larger shift.

Among the complexes given in Table 3, the crystal structure was determined only for **1a**–**1b** [11]; the crystal consists of stacks of alternating 1,4-benzoquinone and 1,4-hydroquinone molecules. The crystal structures have also been determined for two more quinhydrones: the complex of 1,4-naphthoquinone with hydroquinone [22] and the complex of 2-phenyl-1,4-hydroquinone with *p*-chlorobenzoquinone [23]. The spectral data suggest that the other crystalline quinone–hydroquinone complexes have a similar characteristic quinhydrone structure.

Among two conjugated complexes, e.g., **2a**–**4b** and **4a**–**2b**, the shift of the CT band in going from solution to the crystal is larger for a weak donor–acceptor pair, in this case for **4a**–**2b**. Since thermochemical transformations of quinhydrones occur in the direction of increasing difference $I_D - E_A$ [10], e.g., **2a**–**4b** → **4a**–**2b**, the EDA properties weaken and the PDA properties are enhanced in the course of the reaction. Strong electron donors and acceptors are, respectively, weak proton donors and acceptors. Hence, the strength of EDA interactions inversely correlates with the strength of hydrogen bonding in complexes in which both kinds of interactions are realized. Crystalline quinhydrones and some other EDA complexes with hydrogen bonding are just such complexes.

The combined but oppositely directed effect of EDA and PDA properties of quinones and hydroquinones levels off the CT energy in the series of complexes, so that it becomes only weakly dependent on the difference $I_D - E_A$, whereas for the same complexes without hydrogen bond in solution the correlation $E_{CT} \sim I_D - E_A$ is linear with the slope close to unity. In other words, the H bond compensates to a certain extent the variation of the EDA properties of interacting molecules; as a result, in the solid state strong and weak donor–acceptor pairs have close E_{CT}.

The strength of the hydrogen bond can be estimated from the shift of the OH stretching vibration frequency ν_{OH}, using an empirical formula

$$E_H = 0.33(\Delta\nu_{OH} - 40)^2 \text{ kcal mol}^{-1}. \quad (3)$$

Estimations show that, the stronger the H bond, the larger the shift of the CT band upon H bond formation; this fact confirms the regular correlation between these two quantities. For two conjugated complexes **4a**–**2c** and **2a**–**4c**, the difference in the H bond energy is 0.6 kcal mol^{-1}, which amounts to approximately 10% of ΔE_{CT}. Hence, small changes in the H bond energy in the ground state can cause significant shifts of CT bands.

4. CRYSTALLINE QUINHYDRONES WITH INCLUDED SOLVENT MOLECULES

The CT energies (Table 3) were determined for solid quinhydrones pelletized with KBr; in these samples, the complexes mainly preserve the crystalline structure [14]. Since E_{CT} strongly depends on the state of the H bond, a question arises: Is it possible to affect the H bond strength by modifying the crystal structure? One of the modification procedures is inclusion of foreign molecules in the crystal lattice to obtain host–guest structures. The incorporated molecules alter the interstack and interplanar spacings and thus affect the H bond strength. Examples of such structures are complexes of tetracyanoquinodimethane (TCQ) with benzidine [24]. Experiments on preparation of inclusion complexes from quinhydrones failed, because such complexes appeared to be unstable in the crystalline form.

We succeeded in growing the crystals of the complexes at low temperature. By slow cooling of a solution of BQ–HQ to a temperature from –40 to –60°C in a mixture of acetonitrile with chloroform or methylene chloride at a definite ratio of the polar and nonpolar components (1 : 1.5 to 1 : 2), we obtained a finely crystalline blue suspension which did not settle within several hours. The crystals are so small that are not observed visually, and their formation is judged only from certain turbidity of the mixture.

The absorption spectrum of the finely crystalline suspension (Fig. 4) depends on the composition of the solvent mixture and kind of the inert component: $CHCl_3$ or CH_2Cl_2. With an increase in the content of the nonpolar component (e.g., methylene chloride), the frequency of the CT band decreases. The decolorization of the solution on heating and its coloring on cooling are fully reversible; however, we failed to isolate blue crystals. The lowest-frequency position of the CT band of the crystalline complex, 13000 cm^{-1}, is shifted relative to E_{CT} of the solid complex by 4000 cm^{-1} and relative to the solution in which the EDA complexes exist as non-hydrogen-bonded pairs by a value as large as 11000 cm^{-1}.

Presumably, in crystallization from a mixed solvent a structure incorporating solvent (e.g., chloroform) molecules is formed, favoring formation of a strong hydrogen bond and hence decreasing the CT energy. The energies of the charge-transfer excited states (13000 cm^{-1}) are very low for relatively weak electron donors and acceptors, BQ and HQ, which suggests that the CT states are stabilized by certain specific mechanisms.

Thus, the EDA and PDA characteristics of quinones and hydroquinones show inverse correlation with each other, i.e., the higher the electron affinity of a quinone, the lower its proton affinity (capability for H bonding), and the higher the electron-donor power of a hydroquinone, the lower its proton-donor power. This correlation is quite obvious, as it is associated with the opposite signs of charges of electron and proton, and has profound chemical consequences, the main of which is a considerable decrease and leveling of the energies of excited levels of the complexes, determining the reaction rates.

5. PICOSECOND TRANSIENT ABSORPTION SPECTRA

The product of hydrogen transfer in quinhydrones is the conjugated crystalline complex; the activation

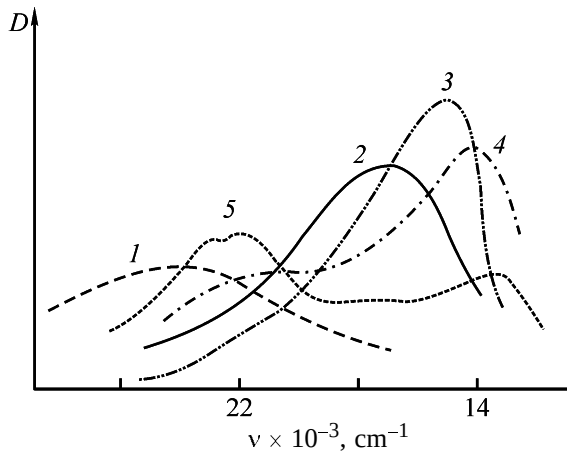

Fig. 4. Absorption spectra of *p*-benzoquinone–hydroquinone complex: (*1*) solution in acetonitrile, 25°C; (*2*) crystalline complex in KBr; and (*3*–*5*) microcrystalline suspension in mixed solvents, –50°C: (*3*, *4*) acetonitrile–methylene chloride, 1 : 1.5 and 1 : 2, respectively, and (*5*) acetonitrile–chloroform, 1.5 : 1.

energy of the thermochemical reaction is comparable with the CT energy [5]. These data suggest that the excited state of hydrogen-bonded complexes participates in chemical transformations of quinhydrones, but the lifetime and deactivation pathways of these two states are studied insufficiently. The excited states of the complexes can be formed along two pathways: (1) photoexcitation of a molecule of one of the components, followed by formation of an exciplex with a molecule of the other component in the ground state (luminescence quenching), and (2) excitation of the complex in the ground state. The first pathway was examined in basic studies [25–28] and other papers. However, with this excitation pathway it is impossible to determine the energies of the excited states (exciplexes), which is necessary for evaluating the probability of thermal transformations.

The second pathway yields the same excited species as does the first pathway, but it allows determination of the energies of the levels and hence evaluation of the probability of their thermal population. In this connection, it is very interesting to examine the transient spectra in excitation of solid quinhydrones in the CT band in the ground state.

The time-resolved transient absorption spectra in the range 420–765 nm were recorded on a picosecond spectrometer [29]. The optical paramagnetic generator used allowed continuous adjustment of the excitation wavelength in the whole visible range. The excitation pulse energies were about 0.05 mJ at λ_{exc} = 500–530 nm and 0.3 mJ at λ_{exc} = 532 nm; the pulse width

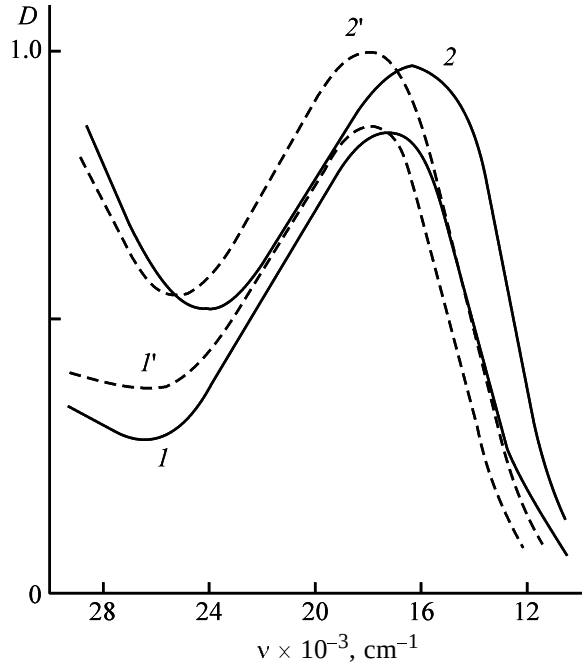

Fig. 5. Absorption spectra of complexes (solid-phase mixing) in KBr: (*1*) MHQ–BQ (**2a**–**1b**), (*2*) MHQ–CBQ (**2a**–**4b**), and (*1'*, *2'*) respective conjugated complexes HQ–MBQ (**1a**–**2b**) and CHQ–MBQ (**4a**–**2b**) after heating.

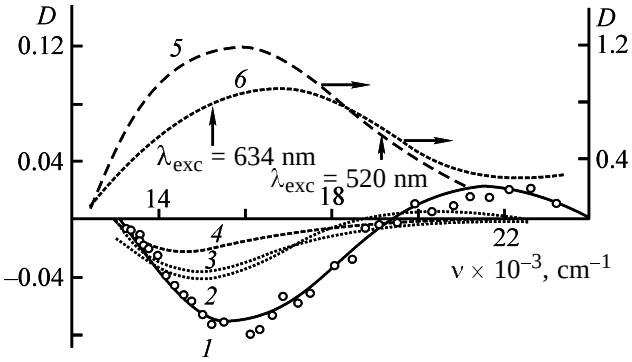

Fig. 6. (*1*–*4*) Transient spectra and (*5*, *6*) stationary absorption spectra of complexes **7a**–**1b** and **1a**–**7b**, respectively, in KBr pellets (solid-phase mixing). Excitation of (*1*, *2*) complex **7a**–**1b** at λ = 634 nm and (*3*, *4*) complex **1a**–**7b** at λ = 520 nm. was 20 ps. The fluctuation of the laser beam on microcrystals of the sample pelletized with KBr caused scattering of the measured optical densities; therefore, the observed spectral curves were subjected to mathematical treatment. The kinetic curves were approximated by a sum of several (usually two) exponents:

$$A(t) = A_{10}\exp(-t/t_1) + A_{20}\exp(-t/t_2). \quad (4)$$

Conjugated complex **II** absorbs at higher frequencies compared to **I** [Eq. (1)], but the shift does not exceed 1000–2000 cm^{-1}; e.g., for the transformations **2a**–**1b** → **1a**–**2b** and **2a**–**4b** → **4a**–**2b**, the shifts are 1000 and 1800 cm^{-1}, respectively (Fig. 5). The CT bands of the initial (**I**) and conjugated (**II**) complexes noticeably overlap because of their large width (5000–7000 cm^{-1}); therefore, both complexes are excited by laser irradiation in the CT band. This fact is one of the causes of low photochemical activity of quinhydrones.

The large width of the CT bands may be caused both by the structural nonuniformity of the polycrystalline sample and by the distribution of the electronic transition energies in the ordered system of the hydrogen-bonded complex. Two elucidate the broadening mechanism, two wavelengths were chosen on the low- and high-frequency wings of the CT band. Figure 6 shows the stationary and transient spectra of crystalline complexes **7a**–**1c**. Similar pattern is observed with the other complexes **1a**–**1b** and **1a**–**2b**.

The decolorization curve (decrease in the optical density) of the ground state is similar to the charge-transfer band in the stationary spectrum, and at the delay τ = 0 ps both bands have the same frequency, 15800 cm^{-1}. Comparison of the optical densities in the stationary and induced spectra shows that each laser pulse causes excitation of 5–15% of the molecules of the complex. Hence, during recording of the spectrum (more than 1000 laser pulses), each molecule of the complex undergoes repeated excitation to the charge-transfer state. In the range of positive absorption, 20000–24000 cm^{-1}, despite high noise level, two weak bands were detected at 21000 and 23000 cm^{-1}. The nature of these bands, which were assigned to radical species, will be considered below.

6. KINETICS OF TRANSIENT SPECTRA

The deactivation kinetics of the excited state (Fig. 7, curve *1*) can be approximated by two exponents with characteristic times of 80 and 3500 ps. A change in the sign of the optical density at about 200 ps indicates that the positive absorption associated with radical ions disappears faster than the induced absorption assigned to the complex in the excited state. Hence, in the time interval between the primary event of the electron transfer due to photoexcitation and the restoration of the absorption of the ground state of the initial complex, relaxation processes occur in the excited charge-transfer state. These processes are associated with the proton transfer and can be monitored only kinetically. Similar kinetic curve was obtained for the conjugated complex **7a**–**1b**.

The kinetic curve of the decrease in the induced absorption at 17212 cm^{-1} (591 nm) in the region of the CT band [ν_{exc} = 19230 cm^{-1} (λ_{exc} = 520 nm)] (Fig. 7, curve *3*) also consists of two portions: fast decay with a rate constant of 7×10^9 s^{-1} and slow decay (1.85×10^8 s^{-1}). Excitation on the long-wave wing of the CT band [ν_{probe} = 15780 cm^{-1} (λ_{probe} = 610 nm)] gives rise to similar kinetic curves. Hence, the kinetics of the photochemical states is independent of the excitation wavelength in the region of the CT band, and the excited states of these samples obtained by solid-phase mixing are deactivated in two steps with the rates differing by a factor of 40.

An essentially different pattern was observed with the complexes prepared by crystallization from CH_2Cl_2. In this case, the decay curves can be approximated by a monoexponential kinetic curve with a lifetime of 1700 ps (Fig. 7, curve *2*), and the contribution of the initial fast step is insignificant. The kinetics depends not only on the sample preparation procedure (solid-phase mixing or crystallization) but also on the degree of grinding the crystals prior to pelletizing with KBr. Intense grinding of the crystals leads to a two-step kinetics characteristic of solid-phase mixing.

Coincidence of the maximum (15800 cm^{-1}) and shape of the band in the stationary and transient spectra at $\tau = 0$ and weak dependence of these characteristics on the excitation wavelength (Fig. 6) indicate that broadening of the CT band is caused by the nature of the electronic transitions in the crystalline phase of the sample, rather than by its structural nonuniformity.

At a long delay time of the probing pulse, the absorption band in the transient spectrum is shifted toward lower frequencies (Fig. 6). This shift is characteristic of all the examined samples and is caused by rapidly growing negative absorption at 13000 cm^{-1}, whose summation with the induced absorption causes the shift of the band maximum. As the probing frequency is decreased, the maximum of the kinetic curve shifts from 300 (472 nm) to 800–1000 ps (974 nm). The induced absorption is of low intensity in this spectral range; therefore, the negative absorption should be assigned to emission of the complex. Its summation with the induced absorption causes a shift of the band maximum. The luminescence band of the crystalline complex arising from the recombination of radical ions is very broad; its maximum is apparently in the range 10000–13000 cm^{-1}.

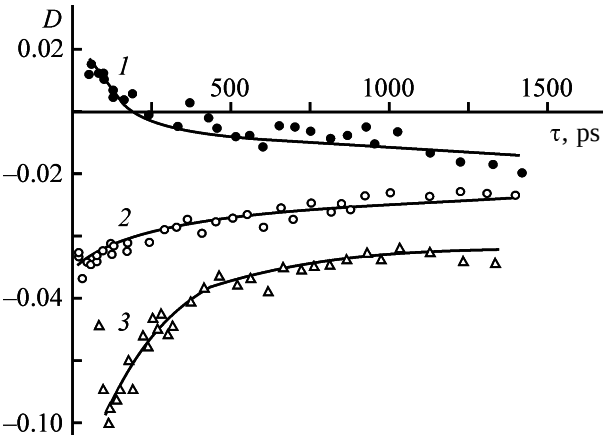

Fig. 7. Kinetic curves of transient absorption of complex **7a**–**1b** at probing wavelengths. (*D*) Optical density and (τ) time. λ, nm: (*1*) 438 (λ_{exc} = 532 nm), (*2*) 586 (λ_{exc} = 512 nm), and (*3*) 581 (λ_{exc} = 520 nm). The complexes were prepared by (*1*, *2*) crystallization and (*3*, *4*) solid-phase mixing.

7. THERMOCHEMICAL AND PHOTOCHEMICAL TRANSFER OF A HYDROGEN ATOM

The hydrogen atom transfer as an elementary chemical process consists of successive steps of electron and proton transfer, which are observed separately in time-resolved photophysical experiments [25–27, 30] or in thermochemical reactions at sufficient stability of the intermediate radical ion species [31]. However, in the majority of chemical reactions the steps of the electron and proton transfer are not registered separately and merge into a common process of hydrogen atom transfer. Therefore, chemical reactions are usually considered in terms of the traditional concept of the transition state [32], without considering the electron transfer as a necessary and essential step of the reaction.

Quinhydrones are a convenient model for studying the mechanism of the hydrogen atom transfer [33], since redox transformations occur in an ordered crystalline phase, and the measured thermodynamic characteristics can be correlated with definite electronic states of the crystal. In the course of the reaction, the crystalline state is preserved, with only slight changes in the unit cell parameters; therefore, the transfer of the hydrogen atom (electron + proton) can be studied in the purest form.

In [8–10] we used the procedure of solid-phase mixing, which allows preparation of finely crystalline samples, apparently with a fairly high content of lattice defects. The reaction progress was monitored by

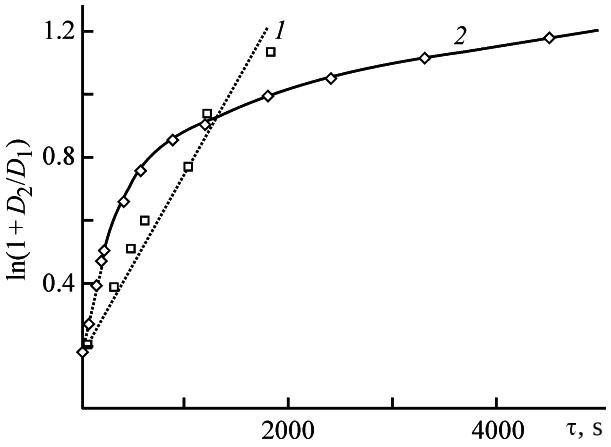

Fig. 8. Thermokinetic curves of transformations of quinhydrone **7a**–**1b**. (D_1, D_2) Optical densities of absorption bands at 872 (*p*-benzoquinone) and 900 cm^{-1} (phenylbenzoquinone).

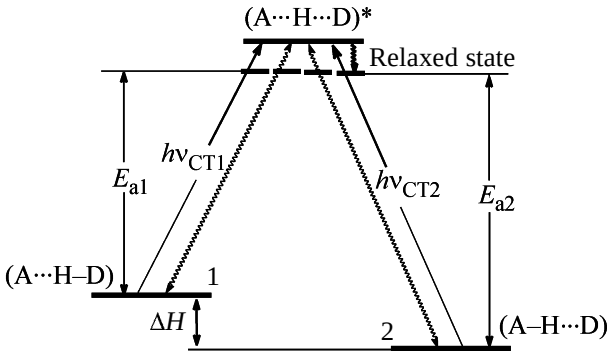

Fig. 9. Energy diagram of the thermal transfer of hydrogen atom in crystalline complexes.

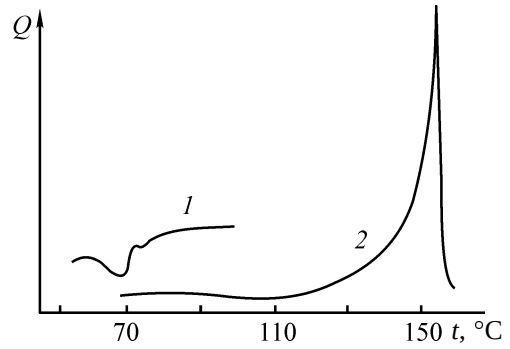

Fig. 10. Calorimetric curves (2 deg min^{-1}) of solid-phase complexes: (*Q*) endothermic effect and (*t*) temperature. (*1*) MHQ–BQ (solid-phase mixing) and (*2*) HQ–BQ (crystallization).

IR spectroscopy, by absorption bands of one of the components. This procedure is inapplicable to symmetrical complexes such as *p*-benzoquinone–hydroquinone with mutual transformations of the components. As far as we know, only in a single paper [19] the deuterated components were used, which allowed the reaction monitoring; however, the results of that study were interpreted using the traditional scheme.

In the case of the ideal structure of a complex, transformation (1) can be considered as a first-order reaction, which is described by the equation

$$-\ln(1 - x/x_0) = kt \quad (5)$$

at $k_{-1} = 0$. In a real crystal, the presence of several structural modifications complicates the reaction kinetics, and it becomes multistep rather than monoexponential (Fig. 8).

An important feature of these systems is that the transformation **I** → **II** is strictly equimolar, with the crystal structure of the complex remaining essentially unchanged. Therefore, the kinetic curves can be constructed from variations in the concentration of any of the four system components. However, to calculate the thermokinetic characteristics, it is appropriate to use the initial portions of the kinetic curves (Fig. 8). Thermochemical reaction (1) in the sollid phase goes virtually to completion in a narrow temperature range, whereas in solution an equilibrium [8] is attained.

The spectral and thermochemical characteristics of the complexes prepared by solid-phase mixing are listed in Table 3. The measurement procedure can be considered using as examples two complexes containing the same donor, MHQ (**2a**), and two different acceptors, BQ (**1b**) and CBQ (**4b**). For MHQ–BQ, the activation energy is 41 kcal mol^{-1} (14300 cm^{-1}), with the preexponential term of $10^A = 10^{24}$ s^{-1}; its large value suggests the cooperative character of the reaction. The activation energy of the thermal reaction, 41 kcal mol^{-1}, is close to the CT energy in the crystal, 48 kcal mol^{-1}. In the case of MHQ–CBQ, the activation energy is 35 kcal mol^{-1} at $A = 21$. Comparison of two structurally related complexes HQ–CBQ and MHQ–CBQ reveals a clear correlation between the variations in E_{CT} and E_a (Table 3).

Figure 9 shows the energy scheme of solid-phase transformations of quinhydrones, with the pathways of photochemical and thermal transformations (zigzag lines). Neglecting the entropy of the reaction, the difference between the energies of the optical charge-transfer transitions for the final (2) and initial (1) complexes should be equal to the heat of the reaction:

$$\Delta H = E_{CT2} - E_{CT1}. \quad (6)$$

We were able to check this important conclusion experimentally. The thermal effect of the reaction MHQ–BQ → HQ–MBQ (Fig. 10), determined to be $\Delta H = -9$ kJ mol^{-1} by integration of curve *1*, reas-

onably agrees with the difference $E_{CT2} - E_{CT1} = -12$ kJ mol^{-1}.

It is of interest to study redox transformations of quinhydrone crystals prepared from solution. Only two complexes containing phenylhydroquinone, **7a**–**1b** (PHQ–BQ) and **7a**–**4b** (PHQ–CBQ), appeared to be suitable for this purpose. Their crystals were grown from methylene chloride at low temperature. Platelike crystals of complex **7a**–**1b** are stable in air for several months. CBQ is a stronger electron acceptor than BQ (E_A^{calc} = 2.28 and 2.06 eV, respectively), which accounts for the low-frequency shift of the CT band of the complexes in the solid phase (from 16000 cm^{-1} for **7a**–**1b** to 15400 cm^{-1} for **7a**–**4b**) and for an increase in the reactivity of the corresponding quinhydrones. Crystalline complex **7a**–**4b** at room temperature slowly transforms into the conjugated complex **4a**–**7b**.

In contrast to the complexes studied in pressed KBr pellets (solid-phase mixing), in this case the crystals of the quinhydrones were heated in special ampules without mechanical treatment, so as to avoid formation of crystal defects. The procedure for preparing the complex significantly affects the reaction kinetics. In solid-phase mixing of the components, the kinetics is clearly two-step (Fig. 8), whereas for quinhydrones prepared by crystallization from solution the kinetics is strictly one-step, indicating that the chemical process occurs by a single mechanism.

The kinetic curves show that the reaction **7a**–**1b** → **1a**–**7b** with the crystalline complex in the narrow temperature range 115–130°C is strictly monomolecular, with the reaction rate being independent of the conversion (Fig. 8). It is interesting that the reaction onset temperature in crystalline quinhydrones is 5–10°C higher than the melting point of one of the components. The first, fast step of the reaction of complex **7a**–**1b** prepared by solid-phase mixing occurs at 50°C lower temperatures, and this acceleration of the reaction is apparently due to the defectiveness of the complex.

A kinetic study of the reaction **7a**–**1b** → **1a**–**7b** with the crystals grown from solution gives the activation energy E_a = 42.2 kcal mol^{-1} (Fig. 11). The reaction rate is described by the equation

$$k\ (s^{-1}) = 10^{20} \exp(-176/RT).$$

The fact that the activation energy of the thermochemical reaction (14800 cm^{-1}) is close to the CT energy (16000 cm^{-1}) confirms the previous conclusion [5] that the thermal electronic excitation of the complex of the reagents is the primary elementary step of the reaction.

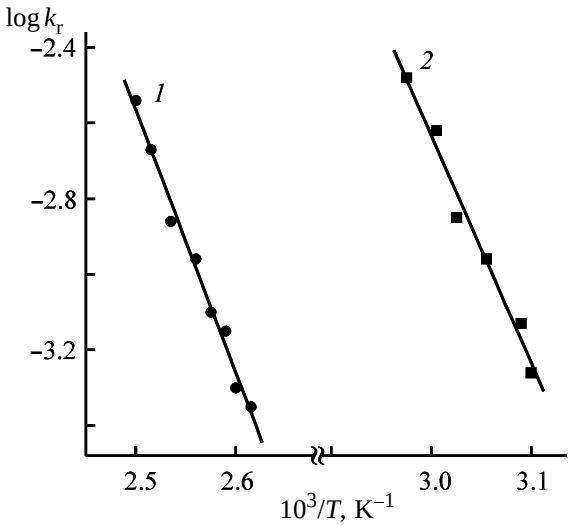

Fig. 11. Rate constant k_r of the reaction of quinhydrone **7a**–**1b** as a function of temperature T: (*1*) crystals grown from solution and (*2*) solid-phase mixing of components.

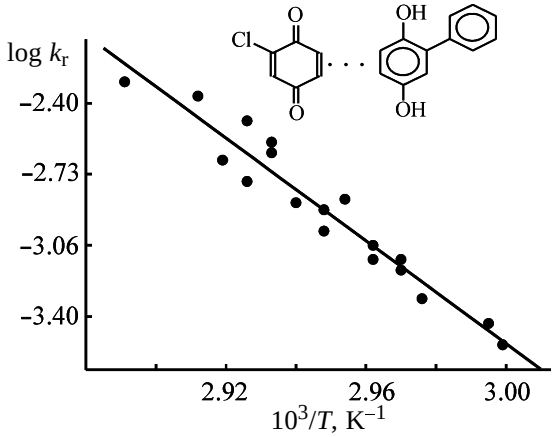

Fig. 12. Rate constant k_r of the reaction **7a**–**4b** → **4a**–**7b** as a function of temperature T (crystals grown from CH_2Cl_2 solution).

In solid-phase mixing, compared to the crystallization from solution, the rate of the redox transformation of complex **7a**–**1b** sharply increases (Fig. 11), apparently owing to the defectiveness of the crystal structure:

$$k\ (s^{-1}) = 10^{21} \exp(-155/RT).$$

the reaction acceleration is mainly due to a decrease in the activation energy to 37.3 kcal mol^{-1}.

In the case of very reactive complex **7a**–**4b** prepared by crystallization from CH_2Cl_2, the kinetic curves of the reaction **7a**–**4b** → **4a**–**7b** are linearized in the coordinates $\ln(1 + D_2/D_1)$–τ, as in the case of **7a**–**1b**, indicating that the reaction is strictly monomolecular. Certain scatter of the rate constant (Fig. 12) is caused by partial decomposition of the complex due

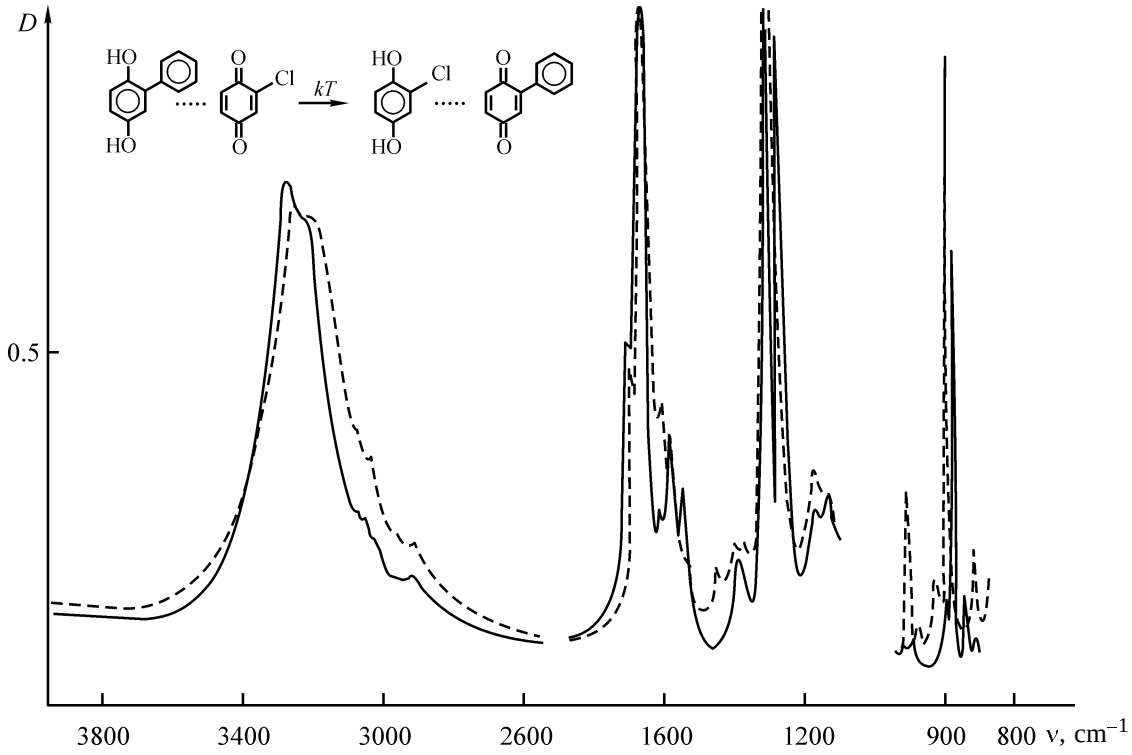

Fig. 13. IR absorption spectra of the (solid line) crystalline complex **7a**–**4b** grown from CH_2Cl_2 and (dashed line) reaction product **4a**–**7b** prepared by heating the initial complex at 79°C. (*D*) Optical density and (ν) wavenumber.

to sublimation of chlorobenzoquinone **4b** at high temperatures ($t^0 > t_m$ = 56°C). The activation energy of the reaction is 37.4 kcal mol^{-1} (13000 cm^{-1}), which is close to the CT energy of the complex, 15400 cm^{-1}.

Thus, a study of two quinhydrone complexes prepared by crystallization from solution confirmed our conclusions [8–10] that the activation energy of the thermal reaction is close to the energy of the optical charge-transfer transition; owing to the strictly monomolecular character of the reaction, the kinetic characteristics can be determined more accurately. The high preexponential term, 10^{20}–10^{21}, is indicative of the cooperative character of the electron and proton transfer in an ordered crystal lattice of the complex.

The IR spectra of the initial (**7a**–**4b**) and conjugated (**4a**–**7b**) complexes (Fig. 13) contain extremely narrow bands characteristic of the crystalline states. Each of the two OH stretching vibration bands, 3275 and 3230 cm^{-1}, belonging to two nonequivalent hydroxy groups, has the width as small as ~100 cm^{-1}. The conjugated complex **4a**–**7b** absorbs at lower frequencies, 3250 and 3200 cm^{-1}, suggesting stronger H bonding between strong proton donor CHQ (**4a**) and strong proton acceptor PBQ (**7b**), compared to the components of the initial complex, **7a** and **4b**. The redox transformation **7a**–**4b** → **4a**–**7b** is accompanied by an increase in the CT energy from 15400 to 16000 cm^{-1} as a result of weakening of the EDA properties of the components and of a 50 cm^{-1} decrease in the OH stretching vibration frequency, suggesting strengthening of the hydrogen bond.

The primary event in the laser excitation at the CT band,

$$(Q\cdots H_2Q) \xrightarrow{h\nu} {}^1(Q^{\bullet-}\cdots H_2Q^{\bullet+}), \qquad (7)$$

is the electron transfer yielding radical species responsible for the absorption at 20000–24000 cm^{-1} in the transient spectra (Fig. 6). In the case of a thermodynamically favorable reaction, e.g., **7a**–**1b** → **1a**–**7b**, enhancement of the PDA properties caused by the electron transfer stimulates the proton transfer giving rise to semiquinone radicals, which is followed by the transfer of the second proton with the formation of the conjugated complex **1a**–**7b**:

$$(Q_1)\cdots(H_2Q_2) \underset{h\nu^f}{\overset{h\nu^a}{\rightleftarrows}} {}^1[(Q^{\bullet-})_1\cdots(H_2Q^{\bullet+})_2]$$

$$\rightleftarrows [(HQ^{\bullet})_1\cdots(HQ^{\bullet})_2 \rightleftarrows [H_2Q^{\bullet+})_1\cdots(Q^{\bullet-})_2]$$

$$\xrightarrow{h\nu^f} (H_2Q)_1\cdots(Q)_2. \qquad (8)$$

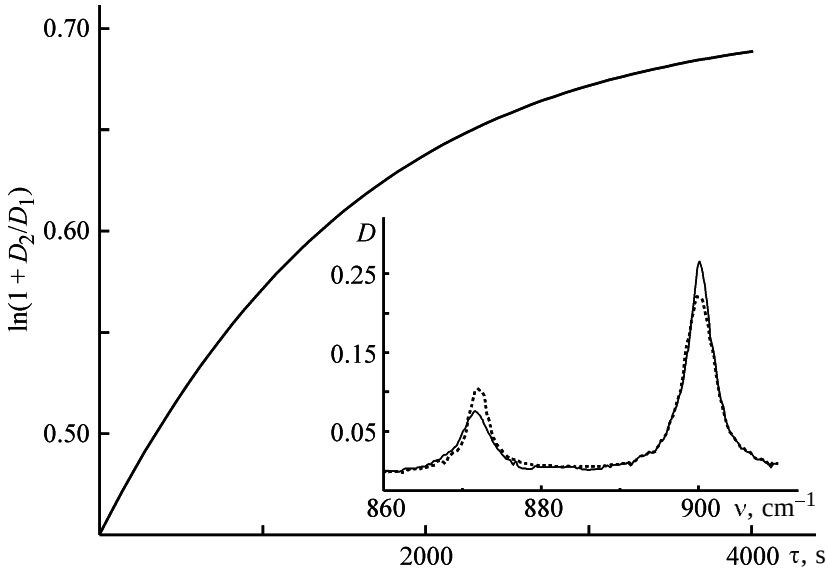

Fig. 14. Photochemical reaction **7a**–**1b** → **1a**–**7b** in a KBr pellet upon irradiation with a 1 W argon laser. Insert: IR spectra of the complexes. (*D*) Optical density and (τ) time; (ν) wavenumber.

It is difficulty to detect semiquinone radicals in the transient spectra because of the low intensity of the absorption bands; however, their formation is confirmed by the kinetic data. In particular, faster decrease in the absorption of radical ions $(H_2Q^{\cdot+})_1\cdots(Q^{\cdot-})_2$ compared to the decrease in the induced absorption (Fig. 6) suggests the presence of an intermediate step associated with the proton transfer. The radicals arising in the process are unstable and rapidly transform into the conjugated complex upon transfer of the second proton.

Because of the high rate of the thermal redox reaction, it is very difficult to detect the photochemical transfer of the hydrogen atom. Nevertheless, it is possible to monitor the slow photochemical reaction **7a**–**1b** → **1a**–**7b**, occurring upon irradiation of a sample of complex **7a**–**1b** with a defocused beam of a continuous 1 W argon laser (Fig. 14). A considerably weaker effect is attained by irradiation with a harmonic of a pulse garnet laser (532 nm, 1 mW); during the irradiation (several hours), the crystalline complex undergoes repeated excitation to the CT state. Hence, the photochemical reaction [Eq. (8)] occurs with a low efficiency, probably because of the strong overlap of the CT bands of the initial and final complexes.

8. HYDROGEN BOND IN THE ELECTRONICALLY EXCITED STATE OF AN EDA COMPLEX IN SOLUTION

The electron–proton effect is manifested to the greatest extent in crystalline quinhydrone complexes; however, this phenomenon is general and should be manifested in diverse systems, including complexes in solution. For pair complexes A···H–D, the coexistence of an electron donor–acceptor bond and an H bond is improbable at plane-parallel arrangement of the molecules but can be realized in ternary and more complex structures. Ternary complexes A···D–H···X were studied in [6, 34–37].

Stabilization of the excited states of the complexes by H bonding can be estimated theoretically; however, the nature of this interesting phenomenon remained incompletely understood. The shifts of the absorption and luminescence bands of molecules upon H bond formation usually do not exceed 0.04–0.07 eV [38, 39], which is an order of magnitude lower than the effects observed in the complexes. In this connection, it is interesting to consider EDA complexes in which the electron donor (e.g., phenol) is also a proton donor and hence can form a hydrogen bond with the third component, e.g., a solvent molecule.

The EDA complex of chloranil with anisole (I_D = 8.22 eV, I_D^{calc} = 8.45 eV), which is an analog of phenol (I_D = 8.5 eV, I_D^{calc} = 8.76 eV) but contains no labile hydrogen atoms, is characterized by a charge-transfer band at 21800 cm^{-1} with the intensity f = 0.014 in CCl_4 (calculation: 25250 cm^{-1}, f = 0.003). For this complex, the CT band is not noticeably shifted on adding to CCl_4 aprotic solvents (0.1 M) acting as proton acceptors, but somewhat increases in neat aprotic solvents; for example, in tetrahydrofuran (THF), the chloranil–anisole complex absorbs at 23200 cm^{-1}.

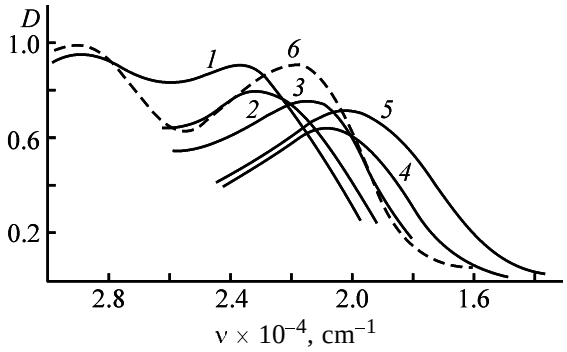

Fig. 15. Absorption spectra (*1*, ×40; *2*–*5*, ×10) of complexes of chloranil (0.002 M) with phenol in CCl_4 containing various additives. Additive: (*1*, *2*) none, (*3*) acetonitrile, (*4*) THF, and (*5*) dimethylacetamide. Phenol concentration, M: (*1*) 0.005 and (*3*–*5*) 0.035. (*6*) Absorption spectrum of the chloranil–anisole complex.

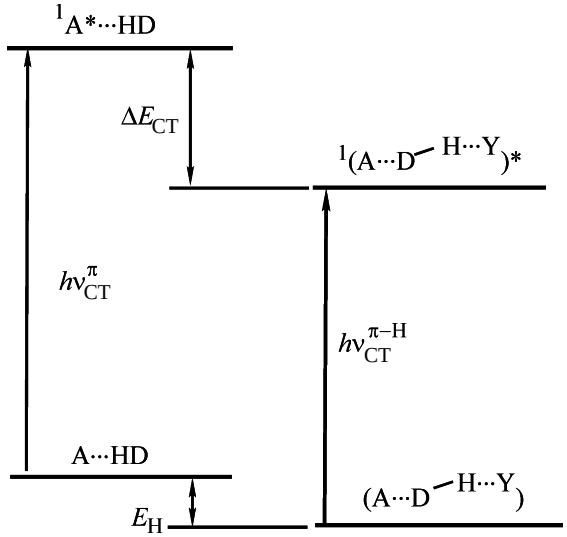

Fig. 16. Scheme of the energy levels of an EDA complex upon formation of an H bond.

The enthalpy of formation of the chloranil–anisole complex in CCl_4 was found to be 3.2 kcal mol^{-1}.

In the absorption spectrum of the complex chloranil (Cl)–phenol (Ph) (Fig. 15), at a low phenol concentration (0.005 M), new bands at 24000 and 29000 cm^{-1} appear along with the intrinsic bands of Cl and Ph. The first of these bands is shifted relative to the CT band of the Cl–anisole complex by 0.28 eV, which is equal to the difference between the ionization potentials of phenol and anisole; hence, this is the CT band. The band at 29000 cm^{-1} is assigned to the n–π^* transition in the Cl molecule perturbed by the effect of the electron donor (for the free molecule in CCl_4, the frequency is 26800 cm^{-1}).

Small (1–3 vol %) additions to CCl_4 of proton-acceptor solvents ensuring complete binding of phenol cause a considerable shift of the CT band of the Cl–Ph complex, but exert no effect on the position of the CT band of the Cl–anisole complex. The shifted bands of the Cl–Ph complex, as a rule, are symmetrical (Fig. 15) and undergo reversible changes with temperature, which confirms their assignment as CT bands.

The shift of the CT band unambiguously correlates with the energy of the hydrogen bond between phenol and the proton-acceptor solvent. For the ground electronic state, this energy was estimated from the low-frequency shift of the OH stretching vibration frequency using empirical relationship (9):

$$E_H = 0.33(\Delta\nu_{OH} - 40)^{1/2}. \quad (9)$$

For the selected solvent series, E_H does not exceed 0.3 eV and is close to the energy of the H bond in the ground state of the EDA complex. Neglecting the entropy of the electronic transition, the level of the excited state of the complex will decrease upon H bond formation by the value

$$E_{CT} = h\nu_{CT}^{\pi} - h\nu_{CT}^{\pi-H} + E_H, \quad (10)$$

where $h\nu_{CT}^{\pi}$ and $h\nu_{CT}^{\pi-H}$ are the transition frequencies for the complexes without and with H bond, respectively (Fig. 16).

The stabilization energy ΔE_{CT}, which is essentially the H bond energy in the excited state of the complex, linearly correlates with the H bond energy in the ground state, with a slope of 2.6 (Fig. 17, line *A*). Hence, in the Franck–Condon excited state the H bond energy increases by a factor of 2.6 compared to the ground state.

Figure 17 also shows the spectral shifts for the complex of chloranil with 2,4-dichlorophenol, which are close to the corresponding shifts for the chlorophenol complexes [34]. The calculation gives equal ionization potentials for phenol and chlorophenol (8.76 eV), and for anisole and chloroanisole (8.45 eV), but the proton-donor properties of phenol are stronger (pK_a of chlorophenol and phenol 9.38 and 9.98, respectively), which accounts for the higher energy of the H bond in the ground state of chlorophenol, compared to phenol. The correlations of ΔE_{CT} with E_H appeared to be common for the complexes Cl–Ph and Cl–chlorophenol [34]. Similar correlations are observed with a number of other complexes.

A considerable difference in the spectral shifts for the two cases, excitation at the CT band of the EDA complex and excitation at the phenol band of the

$Ph^{\bullet+}$⋯THF		0.106	0.290	14.44	2.71	12.56

H-bonded complex, is caused by the charge distribution in the phenol molecule in the excited state. In the first case, the excitation results in the electron transfer between the phenol and chloranil molecules, and the hydrogen bond is formed between the proton acceptor (dioxane, DME) and phenol radical cation whose proton-donor power is considerably enhanced by the loss of an electron. In the second case, the electron density is redistributed within the phenol molecule, and the enhancement of the proton-donor power should be less significant.

Hence, the effects of H bond in the excited state of an EDA complex consist in that the electron transfer considerably enhances the proton donor–acceptor properties of the molecules constituting the complex.

Experimental study of hydrogen bonding of components of the EDA complex in the excited state, radical anion $A^{\bullet-}$ and radical cation $DH^{\bullet+}$, involves considerable problems due to the short lifetime and low concentration of these species.

The energy of hydrogen bonding of the phenol radical cation $Ph^{\bullet+}$ with the THF molecule was calculated theoretically; the results were compared to the experimental shifts of the charge-transfer bands (Table 4).

The proton-donor power of Ph (its capability for hydrogen bonding) depends on the electronic state [40]: $S_0 \approx T_1 < S_1$. The charge on the hydroxy group increases in the same direction (Table 4); the change is the most significant in going to the radical cation $Ph^{\bullet+}$. The calculated heat of formation of an H bond of Ph with THF (2.73 kcal mol^{-1}) reasonably agrees with experimental data (3–4 kcal mol^{-1}) for such hydrogen bonds [43]. To calculate the heat of H bond of Ph with THF in the singlet excited state ($-\Delta H^*$), we took the optimized geometric parameters for the S_1 state. The value obtained, 4.11 kcal mol^{-1}, somewhat exceeds the corresponding value for the ground state (2.73 kcal mol^{-1}), which is consistent with the experimental data for the H bond of phenol with dioxane [41]: $-\Delta H(S_0) = 5.5$, $-\Delta H(S_1) = 6.5$ kcal mol^{-1}.

A PM3 calculation for ohenol in the triplet state gives the H bond energy coinciding with that for the ground state (Table 4).

The calculated potential curves of H bonds of phenol and $Ph^{\bullet+}$ radical cation with tetrahydrofuran (Fig. 18) differ essentially in both the depth and position of the minimum, which is due to the considerably enhanced proton-donor power of $Ph^{\bullet+}$ compared to phenol, and also to the contribution of the ion–dipole interactions to the total heat of H bond formation.

The correlation between the calculated heats of formation of H bonds of phenol in the radical cation

Proton acceptors: (*1*) nitromethane, (*2*) acetonitrile, (*3*) dioxane, (*4*) diethyl ether, (*5*) dimethylformamide, (*6*) THF, (*7*) dimethylacetamide, (*8*) DMSO, (*9*) hexamethylphosphoramide, and (*10*) dimethyl ether. (*C*) Correlation between the calculated heats of the H bond formation of phenol radical cation with proton acceptors and the respective quantities for molecular phenol.

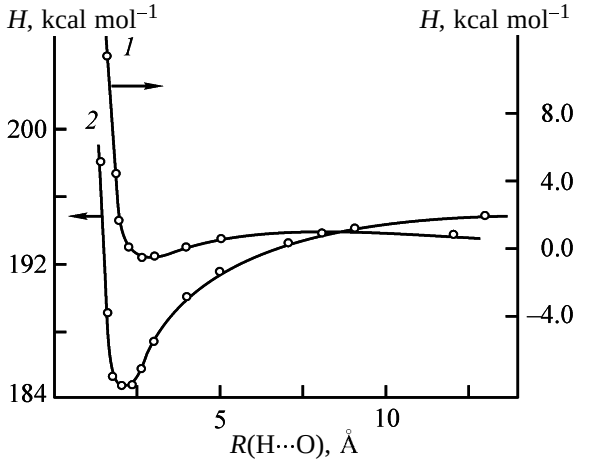

Fig. 18. Calculated heats *H* of formation of an H bond of (*1*) phenol and (*2*) phenol radical cation with THF, as functions of the H···O distance *R*.

($Ph^{\bullet+}$) and ground (Ph) states (Fig. 17, curve *C*), at a certain scatter, can be, on the whole, approximated by a straight line with a slope of 4.1, which is comparable with the slope (2.6) of the linear correlation between the H bond energies in the excited and ground states of the EDA complex (Fig. 17, curve *A*).

The calculations confirm the qualitative conclusion that considerable low-frequency shifts of the charge-transfer bands of EDA complexes in the presence of proton acceptors are caused by H bonding between the electron donor (in our case, phenol in the radical cation form) and a proton acceptor acting as a third component. The second component of the EDA complex, electron acceptor chloranil (Cl), in the excited CT state becomes a radical anion; therefore, it can also be expected to form a stronger H bond compared to the ground state. The calculation results confirm this assumption: The heat of formation of an H bond of Cl with formic acid (13.7 kcal mol^{-1}) exceeds by a factor of more than 4 the corresponding value for chloranil in the ground state (3.0 kcal mol^{-1}).

Table 5. CT energy of EDA complexes in CCl_4 (E_{CT}) and in CCl_4 with addition of DMSO (E^{H}_{CT})

Complex	E_{CT}	E^{H}_{CT}	$(E_{CT} - E^{H}_{CT})/E_{CT}$
	cm^{-1}

TNB–Ph	30500	27200	0.108

Replacement of phenol by a stronger electron donor, α-naphthol (NPT; I_D = 7.78 eV [16], I_D^{calc} = 8.13 eV), decreases the absolute value of the shift of the CT band upon formation of an H bond Ph···DMSO by a factor of more than 2 (Table 5), although phenol and α-naphthol differ in the proton-donor power insignificantly ($\Delta\nu_{OH}$ 371 and 390 cm^{-1}, respectively). Passing to a stronger electron acceptor, TCE (E_A 2.8 eV), is accompanied by a further decrease in the shift of the CT bands. These data show that enhancement of EDA interactions, evaluated by the difference $I_D - E_A$, causes a decrease in the shift of the CT band due to H bonding.

CONCLUSION

Thus, interaction of an electron and proton donor DH with an electron and proton acceptor A in a typical case involves formation of specific electronically excited states denoted as (D···H···A)*, which are characterized by the conjugation of two fundamental processes, electron transfer (excitation) and proton transfer. The energy of this state is determined, on the one hand, by the electron donor–acceptor properties of the components DH and A and, on the other hand, by the proton donor–acceptor processes of DH and A. The characteristics of the two coexisting and conjugated interactions, EDA complexation and H bonding, show inverse correlation: The stronger the EDA interaction between DH and A, i.e., the lower the charge-transfer energy, the weaker the H bond D–H···A. Owing to the effect of the hydrogen bond in the excited state of the EDA complex, the CT energy decreases relative to the complex without H bonding by a value as large as 1.5 eV and more, falling in the range characteristic of thermal excitations (<1 eV). Such low-lying electronic states (D···H···A) are efficiently populated at room temperature; hence, they are responsible for the thermal transfer of a hydrogen atom, which is involved in many organic catalytic reactions.

The interrelation between the two fundamental processes, electron transfer (excitation) and proton transfer, is determined by the electron–proton effect underlying many physical (luminescence quenching with hydrogen bond, electrical conductivity of hydrogen-bonded systems) and chemical (hydrogen atom transfer, acid–base catalysis) phenomena. Any factor decreasing the energy of the electronically excited level of the complex of the reactants and hence increasing the reaction rate should be considered as an

element of catalysis. In this sense, the electron–proton effect that we discovered makes the most powerful catalytic action. The classical catalytic system reactant 1 + reactant 2 + catalyst is only a particular case of catalysis. Considerably more widespread are bimolecular reactions of the type reactant 1···interaction 1 + interaction 2···reactant 2 in which the reactant molecules form several types of bonds with each other, e.g., a charge-transfer complex and an H bond. In the process, the catalytic effect is exerted not by an external agent (catalyst) but by a specific interaction between the reactant molecules, e.g., by a hydrogen bond. In ternary complexes A···D–H···X, in which the EDA interaction A···DH is supplemented by a hydrogen bond with a third component X, the effect of the external hydrogen bond D–H···X is also very significant: a decrease in the CT energy exceeds several times the H bond energy in the ground electronic state. As expected, in such complexes the catalytic effect of the H bond decreases with a decrease in the absolute value of the CT energy, i.e., in going to strong EDA pairs absorbing in the IR range.

The experimental data presented in this paper allowed us not only to develop a new approach to the phenomenon of catalysis, based on the electron–proton interaction, but also to disclose the nature of elementary chemical processes. The so-called noncatalytic reactions actually involve an element of catalysis associated with hydrogen (or other) bonds arising between the reactant molecules in the excited electronic state.

Norilsk Nickel Mining and Metallurgical Open Joint-Stock Company, Norilsk, Taimyr autonomous okrug, Russia

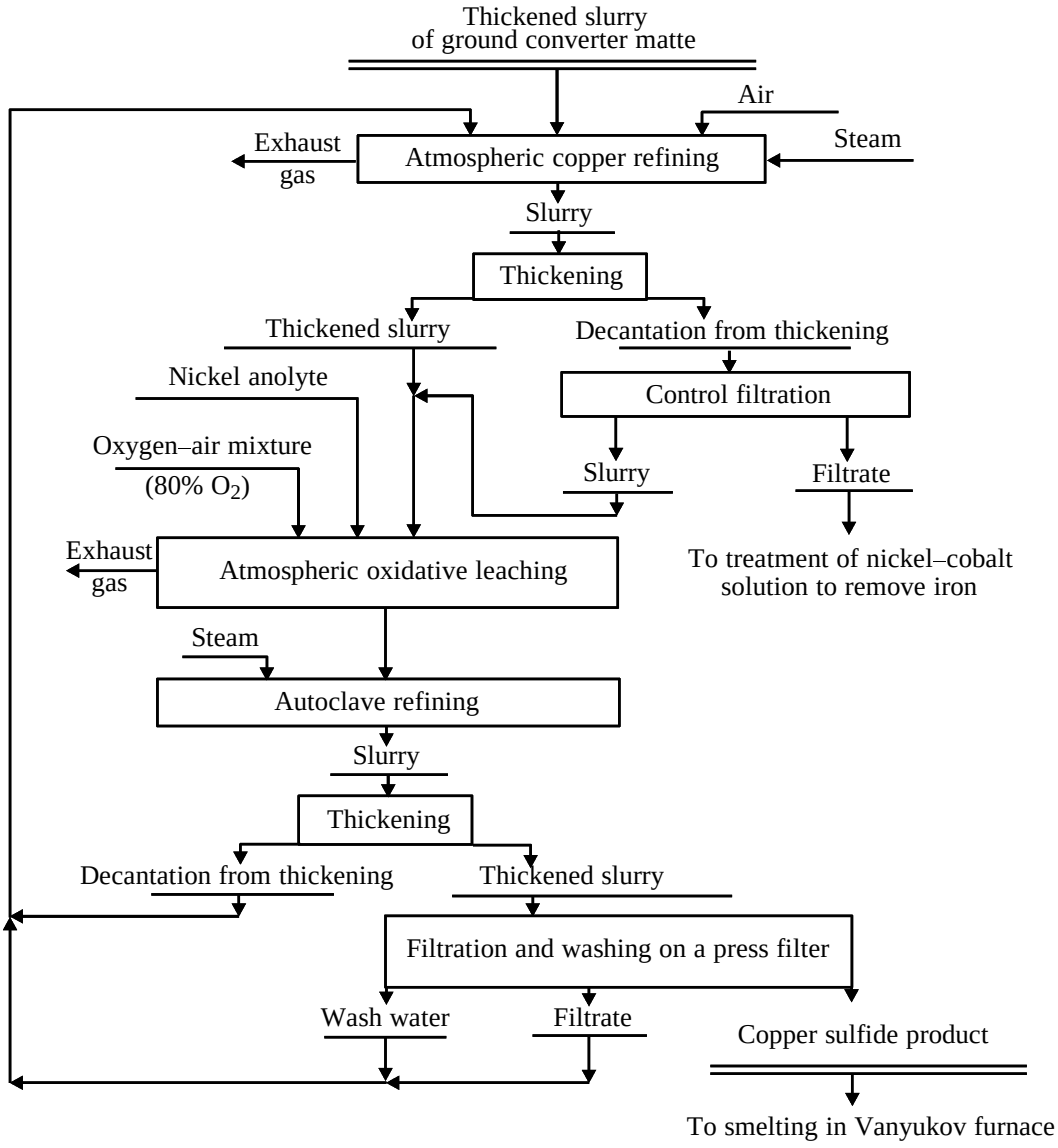
Received August 18, 2005

Abstract—Oxidative leaching of a solid product of copper refining was studied in a laboratory, with autoclave oxidation replaced with that in the atmosphere. The extent of the chemical reactions that occur in atmospheric oxidative leaching and autoclave refining in the technology of sulfate leaching of high-copper converter matte was determined.

In 1998–2003, specialists from the Norilsk Nickel Mining and Metallurgical Open Joint-Stock Company developed a process for sulfate leaching of high-copper converter matte and carried out semicommercial tests in the continuous mode. The scheme of processing by leaching includes atmospheric copper refining (ACR) with the starting converter matte and autoclave-oxidative leaching (AOL) of the ACR cake, with the subsequent autoclave refining (AR). The process developed makes it possible to obtain high-quality target products: nickel–cobalt solution containing no more than 1 mg dm^{-3} metal impurities and a copper sulfide product (CSP) containing no more than 0.5% nickel and iron [1]. The technology of hydrometallurgical processing of converter matte is to be implemented at the Nadezhdinskii metallurgical plant (NMP) of the Norilsk Nickel Mining and Metallurgical Company.

The process of autoclave leaching of converter matte is accompanied by oxidation of 9.4% of the sulfide sulfur to the sulfate form [2]. Depending on the conditions of the oxidation stage, the overall recovery of sulfur into solution in AR (in processing of the ACR cake) is 18–25%. The accumulation of sulfate ions in reusable solutions makes necessary control over the sulfur balance. The excess sulfur is removed in the form of sulfate ions with technical-grade soda, whose gross expenditure impairs the technical and economical parameters of the process.

To diminish the overall recovery of sulfur into an AR solution, it was suggested to modify the conditions of the oxidative leaching stage: to pass from the autoclave version to the atmospheric process (see scheme). The lowering of the parameters of the oxidative leaching stage makes it possible to reduce the formation intensity of sulfate sulfur through kinetic hindrance to side reactions of direct oxidation of sulfides.



At the same time, in passing from the autoclave process to atmospheric oxidative leaching (AtOL), the presence of soluble copper forms is insufficient for effective refining of CSP to remove nickel. To make up for this deficit, it was suggested to introduce into the AR procedure an additional amount of copper sulfate in the form of a preliminarily prepared copper-containing solution. The specific expenditure of the copper-containing solution in the AR procedure was determined from the occurrence conditions of the classical reaction of refining [3]

$$M + CuSO_4 \rightarrow MSO_4 + Cu, \qquad (1)$$

where M is Ni, Fe, or Co. This parameter was found to be 1.1–1.5 g Cu/g Ni contained in the AtOL cake.

To determine more precisely the parameters of atmospheric leaching of high-copper converter matte, a laboratory search was conducted, primarily aimed (i) to determine whether it is possible in principle to replace the autoclave oxidation stage with the atmospheric process, provided that a CSP with Ni content less than 0.5% is obtained; (ii) to find the optimal conditions of converter matte leaching in performing the oxidation stage under atmospheric conditions; and (iii) to determine the degree of sulfur oxidation in

Flowsheet of atmospheric and autoclave leaching of high-copper converter matte.

AtOL and AR processes carried out in the optimal mode.

EXPERIMENTAL

Solid products obtained in ACR under semicommercial conditions and model solutions with a composition reproducing that of the nickel anolyte formed upon electroextraction of nickel were used in the study. The laboratory analysis of the stage of atmospheric leaching was made in a 1.0 dm^3 laboratory autoclave equipped with a stirrer and a temperature control system. Technical-grade oxygen fed from a cylinder served as an oxidizing agent. Its flow rate was controlled using the readings of a rotameter. In the laboratory studies, the autoclave was not sealed hermetically, with the line for the exhaust gas opened and no excess pressure created in the system. The stirring rate was about 2800 rpm. The temperature was controlled in the automatic mode.

The autoclave was charged with a model solution and then stirring and heating were switched on. After a temperature of 90–95°C was reached, the starting solid material was introduced and supply of oxygen was commenced at a flow rate of 1.0 $dm^3\,min^{-1}$ per 1 dm^3 of slurry during the entire experiment. The time of an experiment was measured from the beginning of

feeding of the oxidizing agent. After AtOL was complete, the oxygen feeding was terminated and the slurry was sampled for chemical analysis. After that, the autoclave was hermetically sealed and purged with nitrogen, and the AR procedure was performed. After the experiment was over, the autoclave was cooled and discharged. The resulting slurry was filtered and then necessary weight and volume measurements were made and the chemical composition of the solid and liquid phases was determined.

It was found previously that the optimal specific expenditure of the acid in AOL is 30–36.3 wt % [4]. At the same time, chemical transformations that occur when the oxidation stage is performed in autoclave and atmospheric conditions may have different mechanisms. For example, the optimal specific expenditure of the acid in atmospheric leaching of a copper concentrate obtained in flotation separation of converter matte, calculated taking into account the chemical reactions and confirmed by experiment, was 24 wt % [5]. With account of the available data, the specific expenditure of the acid in AtOL was, originally, 27–28%, which corresponded to a liquid-to-solid phase ratio l : s = 3.5 : 1.

In the first stage of the study, a set of laboratory experiments aimed to determine the optimal duration of the AtOL procedure were carried out. The autoclave refining of the slurry formed in the atmospheric stage was performed under the standard conditions (T = 150°C, τ = 2 h). It was found that the optimal duration of the atmospheric oxidation stage is 150 min. In this case, the residual content of nickel in the sulfide copper product was 4.2% at an overall recovery of copper equal to 8.9% (Table 1, procedure no. 1).

In a search for ways to diminish the residual content of nickel in the CSP, a set of experiments concerned with the influence exerted by parameters of the autoclave refining on this quantity were performed. The results obtained are listed in Table 1 (procedure nos. 1–4), whence follows that elevating to 190°C the temperature at which the autoclave refining is carried out lowered the concentration of nickel in the CSP to 1.93%, and making longer (3 h) the duration of the AR stage at 190°C diminished the residual content of nickel in the CSP to 1.74% at the overall recovery of sulfur into solution equal to 11.2%.

It was decided that there is no point in improving the parameters of the autoclave refining, and, therefore, the efforts in a search for ways to diminish the residual concentration of nickel in CSP were concentrated in optimization of parameters of the AtOL technique.

The main goal of further research was to determine the liquid-to-solid phase ratio l : s in the feed for AtOL (Table 1, procedure nos. 3, 5–7). It follows from Table 1 that the optimal ratio for AtOL is l : s = 5 : 1, at which the content of nickel in the CSP was 0.76%, and the overall recovery of sulfur into solution, 15.1%. On raising the initial l : s ratio to 5.0 : 1, the amount of the acid consumed in leaching of sulfides increases from 28 to 40.5% relative to the mass of the starting solid phase. The curves describing how the compositions of the solid and liquid phases of the slurry formed in autoclave refining depend on the specific expenditure of the acid in AtOL (see figure) show an extremum: if the amount of acid involved in the process exceeded the optimal value (~41%), the quality of the CSP was impaired.

The minimum residual content of nickel in the modes studied was 0.76%. However, implementation of the AR mode developed by the authors (190°C) requires that a new autoclave equipment with enhanced process characteristics should be installed at NMP. The working temperatures of the 50 stills at NMP is 150°C, which makes impossible carrying out AR at 190°C. In order to determine whether the temperature parameters can be lowered, an experiment was carried out with the AtOL stage at l : s = 5 : 1 and AR temperature of 150°C (Table 1, procedure no. 8). The results obtained indicate that lowering the AR temperature to 150°C at the optimal expenditure of the acid leads to an increase in the overall recovery of sulfur to 13.9%, and in the residual content of nickel in the CSP, to 0.93%.

Comparison of the parameters of the atmospheric leaching technique with those of the autoclave method shows that the overall recovery of sulfur into solution is higher in autoclave oxidation. However, oxidation under atmospheric conditions failed to ensure a nickel content of CSP lower than 0.5%.

To determine the phase composition and structure of the starting and final solid products of ACR, AtOL, and AR, a mineralogical study was carried out.[1]

A study of the solid product of ACR revealed that the main phase component of a sample was relict

[1] The mineralogical study was carried out at Gipronikel' Institute Open Joint-Stock Company (St. Petersburg) by L.N. Ertseva by means of X-ray diffraction and optical analyses, scanning electron microscopy, and X-ray fluorescence microprobe analysis.

Table 1. Results of a laboratory study of the atmospheric oxidative leaching and autoclave refining

* Numerator, content in the solid phase; denominator, that in solution.

djurleite $Cu_{1.96}S$ with virtually zero content of iron. The finely dispersed part of the residue was mainly composed of copper sulfide (mostly of secondary origin). The sample of the solid residue contained both particles containing all the three components and particles containing no metallic phase, whose dissolution led to a decrease in the total content of iron and cobalt in the solid residue, compared with the starting converter matte. The decrease in the content of iron in the solid phase is also due to its leaching-out also from the bornite component of copper sulfide, with probable formation of a secondary copper sulfide. The phase component of nickel sulfide contained a considerable amount of copper impurity and had a formula close to $Ni_{50}Cu_{10}S_{40}$, which stoichiometrically corresponded to a mixture of $Cu_{2-x}S$ and Ni_3S_2. A minor part of nickel sulfide was in the form of millerite.

According to the results of an X-ray diffraction analysis, a sample of the solid product of AtOL was mainly composed of digenite $Cu_{1.765}S$ and covelline CuS; the sample also contained an appreciable amount of millerite γ-NiS and trace concentrations of polydymite Ni_3S_4. The sample contained no oxygen or oxygen-containing phases. No elementary sulfur in the AtOL cake was detected either.

The metallic phase was completely absent, which pointed to the large extent of its leaching-out by the reaction [6]

$$M + H_2SO_4 + 0.5O_2 \rightarrow MSO_4 + H_2O, \quad (2)$$

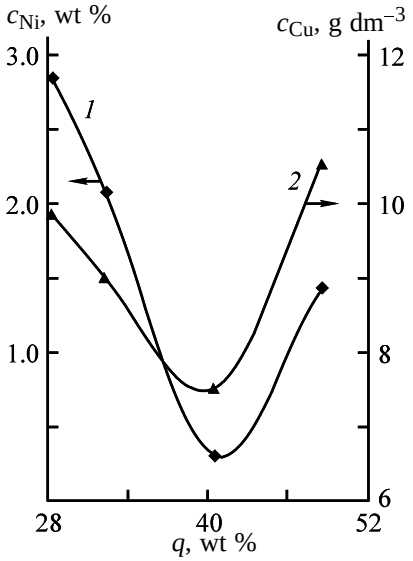
where M = Ni, Fe, Cu, or Co.

The recovery of cobalt into solution in AtOL quantitatively corresponded to that in the case of a complete dissolution of the metallic phase. Consequently, cobalt sulfides were not leached-out when the oxidation stage was performed under atmospheric conditions.

The matrix component had the form of a mixture of dispersed phases of composition $Cu_{15}Ni_{40}S_{46}$, which was identified as a mixture of digenite and millerite. Compared with the ACR cake, the Ni/Cu ratio in nickel sulfide decreased to 2.7. In view of the above-mentioned increase in the content of copper in the nickel matrix, the formation of millerite and digenite is probably provided by parallel occurrence of two processes: "cementation" of copper on heazlewoodite [reaction (3)] and acid dissolution of the forming chalcosine [reaction (4)]:

$$Ni_3S_2 + 2CuSO_4 \rightarrow NiS + 2NiSO_4 + Cu_2S \quad (3)$$

$$Cu_2S + 0.2H_2SO_4 + 0.1O_2 \rightarrow Cu_{1.8}S + 0.2CuSO_4 + 0.2H_2O \quad (4)$$



$$Ni_3S_2 + 0.2H_2SO_4 + 1.8CuSO_4 + 0.1O_2 \rightarrow NiS + 2NiSO_4 + Cu_{1.8}S + 0.2H_2O. \quad (5)$$

The extent of this reaction with respect to heazlewoodite was determined by the Ni/Cu ratio in nickel sulfide, reaching a value of 2.7.

The formation of trace amounts of polydymite is presumably due to acid dissolution of millerite [6]

$$4NiS + H_2SO_4 + 0.5O_2 \rightarrow Ni_3S_4 + NiSO_4 + H_2O. \quad (6)$$

A part of the acid contained in the starting solution was spent for dissolution of nickel from heazlewoodite

Residual content of nickel in CSP, c_{Ni}, and concentration of copper in the AR solution, c_{Cu}, vs. the specific expenditure of the acid in the AtOL procedure, q.

and of iron isomorphically present in heazlewoodite, by the reaction

$$M_3S_2 + H_2SO_4 + 0.5O_2 \rightarrow MSO_4 + 2MS + H_2O, \quad (7)$$

where M is Ni and Fe contained in heazlewoodite.

Further dissolution of iron occurred by the reaction [7]

$$Ni_3S_2 \cdot FeS + 2H^+ + 0.5O_2 \rightarrow 3NiS + Fe^{2+} + H_2O. \quad (8)$$

The extent of reactions (7) and (8) was determined by the recovery of nickel and iron into solution.

Chalcosine contained in the copper sulfide phase and in the nickel sulfide matrix was completely oxidized to digenite in accordance with Eq. (9), with a part of digenite reacting with oxygen to give covelline [6]:

$$5Cu_2S + 0.5O_2 + H_2SO_4 \rightarrow 5Cu_{1.8}S + CuSO_4 + H_2O, \quad (9)$$

$$5Cu_{1.8}S + 4H_2SO_4 + 2O_2 \rightarrow 5CuS + 4CuSO_4 + 4H_2O. \quad (10)$$

The recovery of sulfur into solution in the experiment was 3.78%, which was due to the occurrence of direct oxidation of a certain amount of covelline [3]:

$$CuS + 2O_2 \rightarrow CuSO_4. \quad (11)$$

The main chemical reactions in AtOL and their extents are listed in Table 2.

Table 2. Calculated extents of the main chemical reactions in AtOL

$FeS \cdot Ni_3S_2 + H_2SO_4 + 0.5O_2 = FeSO_4 + 3NiS + H_2O$			28.2	12.47	15.83
$Cu^0 + H_2SO_4 + 0.5O_2 = CuSO_4 + H_2O$	Cu	21.35	100.0	0.19	0.84
$Ni_3S_2 + H_2SO_4 + CuSO_4 + 0.5O_2 = NiS + 2NiSO_4 + CuS + H_2O$			–	–11.53	–51.72
$5Cu_2S + 0.5O_2 + H_2SO_4 = 5Cu_{1.8}S + CuSO_4 + H_2O$			100.0	9.40	42.14
$5Cu_2S + 4H_2SO_4 + 2O_2 = 5CuS + 4CuSO_4 + 4H_2O$			53.1	19.96	89.51
$CuS + 2O_2 = CuSO_4$			10.8	3.34	14.96

According to the results of mineralogical studies, a sample of the solid product of AR was composed of a mixture of particles bound into conglomerates by the disperse mass of virtually nickel-free copper sulfide.

Under the conditions of the AR procedure, copper sulfide contained in the starting solution and additionally introduced into the copper-containing solution entered into reactions with nickel, iron, and cobalt sulfides [8]:

$$6NiS + 9CuSO_4 + 4H_2O \rightarrow 5Cu_{1.8}S + 6NiSO_4 + 4H_2SO_4, \quad (12)$$

$$8Co_3S_2 + 27CuSO_4 + 4H_2O \rightarrow 15Cu_{1.8}S + 24CoSO_4 + 4H_2SO_4, \quad (13)$$

$$6CoS + 9CuSO_4 + 4H_2O \rightarrow 5Cu_{1.8}S + 6CoSO_4 + 4H_2SO_4, \quad (14)$$

$$6FeS + 9CuSO_4 + 4H_2O \rightarrow 5Cu_{1.8}S + 6FeSO_4 + 4H_2SO_4. \quad (15)$$

In this case, reactions (12), (13), and (15) were complete, and the extent of reaction (14) was determined by the recovery of cobalt into the AR solution.

It was established by means of X-ray fluorescence microprobe analysis and scanning electron microscopy that the matrix component was a mixture of several phases of average composition $Cu_{18}Ni_{30}S_{50}$, which best corresponded to a mixture of digenite and polydymite. The presence of polydymite in the sample was also confirmed by diffraction methods. No other nickel sulfides were detected in the sample. Thus, the volume of polydymite in the sample of the AR cake somewhat increased, compared with the AtOL sample, on the background of a decrease in the total amount of nickel in the former, which indicates that millerite recrystallizes into polydymite [9]:

$$3.2NiS + 0.8CuSO_4 + CuS \rightarrow 0.8Ni_3S_4 + Cu_{1.8}S + 0.8NiSO_4. \quad (16)$$

Table 3. Calculated extents of the main chemical reactions in autoclave refining of the solid product of AtOL

(17)				99.00	–14.64	27.83	46.82

Copper sulfide had a composition $Cu_{1.77}S$, corresponding to digenite formed by the reaction [3, 6, 8, 9]:

$$6CuS + 3CuSO_4 + 4H_2O \rightarrow 5Cu_{1.8}S + 4H_2SO_4. \quad (17)$$

The extent of this reaction was determined by the experimentally determined transfer of sulfur into solution.

The recovery of iron in AR also occurred via decomposition of the "iron" component of bornite ($Cu_4^+Cu_{0.5}^{2+}Fe^{3+}S_4 \overrightarrow{\leftarrow} 2Cu_2S + 0.5CuS + 0.5Fe_2S_3$), with digenite acting as a reducing agent for iron(III). The overall reaction can be written as

$$4Fe_2S_3 + 12CuSO_4 \rightarrow 4Fe_2(SO_4)_3 + 12CuS \quad (18)$$

$$5Cu_{1.8}S + 4Fe_2(SO_4)_3 \rightarrow CuSO_4 + 5CuS + 8FeSO_4 \quad (19)$$

$$4Fe_2S_3 + 8CuSO_4 + 5Cu_{1.8}S \rightarrow 12CuS + 8FeSO_4 \quad (20)$$

The main chemical reactions of the AR procedure and their extents are listed in Table 3.

CONCLUSIONS

(1) In the oxidation stage of leaching under atmospheric conditions, the content of nickel in the copper sulfide product is less than 1.0%. The key condition for a decrease in the residual content of nickel is that the atmospheric oxidative leaching should be performed at l : s = 5 : 1, which corresponds to a specific expenditure of the acid equal to about 41% relative to the mass of the solid phase.

(2) The optimal conditions of the successive procedures of atmospheric oxidative leaching and autoclave refining are as follows: leaching temperature, 90–95°C; oxygen flow rate, 1.0 $dm^3\,min^{-1}$ per 1 dm^3 of slurry; stirring rate, ~2800 rpm; l : s ratio in the feed for atmospheric oxidative leaching, 5 : 1

(acid expenditure ~41 wt %); duration of leaching, 150 min; refining temperature, 150°C; duration of refining, 120 min; specific expenditure of the copper-containing solution in refining, 1.1–1.5 g Cu/g Ni in the solid product of atmospheric oxidative leaching.

(3) The amount of dissolved sulfides of nonferrous metals and the degree of oxidation of the sulfide sulfur to the sulfate form are lower in atmospheric oxidation, compared with the autoclave process. The overall recovery of sulfur into solution in atmospheric oxidative leaching in the optimal mode was 13.9%, which is considerably lower than that in the oxidation stage carried out under autoclave conditions.

(4) Basic copper sulfates and oxide compounds of iron are not precipitated in atmospheric oxidative leaching. No elemental sulfur is detected in leaching cakes.

(5) A specific feature of the copper sulfide product obtained in the oxidation stage performed under atmospheric conditions is that it contains polydymite in an amount exceeding that formed in the leaching stage. The formation of polydymite gives no way of recommending the atmospheric oxidation mode for processing of nickel-containing converter mattes, because even introduction of considerable amounts of copper sulfate fails to ensure deep refining of the copper sulfide product to remove nickel.

(6) The choice of an oxidative leaching mode for high-copper converter matte will be determined by the technology of further processing of the copper sulfide product. In the case of a hydrometallurgical processing scheme, which involves autoclave leaching, it is advisable to use the atmospheric oxidative leaching mode. The pyrometallurgical mode requires a greater extent of nickel removal from the copper sulfide product (to <0.5%), which makes it necessary to carry out the oxidative leaching procedure in the autoclave mode.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Production of Complex Nitrogen–Potassium and Nitrogen–Magnesium Fertilizers from Substandard Urea Fractions

A. S. Kolyshkin and V. Z. Poilov

Perm State Technical University, Perm, Russia

Received May 4, 2005

Abstract—The production of NK and NMg fertilizers of various compositions from urea and finely crystalline potassium sulfate or urea and caustic magnesite powder was optimized. The commercial characteristics (qualitative composition, hygroscopicity, and strength) of the granulated NK and NMg fertilizers obtained were studied. The possibility of undesirable chemical reactions occurring on fusing potassium sulfate or magnesium oxide with urea in the fertilizer mixture was studied by X-ray phase analysis and IR spectroscopy.

Presently granulated urea produced at the nitrogen industry plants by the method of prilling (spraying the melt in a granulation tower) has insufficient mechanical strength of the granules, which results in the formation of a significant part (2–5 wt %) of substandard product, which is returned to the starting point of the process (into a urea melt). As a result, the net cost of commercial urea increases. Moreover, on storage, transportation, and reloading of urea, its consumer quality decreases owing to mechanical crushing of urea granules. The problem is aggravated also by the fact that the market of prilled urea is narrowing progressively in the last few years [1].

At the same time, substandard urea fractions with a high content of nitrogen would be most appropriate for use as a nitrogen-containing component of complex fertilizers being in the greatest consumer demand. The second component of fertilizers could be substandard finely crystalline products containing potassium and magnesium components in the form taken up by plants. These products are not in demand as individual fertilizers owing to extremely small size of the particles.

By their availability, harmlessness, and correspondence to the claimed characteristics of the end product, finely crystalline technical-grade K_2SO_4 can be used as a potassium-containing component of NK fertilizers, and magnesite caustic powder containing 85 wt % MgO, as a magnesium-containing component of NMg fertilizers. However, a mechanical mixture of nutritive components will not have the required commercial characteristics. Therefore, we have suggested a process for fusing powdered K_2SO_4 and MgO with substandard fractions of urea.

Understanding of physicochemical features of processes occurring in a urea melt is very important for successful promotion of this technology. Thus, when obtaining mixed complex fertilizers, it is necessary to take into account the fact that some starting salts and end products must not be mixed, since undesirable chemical reactions can occur upon their contact. These reactions can result in losses of nutritive materials and in deterioration of the physical properties of the fertilizers [2].

Pozin [3] indicates that the problem of fertilizer antagonism has not been studied adequately; however, he points to a possibility of mixing K_2SO_4 with urea. According to [4, 5], complex compounds of the compositions $MSO_4 \cdot CO(NH_2)_2$, $MSO_4 \cdot 2CO(NH_2)_2$, $MSO_4 \cdot 4CO(NH_2)_2$, and $MSO_4 \cdot 6CO(NH_2)_2$ are formed in aqueous solutions of alkali (or alkaline-earth) metal sulfates and urea. Such compounds may also be formed in the reaction of molten urea with K_2SO_4 dissolved in it.

The suspension of MgO in water has a weakly basic reaction. Hence, urea can be hydrolyzed to give as the final product the corresponding carbonate and ammonia [6]:

$$2CO(NH_2)_2 + Mg(OH)_2 \rightarrow Mg(OCN)_2 + 2NH_3 + 2H_2O, \quad (1)$$

$$Mg(OCN)_2 + 3H_2O \rightarrow MgCO_3 + 2NH_3 + CO_2. \quad (2)$$

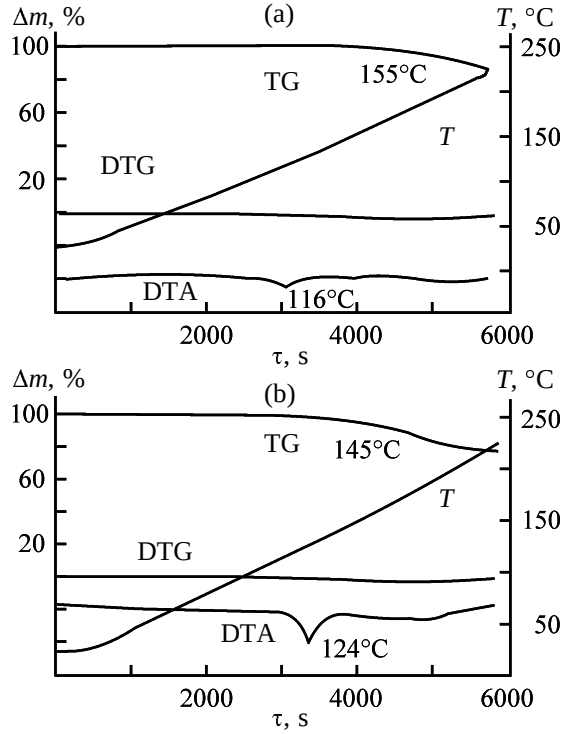

Fig. 1. Derivatogram of a urea fertilizer mixture containing (a) 70% K_2SO_4 and (b) 50% caustic magnesite powder. (Δm) Weight loss, (T) temperature, and (τ) time.

Moreover, reaction (3) is possible:

$$Mg(OCN)_2 + 2H_2O \rightarrow MgCO_3 + CO(NH_2)_2. \quad (3)$$

These reactions must inevitably result in losses of the nutritive component, nitrogen.

Therefore, one of our goals was to study the physicochemical processes occurring on fusing urea with finely crystalline additions, and primarily the processes that can result in the loss of nitrogen.

The most important commercial characteristics of any fertilizer are also hygroscopicity and strength of granules. The capability of polycrystalline products for agglutination and clotting in storage is associated with their hygroscopicity. The content of hygroscopic moisture in a substance affects its friability and capability for thermal decomposition, freezing together, etc. The technology of further treatment and storage of a substance depends on its hygroscopicity.

Therefore, another goal of our study was to optimize the process of fusing urea with finely crystalline additions with the aim of improving commercial characteristics (qualitative composition, hygroscopicity, and strength) of the resulting fertilizers.

The synthesis of complex NK and NMg fertilizers included the following stages: preparation of a fertilizer mixture of a varied composition, its melting at 140°C in an isothermal reactor, solidification of the fertilizer mixture melt on a cooled surface, grinding of the resulting slab, and the separation of the complex fertilizer granules with segregating the commercial fraction.

The qualitative composition of complex fertilizers was determined by IR spectroscopy. The IR spectra were recorded on a Specord 75-IR spectrometer. The samples were prepared as KBr pellets. We determined the parameters of thermal stability of the samples of NK and NMg fertilizers with a Q 1500 D derivatograph (Hungary) in the range 20–600°C at a heating rate of 2.5 and 5 deg min^{-1}. Calcined Al_2O_3 was used as a reference.

We carried out the X-ray analysis on a DRON-3M diffractometer with a monochromator on a primary beam and CuK_α radiation. We set the rate of the sample rotation at 2 or 4 deg min^{-1}. The samples of the materials to be analyzed were prepared as powders. The diffraction patterns were treated by the standard procedure [7].

To study the hygroscopicity of the fertilizers, we used Pestov's method consisting in the estimation of the critical humidity [8]. We estimated the strength of the samples of solidified melt of complex fertilizers with a 2054 P-5 device. Samples in the form of cylindrical pellets 12 mm in diameter and 16–36 mm long were tested for the critical compression stress. We calculated the critical strength as the ratio of the sample failure stress to the area of its failure (area of the longitudinal section of the cylindrical sample).

The first effect (endothermic) corresponding to urea melting is observed in the derivatograms of the $CO(NH_2)_2$–K_2SO_4 and $CO(NH_2)_2$–MgO fertilizer mixtures (Figs. 1a, 1b) at the temperature approximately 10–15°C lower than the melting point of pure urea (132°C). The reaction with a weight loss (urea decomposition) starts at temperatures higher than 145°C for the mixture of urea with magnesium oxide and higher than 150–155°C for urea and for the mixture of urea with potassium sulfate. A decrease to 145°C in the temperature of the onset of urea decomposition may be due to a catalytic effect of pulverized MgO particles on the urea decomposition, as they represent a ready seed for the primary nucleation of a solid phase of urea decomposition products. Nevertheless, the DTA data show that the systems under study are stable up to the temperatures 10–20°C higher than the melting point, which allows melting of fertilizer mixtures without losing nitrogen.

The IR spectra and the X-ray and thermographic data for these mixtures showed that no specific reactions occur when K_2SO_4 is added to a urea melt at 140°C.

However, the IR spectra of NMg fertilizers prepared at the same temperature contain a weak absorption band at 2170 cm^{-1} indicative of the presence of cyanate ions in the granulate [9]. This fact suggests that urea in the melt reacts with finely dispersed MgO to give magnesium cyanate by reaction (1). The intensity of the absorption band of cyanate ions does not depend on the MgO content in the mixture.

The differential thermal analysis of $CO(NH_2)_2$–MgO mixtures (Fig. 1b) revealed no effect corresponding to reaction (1), probably because this effect is obscured by a strong endothermic effect of urea melting. The X-ray analysis confirms the fact that the NMg fertilizer basically consists of the phases of urea and magnesium oxide; the phase of magnesium cyanate was not detected.

Hence, the content of magnesium cyanate in the granulate is low, and the nitrogen loss due to its formation is insignificant. The mechanism of magnesium cyanate formation remains to be elucidated. However, apparently, the minor content of magnesium cyanate is associated with the low solubility of MgO in the urea melt and with the short time of MgO contact with the urea melt.

The X-ray phase analysis showed that a substantial part of the pure urea melt solidifies in the amorphous state. As solid finely dispersed particles of K_2SO_4 or MgO are introduced into the melt, the urea structure becomes considerably less amorphous. This is associated with an increase in the crystallization rate, since the crystallization is possible on ready nuclei of a solid phase with a minimal overcooling of the melt.

Thus, we found by the physicochemical methods of analysis that undesirable chemical reactions in the fertilizer mixture melt resulting in significant losses of precious nutritive components do not proceed when K_2SO_4 or MgO is melted together with urea.

The laboratory studies of the synthesis of nitrogen–potassium (or nitrogen–magnesium) fertilizers have shown that the N : K_2O ratio in the NK fertilizer must be no less than (1.2–1.3) : 1, and the N : MgO ratio in the NMg fertilizer, no less than (1.0–1.1) : 1.5. A lower content of urea results in a decrease in the fluidity of the melt, which complicates its unloading from the melting pot and forming of a melt layer of the desired thickness on a cooled crystallizer surface.

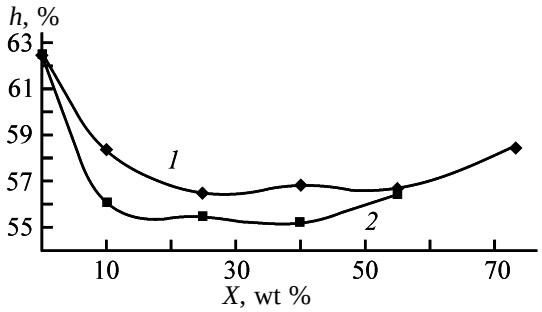

Fig. 2. Plot of hygroscopic point of (*1*) NK and (*2*) NMg fertilizers vs. content *X* of (*1*) K_2SO_4 and (*2*) MgO. (*h*) Relative humidity.

The N : K_2O ratio exceeding 3 : 1 results in obtaining nonuniform granules owing to the melt segregation in the course of its slow solidification.

We studied the hygroscopicity of the fertilizers using samples of the commercial fraction from 2 to 5 mm. The results of replicate experiments are summarized in Fig. 2.

The hygroscopicity of the complex NK and NMg fertilizers is higher than that of granulated urea, since two different crystal phases are present in their granules. Figure 2 shows that the critical humidity passes through a minimum and then starts to increase as the N : K_2O or N : MgO ratio in the fertilizer increases, i.e., as the content of urea increases, the fertilizer initially becomes less hygroscopic. This can be accounted for by the fact that the probability of the formation of fractures in the bulk and on the surface of the granules decreases as the amount of urea in the fertilizer increases. The granules have a more monolithic structure, which results in a decrease in the adsorbing surface area of the material.

With regard to the fact that the critical air humidity for the granules of the fertilizers obtained is low, it is necessary to make provisions for packaging the product in the production process.

We also studied the indices of strength of solidified melt of complex fertilizers based on urea. In the general case, the influence of dispersed particles of K_2SO_4 and MgO on the strength of the granules seems to be associated with changes in the kinetics of the structure formation, with the formation of dendritic crystals piercing the granule volume, and with the changes in the strength of single phase contacts and in their concentration. Insoluble finely dispersed modifying additives introduced into the urea melt create a large surface area of phase contact, which accelerates the nucleation of urea particles adsorbed on the nuclei of the solid phase. An increase

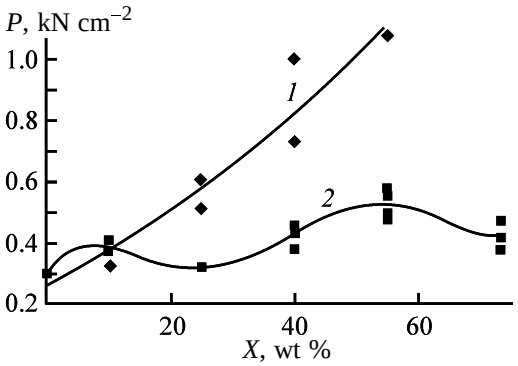

Fig. 3. Plot of mechanical strength *P* of samples vs. composition of the crystallized melt of fertilizer mixture. (*X*) Content of (*1*) MgO and (*2*) K_2SO_4.

in the strength of such a microheterogeneous structure is defined by a large number of forming bonds and contacts between two crystal phases.

In such materials, the matrix takes the whole load, and dispersed particles of a reinforcing filler inhibit the development of plastic deformation offering a resistance to the movement of both single dislocations and dislocation formations (subinterfaces and grain boundaries) [10].

The strength of NK fertilizer pellets is slightly higher than the strength of pure urea pellets (Fig. 3). A maximal strength is attained at the 55 wt % content of K_2SO_4 in the melt. The further increase in the K_2SO_4 concentration in the melt results in a minor decrease in the strength of the pellets, which seems to be associated with a decrease in the number of single interfacial contacts and with poor wetting of the solid phase particles owing to a deficiency of the liquid phase in the suspension consisting of molten urea and solid potassium sulfate. Presumably, at a low content of urea, the interfacial contacts are weakened, and at a high content of urea, the strength decreases owing to a lower strength of urea crystals compared to the crystallizate obtained by fusing urea with potassium sulfate.

The strength of NMg fertilizer pellets increases over the whole interval of the suspension fluidity as the MgO concentration in the fertilizer increases (Fig. 3). This is due to the better wetting of MgO particles (caustic magnesite powder) owing to their smaller size compared to the K_2SO_4 particles. As a result, MgO particles form a larger number of crystallization centers with a larger interface surface in the urea melt, which is accompanied by a stronger reinforcing effect.

CONCLUSIONS

(1) It was found by physicochemical methods that, when potassium sulfate is fused with urea at 140°C, no undesirable chemical reactions occur in the fertilizer mixture melt and the loss of valuable nutritive components is negligible.

(2) Finely dispersed magnesium oxide dissolved in the urea melt forms magnesium cyanate. However, the rate of this reaction is low; therefore, the amount of forming magnesium cyanate is on the impurity level.

(3) Owing to relatively high hygroscopicity of the resulting fertilizers, the product must be packaged. The optimal compositions providing the maximal strength of the samples of NK and NMg fertilizers have been determined.

(4) A substantial part of the melt of pure urea crystallizes in an amorphous state. The introduction of solid finely dispersed particles of potassium sulfate or magnesium oxide into the melt decreases the amorphization of its structure, promoting the crystallization and reinforcement of the structure of the solidified melt.

Abstract—Methods for synthesis of zinc oxide hydrosols by peptization and condensation were developed. The basic colloid-chemical properties of the sols were determined: electrokinetic properties, size and phase composition of particles, and stability of hydrosols against introduction of electrolytes. The possibility of obtaining antibacterial and UV-protecting cosmetic preparations from the hydrosols obtained was demonstrated.

Owing to the combination of diverse physical and chemical properties (high melting point and heat conductivity, ability to effectively absorb UV light, high photosensitivity, largely unique piezo- and pyroeffects, rather strong luminescence, etc.), zinc oxide ZnO is extensively used in a wide variety of industries. In particular, introduction of zinc oxide into cosmetic creams and gels makes them sunlight-protective and antibacterial [1]. The efficiency of their action largely depends not only on the concentration of the active substance, zinc oxide, but also on the size of its particles, their modification, and degree of polydispersity. In particular, the higher the dispersity of the particles, the more effective a preparation on their basis [2]. This means that the task of obtaining as fine particles of this oxide as possible is a matter of current interest.

Here we demonstrate the possibility of synthesizing highly dispersed zinc oxide by the sol–gel method. This technique was chosen because it can yield nanomaterials with controlled polydispersity and prescribed particle size.

We chose zinc nitrate as a precursor owing to its ready availability and nontoxicity. It should be noted that synthesis of nanodispersed ZnO by the sol–gel method has already been described in the literature [3, 4], but the synthesis was performed from other materials (zinc alkoxides or organometallic compounds), whose use in cosmetology is prohibited. As for other ways to obtain zinc oxide, which are not based on the sol–gel technology, they can also be found in the literature, but are rather complicated and exotic (decomposition in an electric arc, laser evaporation of a target, etc. [5, 6]). In view of the aforesaid, we suggest a rather easy procedure for preparing highly dispersed ZnO (in the form of a sol) by hydrolysis of $Zn(NO_3)_2$.

EXPERIMENTAL

The hydrosol was synthesized by two methods, peptization and condensation. The concentration of all the sols was determined gravimetrically, both in a sol itself and in the ultrafiltrate obtained from the sol. The ultrafiltration was done in a standard cell equipped with polysulfone membranes. The size of sol particles was monitored by photon-correlation spectroscopy (PCS), using the known procedure [7]. The phase composition of sol particles was determined by X-ray diffraction analysis on a DRON-3 diffractometer with CuK_α radiation (1.54051 Å).

In the peptization method, a hydroxide freshly precipitated from a nitrate solution with ammonia was washed with distilled water and then peptized either with an electrolyte (zinc nitrate) solution or with dilute nitric acid. It should be noted that heating of a freshly precipitated and washed zinc hydroxide in distilled water (without any peptizing agent) to 90°C also yields a stable hydrosol.

To develop a technique based on the condensation method, we used as a basis the procedure described for hydrosols of Fe(III) and La(III) [8]. In this method, a certain amount of a $Zn(NO_3)_2$ solution is introduced with vigorous stirring into a boiling aqueous ammonia solution of a known concentration. The resulting suspension is subjected to an ultrasonic treatment for 2 min. On cooling, a transparent opalescent hydrosol is obtained. However, the concentration of such sols is not high (about 0.03 wt %), which is considerably lower than the value provided by the peptization

method. When speaking about the concentration, we should specify that the content of Zn(II) in the ionic form (in the ultrafiltrate) is virtually zero, i.e., the sols produced by peptization and condensation contain virtually no electrolyte.

The main parameters of the hydrosols obtained and the conditions of their synthesis are listed in Table 1. It can be seen that the region of aggregative stability of all the hydrosols lies within the range of pH 6.0–7.5. The virtually neutral medium does not hinder their use in cosmetology and medicine. We established by X-ray diffraction analysis that, irrespective of the synthesis procedure, particles of all the hydrosols are particles of ZnO with a hexagonal structure of the wurtzite type.

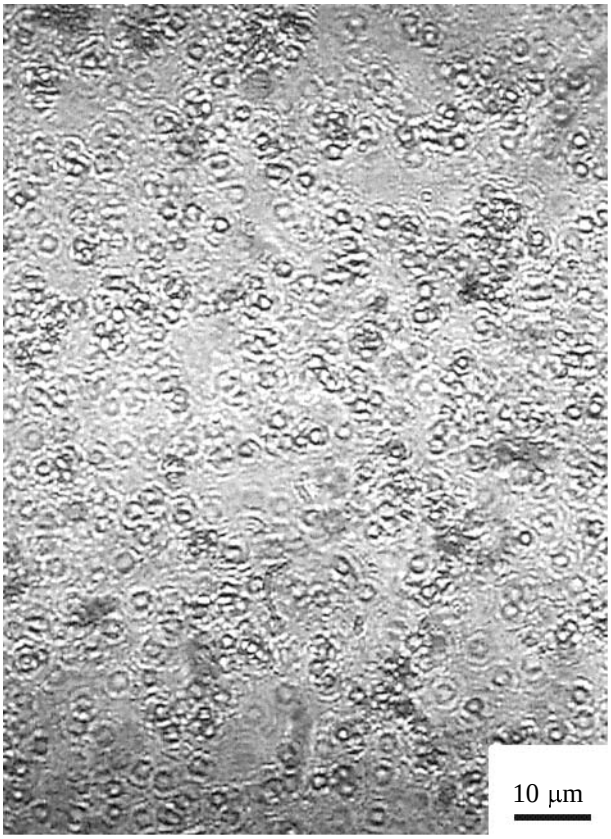

Fig. 1. Micrograph of particles of a dried hydrosol.

We chose for further studies, aimed to determine the basic colloid-chemical properties of the hydrosols obtained, hydrosol no. 2 synthesized by peptization (Table 1), because the concentration of its dispersed phase is the highest. A visual inspection under a microscope revealed that all of its particles are spheres with a nearly monodisperse size distribution (Fig. 1).

Here, we should mention the fact that a sol dried on a glass substrate was used in the microscopic studies. In the course of drying, particles aggregate, so that their size in micrographs considerably exceeds that determined by the PCS method in the dispersion medium (Table 1). To evaluate the aggregative stability of the hydrosol, the ζ potential and coagulation thresholds in the presence of certain electrolytes were determined by macroelectrophoresis and turbidimetry, respectively.

Figure 2 shows how the optical density and ζ potential of the hydrosol depend on pH of the dispersion medium. The ζ potentials were calculated by the Helmholtz–Smoluchowski equation. As seen from Fig. 2, the electrokinetic potential is not high ($\leq$37 mV), with the particles positively charged. However, these rather low values are in good agreement with published data for other hydrosols, which are stable in weakly acidic or weakly alkaline media [8, 9]. The data in Fig. 2 are rather consistent. As already noted, the region of aggregative stability of this hydrosol lies at pH 6.5–7.5. It is in this pH range that the minimum optical density (smallest particle size) and highest ζ potential, corresponding to the largest electrostatic component of the disjoining pressure, are observed. At pH < 6, the hydrosol particles dissolve, and at pH > 10 the excess amount of the electrolyte causes phase separation in the system.

Additional information about the aggregative stability is yielded by the coagulation thresholds with respect to electrolytes. Furthermore, the knowledge of these values is also highly advantageous in development of cosmetic formulations in which this hydrosol is to be used, because most of cosmetic formulations contain an electrolyte. The role of electrolyte in such formulations is rather diverse, from viscosity and pH adjustment to introduction of the required amount of microelements. The most widely used electrolyte is sodium chloride, and, therefore, we studied the behavior of the sol in its presence, as well as upon introduction into the system of other sodium salts: nitrate and sulfate.

The coagulation thresholds for sodium nitrate and chloride coincide (7.5 mM), and that for sodium sulfate is 0.14 mM. Knowing the coagulation thresholds, we can find by what mechanism, concentration or neutralization, coagulation occurs. This can be done in several ways, the simplest of which is the Schulze–Hardy rule. According to this rule, in the case of the concentration mechanism, the coagulation thresholds (C_c) associated with electrolytes with a charge of counterions (z) equal to 1 (chloride and nitrate, in the case in question) and 2 (sulfate) relate as 1 : 1/64, i.e., $C_c = \text{const}/z^6$. In our case, the coagulation thresholds relate as 1 : 1/54, which reasonably agrees with the value given by the rule and suggests that the coagulation occurs by the concentration mechanism.

The rather high coagulation thresholds and low ζ potentials suggest that the aggregative stability of the given hydrosol is provided not only by the electrostatic factor of the disjoining pressure. In all probability, a developed hydrated layer is formed on zinc oxide particles by bulky complex ions $[Zn(H_2O_4)]^{2+}$. This layer ensures the stability of the sol also via the structural component. The presence of this layer has been confirmed for numerous hydrosols including, in particular, sols of basic copper salts in a virtually neutral medium [10].

Thus, the set of studies we performed yielded an aggregatively stable zinc oxide hydrosol and data on its basic properties.

The goal of the second stage of our research was to obtain some cosmetic formulations based on the given sol. In the process, it was of interest to reveal whether they are antibacterial and(or) sunlight-protective and how high is their efficiency, compared to formulations containing macrodispersed zinc oxide.

Preliminary studies revealed that the zinc oxide hydrosol is stable in the presence of such surfactants and polymers frequently used in cosmetics as cremophors and hydroxyethyl cellulose (HEC). Because cremophors are nonionic surfactants and HEC is a weak polyelectrolyte, they do not cause coagulation of sol particles. Moreover, HEC is a rather efficient stabilizer. Therefore, we took as a model system the formulation of a cosmetic cream given in Table 2. In introduction of nanodispersed zinc oxide into this formulation, water was replaced with a 0.25% hydrosol.

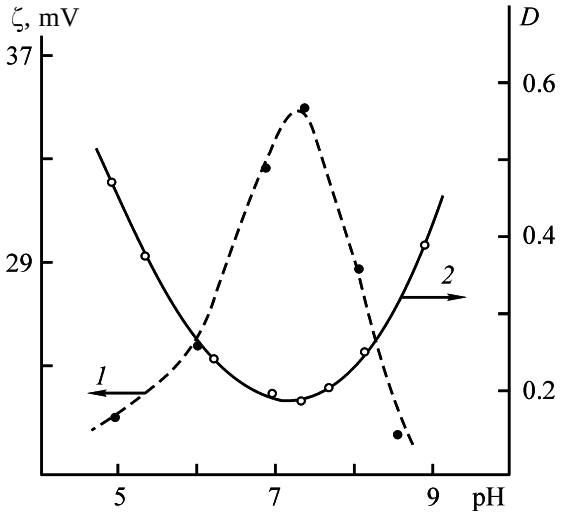

Fig. 2. (*1*) Electrokinetic ζ potential and (*2*) optical density D vs. pH of the dispersion medium of the hydrosol. Concentration of the dispersed phase 0.35 wt %.

The formulation is a homogeneous white system, fairly well absorbed by skin. It is thermally stable and resistant to phase separation during centrifugation. From the standpoint of rheology, this system is a typical pseudoplastic that is well deposited onto skin and distributed over its surface.

To study the antibacterial activity, a formulation

Table 2. Basic composition of a cosmetic formulation

Ingredient*	Content, wt %
Mixture of oxyethylated derivatives of cetearyl and stearyl alcohols (Cremophor A-25)	5.0
Cetearyl alcohol	3.5
Paraffin oil	10.0
HEC	0.05
Vaseline oil	2.0
Conserving agent	0.05

containing nanodispersed zinc oxide was subjected to a standard test. In this method, growth of test strains of microorganisms is suppressed by a preparation subjected to testing. Bacterial cultures were cultivated for 18–20 h at 37°C on a blood agar with subsequent staining (prior to analysis) by Grumm [11]. We introduced dropwise into a Petri dish with a bacterial cultures of the Streptococcus agelactae family, *Staphylococcus aureus sp*., and *Pseudomonas aeruginosa* 2 ml of zinc oxide hydrosol (0.25 wt %) or the same amount of a 10-fold diluted cosmetic formulation. As controls served Petri dishes with growth media and the corresponding test strains, into each of which 2 ml of distilled water was introduced. The inoculations were incubated for 48 h and then a microscopic analysis was made. It was found that, in the presence of both a pure hydrosol and a cosmetic formulation based on it, the abundance of colonies significantly decreases. Raising the concentration of the hydrosol in the formulation by a factor of 2 completely suppresses the growth of the microorganisms.

The method for determining the sunlight-protective properties of a cosmetic formulation is based on absorption of the UV light by the formulation deposited as a thin layer on a solid surface [11]. The tests were performed as follows. The formulation was deposited onto a quartz plate in such a way that no air bubbles appeared. The sample was covered from above with an identical quartz plate and the layer thickness was brought to 0.01 mm. Clean plates of exactly the same thickness served as reference. The UV spectra of the sample were recorded in the 260–350 nm range. The spectra obtained are shown in Fig. 3. The optical density increases in the presence of the hydrosol, with the effect for the hydrosol being more pronounced than that in the presence of a macrodispersed zinc oxide. This may be due to a more uniform distribution of nanoparticles in the formulation and to a higher monodispersity of the dispersed phase. In addition, a tendency is observed for the absorption peak to be shifted to longer wavelengths, which indicates that the sunlight-protective effect is enhanced. Additional studied revealed that introduction of the hydrosols into the sunlight-protective complex TiO_2 + Al_2O_3 + SiO_2 + *N*-acrylate markedly enhances its efficiency.

CONCLUSIONS

(1) Zinc oxide hydrosols stable in a neutral medium were synthesized by hydrolysis of zinc nitrate. Suggestions were made concerning the factors providing the aggregative stability of these sols (electrostatic and structural components of the disjoining pressure).

(2) It was found that introduction of these hydrosols into cosmetic creams enhances their antibacterial and sunlight-protective activity, compared to formulations based on macrodispersed zinc oxide.

Received January 26, 2005

Abstract—Leaching-out of lanthanides from waste phosphosemihydrate with 20–30% sulfuric acid solutions was studied.

Upon processing of the Khibiny apatite concentrate by the semihydrate technology to obtain wet-process phosphoric acid, the main part of lanthanides is contained in calcium sulfate semihydrate [technical name of the product: phosphosemihydrate (PSH)] [1, 2]. Sulfuric acid leaching can be used for recovery of lanthanides [3, 4].

In [3, 4], the sulfuric acid leaching was performed with low-concentration solutions ($c_{H_2SO_4} \le 10$ wt %) at high l : s = (5–10) : 1. A high degree of recovery of lanthanides into solution was achieved (up to 84%), but the concentration of lanthanides in solution, $c_{\Sigma Ln_2O_3}$, did not exceed 1 g l^{-1}. All attempts to raise $c_{\Sigma Ln_2O_3}$ in leaching solutions failed.

In the process, it was established that, in leaching of several portions of PSH with the same sulfuric acid solution at l : s = 3 : 1, leaching time of 2–3 h, and $c_{H_2SO_4}$ subsequently raised to 12–24 wt %, the concentration of lanthanides in solution increased to 3 g l^{-1} and more, but the recovery of lanthanides in each stage did not exceed 30–40% and decreased as $c_{\Sigma Ln_2O_3}$ became higher [3]. With a solution with $c_{H_2SO_4}$ = 25 wt % and l : s = 5 : 1, the recovery of lanthanides into solution was 30% at $c_{\Sigma Ln_2O_3}$ = 0.34 g l^{-1} [5].

The experimentally determined concentration of lanthanides in leaching solutions is considerably lower than the solubility of lanthanide sulfates in sulfuric acid solutions. However, the reason for this fact has not been established.

The large volumes of the solutions involved and low concentration of lanthanides in them strongly hinder their processing to recover lanthanides and subsequent utilization in manufacture of wet-process phosphoric acid. This makes studies aimed to improve the leaching technology a matter of current interest.

The goal of this study was to examine leaching-out of lanthanides from waste PSH with sulfuric acid solutions of medium concentrations (20–32 wt %) and to reveal the factors limiting the accumulation of lanthanides in leaching solutions.

EXPERIMENTAL

Experiments were carried out with waste PSH[1] with a moisture content of 20 wt %. It contained 0.56 wt % ΣLn_2O_3 in terms of a dry product.

The influence exerted by the conditions of leaching with sulfuric acid solutions of medium concentration ($c_{H_2SO_4}$ = 20–32 wt %) on the processing efficiency was analyzed. The leaching time was 1 h, because this time is sufficient according to [6]. After the leaching was complete, the solid phase was separated from the solution by filtration. In some of the experiments, the same portion of the sulfuric acid solution was used to successively process two portions of the starting PHS (double-stage leaching). The concentration of the sum of lanthanides $c_{\Sigma Ln_2O_3}$ and c_{CaO} were determined by the oxalate gravimetric technique, in which the relative determination error was 0.3 rel % and more for the lanthanide concentrations in the range under study [7]. The concentrations of individual oxides were determined by atomic-emission spectrometry with inductively coupled plasma on a Perkin–Elmer Plasma 400 instrument. The sums of lanthanides determined by different methods were in good agreement.

* The small amount of SrO was neglected; the same in Tables 2, 3.

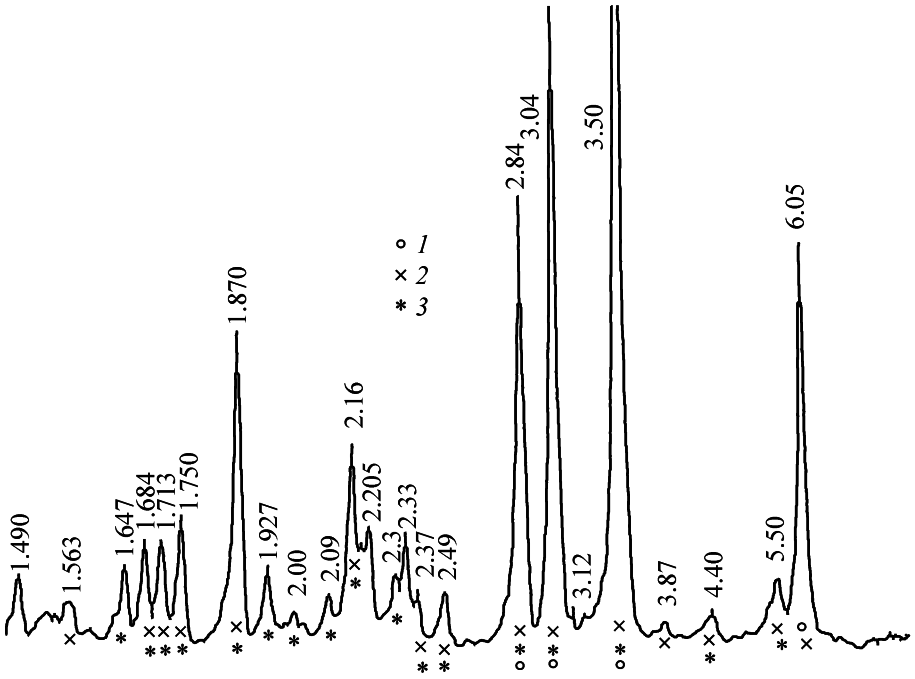
Table 2. Efficiency of leaching-out of lanthanides with sulfuric acid from PSH at different temperatures and l : s = 2.5

Run no.	*T*, °C	$c_{H_2SO_4}$, wt %	Concentration in solution, g l^{-1}		ΣLn_2O_3 recovered into solution, %
			ΣLn_2O_3	CaO	
1	20	28	0.67	0.27	30.0
2	30	28	0.86	0.41	38.6
3	40	28	0.78	0.48	34.6
4	30	31	0.60	0.32	26.8
5	40	31	0.64	0.38	28.4

Table 1 lists the results obtained in determining how the efficiency of leaching-out of lanthanides from PSH depends on $c_{H_2SO_4}$ in the leaching solution at 20°C. It can be seen that it is fairly high at $c_{H_2SO_4}$ = 20–25 wt % and grows as the l : s ratio increases from 2 to 2.5. As $c_{H_2SO_4}$ is raised further to 30 wt %, the recovery of lanthanides into solution decreases even at a larger ratio l : s = 2.5.

The anomalous results of run nos. 8–11 can probably be accounted for by dissolution, in leaching-out of lanthanides with solutions with $c_{H_2SO_4} \geq 25$ wt %, of lanthanide compounds (primarily hydrated orthophosphates) by the reaction

$$LnPO_4 \cdot nH_2O + H_2SO_4 = Ln_2(SO_4)_3 + H_3PO_4 + gH_2O \quad (1)$$



and their precipitation from solution via secondary formation of sparingly soluble lanthanide compounds by the reaction

$$Na_2SO_4 + Ln_2(SO_4)_3 + 2H_2O = 2NaLn(SO_4)_2 \cdot H_2O. \quad (2)$$

Indeed, solutions obtained in leaching-out with sulfuric acid of medium concentrations are metastable and form precipitates in storage. The solution obtained in run no. 10 was somewhat more stable and did not have enough time to decompose during the experiment.

A study of the precipitates demonstrated that they poorly dissolve in a large excess of water. The composition of a typical precipitate is as follows (wt %): Na_2O 3.98, K_2O 0.22, ΣLn_2O_3 31.4, CaO 13.4. The most probable main phase is a solid solution of double sulfates $Na_xK_{1-x}La(SO_4)_2 \cdot nH_2O$, in which about 70% of ΣLn_2O_3 is bound. About 30% of ΣLn_2O_3 cocrystallizes with calcium compounds at a molar ratio ΣLn_2O_3 : CaO = 0.123. Data of an X-ray phase analysis (see figure) confirm that the main phases of the precipitate are hydrated calcium sulfate $CaSO_4 \cdot 0.67H_2O$ and double sulfate of lanthanides and sodium.

If solutions with $c_{H_2SO_4}$ = 28–31 wt % are used for leaching, elevating the leaching temperature to 40°C has virtually no effect on the recovery of lanthanides into the leaching solution, which remains low, but somewhat raises c_{CaO} (Table 2).

X-ray diffraction pattern of a precipitate from the leaching solution. (*1*) $CaSO_4 \cdot 0.67H_2O$, (*2*) $NaCe(SO_4)_2 \cdot H_2O$, and (*3*) $NaLa(SO_4)_2 \cdot H_2O$. Interplanar spacings, Å, are indicated.

The recovery in the second stage of double-stage leaching in all the runs (Table 3) was somewhat lower than that in the first stage, but acceptable, except for the solution containing 25 wt % H_2SO_4. Virtually no accumulation of lanthanides was observed. With $c_{H_2SO_4}$ raised at a constant temperature, the content of CaO in the leaching solution decreased. Thus, effective accumulation of lanthanides in sulfuric acid leaching of PSH is possible if $c_{H_2SO_4} \leq 24$ wt %.

The relative content of most of individual lanthanides in leaching solutions is largely similar to their relative content in the apatite concentrates; however, accumulation of holmium, erbium, and ytterbium is observed (Table 4).

The lower content of yttrium in solution is due to its lower content in the starting PSH, the latter being probably associated with the loss in PSH washing with water to remove phosphoric acid. In the second stage of leaching, the relative, with respect to cerium, concentrations of all the lanthanides increase, i.e., the recovery of lanthanides into solution is largely determined by the difficulty of cerium transfer to solution.

Use of sulfuric acid solutions with concentrations exceeding those used in earlier studies [3, 4] may make the leaching time shorter. Therefore, we examined the effect of the leaching time on the recovery of lanthanides (Table 5).

Yb_2O_3	–	0.0037	0.004

As can be seen from Table 5, the maximum $c_{\Sigma Ln_2O_3}$ in solution, corresponding to a recovery of 85.3–96.4%, is reached in 20–25 min with solutions with $c_{H_2SO_4}$ = 24–30 wt% used to leach PSH at Ammofos Company. Further increase in the leaching time led to a decrease in $c_{\Sigma Ln_2O_3}$ in solution. With $c_{H_2SO_4}$ raised to 32 wt % and more, the maximum recovery is reached during the first 5 min and then $c_{\Sigma Ln_2O_3}$ starts to gradually decrease.

The optimal leaching time and the maximum achievable degree of recovery decreased as $c_{H_2SO_4}$ was raised from 24 to 30 wt %. Elevating the temperature to 40°C affected the recovery efficiency of lanthanides only slightly. The maximum recovery of lanthanides into solution (96.4%) was reached with a sulfuric acid solution with $c_{H_2SO_4}$ = 24 wt % used in leaching.

The variation of c_{CaO} in the leaching solution (Table 6) had a more complicated nature; however, c_{CaO} also decreased by the end of the process, which is due to cocrystallization of a part of calcium sulfate with precipitated lanthanide compounds.

In sulfuric acid leaching of waste PSH, phosphorus, sodium, and potassium impurities pass into solution in addition to lanthanides. The solubility of hydrated orthophosphates, fluorides, and double sulfates of lanthanides with sodium and potassium, in which form lanthanides may be present in PSH and in leaching solutions, changes only slightly in the presence of

* PSH batch no. 1; run nos. 2–4 with PSH batch no. 2.

minor concentrations of PO_4^{3-} ions. These ions may pass from waste PSH into leaching solutions [9–11].

The solubility of double sulfates of lanthanum and cerium with sodium in sulfuric acid and sulfuric–phosphoric acid solutions of medium concentrations is low [10]. Therefore, even a small excess of sodium in the solutions must hinder leaching-out of lanthanides by decreasing the solubility of their double sulfates with sodium to an even greater extent. Therefore, we examined the influence exerted by the sodium concentration c_{Na_2O} in leaching solutions on the efficiency of recovery of lanthanides. As seen from Table 7, an increase in c_{Na_2O} (upon addition of Na_2SO_4) leads to a pronounced decrease in the recovery of lanthanides into solution.

Thus, it may be assumed that the transfer of lanthanides to solution in leaching of waste PSH with H_2SO_4 solutions of medium concentration is governed by simultaneous occurrence of two processes: (i) dissolution of hydrated orthophosphates and (ii) formation and precipitation of double sulfates with sodium. The solubility of double sulfates of lanthanum and cerium, which constitute the most part of lanthanides present in the apatite concentrate, is the highest at $c_{H_2SO_4}$ = 10–12 wt % [9]. Therefore, raising the concentration $c_{H_2SO_4}$ not only accelerates the dissolution of hydrated orthophosphates, but also makes faster the secondary precipitation of double sulfates. The secondary precipitation of double sulfates is also enhanced on raising the concentration of sodium cations.

CONCLUSIONS

(1) A primary process of dissolution of hydrated orthophosphates and a secondary process of precipitation of double sulfates of lanthanides with sodium occur in leaching-out of lanthanides from waste phosphosemihydrate with H_2SO_4 solutions. The former leads to an increase in the concentration of lanthanides, and the latter, to a decrease in the recovery of lanthanides into solution.

(2) Raising the sodium concentration in a leaching solution impairs the efficiency of leaching-out of lanthanides because of the formation of double sulfates of lanthanides with sodium, which are sparingly soluble in H_2SO_4 solutions of medium concentrations.

(3) Lanthanides are effectively leached-out from waste phosphosemihydrate with sulfuric acid solutions of medium concentrations (20–24 wt %) at l : s = (2–2.5) : 1. Use of the same sulfuric acid solution for successive leaching-out of lanthanides from two PSH batches yields solutions with a concentration of lanthanides of about 3 g l^{-1} at a medium l : s = 1 and recovery of lanthanides into solutions of up to 56%.

(4) The relative amounts of lanthanides in leaching solutions approximately correspond to those in the starting apatite concentrate, with, however, a tendency toward accumulation of holmium, erbium, and ytterbium.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Synthesis of Complex Tungsten–Zirconium Carbonitrides

S. N. Perevislov, I. B. Panteleev, and S. S. Ordan'yan

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received September 23, 2005

Abstract—The process parameters (temperature, atmosphere, and composition) of the synthesis of complex carbonitrides $W_{1-x}Zr_xC_{1-y}N_y$ were determined. The area of formation of homogeneous carbonitrides in synthesis from refractory compounds and from WC and zirconium oxide was found. The conditions of appearance of the hemicarbide W_2C were elucidated. The possibility of fabricating homogeneous carbonitrides (CNs) at the lower temperature of the synthesis by increasing fineness of the starting components by vibrogrinding was examined.

Nitrogen-containing compounds, and carbonitrides of the Group IV–VI metals in particular, can be considered as very promising components of hard alloy cutting tools based on tungsten carbide. Carbonitrides occupy the intermediate place between carbides and nitrides and possess a complex of physicochemical properties including high hardness, high heat conductivity, and ability to sustain low-temperature microplastic deformation. At the same time, they are free from the main drawback typical of nitrides consisting in that the angle of wetting of a metal binder with the melts is close to zero. At the same time, the presence of nitrogen largely decreases the friction coefficient and adhesion to the treated metal, which enhances the cutter performance.

The cubic carbonitrides in a mixture with tungsten carbide can partially dissolve it with the formation of carbonitrides of a complex composition. Such processes should inevitably lead to the appearance of diffusion porosity (Frenkel–Kirkendall effect) and result in the deterioration of mechanical properties (bending strength and hardness). To eliminate this drawback, preliminary synthesis of complex carbonitrides may be suggested. To obtain high-purity stoichiometric preparations, it is the most reasonable to use carbides and nitrides of tungsten and of Group IV–VI transition metals.

The reaction of WC with zirconium nitride and zirconium carbide can yield a new interstitial phase, a solid solution of complex carbonitride (CN) of the general formula $(W_{1-x}Zr_x)(C_{1-y-z}N_y\square_z)$, where $\square$ designates the vacancies in the nonmetal sublattice. For stoichiometric compositions, the area in which such compounds can exist can be presented by the section in the four-component system W–Zr–C–N (Fig. 1), formed by the binary compounds WC and WN (hexagonal crystal system), and by ZrC and ZrN (cubic crystal system).

Tungsten nitride WN decomposes above 600°C. This restricts the choice of compositions and makes carbonitride synthesis feasible only for compositions in the WC–ZrC–ZrN pseudoternary system. Thus, the dashed line in Fig. 1 is the conventional boundary of the area of compositions wherein the complex carbonitrides can be synthesized from carbides and nitrides without participation of WN.

The mutual solubility of WC and ZrC was studied elsewhere [1–6]. The results are summarized in Table 1.

Data on the solubility of WC in zirconium nitride are lacking. Zirconium carbide and zirconium nitride form a continuous series of solid solutions over the entire concentration range [7].

To elucidate the mechanism and parameters of the synthesis, we used in this study pure grade WC, ZrC, and ZrN powders produced by the Donetsk Plant of Chemicals (fineness 10–30 μm). The components were triturated in a titanium mortar with ethanol, and the mixture was dried and pressed. The heat treatment was done within 1300–1900°C. The samples were kept at constant temperature for different times under a pressure of 1.2 atm in ultrapure argon. The phase analysis of the synthesis products was performed with a DRON-3 diffractometer (copper anode, Ni-filter). To control the stoichiometry, the samples of homogeneous carbonitrides were selected and the content of carbon and nitrogen in them was determined by chemical analysis. The loss of carbon and nitrogen did not exceed 5 at. %.

The phase composition of the samples heat-treated at 1700°C for 1 h is presented in Fig. 2a. The homogeneous zirconium carbonitride was formed for compositions along the ZrC–ZrN line, in good agreement with the data from [7]. Two phases, tungsten carbide and cubic complex carbonitride, were detected in the heat-treated WC–ZrC–ZrN ternary mixtures. The X-ray diffraction patterns of the samples heated within 1300–1800°C for 10–60 min were recorded at a lower scanning rate to analyze the shape of reflections. The analysis shows that zirconium carbonitride is formed first and solvent may be ZrC, with its crystal lattice being a basis for the formation of zirconium carbonitride. Because ZrC and ZrN are isostructural compounds, diffusion of nonmetal ions becomes of decisive importance. The radius of the carbon atom (R_C = 0.077 nm) is somewhat larger than of the nitrogen atom (R_N = 0.070 nm). Therefore, we can state that ZrN dissolves in ZrC. As the synthesis temperature is increased, the forming ZrCN intensely dissolves tungsten carbide to yield a complex carbo-

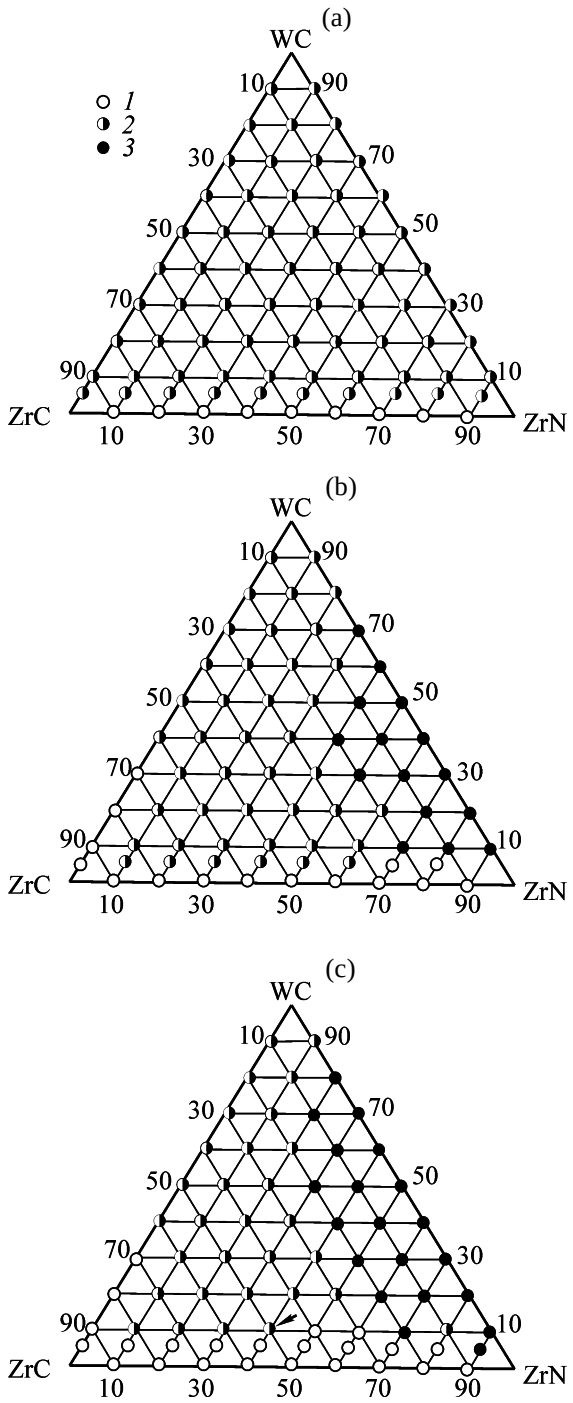

Fig. 2. Phase composition of samples of the WC–ZrC–ZrN system heat-treated at various temperatures. *T*, °C: (a) 1700, (b) 1800, and (c) 1900. (*1*) Carbonitride, (*2*) carbonitride + tungsten carbide WC, and (*3*) carbonitride + tungsten carbide WC + W_2C.

nitride $(W_{1-x}Zr_x)(C_{1-y-z}N_{yz})$. This procedure is reasonable, because ZrC and ZrN have the face-centered cubic (fcc) structure with close unit cell parameters (a_{ZrC} = 0.4683, a_{ZrN} = 0.4537 nm). Moreover, for the formation of ZrCN only redistribution of carbon and nitrogen atoms, whose atomic radii are considerably smaller than those of metals (R_{Zr} = 0.160, R_W = 0.139 nm), is sufficient. At the same time, in formation of a solid solution of hexagonal WC in carbonitride with the fcc lattice, large energies (and high temperatures) are required for the redistribution of metal atoms by diffusion.

At the heat-treatment temperature increased to 1800°C (Fig. 2b), the third phase, tungsten semicarbide W_2C, is detected in a number of compositions. Probably, WC is formed by thermal dissociation of zirconium nitride followed by decarbonization of excess WC owing to the diffusion of carbon atoms into the crystal lattice of defective ZrN_x.

For the compositions located along the WC–ZrC line on the side of zirconium carbide, the $W_{1-x}Zr_xC$ solid solutions are formed, in agreement with the data of [3, 4, 6]. At the same time, on the side of WC, the solubility process was not detected, as in [2, 6].

The homogeneous tungsten–zirconium carbonitride free from the impurities of starting components and W_2C is formed only for two compositions having a low concentration of tungsten and high concentration of nitrogen. The low solubility of WC in the nitrogen-containing zirconium phases is likely due to the difficulty of incorporation of W atoms into the stressed lattice of the forming carbonitride $ZrC_{1-x}N_x$. It appears to be lower than solubility in pure zirconium carbide. However, in the case of the WC–ZrN compositions, the solubility is virtually lacking (at the indicated heat-treatment temperature and component fineness).

At heat-treatment temperature raised to 1900°C (Fig. 2c), the homogeneous CNs are formed for all the compositions along the $W_{0.05}Zr_{0.95}C_xN_y$ line and for a number of compositions along the $W_{0.1}Zr_{0.9}C_xN_y$ line. At the same time, owing to possible loss of nitrogen from zirconium nitride, the carbon redistribution results in the appearance of W_2C in even larger number of compositions, predominantly in those formed from the stocks with a low concentration of ZrC.

The probability of appearance of tungsten semicarbide and the pathway of the solid-phase reactions can be described by the method in which equations of equilibrium thermodynamics are used to simulate the chemical and phase transformations. We used a complex of methods involving the computer algorithms for solving equations and the chemical thermodynamic database [8]. The feature of this system is that the program complex, depending on the parameters of state (temperature, pressure, and composition), calculates the whole set of interconnected reactions and substances.

In this study, the chemical and phase transformations for an arbitrarily chosen composition $W_{0.1}Zr_{0.9}\cdot C_{0.4}N_{0.6}$ (indicated by the arrow in Fig. 2c) were simulated and calculated on the basis of the Gibbs energy minimization.

The main conclusion made from the results of the calculation is that, theoretically, W_2C can appear starting from 1500°C, irrespective of the WC concentration in the starting mixture in the presence of ZrN.

The calculated variations with temperature of the composition of the starting mixture and reaction products present in the condensed phase show that the most temperature-sensitive compound is tungsten carbide, whereas zirconium compounds are virtually insensitive.

The results of the thermodynamic calculations and practical syntheses show that the probability of formation of tungsten semicarbide increases with increasing synthesis temperature, which is confirmed by the experiment.

The synthesis of complex carbonitrides from expensive refractory compounds is very expensive and, in all probability, unacceptable for industry. An alternative is the carbothermal synthesis of carbonitrides in argon with oxides as starting materials and carbon as reducing agent. With zirconium oxide as starting material, the net cost of the product is lower and the range of CN compositions can be somewhat extended toward higher concentrations of tungsten and nitrogen.

The practical fabrication of refractory carbide alloys shows that the synthesis of complex titanium–tungsten carbide from oxides WO_3 + TiO_2 involves problems with keeping the prescribed carbon concentration, and appearance of free carbon is possible [9]. It is recommended to perform the synthesis from a mixture WC + TiO_2 + C, and this is widely used in industry.

In view of these recommendations, we decided to perform a pilot synthesis of complex zirconium–tungsten carbonitride by the reaction

$$WC + ZrO_2 + C + N_2 \rightarrow (W, Zr)CN + CO\uparrow$$

lattice with carbon and nitrogen with the formation of ZrCN. Then, tungsten carbide will be dissolved in it to yield the homogeneous cubic phase of complex zirconium–tungsten carbonitride $W_{1-x}Zr_xC_{1-y}N_y$.

The compositions chosen for the study are shown in Fig. 3. The phase composition of the samples heat-treated at different temperatures is given in Table 2.

The synthesis of homogeneous carbonitride at 1600°C is incomplete for all the compositions, whereas that at 1700°C is complete in almost all the cases. This temperature is considerably lower than the temperature of CN formation from refractory compounds, which is associated with high fineness of ZrO_2 (about 1 μm).

To form a homogeneous CN from compositions containing 50 at. % W and more, it is necessary to increase the time of the isothermal annealing, or, which is more reasonable, to increase the WC fineness, e.g., by vibrogrinding of the starting material.

Grinding to a fineness of 0.5–1.0 μm, a value commonly used in the hard-alloy technology, results in the activation of interdiffusion processes in the CN synthesis. The experiment was performed with four compositions (nos. 2, 3, 5, and 6) differing in the component ratios. The starting components were ground in a vibration mill in ethanol for 0.5, 1, 3, and 5 h. The synthesis temperature was 1600 and 1700°C, and the time of the isothermal annealing, 1 h. The results of the phase analysis of the carbonitride samples of the prescribed composition are summarized in Table 3. To obtain a homogeneous CN, mixing of the starting components and their grinding in a vibration mill for 3 h, followed by the synthesis at 1700°C, are optimal.

CONCLUSIONS

(1) To prepare complex carbonitrides $W_{1-x}Zr_x \cdot C_{1-y}N_y$, a temperature of 1700°C, nitrogen atmosphere, and isothermal annealing for 1 h at the final temperature are the optimal parameters.

(2) The region in which homogeneous carbonitrides are synthesized from refractory compounds is limited by the tungsten concentration of 20 mol %, and the region in which they are synthesized from WC and zirconium oxide, by the W concentration of 60 mol %.

(3) Theoretically, W_2C can appear starting from 1500°C, irrespective of the WC concentration in the starting mixture.

(4) From the starting components ground in a vibration mill for 3 h to increase fineness, the homogeneous CNs are formed at a lower temperature of the synthesis.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Extraction of Nitric Acid from Chloride–Nitrate Solutions

V. N. Lebedev

Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Raw Materials, Kola Scientific Center, Russian Academy of Sciences, Apatity, Murmansk oblast, Russia

Received March 25, 2005; in final form, September 2005

Abstract—The extraction of nitric acid from chloride–nitrate solutions simulating solutions that result from eudialyte breakdown with hydrochloric acid after extractive recovery of rare-earth elements was studied. A general flowsheet was suggested for the extraction of rare-earth elements from chloride solutions and utilization of nitrate ions as concentrated solutions of nitrates used in recycling.

Hydrochloric acid is used in processing rare-metal raw materials to transfer main components into solution. When concentrates contain rare-earth elements (REEs) with a considerable amount of acid-soluble impurities, problems arise with the recovery of REEs from solution, as REEs do not form extractable chloride complexes. One of possible alternatives of their recovery is extraction with neutral agents after adding nitrate ions to the solution. Such procedures for their recovery during processing perovskite and eudialyte using HCl were suggested in [1, 2]. However, in view of the inadmissibility of dumping nitrate ions and high cost of nitric acid, nitrates should be recoveed from chloride–nitrate solutions.

Nitric acid is extracted with tributyl phosphate much better than hydrochloric acid. It was found that HNO_3 suppresses the extraction of HCl from a mixture of acids. In turn, hydrochloric acid and $CaCl_2$ are salting-out agents for HNO_3 [3–5]. This study concerns systems containing simultaneously a mixture of various chlorides and nitrates. Conditions for applying the extraction to recovery of nitrate ions from such solutions are considered.

EXPERIMENTAL

The experiments were carried out with a solution simulating a raffinate of REE extraction in the technology of processing eudialyte using hydrochloric acid [1]. The solution contained (M): $CaCl_2$ 0.9, $AlCl_3$ 1.0, $MnCl_2$ 0.25, and $NaNO_3$ 2.8. To carry out the extraction of HNO_3, an equivalent (with respect to nitrate ions) amount of hydrochloric acid was added to a chloride–nitrate solution. A solution containing 80% TBP in dodecane was used as extractant. The mixtures were shaken in separatory funnels for 3 min. After separating the phases, the total acidity was determined; in the organic phase, the content of Cl^- ions was determined by titration with silver nitrate and the content of CaO and MnO, by flame photometry. The data on the HNO_3 distribution are given in Table 1.

Table 1. Extraction of nitric acid from a mixed electrolyte solution

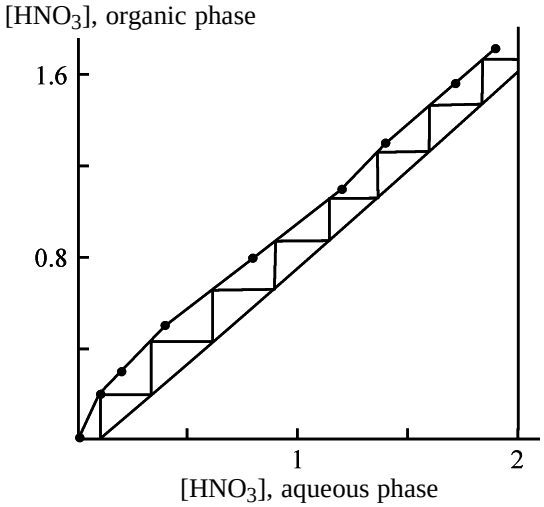
	aq	2.42				

1070-4272/05/7811-1772 © 2005 Pleiades Publishing, Inc.

It follows from Table 1 that HNO_3 is selectively extracted from the mixed solution of salts and acids. The presence of chloride salts in total of up to 5 M considerably increases the distribution coefficients; therefore, HNO_3 is extracted much better compared to the published data [3–5]. Chloride ions are extracted insignificantly, mainly in the form of the acid, because the extraction of $CaCl_2$ and $MnCl_2$ is suppressed in the presence of nitrate ions, as it was found earlier [1]. The extraction of hydrochloric acid, Ca^{2+}, and Mn^{2+} is minimal at the acidity of 0.6–1.5 M.

As HNO_3 is extracted, the concentration of nitrate ions in the aqueous phase decreases, and an increase in the extraction of $CaCl_2$, $MnCl_2$, and also of hydrochloric acid owing to the salting-out effect of chlorides should be expected [6]. Therefore, the conditions for complete extraction of HNO_3 from the solution of chlorides and nitrates were studied in more detail by the exhaustive extraction at the volume ratio of the organic and aqueous phases o : aq = 1 : 1. Hydrochloric acid was introduced in the stoichiometric (with respect to nitrate ions) amount and in excess of 0.5 M. The solution contained Ca^{2+}, Mn^{2+}, and Al^{3+} in the above-mentioned amounts, and up to 1 M $NaNO_3$. The results of the extraction are given in Table 2.



It follows from Table 2 that 93–97% of nitric acid is recovered into the organic phase in 3–4 steps of the exhaustive extraction. An excess of hydrochloric acid considerably increases the HNO_3 distribution coefficient. The amount of coextracted chloride ions increases as the concentration of nitrate ions decreases. The isotherm of the nitric acid extraction with 80% TBP and the calculated number of steps required for its isolation are given in the figure. It is seen from the figure that the extraction of HNO_3 is possible at o : aq = 1 : 1.1; in this case, the concentration of HNO_3 in the extract cannot exceed 1.65 M, and therefore it will be approximately the same in the backwash. The utilization of dilute HNO_3 involves certain problems, as it is unlikely that the evaporation can be economically feasible. However, the process of HNO_3 extraction can become feasible in the case when sodium and calcium nitrates are obtained in the backwash. Their concentration in the backwash can be brought to 6–8 M, which is sufficient for using them in a recycle, by applying lime milk or an alkali of the required concentration in equivalent amounts for the backwashing.

The process involves the addition of $NaNO_3$ or $Ca(NO_3)_2$ to 2–3 M in productive solutions from the breakdown of rare-earth concentrates with hydrochloric acid, the extraction of REE nitrates with a neutral organophosphorus extractant, the addition of an equivalent (with respect to nitrate ions) amount of hydrochloric acid to chloride–nitrate raffinate-1, the extraction of HNO_3 with a neutral organophosphorus extractant, and the backwashing of nitric acid with NaOH or CaO to obtain concentrated solutions of $NaNO_3$ or $Ca(NO_3)_2$ used in recycling. The extraction of REEs with TBP from chloride solutions

with the utilization of the added nitrate ions can be presented by the flowsheet shown in the scheme.

CONCLUSION

The extraction of nitric acid from chloride–nitrate solutions simulating solutions that result from the breakdown of eudialyte with hydrochloric acid after the extractive recovery of rare-earth elements was studied. The recovery is attained by introducing hydrochloric acid into solution in an amount equivalent to nitrate ions. Higher distribution coefficients were obtained when an excess of the acid over the stoichiometric amount of nitrate ions was introduced. The nitrate ions can be backwashed with alkaline reagents to obtain concentrated solutions used in recycling.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Extraction Kinetics of Copper Ions from Aqueous Solutions with a Mixture of Oleic Acid and Triethanolamine

L. A. Voropanova and V. N. Yakovleva

North-Caucasian Mining and Metallurgical Institute, State Technological University, Vladikavkaz, North Ossetia, Russia

Received March 2, 2005; in final form, September 2005

Abstract—Solvent extraction of copper(II) ions from aqueous solutions with a mixture of oleic acid and triethanolamine in kerosene is studied.

Selective extraction of copper(II) from aqueous solutions containing other metals was studied, e.g., in [1–3]. In our previous papers we reported on the extraction of Cu(II) from aqueous solutions with a mixture of oleic acid and triethanolamine in benzine or kerosene and also in industrial lubricating oil (SP-3 grade) [4–6]. The best extraction characteristics were obtained in the pH range corresponding to hydration of Cu(II) in aqueous solutions.

In this study we examined the kinetics of solvent extraction of copper(II) from aqueous solutions with a mixture of oleic acid and triethanolamine in kerosene at pH 7.

The initial solutions were prepared from $CuSO_4 \cdot 5H_2O$ (chemically pure grade). Since pH changed in the course of extraction, the desired pH 7 was maintained by adding sulfuric acid with continuous stirring during the first 2 h. Then pH changed only slightly, i.e., 2 h is the time sufficient for establishing the extraction equilibrium. In the experiments, pH was determined with a pH-121 pH-meter.

The Cu(II) concentration in the initial solution and raffinate was determined by volumetric titration and on a KFK-3 photocolorimeter, and that in the extract, as the difference.

As an extractant we used a mixture of oleic acid (10–12 wt %) and triethanolamine (4.5–6.0 wt %) in kerosene.

It was demonstrated previously [4–6] that, in the course of extraction, the volumes of the organic (o) and aqueous (aq) phases change insignificantly.

As extraction characteristics we used the distribution coefficient D [ratio of Cu(II) concentrations in the extract and raffinate] and the degree of recovery E (weight ratio of copper in the extract and initial solution, %).

Data on the extraction of copper(II) at various initial solution concentrations c_0 are given in Table 1.

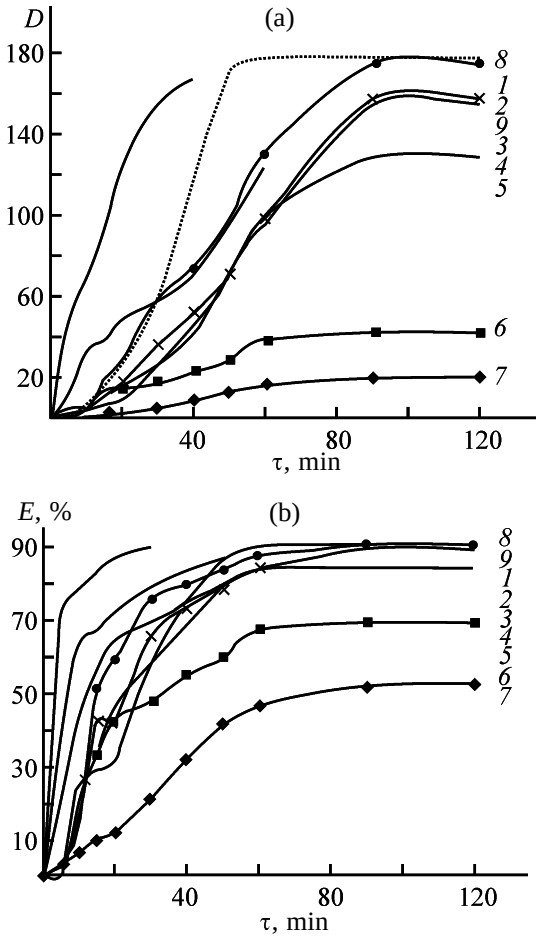

Fig. 1. (a) Distribution coefficient D and (b) degree of recovery E as functions of the time τ. Temperature, K: (*1–7*) 293 and (*8, 9*) 303. Initial Cu(II) concentration c_0 (mM): (*1*) 8.06, (*2*) 15.94, (*3*) 24.14, (*4*) 31.31, (*5*) 40.44, (*6*) 54.80, (*7*) 71.09, (*8*) 8.30, and (*9*) 23.47.

Figures 1a and 1b show the distribution coefficient D and degree of recovery E as functions of the time and initial Cu(II) concentration.

The results show that D and E increase with increasing c_0, temperature, and extraction time.

Table 2 shows the effects of the o : aq ratio and extraction time on the extraction of Cu(II) at c_0 = 23.56 mM. The corresponding data on D and E are plotted in Figs. 2a and 2b as functions of the time and o : aq ratio.

As seen, with increasing o : aq ratio, the extraction of copper(II) into the organic phase and extraction rate increase, and the equilibrium distribution coefficient passes through a minimum.

Figure 3 shows the distribution coefficient D as a function of the o : aq ratio at τ = 90 min. The experimental dependence can be fit by Eq. (1):

50	1.69	123.95			

$$D = -1766.7(\text{o : aq})^3 + 2158.7(\text{o : aq})^2 - 790.98(\text{o : aq}) + 155.66. \quad (1)$$

By solving Eq. (1) for the minimal D we obtain: D_{min} = 58.6430, o : aq = 0.27826 = 1 : 3.5938, and τ = 90 min.

The occurrence of a minimum suggests that the extraction at o : aq = 1 : 3.5938 is accompanied by formation of a well-defined Cu(II) complex with extractant and water.

According to [4], the mechanism of extraction can be represented by complexation equation (2):

$$4(Cu^{2+})_{aq} + 5(RCOOH \cdot R'_3N)_o + x(OH^-)_{aq} + y(H_2O)_{aq} = [Cu_4(OH)_x(RCOOH \cdot R'_3N)_5 \cdot y'H_2O]_o + y''(H_2O)_{aq}. \quad (2)$$

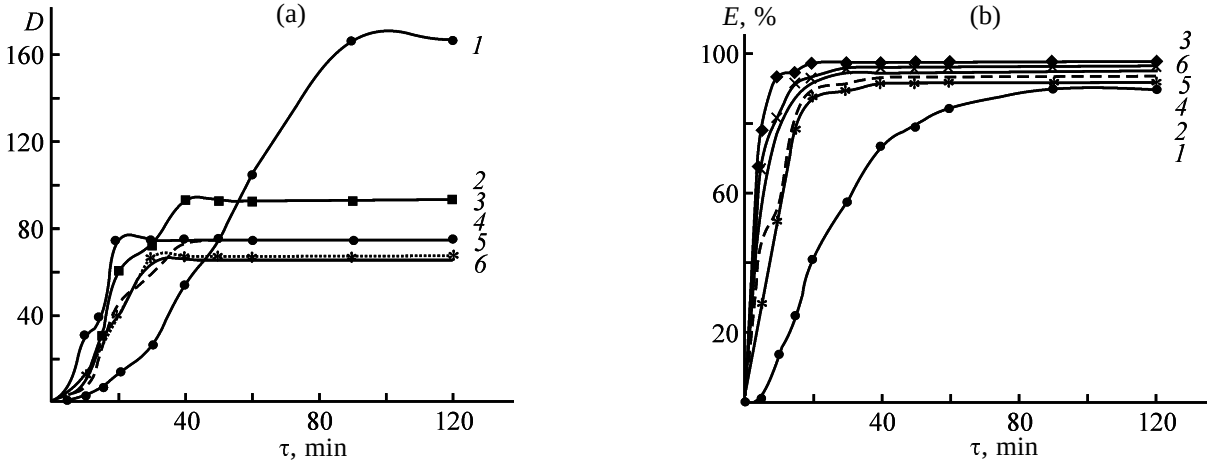

Fig. 2. (a) Distribution coefficient D and (b) degree of recovery E as functions of the time τ at c_0 = 23.56 mM. o : aq: (*1*) 1 : 19, (*2*) 1 : 9, (*3*) 3 : 7, (*4*) 3 : 17, (*5*) 1 : 4, and (*6*) 1 : 3.

It was experimentally demonstrated that, in settling the emulsion after extraction, the mean floating rate of the drops of the oil phase is $U = 0.014129$ cm s^{-1}. Using the Stokes equation

$$U = 2g(\rho - \rho_0)r^2/(9\eta), \quad (3)$$

where $g = 9.8$ m s^{-2} is the acceleration of gravity; $\rho = 0.86$ and $\rho_0 = 1.0$ g cm^{-3} are the densities of the extract and raffinate, respectively; r is the mean radius of the dispersed extract particles (cm); $\eta = 1.005$ cP is the viscosity of the raffinate; and $U = 0.014129$ cm s^{-1} is the floating rate of the drops of the oil phase in settling the emulsion, the mean radius of the extract particles was estimated to be $r = 0.02158$ cm.

Using the least-squares method, we analyzed the experimental kinetic parameters of the process by the film kinetics equation [2], corresponding to the stage of diffusion in the layer around the extract particle:

$$F(\tau) = Q/Q_\infty = 1 - \exp(-K\tau) \quad (4)$$

or

$$\ln(1 - F) = -K\tau \quad (5)$$

and also by the gel kinetics equation, corresponding to diffusion in the interior of the extract particle:

$$F(\tau) = Q/Q_\infty = 1 - (6/\pi^2)\sum_{n=1}^{\infty}(1/n^2)\exp(-n^2B\tau), \quad (6)$$

where $F(\tau)$ is the current degree of extraction (against the limiting value); Q, current extraction; Q_∞, limiting extraction; and K, constant in the kinetic equation

$$B = \pi^2 D/r^2, \quad (7)$$

where D is the diffusion coefficient (cm^2 s^{-1}); r, mean grain size of the anion exchanger (cm); τ, time (s); and n, natural integers.

According to Eq. (5), in the case of film kinetics, $\ln(1 - F)$ should be in direct proportion to τ. In the case of gel kinetics, the argument of the function $X = B\tau$ depends linearly on the time. This argument can be determined using the Boyd, Adamson, and Myers' Tables.

In Table 3 we present the results of kinetic analysis using Eqs. (4)–(6).

The results show that the process kinetics is controlled by the external diffusion of copper(II) to the surface of a drop of the extractant (film kinetics), while elevated temperature, higher o : aq ratio, and vigorous stirring favor transition to the internal-diffusion control.

The mean diffusion coefficient of Cu(II) in the

8.30	303	1 : 19	0.6684	0.9581

oil phase was found by Eq. (7) to be $D = 2.361 \times 10^{-6}$ cm^2 s^{-1} (o : aq = 1 : 4, τ = 20 min, B = 3.0, and r = 0.02158 cm).

CONCLUSIONS

(1) The extraction rate of copper(II) with a mixture of oleic acid and triethanolamine in kerosene depends on the initial solution concentration, stirring rate, organic to aqueous phase ratio, temperature, and extraction time.

(2) The distribution coefficient D and the degree of recovery E increase with increasing initial solution concentration, temperature, and extraction time.

(3) With increasing o : aq ratio, the extraction of copper(II) into the organic phase and extraction rate increase, and the equilibrium distribution coefficient passes through a maximum.

(4) The extraction kinetics is controlled by the external diffusion of copper(II) to the surface of a drop of the extractant (film kinetics), while elevated temperature, higher o : aq ratio, and vigorous stirring favor transition to the internal-diffusion control.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Combustion of a Layered System Based on Sodium Chlorate

O. N. Kirsanov

Prikladnaya Khimiya Russian Scientific Center, Federal State Unitary Enterprise, St. Petersburg, Russia

Received December 29, 2003

Abstract—The velocity of combustion under atmospheric conditions in a constant-volume bomb of formulations based on sodium chlorate and polyethylene in the form of tubes (layered system) was subjected to a comparative study in relation to the type of additive, layer porosity, and fraction composition of sodium chlorate.

This study, proceeding with the previously commenced investigations, mostly served needs of the mining and building industries [1]. Our primary goal was to search for additives that affect the combustion velocity of the basic formulation. This is necessary if the geology of the rock being mined is taken into account. It is known [2] that the combustion of heterogeneous condensed systems is affected by such factors as the type of additives and their fraction composition and porosity. In studying the process mechanism, it is of primary importance to find out whether a chemical reaction in question is autocatalytic. According to [3], the thermal decomposition of $KClO_3$ mainly occurs in accordance with the equation

$$2KClO_3 \rightarrow 2KCl + 3O_2 \quad (1)$$

to give O_2 and KCl and is autocatalytic (KCl is the decomposition catalyst).

In the process under study, combustion of $NaClO_3$ + polyethylene (PE), the decomposition of $NaClO_3$ is one of the first stages. It could be assumed that this reaction is also autocatalytic and affects the overall process. Therefore, it was necessary to primarily study the influence exerted on the process by the NaCl additive. Other additives were considered also: SiO_2, $NaHCO_3$, Na_2CO_3, KCl, Al_2O_3, Co_3O_4, CuO, Ni_2O_3, and MnO_2. Silica and alumina were assumed to be inert additives diminishing the combustion velocity in proportion to the mass introduced. $NaHCO_3$ and Na_2CO_3 were used as additives because of their low thermodynamic stability in a flame ($NaHCO_3$ decomposes with heat absorption at 100–150°C; Na_2CO_3 does so above 851°C, also with an endothermic effect [4]). According to [5], MnO_2 lowers the decomposition temperature of $NaClO_3$ from 350 to 160°C. The effect of KCl on the process was expected to be similar to that of NaCl.

EXPERIMENTAL

The combustion of the formulation composed of $NaClO_3$ and PE was experimentally studied on a setup similar to that used in [1]. We measured the time of propagation of the combustion front between two reference points spaced by l = 40 mm and each situated at a distance of 10 mm from the vessel edge to preclude any influence of nonstationary conditions on the measurement results. The measuring system included two electric circuits with a single dc power source (V = 25 V) connected to the electrically conducting case. Each circuit had an electric contact inserted through a ceramic insulating channel into the case. The instants of time at which the combustion front passed the reference points were recorded as successive closures of the contacts of the two electric circuits connected to a P14M electric stopwatch. The tests were performed under atmospheric pressure at ambient temperature. All the additives except SiO_2 were of chemically pure grade. We used as oxidizing agent $NaClO_3$ of a 25–150-μm fraction (60% 25–65-μm fraction). The mass of $NaClO_3$ in a run was varied within 20–24 g. The mass of the experimental vessel was measured. In studying the layered system, we first charged the vessel case (∅25 × 2.0, Cr19Ni9Ti steel) with tubes of required dimensions in an amount (mass) necessary according to a calculation. A preliminarily prepared mixture of $NaClO_3$ with an additive of the required composition was charged to a height of 60 mm into the assembly weighed on a VLK-500 balance in several stages with tapping at the case (manual vibrational compaction). The scatter

Table 1. Relative changes in the linear combustion velocity Z upon introduction of additives into $NaClO_3$

Additive, wt %	Z upon introduction of indicated additive									
	NaCl	KCl	SiO_2	$NaHCO_3$	Na_2CO_3	Al_2O_3	Ni_2O_3	Co_3O_4	CuO	MnO_2
1.3							0.98	1.04	1.04	1.1
2.4										1.15
4.8	1.0	0.77								1.35
9.1	0.96	0.93	0.85	0.62	0.67	0.94				1.43

in the bulk density did not exceed ±7% in this case. The fuel formulation was ignited by setting fire to a weighed portion (~1 g) of a PTT paste with a Nichrome coil (V = 12 V, R = 1 Ω). To obtain more reliable results, we performed each test at least twice. The linear combustion velocity of a formulation (mm s^{-1}) was found as

$$U = l/t_c^{-1}, \quad (2)$$

where l is the distance between the reference points (mm), and t_c is the time of formulation combustion between these points (s). The total relative measurement error of the linear combustion velocity did not exceed ±3%.

The relative change in the linear combustion velocity Z was found using the formula

$$Z = U/U_t, \quad (3)$$

where $U_t = 2.211x\exp(-0.78x)$ (mm s^{-1}) is the combustion velocity calculated from the oxidant excess factor x found in a given experiment.

The basic results we obtained in a study of the effect of additives on the linear combustion velocity are listed in Table 1.

Table 1 shows that the linear combustion velocity decreases to the greatest extent for formulations with addition of $NaHCO_3$ and Na_2CO_3, and the maximum increase in the combustion velocity is observed with the MnO_2 additive. The effect of nickel, cobalt, and copper oxides on the linear combustion velocity in the range studied is less pronounced than that of MnO_2. The decrease in the linear combustion velocity upon addition of Al_2O_3 was smaller than that in the presence of SiO_2. In both cases, a conglomerate was formed. If SiO_2 was introduced in the form of a sand, this conglomerate concentrated at the vessel outlet, whereas in the case of Al_2O_3 it was formed throughout the vessel.

According to [2], introduction of an inert additive may either raise the mass rate of combustion, or reduce it, but by a factor of no more than 1.11 or 1.25 upon introduction of the additive in an amount of 10 or 20%, respectively. The discrepancy between these and our results is insignificant. Introduction of 4.8 wt % NaCl into the formulation had no effect on the linear combustion velocity, whereas introduction of 9.1 wt % led to a change considerably smaller than the expected value (estimated assuming NaCl to be an inert additive). Thus, we may conclude that the combustion of the $NaClO_3$ + hydrocarbon formulation is an autocatalytic process, i.e., the NaCl additive acts as an initiator. As already noted, MnO_2 leads to an increase in the linear combustion velocity of the layered $NaClO_3$ + PE formulation, and this increase is the more pronounced, the higher the fraction of the additive introduced into the formulation. This relationship can be expressed for the range under study (with a correlation coefficient of 0.95) as

$$U = 1.4c^{0.5} + 1.01, \quad (4)$$

where c is the MnO_2 content relative to its sum with $NaClO_3$ (mass fraction).

The insignificant influence of the Al_2O_3 additive on the linear combustion velocity could be attributed to a pressure buildup within the vessel because of the increased resistance (conglomerate formation). In view of this circumstance, we carried out additional experiments. For this purpose, a pipe was welded-in into the lower part of the vessel, and a TNMP-100 vacuum gage [GOST (State Standard) 2648–78] was connected to this pipe. Measurements demonstrated that there is no rarefaction observed in [6] in a study of the combustion of pyroxylin and NH_4ClO_4 with combustible additives. By contrast, a rise in pressure (10 kg m^{-2}) was observed both for a pure layered system and for that with additives. The absence of scatter in the pressure difference can probably be understood as follows: the hydraulic resistance of the formulation layer is mostly determined by the presence of a large number of tubes, rather than by the powdered mass of $NaClO_3$ with or without additives.

Table 2. Effect of the fraction composition on the linear combustion velocity

In charging a layered system, it is necessary that the density (or porosity) of the layer as a whole and intertube spaces in particular should be the same. The porosity of the main layer can be evaluated by varying the fraction composition of the oxidizing agent. The influence exerted by the intertube space was studied both by charging the vessel with tubes separately filled with $NaClO_3$ or by sealing the intertube space with technological plugs (wires, rods). The tests we performed demonstrated an insignificant drop in the linear combustion velocity in the case of such a change in the porosity of the intertube space (within the measurement error). This is apparently due to a decrease in the combustion surface area and to a change in the oxidant excess coefficient. In this case, the relative fall of the linear combustion velocity (found using the procedure described above) was by a factor of no more than 1.03.

The effect of the fraction composition of the oxidizing agent on the linear combustion velocity is illustrated by Table 2.

Table 2 shows that, as the grain size decreases, the charge density becomes higher. As for the oxidant excess factor x and the linear velocity U, the effect of the fraction composition on these parameters is ambiguous. As the $NaClO_3$ grain size is decreased, the mass rate of combustion, $U_m = U\rho$, tends to grow. The rise in the mass rate of combustion with increasing density is characteristic of secondary explosives (hexogen, Tetryl), nitroglycerol powder, thermite formulations, etc. [2, 6]. In combustion of the formulation in question, $NaClO_3$ melts (mp 255°C), liquefies, and decomposes with heat release (54.76 J mol^{-1}) [5]. Thus, it would be expected that the contribution of the exothermic reaction in the condensed phase to the overall reaction is quite apparent for the formulation in question.

In order to make sure that the combustion of a layered system constituted by $NaClO_3$ mixed with hydrocarbons occurs in the nondetonation mode and the reaction is autocatalytic, we performed tests in a constant-volume bomb (V = 338 cm^3). The pressure was measured with a DD-10 pressure gage (natural frequency 10 kHz) with the signal recorded by an H-117 loop oscillograph (working frequency range of the measuring loop 1200 Hz). The maximum admissible measurement error was ±10%. The formulations studied were charged into textolite vessels with inner diameter of 38 mm, placed on the bottom of the bomb. The ignition was done by setting fire to a weighed portion (2 g) of black powder (BP).

Table 3 lists the charge mass m, combustion time t_{max}, and maximum pressure P_{max} developed in combustion of the formulations: BP, $NaClO_3$ + PE as powder ($NaClO_3$ + PEP), $NaClO_3$ + diesel fuel ($NaClO_3$ + DF), $NaClO_3$ + PE as tubes (layered system $NaClO_3$ + PET), and $NaClO_3$ with 9.1% NaCl + PE as tubes (layered system $NaClO_3$ + PET + NaCl).

Among the results not represented in Table 3, we should mention an increase in the induction period for chlorate formulations subjected to prolonged storage in open air. However, this circumstance invites further investigation.

Figure 1 shows superposed oscillograms obtained in recording the reduced (to the maximum value) pressure in the bomb and computer processing of the results for the $NaClO_3$-based formulations under

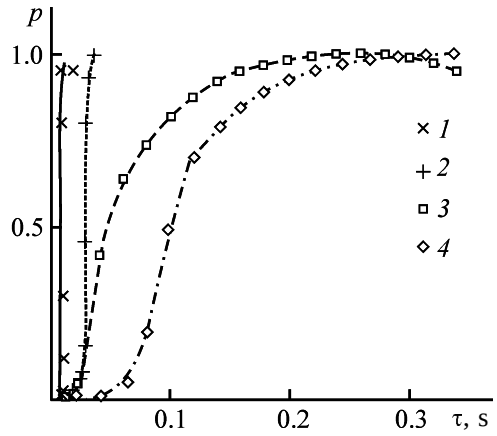

Fig. 1. Reduced pressure p in combustion in a bomb vs. time τ at different compositions. Formulation: (*1*) $NaClO_3$ + PE as a powder, (*2*) $NaClO_3$ + DF, (*3*) $NaClO_3$ + PE as tubes (layered system), and (*4*) $NaClO_3$ + PE as tubes (layered system) with addition of 9.1 wt % NaCl to sodium chlorate (1 : 10).

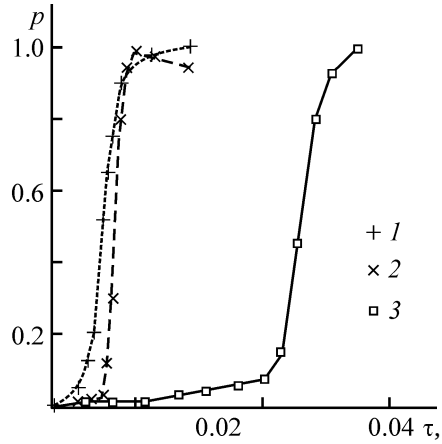

Fig. 2. Reduced pressure p in combustion of different formulations in the bomb vs. time τ for fast processes. Formulation: (*1*) black powder, (*2*) $NaClO_3$ + PE as a powder, and (*3*) $NaClO_3$ + DF

study. Figure 2 shows on another scale pressure records for the first three formulations in Table 3, whose combustion velocity is the highest. The specific working capacity of combustion products, RT, was calculated for the first two formulations for the conditions of the bomb used. It was ~392.7 kJ kg^{-1} for black powder and ~626.5 kJ kg^{-1} for $NaClO_3$ with a PE powder. The latter value is somewhat different from the value of 717.7 kJ kg^{-1} found by preliminary calculation (NaCl in the vapor state). The critical temperature found for NaCl by the Liedersen method [7] from the boiling point of 1440°C [4] was 2933 K. Analysis of the values obtained shows that the extent of the process for $NaClO_3$ with a PE powder does not exceed 0.87. The oscillograms in Fig. 1 show the difference in the rate of pressure buildup in the bomb. The duration of the main combustion process is milliseconds to hundredths of a second for black powder and $NaClO_3$ mixed with diesel fuel of PE powder (Fig. 2) and is approximately an order of magnitude longer for a layered system ($NaClO_3$ + PE tubes). This indicates that the combustion of the layered system is of nondetonation nature. It should be noted that the combustion time of a layered system with addition of 9.1% NaCl is considerably shorter than that without the additive, mostly because of a decrease in the duration of the induction period, i.e., the NaCl additive has a catalytic effect in the initial stage of the reaction. In their main (as regards time) part, the curves run virtually in parallel. Thus, there is good reason to describe the combustion of the formulation under consideration in the bomb in terms of autocatalytic reactions [8]. The same results could be obtained using the Erofeev equation [9] for describing the process; however, physicochemical interpretation of the equation coefficients obtained in this case is difficult (the exponent for some of the runs exceeds 30). Consequently, it is preferable to use in deriving the process equation the description scheme considered in [8]. If we assume that the final pressure in the bomb is determined by the mass of the charge (initial concentration [A], initiator concentration [B]), the modified starting expression for the autocatalytic reaction in terms of the extent of the process, equal to the ratio between the pressure and the maximum pressure, can be represented as

$$d\alpha/dt = k_1(1 - \alpha)(\beta + \alpha), \quad (5)$$

where α is the extent of the process (reduced pressure in the bomb); β = [A]/[B], fraction of the initiator in the total mass; and $k_1 = k$[A].

The solution to this differential equation has the form

$$\alpha = \beta\frac{e^{(\beta+1)k_1t} - 1}{1 + \beta e^{(\beta+1)k_1t}}. \quad (6)$$

The results of processing of the oscillograms obtained in studying the combustion processes in a constant-volume bomb using the Mathcad software package are listed in Table 4 for formulations based on $NaClO_3$.

Table 4. Equation coefficients

Coefficient	PE powder	Diesel fuel	Tubes	
			PE	PE + NaCl
β	0.03	0.003	0.003	0.091
k_1	875	1050	55	43

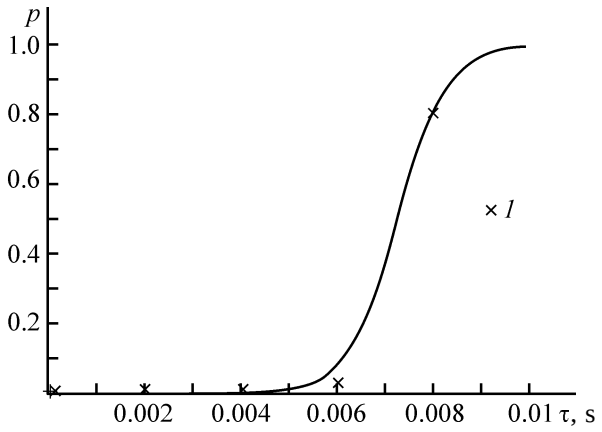

Fig. 3. Comparison of the experiment (point 1) with the calculation for a formulation composed of sodium chlorate with powdered polyethylene at the equation coefficients $\alpha = 10^{-6}$ and $k_1 = 1900$ (solid line).

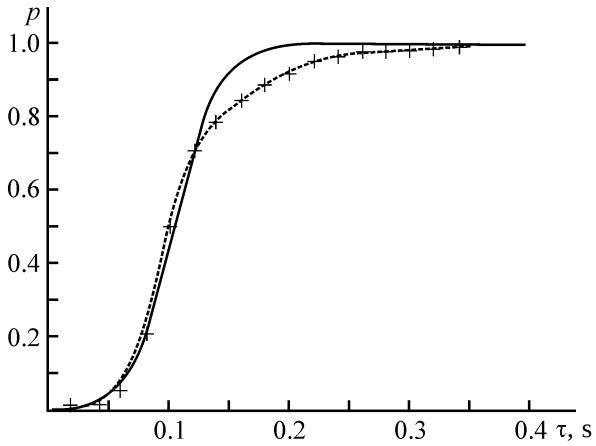

Fig. 4. Comparison of the experiment (dashed line) with the calculation (solid line) for the layered system. Equation coefficients $\beta = 0.003$, $k_1 = 55$.

The first row in Table 4 lists values of β, the fraction of NaCl initiator in $NaClO_3$. For the first three compositions, the NaCl content β is at the level required by GOST, 0.3%. For the last composition, we indicate the real fraction of NaCl specially introduced into $NaClO_3$ to verify the autocatalytic nature of the combustion of $NaClO_3$ mixed with hydrocarbons. For the first two compositions with explosive pressure buildup in the bomb, we obtained large values of k_1, whereas for the last two compositions, they are approximately 15–25 times smaller. The correlation coefficient is no less than 0.95 for all the cases. The coincidence with the experiment is nearly complete for extents of the process of up to 0.8. Further, the calculated curve runs more steeply than the experimental one. Such a deviation of the calculated curve from the experiment for large conversions has been reported extensively [2, 6, 9]. Figures 3 and 4 compare experimental data with results of calculations by Eq. (6) for a PE powder mixed with $NaClO_3$ and PE tubes with $NaClO_3$ (layered system), respectively. The deviation of the calculated curve from the experimental one in the final stage is due to the nonadiabatic nature of the process. There are two ways to obviate this difficulty. The first is to take into account the change in temperature in the equation for the reaction rate and to supplement it with a heat loss equation. This yields a system of two nonlinear differential equations, which cannot be integrated by quadratures. The second, suggested by Ya.B. Zel'dovich, consists in selecting the law of heat loss variation (cooling of the system constituted by the bomb and combustion products) for the given conditions of the experiment. Following the second way, we take the law of variation of the reduced rate constant k_1 with account of changes in the temperature of the system in the form

$$k_1(t) = 1/(a/T_0 + bt), \quad (7)$$

where T_0 is the initial (calculated adiabatic) temperature of the system; t, time; and a, b, coefficients to be determined.

The equation of the autocatalytic reaction can be written with account of the cooling law as follows:

$$\alpha(t) = \frac{\beta[\exp(\beta + 1)k_1(t)t - 1]}{1 + \beta\exp(\beta + 1)k_1(t)t}. \quad (8)$$

Figure 5 compares the experimental dependence of the extent of the process for the layered system with account of nonadiabaticity ($a = 33.2$, $b = 0.07$). It can

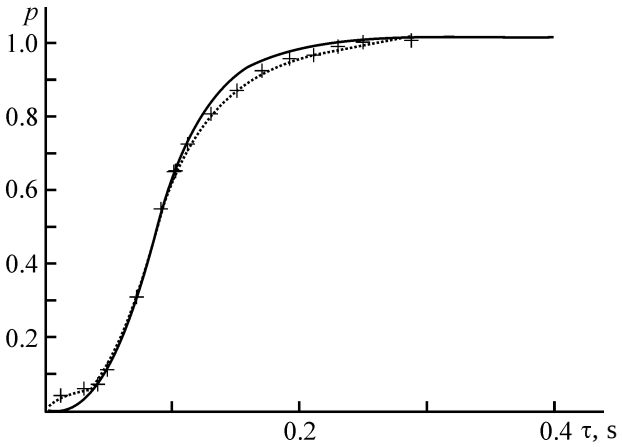

Fig. 5. Variation of the extent of the process with time τ for the layered system. Comparison of the results of a calculation that takes into account the nonadiabatic nature of the system (solid line) with the experiment (dashed line).

be seen that the calculated curve virtually coincides in this case with the experimental value, especially after the extent of the process reaches a value of 0.5, with a correlation coefficient of 0.99. At the same time, if we take an initiator fraction of 10^{-6} and k_1 = 1900 for a PE powder mixed with $NaClO_3$, we achieve a nearly complete coincidence with the experiment (Fig. 3, correlation coefficient 0.99). A similar result is also obtained for a diesel fuel with $NaClO_3$ at $\beta = 10^{-8}$ and k_1 = 950. With these assumptions made, we should accept that the role played by the initiator is minimized and the process is probably initiated by another mechanism (in all probability, of the chain-thermal type). Naturally, the equation coefficients will have other values for a bomb with other parameters, but these values will be of the same order of magnitude. Without pretending to be of metrological importance, the values of the equation coefficients presented here can be used as additional evidence in favor of the hypothesis that the combustion of the layered system is of nondetonation nature.

We use an analytical description because mathematical simulation of processes is considerably less expensive than full-scale experiments. In our case, it allows determination of the influence exerted by such parameters as the charge length, charging density, formulation composition, etc. on the combustion velocity of the system, evaluation of the outflow velocity of combustion products from the burning surface, and its comparison with the critical value at which the combustion mode changes from deflagration- to detonation-type.

CONCLUSIONS

(1) The dependence of the linear combustion velocity of formulations based on sodium chlorate and polyethylene tubes (layered system) with NaCl, KCl, $NaHCO_3$, Na_2CO_3, CuO, Co_3O_4, NiO, and MnO_2 additives was analyzed under atmospheric conditions.

(1.1) Introduction of the above additives in an amount of 9.1 wt % makes it possible to either reduce the linear combustion velocity by a factor of 15–1.6 (with $NaHCO_3$ and Na_2CO_3) or to raise it by a factor of approximately 1.4 (with MnO_2).

(1.2) The effect of SiO_2 is close to the theoretical value for an inert additive: addition of 9.1 wt % diminishes the linear velocity by a factor of 1.18. Addition of the same amount of Al_2O_3 has a weaker effect (decrease by a factor of 1.06).

(1.3) CuO, Co_3O_4, and NiO have virtually no effect of the combustion velocity (an increase by a factor of no more than 1.04).

(1.4) Addition of up to 9.1 wt % NaCl has virtually no effect of the linear combustion velocity of the layered system. This fact can be interpreted as evidence in favor of the autocatalytic nature of combustion of the formulation under consideration.

(1.5) The effect of KCl on the whole process is close to that of Al_2O_3, but without formation of the conglomerate typically formed in combustion of formulations with SiO_2 and Al_2O_3 additives.

(2) The "artificial" porosity of the intertube space has virtually no effect on the linear combustion velocity.

(3) The dynamic pressure developed in combustion of a layered system is about 10 kg m^{-2} for the compositions studied.

(4) The combustion in a constant-volume bomb in textolite vessels with an inner diameter of 38 mm has explosive nature for black powder and formulations composed of sodium chlorate with diesel fuel or powdered polyethylene. The combustion time of a layered system exceeds by one to two orders of magnitude that for the systems considered above, which clearly points to a nondetonation combustion mode.

(5) In the case of combustion of a layered system in the bomb, introduction of 9.1 wt % NaCl into $NaClO_3$ makes the induction period shorter, which also confirms the autocatalytic nature of the combustion of formulations based on sodium chlorate and hydrocarbons.

(6) An equation for autocatalytic reactions, with the nonadiabatic nature of the process taken into account as suggested by Ya.B. Zel'dovich, can be used to describe with a sufficient reliability the combustion of a layered system based on sodium chlorate in a closed space.

(7) The best agreement between the experiment and calculation for explosive processes with sodium chlorate as oxidizing agent and powdered polyethylene or diesel fuel as combustible is achieved when the NaCl concentration in the equation is minimized (10^{-6}–10^{-8} mass fraction instead of the value of 0.003 recommended by GOST).

ACKNOWLEDGMENTS

The author is sincerely grateful to V.B. Ulybin for permanent support of the study and a number of valuable remarks taken into account in preparing the manuscript.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Thermodynamic Characteristics of the Amphoterism of $M(OH)_2$ Hydroxides in Aqueous Media

E. V. Shkol'nikov

St. Petersburg State Forestry Engineering Academy, St. Petersburg, Russia

Received April 7, 2005

Abstract—Dependences of the molar solubility of amorphous and crystalline hydroxides $M(OH)_2$ on pH of aqueous alkaline nonoxidizing medium at 25°C, and also step constants of basicity and acidity of amphoteric hydroxides $M(OH)_2$ (M = Be, Mn–Zn, Cd, Sn, Pb) were calculated by the thermodynamic method.

The effects of pH on the molar solubility of solid hydroxides of Group II elements in aqueous–alkaline media was calculated earlier [1] by the thermodynamic method. Of interest is the thermodynamic calculation of the solubility of amphoteric hydroxides $M(OH)_2$ for M = Sn, Pb, and 3*d* elements from Mn to Cu. The results of such calculations can be used in the potentiometric analysis and in the determination of conditions for hydrolysis and for practically complete precipitation or efficient masking of cations in the form of soluble hydroxo complexes [2–5]. The amphoterism of hydroxides has been studied insufficiently, and quantitative data on the solubility in aqueous media and on the acid–base properties of ampholytes $M(OH)_2$ are scanty and often contradictory. Thus, according to [3], freshly precipitated hydroxides $M(OH)_2$ are practically water-insoluble, have indications of amphoterism, start to dissolve in alkalis at pH from 10–10.5 (M = Sn, Zn, Pb) to 13.2–14.1 (M = Ni, Be, Fe, Cd, Cu, Mn, Co), and dissolve completely at pH 12–13.5 (M = Zn, Sn). According to [6], $Mn(OH)_2$ and $Fe(OH)_2$ are practically insoluble, and $Ni(OH)_2$ is difficultly soluble in alkalis. According to [7], amorphous precipitates $Cu(OH)_2$ and $Fe(OH)_2$ are soluble in concentrated alkalis; $Co(OH)_2$ is formed as a finely dispersed blue precipitate transforming upon aging into a pink modification soluble in boiling concentrated alkali. No data on the amphoterism of $Mn(OH)_2$ and $Ni(OH)_2$ are given in [7]. According to [2, 7, 8], ampholytes $M(OH)_2$ have weak basic properties, which dominate over acid properties.

Using the procedure from [1], we continued the thermodynamic calculation of the solubility of amorphous and crystalline hydroxides $M(OH)_2$ in pure water and in aqueous–alkaline medium (with additions of NaOH) at pH 7–15 and 25°C. The standard free energies ΔG_f^0 of formation of ions in aqueous solutions, which are necessary for calculating the thermodynamic solubility constants K_s^0 (SP^t), were taken from [9], and the free energies ΔG_f^0 of formation of solid hydroxides at 298 K, from handbooks [10, 11] or were calculated [12]. The molar solubilities of $M(OH)_2$ in pure water and in aqueous NaOH solutions were calculated taking into account the solution ionic strength and the formation of mononuclear hydroxo complexes using the data of [2], and, for the case of nickel(II) and tin(II), the data from the handbook [3]. The calculations were carried out by the generalized equation

$$S = \frac{K_s^0}{f_{M^{2+}} f_{OH^-}^2} \sum_{i=0}^{n} \beta_i [OH^-]^{i-2},$$

where the constant K_s^0 characterizes heterogeneous chemical equilibrium (2); $f_{M^{2+}}$ and f_{OH^-} are molar activity coefficients of M^{2+} and OH^- ions; $\beta_0 = 1$; β_1, β_2, β_3, and β_4 are overall stability constants of the hydroxo complexes MOH^+, $M(OH)_2$, $M(OH)_3^-$, and $M(OH)_4^{2-}$.

The molar solubility of $M(OH)_2$ in 1 M NaOH solution was calculated by the simplified formula $s = 1.06 K_s^0 \Sigma \beta_i$.

We found the equilibrium concentration of free OH^- anions and pH of saturated solutions of hydroxides in pure water (shown in the figure by arrows) by solving a system, as a rule, of three equations [1] using Cardano's method for the reduced cubic equation. For tin(II) and copper(II) hydroxides, we solved systems of four equations taking into account the formation of the complexes $Sn(OH)_3^-$ and $Cu_2(OH)_2^{2+}$,

* A is amphoterism parameter.
** Freshly precipitated amorphous.

respectively [2]. The mole fraction $x^0_{M^{2+}}$ of free M^{2+} cations in saturated aqueous solutions of $M(OH)_2$ was calculated similarly to [1] using data of [2, 3].

The calculated results are given in Table 1, where $pK_s^0 = -\log K_s^0$; s^0 and pH^0 are molar solubilities of solid hydroxides in water and pH of saturated aqueous solutions at 25°C, respectively.

Table 1 shows that the pK_s^0 values calculated by the thermodynamic method satisfactorily agree with the reference data [3]. The K_s^0 values for certain modifications of the hydroxides were unknown previously. The solubility of freshly precipitated amorphous hydroxides is higher than that of crystalline modifications. Free M^{2+} cations dominate ($x^0_{M^{2+}} > 0.5$) in saturated aqueous solutions of solid hydroxides (pH^0 7.6–10.4), except for α-$Co(OH)_2$ and amorphous $Cu(OH)_2$ (Table 1). Free Sn^{2+} cations dominate in acid solutions (pH < 3) where they can be determined by potentiometric methods, as well as other M^{2+} cations. The calculated average numbers of ligand $\bar{n}$ in hydroxo complexes (Bjerrum's function) at pH 15 lie in the interval 3–4 for all the hydroxides in Table 1, i.e., the amphoterism conditions $\bar{n} > 2$ are met [1]. The minimal solubility of $M(OH)_2$ precipitates is observed at the optimal concentration of OH^- ions when neutral complexes $M(OH)_2$ dominate in solution among equilibrium species. We found pH_{opt} and then s_{min} from the condition of the maximal mole fraction $x_{M(OH)_2}$, as it was done in [1]. The values of $ps_{min} = -\log s_{min}$ at 25°C are given in Table 1 and partly in the figure, where a strong negative effect of common OH^- ions on the solubility of $M(OH)_2$ in alkali is seen, except for $Sn(OH)_2$, α-$Zn(OH)_2$, and α-$Co(OH)_2$. The effect of common OH^- ions is virtually absent with $Sn(OH)_2$ and HgO [1] (see figure, curve *6*). The analysis shows that high stability constants β_2 of neutral complexes $M(OH)_2$ and their high mole fractions in aqueous solution ($x_{M(OH)_2} \geq 0.9$) are the conditions for the absence of this effect. In the cases of α-$Co(OH)_2$ and α-$Zn(OH)_2$, the common ions decrease by a factor of 2 the solubility in alkali (see figure, curves *2* and *5*), and with the crystalline hydroxide $Fe(OH)_2$ (curve *3*) the effect is the strongest (by a factor of 350).

To estimate quantitatively the amphoterism of hydroxides, we used the ratio ($A > 1$) of their molar solubilities in an alkaline medium with pH 14.7 (5 M NaOH solution) and in pure water. As follows from Table 1 and the calculations [1], the amphoterism parameter A of crystalline hydroxides $M(OH)_2$ decreases in the series Sn > Pb ~ Zn > Cu > Be > Ni > Mn > Co ~ Fe > Cd. The results of the calculations basically agree with scanty experimental data on the solubility of solid hydroxides $M(OH)_2$ in water and alkalis [3–8]. Unlike the data of [6], our calculation shows a 12–15-fold increase in the solubility of $Fe(OH)_2$ and $Mn(OH)_2$ crystals upon the replacement

Solubility *s* of solid hydroxides as a function of pH of aqueous-alkaline medium at 25°C. Hydroxide: (*1*) $Mn(OH)_2$, (*2*) α-$Co(OH)_2$, (*3*) $Fe(OH)_2$, (*4*) $Ni(OH)_2$, (*5*) α-$Zn(OH)_2$, (*6*) $Sn(OH)_2$, (*7*) freshly precipitated $Cu(OH)_2$, and (*8*) $Pb(OH)_2$.

of water by a 5 M NaOH solution (Table 1). Polycondensation, polymerization, and crystallization processes occurring on aging amorphous precipitates considerably decrease the solubility of the hydroxides in water and alkalis [7, 8] with decreasing *s* and *A* (Table 1). Stable crystalline $M(OH)_2$ modifications have the lowest values of these parameters. Their molar solubility in 5 M NaOH solution at 25°C decreases in the order $Sn(OH)_2$ > α-$Zn(OH)_2$ > $Pb(OH)_2$ > $Cu(OH)_2$ > β-$Be(OH)_2$ > $Mn(OH)_2$ > β-HgO > β-$Co(OH)_2$ > β-$Cd(OH)_2$ > $Ni(OH)_2$ > $Fe(OH)_2$ from 0.76 to 3.1×10^{-5} M, respectively, for $Sn(OH)_2$ and $Fe(OH)_2$. Under these conditions, the solubility of the hydroxides does not exceed 0.05 g l^{-1} (starting from β-$Be(OH)_2$); therefore, for its increase, heating in more concentrated alkalis is necessary, whereas in the case of the readily oxidizable hydroxides $Fe(OH)_2$, $Mn(OH)_2$, and $Co(OH)_2$ a reducing atmosphere is also required [7, 8]. Despite high values of amphoterism parameter *A*, the solubility of beryllium and copper(II) hydroxides in 5 M NaOH solution is low (10^{-3} and 0.015 M) because of low values of K_s^0 and s^0 (Table 1).

Amphoteric electrolytes (ampholytes) in which the M–O bonds are similar to O–H bonds in the ionicity [1] are capable of donating or accepting hydroxide ions and protons, transforming into the corresponding ions. Therefore, we supplemented the comparative characteristics of acid–base properties of stable crystalline hydroxides by a calculation of the thermodynamic parameters ΔG_{298}^0 and pK_{298} (*K* is an equilibrium constant) of heterogeneous reactions (1) and (2) in saturated aqueous solution:

$$M(OH)_2(cr) \rightleftarrows MOH^+(sol) + OH^-(sol), \quad (1)$$

$$M(OH)_2(cr) \rightleftarrows M^{2+}(sol) + 2OH^-(sol), \quad (2)$$

$$M(OH)_2(cr) \rightleftarrows H^+(sol) + HMO_2^-(sol), \quad (3)$$

$$M(OH)_2(cr) \rightleftarrows 2H^+(sol) + MO_2^{2-}(sol). \quad (4)$$

The values of pK_{298} calculated using data of [2, 3, 9–11] are given in Table 2, which shows that the basic properties of amphoteric hydroxides $M(OH)_2$, except for $Sn(OH)_2$, dominate over the acid properties. This conclusion is also proved by the calculation of pK_{298} for chemical equilibria (5)–(7) in alkaline and acidic media.

$$M(OH)_2(cr) + OH^-(sol) \rightleftarrows M(OH)_3^-(sol), \quad (5)$$

$$M(OH)_2(cr) + 2OH^-(sol) \rightleftarrows M(OH)_4^{2-}(sol), \quad (6)$$

$$M(OH)_2(cr) + H(sol) \rightleftarrows MOH^+(sol) + H_2O(l), \quad (7)$$

$$M(OH)_2(cr) + 2H^+(sol) \rightleftarrows M^{2+}(sol) + 2H_2O(l). \quad (8)$$

It is seen from Table 2 that zinc and tin(II) hydroxides are the most readily soluble in alkalis, whereas $Mn(OH)_2$, $Cd(OH)_2$, $Co(OH)_2$, and $Zn(OH)_2$ are the most readily soluble in acids.

Thermodynamic constants of basicity ($K_{b,1}$, $K_{b,2}$) and acidity ($K_{a,1}$, $K_{a,2}$) of the ampholytes $M(OH)_2$ dissolved in water as neutral complexes are given in Table 3. Along with the values calculated on the basis of the data form [2, 3, 9], p*K* values from the monograph [8] are also presented.

Table 3 shows that $K_{a,1}$ is higher than $K_{b,1}$ only for $Sn(OH)_2$ molecules in solution. For all the other dissolved ampholytes $M(OH)_2$, the base properties dominate ($K_{b,1} > K_{a,1}$), being the most pronounced

Table 2. Thermodynamic constants of heterogeneous equilibria for stable crystalline hydroxides in water [(1)–(4)], alkaline [(5), (6)], and acidic [(7), (8)] media

Hydroxide	pK_{298} for indicated equilibria

$Cd(OH)_2$	3.72	3.91 4.2 [8]	12.06	–
$Hg(OH)_2$	11.22	10.59 10.4 [8]	14.80	–

for $Mn(OH)_2$, $Fe(OH)_2$, and $Cd(OH)_2$ and the weakest for $Hg(OH)_2$.

CONCLUSIONS

(1) The molar solubility of hydroxides $M(OH)_2$ in water decreases as the thermodynamic stability of solid hydroxides and hydroxo complexes in aqueous solution increases. It decreases also on passing from amorphous to stable crystalline modifications.

(2) The effect of pH of an aqueous-alkaline nonoxidizing medium on the molar solubility of solid hydroxides $M(OH)_2$ (M = Sn, Pb, and 3*d* elements Mn–Cu) was calculated by the thermodynamic method. It was found that these hydroxides meet the amphoterism condition (the average ligand number in the hydroxo complexes $\bar{n} > 2$ at pH 14–15). The amphoterism was assessed quantitatively [parameter *A* increases in the range from 12 for $Fe(OH)_2$ to 1.4×10^5 for $Sn(OH)_2$].

(3) The minimal solubility and the values of pH corresponding to the most complete precipitation of the amphoteric hydroxides $M(OH)_2$ were calculated in view of the formation of hydroxo complexes.

(4) The calculation of the thermodynamic constants for heterogeneous acid–base equilibria in aqueous media and also of basicity and acidity step constants of neutral complexes $M(OH)_2$ shows that their base properties dominate. Such properties are the most noticeable in case of the ampholytes $Mn(OH)_2$, $Fe(OH)_2$, and $Cd(OH)_2$ and are the weakest in the case of $Hg(OH)_2$. Only in the case of $Sn(OH)_2$ weak acid properties noticeably dominate over weak base properties.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Viscous Flow of Concentrated Aqueous Solutions of $NiCl_2$ + $FeCl_2$

V. N. Tseluikin and N. D. Solov'eva

Technological Institute, Saratov State Technical University, Engels, Saratov oblast, Russia

Received February 17, 2005; in final form, September 2005

Abstract—The dynamic viscosity, apparent molar volume, enthalpy, and Gibbs energy of activation of a viscous flow of concentrated aqueous solutions of $NiCl_2$ + $FeCl_2$ were calculated. The concentration dependences of these parameters were analyzed in terms of structural transformations. A polynomial approximation of the concentration dependences of the dynamic viscosity of the solutions under study was performed using MATLAB 6.1 software package.

The internal friction in a fluid, the energy of interaction between particles, and structural transformations occurring when the concentration and temperature of a solution are changed can be characterized by analyzing the dynamic viscosity [1–3]. Previously we studied the viscous flow of $NiSO_4$ and $NiCl_2$ solutions [4]. The aim of this study was to examine the concentration dependences of the dynamic viscosity of a two-component solution of $NiCl_2$ + $FeCl_2$ with a constant concentration of iron(II) chloride (1.20 M). These salts are the main components of chloride electrolytes used in deposition of the iron–nickel alloy.

EXPERIMENTAL

The dynamic viscosity η (cP) was calculated using the relation

$$\eta = \nu\rho,$$

where ν is the kinematic viscosity (cSt), and ρ is density (g cm^{-3}).

The kinematic viscosity was determined using a VPZh viscometer with a capillary diameter of 0.56 mm [GOST (State Standard) 10028–81]. The density was measured pycnometrically. The measurement error was 0.2–0.4%. The reproducibility of the experimental results was confirmed by calculating the Cochran test [5].

The competitive action of disrupting and stabilizing factors leads to a nonmonotonic run of the concentration dependences of the dynamic viscosity of the solutions under study (Fig. 1). It is known [6, 7] that, when penetrating into structural voids of water, ions with crystallographic radii exceeding 0.130 nm (void size) deform these voids and rupture hydrogen bonds between molecules. The radius of the Cl^- ion is 0.181 nm [8], and, apparently, chloride ions characterized by negative hydration will disrupt the structure of the solvent. However, Ni^{2+} and Fe^{2+} ions, whose radii are 0.074 and 0.080 nm, respectively, will stabilize the solution structure by being freely accommodated in the voids and binding free water molecules into hydrate complexes. The considerable increase in the viscosity of two-component solutions at $NiCl_2$ concentrations of 3.10–3.86 M (Fig. 1) is probably due to formation of a new structure of the solution, constituted by hydrated ions bound together by hydrogen bonds.

The significant changes in the structure of $NiCl_2$ + $FeCl_2$ solutions are indicated by the nonlinear concentration dependence of the apparent molar volume Φ_V

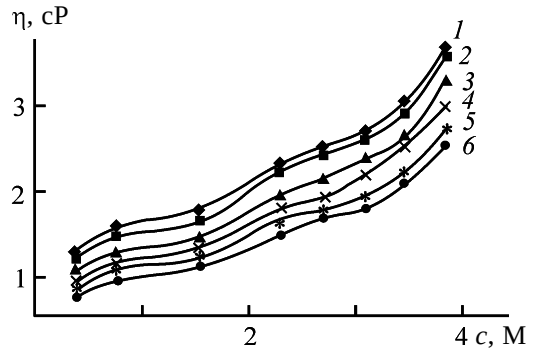

Fig. 1. Dynamic viscosity η vs. the concentration c of $NiCl_2$ in a solution with 1.20 M $FeCl_2$. T (°C): (*1*) 20, (*2*) 30, (*3*) 40, (*4*) 50, (*5*) 60, and (*6*) 70.

	0.39	0.77	1.54	2.30	2.70	3.10	3.47	3.86
20	94.2	94.7	95.1	95.9	96.2	96.4	96.7	97.3
30	97.2	97.8	98.2	99.0	99.4	99.7	99.9	100.5
40	100.1	100.7	101.1	102.0	102.4	102.7	103.0	103.6
50	103.0	103.6	104.1	105.0	105.4	105.8	106.2	106.7
60	105.9	106.6	107.1	108.1	108.4	108.7	109.1	109.8
70	108.8	109.5	110.0	111.0	111.6	111.8	112.2	112.8

(Fig. 2). Φ_V was calculated in terms of the approach suggested by Onori [9]:

$$\Phi_V = (V - X_1V_1)/X_2,$$

where V is the average molar volume of the solution, defined by

$$V = (X_1M_1 + X_2M_2)/\rho,$$

X_1, X_2, M_1, M_2, mole fractions and molecular weights of the solvent and solute; and V_1 is the volume of 1 mol of free molecules of water. This volume can be calculated by the formula

$$V_1 = (1 - x)V_s,$$

where x is the mole fraction of water molecules in the voids, and V_s is the molar volume of the skeleton.

The apparent molar volume of ions increases through a decrease in the amount of water subjected to electrostriction and is complete when no water remains in the solution outside the coordination sphere of the cations. The deviation from linearity of the Φ_V–$c^{1/2}$ dependence for the solutions under study (Fig. 2) may indicate that the limit of complete hydration is reached. The increase in the apparent molar volume on raising the temperature from 40 to 50°C is probably due to deformation and rupture of hydrogen bonds in the structure of the solvent and to simultaneous binding of free water molecules into hydrate complexes.

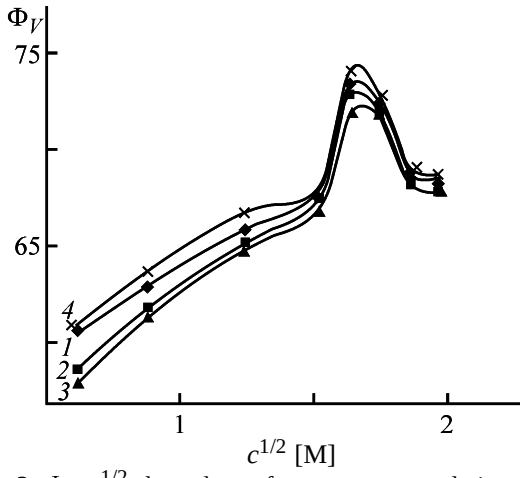

Fig. 2. Φ_V–$c^{1/2}$ dependence for an aqueous solution containing $NiCl_2$ and 1.20 M $FeCl_2$. (c) $NiCl_2$ concentration. T (°C): (*1*) 20, (*2*) 30, (*3*) 40, and (*4*) 50.

As water is an associated fluid, the viscous flow is accompanied by a structural deformation, which requires energy expenditure. The energy expenditure for a viscous flow can be evaluated using the Eyring theory [10]. The Gibbs energy of the solutions under study was calculated in terms of this theory by the formula

$$\Delta G_\eta^* = RT\ln(\nu\overline{M}/hN_A),$$

where R is the universal gas constant; T, absolute temperature; $\overline{M}$, average molecular weight ($\overline{M} = \Sigma M_iN_i$, M_i and N_i, molecular weights and mole fractions of solution components); h, Planck constant; and N_A, Avogadro number.

The Gibbs energy of activation of a viscous flow of $NiCl_2$ + $FeCl_2$ solutions (Table 1) markedly exceeds ΔG_η^* of single-component $NiSO_4$ and $NiCl_2$ electrolytes [4]. This indicates that the structure of two-component solutions is more ordered.

The equation [10]

$$\Delta H_\eta^* = R\frac{d\log\nu}{d(1/T)}$$

was used to calculate the enthalpy of activation of a viscous flow in the solutions under study at T = 20–70°C.

Enthalpy of activation of a viscous flow, ΔH_η^*, for aqueous solutions of $NiCl_2$ + 1.20 M $FeCl_2$

c_{NiCl_2}, M	ΔH_η^*, kJ mol^{-1}
0.39	9.0
0.77	8.4
1.54	7.8
2.39	7.5
2.70	7.1
3.10	7.0
3.49	6.4
3.86	6.4

The values of ΔH_η^* for $NiCl_2$ + $FeCl_2$ solutions are lower than the enthalpies of activation of a viscous flow of water (ΔH_η^* for water is 16.26 kJ mol^{-1} [7]), which indicates that the process can easily pass from one equilibrium position to another, and, consequently, the structure of the solution is disordered. The decrease in the height of the potential barrier with increasing viscosity can be understood if it is assumed that a new polyion structure, whose elements are hydrated ions of the solution and water molecules, is formed in concentrated solutions close to saturation. The structure being formed is less stable than the water skeleton.

Representation of the concentration dependence of the dynamic viscosity in the form of a polynomial allows its adequate mathematical description [7]. The functions polyfit(*x*, *y*, *n*) and polyval(*x*, *y*) of the MATLAB 6.1 software package [11] were used to perform a polynomial approximation of experimental data at concentrations in the range 0.3–4 M, using the least-squares method. The approximating polynomial has the form

$$\eta = a_0 + \sum_{i=1}^{n} a_i c^i,$$

where *a* is a coefficient and *c* is the electrolyte concentration (M).

An analysis of the experimental data with approximating polynomials of the order *n* = 3–10 demonstrated that, as in the case of single-component $NiSO_4$ and $NiCl_2$ electrolytes [4], the adequate mathematical model of the dynamic viscosity of $NiCl_2$ + $FeCl_2$ solutions is a 7th-order polynomial (Table 2).

CONCLUSIONS

(1) The behavior of the dynamic viscosity, activation characteristics of the viscous flow, and apparent molar volume of $NiCl_2$ + $FeCl_2$ electrolytes with increasing concentration and temperature indicates that complex structural transformations occur in these electrolytes, which are accompanied by disintegration of the structure of the solvent, hydration of ions, and formation of a new polyion structure in concentrated solutions close to saturation.

(2) The resulting polynomial models of the dynamic viscosity of the solutions studied make it possible to calculate this parameter at concentrations in the range 0.3–4 M. A 7th-order polynomial was accepted as an adequate mathematical model.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Kinetic Aspects and Heats of Reaction between Components in Thermal Decomposition of Ammonium Nitrate–Calcium (Magnesium) Carbonate Mixtures

Yu. I. Rubtsov, A. I. Kazakov, M. K. Rustambekov, and M. S. Starshinov

Institute for Problems of Chemical Physics, Russian Academy of Sciences, Chernogolovka, Moscow oblast, Russia

Received February 22, 2005

Abstract—The kinetics of heat absorption in thermal decomposition of commercial ammonium nitrate–calcium (magnesium) carbonate mixture and a model mixture of ammonium nitrate and calcium carbonate was studied. Rate equations of the processes and temperature dependences of constants in these equations were determined. The heats of these reactions were calculated.

It is known that manufacture, transportation, and storage of a nitrogen fertilizer, ammonium nitrate (AN), is associated with a certain danger of its explosive transformation. This transformation may result from a detonation explosion of AN, initiated by an external shock wave, or be caused by its spontaneous thermal ignition upon violation of the required temperature mode of storage or in a fire during transportation or storage. More than 80 major accidents caused by explosive transformations of AN have been described; these reports are reviewed in [1]. Most frequently, such explosions are caused by spontaneous thermal ignition of AN in fires in storehouses and cars.

That is why the possible reasons for such explosions of AN and, in particular, for its spontaneous thermal ignition have been studied extensively [2–5]. A considerable attention has been given to analysis of the kinetic aspects of heat release in thermal decomposition of AN and to the influence exerted by various factors on its rate, because the main cause of thermal explosions is the disturbance of the equilibrium between heat release and heat removal across the boundaries of the system [5]. It was established that the rate of heat release is determined by the content of HNO_3 molecules in the system and an increase in this rate in the course of decomposition is due to accumulation of HNO_3. Accordingly, introduction of minor amounts of additives that can bind HNO_3 makes lower the rate of heat release.

As a main way to diminish the detonation capacity of AN, it is recommended to lower its nitrogen content to below 28% by introducing various additives, primarily ammonium carbonates and phosphates. At present use of AN with nitrogen content higher than 28% in agriculture is either prohibited or strictly limited in some countries (pure AN contains more than 34.8% nitrogen). This goal is achieved in production of ammonium nitrate–calcium (magnesium) carbonate (CAN; AN with addition of 20–40% limestone, chalk, or dolomite), whose manufacture is being set-up in Russia now. In doing so, a question arises as to whether granulation of mixtures of this kind is safe, compared with pure AN. The possible difference in safety is primarily determined by that in rates of heat release in thermal decomposition of these fertilizers. The aim of this study was to find the rates of thermal decomposition of CAN and to compare the data obtained with the rates for ordinary AN. It has been established previously [6] that introduction of less than 1% ammonium phosphates into AN markedly reduces the rate of heat release in thermal decomposition and slows down the self-acceleration of the reaction. The latter occurs through a decrease in the excess amount of HNO_3 both in model mixtures of AN with phosphates and in a commercial sample of ammonium nitrate with a phosphate-sulfate additive. Introduction of carbonates into AN must, in principle, exert a similar influence, but a markedly larger amount of the additive may lead not only to quantitative, but also to fundamental changes.

EXPERIMENTAL

We studied the kinetics of heat release on a DAK-1-2 automated differential calorimeter [7]. Commonly, AN is decomposed in a sealed ampule, as

1070-4272/05/7811-1795© 2005 Pleiades Publishing, Inc.

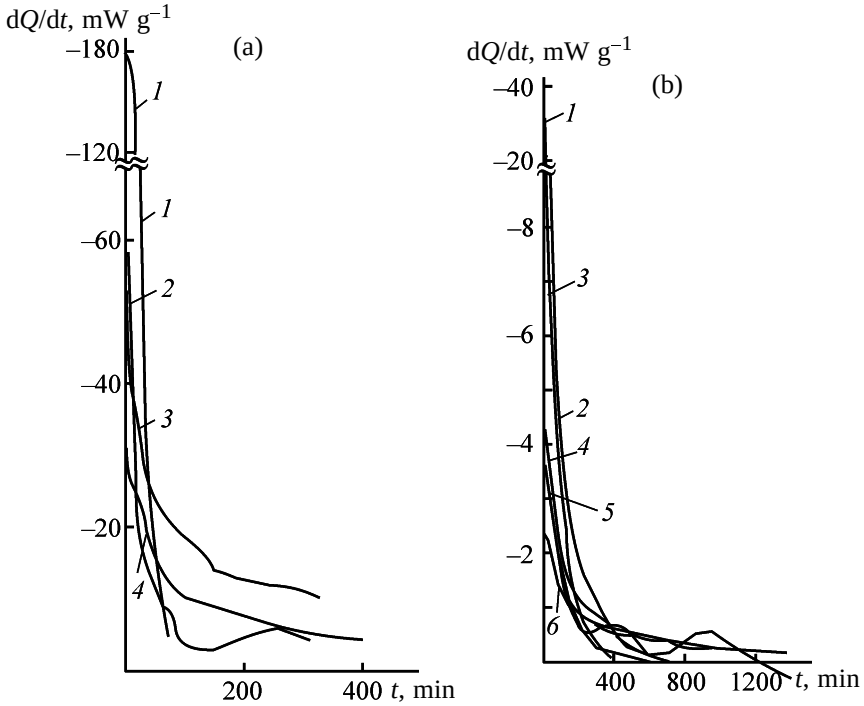

Fig. 1. Heat absorption rate dQ/dt vs. time t in thermal decomposition of (a) a mixture of AN and $CaCO_3$ and (b) CAN. Decomposition temperature, °C: (a) (*1*) 222.5, (*2*) 211.0, (*3*) 202.4, and (*4*) 192.7; (b) (*1*) 234.7, (*2*) 219.5, (*3*) 207.3, (*4*) 202.8, and (*5*) 188.1.

it was done in [6]. However, a certain amount of NH_3 and CO_2 is evolved in mixing of components in manufacture of CAN, and, therefore, the mixer is equipped with an outlet for their discharge. Therefore, to approach the industrial conditions, we used long glass ampules that extended beyond the limits of the calorimeter and allowed discharge of gaseous reaction products into the atmosphere. The gas pressure within the ampule is always equal to the atmospheric pressure. Under these conditions, too, the ampule will always contain a certain amount of NH_3, which will shift the equilibrium of AN dissociation and make lower the concentration of HNO_3 in the melt, but ammonia will not be accumulated and its content in the gas and, accordingly, in the AN melt will decrease as the reaction rate will become lower. These conditions are rather close to those of the real industrial process.

We studied the thermal behavior of a model mixture of analytically pure grade AN with calcium carbonate of the same grade in the temperature range 192.7–222.0°C, with mechanical mixtures of the components taken in a 50 : 50 mass ratio at a total mass of 0.5 g. The absence of the granulation operation in this case is of no importance because the study was performed at temperatures above the melting point of AN and grains would anyway melt. The system under study had the form of molten AN melt with $CaCO_3$ particles embedded in the melt.

It was established that, in contrast to any of the previously studied AN-based fertilizer samples, in which heat release was always observed at all temperatures exceeding the melting point of AN, heat absorption occurs in the model samples under study during a rather long time. The obtained heat absorption curves are shown in Fig. 1. The initial portion of these curves is described by a first-order kinetic equation, and the temperature dependence of the initial rate of heat absorption, k_1 (W g^{-1}), has the form

$$k_1 = -8.1 \times 10^{12} \exp(-129.5 \times 10^3/RT).$$

An analysis of published data on CAN properties [8] demonstrated that, in mixing of an AN melt with $CaCO_3$, there occurs a rather slow exchange reaction between these salts to give ammonium carbonate, which, in turn, decomposes into NH_3, CO_2, and H_2O. Ammonia and carbon dioxide are mostly released into the gas phase, and H_2O may be partly retained in the melt in the form of calcium nitrate hydrate. The evolving gaseous products agitate the mixture. This process occurs with absorption of heat (for a thermodynamic calculation of the heat of this reaction, see below) and its rate under the experimental conditions is higher than that of heat release in decomposition of AN, which predetermines the overall absorption of heat in the system.

We paid primary attention to a study of experimental CAN samples based on dolomite. Compared with limestone and chalk, this mineral is a considerably less reactive toward acid products and does not dissolve in dilute acids under ordinary conditions [8]. Therefore, it was important to find out whether the heat absorption effect, observed in examination of the model mixture of AN and $CaCO_3$, will be manifested for a fertilizer with dolomite. The formation and decomposition of ammonium carbonate in a mixture of this kind will be governed by the reaction of dolomite with HNO_3, but at a temperature markedly exceeding room temperature.

We examined the kinetics of heat absorption in thermal decomposition for two experimental samples of a calcium–ammonium fertilizer of the following composition (%): sample no. 1: AN 75, dolomite 25, and SO_4^{2-} 0.5; sample no. 2: AN 75, dolomite 25, SO_4^{2-} 0.5, and lilamine AS-6/2 0.08. The samples only differ in that sample no. 2 contains a lilamine-based anticaking coating on the grain surface. In both samples, we used dolomite of the following chemical composition (%): CaO(tot) 29.9, MgO(tot) 19.3, SiO_2 5.4, Fe_2O_3 0.42, Al_2O_3 0.45, and H_2O 0.2; and granulometric composition (%) >3 mm 0, >1 mm 0.2, 1–0.63 mm 0.1, 0.63–0.25 mm 1.2, 0.25–0.1 mm 67.2, and <0.1 mm 31.3.

We analyzed the kinetics of heat absorption in decomposition of sample nos. 1 and 2 in the temperature range 188.1–234.0°C. The curves of heat absorption rates for sample no. 1 are shown in Fig. 1b. For sample no. 2, they are for the most part similar, with minor quantitative differences. It can be seen that, at all temperatures, heat absorption occurs during a rather long time from the very beginning of the experiment, and the rate of this heat absorption gradually decreases to about 0.1–0.2 mW g^{-1}. Only at 234°C a minor heat release is observed after 20–23 h, whereas at lower temperatures there is virtually no significant heat release from sample nos. 1 and 2 during 24 h. The reproducibility of the rates of heat absorption or release, obtained in the final stages of the experiments, is low, which is probably due to very small absolute values of these rates and to an insufficient compositional homogeneity of technical-grade samples. Solid dolomite particles in the AN melt are agitated, as in the case of calcium carbonate, by the evolving gaseous products.

The heat absorption is the highest at the beginning of the process and then decreases, which is apparently due to consumption of the components and passivation of the surface of dolomite particles by products of the exchange reaction. As temperature increases, the rate of heat absorption grows, as it should be for the rate of a chemical reaction. The resulting heat absorption curves can be described, in their initial portions, by a first-order kinetic equation:

$$dQ/dt = k_1(1 - Q/Q_1),$$

where dQ/dt is the rate of heat absorption (mW g^{-1}); k_1, rate constant (mW g^{-1}); and Q and Q_1, running and final heats of the process in the initial stage, respectively (J g^{-1}).

Selected numerical parameters of the heat absorption curves are listed in Table 1; the decomposition heat was calculated by integrating the experimental curves for heat absorption rates. The quantity Q_- (J g^{-1}) in the table is the overall heat absorption measured during the experiment, which is the sum of heat absorption in the initial stage (Q_1) and of that in the subsequent stages. The quantity Q_{tot} (J g^{-1}) is an algebraic sum of the absorbed and released heat, recorded during the time of the experiment (t_{fin}, h). In the runs in which no heat was released at the end of the process, Q_{tot} is equal to the overall heat absorption Q_- during the experiment, in which case the figures in columns 5 and 6 coincide. In those runs in which $Q_- < Q_1$, the process was terminated before the completion of the final stage, and Q_1 was found by interpolation of the linear dependence of dQ/dt on Q to zero rate. The quantity $(dQ/dt)_{fin}$ (mW g^{-1}) corresponds to the rate at the end of the run.

The temperature dependence of the rate constants k_1 for sample nos. 1 and 2 has the following form: sample no. 1: $k_1 = -8.1 \times 10^{11} \exp(-129.5 \times 10^3/RT)$; sample no. 2: $k_1 = -9.6 \times 10^{12} \exp(-140.3 \times 10^3/RT)$.

The heat absorption rates obtained in the case of CAN (sample no. 1) decomposition are approximately an order of magnitude lower than those in decomposition of a mixture of AN with $CaCO_3$, which is primarily due to the lower reactivity of dolomite. The heat absorption rates in decomposition of sample no. 2 are, on the average, somewhat lower than those for sample no. 1, which is due to presence of an organic coating on grains of sample no. 2. This coating is oxidized by the AN melt with heat release. Because the share of this coating in the sample is only 0.08%, the contribution of its oxidation to the overall process is small and it can only somewhat reduce the observed rate of heat release. The oxidation leads to formation on the sample surface of a well-noticeable thin polymeric film, which hinders pouring-out of the molten mixture from the ampule, and this confirms that the

oxidation reaction does occur. In a melt of granulated AN, this reaction is very fast and is manifested in an increase in the initial rate of heat release, which makes shorter the calculated adiabatic induction period of ignition. In the mixture in question, this heat release proceeds at a considerably lower rate because of the lower concentration of nitric acid. It is compensated by a stronger heat absorption in the exchange reaction, so that the safety of the process is virtually not changed at all by the presence of an organic coating and there is no overall heat release with the organic coating, too.

The kinetic data presented above were obtained for an open ampule and small (0.5–1 g) sample masses. Under industrial conditions, gas discharge is more difficult, primarily because of the large mass of a mixture being processed. To determine whether this circumstance can affect the fundamental aspects of heat absorption, we performed an experiment at 234°C in a sealed ampule, in which all products are retained and accumulated in the gas over the sample. The initial rate of heat absorption under these conditions is 2–3 times lower, compared with an open ampule, which is probably due to hindered evolution of NH_3 and H_2O into the gas phase, but all the fundamental aspects of heat absorption are preserved: there is no heat release under these conditions during the first 10–20 h.

We performed a thermodynamic calculation of the reactions

$$CaCO_3 + 2NH_4NO_3 = Ca(NO_3)_2 + 2NH_3 + CO_2 + H_2O, \quad (1)$$

$$CaCO_3 \cdot MgCO_3 + 4NH_4NO_3 = Ca(NO_3)_2 + Mg(NO_3)_2 + 4NH_3 + 2CO_2 + 2H_2O \quad (2)$$

on the basis of the standard enthalpies of formation of the reactants, taken from the handbook [9]. Instead of the unknown standard enthalpy of dolomite formation, we took the sum of the standard enthalpies of formation of calcium and magnesium carbonates and the calculation was performed for formation of both liquid and gaseous water. The following heats were obtained: reaction (1): –435 kJ mol^{-1} $CaCO_3$ for water in the melt and –481 kJ mol^{-1} $CaCO_3$ for water in the gas; reaction (2): –715 kJ mol^{-1} dolomite for water in the melt and –807 kJ mol^{-1} dolomite for water in the gas. If these values are used and the excess, over the equivalent composition, amount of AN in the fertilizer is considered an inert constituent, the following maximum possible amounts of heat absorption can be obtained per gram of sample nos. 1 and 2: –982 J g^{-1} for water in the melt and –1104 J g^{-1} for water in the gas.

The heats for liquid and gaseous water are not strongly different, both being several times the heats obtained in experiments for sample nos. 1 and 2. Surely, the heat absorption may somewhat decrease because of the heat release in decomposition of AN, but this rate cannot be significant in the presence of a major excess of NH_3. Comparison of the calculated heats with the experimental values (Table 1) shows that the extent of the exchange reaction reaches during the experiment a comparatively small value of no more than 15%. In principle, a reaction with heat absorption may proceed for a very long time. During our experiments, the rate of heat absorption decreases very strongly, to virtually zero, despite the comparatively small extent of the reaction. This is apparently caused by the following two factors. The first is hindrance to the reaction of molten AN with solid dolomite, caused by formation and growth on the dolomite surface of a

layer constituted by reaction products and impurities in dolomite, which do not react with AN. The second is an increase in the relative role of heat release via thermal decomposition of AN, which occurs at a small, but gradually increasing rate.

The decrease in the rate of the exchange reaction will also automatically lead to a decrease in the rate of NH_3 formation, which, in an open ampule, will make smaller the content of NH_3 in the melt. To a first approximation, it can be considered that there exists equilibrium between ammonia in the gas and that in the melt. For this reason, the content of HNO_3 molecules in the AN melt will gradually increase, thus accelerating the thermal decomposition of AN, which occurs with heat release: about 1450–1650 J per gram of decomposed AN. Therefore, it would be expected that the rate of heat release via decomposition of AN will become, even before the completion of the exchange reaction, higher than the rate of heat absorption in the exchange reaction. As a result, an overall heat release will be observed, which is probably the case in our experiments, especially at 234°C. While the exchange reaction proceeds, the decomposition cannot be self-accelerating, because the increase in the rate of thermal decomposition of AN is determined by accumulation of HNO_3 in AN, and the released NH_3 will primarily neutralize the excess HNO_3 and thereby eliminate the acceleration of the process. About 0.1 mol HNO_3 is released in decomposition from 1 mol AN, and 1 mol NH_3 per mole of AN that entered into the reaction is released in the exchange reaction. Consequently, a 10 times slower rate of the exchange reaction involving AN, compared with that of thermal decomposition, is sufficient for neutralizing the excess HNO_3. In this case, the absorption of heat in the exchange reaction will decrease by the heat of neutralization of nitric acid by ammonia. A direct reaction of the excess HNO_3 with dolomite to give the corresponding metal nitrates, carbon dioxide, and water is quite possible. In the end, we can make a rather reliable conclusion that, even when the rate of heat release in AN decomposition will exceed the rate of heat absorption in the exchange reaction, the rate of the observed heat release will be lower than the initial rate of heat release for pure AN. Only after the main part of dolomite is consumed, accumulation of nitric acid and acceleration of the AN decomposition proper will become possible, with no more than a third of the initial amount of AN remaining, and the time in which this situation is reached will be many times the duration of our experiments.

For the heat release rates of about 1.13–1.93 mW g^{-1}, experimentally obtained at 234°C, the calculated duration of the adiabatic induction period is 21–12 h, respectively. For pure AN the value at the same temperature is 0.56 h. Approximately the same ratio between the adiabatic induction periods of pure AN and the fertilizers under study must be preserved at lower temperatures, because the variation of these values is governed by the activation energy of AN decomposition. The adiabatic induction period should be counted-off for CAN from the instant of transition to heat release, which was not reached at lower temperatures. Because data on the rates of heat release are lacking, it is impossible to calculate the adiabatic induction periods for lower temperatures, and there is no warming-up of the system upon heat absorption.

Table 2. Initial heat absorption rates and times of completion of the first stage at temperatures of CAN granulation

Sample no.	T, °C	k_2, mW g^{-1}	t, h
1	170	–0.42	100
2	170	–0.23	210
1	180	–0.89	48.3
2	180	–0.53	92.0
1	190	–1.8	24.0
2	190	–1.2	41.6

From the experimental curves describing the time dependence of the heat absorption rates, we determined the reaction times (s) in which the heat absorption in the initial stage reached a value Q_1 and found the temperature dependences of these times: $t = 1.6 \times 10^{-9} \exp(121.5 \times 10^3/RT)$ for sample no. 1 and $t = 4.0 \times 10^{-11} \exp(138.2 \times 10^3/RT)$ for sample no. 2. Using the temperature dependences of the rate constant of heat absorption and of the time in which heat Q_1 is absorbed, we calculated the initial rate of heat absorption (mW g^{-1}) and the time in which the first stage of heat absorption is complete (h) for the technological granulation temperatures of 170–190°C (Table 2). It should be noted that the completion of the first stage of heat absorption does not mean that there is no more heat absorption at all, it continues for a long time and obeys another kinetic law.

To confirm the above conclusion that accelerated decomposition of AN in the presence of dolomite is impossible, we performed at 209.8°C an experiment on thermal decomposition of a 50 : 50 (by mass) mixture consisting of a sample of technical-grade AN, in which a strong self-acceleration of its decomposition is observed with the corresponding heat release, and sample no. 1 containing 25% dolomite. Heat absorption was observed during the entire experiment, with

the rate curve qualitatively similar to those shown in Fig. 1b. The heat absorption rate in the mixture was lower than that in sample no. 1, but the content of dolomite in the mixture was smaller, too. During the time of the experiment, a fast decomposition process with heat release should have developed in the AN sample in accordance with the pattern of its thermal decomposition [5]. However, this is not the case because both dolomite and NH_3 released in the exchange reaction bind the excess HNO_3, and, accordingly, the decomposition is not accelerated.

All the above experimental data on the kinetics of heat absorption, combined with the results obtained in calculating the heats of the processes and in assessing the possibility of transition to the overall heat release, unambiguously demonstrate that the safety of processing of CAN is considerably better than that for technical-grade AN. In the process temperature range 170–190°C, and even at substantially higher temperatures of up to 219°C, any substantial warming-up of sample nos. 1 and 2 studied, and the more so the spontaneous thermal ignition are impossible under these conditions, at least during the first 24 h of decomposition. In further development of the process, there occurs transition to heat release, but the heat release rates are low and the calculated adiabatic induction periods markedly exceed the corresponding values for AN.

It should be noted that, in manufacture of CAN, a mixture of AN with dolomite is force agitated in granulation. Because the mass in the apparatus is rather large, the gases released in the exchange reaction upon termination of the process cannot prevent the process suspension from settling. This may result in that, in the end, AN containing no filler and consequently corresponding to technical-grade AN as regards the thermal decomposition criteria may remain in the upper layer. Thus, a better safety of industrial manufacture of CAN is provided under conditions of a working shop only when the production regulations are observed.

CONCLUSIONS

(1) In heating of a model mixture of AN with calcium carbonate and of CAN samples at temperatures lower than 219°C for at least 24 h, there occurs an overall heat absorption, with warming-up of the substance and its spontaneous thermal ignition being impossible.

(2) Heat absorption occurs in the exchange reaction between calcium carbonate or dolomite and AN.

(3) The release of ammonia in the exchange reaction makes lower the rate of thermal decomposition of AN via binding of nitric acid, and, therefore, presence of a limestone additive virtually eliminates the self-acceleration of the AN decomposition.

(4) The whole set of the data obtained demonstrates that, under conditions of a working shop, the safety of high-temperature processing of CAN considerably exceeds that for AN manufactured as a fertilizer.

SORPTION AND ION-EXCHANGE PROCESSES

Selective Sorption of Pd(II) from Nitric–Nitrous Acid Solutions Simulating PUREX Raffinates with Polymethylene Monosulfide

G. R. Anpilogova and Yu. I. Murinov

Received June 8, 2005

Abstract—Static sorption of Pd(II) from nitric and nitric–nitrous acid solutions, simulating PUREX raffinates, with laboratory and semicommercial samples of polymethylene monosulfide is studied. The selectivity of Pd(II) recovery from the simulated solutions is determined.

Currently there is a need in developing hydrometallurgical methods for selective recovery of fission palladium from high-level raffinates, generated in the course of reprocessing of spent nuclear fuel using PUREX process [1, 2]. These aqueous solutions contain 2–3.5 M HNO_3, up to 5 mM Pd(II), and also up to 10 mM radiolytic HNO_2 [2–4]. Tatarchuk *et al*. [2] have demonstrated that, because of strong effect of nitrous acid in the raffinates, nitric acid solutions cannot be considered as an adequate model in studying sorption recovery of Pd(II). In simulated nitric–nitrous acid solutions containing 5 mM Pd(II), 2–3 M HNO_3, and up to 10 mM HNO_2, the dominating Pd(II) species are Pd^{2+} aqua cation, $[PdNO_2]^+$ (<20%), and $[Pd(NO_2)_2]$. The rate of Pd(II) extraction from such solutions with organic sulfides is considerably higher than that from nitrate and chloride solutions [2].

Since polymethylene monosulfide (PMS), complexing heterochain sorbent, demonstrates high efficiency and selectivity in recovering Pd(II) from highly saline nitric acid solutions at room temperature over a wide range of HNO_3 concentrations (0–5 M) [5], it was advisable to examine the applicability of this sorbent for selective recovery of Pd(II) from acidic nitrate–nitrite solutions simulating PUREX raffinates.

Therefore, in this study we examined the efficiency and selectivity of the sorption of Pd(II) from such simulated solutions with laboratory and semicommercial samples of PMS.

EXPERIMENTAL

In this study we used two different PMS samples: PMS1 synthesized under laboratory conditions and PMS2, semicommercial sample partially oxidized as a result of long-term storage (for several years), as an aqueous paste (22% H_2O). PMS1 was used as prepared. PMS2 was conditioned as described in [5]. The samples were screened to obtain the 0.010–0.020-cm fraction. The composition of the samples, bulk density *d*, and the terminal acidic group concentration are given in Table 1. The static exchange capacity ($SEC_{0.1\ N\ NaOH}$) was determined by the procedure described in [6].

The sorption characteristics of the samples with respect to Pd(II), Fe(III), and Pr(III) were determined in the static mode at s : l = 1 : 200 at room temperature (19 ± 1°C) or in temperature-controlled cells at 20 ± 0.5°C (UH-4 thermostat). The contacting time was 4 h, and the stirring rate, 800 rpm (magnetic stirrer). Sorption of the metals from nitrate–nitrite solutions was studied in the dark.

To prepare the working solutions, we used commercial aqueous palladium(II) nitrate (5 M, pure grade), HNO_3 and $NaNO_3$ (analytically pure grade), $NaNO_2$ and $Fe(NO_3)_3 \cdot 9H_2O$ (chemically pure grade), $Pr(NO_3)_3 \cdot 6H_2O$ (pure grade), and also 25% aqueous ammonia (ultrapure grade) and NH_4NO_3 (pure grade) for preparation of the eluents. The Pd(II) solution was activated prior to use according to the procedure described in [5]. In the experiments we used nitrate and nitrate–nitrite solutions containing 5.1 ± 0.1 mM Pd(II) and 2–4 M HNO_3, simulating PUREX raffinates in the concentrations of a series of components: Pr(III) 0.0177, Fe(III) 0.0210, and $NaNO_3$ 0.0754 M in mixed nitrate solutions and 0.010 M $NaNO_2$ in nitrate–nitrite solutions. Also we used individual Pr(III) nitric and nitric–nitrous acid solutions.

Table 1. Characteristics of PMS samples

Sample	Content, %					$SEC_{0.1\ N\ NaOH}$, mg-equiv g^{-1}	d, g cm^{-3}
	C	H	S	Cl	ash		
PMS1	26.1	4.1	69.7	0	0.0	0.6	0.129
PMS2	25.8	4.4	64.2	0	3.0	1.4	0.333

The electronic absorption spectra of the nitrate and nitrate–nitrite solutions of Pd(II) in the range 350–500 nm were recorded on a Specord M40 spectrophotometer using 1- and 0.2-cm quartz cells, respectively, relative to water or a mixed solution containing 2 M HNO_3 as a reference. A day after preparation, the extinction coefficients ε of the individual and mixed nitrate solutions of Pd(II) were 104–113 at 401–411 nm and 102–112 at 397–406 nm, respectively, in the HNO_3 concentration range 2–4 M, suggesting that no polynuclear species of Pd(II) are formed [5] and also that similar Pd(II) complexes are formed in both individual and mixed nitrate solutions. According to the visible spectra, the nitric acid solutions of Pd(II) are stable for at least a month. The extinction coefficients of the nitrate–nitrite solutions at λ = 388–389 nm {absorption band of the mono- and dinitroaqua complexes of Pd(II) [4]} slowly decreases with time as a result of decomposition of HNO_2 and decrease in the concentration of the nitrite complexes of Pd(II) [2]. The nitrate–nitrite solutions were used a day after preparation.

The Pd(II) concentration in the nitrate and nitrate–nitrite solutions was determined spectrophotometrically with tin chloride [7] on a Specord M40 spectrophotometer. The presence of Pr(III) and Fe(III) did not interfere with determination of Pd(II) in mixed solutions. The Fe(III) concentration in the mixed solutions was determined chelatometrically with Na_2EDTA in 0.1 M HCl in the presence of sulfosalicylic acid [8] to within 1.4%. In this case, Pr(III) and Pd(II) did not interfere. Pr(III) in the individual solutions was determined by EDTA titration at pH 5.8 (acetate buffer) with Xylenol Orange [8] to within <0.6%. Pd(II) in aqueous ammonia eluates was determined by atomic absorption spectroscopy on a Hitachi 508 instrument.

The IR spectra of the sorbents in the ranges 200–4000 and 1300–1500 cm^{-1} were recorded on a Specord M80 spectrophotometer in Nujol and hexachlorobutadiene, respectively.

The higher concentration of the terminal acidic groups in PMS2 (Table 1) is an indication of lower molecular weight of this sample. The IR spectra of the sorbents demonstrate the differences in the qualitative and quantitative compositions of the terminal groups and also in the degree of oxidation of the sulfide groups in the samples. In PMS1, the terminal groups are sulfhydryl groups, as demonstrated by the absorption band at 2550 cm^{-1} {ν(SH) [9, 10]}, and also small amount of the sulfonate groups in the hydroxonium form $RSO_2O^-H_3O^+$ {medium-intensity band $\nu_{as}(SO_2)$ at 1174 cm^{-1}; weak band $\nu_s(SO_2)$ at 1012 cm^{-1} [9, 10]; to vibration bands of hydroxonium we could assign the broad weak band in the range 3100–3600 cm^{-1} with a maximum at 3440 cm^{-1} [$\nu_1(A_1)$, $\nu_3(E)$], the band at 1174 cm^{-1} [$\nu_2(A_1)$, and weak bands at 1632 and 1600 cm^{-1} [$\nu_4(E)$] [11]}. The sample PMS1 contains small amount of the oxidized groups: sulfoxide {very weak band ν(S=O) at 1060 cm^{-1} [9, 10]} and sulfonic groups {weak band $\nu_{as}(SO_2)$ at 1368 cm^{-1} and the band $\nu_s(SO_2)$ at 1174 cm^{-1} [9, 10]}. In PMS2, the terminal groups are primarily sulfonate groups in the hydroxonium form, as demonstrated by the medium-intensity bands $\nu_{as}(SO_2)$ and $\nu_2(A_1)$ of hydroxonium at 1176 cm^{-1} and ν(S–O) at 706 cm^{-1} [12], the strong band $\nu_s(SO_2)$ at 1012 cm^{-1}, and also by more intense (as compared to PMS1) absorption bands of hydroxonium at 3368 [$\nu_1(A_1)$], 3310 [$\nu_3(E)$], and 1640 and 1600 cm^{-1} [$\nu_4(E)$]. The low intensity of the bands of the sulfoxide groups ν(S=O) suggests low content of these groups in PMS2. The medium intensity of the bands of the sulfonic groups $\nu_{as}(SO_2)$ at 1368 cm^{-1} and $\nu_s(SO_2)$ at 1176 cm^{-1} is indicative of higher content of these groups in PMS2 as compared to PMS1.

The study of the chemical stability of PMS in 2–4 M HNO_3 showed that, at s : l = 1 : 200, contacting of PMS1 for 4 h increases the content of the sulfonic groups and, to smaller extent, of the sulfoxide groups. In the IR spectra of the sample, the relative intensity of the bands of sulfonic groups increased with increasing HNO_3 concentration. The lower molecular weight and higher concentration of the oxidized groups in PMS2 cause larger loss through oxidative oligomeri-

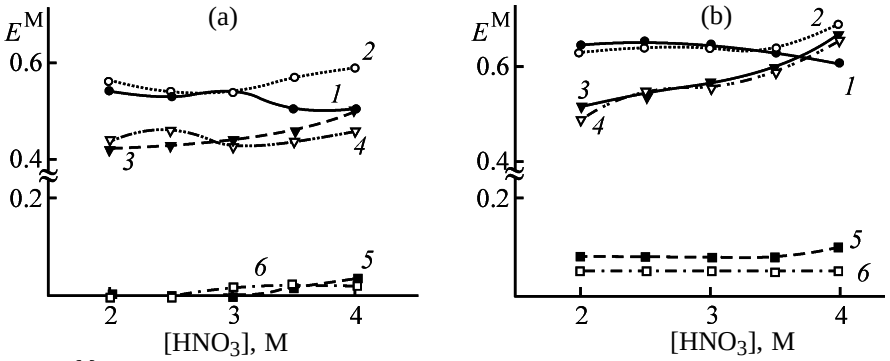

Fig. 1. Sorption capacity E^M of (a) PMS1 and (b) PMS2 samples with respect to (*1–4*) Pd(II) and (*5, 6*) Fe(III) as a function of the composition of nitrate and nitrate–nitrite solutions: (*1*) individual Pd(II) nitrate solutions, (*2, 5*) mixed nitrate solutions, (*3*) individual Pd(II) nitrate–nitrite solutions, and (*4, 6*) mixed nitrate–nitrite solutions.

zation upon long-term contacting with strong HNO_3 solutions. The loss in PMS1 and PMS2 in 8 h of contacting with 4 M HNO_3 was <8 and 10%, respectively. Therefore, we have not studied the equilibrium sorption characteristics, as requiring prolonged contact (about 30 days [5]) of the phases.

The dependences of the nonequilibrium sorption capacity for Pd(II) on the solution composition are generally similar for both samples (Fig. 1). In this case, E^{Pd} of PMS2 is somewhat higher in all the solutions studied, as compared to less hydrophilic PMS1. Increased concentration of strongly hydrophilic sulfonic and sulfonate groups in PMS2 is reflected in higher wettability and swellability, enabling us to expect better kinetic characteristics of sorption of Pd(II) as compared to PMS1 [9]. The dependence of the sorption capacity of the samples for Pd(II) on the acid concentration in the individual Pd(II) solutions in nitric acid (Figs. 1a and 1b, curves *1*) is similar to that presented in [5]. The decrease in the sorption of Pd(II) at a nitric acid concentration above 3 M is caused by partial dissolution of the sorbents through oxidative oligomerization. Increasing salinity in the mixed nitrate solutions has no effect on the sorption of Pd(II) at a nitric acid concentration below 3 M (Figs. 1a and 1b, curves *1, 2*). The increase in E^{Pd} with increasing HNO_3 concentration to above 3 M is probably due to increase in the permeability of the sorbents because of increasing concentration of the oxidized groups, and also to decrease in the solubility of the resulting oligomers and their Pd(II) complexes with increasing salinity, which is caused by decreasing activity of the solvent and dielectric constant of the solution [13, 14]. Further reason could be sorption of Fe(II) on the oxidized groups of PMS (curves *5*). Evidently, the complexation of Fe(III) with the sulfoxide and sulfonic groups eliminates their further oxidation to sulfonate, thus preventing break of the polymer chain.

The Pd(II) recovery from the individual and mixed nitrate–nitrite solutions regularly increases with increasing acid concentration. In this case, increase in the salinity has no significant effect on the sorption of Pd(II) (Fig. 1, curves *3, 4*). The nonequilibrium sorption capacity of the samples with respect to Pd(II) is lower in the nitrate–nitrite solutions, especially, at low acid concentrations (Fig. 1), which can be attributed to different rates of sorption of Pd(II) complexes from nitrate and nitrate–nitrite solutions.

The lack of the effect of the stirring rate above 600 rpm on the rate of Pd(II) recovery from all the solutions studied, and also the observed linearity of the initial sections of the kinetic curves linearized in the coordinates E^{Pd}–$\tau^{1/2}$ suggest pore-diffusion-controlled kinetics of the sorption of Pd(II) from nitrate and nitrate–nitrite solutions [6]. We have demonstrated previously [5] that the sorption kinetics of $[Pd(H_2O)_4]^{2+}$ from 1 M HNO_3 with PMS is controlled by pore diffusion with a mobile front of sorption and variable coefficient of the inner diffusion. It was demonstrated by X-ray photoelectron spectroscopy that chloro complexes of platinum metals (Pd, Pt) labile with respect to inner-sphere substitution are sorbed primarily in the PMS surface layer, while sorption of inert Rh and Ir chloro complexes results in more uniform distribution of the metals throughout the bulk of the sorbent [15]. Data on extraction of Pd(II) from nitrate–nitrite solutions with dialkyl sulfides [2] show that the extraction rate of Pd(II) complexes increases in the order $Pd^{2+} \ll [Pd(NO_2)_2] < [PdNO_2]^+$. Therefore, it may be suggested that the rate of interaction of Pd(II) mono- and dinitro complexes with the sulfide groups of PMS is considerably higher than for $[Pd\cdot(H_2O)_4]^{2+}$, and, in sorption of nitro complexes, a com-

Table 2. Distribution coefficients of Pd(II) and Fe(III) and $K_{Pd/Fe}$ partition coefficients in sorption from mixed nitrate and nitrate–nitrite solutions (s : l = 1 : 200, τ = 4 h)

Solution (2–4 M HNO_3)	PMS1			PMS2		
	K_d^{Pd}	K_d^{Fe}	$K_{Pd/Fe}$	K_d^{Pd}	K_d^{Fe}	$K_{Pd/Fe}$
	ml g^{-1}			ml g^{-1}		
Nitrate	235–288	0–2.0	∞–146	341–445	4.0–5.0	86–91
Nitrate–nitrite	147–161	0–1.2	∞–131	178–357	2.4–2.5	74–144

pact surface layer of sorption complexes is rapidly formed, thus decreasing the effective coefficient of inner diffusion. The evidence in favor of this suggestion is that the Pd(II) sorption rate decreases on passing from the nitrate solution (Fig. 2, curve *3*) to the nitrate–nitrite solutions (curves *1*, *2*) and also with increasing concentration of nitro complexes in the initial solution (curves *2* and *1*). Whereas in the initial sections of the kinetic curves (τ ≤ 5 min) the sorption rate from the indicated kinds of solutions is characterized by close $dE^{Pd}/d\tau$ values of about $(1.3–1.6) \times 10^{-2}$ mmol g^{-1} min^{-1} (determined by graphical differentiation of the kinetic curves shown in Fig. 2), already at τ = 30 min $dE^{Pd}/d\tau$ decreases considerably in the order nitrate solution > nitrate–nitrite solution (ε_{388} = 836) > nitrate–nitrite solution (ε_{388} = 1010), being 2.1×10^{-3}, 1.4×10^{-3}, and 9.5×10^{-4} mmol g^{-1} min^{-1}, respectively.

The decrease in $\varepsilon_{388–389}$ of the nitrate–nitrite solutions with increasing HNO_3 concentration from 2 to 4 M (for example, from 1003 to 736 for mixed solutions a day after preparation) and also the appearance

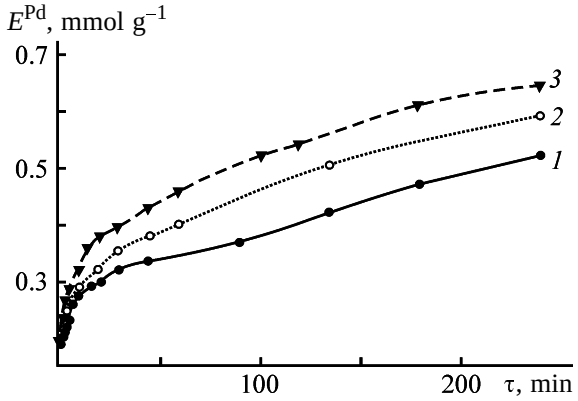

Fig. 2. Kinetic curves of sorption of Pd(II) from (*1*, *2*) individual nitrate–nitrite and (*3*) nitrate solutions on PMS at [HNO_3] = 2 M. (E^{Pd}) Sorption capacity and (τ) time. (*1*) Nitrate–nitrite solution a day after preparation (ε_{388} = 1010) and (*2*) same solution 7 days after preparation (ε_{388} = 836).

of a new band at 372 nm (as a shoulder at the band with a maximum at 388 nm) in the UV spectra at HNO_3 concentration above 3 M suggest that the concentration of nitro complexes decreases and free HNO_2 is formed [4], which corresponds to the shift of the complexation equilibrium to the left [2]:

$$Pd^{2+} + HNO_2 \rightleftarrows [Pd(NO_2)]^+ + H^+,$$

$$[Pd(NO_2)]^+ + HNO_2 \rightleftarrows [Pd(NO_2)_2] + H^+.$$

Therefore, the increase in the Pd(II) recovery from nitrate–nitrite solutions with increasing acid concentration is caused by both increase in the hydrophilicity of the sorbent as a result of increasing concentration of oxidized groups and decrease in the concentration of nitro complexes in the initial solution.

It was demonstrated that Pr(III) is not sorbed from individual nitrate and nitrate–nitrite solutions of praseodymium nitrate over the HNO_3 concentration range 2–4 M with PMS1 and PMS2. Iron(III) is sorbed from simulated solutions with a low distribution coefficient K_d^{Fe}. Therefore, Pd(II) can be separated from iron with a fairly high partition coefficient $K_{Pd/Fe}$ (Tables 2, 3). Increase in the content of oxidized groups in PMS during storage as an aqueous paste, and also with increasing acid concentration and contacting time decreases the selectivity of Pd(II)–Fe(III) separation (Fig. 1; Tables 2, 3).

At s : l = 1 : 100, Pd(II) can be fully recovered from mixed nitrate and nitrate–nitrite solutions by sorption on PMS2 in 4 and 5 h, respectively, at high distribution and partition coefficients. The degree of Pd(II) recovery by single-step sorption on PMS1 is insufficient (Table 3).

In view of the fact that, in extractive recovery of Pd(II) from chloride and nitrite solutions with dialkyl sulfides, Pd(II) can be fully backwashed with ammonia solutions [14], it was advisable to study the possibility of desorption of Pd(II) sorbates on

Table 3. Recovery of Pd(II) from mixed nitrate and nitrate–nitrite solutions ([HNO_3] = 2 M; s : l = 1 : 100)

Solution	Sample	τ, h	Pd(II) recovery, %	K_d^{Pd}	K_d^{Fe}	$K_{Pd/Fe}$
				ml g^{-1}		
Nitrate	PMS1	4	95	1900	0.5	3876
	PMS2	4	100	∞	1.0	∞
Nitrate–nitrite	PMS1	4	76	316	0.5	645
	PMS1	5	82	453	2.2	204
	PMS2	4	94	1650	0.6	2723
	PMS2	5	99	10 400	2.5	4211

PMS2 obtained after sorption from individual nitrate (E^{Pd} = 0.52 mmol g^{-1}) and nitrate–nitrite (E^{Pd} = 0.42 mmol g^{-1}) solutions at [HNO_3] = 2 M using ammonia solutions. The desorption of Pd(II) with 6 and 12 M NH_4OH solutions containing 0.1 M NH_4NO_3 at s : l = 1 : 100 and τ = 4 h was determined to be 6.7 and 11.5% and 11.6 and 11.4% for the sorbates obtained from the nitrate and nitrate–nitrite solutions, respectively.

CONCLUSIONS

(1) Polymethylene monosulfide efficiently sorbs Pd(II) at room temperature from nitrate–nitrite solutions simulating PUREX raffinates. Over the practically significant HNO_3 concentration range (2–3.5 M), Pd(II) can be completely separated from lanthanides [Pr(III)] and, at sufficiently high partition coefficients, from Fe(III).

(2) Increase in the content of oxidized sulfonic and sulfonate groups in the sorbent as a result of long-term storage in the form of an aqueous paste and also with increasing acid concentration in the solution and contacting time makes the sorbent more hydrophilic, thus increasing the sorption rate and Pd(II) recovery. At the same time, the separation of Pd(II) from Fe(III) becomes less efficient.

(3) Decrease in the concentration of Pd(II) nitro complexes in the course of storage of the nitrate–nitrite solution and also with increasing acid concentration increases the sorption rate and nonequilibrium sorption capacity of the sorbent for Pd(II).

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of Silver and Chemiluminescent Activity of Clinoptilolite

Abstract—Sorption conditions of ions and colloidal particles of silver by a zeolite (clinoptilolite) and clays, and specific features of distribution of absorbed silver in clinoptilolite grains were studied. Temperature dependences of the intensity of heterogeneous chemiluminescence from samples of natural clinoptilolite and its modified forms were obtained. The activation energies of the luminescence-active chemisorption of oxygen on electron-donor centers of the zeolite surface and relative amount of centers were determined.

Active search for effective means for concentrating noble metals and ways to diminish their loss in their secondary absorption by minerals in the slurry during leaching, and also the need to elucidate the mechanism of sorption processes that occur in nature make urgent a study of sorption of ions and colloidal particles of gold and silver on inorganic ion exchangers and minerals [1, 2]. A known mineral sorbent is a natural zeolite, clinoptilolite, whose deposits widely occur in Russia and other countries [3]. The considerable resources of the zeolite, simplicity of its mining, and its unique properties (acid resistance, selectivity, thermal stability, etc.) promote studies of its structure [4] and properties, aimed to reveal the possibility of modifying this zeolite and extending its application areas [3, 5, 6].

Previously we studied the absorption of complex cations of gold and silver from acid thiourea solutions by clinoptilolite from the Dzegvi deposit (Georgia) [7]. Later, data on the mechanism and kinetics of gold sorption in the form of complex anions from hydrochloric acid solutions were reported [8]. Further, studies of the physicochemical parameters of zeolite samples from deposits of Eastern Siberia and Far East and the concentration of noble metals by these zeolites were continued [9–11].

The aim of this study was to examine sorption of ions and colloidal particles of silver by a natural zeolite (clinoptilolite) and clays and to reveal possibilities of using heterogeneous chemiluminescence for analysis of the chemiluminescent activity of the surface of clinoptilolite, its modified forms, and products of silver sorption.

The clinoptilolite from the Shivyrtuiskoe deposit (Transbaikalia) with grain size from 0.4 to 2.8 mm was studied.[1]

The chemical composition of the clinoptilolite (%) is presented below: SiO_2 61.90, Al_2O_3 11.50, Fe_2O_3 2.20, FeO 0.10, CaO 4.20, $CaCO_3$ 1.10, CaF_2 3.30, MgO 1.50, K 2.68, Na 0.76, Mn 0.12, calcination loss 10.64.

In addition to clinoptilolite, the zeolite tuff contains an admixture (up to 20%) of clayey minerals (montmorillonite, kaolinite, etc.), micas, quartz, and iron oxides. In the composition of the crystalline phase, the sample is close to clinoptilolite from the Tedzami deposit (Georgia) [9].

As a major part of impurity minerals in clinoptilolite tuffs is, as a rule, constituted by clays, which also exhibit sorption properties, we studied also the sorption of silver by the most typical samples of clays from deposits of Irkutsk oblast and by palygorskite (Cherkassy deposit, Ukraine). Data on the chemical composition of the clays are listed in Table 1.

The Bulusinsk clay is a mixture of kaolinite and montmorillonite, and the Novorazvodninsk clay, a mixture of silicon oxide with montmorillonite, albite, and kaolinite.

Silver(I) solutions were obtained by dissolving a precisely weighed portion of silver nitrate of chemically pure grade in double-distilled water (pH 6.9).

[1] The zeolite and data on its chemical composition were placed at authors' disposal by Priargunskii Mining and Chemical Combine, Joint-Stock Company.

1070-4272/05/7811-1806 © 2005 Pleiades Publishing, Inc.

Silver colloidal solutions were prepared by the known procedure [12]; the pH value of these solutions was 7.5. Emission of light from colloidal particles in the solutions obtained was observed in a dark-field condensing lens. It was found, using the electrophoresis technique, that silver particles are positively charged under the experimental conditions.

Experiments on sorption of ions and colloidal particles of silver were carried out in the dark under static conditions with agitation for 24 h; the weighed portion of the zeolite was 0.1 g, and the volume of the silver solution, 20 ml. We examined the influence exerted by the duration of sorption, $V:m$ ratio (V, solution volume, ml; m, weighed portion of the sorbent, g), and content of silver in the initial solutions on the sorption of silver colloidal particles and silver ions by clinoptilolite. The content of silver in solutions after separation of the minerals was determined by the atomic-absorption method on a Saturn spectrometer. The sorption parameters were calculated from the difference of silver concentrations in solution before and after sorption.

The sodium and hydrogen forms of clinoptilolite were obtained by treating a starting sample with 1 M solutions of NaCl and HCl, respectively, with the subsequent washing to remove chloride ions; silver-containing samples were produced by sorption of Ag^+ from 2.39 mM $AgNO_3$ solutions.

The mechanochemical activation of the zeolite was performed by ultrafine grinding in an AI-2.30 high-energy-intensity planetary centrifugal mill in dry air at an acceleration of $40g$ (g = 9.8 m s^{-2}). The grinding was done for 1, 5, 15, and 30 min in 80 cm^3 feldspar drums. Feldspar balls 7 mm in diameter were used as grinding bodies. The mass of the clinoptilolite charge was 5 g, and that of the balls, 50 g.

To study the luminescent properties of clinoptilolite, its weighed portions (0.2 g) were thoroughly ground in a mortar and compacted into pellets. The luminescence from the samples was recorded with a photomultiplier in the blue-green spectral range selected with an SZS-22 glass light filter, with heating in air at a rate of 2 deg s^{-1}.

An X-ray fluorescence microprobe analysis of cross sections of clinoptilolite grains and of samples after sorption of silver from colloidal and true solutions was performed on a Camebax SX-50 X-ray fluorescence microanalyzer. Zeolite grains were preliminarily embedded in epoxy resin, ground, and polished.

It was preliminarily found that clinoptilolite effectively absorbs silver colloidal particles and silver ions, which are recovered to a greater extent. The sorption is accompanied by an increase in pH, as a rule by 0.5, both in colloidal and true ionic solutions. To determine why the pH changes, the following experiment was carried out: 0.1-g portions of the zeolite were poured over with 20 ml of distilled water. During the time of contact (24 h), the pH of water increased from 7.0 to 7.5. It may be assumed that in sorption of silver by clinoptilolite, too, the increase in the solution pH occurs not only upon absorption of silver, but also through hydrolysis of the zeolite surface.

Table 1. Chemical composition of clay samples

Component	Clay composition, wt %		
	Novorazvodninsk deposit	Bulusinsk deposit	palygorskite
SiO_2	64.30	53.60	55.40
Al_2O_3	12.60	27.00	10.80
Fe_2O_3	5.50	3.90	6.10
CaO	3.60	0.30	0.90
MgO	2.60	0.50	7.50
Na_2O	6.05	0.12	0.27
K_2O	0.22	1.20	1.00
TiO_2	0.17	0.65	–
H_2O	3.60	3.90	1.30
Calcination loss	1.36	8.83	16.73

The dependences of silver sorption by clinoptilolite on the process duration (Fig. 1a) indicate that the sorption equilibrium in the system constituted by the zeolite and the silver solution is attained in 6 h. Raising the sorption duration to 48 h does not lead to any improvement of the sorption parameters. The time of half-sorption is 40 min in both cases.

The effect of the V/m ratio on the parameters of silver sorption by clinoptilolite was studied in solutions with a silver concentration of 50 mg l^{-1} (Table 2). The contact duration was 24 h.

Under the conditions studied, silver ions are absorbed more effectively; making smaller the V/m ratio favors more complete recovery of colloidal silver(I).

The influence exerted by the content of silver on its absorption by clinoptilolite was studied with the silver concentration varied from 10 to 160 mg l^{-1} at V/m = 200 and sorption duration of 24 h (Fig. 1b). In the concentration range studied, the capacity of clinoptilolite for silver ions exceeds that for colloidal particles. An analysis of silver solutions for the content of alkali

Table 2. Effect of the *V*/*m* ratio on the recovery of silver by clinoptilolite

Solution	Recovery of silver, %, at indicated *V*/*m*			
	50	100	200	400
Colloidal	85.3	72.5	50.8	37.2
Silver(I)	93.4	81.1	58.6	45.5

Table 3. Leaching-out of metal ions from the clinoptilolite structure in silver sorption

Silver	Sorption capacity of mineral, mg g^{-1}	Amount of leached-out ions (relative to their content in zeolite), wt %				
		Na	K	Ca	Mg	Fe
Colloidal	10.8	51.3	3.7	2.3	1.7	0.9
Truly dissolved	14.8	64.7	3.7	0.6	0.4	0.6

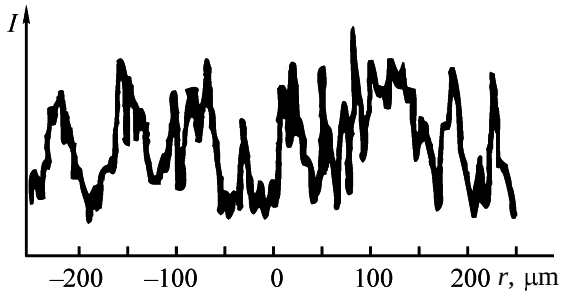

Fig. 2. Distribution of absorbed silver within a grain of the starting clinoptilolite. Scanning range 500 μm, scanning step 50 μm. (*I*) Intensity and (*r*) distance.

and alkaline-earth metal ions after their contact with the zeolite demonstrated that the absorption of silver is accompanied by transfer of a considerable amount of sodium ions, as well as those of potassium, calcium, magnesium, and iron, into solution from the structure of the mineral (Table 3). However, part of sodium and potassium ions can also be leached out from the zeolite structure when clinoptilolite is brought in contact with water. For example, upon a 24-h contact of clinoptilolite with water, sodium and potassium ions pass into solution in amounts of up to 19.2 and 0.7 wt %, respectively, relative to their content in the mineral.

It should be noted that, in sorption of silver from both true and colloidal solutions, sodium ions are more intensively leached out from the zeolite structure, compared with potassium ions, and a larger amount of sodium ions that passed into solution corresponds to a larger amount of sorbed silver. The absorption of colloidal silver particles is accompanied by an increase in the amount of calcium, magnesium, and iron ions that passed into solution from the zeolite structure, compared with sorption of silver ions. The clinoptilolite under study contains a nearly three times larger amount of potassium ions, compared with sodium (Table 1); however, sodium ions most actively pass into solution in sorption of silver.

Examining the grains of silver-containing samples of the starting and modified clinoptilolite by X-ray fluorescence microanalysis revealed the presence of silver throughout the zeolite grains and its nonuniform distribution in the grains. Figure 2 shows as an example a typical distribution of absorbed silver ions in a clinoptilolite grain. A similar distribution is observed in sorption of colloidal silver, i.e., the distribution of this kind is characteristic of all the samples studied, irrespective of the nature of solutions from which it is recovered. A considerable part of absorbed silver is contained in those microregions of the grains

which contain impurity minerals. Figure 3 shows a typical energy spectrum of a microscopic part of the cross section of a grain. The spectrum shows, in addition to the lines of silicon and absorbed silver, those of iron and titanium, contained in the corresponding oxides. It may be assumed that impurity minerals, primarily iron and titanium oxides, are involved in absorption of ions and colloidal particles of silver by clinoptilolite tuff. In our previous study [7] in which the sorption of complex silver cations by clinoptilolite from thiourea solutions was examined by X-ray fluorescence microanalysis, we also noted that regions in which sorbed silver and iron of impurity minerals are distributed coincide. The revealed involvement of iron and titanium oxides in sorption makes it possible to explain the nature of the anion-exchange properties of clinoptilolite, because the ability of clinoptilolite to absorb complex metal anions is known [8]. The anion-exchange properties of clinoptilolite may be accounted for by the involvement in sorption of oxides and hydrated oxides of iron, titanium, and other transition metals, which are contained in clinoptilolite tuff.

It was found in studying the sorption of silver by clays that clayey minerals absorb silver ions from nitrate solutions (Fig. 4). Similar data were obtained in concentration of silver from colloid solutions. Comparison of the parameters of silver sorption by clays and clinoptilolite shows a considerable advantage of clinoptilolite. The results obtained suggest that the contribution of clayey components to the parameters of silver sorption by clinoptilolite tuff does not exceed 10%.

To obtain evidence concerning active centers on the surface of clinoptilolite and its modified forms, the chemiluminescent properties of the zeolite were studied. It is known that heating of inorganic substances in air is accompanied by heterogeneous chemiluminescence (HCL), which occurs upon luminescence-active chemisorption of atmospheric oxygen [13–15]. In this case, oxygen acts as electron acceptor, and, therefore, data obtained in analysis of HCL curves furnish information about the amount and energy state of electron-donor centers on the surface of a substance. The fundamental aspects of HCL from alkali halide crystals have been rather well studied, with the relationship between their chemiluminescent properties and surface defectiveness revealed [13, 14]. The luminescence appearing upon chemisorption of oxygen by electron-donor centers on the surface of inorganic ion exchangers (titanium, zirconium, and aluminum oxides) and products of sorption of metal ions by these ion exchanges was studied previously

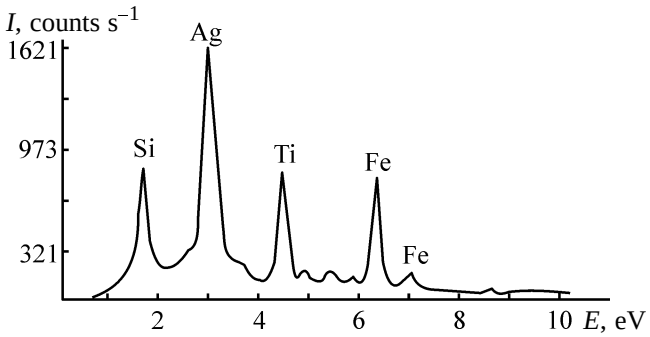

Fig. 3. Energy spectrum of a microregion on the cross section of a grain of the starting clinoptilolite after sorption of colloidal silver. (*I*) Intensity and (*E*) energy.

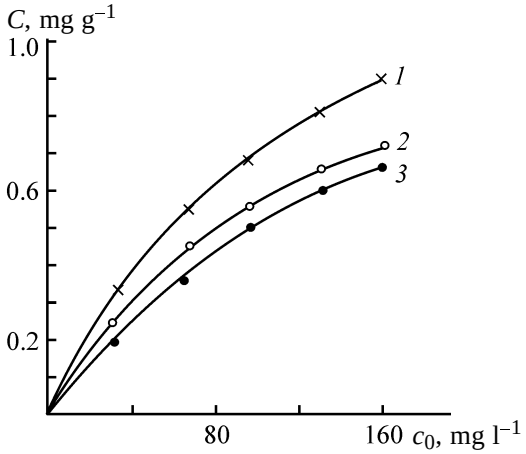

Fig. 4. Effect of the concentration of silver in solutions on the parameters of its sorption by clays. Clay: (*1*) Novorazvodninsk deposit, (*2*) Bulusinsk deposit, and (*3*) palygorskite. (*C*) Sorption capacity of a clay and (c_0) concentration of silver in the starting solutions.

[15]. It was found that heating of a natural zeolite, clinoptilolite, in air also gives rise to luminescence [10, 11].

The temperature dependences of the intensity of luminescence from clinoptilolite lie in the range 500–700 K and show two overlapping peaks with maxima at 545 and 665 K (Fig. 5, curve *1*). As the clinoptilolite under study is a natural mineral, the observed thermally stimulated luminescence may be due not only to chemisorption of oxygen on its surface, but also to release of the stored natural radiative energy. In view of the irreversibility of the luminescence-active chemisorption of oxygen, repeated heating of the sample is not accompanied by luminescence in both cases. At the same time, it is known that HCL appears again upon treatment of the sample surface with water vapor.

To reveal the nature of the observed luminescence from clinoptilolite, the following experiments were

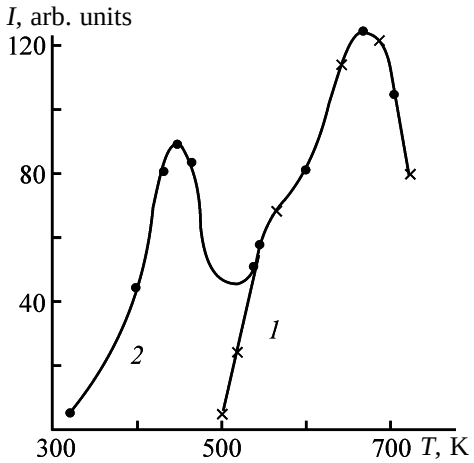

Fig. 5. Thermally stimulated luminescence from the starting clinoptilolite: (*1*) without irradiation and (*2*) after irradiation. (*I*) Relative intensity and (*T*) temperature; the same for Fig. 6.

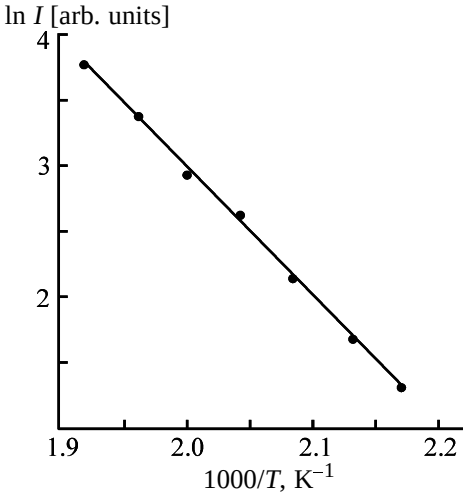

Fig. 6. Linearization of the initial portion of the curve of chemiluminescence from the starting clinoptilolite.

performed. On being heated to 700 K, a sample that lost its chemiluminescent activity was exposed to water vapor. In a repeated heating, the luminescence at 500–700 K was partly restored. Also, the initial sample was subjected to X-ray irradiation. Upon this irradiation, a thermally stimulated luminescence peaked at 450 K (Fig. 5, curve *2*), not observed in unirradiated samples, appeared in addition to the luminescence at 500–700 K.

These experiments give reason to believe that the luminescence observed on heating the starting clinoptilolite in air is HCL.

Formally, the generation of HCL can be represented as

$$L_m + O_2 \rightarrow (L_mO_2) + h\nu,$$

where L_m is a surface center at which luminescence-active chemisorption of oxygen occurs.

Because the concentration of atmospheric oxygen in the experiments is many times that of the L_m centers, its change in HCL can be neglected. In this approximation, the kinetics of HCL is only determined by the rate of variation of the concentration of L_m centers, i.e., will correspond to a first-order kinetics. Therefore, the HCL curves were analyzed using the known methods applied in processing of thermoluminescence curves [16].

Modification of the clinoptilolite surface leads to a change in the HCL intensity and to a redistribution of intensity among the peaks. The initial portion of the first HCL peak is well linearized in the $\ln I$–$1/T$ coordinates (I is the luminescence intensity, arb. units). Figure 6 shows as an example the result obtained in linearization of the initial portion of the chemiluminescence curve for a sample of the starting clinoptilolite. The absolute value of the slope of the thus obtained straight line is ε/k, where ε is the activation energy, and k, Boltzmann constant. Similar data were obtained for clinoptilolite samples in the sodium, hydrogen, and silver-containing forms. For all the samples, the activation energy of luminescence-active chemisorption of oxygen at centers of the "first type" is 0.6 eV.

These results made it possible to approximate the temperature dependence of the intensity of the first HCL peak. The integral HCL curve was decomposed into two peaks and the full width at half-maximum ΔT of the second HCL peak was used to determine the activation energy of luminescence-active chemisorption of oxygen at L_m centers of the "second type":

$$\varepsilon = 2.5kT_m^2/\Delta T - 2kT_m,$$

where T_m is temperature at which the second HCL peak lies.

For all of the samples studied, the activation energy is 0.7 eV.

The fact that the activation energy is invariable for centers of each type indicates that the chemical modification of the surface of the starting clinoptilolite does not give rise to L_m luminescence centers of a new type. As the HCL intensity is proportional to the chemisorption rate, the area delimited by the HCL curve can be used to determine the relative amount of L_m centers of each type. The results of calculations of this kind are listed in arbitrary units in Table 4.

Our results show that chemical treatment of clinoptilolite, leading to a change in the composition and

Table 4. Concentration of L_m centers in samples of zeolite of various forms

Type of center	Concentration of L_m centers, arb. units, in a zeolite of indicated form			
	starting	Na form	H form	Ag form
First, T_m = 545 K, ε = 0.6 eV	54	43	32	31
Second, T_m = 665 K, ε = 0.7 eV	130	140	23	46

amount of exchangeable metal ions in its structure, differently affects the amount of L_m centers. Introduction into the zeolite of an additional amount of sodium ions (sodium form) that substitute part of potassium ions in the zeolite lattice virtually does not change the total concentration of L_m centers and only leads to their redistribution in favor of centers of the second type. Treatment of samples with an HCl solution (hydrogen form), which leads to substitution of a part of sodium and potassium ions in the zeolite structure by hydroxonium ions, makes lower the concentrations of centers of both types, with the amount of centers of the second type decreasing to a greater extent. The amount of L_m centers changes in a similar way upon partial substitution of sodium and potassium ions by silver ions. However, centers of the second type are less sensitive to treatment of zeolite samples with $AgNO_3$, compared with the H form of the zeolite.

These results give reason to believe that L_m centers are formed in clinoptilolite under the action of alkali metal ions. Possibly, these ions are themselves incorporated in L_m centers. This statement is supported by the results obtained in measuring the HCL from clinoptilolite samples subjected to mechanochemical activation. It is known [5] that mechanochemical activation of aluminosilicates primarily affects the structure and properties of their lattice frameworks and leaves unchanged the concentration and activity of exchanging alkali metal ions. Experiments show that, after a mechanochemical activation of clinoptilolite for 1 to 30 min, the HCL curves of activated and initial samples coincide, i.e., mechanochemical activation of clinoptilolite does not lead to any significant changes in the luminescent properties of clinoptilolite samples.

Table 5. Changes in the concentrations of silver, potassium, and sodium ions in solutions upon sorption of silver(I) by the starting clinoptilolite*

c_0(Ag)	c_s(Ag)	c_s(Na)	c_s(K)
mM			
0.37	0.06	0.43	0.10
0.72	0.15	0.74	0.12
1.61	0.61	0.89	0.11
2.39	1.10	1.00	0.12

* c_0, concentration of ions in the starting solutions; c_s, that in solutions upon their contact with clinoptilolite.

It should be noted that, in sorption of silver ions by clinoptilolite, mostly sodium ions, and to a lesser extent potassium ions, are washed out from its structure (Table 5).

Analysis of the whole set of results obtained in studying the sorption of silver and the chemiluminescent activity of the initial and modified clinoptilolites suggests that the first peak in the HCL curve is due to presence of exchange potassium ions in the zeolite structure, and the second peak is associated with presence of sodium ions.

CONCLUSIONS

(1) A study of the sorption of ions and colloidal particles of silver by clinoptilolite and clays demonstrated that the parameters of silver sorption by clinotilolite markedly exceed those for clays. Specific features of the distribution of absorbed silver in clinoptilolite grains were examined: silver is nonuniformly distributed in grains and is more effectively absorbed by those microscopic regions of grains which contain iron and titanium oxides.

(2) Centers of luminescence-active adsorption of oxygen on the surface of the clinoptilolite zeolite were detected. Temperature dependences of the intensity of heterogeneous chemiluminescence from samples of natural clinoptilolite and its modified forms were measured.

(3) The activation energies of luminescence-active chemisorption of oxygen on electron-donor centers on the zeolite surface were evaluated, and relative amounts of these centers were determined. The chemiluminescent properties of clinoptilolite are determined by the nature of exchangeable cations in its structure.

ACKNOWLEDGMENTS

SORPTION AND ION-EXCHANGE PROCESSES

Sorption Properties of Materials Based on Graft Polycaproamide Copolymers

I. V. Lavnikova, G. D. Bakhtina, and V. F. Zheltobryukhov

Volgograd State Technical University, Volgograd, Russia

Received December 16, 2004; in final form, September 2005

Abstract—Sorption of metal ions with a cation exchanger based on a graft polycaproamide copolymer was studied, and the sorption power of the material was evaluated.

Polymer-analogous transformations in grafted copolymer chains are a promising route for introducing new functional groups into pendant chains of polymeric materials [1, 2]. A characteristic example is phosphorylation of grafted polycaproamide (PCA) chains. Increased interest in this procedure for preparing ion-exchange materials is caused by the fact that phosphorylation of pendant chains of polymer macromolecules allows not only improvement of the properties of the starting polymers but also preparation of fibrous polymers capable of ion exchange and complex formation depending on the functional groups introduced.

Ion-exchange fibrous materials have developed surface and better kinetic characteristics than granular ion exchangers. Their exchange capacity is sufficiently high for practical applications and does not decrease in repeated cycles of regeneration with acids and bases. One of advantages of fibrous materials is the possibility of preparing from them articles of any shape: threads, porous plates, woven and nonwoven fabrics, which is especially valuable when the traditional process implementation is unacceptable [3].

Modified polycaproamide fibers with P–OH groups based on graft copolymers of polycaproamide and poly(glycidyl methacrylate) (PGMA) [4] were prepared by phosphorylation of grafted chains with 1-hydroxyethylidenediphosphonic acid (HEDP) [5]. As shown in [6], modification of glycidyl methacrylate (GMA) copolymers at the epoxy group with the aim to prepare a phosphorus-containing sorbent is a promising procedure.

The major factor governing the sorption capacity of fibrous cation exchangers is the presence of a sufficient amount of sterically accessible functional groups capable of ion exchange.

In this study we examined how the phosphorylation conditions affect the composition and sorption properties of fibrous materials based on PCA–PGMA graft copolymers. The degree of phosphorylation was estimated from the phosphorus content in the modified polymer. Because of possible hydrolysis of the ester group in the grafted PGMA, we performed an experiment on determining the static exchange capacity (SEC) of unmodified PCA–PGMA and obtained the value of 0.4 mg-equiv g^{-1}. The influence of the phosphorus content on the sorption properties of the fibers is illustrated by Table 1.

Table 1 shows that SEC depends on the content of phosphoric acid groups in PGMA, which, in turn, is determined by the structure of the modified PCA and phosphorylation conditions. It should be noted that the phosphorylation of fibers containing 43–50% PGMA under the chosen conditions yields a polymer containing 2.9% P, with SEC of 3.9 mg-equiv g^{-1}.

Table 1. Influence of the phosphorus content on the sorption properties of PCA–PGMA copolymer. Graft polymerization: τ = 60 min, T = 80°C, [GMA] = 2.35 M; phosphorylation: τ = 300 min, T = 90°C, [HEDP] = 4.04 M

Content in graft copolymer, wt %		SEC, mg-equiv g^{-1}
PGMA	P	
10	0.5	2.5
16	1,0	2.9
20	1,4	3.3
41	2.9	3.9
43	2.9	3.9
45	2.9	3.9
48	2.9	3.9
50	2.9	3.9

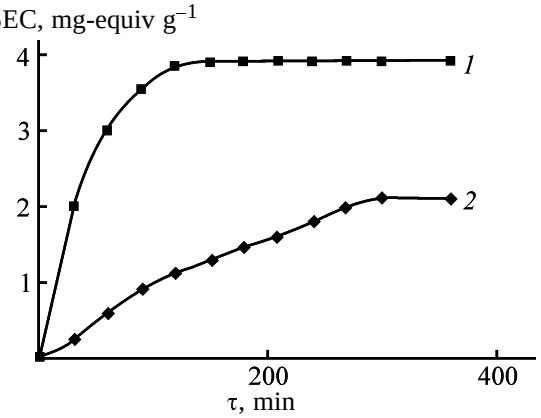
Table 2. Influence of HEDP concentration on the amount of P in the graft copolymer (c_P) and SEC; [PGMA] = 43%, τ = 300 min, bath ratio 30, T = 90°C



HEDP, M	c_P, %	SEC, mg-equiv g^{-1}
0.81	0.7	2.8
1.62	0.87	2.9
2.43	1.2	3.0
3.24	2.0	3.5
4.04	2.9	3.9
4.83	2.8	3.7

Table 3. Degree of recovery of metal ions. Sorption conditions: SEC = 3.9 mg-equiv g^{-1}, initial concentration of metal ions in solution 5 mg l^{-1}, bath ratio 100

Metal ion	Degree of recovery of metal ions, %, in indicated time τ, min					
	30	60	90	120	180	720
Cu^{2+}	25	36	68	80	80	80
Ni^{2+}	21	27	58	68	68	68
Ca^{2+}	19	23	44	56	56	56

An increase in the SEC may be caused by increasing content of P–OH groups capable of ion exchange and complexation. Our results show (Table 2) that it is appropriate to take HEDP as 4.04 M solution. This concentration is sufficient to obtain the maximal content of phosphorus in the copolymer, 2.9% (SEC = 3.9 mg-equiv g^{-1}). Although the phosphorylation is a heterogeneous process, it occurs at a high rate (1.6×10^{-4}–2.2×10^{-4} mol l^{-1} s^{-1}) [5].

The figure shows the kinetic curves of sorption with the ion-exchange material obtained, in comparison with GMF-1 granular sorbent. GMF-1 cation exchanger is prepared by phosphorylation of cross-linked GMA copolymers in the H^+ form [7]. The fibrous sorbent showed higher rate of Na^+ sorption. The equilibrium in the solution–fiber system was attained within 120 min, against 300 min required for GMF-1.

Kinetic curves of sorption of Na^+ cations from 0.1 M aqueous NaOH (20°C, bath ratio 30). (τ) Time. (*1*) Fibrous sorbent prepared in this study and (*2*) GMF-1 granular sorbent.

Data on recovery of the Cu^{2+}, Ni^{2+}, and Ca^{2+} ions from aqueous solutions with the phosphorylated fibrous sorbent are given in Table 3. The degree of recovery of metal ions in 120 min is as follows (%): Cu^{2+} 80, Ni^{2+} 68, and Ca^{2+} 56. The content of the metal ions in solutions before and after sorption was determined compexometrically (see Experimental).

It should be noted that the fibrous ion-exchange sorbent prepared by the above procedure has satisfactory physicomechanical properties (Table 4). A small decrease in the strength parameters is caused by the distortion of the fiber structure by the forming pendant chains, which is consistent with the results of a detailed study [8] of the effect exerted by a graft copolymer on the physicomechanical properties of the modified fiber.

Thus, the suggested sorbent shows promise for recovery of metal ions from aqueous solutions.

EXPERIMENTAL

Phosphorylation of the graft copolymer was performed as follows: The copolymer was treated with a 0.84–4.86 M solution of HEDP for 50–300 min at 70–90°C in a flask equipped with a reflux condenser. After the reaction completion, the resulting copolymer was thoroughly washed with distilled water and dried to constant weight.

The SEC of the cation exchanger was determined as follows [9]. A flask was charged with a 1-g fiber portion, 200 ml of 0.1 N NaOH was added, and the mixture was allowed to stand for 24 h with intermittent shaking. Then the ion exchanger was filtered off, and a 25-ml aliquot of the filtrate was taken and titrated with 0.1 N HCl in the presence of phenolphthalein.

In experiments on recovery of metal ions from aqueous solutions, 25 ml of 5% $CaCl_2$ was added with continuous stirring to a 1-g portion of the fiber, and the system was allowed to stand for 24 h. Then the sorbent was filtered off. To obtain a control solution, 5 ml of the filtrate was taken and diluted with distilled water to a volume of 100 ml. Then 10 ml of a test solution (pH 10) was transferred into a titration flask and titrated in the presence of Eriochrome Black T indicator. After the filtration, the residual amount

Table 4. Physicomechanical properties of fibers

of the metal in the aqueous solution was determined by complexometric titration of a solution aliquot with 0.1 N Na_2EDTA in the presence of Eriochrome Black T indicator until a violet color appeared.

CONCLUSION

A fibrous corbent with a static exchange capacity of 3.9 mg-equiv g^{-1} was prepared from graft copolymers by polymer-analogous transformations. The sorbent is active toward Cu^{2+}, Ni^{2+}, and Ca^{2+} ions; the degree of their recovery from dilute solutions reaches 56–80%.

SORPTION AND ION-EXCHANGE PROCESSES

Variation of the Technical Parameters of Steam-Activated Carbons Based on Peat and Polyurethane–Polyamide Fiber Waste

A. N. Khomutov, V. N. Klushin, and V. M. Mukhin

Mendeleev Russian University of Chemical Engineering, Moscow, Russia
Neorganika Research and Production Association, State Unitary Enterprise, Elektrostal, Moscow oblast, Russia

Received November 25, 2004; in final form, July 2005

Abstract—The wear resistance, porosity, and ion-exchange properties of steam-activated cokes in the form of cylindrical granules, obtained from Dorlastan polyurethane–polyamide fiber waste and cotton grass–sphagnum peat under conditions of purely kinetic control were studied at the combustion loss increased to 50%.

Of much practical importance are such technical parameters of activated carbons as wear resistance, micro-, meso-, and macropore volume, and the total porosity as estimated using various pycnometric liquids [1].

Mechanical resistance is one of the basic properties of carbon adsorbents, decisive in assessing their applicability in processes run in intensive hydrodynamic regimes. Activated carbons with wear resistance above 89%, as estimated by the MIS (sorbent testing procedure) 60-8 [1], are indispensable in hydrometallurgy of noble and rare metals, especially in sorption of platinum group metals from cyanide pulps (according to [2], 89% is the minimal wear resistance for carbon adsorbents to be suitable for application in gold recovery from pulps). High-strength carbon adsorbents with developed micropore structure are typically prepared worldwide using various expensive carbon-containing raw materials. In the former Soviet Union and in the Russian Federation, such activated carbons were based on furfural [3], 2CC coal and phosphoric acid [4], vinylpyridine ion exchangers [5], brown coal raw material [6], and shale phenols and resins [7].

The new technology of preparation of activated carbons with enhanced strength[1] implies the use of polymer wastes with low (virtually zero) coke residue and powdered carbon-containing plant raw materials for preparing molded cokes in a high (35–45%) yield with a mechanical compression strength of up to 400 kgf cm^{-2}, wear resistance of up to 99–99.5% (according to MIS 60-8), and open micropore volume of 0.2–0.25 $cm^3\ g^{-1}$ [8].

In this study we prepared molded carbons from a formulation made of Dorlastan polyurethane–polyamide fiber waste and cotton grass–sphagnum peat. The weight ratios of the components of the formulation and its heat treatment regimes were identical to those required for preparation of carbonizate (a solid carbonized residue from high-temperature heat treatment of the raw material formulation) with the maximal compression strength [8]. When nitrogen-containing polymers are introduced into the raw formulation prepared by the method from [8] in amounts ensuring the maximal strength of the carbonizates, the content of nitrogen in the pyrolysis products increases to 10–14%, and the anion-exchange power of the carbons is enhanced.

The anion-exchange centers in activated carbons arise from hydration of the heteroatoms of nitrogen and oxygen, incorporated in graphite-like networks of carbon matrices. As shown by previous studies of activated carbons, carried out in different times and by different methods, they comprise diverse oxygen- and nitrogen-containing surface functional groups. By contrast to conventional anion-exchange resins, these are electroconducting media with a low electrical resistivity ($\rho \approx 10^{-2}$–$10^{-4}\ \Omega$ cm) [9].

When the surface functional groups dissociate, the charge is delocalized over the entire activated carbon surface. Hence, ion exchange occurs not only at the

[1] Developed at the Chair of Biosphere Protection Technologies, Mendeleev Russian University of Chemical Engineering.

1070-4272/05/7811-1816 © 2005 Pleiades Publishing, Inc.

location sites of the heteroatoms but also over the entire surface, by replacement of the anions from the internal plate of the electrical double layer. According to the second law of thermodynamics, the equilibrium constant for such a process is a function of the difference between the stationary electrode potential and the zero-charge potential of activated carbon [9, 10]. In air, activated carbons immersed in water behave like reversible oxygen electrodes (the electrode potential of activated carbons linearly varies with pH) [9]. Therefore, calculations of the dissociation constants for the surface functional groups by the Henderson–Hasselbach equation, based on the results of direct potentiometric titration of activated carbons, do not make as much sense as those for ion exchangers [11]. The exact number of oxygen-containing functional groups in activated carbons is determined by the Boehm titration procedure [12], polarographically [13], and by cyclic voltammetry [14]. The number of strongly basic nitrogen-containing functional groups is estimated by direct potentiometric titration of the carbons [5].

Steam activation, along with development of the pore structure of carbons, typically decreases the mechanical strength of the end product [15]. Although carbons are activated under conditions of purely kinetic control (under hydrodynamic conditions such that the steam concentration gradient in the bulk of the carbon grain is insignificant, and the steam concentration at the centre of the carbon particle is no less than 90% of the steam concentration on the grain surface), an increase in the combustion loss (a relative loss of the carbon weight due to carbon burnup) during steam activation differently affect the strength of different brands of activated carbons. Activated carbons with a regular structure such as, e.g., FAS-3, AG-95, and coal adsorbents prepared with the use of binders based on shale resins virtually preserve their strength up to combustion losses $\alpha = 50-60\%$ [7, 15]. The volume of macropores and large transient pores (sites at which the failure of sorbents is the most probable) for this type of carbons under the conditions of purely kinetic control cannot substantially increase [16], and they begin to lose their strength during burnup of the micropore walls. Carbons prepared from pressed finely ground plant material wastes lose their strength at lower combustion losses [17, 18], since specific carbon layers are the first to burn up, being replaced by large pores. Published data [17, 18] suggest that, in contrast to carbonizates of FAS or AG carbons, the strongest peat cokes have irregular structure, and the main failure sites in their activated products are extended wedge-shaped or flat mesopores [19]. Nitrogen-containing carbons typically lose certain amount of nitrogen by activation, which affects their strength and ion-exchange power [5].

In standard industrial activation furnaces, the temperature varies within the range corresponding to purely kinetic control. This makes of practical importance monitoring of the technical parameters of carbons under increasing combustion loss throughout this region rather than at specific temperatures.

Therefore, we studied the changes in the total porosity, volumes of the sorbing pores, numbers of strongly basic surface functional groups, and the wear resistance of the molded carbon during steam activation of its carbonizate at different temperatures in the range of purely kinetic control, as estimated by MIS 60-8. The boundaries of the areas of heterogeneous reactions of steam with the carbon material prepared from Dorlastan fiber waste and cotton grass–sphagnum peat were determined earlier [20].

EXPERIMENTAL

Samples of carbonizates were prepared in the form of cylindrical granules with the cross-section diameter of 1 mm [8]. Steam activation was run at the specific consumption of 3 g of steam per gram of the end product at 800, 840, 880, and 900°C in a stainless steel vertical reactor, placed into a SUOL-4 tubular furnace. The combustion loss during activation was increased via increasing the time of keeping of the carbonizates in the reactor. Development of their pore structure was monitored by determining the total pore volumes with respect to water $V_{\Sigma H_2O}$ and carbon tetrachloride $V_{\Sigma CCl_4}$, as well as the total volume of the sorbing pores with respect to benzene V_{sorb} at $p/p_s = 1$ and the micropore volume V_{mi} at $p/p_s = 0.83$ by the standard procedures [1, 19]. The ion-exchange properties of the resulting activated carbons were studied by direct potentiometric titration by the method of many weighed portions [20]. The carbons were titrated in the neutral form, as their conversion into the OH^- form involves capture of significant amounts of the equilibrium solution of alkali with transport pores (comparable with the anion-exchange capacity of the sorbent). To this end, 1-g weighed portions of the freshly cooled carbon were poured over with 50 ml of an aqueous KCl solution (concentration 1 M, $2 < pH < 10$). The pH of the initial solutions was adjusted with HCl or KOH. The molar concentration of the supporting electrolyte during titration was 100 and over times that of the anion of the acid residue or the cation of the base used for adjusting pH. Hence, fluctuations of the concentration of the supporting

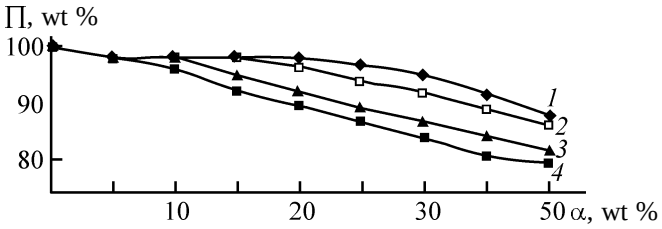

Fig. 1. Wear resistance ∏ estimated by MIS 60-8 as a function of the combustion loss α of the activated carbons obtained at different temperatures. Activation temperature, °C: (*1*) 800, (*2*) 840, (*3*) 880, and (*4*) 900.

electrolyte anions and cations were considered to exert no effect on the equilibrium capacity. The equilibrium was judged from invariance of pH of the solution within 3 days and over. The anion-exchange capacity was estimated from the change of the concentration of the hydrogen ions during establishment of the equilibrium, using the initial and equilibrium pH of the solutions. The data represented as $\Delta A/\Delta\text{pH} = f(\text{pH})$ were processed on a PC into $A = f(\text{pH})$ integrated dependences.

Figure 1 presents the plots of the wear resistance vs. the combustion loss at different temperatures; it shows that the combustion loss at different temperatures differently affects the strength of the activated samples.

It is seen from Fig. 1 that, at α = 10%, the strength of the activated carbons virtually does not tend to decrease and fluctuates around 98% irrespective of the activation temperature. At 800°C, a decrease in the strength with increasing combustion loss is at a minimum. At α = 20–30%, it decreases the stronger, the higher the temperature. At α = 40–50% and temperature of 880–900°C, the strength decreases more prominently but does not drop below 80%, which strongly exceeds the strength of ordinary activated carbons BAU, SKT, and AG. At the combustion loss of 50% and activation temperatures of 800–840°C, the strength does not drop below 90%.

Table 1 presents the pore volumes of the activated carbons with different combustion losses, obtained at different temperatures. It is seen that micropores are the basic type of the sorbing pores for the activated carbons under study. The measured volumes of the micropores and sorbing pores are identical, which suggests that mesopores are virtually lacking. The difference in the total pore volumes, estimated with water and CCl_4 at small combustion losses, suggests that the carbons contain thin pores, accessible to water molecules and inaccessible to CCl_4 molecules.

At the same time, this difference at small combustion losses exceeds V_{mi}, which suggests that the carbon samples with small combustion losses contain ultrathin micropores accessible to water molecules and inaccessible to benzene molecules. With increasing combustion loss, the situation changes: The total pore volumes as estimated with H_2O and CCl_4 are leveled, which, along with increase in V_{mi}, suggests an increase in the micropore size. At α = 40–50%, the parameters $V_{\Sigma H_2O}$ and $V_{\Sigma CCl_4}$ are virtually identical and exceed V_{mi}, which, in the absence of mesopores, suggests that the carbons contain macropores. In this connection, we can state that the pore structure of the carbonizate is also represented by micro- and macropores only. Increase in the volume of the macropores with increasing combustion loss is more prominent at higher activation temperatures (Table 1). These conditions do not favor development of large-volume micropores, in contrast to lower activation temperatures. Figure 1 shows that, at higher activation temperatures, the decrease in the strength of the carbons

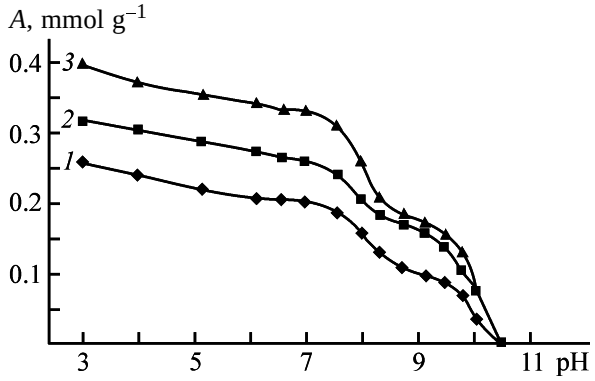

Fig. 2. Equilibrium anion-exchange capacity *A* of activated carbons obtained at 840°C as a function of pH. α, %: (*1*) 10, (*2*) 30, and (*3*) 50.

with increasing combustion loss is more prominent. This does not contradict the published data [6, 9, 21] and suggests that a decrease in the strength of the carbons during activation is mostly due to formation of macropores. It should be noted that steam activation makes it possible to increase the micropore volume of the material under study to 0.4–0.5 $cm^3 g^{-1}$, with the wear resistance of the sample of over 95% being preserved. Such parameters are exhibited by the best domestic carbons AG-95 and FAS-3 utilized in gold mining.

Samples of activated carbons with combustion losses of 10, 30 and 50%, obtained at 840°C, were decalcified by the procedure from [22], washed with distilled water to negative reaction for the chloride ions, and, after calcination under nitrogen at 850°C, subjected to direct potentiometric titration (Fig. 2). Figure 2 shows that the titrated samples of the activated carbons have two types of strongly basic ion-exchanging groups, dissociating at pH 8.5–10 and 7–8.2. The manifestation of the ion-exchanging groups dissociating at pH 8–10 and 6–8 can be due to the pyridine nitrogen and phenolic hydroxy group, occurring in the carbons [22]. Table 2 presents the total number of the ion-exchange centers, dissociating at pH 8.5–10 and 7–8.5, calculated by integration of the titration curves. It is seen that, under increasing combustion loss, the ion-exchange properties of the carbon vary differently from those of the carbons studied in [23]. The reason is that, when the combustion loss decreases to 30%, the number of the ion-exchange centers dissociating at pH 8.2–10 (these centers are due to the presence of nitrogen in the carbon) increases rather than decreases, while the number of those dissociating at pH 7–8.2 (due to the presence of the phenolic hydroxyls in the carbon) remains constant. Further activation to combustion losses of 50% increases the number of the ion-exchanging centers with p*K* 7–8.2 by 0.06 mmol g^{-1}, while the number of strongly basic groups increases by 0.01 mmol g^{-1} only.

Table 2. Total amount *A* of ion-exchanging groups dissociating at pH 7–8.2 and 8.2–10

α, %	*A*, mmol g^{-1}, at indicated pH	
	8.2–10	7–8.2
10	0.12	0.08
30	0.18	0.08
50	0.19	0.14

We checked the adsorption power of the activated carbon sample with α = 40%, obtained at 840°C, with gold cyanide complexes (Central Scientific Research Institute for Geological Exploration). The equilibrium adsorption capacity with respect to the gold ions at the gold residual concentration in solution of 1 mg l^{-1} and pH 10.5 was 22 mg g^{-1}; the wear resistance of this sample, estimated by MIS 60-8, was 98%, while the analogous parameters of the AG-95 commercial sample were 19 mg g^{-1} and 95%, respectively. Thus, the parameters of the activated carbon that we prepared make it suitable for gold mining applications and surpass the corresponding parameters of the commercial sample of activated carbon AG-95.

CONCLUSIONS

(1) Steam activation of carbon material based on polyurethane–polyamide fiber waste and peat yields activated carbons suitable for gold mining applications (wear resistance, as estimated by MIS 60-8, is over 89%, and equilibrium capacity with respect to the gold ions, over 8 mg g^{-1} in adsorption of aurocyanide until the residual concentration of 1 mg l^{-1}).

(2) The wear resistance, estimated by MIS 60-8, and microporosity of the resulting activated carbons correspond to those of the best domestic commercial samples of activated carbons AG-95 and FAS-3, intended for gold mining applications.

(3) Decrease in the wear resistance of the activated carbons based on polyurethane–polyamide fiber waste and peat with increasing combustion loss is associated with increase in the macropore volume.

(4) The anion-exchange centers of activated carbons based on polyurethane–polyamide fiber waste and peat are represented by two types of functional groups dissociating at pH 7–8.2 and 8.2–10.

(5) The number of the ion-exchanging groups of activated carbons based on polyurethane–polyamide fiber waste and peat varies with increasing combustion losses differently from that of activated carbons based on vinylpyridine resins and other nitrogen-containing polymers.

Abstract—γ-Al_2O_3 and amorphous and structured aluminosilicates were modified with iron acetylacetonate $Fe(acac)_3$ in a liquid medium.

One of the most efficient procedures of preparing supported catalysts is atomic layer deposition [1], which allows formation of superfine and uniformly distributed oxide phase [2, 3]. This procedure is based on chemisorption of metal acetylacetonate on the support surface and subsequent thermal decomposition of the complex in an oxygen-containing medium. This process occurs either through formation of hydrogen bonds between acetylacetonate ligand and surface hydroxyls or through substitution of this hydroxyl, which results in formation of a covalent bond between the metal atom and oxygen atom of the support surface [2–4]. Heterogeneity in the distribution of active centers on the support surface can significantly affect the mechanism of chemisorption of the acetylacetonate complex and thus affect the dispersity of the catalytically active phase. For aluminosilicates, the pattern is sophisticated since on their surface there are acidic, neutral, and basic hydroxy groups and also coordination-unsaturated centers formed by Al^{3+} cations [4–6]. Although atomic layer deposition shows much promise for preparing Fe-containing catalysts, which are of particular interest for catalysis [7–10], the possibility of its use for this purpose was not adequately studied.

Therefore, in this study we examined in detail the role of the nature of active centers in chemisorption of iron acetylacetonate on the surface of a series of supports.

EXPERIMENTAL

As supports we used amorphous aluminosilicates with the atomic ratio Si^{4+}/Al^{3+} 6.0 and 7.6, synthesized by coprecipitation or by the sol–gel method similar to that described in [11]. In the first case, 10.75 g of $AlCl_3 \cdot 6H_2O$ and 60 g of $Na_2SiO_3 \cdot 9H_2O$ were dissolved in 400 cm^3 of H_2O, 35 cm^3 of glacial acetic acid was added, and then 25% NH_4OH in the amount required for keeping pH 7.1 was added dropwise with vigorous stirring. The resulting gel was stirred for 1 h, filtered, washed 5 times with hot (363 K) 0.25 M CH_3COONH_4, and dried at 343 K for 24 h. Thus prepared precursor of amorphous aluminosilicate was calcined in an air flow at 923 K for 7 h. The resulting material was denoted as AAS. Partially dealuminated amorphous aluminosilicate, denoted as AAS(D), was prepared by treatment of AAS with 0.5 M $H_2C_2O_4$ for 12 h at 295 K with subsequent washing with deionized water. To remove possible impurities of amorphous SiO_2, air-dry precursor of AAS was treated with 0.5 M Na_2CO_3 for 20 min at 378 K and then the ammonium form of the resulting sample was calcined for 5 h at 923 K. This sample was denoted as AAS(S).

In sol–gel synthesis of structured aluminosilicstes (SASs), we used tetraethyl orthosilicate $Si(OC_2H_5)_4$ and $Al(NO_3)_3 \cdot 9H_2O$ as sources of silicon and aluminum, respectively. Polyethylene glycol (PEG) with a molecular weight of 4400 served as a reagent forming porous structure of SAS, and HNO_3, as a catalyst of hydrolysis and polycondensation of $Si(OC_2H_5)_4$ [11]. To prepare SAS, $Si(OC_2H_5)_4$ was gradually added with vigorous stirring to a solution containing HNO_3, PEG, and $Al(NO_3)_3$. The molar composition of the mixture was $Si(OC_2H_5)_4 : Al(NO_3)_3 \cdot 9H_2O : PEG : HNO_3 : H_2O = 1 : 0.132 : 0.01 : 0.41 : 14.27$. This

Table 1. Atomic ratio Si^{4+}/Al^{3+}, specific surface area, and pore size of the synthesized materials

Sample	Si^{4+}/Al^{3+}	S_{BET}, $m^2\ g^{-1}$	D_{por}, nm
AAS	6.0	411	3.6–4.2
AAS(D)	6.3	420	3.6–4.6
AAS(S)	5.6	425	3.4–4.8
SAS	7.6	429	2.6

mixture was kept in a hermetically sealed autoclave for 20 h at 323 K without stirring. Then, the resulting gel was dried at the same temperature for 170 h, after which PEG was removed by calcination at 873 K for 3 h and a heating rate of 5 K min^{-1}. The NH_4^+ form of SAS was prepared by its threefold treatment with 1.0 M NH_4Cl solution (the ratio solid : liquid = 1 : 20, contact time 12 h) at 298 K, followed by washing with deoinized water to negative reaction for Cl^- ions and drying at 383 K for 18 h. The H^+ form of this aluminosilicate was obtained by calcination of the NH_4^+ form in a thin layer at 773 K for 5 h at a heating rate of 5 K min^{-1}. These materials are denoted as NH_4^+–SAS and H^+–SAS, respectively.

Before modification of the supports with iron acetylacetonate $Fe(acac)_3$, they were heated in a vacuum (1.2 kPa) at 423 K for 2 h. The reaction vessel was cooled to 298 K and filled with dry argon; a solution of $Fe(acac)_3$ in toluene was added, and the resulting mixture was kept with stirring for 3 h. The solid phase was separated by centrifugation and in some cases washed with the fresh solvent and dried in a vacuum at 373 K. The samples were treated with acetylacetone in a similar way. The concentration of the adsorbed complex was determined photometrically using calibration plots (Specord UV-VIS M 40 spectrometer, Carl Zeiss, Jena).

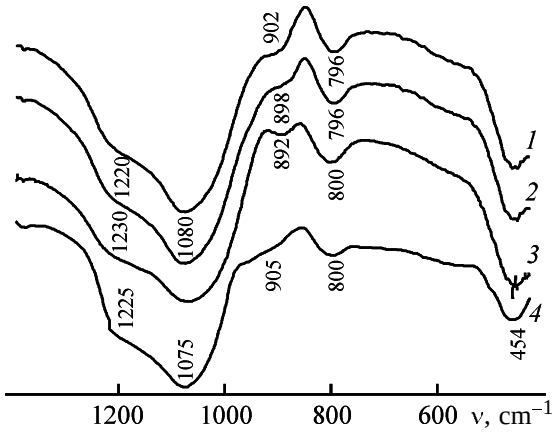

Fig. 1. IR spectra of synthesized aluminosilicates. (ν) Wave number. (*1*) AAS, (*2*) AAS(D), (*3*) AAS(S), and (*4*) SAS.

The isotherms of nitrogen adsorption–desorption (77 K) on the samples preliminarily evacuated at 473 K for 5 h were obtained with a Micromeritics ASAP 2010 adsorption installation. The pore size distribution was determined from the desorption isotherm by the Barrett–Joyner–Halenda (BJH) method [12].

The IR spectra were recorded on a Nicolet Avatar 360 FT-IR spectrophotometer; samples were pelletized with thoroughly dried KBr (1 : 60 ratio).

High-resolution NMR spectra with magic-angle spinning (MAS) and two-dimensional multi-quantum NMR spectra with magic-angle spinning (MQMAS) for ^{27}Al nuclei were recorded on a Bruker Avance 500 spectrometer at 130 MHz and magic-angle spinning rate of 28 kHz. To suppress artefacts of the baseline in unidimensional NMR spectra, we used a two-pulse spin-echo sequence. The pulse frequency was 50 kHz; pulse lengths, 2 and 4 μs; and spin echo delay, 10 μs. The spectrum acquisition number was from 256 to 1024. ^{27}Al chemical shifts were determined relative to saturated $Al(NO_3)_3$ solution. In processing of the MQMAS spectra we used the shearing procedure to obtain the isotropic chemical shift in the second dimension of the two-dimensional spectrum. The NMR spectra were processed using the Xwin-NMR software (Bruker).

The exchange capacity of the synthesized materials was determined at pH 7.0 using their Na^+ forms by the procedure described in [13]. The contact time of the samples with the complex $Cu(EDA)_2^{2+}$ was 30 min, after which they were recovered from the solution by centrifugation. The residual concentration of the complex in the liquid phase was determined by iodometric titration. Then, the exchange capacity was determined by subtracting the residual concentration from the concentration of the complex in the initial solution.

Chemical analysis shows that treatment of amorphous aluminosilicate (AAS) with $H_2C_2O_4$ or Na_2CO_3 solution results in partial removal of Al^{3+} and Si^{4+} ions, respectively (Table 1). However, in so doing, the parameters of the pore structure of this material (Table 1), which, similar to structured aluminosilicate (SAS), is predominantly mesoporous, change insignificantly. This follows from the shapes of isotherms of N_2 adsorption (type IV according to the IUPAC classification [14]) and from the pore size distribution found from these isotherms (Table 1). The IR spectrum of AAS (Fig. 1) contains absorption bands at 1215, 1070, 890, 800, and 454 cm^{-1} corresponding to

vibrations of the =Si–O–Si≡, ≡Si–O–, ≡Si–O–Al=, ≡Si–OH, and ≡Si–O– bonds typical for aluminosilicates [15]. Treatment of this material with $H_2C_2O_4$ solution decreases the intensity of absorption bands corresponding to vibrations of the structural fragments ≡Si–O–Al= (890 cm^{-1}), which suggests their partial decomposition. Comparison of the IR spectra of the initial AAS and the sample treated with Na_2CO_3 solution (Fig. 1) shows that in the latter case the intensities of the shoulder at 1210–1230 cm^{-1} and absorption band at 800 cm^{-1} significantly decrease. This suggests the presence of free SiO_2 in the sample, which can be removed to a large extent by treatment of AAS with a soda solution. However, it is not improbable that in parallel some amount of structure-forming Si^{4+} ions is leached out, which can result in formation of additional active centers formed by coordination-unsaturated aluminum.

The IR spectrum of structured aluminosilicate (SAS) AAS (Fig. 1) also contains absorption bands typical for aluminosilicates [15]. However, contrary to AAS, in this case the absorption band of the structural fragments ≡Si–O–Al= at 890 cm^{-1} is weaker. This may be due to the fact that only a part of oxygen atoms coordinated to aluminum [11] form a chemical bond with Si^{4+}.

The ^{27}Al NMR spectrum of γ-Al_2O_3 contains the signals of Al^{3+} ions with tetrahedral and octahedral coordination [16, 17] with chemical shifts of 70.0 and 5.0 ppm, respectively (Fig. 2). For AAS, along with these signals, there is a signal at approximately 30 ppm, which can be assigned to five-coordinate aluminum [18]. This assumption was checked by two-dimensional multi-quantum (MQMAS) NMR allowing exclusion of erroneous signals arising, e.g., from

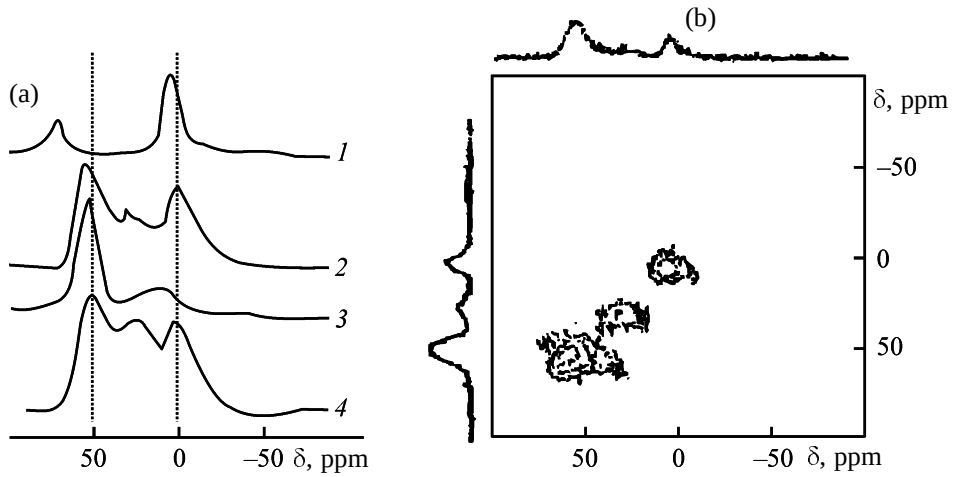

Fig. 2. ^{27}Al NMR spectra of the materials studied. (δ) Chemical shift. (a) (*1*) γ-Al_2O_3, (*2*) AAS, (*3*) SAS, and (*4*) AAS(S) (MAS); (b) AAS (MQMAS).

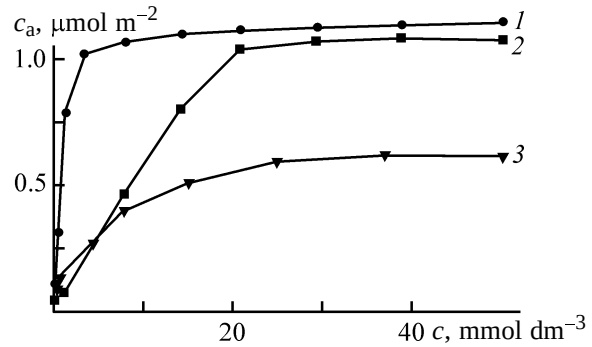

Fig. 3. Isotherms of $Fe(acac)_3$ adsorption on the surface of the supports studied. (c_a) Amount of adsorbed $Fe(acac)_3$ and (c) concentration of $Fe(acac)_3$ in solution. (*1*) γ-Al_2O_3, (*2*) AAS, and (*3*) SAS.

superposition of satellite signals [19]. In the MQMAS spectrum of the AAS sample (Fig. 2) there is a pronounced signal with a chemical shift of approximately 31 ppm, which is absent in the spectra of SAS or γ-Al_2O_3 [15]. Hence, the signal, indeed, reflects the presence of a fraction of Al^{3+} ions with coordination number 5 in this material. In the ^{27}Al NMR spectrum of AAS the signal of aluminum with coordination number 4 is downfield shifted in comparison with γ-Al_2O_3 (Fig. 2). This may be due to the influence of Si^{4+} ions forming fragments ≡Si–OH–Al=, whose presence in the structure of AAS was shown by IR spectroscopy. It is likely that treatment of this material with a Na_2CO_3 solution results in decomposition of a part of these fragments, as suggested by certain change in the ratio of intensities of signals in the ^{27}Al NMR spectrum.

As seen from Fig. 3, the amount of iron acetylacetonate complex adsorbed on the support surface depends on its concentration in solution, due to equilibrium character of protonation of acid-sensitive $Fe(acac)_3$ [3, 20]:

$$Fe(acac)_3 + 3H^+ \rightleftarrows [Fe(acacH)_3]^{3+}. \quad (1)$$

Formation of protonated complex of the $[Fe(acacH)_3]^{x+}$ type (x = 1–3) is favorable for its adsorption [21]; in this case, the degree of fixation depends on the strength and amount of surface acidic groups. Washing of modified γ-Al_2O_3 with toluene removed the most part of sorbed $Fe(acac)_3$ from the support surface (Table 2). This can be explained as follows. As known, $Fe(acac)_3$ is fixed on the γ-Al_2O_3 due to its reaction with coordination-unsaturated centers formed by aluminum cations (c.u.c. Al^{3+}) and also acidic hydroxy groups [3, 21]. As OH groups of γ-Al_2O_3 are weakly acidic and hence show low protonation power, their contribution to this process is hardly significant. Aluminum ions in c.u.c. participating in adsorption of $Fe(acac)_3$ on the surface of this support are in various coordination states: tetrahedral Al^{3+}(tetr) and octahedral Al^{3+}(oct) [3]:

$$Fe(acac)_3 + \text{c.u.c. } Al^{3+} \rightarrow Al(acac)_3 + [Al(acac)_x]_s^{(3-x)+} + Fe_s^{3+} + [Fe(acac)_{3-x}]^{x+}. \quad (2)$$

High extent of coordination unsaturation of Al^{3+}(tetr) [5] is favorable for formation of the delocalized complex $Al(acac)_3$ readily removable from the surface. Its transition to the liquid phase results in appearance of a vacancy, which then participates in chemisorption of Fe^{3+} ions formed as a result of elimination of acetylacetonate ligands. The reaction of $Fe(acac)_3$ with less coordination-unsaturated Al^{3+}(oct) [5] yields localized surface compounds $[Al(acac)_x]_s^{(3-x)+}$, which can block adsorption centers and thus hinder fixation of $[Fe(acac)_{3-x}]^{x+}$ and Fe^{3+} ions [3]. Hence, chemisorption of $Fe(acac)_3$ on the surface of γ-Al_2O_3 predominantly involves c.u.c. Al^{3+}(tetr), whereas c.u.c. Al^{3+}(oct) and weakly acidic hydroxy groups participate in physical adsorption of the complex. However, this interpretation does not consider the role of proton-donor structural fragments ≡Si–O–Al= (Brønsted centers) and silanol groups on the surface of aluminosilicates [5, 6], participating in protonation of the complex. The contribution of proton–donor groups to chemisorption of $Fe(acac)_3$ can be estimated by excluding the influence of other active centers. This can be realized by pretreating the samples with acetylacetone, whose reaction with c.u.c. Al^{3+} results in their selective blocking [3, 4]. Table 2 shows that washing of AAS modified by this procedure with toluene results in removal of only insignificant part of the adsorbed complex. This suggests that its reaction with proton of the structural fragments ≡Si–O–Al= yields tightly fixed chemisorbed surface compounds. It should be noted that the amount of Brønsted centers participating in this process (0.22 mmol g^{-1}) practically coincides with the exchange capacity of AAS (0.26 mmol g^{-1}). C.u.c. Al^{3+} make the same contribution to adsorption of $Fe(acac)_3$, which follows from comparison of the amounts of the chemisorbed complex on the initial AAS and on the sample treated with acetylacetone (Table 2). The significant role of these centers may be due to the fact that, along with c.u.c. Al^{3+}(tetr), AAS contains Al^{3+} with coordination number 5 (Fig. 2, ^{27}Al NMR spectrum). These cations can also form delocalized

$Al(acac)_3$ and thus assist to fixation of $Fe(acac)_3$ in its adsorption.

Insignificant amount of $Fe(acac)_3$ physically sorbed on AAS suggests insignificant contribution of c.u.c. Al^{3+}(oct) and silanol groups to this process. Nevertheless, these groups can promote elimination of acetylacetonate ligands in adsorption of the complex on other centers due to its partial protonation. The amount of the complex adsorbed on dealuminated sample, AAS(D), is somewhat higher than that on the initial amorphous aluminosilicate (Table 2). It is most likely that this is caused by formation of structural defects; however, in this case, the strength of bonding of adsorbed complex with the surface is small. In addition, the role of Brønsted centers and c.u.c. Al^{3+}(tetr, pent) is considerably smaller than that for AAS (Table 2). Hence, decomposition of the structural fragments ≡Si–O–Al= in dealumination of AAS results in formation of considerable amount of silanol groups weakly reactive with respect to $Fe(acac)_3$.

Table 2 shows that treatment of AAS with a Na_2CO_3 solution results in increasing contribution of c.u.c. Al^{3+}(tetr, pent) and acidic ≡Si–OH groups to adsorption of $Fe(acac)_3$ (approximately 0.29 and 0.11 mmol g^{-1}, respectively); in the process, the role of Brønsted centers significantly decreases. This is caused by formation of a large amount of coordination vacancies on aluminum ions and formation of silanol groups due to decomposition of ≡Si–O–Al= and ≡Si–O–Si≡ fragments, respectively. Thus, in treatment of amorphous aluminosilicate with Na_2CO_3 solution the Brønsted centers transform into c.u.c. Al^{3+}(tetr, pent), which is also suggested by variation of the relative intensities of the signals in the ^{27}Al NMR spectrum (Fig. 2).

The amount of the complex adsorbed on structured aluminosilicate (SA) is significantly smaller than that in the case of AAS (Fig. 3, Table 2). This is most probably due to the absence of aluminum with coordination number 5 in this material (Fig. 2). In the ^{27}Al NMR spectrum of SAS, the signal of octahedral aluminum is significantly upfield shifted (13 ppm), which suggests the presence of significant amount of c.u.c. Al^{3+}(oct). This is also suggested by their significant contribution to adsorption of $Fe(acac)_3$ (0.12 mmol g^{-1}, ±50%). It should be noted that at relatively high content of aluminum with coordination number 4 in SAS (Fig. 2, ^{27}Al NMR spectrum) Brønsted centers and c.u.c. Al^{3+} present in this material play an insignificant role in chemisorption of $Fe(acac)_3$ on its surface. This can be explained as follows. As shown previously [11, 12], during formation of SAS the reaction gel contains aluminum ions exclusively in the octahedral coordination state. In removal of the structure-forming agent, these ions are incorporated into the silicate matrix, with their coordination becoming tetrahedral. These Al^{3+}(tetr) ions are surrounded predominantly by oxygen atoms that do not form covalent bonds with silicon atoms. Therefore, Brønsted centers have weak acidity, and $Fe(acac)_3$ molecules sorbed on these centers are readily removed from the surface by washing with toluene. This explanation is confirmed by the significantly lower, compared to H^+-SAS, total sorption capacity of the NH_4^+-SAS sample, which does not contain proton-donor centers (Table 2).

CONCLUSION

Our results suggest that the nature of the active surface centers critically affects the chemisorption of iron acetylacetonate on the surface of aluminum oxide and amorphous aluminosilicates. In the case of amorphous aluminosilicates, the centers with high extent of coordination unsaturation, formed by Al^{3+} ions with coordination number 4 and 5, and also acidic bridging hydroxyls of ≡Si–OH–Al≡ are the dominating centers of $Fe(acac)_3$ chemisorption. Adsorption of this complex on weakly acidic hydroxyls and c.u.c. formed by Al^{3+} ions with octahedral coordination does not result in its fixation on the surface of Al-containing materials.

SORPTION AND ION-EXCHANGE PROCESSES

Selective Sorption of Fe(III) Ions from Ni(II)–Fe(III) Mixtures with Chemisorbents

Institute of General and Inorganic Chemistry, Belarussian National Academy of Sciences, Minsk, Belarus

Received June 15, 2005

Abstract—Selective recovery of Fe(III) ions from two-component nitrate solutions of Fe(III) and Ni(II) with synthetic nickel phosphate, natural chalk, and natural tripoli were studied. The mechanism of selective action of chemisorbents was considered, and high efficiency of the materials considered was demonstrated.

Ion exchange and chemisorption are traditionally used to sorb metal ions. In the latter case, sorbents chemically bind metal ions. Unlike ion exchange, chemisorption is characterized by substantial selectivity.

The capability of inorganic substances for selective chemisorption is caused by formation of new chemical compounds with lower Gibbs energy as compared to the initial state (e.g., less soluble compound), possibility of redox reactions, and other effects [1].

Poorly soluble sulfides, hydroxides, carbonates, and phosphates of some rare-earth and other bivalent metals exhibit chemisorption power with respect to heavy and nonferrous metals. The compounds formed in the process are less soluble than the initial compounds [1–3]. The chemisorption power depends on a number of factors; the major factor is the difference between the solubility products of the initial sorbent and compound formed, ΔSP.

A sorbent suitable for chemisorption of definite ions from mixtures can be found by considering the solubility series of phosphates, carbonates, and hydroxides of double and triple-charged metals.

Chemisorption can be a promising procedure for selective recovery of some nonferrous metal ions from two- and multicomponent solutions.

After deposition of nonferrous metal hydroxides from electroplating waste, filtrates (aqueous solutions containing from 2 to 25 g l^{-1} of alkali, alkaline-earth, and nonferrous metal salts) are formed; with the nonferrous metal fraction being 5–6% of the total metal content [4]. The composition of filtrates depends on the waste processing technology. Such solutions may contain ions of 2–10 nonferrous metals in amounts from 20–30 to 600–800 mg l^{-1}.

Dilute solutions containing nonferrous metals are concentrated using nonselective and selective ion-exchange materials. In the first case, all above metals and in the second case, only nonferrous metals are sorbed [4]. In contrast to selective ion-exchange materials, selective chemisorbents can be used not only for group concentration of nonferrous metals, but also for their separation.

In this study, we used synthetic nickel(II) orthophosphate and natural carbonates for selective sorption of iron(III) from binary solutions containing Fe(III) and Ni(II). Two-component dilute Fe^{3+}–Ni^{2+} aqueous solutions are formed during processing waste from nickel–iron battery electrodes [5] and from electrolytic baths for iron nickel-plating.

EXPERIMENTAL

Amorphous $Ni_3(PO_4)_2 \cdot 8H_2O$ was synthesized as in [6]. A hydrochloric (pH 5) solution of $(NH_4)_2HPO_4$ (5 g) in 100 ml of water was added dropwise to a solution of $NiCi_2 \cdot 6H_2O$ (100 g) in 100 ml of water with stirring at room temperature. The light green precipitate obtained was stored under the mother liquor for 2 h, filtered through a Büchner funnel, washed several times with distilled water, and dried in air and then over P_2O_5.

Tripoli with 30–65 wt % $CaCO_3$ content and chalk[1] were taken as natural sorbents. Chalk and tripoli were ground, and the fraction < 0.025 mm was sifted out before use.

The iron(III) sorption from two-component solutions [iron(III) and nickel(II) nitrates] was studied

[1] Tripoli from Stal'noe deposit (Mogilev oblast) and chalk from Volkovskoe deposit.

1070-4272/05/7811-1827 © 2005 Pleiades Publishing, Inc.

under static conditions at room temperature. The starting solutions were prepared from chemically pure and analytically pure grade crystal hydrates of iron(III) and Ni(II) nitrates. For comparison, sorption of iron(III) from one-component solutions of iron(III) nitrate was also studied. The experiment was performed at the constant bath rario (s : l = 1 : 250). The sorbent sample (0.1 g) was added to 25 ml of the solution studied and stored for a day with intermittent stirring. Then, the solid phase was filtered off, and the iron(III) and nickel(II) contents in the liquid were determined by atomic-absorption spectroscopy on an AAS-220 spectrometer. The concentrations of the initial solutions were varied within the 5–500 mg l^{-1} range.

The solubility product of $Ni_3(PO_4)_2$ was estimated by us at 1×10^{-7}, and that of $FePO_4$ is 10^{-23} in accordance with the reference data [7]. The difference between these SP values is substantial. Therefore, the contact of solid $Ni_3(PO_4)_2$ with a $Fe(NO_3)_3$ solution should lead to the substitution with formation of the less soluble compound

$$Ni_3(PO_4)_2 \cdot 8H_2O\downarrow + 2Fe^{3+} \rightleftarrows 2(FePO_4 \cdot yH_2O)\downarrow + 3Ni^{2+}. \quad (1)$$

As a result, nickel(II) ions pass into the solution, whereas the solid phase transforms into iron(III) phosphate, and hence nickel(II) phosphate can be used for selective sorption of Fe^{3+} ions from Fe^{3+}–Ni^{2+} mixtures.

The capacity of nickel phosphate for iron(III) ions in accordance with Eq. (1), corresponding to complete transformation of nickel phosphate into iron(III) phosphate, amounts to 11.8 mg-equiv g^{-1} (220 mg g^{-1}).

In addition to nickel phosphate, $CaCO_3$ can also be used as selective sorbent of Fe(III) ions from Fe^{3+}–Ni^{2+} mixtures. SPs of $CaCO_3$, $Ni_3(PO_4)_2$, and $FePO_4$ are 4.8×10^{-9}, 6.6×10^{-9}, and 3.47×10^{-11}, respectively. Thus, $CaCO_3$ should selectively sorb iron(III) ions from Fe^{3+}–Ni^{2+} mixtures.

Since iron(III) and aluminum(III) carbonates are instable hydrolytically and undergo hydrolytic decomposition to hydroxides [8], chemisorption of iron(III) ions can be described by scheme (2):

$$3CaCO_3\downarrow + Fe^{3+} \rightarrow FeCO_3\downarrow + 3Ca^{2+} \rightarrow 2Fe(OH)_3\downarrow + 3Ca^{2+} + CO_2. \quad (2)$$

The experimental data obtained are well consistent with the above theoretical consideration and confirm the possibility of using nickel phosphate and calcium carbonate for selective recovery of iron(III) ions from Fe^{3+}–Ni^{2+} mixtures.

The concentrations of metal ions in one-component (Fe^{3+}) and two-component (Fe^{3+}–Ni^{2+}) solutions before and after sorption, pH of the initial and equilibrium solutions, calculated amounts of adsorbed and released into the solution ions (mg-equiv g^{-1}), and the degree of Fe(III) recovery from solutions with various concentrations (%) are listed in the table. The amount of ions adsorbed was calculated by the formula

$$S_{M^{n+}} = \frac{(c_0 - c_s)V}{1000mE_{M^{n+}}},$$

where $S_{M^{n+}}$ is the amount of the metal ion sorbed per gram of the sorbent (mg-equiv g^{-1}); c_0 and c_s, concentrations of the solution before and after sorption (mg l^{-1}); V, solution volume (ml); m, sorbent weight (g); and $E_{M^{n+}}$, equivalent weight of metal ion (mg) equal to 18.67 and 29.35 mg for iron(III) and nickel(II), respectively.

When calculating the amount of nickel(II) transferred into the solution, instead of the difference between the solution concentrations before and after sorption ($c_0 - c_s$) we used the opposite quantity.

Figures 1–3 show the dependences of the Fe(III) sorption capacities for (a) one-component and (b) two-component solutions as functions of Fe(III) concentration for three sorbents: nickel phosphate (Figs. 1a, 1b), natural chalk (Figs. 2a, 2b), and carbonate tripoli (Figs. 3a, 3b).

Nickel phosphate completely recovers iron(III) from solutions with the initial iron concentration of up to 490 mg l^{-1} (one-component solution) and up to 242 mg l^{-1} (two-component solution). The amount of iron(III) sorbed (S_{Fe}) is a virtually linear function of its concentration in the initial solution ($c_0^{Fe^{3+}}$) both for one-component and two-component solutions. The sorption capacities of nickel phosphate for iron(III), S_{Fe}, in one-component and two-component solutions with equal $c_0^{Fe^{3+}}$ are very close. This means that Ni(II) does not interfere with the Fe(III) adsorption from the solution.

As seen from the table, the Ni(II) concentration in the solution after the contact with nickel phosphate increases. This confirms iron sorption in accordance with Eq. (1).

However, the amount of Fe(III) ions sorbed

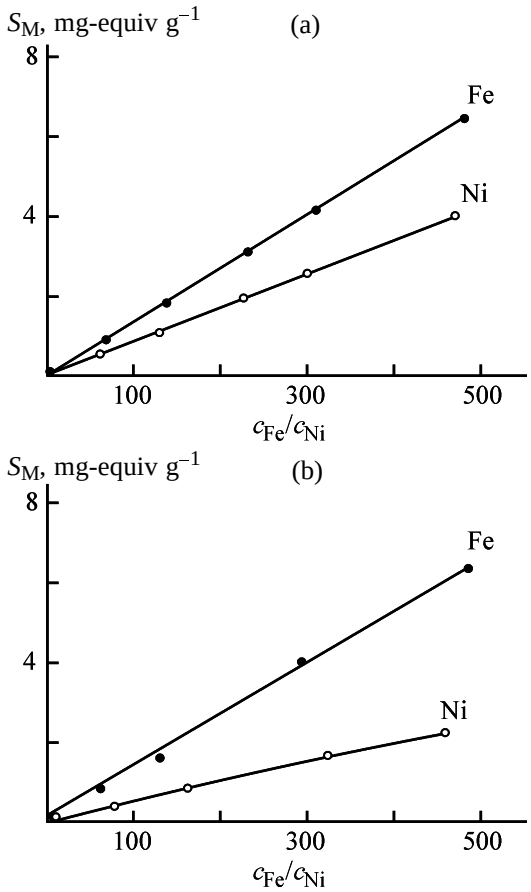

Fig. 1. Sorption of Fe^{3+} ions and release of Ni^{2+} ions S_M in the systems (a) [$Ni_3(PO_4)_2 \cdot 8H_2O_s$ (sorbent)–$Fe(NO_3)_3$ solution] and (b) [$Ni_3(PO_4)_2 \cdot 8H_2O_s$ (sorbent)–$Fe(NO_3)_3$ + $Ni(NO_3)_2$ solution] as a function of c_{Fe}/c_{Ni} ratio, where c_{Fe} and c_{Ni} are concentrations of Fe^{3+} and Ni^{2+} ions in the initial solution (mg l^{-1}), respectively.

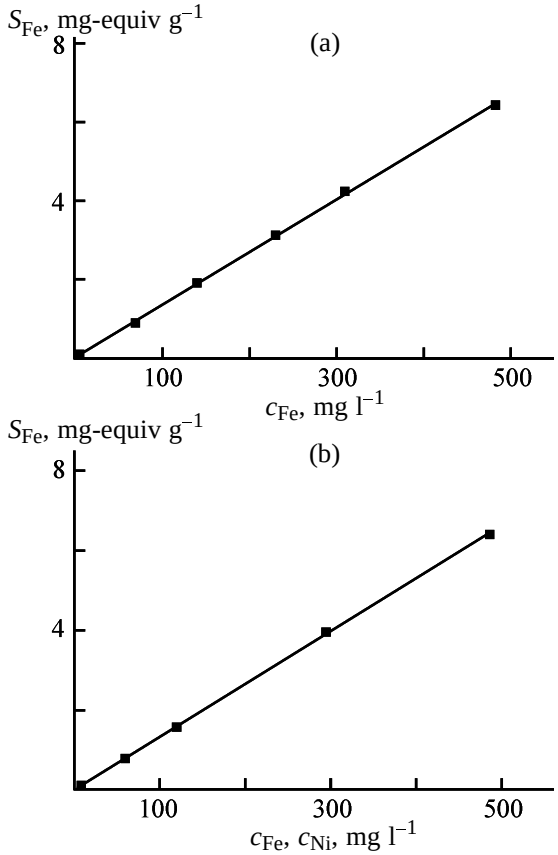

Fig. 2. Sorption of Fe^{3+} ions S_{Fe} with natural chalk as a function of iron(III) ion concentration c_{Fe} in (a) one-component and (b) two-component solutions of $M(NO_3)_n$ (M = Fe, Ni).

(mg-equiv) exceeds the amount of Ni(II) ions transferred into the solution (see table). Correspondingly, the line for nickel transferred into the solution lies lower than the line of iron sorption. Nonequivalent ratio of the sorbed and released ions suggests the occurrence of an additional process not described by Eq. (1).

Phosphates of double-charged metal ions, including Ni^{2+}, form alkaline solutions on contact with water, e.g., pH of aqueous extract of $Ni_3(PO_4)_2 \cdot 8H_2O$ is 7.79. Hence, pH of equilibrium solutions increases after their contact with the sorbent (see table). For instance, the pH values of the initial two-component solutions with iron(III) concentrations from 10 to 490 mg l^{-1} before sorption are 2.45–3.28, and after sorption they become 5.57–6.91. It should be noted that chemisorption and heterogeneous precipitation occur in the near-surface layer of the sorbent, where the ionic concentration and, correspondingly, pH are still higher. pH 6–7 is favorable for $Fe(OH)_3$ precipitation from dilute solutions. Probably, reaction (1) is accompanied by precipitation of $Fe(OH)_3$, and the product of chemisorption is a mixture of iron(III) phosphate and hydroxide. The X-ray phase analysis of this product calcined at 900°C confirms this suggestion. The powder pattern of the product contains iron(III) phosphate and iron(III) oxide reflections.

The S_{Fe}–$c_0^{Fe^{3+}}$ dependences for iron sorption from one-component and two-component solutions with carbonate sorbents are shown in Figs. 2 and 3. They are similar to those of nickel phosphate, except the tripoli–two-component solution system. At the concentration of the initial solution higher than 200 mg l^{-1}, the S_{Fe}–$c_0^{Fe^{3+}}$ curve flattens out, i.e., iron(III) sorption at its concentration higher than 300–400 mg l^{-1} stops. This is caused by the limited content (45%) of the sorbing component, calcium carbonate, in the natural tripoli studied.

The degree of iron(III) recovery with natural car-

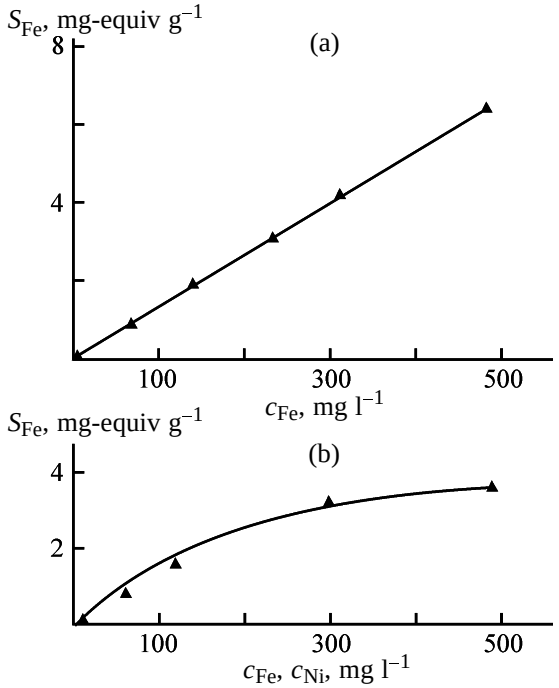

Fig. 3. Sorption of Fe^{3+} ions S_{Fe} with natural tripoli as a function of iron(III) ion concentration c_{Fe} in (a) one-component and (b) two-component solutions of $M(NO_3)_n$ (M = Fe, Ni).

bonate sorbents from one-component solutions is 100% within the entire range of solution concentrations (c_0 < 484 mg l^{-1}). In the case of two-component solutions with the initial iron(III) concentration higher than 240 mg l^{-1}, the solutions after sorption contain small amounts of iron (0.5–0.9 mg l^{-1}).

Similarly to phosphate sorbents, carbonate sorbents exhibit base properties. The pH of aqueous extracts for chalk and tripoli is 7.46 and 8.18, respectively. These high pH values provide a high degree of iron(III) recovery from solutions within the iron concentration range studied. The results of our study are consistent with previous data [9, 10] that the complete deironing of dilute iron(III) solutions with carbonate sorbents is possible at pH > 7. In particular, Shanina *et al.* [9] found that solutions are completely deironed with calcium carbonate at pH 3.5, when the iron(III) concentration is 0.15 g-equiv l^{-1}, whereas in accordance with data of Batalova *et al.* [10] this result is attained at pH > 7 when the iron(III) concentration is 0.005 g-equiv l^{-1}.

CONCLUSIONS

(1) Nickel(II) phosphate, natural chalk, and carbonate tripoli can be used as sorbents for selective sorption of iron(III) ions from two-component Fe^{3+}–Ni^{2+} solutions.

(2) Selective recovery of iron(III) ions from two-component Fe^{3+}–Ni^{2+} solutions with nickel(II) phosphate is caused by heterogeneous exchange reaction with formation of less soluble iron(III) phosphate and deposition of iron(III) hydroxide. Carbonate and phosphate chemisorbents provide 100% recovery of iron(III) ions within a wide range of iron concentrations.

(3) The use of calcium carbonate for selective iron(III) chemisorption is promising because it is a widespread and cheap natural raw material.

Abstract—A new technique for spectrophotometric determination of coproporphyrin III in culture broth, based on its preliminary separation from impurities, was developed. This technique ensures higher accuracy of coproporphyrin III determination than the commonly used method based on sorption of coproporphyrin III on talc.

Porphyrins belong to a vast group of aromatic tetrapyrrole compounds containing four pyrrole rings bound by monocarbon bridges. Most of biologically active tetrapyrroles are metal complexes. For example, heme and siroheme contain iron, chlorophylls and bacteriochlorophylls contain magnesium, etc. [1].

It is known that cancerous growths selectively accumulate coproporphyrin III. On laser irradiation of coproporphyrin III-containing cancerous growth at 401 nm, which corresponds to the maximum of coproporphyrin III absorption [2], a tumor is destroyed by free radicals photochemically generated in the living tissues saturated with oxygen. Thus, in the course of photodynamic therapy of cancerous growth, coproporphyrin III is a photosensitizer. Coproporphyrin III is a low-toxic drug exhibiting broad antitumor effects exceeding those of other antitumor drugs [3].

Coproporphyrin III is a metabolite of *Artrobacter globiformis* microorganisms. In recovery of coproporphyrin III from both culture broth and native solution, its quantitative determination in these media is required. In this study we developed a new technique for determining coproporphyrin III content in culture broth ensuring higher accuracy than the commonly used methods.

A technique for determining proporphyrin III in culture broth based on its sorption on talc powder was described in [2]. According to this method, the initial culture broth is centrifuged to obtain a native solution, and then a weighed portion of talc is added to them. The resulting suspension is stirred and allowed to stand for 24 h in the dark. Thereafter, the talc is filtered off and washed with acidified water with pH 3.5–4.0 at which coproporphyrin III is poorly soluble in water [2]. The coproporphyrin III accumulated on the talc surface is desorbed with a solution of HCl in aqueous acetone. The coproporphyrin-containing desorbate is diluted with 5% aqueous hydrogen chloride, and its optical absorption is recorded at wavelengths 380, 401, and 430 nm. The coproporphyrin III content in the initial culture broth X is calculated by the equation

$$X = [2D_{401} - (D_{430} + D_{380})](V_{el}P)(E \times 1.835V_{cb})^{-1}, \quad (1)$$

where D_{430}, D_{380} and D_{401} are the optical densities of the desorbate diluted with 5% aqueous HCl at 430, 380 and 401 nm, respectively; V_{el}, desorbate volume, ml; V_{cb}, culture broth volume used for preparing native solution; P, dilution factor of desorbate before spectrophotometric determination; $E = 0.667$, specific absorption coefficient; and 1.835, correction factor.

Taking into account that talc has poor sorption selectivity to coproporphyrin III, we expected that the desorbate can contain not only coproporphyrin III but also some foreign species present in culture broth. To check this assumption, the desorbate was subjected to chromatographic separation. Before chromatographic analysis, acetone was removed from the desorbate by evaporation and the remaining solution (15 ml) was applied to a 100-ml column 2 cm in diameter, packed with KSK silica gel. On washing the column with 5% aqueous HCl, three sorption bands were formed. The first sorption band of light brown color, related to impurities, was eluted with 5% HCl and collected as a separate fraction. The middle sorption band of pink color containing coproporphyrin III was also eluted with 5% HCl and collected. The uppermost sorption band of brown color, related to impurities,

Table 1. Sorbent characteristics

Sorbent brand	Average pore diameter, μm	Porosity (specific pore volume), $cm^3\ g^{-1}$	Specific surface area, $m^2\ g^{-1}$	Specific volume of sorbent in column, $cm^3\ g^{-1}$
Sephadex G-15	–	–	–	2.5–3.5
Silokhrom S-80	0.06–0.08	0.7–1.3	70–90	–
Silokhrom S-120	0.03–0.05	0.8–1.2	110–130	–
Silokhrom SKh-2.5	0.066–0.12	1.5–2.0	60–89	
KSK silica gel	0.02–0.05	1.00–1.25	250	–
L silica gel	0.008	0.6–0.75	600–750	–

could not be eluted with 5% aqueous HCl. To elute these impurities, the column was washed with 0.5% aqueous ammonia and the resulting eluate was collected. The residual foreign species remaining in the column were washed off with acidified acetone and also collected. The four fractions eluted from the chromatographic column were diluted to the required volume, and the electronic absorption spectra of the resulting solutions were recorded on an SF-26 spectrophotometer in the wavelength range 360–450 nm with a wavelength step from 2 to 5 nm (Fig. 1). The comparison of the absorption spectra of the fractions obtained by chromatographic separation of the desorbate from talc shows that the maxima of absorption bands of coproporphyrin III and the first fraction of impurities almost coincide. Therefore, the calculation of coproporphyrin III content by the expression $2D_{401} - (D_{430} + D_{380})$ [Eq. (1)] accepted in the technique based on recovery of coproporphyrin III from culture broth by sorption on talc is inaccurate. We found that the technique based on sorption on talc overestimates the coproporphyrin III content in the culture broth by approximately 10%.

In this connection, we developed a more accurate technique for determining the coproporphyrin III content in culture broth. According to this technique, coproporphyrin III is selectively recovered from culture broth by sorption chromatography. To choose a sorbent exhibiting the required selectivity to coproporphyrin III, we tested sorbents of various brands: Sephadex G-15, Silokhrom S-120, Silokhrom S-80, KSK silica gel, and L silica gel. The characteristics of these sorbents are listed in Table 1 [4, 5].

In our experiments, a chromatographic column was packed with sorbent grains 100–200 μm in diameter. The sorbent was preliminarily immersed in water and then loaded into a 100-ml column 2 cm in diameter. A portion of native solution (15 ml) was applied to the column packed with the sorbent. All the native solutions used in our experiments were prepared from the same culture broth sample. The column was successively washed with 5% aqueous HCl, 0.5% aqueous ammonia, and acidified acetone. In the course of washing, the separation of sorption bands was visually observed. We found that species present in the tested native solution are not separated on Sephadex G-15 and Silokhrom S-120. Therefore, these sorbents were discarded. In going to Silokhrom-80, KSK silica gel, and L silica gel, partial separation of coproporphyrin III from impurities was reached. We repeated the chromatographic separation of the components present in the native solution using three above-chosen sorbents. In these experiments, the eluate fractions (5–70 ml) were collected and coproporphyrin III content in them was determined spectrophotometrically. Before analysis, the eluate fractions were diluted with 5% aqueous HCl by a factor of 10–25 depending on their coproporphyrin III content. The optical density of these fractions was measured and the output elution curves were built (Fig. 2). As with 15-ml portions

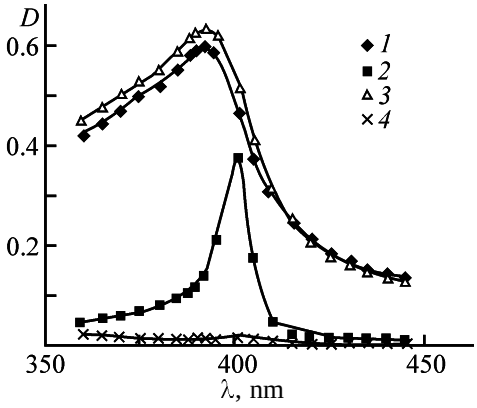

Fig. 1. Electronic absorption spectra of species desorbed from talc and then separated on column packed with KSK silica gel. (*D*) Optical density and (λ) wavelength. Spectra: (*1*) fraction eluted before coproporphyrin III (fraction 1), (*2*) fraction of coproporphyrin III (fraction 2), (*3*) fraction of impurities eluted with 0.5% aqueous ammonia (fraction 3), and (*4*) fraction of impurities eluted with acidified acetone.

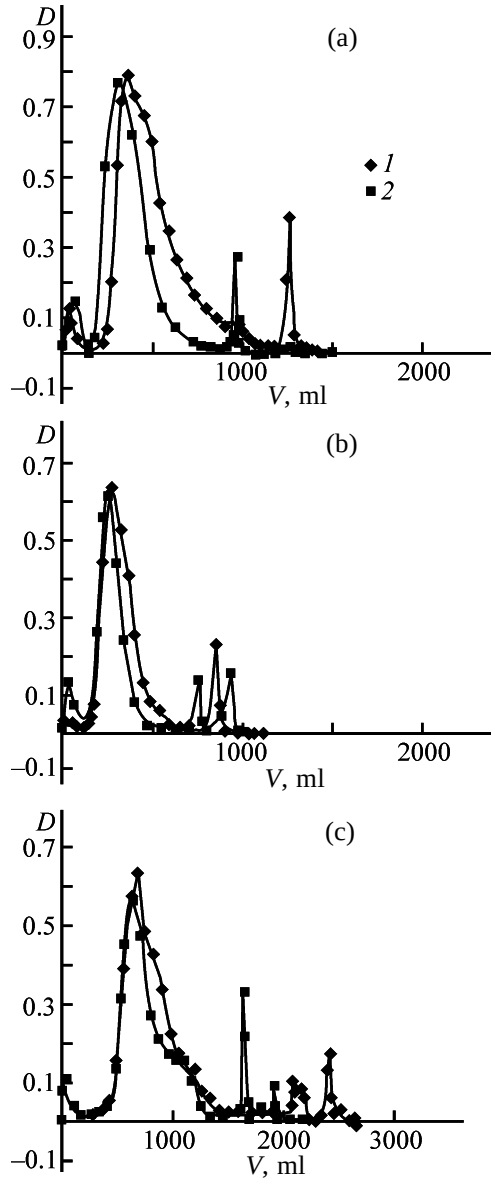

Fig. 2. Elution curves of components of native solution from a column 2 cm in diameter packed with 100 ml of (a) Silokhrom S-80, (b) KSK silica gel, and (c) L silica gel in successive washing with 5% aqueous HCl, 0.5% aqueous ammonia, and acidified acetone. Elution rate 50–70 ml $(h\ cm^2)^{-1}$. (*D*) Eluent optical density at λ = 401 nm and (*V*) eluent volume. Native solution volume applied to column: (*1*) 15 ml and (*2*) 10 ml.

the separation was incomplete, the sample volume was decreased to 10 ml, and better separation was attained on all the three sorbents (Fig. 2).

Taking into account that coproporphyrin III fractions were diluted to different extents, the sorption selectivity of the tested sorbents to coproporhhyrin III was estimated by the optical density of an intermediate undiluted fraction eluted with 5% aqueous HCl between coproporphyrin III and impurity fractions. The optical densities of these intermediate fractions eluted from columns packed with three different sorbents are compared in Table 2.

Table 2. Optical density of intermediate fraction of native solution eluted between coproporphyrin III and impurity fractions

Sorbent	Optical density of intermediate fraction	Native solution volume applied to column, ml
Silokhrom S-80	0.090	10
KSK silica gel	0.150	10
L silica gel	0.190	10

Table 2 shows that in the series of tested sorbents the intermediate fraction eluted from Silokhrom S-80 has the lowest optical density, i.e., this sorbent is the most selective. Along with the sorbents under consideration, we tested Silokhrom SKh-2.5 sorbent whose characteristics, according to published data, are close to those of Silokhrom S-80 (Table 1). This sorbent was used for separating the native solution applied to the column in an amount of 10 ml. The elution curve was obtained, and the optical density of the intermediate fraction was found to be 0.120. Thus, among the sorbents tested Silokhrom S-80 exhibits the highest selectivity to coproporphyrin III.

Our results show that the sorption chromatography is a more efficient technique for recovery of coproporphyrin II from native solution than sorption on talc and can be used for accurate determination of the coproporphyrin III content in culture broth. To perform the chromatographic separation of native solution, the following equipment is required: volumetric flask, column 2 cm in diameter packed with Silokhrom S-80 (100 ml) with a grain size of 100–200 μm, and a spectrophotometer.

The chromatographic separation of native solution was carried out as follows.

A portion of native solution (10 ml) was applied to the column and then the column was washed with 5% aqueous HCl to separate coproporphyrin III from impurities. The coproporphyrin III fraction was collected and its volume was measured. This fraction was diluted to a concentration required for determining the optical density at 380, 401 and 430 nm. Based on these data, the coproporphyrin III content in culture

Table 3. Comparison of coproporphyrin III content in culture broth as determined by chromatographic separation and sorption on talc

Culture broth volume, ml	Coproporphyrin III content in culture broth, mg l^{-1}		$(c_2 - c_1)C_1^{-1} \times 100\%$
	chromatographic method	sorption on talc	
2340	215	235	9.3
3570	348	376	8.0
3820	327	370	13.1

broth was calculated by formula (1), where V_{el} is the volume of coproporphyrin III fraction obtained in eluting 10-ml sample of native solution applied to column, and V_{cb} is the culture broth volume required for preparing 10 ml of native solution.

The following factors contribute to the total error of coproporphyrin III determination by our technique: (1) error in sampling native solution with 10-ml pipette (0.6%), (2) error caused by incomplete separation of coproporphyrin from impurities (0.5%), (3) error in determining the volume of eluted fraction with a volumetric cylinder (0.8%) and (4) error in determining the optical density on an SF-26 spectrophotometer (1%).

The total error of determining coproporphyrin III content in culture broth did not exceed 3%.

Three different samples of culture broth were analyzed for coproporphyrin III by methods based on sorption of coproporphyrin III on talc and chromatographic techniques. The results of these analyses are compared in Table 3.

These data show that the method of coprporphyrin determination based on sorption of coproporphyrin III on talc overestimates the coproporphyrin III content in culture broth by 10% as compared to chromatographic technique. This discrepancy is caused by the fact that talc sorbs not only coproporphyrin III but also foreign components present in the culture broth.

CONCLUSION

To ensure correct spectrophotometric determination of coproporphyrin III content in culture broth, this compound must be separated from impurities. This problem is successfuully solved by sorption chromatography. In recovery of coproporphyrin III by sorption on talc, the overestimated results are obtained due to sorption of impurities. In this case, the coproporphyrin III content can be corrected by multiplying by a factor of 0.9.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Influence of Fabric-Enclosed Positive Electrodes on Self-Discharge Mechanism of Active Masses of Lead Batteries

S. R. Yudilevich and G. A. Kolikova

Istochnik Research Battery Institute, Joint-Stock Company, St. Petersburg, Russia

Received August 8, 2005

Abstract—The self-discharge of lead batteries with fabric-enclosed positive electrodes was studied. The self-discharge mechanism was proposed.

On storage of charged lead batteries, the active materials of electrodes spontaneously react with the electrolyte. On the positive electrode, lead dioxide reacts with sulfuric acid:

$$PbO_2 + H_2SO_4 \rightarrow PbSO_4 + H_2O + 1/2O_2, \quad (1)$$

and alloy components used for fabricating a current lead are oxidized with lead dioxide. In the overall self-discharge balance, the alloy oxidation is not predominant.

The self-discharge of a negative electrode is determined by two reactions: reaction of lead with sulfuric acid

$$Pb + H_2SO_4 \rightarrow PbSO_4 + H_2 \quad (2)$$

and oxidation of lead with oxygen formed by the reduction of lead dioxide

$$Pb + 1/2O_2 + H_2SO_4 \rightarrow PbSO_4 + H_2O. \quad (3)$$

It was estimated in [1] that, in the overall self-discharge balance of the negative electrode, reaction (3) is insignificant, since lead sulfate formed on the surface of active material impedes access of oxygen molecules toward the surface of spongy lead. Reactions (1) and (2) proceed on electrodes independently. The capacity losses by a battery owing to the self-discharge of active materials can differ, because even the same factors, such as, e.g., the electrolyte density, differently affect self-discharge of lead and lead dioxide.

The modern alloys used for fabricating current leads of positive electrodes contain considerably less antimony and other alloying additives. This results in a weaker transfer of corrosion products toward negative active mass and, as a result, in the decreased rate of spontaneous dissolution of lead.

It was established that, with the positive electrode covered by a fabric, the self-discharge of a lead battery can be decreased several-fold [2]. This is partly due to the fact that the antimony transfer from positive to negative electrode is weaker [3].

We studied how fabric envelope affects the loss of capacity by stationary TB-M batteries and by high power (HP) traction batteries in the course of storage.

The current leads to positive electrode of TB-450M batteries were fabricated from the US-1M alloy containing small amount (1.5%) of antimony, and those to the pilot samples of HP traction batteries, from the alloy containing 4% antimony.

The TB batteries were tested from the beginning of the life till the 40th cycle inclusive.

The results of the tests (Table 1) show that not loss, but some increase in capacity is observed for TB-450M batteries stored for 15 days, i.e., within the period of time imposed on TB batteries by GOST [(State Standard) 26881–86] and TU (Technical Specification). The same results were obtained for batteries stored for 18 and 20 days. The loss of capacity by a reference TB-600 battery whose positive electrodes were not enclosed with a fabric and current leads were also fabricated from the US-1M alloys was about 0.4% day^{-1}.

The fact that the fabric-enclosed positive electrodes largely affect the self-discharge rate was also confirmed on pilot HP batteries tested on the 21–22nd and 81–82nd cycles. The HP batteries with positive electrodes made of the same materials without fabric envelope were tested as reference. The capacity of the pilot batteries stored without current for 10 days was

	28th	Capacity, A h	499.4	592
		Change in capacity	–21.7/–0.25	51/0.44
20	32nd	Capacity, A h	515.5	639.0
	33rd	Capacity, A h	532.2	588.4
		Change in capacity	–16.7/–0.16	50.6/0.40

* The quantities in the numerator are in A h, and those in the denominator, in % day^{-1}.

higher by 7% on 22nd cycle and by 3% on 82nd cycle than the capacity attained during the previous discharge. The loss of capacity by the reference batteries for the same time was 4 and 16%, respectively.

The degree of self-discharge (capacity loss) η (%) was calculated by the equation

$$\eta = \frac{C_1 - C_2}{C_1 n} \times 100, \quad (4)$$

where C_1 is the battery capacity immediately after charging (A h); C_2, battery capacity after storage (A h); and n, storage time (days).

Because alloys for preparing current leads to positive electrodes of pilot and reference TB batteries are the same and materials used for fabricating negative electrodes of each battery are the same also, we can conclude that difference in the self-discharge rate is due to the presence of the fabric envelope entirely enclosing the positive electrode.

Anomalous increase in the capacity observed for TB-450M batteries and for pilot BM batteries discharged after the storage without current is likely due to the fact that oxygen escape from the positive electrode immediately after charging is decelerated owing to the presence of fabric envelope. This can cause some increase in the inner resistance of the battery and, as a consequence, some decrease in the discharge capacity. The discharge was performed after 10–20 days of storage, when all the gas from the interelectrode space escaped. Despite the fact that some loss of capacity by the active masses could take place, its value did not exceed the gas-filling effect during the first discharge.

To determine the daily average loss of capacity (self-discharge) of the batteries with fabric-enclosed positive electrodes, the storage time of the TB-450M batteries was increased to 6 months (183 days). The TB-600 reference batteries were tested for comparison. The results of the tests are collected in Table 2. The capacity values of the stored battery before and after the test were reduced to 20°C and the actual degree of self-discharge was calculated. The final self-discharge value with due regard for the battery temperature averaged throughout the storage period

Table 2. Results obtained in testing the self-discharge of TB batteries stored for a long time

Parameter	Battery type	
	TB-450M	TB-600
38th discharge		
Actual capacity, A h	486.5	556.7
Average temperature of discharge, °C	22.5	14.0
Capacity reduced to 20°C, A h	483.4	576.7
Storage time, day	183	165
Average temperature of storage, °C	19.6	16.1
39th discharge		
Actual capacity, A h	400.5	402.6
Average temperature of discharge, °C	24.5	22.5
Capacity reduced to 20°C, A h	395.4	400.0
Change in capacity, A h	88.0	176.7
Actual self-discharge, % day^{-1}	0.10	0.19
Self-discharge (reduced to storage temperature of 20°C), % day^{-1}	≈0.10	0.23

Table 3. Results obtained in testing the self-discharge of positive electrodes of a lead–copper battery

Test conditions		Cell type	$PbSO_4$ amount in active mass of positive electrodes, %
τ, days	*T*, °C		
109	20	Sealed	30.1
109	20	Open	20.5
105	40	Sealed	57.0
105	40	Open	42.6

was determined from the equation

$$\eta_{20} = \eta_{act}[1 + (20 - T_{av})K], \quad (5)$$

where η_{20} is the self-discharge value reduced to a storage temperature of 20°C; η_{act} is the actual self-discharge calculated for a storage temperature T_{av}; K is the correction coefficient calculated for the stationary lead batteries stored for 180 days in the temperature range 15–20°C by data of the Varta Company, and $K = 0.06$.

Thus, after 6 months of storage, the capacity loss is 18% (0.1% day^{-1}) for pilot batteries and 41.4% (0.23% day^{-1}) for reference batteries.

To explain the results obtained, we used data of [4] obtained in studying the self-discharge of the lead–copper battery whose operation is described by the reaction

$$PbO_2 + Cu + 2H_2SO_4 \rightleftarrows PbSO_4 + CuSO_4 + 2H_2O. \quad (6)$$

Unlike lead battery, in this case a well soluble compound, copper sulfate, is formed on the negative electrode. In the limits of solubility of this reaction product, a copper electrode can actively facilitate oxygen depolarization.

It was shown that the self-discharge of sealed lead–copper batteries of SM-330 type is more intense than that of the same batteries with the inner volume accessible to the atmosphere. In the sealed batteries tested during 8 months, the gas pressure in the volume below the lid was monitored. The pressure inside the battery decreased by 40 mm H_2O during two days elapsed from the beginning of the test and then remained constant. The loss of capacity by the sealed SM-330 batteries during the test was 50%, i.e., 0.21% day^{-1} [4].

The self-discharge of a lead–copper power source is described by two reactions. These are reduction of Pb^{4+} to the bivalent state and oxygen evolution [reaction (1)] on the positive electrode and oxidation of copper with the formation of copper sulfate on the negative electrode:

$$Cu + 1/2O_2 + H_2SO_4 \rightarrow CuSO_4 + H_2O. \quad (7)$$

As copper oxidant in reaction (7) serves oxygen formed by reaction (1) and oxygen that appeared in the volume below the lid at the moment of sealing the battery. The decreased pressure is explained by the fact that the rate of the copper oxidation is higher than the rate at which oxygen is formed owing to the lead dioxide reduction.

To ascertain the mechanism of self-discharge of the positive electrode of a lead–copper power source, a test was performed in the cells equipped with copper and lead dioxide electrodes. The cells were tested at 20 and 40°C. Half of cells was sealed, and half was left accessible to the atmosphere. Three cells were tested for each type, i.e., the total number of the tested cells was 12. The self-discharge of the dioxide electrode was estimated from the amount of lead sulfate formed in the active mass of the electrodes after the test (Table 3).

The analysis of the active materials of the positive electrodes shows that sealing of cells accelerates accumulation of lead sulfate, whose amount is 1.5 times larger than that in the electrodes withdrawn from the open-type cells. Increasing the temperature from 20 to 40°C increases approximately twofold the amount of lead sulfate for both sealed and open-type cells.

The influence of sealing on the intensification of self-discharge of the dioxide electrode is likely due to the fact that oxygen formed by reaction (1) is in equilibrium with that dissolved in the electrolyte. The sealed cells, like the sealed batteries, can be considered as systems isolated from the environment. Owing to the reaction of dissolved oxygen with copper, the oxygen concentration in the electrolyte decreases and reaction (1) shifts to the right.

In the open-type cells, the concentrations of gases (nitrogen and oxygen) dissolved in the electrolyte remain virtually unchanged. Therefore, the self-discharge of lead dioxide proceeds at a lower rate, and the analysis of the active materials confirms this conclusion (Table 3).

The self-discharge mechanism considered here for lead–copper batteries suggests the following mechanism of the influence of the fabric envelope on the decrease in the self-discharge rate of the battery. The fabric envelope enclosing the positive electrode

creates a space in a near-electrode layer in which the electrolyte is saturated with oxygen. In accordance with the Le Chatelier principle, the equilibrium of reaction (1) shifts to the left, i.e., the lead dioxide reduction (a process opposite to the self-discharge of sealed lead–copper battery) is decelerated. Moreover, the presence of the fabric envelope in a stored lead battery impedes diffusion of electrolyte with dissolved oxygen toward the negative electrode, which also decreases the self-discharge caused by the oxidation of the active mass of the negative electrode by reaction (3).

Thus, the results obtained show that the decrease in the self-discharge of batteries equipped with a fabric-enclosed positive electrode is due not only to a weaker transfer of antimony [3], but also to decelerated lead dioxide reduction owing to saturation of the near-electrode layer of the electrolyte with dissolved oxygen, and also to decreased oxygen transfer to the negative electrode.

CONCLUSIONS

(1) The self-discharge mechanism was suggested and the increase in the discharge capacity was explained for batteries stored for 10–20 days without current.

(2) In studying the self-discharge of lead batteries with a fabric-enclosed positive electrode, additional factors markedly affecting the electrical characteristics of batteries in the course of exploitation were determined.

(3) The results obtained open prospects for the long-term storage of batteries without intermediate chargings and for a decrease in the exploitation cost of batteries.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Effect of High-Temperature Electrochemical Deposition of Mo_2C Coatings on the Corrosion and Electrochemical Behavior of Titanium

V. V. Malyshev, T. I. Duda, and V. M. Shevchenko

Kiev Polytechnic Institute, National Technical University of Ukraine, Kiev, Ukraine

Received May 12, 2002; in final form, May 2005

Abstract—The possibility of increasing the corrosion resistance of titanium by electroplating molybdenum carbide coatings from the melts was studied.

Molybdenum and molybdenum carbide are widely used as components of corrosion-resistant steels and alloys and of coatings for surface modification. Therefore, the corrosion and electrochemical behavior of molybdenum and molybdenum carbide in aggressive media attracts growing researchers' attention. Various methods are used for surface modification of titanium. For example, the deposition of platinum-group metals increases the corrosion resistance of titanium in hot solutions of acids by several orders of magnitude [1, 2]. However, noble metals are expensive, which makes application of this protection method limited. Alloying titanium with molybdenum shows promise [1, 3, 4]. At the same time, the level of alloying ensuring high corrosion resistance should be no less than 20–25%. This level is successfully attained when, for example, the method of diffusion saturation from solid mixtures with the oxide activator in a vacuum or under argon at 1100–1200°C is used for surface alloying of titanium samples with molybdenum [5]. The method of the high-temperature electrochemical synthesis (HTES) from ionic melts allows the temperature of alloying of titanium with molybdenum, tungsten, and their carbides to be decreased to 800–900°C and alloying time to be shortened considerably. In this case, the corrosion resistance of St.3 and St.45 steels in sodium chloride solutions and in hot concentrated and dilute solutions of hydrochloric, sulfuric, and phosphoric acids considerably increases.

In this study we examined the electrochemical and corrosion behavior of titanium, onto which molybdenum carbide coating was deposited by HTES, in a sulfuric acid solution. Because Mo_2C is in short supply and is brittle at room temperature, it has not found wide application in industry as structural material [1, 8]. At the same time, it is an important alloying component for coating deposition.

Molybdenum carbide was plated onto VT 1–0 titanium by the HTES method from the melts of composition (mol %): 85 Na_2WO_4, 5 MoO_3, and 10 Li_2CO_3 at 800–900°C and a cathodic current density of 0.04–0.12 A cm^{-2} in air. The maximum thickness of the coatings was 50 μm.

An important condition for the successful coating deposition is that the corrosion potential of titanium should be more positive than that of carbide (–1.60 to –1.90 V vs. the reference electrode $(O_2)Pt \mid Na_2WO_4$–0.2 WO_3 in the alloy studied). Therefore, we measured the stationary potentials of titanium in a Na_2WO_4–5 mol % MoO_3 melt containing different amounts of Li_2CO_3 and estimated whether molybdenum carbide coatings with good adhesion to the substrate can be deposited. The stationary potentials were not established for a long time and varied jumpwise. Apparently, this is associated with dissolution of oxygen-containing phases in the surface layer of the electrode. After measuring the potentials, we studied the composition of surface layers formed on titanium and confirmed the presence of oxide phases weakly adherent to the surface. The X-ray phase analysis of the surface layers revealed Ti, TiO, and TiO_2.

To form coatings strongly adherent to the support, it was necessary to remove the oxide phases of titanium. Therefore, prior to the molybdenum carbide deposition, titanium was nickel-plated in aqueous solutions or subjected to surface nitriding at 600–700°C. The stationary potential of nickel at 900°C in the range of the Li_2CO_3 concentrations 5–10 mol % was 0.89–1.07 V, the value considerably more positive than the deposition potential of carbide.

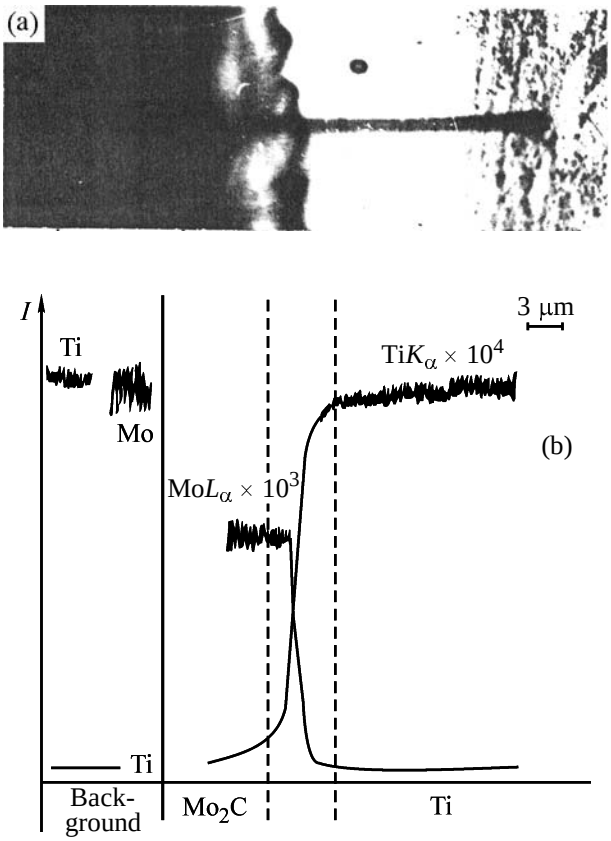

Fig. 3. (a) Electron probe profile and (b) concentration distribution curves of (*1*) titanium and (*2*) molybdenum in the diffusion zone between substrate and coating. (*I*) Radiation intensity.

The photomicrograph of the cross section of the titanium sample coated with molybdenum carbide is shown in Fig. 1. Continuous coatings are clearly observed on chips of the coated samples (Fig. 2). The phase analysis of the surface layer of the coated samples revealed strong reflections associated with molybdenum. The microhardness of molybdenum carbide was 1800–1900 kgf mm^{-2}. In the surface layers adjacent to the support, the microhardness increases, which confirms the mutual diffusion of their elements. The existence of diffusion zone ensuring adhesion between the coating and the support is also confirmed by the analysis of sections on an MS-46 X-ray microanalyzer (Cameca) (Fig. 3). The diffusion zone extends to 5–6 μm.

The corrosion was tested in a 9.5 M solution of sulfuric acid at 70–80°C by recording variations with time of potential and diffusion rate. The corrosion rate was determined from the amount of titanium and molybdenum in the solution, evaluated photocolorimetrically [9]. Also, the anodic and cathodic polarization curves on titanium, molybdenum carbide, and on titanium coated with molybdenum carbide were recorded (potential sweep rate 50 mV s^{-1}). All potentials were recalculated relative to standard hydrogen electrode.

The corrosion potential of titanium coated with molybdenum carbide considerably increases with time, from –(0.59–0.61) to 0.26–0.31 V, going into the passive/active region of titanium (Fig. 4) to a value lower than the corrosion potential of molybdenum carbide by only 0.02–0.04 V. The photocolorimetric analysis of the solution was performed after 5, 10, 15, and 30 h of tests. The average rate of the titanium dissolution calculated after these time intervals for the coated sample was constant (0.005–0.01 g m^{-2} h^{-1}). At the same time, the dissolution rate of titanium at the free corrosion potential is 19.1–19.3 g m^{-2} h^{-1}. Depositing the coatings decreases the rate of the titanium dissolution by a factor of

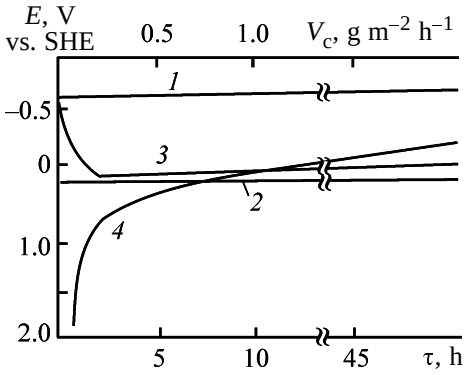

Fig. 4. Variations with time τ of corrosion potential E of (*1*) titanium, (*2*) molybdenum carbide, and (*3*) titanium coated with molybdenum carbide; (*4*) dependence of dissolution rate V_c of titanium on potential.

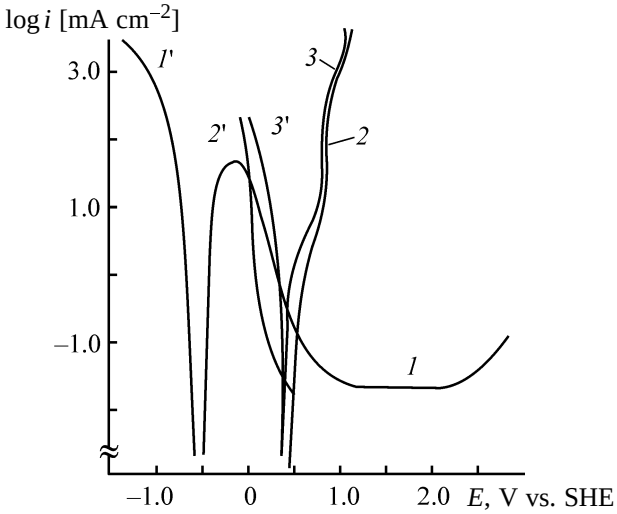

Fig. 5. log i–E curves of (*1*–*3*) anodic and (*1*'–*3*') cathodic polarization of (*1*, *1*') titanium, (*2*, *2*') molybdenum carbide, and (*3*, *3*') titanium coated with molybdenum carbide in 9.5 M sulfuric acid at 75°C. (E) Potential and (i) current density. Polarization rate 50 mV s^{-1}.

2000–4000. The dissolution rate of free titanium at a potential established on the samples coated with molybdenum carbide (300–310 mV) was 0.41–0.50 g m^{-2} h^{-1} (Fig. 4).

For longer corrosion tests, the average rate of the dissolution of molybdenum from the molybdenum carbide coating decreased from 0.03–0.04 g m^{-2} h^{-1} after the first five hours to 0.007–0.011 g m^{-2} h^{-1} after 30 h. Similar change in the average corrosion rate with time was also observed for molybdenum in sulfuric and hydrochloric acid solutions of different concentrations in [10].

According to the anodic polarization curves (Fig. 5), the free corrosion potential of titanium in experimental conditions is from –0.59 to –0.61 V. Titanium is characterized by the narrow region of active dissolution, rather negative passivation potential (from –0.27 to –0.29 V), and large critical passivation current. For molybdenum carbide, the region of the active dissolution does not exist and therefore it is passive up to the overpassivation potential. The anodic polarization curve obtained on titanium coated with molybdenum carbide is similar to that on molybdenum carbide and virtually coincides with it at a polarization potential exceeding 1.0 V. The potential of the coated titanium is close to the overpassivation potential of molybdenum carbide. The molybdenum carbide dissolution with the formation of molybdate ions is the main process responsible for the anodic current in the passive and transpassive regions.

The cathodic polarization curves show that the efficiency of the cathodic processes on molybdenum carbide and on titanium coated with Mo_2C is considerably higher than on pure titanium (Fig. 5). The cathodic curve taken on molybdenum carbide intersects the anodic curve taken on titanium virtually in the very beginning of the active/passive region. Therefore, at comparable areas, the molybdenum cathode cannot provide complete passivation of the titanium anode. The cathodic curve taken on molybdenum carbide coating intersects the anodic curve of titanium just near the passivation region. Therefore, this material as cathodic coating is more efficient.

CONCLUSIONS

(1) The electroplated molybdenum carbide coating transfers titanium into the passive state and decreases the rate of its corrosion in a 9.5 M H_2SO_4 solution at 70–80°C by a factor of 2000–4000.

(2) The anodic and cathodic behavior of titanium coated with molybdenum carbide is determined by the electrochemical properties of molybdenum carbide. The efficiency of the cathodic process on the coating plated onto titanium is somewhat higher than that on molybdenum carbide. This enables transfer of titanium into the passive state and ensures its electrochemical protection.

Abstract—A new procedure was developed for synthesis of aromatic and heteroaromatic acids and their derivatives (esters, salts) by carbonylation of the corresponding aryl halides. The acids are selectively formed in a high yield under very mild conditions. Highly active catalytic systems, base-containing alcoholic solutions of cobalt carbonyl modified with epoxides, were used to activate aryl halides.

Aromatic acids and their derivatives (esters and salts) are widely used both in preparative organic chemistry and as commercial raw materials to produce pharmaceuticals, plant protecting agents, paint and varnish materials, lubricants, and corrosion inhibitors. In addition, aromatic carboxylic acids are used as the base of modern liquid-crystal materials. Di- and polyaryl carboxylic acids are used in production of polyester fibers and liquid-crystal thermoplastics as well as electroluminophores in development of new equipment.

The conventional methods for preparing aromatic acids under industrial and laboratory conditions are different and involve classical organic reactions: alkylation, acylation, oxidation, and cyanidation. The disadvantages of these methods are their low selectivity and high consumption of raw materials. The synthesis is multistep and requires complex process schemes. Many of these methods are environmentally hazardous.

Recently, researchers turned attention to an alternative one-step selective procedure for preparing aromatic carboxylic acids: carbonylation of the corresponding aryl halides. Aryl halides are readily available and cheap. However, these compounds, especially the cheapest aryl chlorides, have low reactivity.

Originally, "soft" aryl halides (iodides and bromides) were used for this purpose. These compounds can be activated by oxidative addition to complexes of palladium in a low oxidation state [1–3].

At the same time, alkylaromatic halides are carbonylated under extremely mild conditions in alcohols in the presence of a base and conventional catalyst of oxosynthesis, octacarbonyldicobalt [1, 4, 5].

Alkylcobalt carbonyl complexes are formed *in situ* by the reaction of alkyl halides reactive in nucleophilic substitution (e.g., methyl chloroacetate) with dicobalt octacarbonyl in alcoholic solutions containing a base. These complexes can activate weakly active aryl halides, involving them in carnolylation [6]. In this case, alkyl halides are cocatalysts (activators) of cobalt carbonyl in carbonylation of aryl halides:

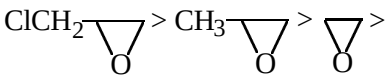
$$\mathrm{ArHal + CO} \xrightarrow[\mathrm{ROH + B}]{\mathrm{Co_2(CO)_8 + A}} \mathrm{ArCOOR},$$

where A and B are cocatalyst and base, respectively.

The facts that acceptor substituents accelerate carbonylation of substituted bromobenzenes and one-electron acceptors (nitrobenzene and anthraquinone) inhibit carbonylation of aryl halides suggests radical anion mechanism of aryl halide activation ($S_{RN}1$). The actual carbonylation catalyst is, apparently, the anionic complex $[RCo(CO)_3COOCH_3]^-$ formed by the nucleophilic attack of the carbon atom of one of the carbonyl groups by the methylate anion. The nucleophilic power of this complex is high. Since benzyl chloride is also carbonylated under these conditions, its was gradually fed by a special procedure to the reaction mixture to maintain the catalyst in the active form and to increase the conversion (see figure). A series of valuable aromatic acids were prepared by carbonylation of the corresponding aryl halides in

1070-4272/05/7811-1844© 2005 Pleiades Publishing, Inc.

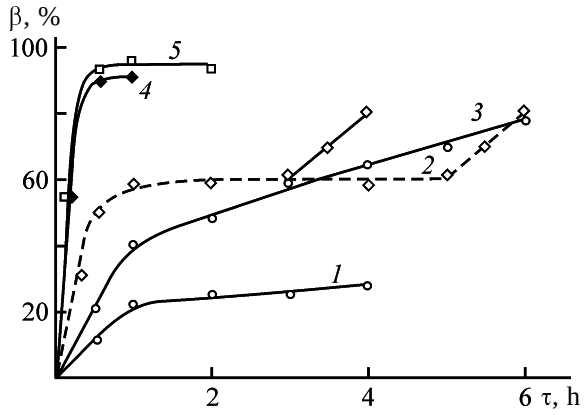
methanol in the presence of cobalt carbonyl–benzyl chloride–base catalytic system. This system is the most suitable for carbonylation of 5,6-dichloroacenaphthene to acenaphthene dicarboxylic acid used for preparing a valuable commercial product, 1,4,5,8-naphthalenetetracarboxylic acid [9].



To prepare more efficient catalytic systems for carbonylation of aryl halides, dicobalt octacarbonyl was modified.

Since aryl halides are activated by strongly nucleophilic anionic cobalt complexes, we examined catalytic systems generating new reactive intermediate anionic cobalt complexes.

It is known [10] that $Co(CO)_4^-$ in alcoholic solutions containing a base undergoes nucleophilic attack of epoxides to form immediately anionic alkylcobalt carbonyl complexes in which the negative charge is localized on the alkyl group. We suggest that catalytic properties of these complexes will differ from those of the anionic complexes formed with alkyl halides after attack of methylate anion on the carbonyl group of the neutral alkylcobalt carbonyl complex. Indeed, as seen from the figure, the cobalt carbonyl–olefin oxide system is more active by a factor of approximately 2 than our most active alkylcobalt carbonyl catalytic system containing benzyl chloride [7–9]. Based on these results, we developed a series of highly active catalytic systems [8, 11, 12] containing olefin oxides, epichlorohydrin, and ethylenechlorohydrin as cocatalysts (see figure). All these cocatalysts, as well as epoxides, form intermediate anionic complexes, with epichlorohydrin being more active owing to the presence of two functional groups. These cocatalysts are not consumed by the parallel pathway of self-carbonylation (as does benzyl chloride). These compounds may undergo methanolysis but this reaction is insignificant in the presence of weak bases such as alkali metal carbonates. The methanolysis products, monomethyl ethers of glycols can be readily separated from the target products, arylcarboxylic acids.



An important advantage of epoxide cocatalysts is the absence of halogen atom in their composition. Hence, the base is not consumed for binding the halogen. Propylene oxide is the most available, cheap, and convenient in use.

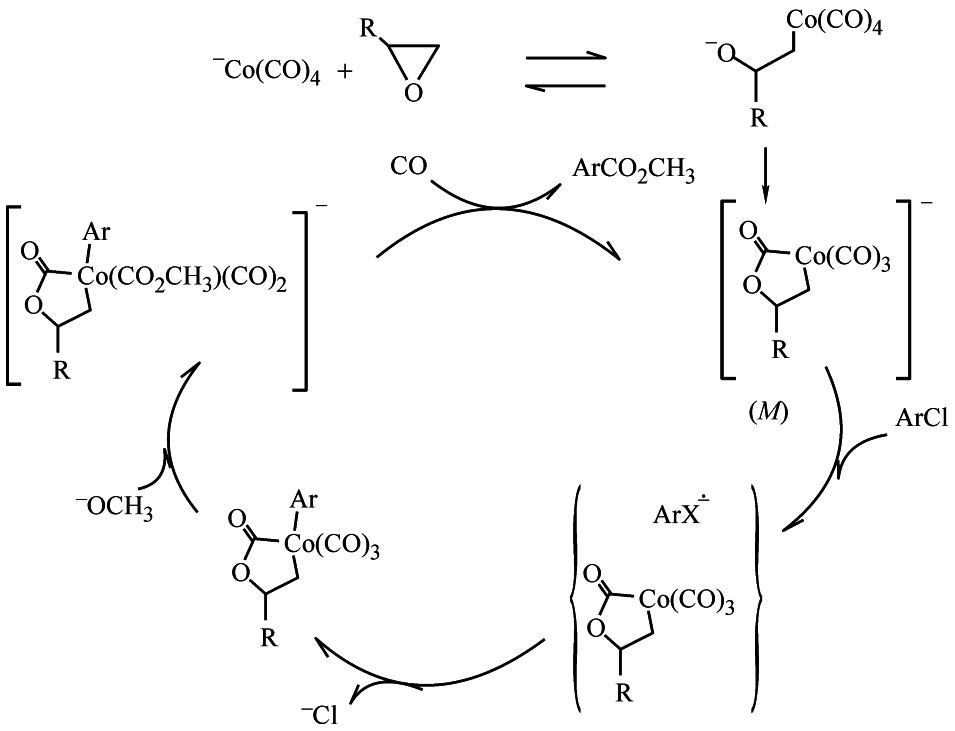
The activity of the examined cocatalysts decreases in the following order:

$> CH_3$$> $$> OHCHRCH_2Cl >$

$PhCH_2Cl > p\text{-}ClC_6H_4CH_2Cl > CH_3I > C_2H_5I > C_2H_5Br > n\text{-}C_8H_{17}Br > ClCH_2COOCH_3$.

Conversion β of α-chloronaphthalene in the presence of different cocatalysts: (*1*) $ClCH_2COOCH_3$, (*2*) $PhCH_2Cl$ (dashed line reflects the reaction course after introduction of additional portion of benzyl chloride), (*3*) $C_8H_{17}Br$, (*4*) $ClCH_2CH_2OH$, and (*5*) $CH_3CH\!-\!CH_2$ (O) as a function of time τ. T = 60°C, P_{CO} = 1 atm, $[Co_2(CO)_8]$ = 0.017 M.

The mechanism of carbonylation of aryl halides in the presence of $Co_2(CO)_8$–epoxide catalytic system is similar to that of the reaction catalyzed by cobalt carbonyl modified with benzyl chloride [4, 8]. The mechanism of carbonylation of aryl halides in the presence of cobalt carbonyl–epoxide–base catalytic system can be described by a catalytic cycle (see scheme).



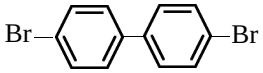
In this system, $Co(CO)_4^-$ anion reacts with epoxide with opening of the three-membered epoxy ring to form intermediate anionic complex. Probably, this complex is subjected to cyclization into negatively charged metallalactone M which is a "true" catalyst of aryl halide carbonylation.

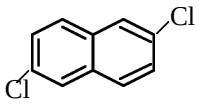
This complex is highly nucleophilic and activates ArHal by the $S_{RN}1$ mechanism (which is confirmed by the fact that this reaction is inhibited by aromatic nitro compounds and other one-electron acceptors) via formation of arylalkylcobalt carbonyl complex. Formation of metallalactones from metal carbonyls has been demonstrated with an example of alkylcobalt carbonyl complexes of iron [13].

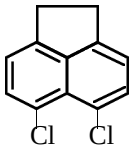
The main examples of highly efficient synthesis of mono- and polyaromatic acids performed for the first time by carbonylation of the corresponding aryl halides in methanol in the presence of $Co(CO)_4^-$–propylene oxide–K_2CO_3 catalytic system are presented in Tables 1 and 2.

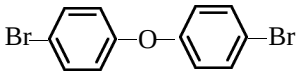
As seen from Tables 1 and 2, $Co(CO)_4^-$–propylene oxide–K_2CO_3 catalytic system can be used for selective synthesis of aromatic mono- and dicarboxylic acids in a high yield in methanol under very mild

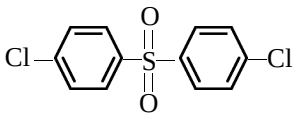
Catalytic cycle of ArHal carbonylation











conditions. This method is suitable for both laboratory preparation and industrial production of aromatic carboxylic acids. It should be noted that a large amount of the activator (epoxide) should be used to prepare the target product in a high yield. This is due to consumption of the epoxide by its methanolysis with the solvent in the presence of a weak base. However, this fact does not minimize the importance of both the laboratory and industrial procedures. Methanolysis of propylene oxide and ethylene oxide (more convenient

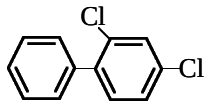
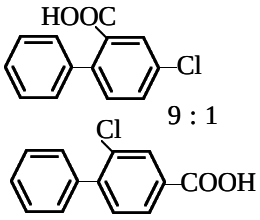
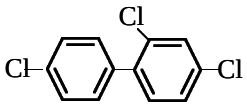
for industrial purposes) yields monomethyl ether of propylene glycol and methyl Cellosolve, respectively. These compounds are quite compatible as solvents with methanol and can be readily separated from the aromatic carboxylic acid (the main reaction product). If necessary, they can be recovered separately in the step of methanol regeneration.

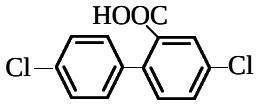
A number of aromatic carboxylic acids were successfully prepared from the corresponding aryl halides by this procedure in a 100-l pilot reactor. This method was also tested for dechlorination of environmentally hazardous highly heat-resistant dielectrics prepared from polychlorobiphenyls (PCB). These compounds belong to the family of dioxin-like stable organic pollutants. For this purpose, we tested the new catalytic systems. Previously we found that the least reactive aryl chlorides, chlorobenzene, chlorodiphenyl, and 4,4'-dichlorodiphenyl, are not carbonylated. At the same time, model PCB (congeners) containing 3–4 chlorine atoms are carbonylated under these conditions to form various polychlorobiphenylcarboxylic acids (Table 3).

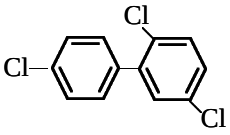
We found that from 1 to 4 halogen atoms can be involved in the carbonylation. Carbonylation of individual PCBs is a new procedure for preparing a series of polyaromatic and polyhaloaromatic carboxylic acids which can be used for both laboratory synthesis and industrial production of a number of unique chemical products for preparing new (e.g., electroluminescent) materials. It should be noted that many of these compounds were prepared for the first time by the above procedure. Thus, we proposed a new procedure for processing PCBs under mild conditions in the presence of available catalytic systems [14].

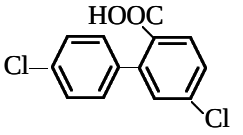


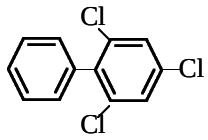


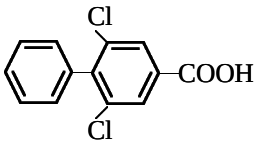


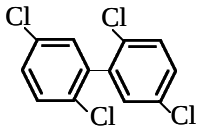


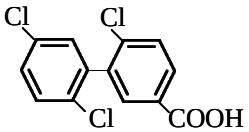


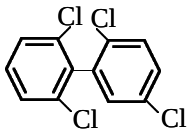


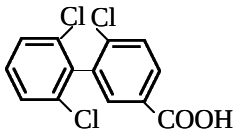












EXPERIMENTAL

Carbonylation was performed in laboratory temperature-controlled glass reactors in a CO flow under vigorous stirring at atmospheric pressure. The reaction products were analyzed by GLC and ^{1}H NMR spectroscopy. The products were identified by NMR (PFG, DQF ^{1}H, ^{1}H COSY; PFG ^{1}H, ^{13}C HMQC; PFG ^{1}H, ^{13}C HMBC) spectroscopy and mass spectrometry.

CONCLUSIONS

(1) A new procedure was developed for preparing aromatic and heteroaromatic carboxylic acids and their

Table 3. Carbonylation products of individual PCBs

Initial PCB	Reaction products
	
	
	
	
	
	

derivatives (esters and salts) by carbonylation of the corresponding aryl halides in the presence of new catalytic systems containing cobalt carbonyl modified with epoxides.

(2) Carbonylation occurs in a high yield and with a high selectivity under mild conditions (CO pressure of 1–3 atm) in alcoholic solutions containing a base.

(3) A series of mono- and dicarboxylic aromatic acids were prepared for the first time by this procedure.

Abstract—Carbon nanotubes modified with manganese dioxide were prepared. Manganese dioxide was deposited by reduction of $KMnO_4$ in solution using formic acid or nanotube carbon. The electrochemical properties of oxygen electrodes containing nanotubes modified with manganese dioxide were studied.

Since oxygen or air electrodes can be used in fuel cells and metal–air power sources, their utilization in chemical power sources seems very promising. These electrodes produce no environmental problems, save rare materials, and decrease the cost and increase the capacity of power sources.

Electrochemical reduction of oxygen is a rather complex process [1–5], and it strongly depends on catalysts. At present, a wide series of catalysts are used for oxygen reduction, including platinum, rhodium, iridium, silver, La_xMnO_3, MnO_2, activated carbons, nickel oxides, spinels ($NiCo_2O_4$, $MnCo_2O_4$, $CoAl_2O_4$), perovskites ($LaCoO_3$, $La_{1-x}Sr_xCoO_3$, $La_{1-x}Sr_xMnO_3$, $La_{1-x}Ca_xCoO_3$, etc.), macrocyclic complexes, their polymers, and pyropolymers [6].

Discovery of carbon nanomaterials, in particular, nanotubes (NTs) opens up possibilities for preparing new catalyst materials by applying known catalysts to the surface or intercalating them inside carbon NTs. In this case, we can expect synergistic affect (owing to interaction of the catalyst particles with carbon nanostructures) and thus formation of catalysts with better characteristics than those of the carbon materials and metal-containing catalysts used separately [7, 8]. It is known that activated carbons can interact with some metal ions with the deposition of the metal on carbon [9]. In the reaction of metal ions and oxidized carbon (OC), carbon is oxidized and thus acts as reducing agent. The resulting metal–carbon composites can be effective catalysts.

Since carbon NTs exhibit high electrical conductivity and developed specific surface area and can form mesoporous three-dimensional structures, their use as catalyst supports shows promise. It is known that weakly ordered carbon is first consumed in oxidation of carbon NT in aqueous solutions with various reagents [10]. Hence, oxidative atmosphere would allow precipitation of metals on the carbon NTs with their simultaneous treatment to remove weakly ordered carbon.

In this paper we examined the effect of interaction between the catalyst and support (nanotubes) on the electrochemical properties of oxygen electrodes prepared from the resulting material. This interaction was studied using carbon NTs modified with manganese dioxide.

EXPERIMENTAL

As supports we used multilayer carbon NTs; these NTs were modified with MnO_2 prepared by reduction of potassium permanganate in solution using formic acid or nanotube carbon, according to the following reactions:

$$2KMnO_4 + 3HCOOH \rightarrow 2MnO_2(aq) + 2KHCO_3 + CO_2 + 2H_2O, \quad (1)$$

$$4KMnO_4 + 3C + H_2O \rightarrow 4MnO_2(aq) + 2KHCO_3 + K_2CO_3. \quad (2)$$

It should be noted that the above equations do not take into account the possibility of formation of the hydroxy and carboxy groups bound with nanotubes. With this fact taken into account, the loss of nanotube carbon in the course of MnO_2 deposition in accordance with Eq. (2) should be smaller than at complete oxidation of carbon to carbonate.

The multilayer carbon NTs were obtained by catalytic pyrolysis of ethylene on a catalyst prepared by precipitation of metal hydroxides with ammonia from solutions of aluminum nitrate, iron acetate, and am-

1070-4272/05/7811-1849 © 2005 Pleiades Publishing, Inc.

monium molybdate at Al : Fe : Mo atomic ratio of 1 : 1 : 0.07. To decrease agglomeration of NTs, Aerosil A-300 (pyrogenic silicon dioxide) was supplied into the reactor [11]. As a result, we obtained a black powdered product with a bulk density of 25–30 g dm^{-3}. The external diameter of carbon NTs varied from 10 to 30 nm, their specific surface area was 230 m^2 g^{-1}, and the content of mineral impurities in the crude product was 15–20%. Nanotubes were treated with a solution of hydrofluoric acid to remove the impurities of catalysts and Aerosil and then were used in further experiments as aqueous paste without drying.

In the course of deposition of manganese dioxide on the NT surface, the amount of $KMnO_4$ was determined so as to provide the content of MnO_2 in the NT + MnO_2 composite of 9, 16.7, 50, and 80 wt % (recalculated to anhydrous MnO_2). Actually, under given conditions hydrated MnO_2 was deposited.

Manganese dioxide was deposited on NTs by two procedures. In the first procedure, $KMnO_4$ was reduced with formic acid in the presence of NT suspension in accordance with Eq. (1). It was found that at mixing of the aqueous solution of potassium permanganate with NT suspension without heating the reduction of $KMnO_4$ proceeds to some extent, and then the reaction sharply decelerates. It should be noted that, with increasing $KMnO_4$ charge, the fraction of permanganate participating in the reaction with NT suspension without heating decreases. Probably, only certain sections of the NT surface with a defective structure participate in the reaction under the above conditions. The reaction can be activated with formic acid. The aqueous paste of purified NTs (73.5 g, 6.8 wt % dry matter) was placed into a beaker and diluted with water (430 ml) with stirring. The solution of potassium permanganate (1.82 g) in water (50 ml) was added to the solution of NT suspension with stirring, and the mixture was stirred with a mechanical stirrer for 1 h at room temperature. Then, formic acid [64% of stoichiometric amount calculated from Eq. (1)] was added to the reaction mixture over a period of 20 min with continuous stirring. The color of potassium permanganate disappeared within 50 min. The resulting reaction mixture consisted of coarse NT aggregates and colloidal brown suspension of hydrated MnO_2; it was boiled for 1 h, and in this time all colloidal particles of manganese dioxide were adsorbed on the nanotubes. After coagulation, we observed black flakes in the transparent colorless liquid. The product was filtered off, washed with water, and dried at 120°C in air; the yield of the product, designated as M-16.7MC, was 6.1 g. The calculated content of MnO_2 (recalculated to the anhydrous compound) was 16.7% relative to MnO_2 + NT total weight.

The materials with 50 and 80% content of MnO_2 relative to MnO_2 + NT total weight (M-50MC and M-80MC samples) were prepared by similar procedures. In these cases, the charge of $KMnO_4$ was increased to obtain the required content of MnO_2, whereas the amount of formic acid for complete reduction of $KMnO_4$ (disappearance of a rose halo around the sample drop on a paper filter) was 80 and 89% of stoichiometry for M-50MC and M-80MC, respectively. Thus, only a small amount of $KMnO_4$ was reduced with NT carbon before addition of formic acid. In these experiments, complete adsorption of MnO_2 particles on NTs after reduction with formic acid and subsequent boiling of the reaction mixture was not attained. The products were mechanical mixtures of NTs coated with unknown amount of MnO_2 and excess MnO_2 as a separate phase.

The second procedure of NT modification with manganese dioxide is based on reduction of $KMnO_4$ solution with NT carbon on boiling. As seen from Eq. (2), 1 g of MnO_2 is formed at consumption of 0.1036 g of carbon. Thus, significant amount of MnO_2 can be deposited with consumption of a relatively small amount of NT carbon (especially weakly ordered fraction). In these experiments, NT suspension was mixed with a solution of $KMnO_4$ and boiled with stirring up to disappearance of the permanganate color. For example, 40.6 g of purified NT paste (6.8 wt % of dry matter) was diluted with water (250 ml), and a solution of $KMnO_4$ (4.55 g in 250 ml H_2O) was added with stirring. The mixture was heated and boiled with stirring for 40 min up to complete disappearance of the permanganate color. The reaction yielded black flaky precipitate and a brownish transparent solution (probably due to the formation of MnO_2 sol). To prevent transition of adsorbed MnO_2 into the sol, the product was washed with NH_4HCO_3 and dried in air at 120°C. The yield of the product, designated as M-50C, was 5.20 g. The calculated content of MnO_2 (recalculated to the anhydrous compound) was 50%. In our calculations we took into account that certain fraction of NT carbon was consumed in the reaction [Eq. (2)].

Samples with other contents of manganese oxide were prepared by the similar procedure, and the time of boiling required for complete reduction of $KMnO_4$ for samples M-9C, M-16.7C, M-50C, and M-80C was 5, 20, 40, and 75 min, respectively.

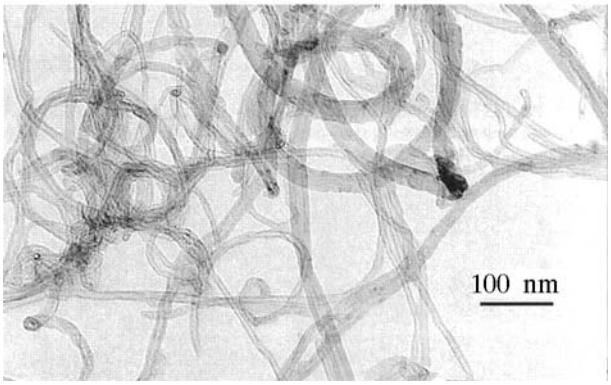

Fig. 1. Electron microscopic pattern of initial carbon nanotubes.

The oxygen electrodes were prepared by pressing. The hydrophobic layer consisted of acetylene black (0.07 g cm^{-2}) containing polytetrafluoroethylene (25%) and the active layer, 0.02 g cm^{-2} NT modified with manganese dioxide and containing 5% polytetrafluoroethylene. The measurements were carried out on a model of zinc–oxygen current cell [12] with analytically pure grade 5 M KOH as electrolyte. In our measurements we used zinc auxiliary electrode and silver chloride reference electrode. All the potentials are given with respect to the silver chloride reference electrode. The electrochemical characteristics were recorded in the galvanostatic mode. Oxygen was produced using a U-shaped electrolyzer with alkali electrolyte; it was supplied to the oxygen electrode under an excess pressure of 0.1 atm. Before operation, the electrode was purged with oxygen for 1 h. In the course of measurements, the current in the electrolyzer was higher than the current at the oxygen electrode by a factor of 3.

The microscopic patterns were recorded on a JEM-100 CXII transmission electron microscope.

The microscopic patterns of the initial NT and NT modified with MnO_2 are shown in Fig. 1 and Figs. 2a and 2b, respectively. As seen from Fig. 2a, modified NTs prepared by reduction of $KMnO_4$ with NT carbon (50% MnO_2 in the MnO_2 + NT composite recalculated to the dry components) contain fine particles (probably MnO_2) covering the nanotube surface. If the reduction was performed with formic acid (Fig. 2b), the surface of nanotubes is clean, and the sample consisted of a mixture of coarser particles and nanotubes. It should be noted that the reduction of $KMnO_4$ with NT carbon on boiling yields a black product with a MnO_2 content of 80%, whereas reduction with formic acid yields brown Mn(IV) hydroxide; this product is probably amorphous.

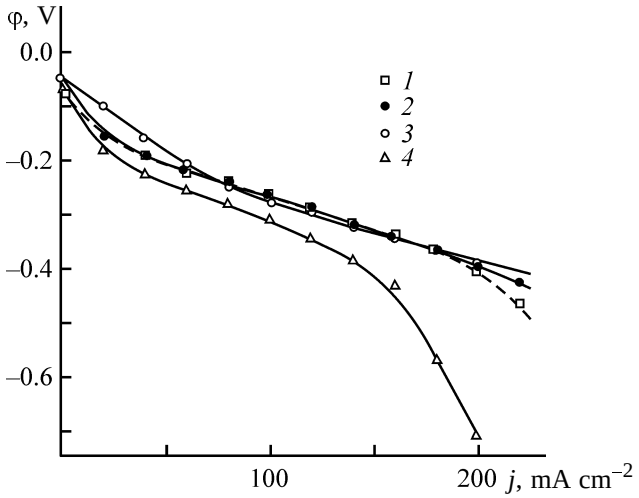

Fig. 3. Voltammetric curves of oxygen electrodes containing carbon nanotubes modified with different content of MnO_2. MnO_2 content, %: (*1*) 9 (M-9C), (*2*) 16.7 (M-16.7MC), (*3*) 50 (M-50C), and (*4*) 80 (M-80C). (φ) Potential and (*j*) current density; the same for Fig. 4.

The dependence of the electrochemical characteristics of the oxygen electrode containing NTs modified with manganese dioxide as influenced by the content of MnO_2 is shown in Fig. 3. The increase in the

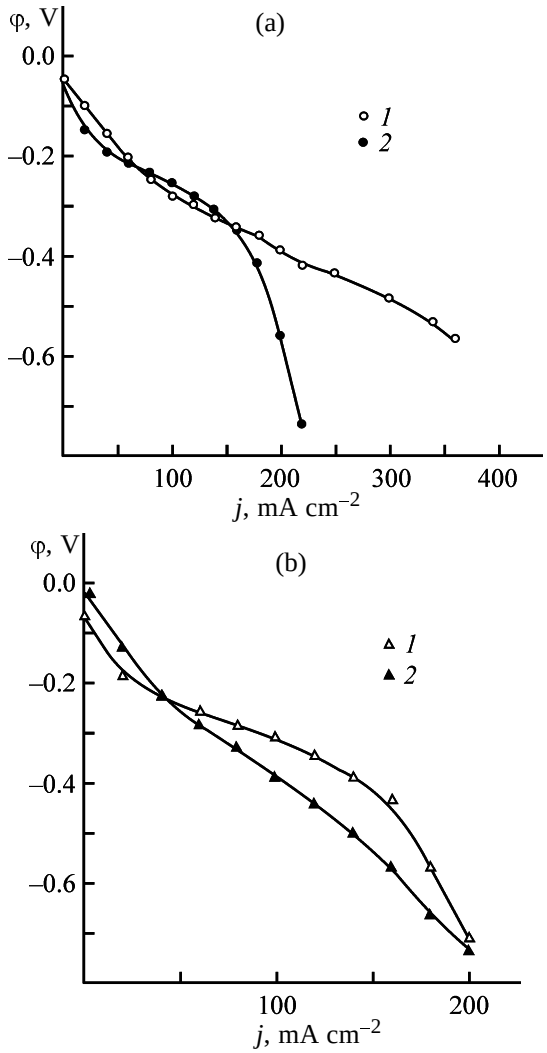

Fig. 4. Voltammetric curves of oxygen electrodes containing carbon nanotubes modified with (a) 50 and (b) 80% MnO_2 prepared by different procedures. $KMnO_4$ was reduced with (*1*) NT carbon and (*2*) formic acid.

electrochemical characteristics of electrodes with increasing MnO_2 content from 9 to 16.6 and 50% (Fig. 3, curves *1*–*3*) is probably due to the formation of uniformly distributed MnO_2 with the optimal structure. The decrease in these characteristics with increasing MnO_2 content to 80% is due to the nonoptimal structure and formation of excess manganese dioxide as a separate phase, which has no contact with NTs.

The effect of the procedure of MnO_2 preparation on the electrochemical properties is also of particular importance. The voltammetric curves of the electrodes containing NTs modified with 50% MnO_2 and prepared by reduction of NT suspension with formic acid and with NT carbon without formic acid are shown in Fig. 4a (curves *2* and *1*, respectively). The corresponding curves for the electrodes containing NTs modified with 80% MnO_2 and prepared by reduction of NT suspension with formic acid and NT carbon are shown in Fig. 4b (curves *2* and *1*, respectively). As seen from Figs. 4a and 4b, the electrochemical parameters of the electrodes prepared by reduction of $KMnO_4$ with NT carbon are higher than those of the electrodes prepared by reduction with formic acid. This is probably due to the fact that the reduction of $KMnO_4$ with NT carbon yields nanosize MnO_2 which coated directly the NT surface (Fig. 2a) and did not accumulate as a separate phase having no contact with the NT surface. In the case of reduction of $KMnO_4$ with formic acid, colloidal manganese dioxide particles are absorbed by NT to a certain limit (in our experiments up to 16.7% MnO_2). However, with the subsequent increase in the $KMnO_4$ content, excess MnO_2 is formed, which is not bound to the NT surface and thus deteriorates the electrode properties (Fig. 4b).

CONCLUSIONS

(1) Carbon nanotubes coated with the catalyst can be used as materials for fuel cells.

(2) Manganese dioxide deposited on the nanotube surface exhibits better electrochemical characteristics as a component of oxygen electrodes than does pure manganese dioxide.

(3) Oxygen electrodes prepared using nanotubes modified with 50% manganese dioxide exhibit the best voltammetric characteristics.

Received September 20, 2004

Abstract—The possibility of increasing the yield of target products and *para*-selectivity of toluene disproportionation on modified zeolites by optimization of their microporous structure was studied.

Benzene and xylenes (especially *p*-xylene) are widely used in industry. The main method of the synthesis of the above compounds is alkene dehydrocyclization. In the process, benzene (BZ) and xylenes (XLs) are formed together with large amounts of toluene (TL). Disproportionation of TL allows an increase in the production of BZ and XLs.

The TL disproportionation (TD) is an acid-type reaction and is catalyzed by H forms of zeolites [1, 2]. A study of TD on Y and M type zeolites and on pentasils showed that TD proceeds with the highest efficiency but with low selectivity on HY and on catalysts based on Y, with rapid deactivation of the catalysts. The catalysts based on mordenite are less active but more selective and stable than Y-based catalysts. The pentasil-based catalysts (ZSM-5) are less active but very selective and stable. They are also characterized by high selectivity for *p*-xylene (*p*-XL).

Thus, development of new zeolite catalysts of TD should involve either Y- and M-based zeolite catalysts or enhancing the activity of ZSM-5. Taking into account that mordenite catalysts are highly active, selective [3–5], have commercial application [6], and are more stable with respect to modification than Y, we believe that the synthesis of more selective and active M-based catalysts for TD is possible.

In this study, we examined the effects of modifying synthetic mordenite on the selectivity of TD and *p*-XL yield.

EXPERIMENTAL

Na-exchanged zeolites Y (Y), synthetic mordenite M (M), ZSM-5, and natural mordenite (NM) from Chananab deposit (Azerbaijan) were initial materials for the catalyst synthesis. The samples were synthesized by decationization of the initial zeolites by ion exchange with 2 M NH_4Cl followed by calcinations at 823 K and dealumination with 2.5 M HCl [7]. After these procedures, the SiO_2/Al_2O_3 ratio for M was determined by the method suggested in [8]. Then, the zeolites obtained were modified with a rare-earth element (REE) (Gd) by the ion-exchange procedure (0.5 mol % Gd_2O_3) and with a transition metal (Co) by ion-exchange impregnation (2.5 wt %). The modified zeolites were molded with a binding agent, alumina gel, taken in the amount of 25 g of Al_2O_3 per 100 g of dry catalyst.

The catalytic conversion of TL was studied at atmospheric pressure in a flow-type catalytic apparatus equipped with an adiabatic reactor. Experiments were performed within the 673–748 K range at the space velocity of 1 h^{-1} and H_2/toluene ratio of 3.

The products of TL conversion were analyzed chromatographically on a capillary column (50 × 0.25 mm) coated with liquid-crystalline phase, methoxyethoxyazobenzene (T = 360 K; carrier gas argon).

Adsorption properties of the catalysts were studied gravimetrically on a vacuum device equipped with a McBain quartz balance. Benzene was used as an adsorbate. Experiments were performed at 293 K within the range of relative pressures p/p_0 0–0.3. Isotherms of benzene adsorption on zeolites used as catalysts are related to type I isotherms in accordance with Brunauer classification and are well described by the Dubinin–Radushkevich equation [9]

$$\ln a = \ln W_0\rho - K[RT\ln(p_0/p)]^2,$$

where a is the amount of the adsorbate sorbed

* (EBZ) Ethylbenzene, (PMBZ) polymethylbenzene, and (AN) alkanes C_1–C_2.

(mg g^{-1}); ρ, adsorbate density (g cm^{-3}); and W_0, the volume of adsorption area (cm^3 g^{-1}), which is found by extrapolation of the isotherms obtained to $p_0/p = 1$.

In accordance with the theory of micropore volume filling TMVF [9], the parameter K related to the cross section of zeolite micropore inlets is calculated from the shapes of the Dubinin–Radushkevich isotherms obtained. The results listed in Table 1 show that BZ and XL are the main products of TD.

We also detected among the products ethylbenzene (EBZ), polymethylbenzene (PMBZ), and alkanes C_1–C_2 (AN). Formation and distribution of these products indicate that toluene transforms along different pathways. Large amounts of BZ and XL formed show that TD makes the prevalent contribution to TL transformations; other arenes and AN are formed by side reactions: XL disproportionation, realkylation, hydrodealkylation, etc., which are also acid-catalyzed reactions. As a result, the selectivity is an ambiguous quantity. For instance, when determining the selectivity for TD products found as the weight ratio of BZ + XL to converted TL, the fraction of benzene formed by TD and the conversion of TL are not quite clear because of the occurrence of XL disproportionation and hydrodemethylation, which is confirmed by the presence of the above-mentioned compounds among the conversion products. However, taking into account small amounts of trimethylbenzenes formed, whose participation in BZ and TL transalkylation is insignificant, we can consider the XL mole fraction in the product mixture as the initial value characterizing the TD selectivity.

Thus, the yields of toluene conversion products can be characterized by selectivities for target products, namely, for BZ and XL sum, and for TD. Taking also into account that *p*-XL is of particular significance among XLs [10], the selectivity for *p*-XL should be considered separately. The experimental yields of particular products are listed in Table 1, and quantities reflecting the selectivity for target products (BZ + ΣXL/TL conversion), for TD (molar ratio ΣXL/BZ), and for *p*-XL (γ = *p*-XL/ΣXL), in Table 2.

As follows from Table 2, the activity of cobalt–mordenite (CoM) catalysts weakly depends on the zeolite dealumination (5–8%). The same conclusion follows from the comparison of the selectivities of these catalysts. Such a behavior of Co–M systems is caused by the diffusion control of the TL conversion. This is confirmed by the independence of the catalyst activity in TD from temperature within the 673–748 K range. Hence, the TL conversion and product yields are, to a first approximation, limited by thermodynamic features of TL transformations and by the probable subsequent transformations of the molecules formed. The process control by diffusion of the reactant to active centers and of the reaction products from the reaction zone can be associated with molecular-sieve properties of zeolites. Such a dependence is known for H forms of the zeolites used [11].

It follows from Table 2 that the mole ratio of XL and BZ formed at 673 K is practically independent of the SiO_2/Al_2O_3 ratio in mordenite catalysts. As temperature is increased from 673 to 723 K, $\beta = \Sigma$XL/BZ corresponding to HM_{10} and HM_{30} samples decreases, whereas for HM_{25} it remains constant. It is interesting that γ characterizing *para*-selectivity for all these samples remains unchanged. Thus, in TL conversion, the distribution of disproportionation products weakly

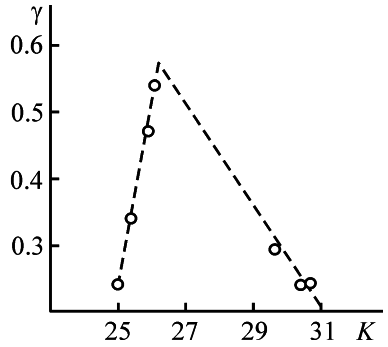
* (α) Toluene conversion. ** (S) Selectivity to BZ and XL.

depends on the temperature. Modifying HM_{25} with REE [M_{25}(I)] does not affect the TD selectivity. The TD selectivity increases by 10–11% only when HM_{25} is modified with Co and REE. At similar modifications of different zeolites, the TD selectivity depends on their nature (Table 2), similarly to unmodified zeolites [11]. These results demonstrate the influence of molecular-sieve properties of zeolites studied on the selectivity of TL conversion. However, whereas in the series of unmodified zeolites ZSM-5, HM, HY ZSM-5 is the most selective, after modifying with Co and REE the selectivity of this zeolite decreases and that of HM_{25}(II) increases. Then, the selectivity series becomes as follows: HM_{25}(II) > ZSM > HY.

The most substantial changes are observed for γ. As seen, the *p*-XL yield decreases with dealumination of the synthetic mordenite with other catalyst parameters remaining practically constant. Modifying of HM_{25} with REE also decreases *p*-XL yield. The modifications performed do not affect the activity of M catalysts, but favor attaining equilibrium distribution of isomeric XLs in TD [12]. Taking into account that enrichment of TD products with the "narrowest" XL isomer (i.e., *p*-XL) is associated with a decrease in size of zeolite micropores [11], the above-mentioned decrease in γ in the series of M catalysts can be attributed to an increase in the cross section of micropore inlets. In this case, modification of HM_{25} with Co and REE simultaneously gives an opposite effect. Hence, the substantial increase in the selectivity for TD and *p*-XL is associated with a decrease in the inlet cross section in modified HM_{25} as compared to the other HMs.

Table 2 allows comparison of the catalytic properties of zeolite samples in TL conversion in relation to the micropore inlet cross sections for various types of zeolites identically modified with Co and REE. It should be noted that, in the series HY, HM_{25}(II), HZSM-5, and HNM, the cross sections of the inlets to wide micropores of zeolites decrease. The comparison of the catalytic properties of samples prepared from these zeolites shows that only their activity in TL conversion varies in the same order. The other catalytic parameters listed in Table 2, in contrast to [11], show different trends. Thus, modifying with Co and REE substantially promotes only HM_{25}.

Previously Gnep *et al*. [13] suggested to use the sensitivity of XL transformation to zeolite microporous structure for identification of the nonmodified zeolite type. As mentioned above, the major pathway of TL transformation is disproportionation complicated by the further transformations of XLs formed. Therefore, ambiguous influence of the modification on the selectivity of TL conversion may be due to changes in microporous structure of the zeolites considered.



To estimate the effect of modification on the zeolite microporous structure, we studied the adsorption properties of the TD catalysts synthesized for BZ. The isotherms measured are well described by the Dubinin–Radushkevich two-parameter adsorption equation. The values of parameters are listed in Table 2 and can be interpreted in terms of TMVF [9]. In accordance with these data, only within the range of SiO_2/Al_2O_3 ratios from 10 to 25 the volume of adsorption space W_0 noticeable changes, with an increase in the catalyst activity by 4%. The further dealumination of HM_{25} to SiO_2/Al_2O_3 = 30 and modification with REE or REE + Co affects W_0 insignificantly; however, it should be noted that the catalyst

activities and W_0 vary similarly. Such a sensitivity of TL conversion to W_0 is an evidence of reactant interaction with active centers located in micropores. At the same time, whereas the selectivities S for the target products remains practically constant, i.e., independent of W_0, the HM_{25}(II) sample, in contrast to the other catalysts of HM series, exhibits higher selectivity for TD. The elevated selectivity for TD of this sample cannot by the result of somewhat elevated W_0 (Table 2).

In contrast to the quantities characterizing the selectivity of TD, the β-γ selectivity for *p*-XL is more sensitive to modification. High sensitivity of γ to modification is attributable to substantial difference between the kinetic diameters of *p*-XL (0.66 nm) and *o*-XL and *m*-XL (0.76 nm) [14]. Taking into account closeness of the kinetic diameters of BZ, TL, and *p*-XL, we can suggest that the diffusion of the reactant to active centers and of products (*p*-XL and BZ) from the reaction zone follows the same relationships, whereas large kinetic diameters of *o*-XL and *m*-XL can complicate removal of these products from the reaction zone. Hence, the yield of products of TL transformations on zeolite catalysts depends on the cross section of zeolite micropore inlets. Also, apparently, depending on inlet cross sections, the cases are possible when the internal space of micropores is inaccessible to reactant (HNM), or, vice versa, *o*-XL and *m*-XL will freely escape from the reaction zone (zeolite of HY type).

Table 2 shows that modification of HMs affects the adsorption parameter *K*. This parameter, related to the diameter of zeolite micropore and channel inlets, increases with dealumination and decreases with introduction of REE. At the same time, introduction of Co into the sample containing REE increases *K*. However, in this case, *K* (0.027) is less than in the absence of REE (0.029). The comparison of the adsorption parameter *K* with the catalytic parameter γ shows that *K* corresponding to maximal γ has an intermediate value in the series of modified HMs studied. This indicates that there is some optimal diameter of micropore inlet, favoring selective TD and elevated yield of *p*-XL.

To comment upon this suggestion, let us consider the results of TL transformation on a series of catalysts prepared from various types of zeolites. In the series HY, HZSM, and HNM, the highest *para*-selectivity γ is shown by HZSM. At the same time, wide-pore zeolite HY (W_0 = 0.165 $cm^3\ g^{-1}$) and narrow-pore HNM (W_0 = 0.021 $cm^3\ g^{-1}$) exhibit approximately equal *para*-selectivity. Obviously, in this case,

para-Selectivity of toluene transformation γ as a function of the parameter *K* of Dubinin–Radushkevich adsorption equation.

the above effect of the loss of molecular-sieve properties takes place because of *o*-XL and *m*-XL free diffusion from the reaction zone (for HY) or, vice versa, inaccessibility of the inner pore space to TL (for HNM). On the one hand, due to this effect the HY activity is the highest and that of HNM is the lowest. On the other hand, the *para*-selectivity of HNM is close to that of HY, and selectivity for TD, to that of HZSM. The above-mentioned coincidence of HNM an HZSM properties in TD and the difference in the behavior of the HY sample may be due to features of the subsequent XL transformations on these catalysts. As shown in [15–17], TD proceeds on HNM and HZSM in the surface layer and on HY, inside micropores.

In the series of catalysts prepared from various types of zeolites, an HM_{25}(II) sample stands out by higher selectivity in TD and *p*-XL formation, and in the activity it is inferior only to HY. In view of the above reasonings, high activity of this sample can be associated with accessibility of the inner volume of mordenite micropores. It is seen from the comparison of W_0 values that these pores are larger than the pores of HZSM and smaller than the pores of HY. Probably, the structure of HM_{25} pores is such that side transformations of TL are sterically hindered and diffusion of BZ and *p*-XL is easier compared to HZSM. Indeed, the adsorption parameter *K* of of Dubinin–Radushkevich equation occupies an intermediate position between the values of this parameter for HY and HZSM (Table 2). Thus, the selectivity in *p*-XL formation is governed by the size of inlets to wide pores of zeolites and thus can be characterized by the parameter *K* of Dubinin–Radushkevich adsorption equation. The dependence of the parameter γ on *K* is shown in the figure. As seen, the γ–*K* curve consists of two branches. The left branch corresponds to worsening of molecular-sieve properties due to a decrease in accessibility of zeolite micropores to the reactant, and the right

branch corresponds to worsening of molecular-sieve properties because of easier diffusion of large molecules of products (*o*-XL and *m*-XL) from the reaction zone in micropores. Intersection of these branches corresponds to the maximum possible *para*-selectivity and hence to the optimal microstructure of zeolite catalyst for TD.

CONCLUSIONS

(1) The selectivity of toluene conversion is governed by two cross sections of micropore inlets in zeolite catalysts: the lower limit is dictated by diffusion of the reactant to active centers located in micropores, and the upper limit, by removal of larger products from the reaction zone.

(2) The yield of the target products of toluene conversion and selectivity of TD on modified zeolites can be increased by optimization of their microporous structure.

Abstract—The effect of impregnation in aqueous solutions of $AgNO_3$ and subsequent calcination of manganese oxide surface structures produced on a titanium substrate by plasma-electrolytic oxidation on their catalytic activity in oxidation of CO was studied.

The most efficient catalysts for catalytic oxidation of CO are precious metals [1]. However, these metals are expensive and their pretreatment is complicated. Therefore, a considerable attention is given to formation processes and properties of catalysts based on compounds of nonprecious metals and, in particular, oxides [2]. Recently, composite structures containing a metal with a deposited oxide layer and a catalytically active additive have been finding increasing use [3, 4]. An important advantage of the composites of this kind is the high thermal and electrical conductivity of the substrate.

Manganese oxides are among the most active oxidation catalysts [5, 6]. Manganese oxides are, as a rule, deposited onto metals by pyrolytic and electrochemical methods [7, 8].

Oxide systems of various compositions with a developed surface can be formed on metals by plasma-electrolytic treatment (PET) [9]. A specific feature of this technique is that high-temperature reactions occur on local areas of the surface under the action of electric discharges. These reactions include thermolytic transformations of solution components at the anode and incorporation of the forming insoluble compounds into the surface structures. In many cases, the film thus formed is a "sandwich" constituted both by oxides of a metal being treated and by compounds based on electrolyte components.

Recently, conditions (electrolytes, modes) have been suggested under which layers containing compounds of bi-, tri-, and polyvalent metals can be formed by plasma-electrolytic oxidation on rectifying metals [10–12]. In particular, manganese oxide layers with a layered structure ($Ti/TiO_2/Mn_2O_3–Mn_3O_4$) have been obtained on titanium in aqueous electrolytes containing $Na_2B_4O_7$ and $Mn(CH_3COO)_2$ [10–12]. The content of manganese in the surface layer (2 to 60 wt %) and the morphology of the resulting oxide structures depend both on the concentration of manganese acetate in the electrolyte and on the formation conditions. These PET films on titanium catalyze CO oxidation at temperatures in the range 200–350°C [13]. The catalytic activity of structures of this kind compares well with that of manganese oxide layers obtained on the surface of titanium by the conventional pyrolytic method. The rate of CO conversion by the anodic structures formed depends on their content of manganese.

It is known [14–17] that addition of silver to certain metal oxides markedly improves their catalytic properties. In addition, silver is relatively accessible, compared with other precious metals. In this study we examined the influence exerted by silver additives on the composition and catalytic properties of manganese oxide films formed on titanium by plasma-electrolytic oxidation.

EXPERIMENTAL

Oxide layers were formed on $0.5 \times 2.5 \times 0.08$ cm^3 titanium (VT1-0) plates. The samples were preliminarily chemically polished in a mixture of concentrated acids ($HF : HNO_3 = 1 : 3$) at 60–80°C for 2–3 s, washed with distilled water, and dried in air.

The oxidation was done in an electrochemical cell in the form of a 0.5-l glass vessel. A hollow stainless

Composition and catalytic activity of Ag,MnO_x oxide layers on titanium

Sample no.	c_{AgNO_3}, M	T_{cal}, °C	Elemental composition, at. %	Phase composition	Maximum conversion α_{CO}, %	T_{50}, °C
1	–	300	17.3 Mn, 1.9 Ti	Mn_3O_4	97 (350°C)	218
2*	1×10^{-4}	300	0.2 Ag, 17.4 Mn, 26.7 Ti	Mn_3O_4	58 (400°C)	319
3	1×10^{-3}	300	1.0 Ag, 26.0 Mn, 35.0 Ti	Mn_3O_4**	64 (350°C)	260
4	1×10^{-2}	300	0.8 Ag, 17.8 Mn, 8.1 Ti	Mn_3O_4**	80 (350°C)	250
5	1×10^{-1}	300	4.6 Ag, 15.0 Mn, 3.2 Ti	Mn_3O_4**	100 (215°C)	180
6	1×10^{-1}	300	7.1 Ag, 20.0 Mn, 1.7 Ti	Mn_3O_4**	100 (200°C)	162
7	1×10^{-1}	400	0.3 Ag, 21.0 Mn, 14.0 Ti	Mn_2O_3	77 (450°C)	388
8	1×10^{-1}	500	2.8 Ag, 17.2 Mn, 10.6 Ti	Mn_2O_3	70 (450°C)	378

* Kept in an $AgNO_3$ solution for 1 h (sample nos. 2–5, 7, 8) and 24 h (sample no. 6).
** Presence of the indicated phase is possible.

steel cathode, fabricated in the form of a coil simultaneously serving as a condenser, was placed within the vessel. The electrolyte composed of 0.1 M $Na_2B_4O_7$ and 28.8×10^{-3} M $Mn(CH_3COO)_2$ was agitated with a magnetic stirrer. The electrolytes were prepared from commercial chemicals of chemically pure grade and distilled water.

The oxide structures were formed under galvanostatic conditions at a constant current density I = 0.2 A cm^{-2} in the course of 4 min, with a thyristor power source of the TEP4-100/460H type with unipolar current pulses. After the PET treatment, the samples were washed with distilled water and dried in air at room temperature.

Silver was introduced by impregnating the manganese oxide layers obtained in 0.0001–0.1 M aqueous solutions of $AgNO_3$ for 1 h. After the impregnation, the samples were calcined in air in a muffle furnace at 300 to 500°C for 4.5 h.

Data on the phase composition of the surface structures were obtained with a DRON-2.0 X-ray diffractometer (CuK_α radiation), and the elemental composition was determined with a JXA-5A X-ray fluorescence microanalyzer (Japan).

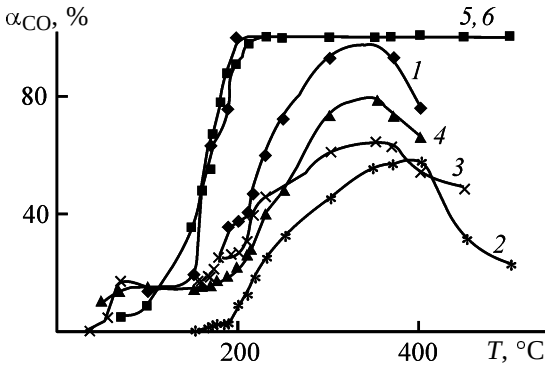

Fig. 1. CO conversion α_{CO} vs. the reaction temperature T in the presence of $Ti/TiO_2/MnO_x,Ag$ structures. Silver content c_{Ag}, at. %: (*1*) 0, (*2*) 0.2, (*3*) 1.0, (*4*) 0.8, (*5*) 4.6, and (*6*) 7.1.

The catalytic activity of the samples was determined on a BI-CATflow universal flow-through catalytic installation (manufactured by the Institute of Catalysis, Siberian Division, Russian Academy of Sciences). Finely cut samples (~$1.0 \times 1.0 \times 0.8$ mm^3) with a total area before cutting of 16 cm^2 were placed in the active zone (d = 0.9 cm, h = 3 cm) of a tubular quartz reactor. The gas flow rate was 50 ml min^{-1}. The starting reaction mixture contained (%) Ar 75, O_2 20, and CO 5.

The content of CO at the reactor outlet was determined with an LKhM-8MD chromatograph with a thermal conductivity detector. Analysis parameters: length of a column with Ca5A molecular sieves, 1 m; inner diameter of the column, 3 mm; detector current, 75 mA; flow rate of the carrier gas, 20 ml min^{-1}.

The table and Fig. 1 present data on the phase and elemental compositions and the results obtained in a study of the catalytic activity of TiO_2/MnO_x structures formed by the PET method on titanium, impregnated with $AgNO_3$ solutions, and then calcined. The catalytic activities of the samples were compared on the basis of temperatures of 50 and 100% conversions of CO into CO_2, T_{50} and T_{100}, respectively. It can be seen that the elemental composition of calcined oxide layers depends on the concentration of $AgNO_3$ used to impregnate the samples. A considerable difference in the titanium content is observed between the surface layers being analyzed in the samples under study: starting sample (no. 1, without calcination) and those impregnated in dilute solutions and calcined (nos. 2, 3). As the concentration of $AgNO_3$ increases, the con-

tent of titanium in the layers decreases and approaches that in the starting sample, whereas the content of silver grows. In all of the samples studied, the concentration of manganese does not change so significantly (within 15–26 at. %). According to the results of an X-ray phase analysis, the oxide films contain crystalline manganese oxide and no crystalline compounds of silver and titanium.

The table and Fig. 1 show that impregnation of the samples in dilute silver nitrate solutions, followed by calcination, impairs their catalytic activity. For example, the half-conversion temperature T_{50} is 218°C for the starting sample (no. 1) and increases to 319°C for samples containing a minor amount of silver. If the concentration of the impregnating solution is raised further, with the corresponding increase in the content of silver and decrease in that of titanium in surface structures, the catalytic activity increases. For example, T_{50} is 180°C at a silver content of 4.6 at. %.

The type of the temperature dependence of the CO conversion α_{CO} is also determined by the content of silver, c_{Ag}, in the manganese oxide layers (Fig. 1). The conversion of CO into CO_2 reaches 100% at 200°C for a sample with c_{Ag} = 7.1 at. % and at 215°C for that with c_{Ag} = 4.6 at. % and remains at this level up to 500°C. At a lower c_{Ag} (0.2–1.0 at. %) in the manganese oxide layers, 100% conversion is not reached in the temperature range under study under the given experimental conditions. Moreover, the maximum CO conversion α_{CO} decreases as the reaction temperature becomes higher. It should be noted that the dependence $\alpha_{CO} = f(T)$ exhibits a similar behavior for a manganese oxide catalyst without silver additives (Fig. 1, curve *1*).

The effect of the calcination temperature on the phase and elemental composition and the catalytic activity was studied for TiO_2/MnO_x, Ag layers (see table, sample nos. 5, 7, and 8; Fig. 2). Raising the calcination temperature from 300 to 500°C leads to changes in the phase composition: layers calcined at high temperatures contain crystalline Mn_2O_3, rather than Mn_3O_4. In addition, the content of titanium in the surface part of the layers, which is analyzed, increases, that of silver decreases, and that of manganese changes only slightly. Simultaneously with the increase in the amount of titanium in the surface layer, the catalytic activity of the systems under study decreases, as it also does when the amount of titanium increases because of changes in the impregnation conditions (sample nos. 2–6). Consequently, raising the calcination temperature of TiO_2/MnO_x, Ag layers on titanium from 300 to 500°C impairs their catalytic activity.

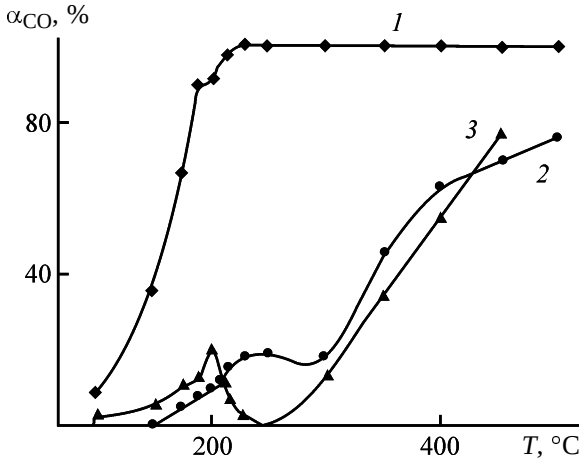

Fig. 2. CO conversion α_{CO} vs. the reaction temperature T in the presence of $Ti/TiO_2/MnO_x$, Ag structures calcined at (*1*) 300, (*2*) 400, and (*3*) 500°C. Concentration of the impregnating solution 0.1 M.

The results obtained demonstrate that introduction of silver affects the catalytic properties of the manganese-containing oxide structures on titanium, studied here. However, the nature of this influence differs from the known dependences for bulk oxide catalysts of the MnO_x type.

It is known [14–17] that introduction of silver into transition metal oxides improves their catalytic properties. In particular, bulk samples obtained by coprecipitation of manganese and silver nitrates were studied in [17]. It was shown that addition of minor amounts of silver (up to 5 mol %) enhances the catalytic activity of MnO_x in CO oxidation. For example, the half-conversion temperature of CO, T_{50} is 430°C for silver and 180°C for MnO_x, being as low as 73°C for Ag(5%)/MnO_x. However, raising the silver content to 10–20 mol % impairs the activity of the catalyst. Lin *et al.* [17] believe that, at a low content of silver, it interacts with manganese oxide with a synergistic effect, which is responsible for the high activity of this system at low temperatures.

Introduction of minor amounts of silver (0.2–1.0 at. %) into preliminarily formed manganese oxide layers on titanium leads to a decrease in the catalytic activity. This is manifested in that the half-conversion temperature increases from 218 to 319°C.

Introduction of silver improves the catalytic properties and leads to a decrease in T_{50} and to a change in the run of the $\alpha_{CO} = f(T)$ curves beginning at its content in the surface layer exceeding 4 at. % (see table,

Fig. 1). This is presumably due to the fact that the structures under study are complex systems containing not only catalytically active compounds, but also compounds of titanium and, in particular, TiO_2, which is low-active in oxidation of CO [18].

As the characteristic feature of most of silver compounds is that they are readily reduced to metal [19], silver is, in all probability, present in the surface layers studied in the form of metal particles. The radii of both the Ag atom (0.1445 nm) and Ag^+ ion (0.1011 nm) rather strongly differ from those of manganese ions (Mn^{2+}, 0.083 nm; Mn^{4+}, 0.052 nm [20]), and, therefore, formation of solid solutions is unlikely. Formation of silver oxide Ag_2O via decomposition of silver nitrate is virtually impossible, because this oxide is unstable an readily decomposes at temperatures exceeding 100°C [19].

It follows from the data obtained (see table) that the variation of the catalytic properties correlates with that of the titanium content in the surface layer: as the titanium content increases, the catalytic activity falls. The amount of titanium depends on the annealing temperature and on the concentration of the impregnating solution. The content of titanium in the oxide layers presumably changes as a result of impregnation and the subsequent annealing because of the thermal diffusion of titanium from deep in the film toward its surface. It is noteworthy that an increase in the content of titanium was also observed on annealing the starting, unimpregnated, samples [13]. In addition, raising the annealing temperature also leads (see table, sample nos. 5, 7, 8) to an increase in the content of titanium in the surface layers. Simultaneously, the content of silver in the surface layers tends to decrease, i.e., silver moves deeper into the layer. Thereby, the number of catalytically active centers on the surface of the structures under study becomes smaller.

Because the concentration of manganese in the surface layer changes only slightly, the diffusion of titanium and silver presumably occurs mainly via pores and cracks. However, it is unclear in this case why the surface part of the films is not enriched with titanium after their impregnation in concentrated $AgNO_3$ solutions. In addition, it is not improbable that the surface layer dissolves in dilute silver nitrate solutions, with areas of metallic titanium appearing on the surface. Also, partial deactivation of the catalysts may be due to the possible formation (crystallization), upon annealing, of spinel compounds of the Mn_2TiO_4 type in the surface layer. Compounds of this kind have been found in manganese oxide structures formed on titanium by the PET method in electrolytes containing manganese polyphosphate and acetate [21], sodium tetraborate and manganese sulfate [12], and sodium sulfate and manganese acetate [22].

CONCLUSIONS

(1) Silver introduced in minor amounts (up to 1 at. %) impairs the catalytic activity in CO oxidation of manganese oxide layers formed on titanium by plasma-electrolytic treatment, and that present in larger amounts (4–7 at. %) enhances the catalytic activity of these layers.

(2) At an approximately invariable content of manganese, the activity of the catalyst depends on the silver/titanium ratio in the surface layer: the larger this ratio, the higher the catalytic activity.

(3) The maximum activity was found for Ti/TiO_2, MnO_x, Ag structures fabricated by impregnation of manganese oxide layers in 0.1 M $AgNO_3$ with subsequent annealing at 300°C.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Determination of Nitrate Concentration in Natural Waters

V. Rutkoviene, V. Grazuliaviciene, L. Cesoniene, and A. Kusta

Lithuanian Agricultural University, Kaunas region, Lithuania

Received August 11, 2005

Abstract—Three methods of determining nitrate ion concentration in natural waters, namely, the potentiometric method, the spectrophotometric method using sodium salicylate, and the spectrophotometric method using 4-fluorophenol after distillation, are compared. Factors influencing the accuracy and reproducibility of the measurements are determined, and the statistical evaluation of the results obtained is given.

Nitrates are an inherent component of natural water. The amount of nitrates in surface waters is usually insignificant, but their concentration in subsoil waters is high [1]. In rural places, the inhabitants most often use water from dugout wells. Water enters dugout wells from subsoil aquifers which are the least protected from the surface pollution. Therefore, it is extremely susceptible to chemical and microbiological pollution [2]. The subsoil water is most often polluted with nitrates, and their concentration exceeds the background concentration in the nature [3–5].

An increase in the water pollution with nitrates makes it necessary to monitor the quality of potable water, to estimate the influence of the environmental factors on the water quality, and to determine how these compounds enter the natural water sources. Reliable and efficient methods of determining the nitrate concentration in water are necessary for these studies. Since the concentrations of nitrates in natural waters are essentially different, it is important to select procedures suitable for a wide concentration range. Potentiometric, voltammetric, polarographic, and spectrophotometric methods are used for determining nitrate concentrations [6, 7]. The spectrophotometric methods are based on the reaction of nitrates with certain reagents and on the measurement of the optical density of a light-absorbing solution of a colored compound formed in the reaction. Phenoldisulfonic acid, sodium salicylate, 4-fluorophenol, and 2,6-dimethylphenol are used to obtain colored compounds [8–11]. The spectrophotometric methods of determining nitrate concentrations with phenoldisulfonic acid and sodium salicylate are used in the analysis of potable and surface waters. These methods allow the nitrate concentrations of 2.0 and 25 mg l^{-1}, respectively, to be determined in an undiluted sample. In the case of high nitrate concentrations, samples must be diluted, which can affect the accuracy of the measurements. The nitrate concentrations of up to 250 mg l^{-1} in water are determined by the spectrophotometric method using 4-fluorophenol without diluting a water sample.

When selecting a method, we must take into account not only the nitrate concentration, but also the presence of other ions in water under study. The presence of chlorides, nitrites, sulfates, and other ions can affect the accuracy of the measurements.

The accuracy of the method depends on the characteristics of devices in use. For example, when determining the nitrate ion concentration potentiometrically, the sensitivity and selectivity of the electrodes in use determine the accuracy of the measurements to a large extent.

The aim of this study was to assess the expediency of using various methods of determining nitrate concentrations in natural waters and to examine how specific features of a particular method and concomitant ions affect the accuracy and reproducibility of the results.

EXPERIMENTAL

We determined nitrate concentrations by the following methods.

(I) Spectrophotometric method with sodium salicylate [6, 8]. To construct a calibration plot, we used reference solutions with nitrate concentrations from 0.1 to 10 mg l^{-1}. We measured the optical density of the solutions using a Genesys 5 spectrophotometer at a wavelength of 410 nm. We used cells with a layer thickness of 1 and 5 cm.

147.0	I	100	147.2	145.9–148.4	2.2	0.13
	II	–	147.1	146.2–147.9	1.4	0.04
	III	–	133.8	126.1–141.4	4.8	–9.01

(II) Spectrophotometric method with 4-fluorophenol after distillation [9]. To construct a calibration plot we used reference solutions with nitrate concentrations from 8 to 200 mg l^{-1}. We measured the optical density at a wavelength of 430 nm. We used cells with a layer thickness of 1 cm. We uased a UDK 130 D apparatus for steam distillation and a Genesys 5 spectrophotometer. Chloride and nitrite ions interfere with the determination of nitrate concentrations by the above methods.

(III) Potentiometric method [7]. To calibrate the device, we used solutions with nitrate concentration from 5 to 250 mg l^{-1}. We used 1 M solution of ammonium sulfate to support a constant ionic strength of the solution. Measurements were made with a 692 METROHM AG CFH-9101 Herisau pH-meter. Chlorides, nitrites, sulfates, and bromides are interfering ions.

As the subjects of the study we used model solutions and water of the dugout wells. We used sodium nitrate (analytically pure grade) dried at 110°C for 2 h to prepare model solutions containing 12.0, 54.7, 77.0, 100.0, and 147.0 mg l^{-1} nitrate ions. For each water sample we carried out five replicate determinations.

We determined the concentration of interfering ions by the following methods: the concentration of nitrites, by the spectrophotometric method and the concentration of chlorides, by titration with a silver nitrate solution [12, 13].

Studies with model solutions free from foreign ions make it possible to evaluate more accurately the effects exerted on the measurement accuracy by the cell nonuniformity, dilution, and other factors associated with the sample preparation.

The statistical evaluation of the determination results, performed using the Statistica program, is given in Table 1. It is seen that the most reproducible results were obtained in the potentiometric determination of the nitrate concentrations. This is due to the simplicity of the method and of the technique of the water sample preparation. Spectrophotometric methods are characterized by larger standard deviations, because of the errors introduced during the preparation of water samples for the analysis (dilution, distillation) and in measurement of the optical density.

When using spectrophotometers with holders for several cells, the optical density of several samples can be determined simultaneously (seven samples in the case of Genesys 5). In this case, the measuring errors may arise from the nonuniformity of the cells: although they are of the same thickness, they are not identical. To reveal the influence of the cell nonuniformity on the measurement accuracy, we measured the optical density of each water sample in seven different cells of the same length. We used cells with a layer thickness of 1 cm. Thus found nitrate concentrations are given in Fig. 1, and standard deviations for these measurements, in Fig. 2. The greatest scattering of the results is observed when determining nitrate

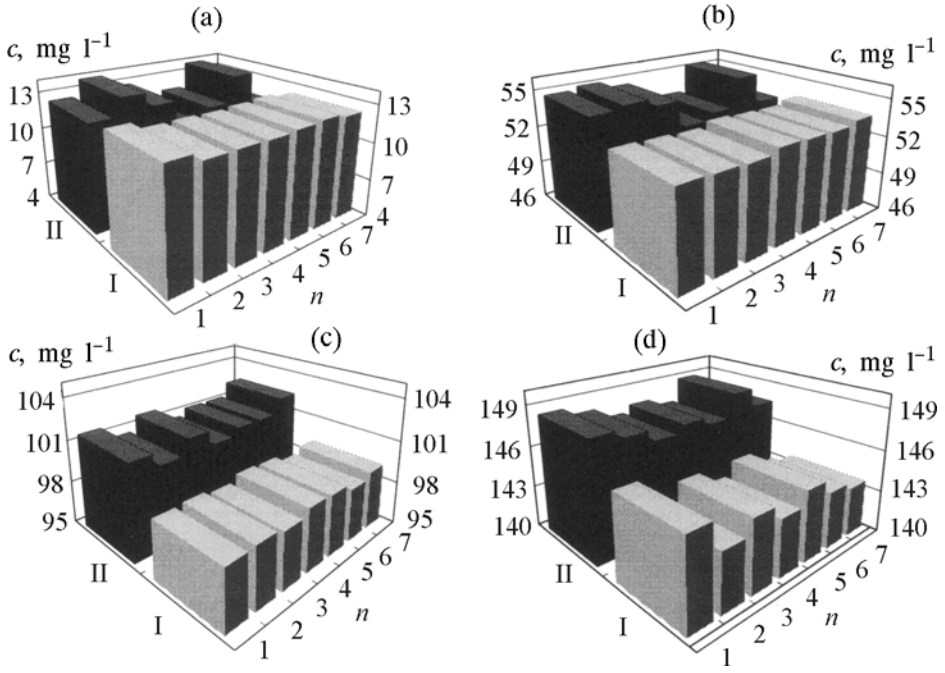

Fig. 1. Nitrate concentrations determined by measuring optical density with seven different cells, *n*, with a layer thickness of 1 cm. (*c*) Measured concentration of nitrates in model solutions. Actual concentration, mg l^{-1}: (a) 12.0, (b) 54.7, (c) 100.0, and (d) 147.0; the same for Fig. 2. Method: (I) with sodium salicylate and (II) with 4-fluorophenol after distillation.

concentrations with 4-fluorophenol. When determining the nitrate concentration with sodium salicylate, the nonuniformity of the cells affects the reproducibility of the results only slighly.

The difference between the standard deviations given in Table 1 and in Fig. 2 for the method using sodium salicylate demonstrates the effect of dilution on the reproducibility of the results, since we diluted water samples by factors of 10, 50, and 100 when determining of concentration of nitrate ions by this method. The largest standard deviation was obtained at 100-fold dilution of the sample.

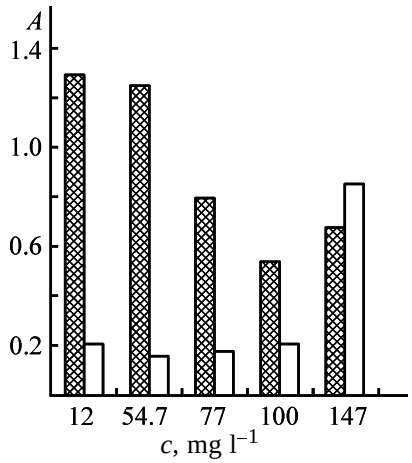

Fig. 2. Standard deviations *A* of nitrate concentrations *c* determined in seven different cells with a layer thickness of 1 cm: (left bars) with 4-fluorophenol and (right bars) with sodium salicylate.

As seen from these data, the spectrophotometric method is the most accurate. However, when selecting a reagent, we must take into account the concentration of nitrates in water. At relatively high nitrate concentrations in water, the most reliable results are obtained with 4-fluorophenol. The spectrophotometric method with sodium salicylate is also suitable for the determinations in a wide concentration range. In this case, the choice of the optimal procedure for the sample dilution substantially increases the reproducibility of the measurements.

The largest deviations of the found concentrations from the actual values are observed with the potentiometric method.

The results of determining nitrate concentrations in water of ten dugout wells and the concentrations of interfering ions (nitrites and chlorides) are given in Table 2. The concentrations of nitrate ions in water of dugout wells lie in the range 4–200, and the concentrations of nitrites, in the range 0.013–0.225 mg l^{-1}. Such a ratio of nitrate and nitrite concentrations is typical for the most part of natural waters, including also water from dugout wells. This is confirmed by the results of long-term studies [14]. The determina-

			III	–	6.4	6.2–7.2	0.2

tion of the nitrate ion concentration by spectrophotometric methods gives overestimated results when the content of nitrites is higher than 0.7 mg l^{-1} [8]. Thus, the presence of nitrites in the amounts typical for natural waters does not affect the accuracy of determining nitrates.

The concentration of chlorides in waters under study is 28–142 mg l^{-1}. When determining the concentration of nitrates (by the method using 4-fluorophenol), we added a solution of tin(II) sulfate to water samples to neutralize the influence of chlorides. For the method using sodium salicylate, the presence of chlorides has no effect on the measurement results.

The concentrations of nitrates measured potentiometrically appeared to be lower than the concentrations determined by the spectrophotometric methods, which is also the case with model solutions.

CONCLUSIONS

(1) Concentration of nitrates in water under study must be taken into account when selecting a method for determining the nitrate concentration in natural waters.

(2) The spectrophotometric method using 4-fluorophenol after distillation is acceptable for determining high nitrate concentrations (>20 mg l^{-1}). However, attention must be paid to the factor of nonuniformity of cells when using spectrophotometers with multicell holders.

(3) The spectrophotometric method using sodium salicylate is more versatile, but it is necessary to select the optimal procedure for diluting a water sample.

(4) The potentiometric method is less reliable, but it gives the most reproducible results; this method is

appropriate for measurements requiring no special accuracy.

(5) The presence of chlorides and nitrites in natural water does not substantially affect the measurement accuracy.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Foam Separation of Nickel and Copper Ions from Dilute Aqueous Solutions

S. A. Levichev and O. L. Lobacheva

Received June 3, 2005

Abstract—The minimal expenditure of anionic surfactant, sodium dodecyl sulfate, required for decreasing concentrations of nickel and copper ions to the maximum permissible concentration was determined experimentally. A possibility of selective recovery of nickel ions by foam separation with sodium dodecyl sulfate under conditions of complex formation of copper cations with thiosulfate anions was studied.

The maximum permissible concentrations (MPCs) for nickel and copper cations in water are steadily decreased. Fairly recently they were 0.1 mg l^{-1} for nickel and 1.0 mg l^{-1} for copper [1]. The problems of recovery of salts of these metals from wastewaters were solved by precipitation flotation [2–5], flotation with a carrier [6], and foam separation [7–9].

Here we present the results of experiments on foam separation of dilute aqueous solutions containing copper and nickel salts both separately and in combination, aimed to determine the expenditure of surfactant, sodium dodecyl sulfate (SDS), and assess the possibility of separate recovery of these cations.

One of the mechanisms of foam recovery of ions from dilute aqueous solutions is ion exchange [10, 11]. Due to adsorption on the bubble walls, a layer of surface-active ions is formed. In the case of anionic surfactants these are anions and in the case of cationic surfactants, cations. These adsorption layers attract counterions. As a result, diffusion layers of counterions held by Coulomb interaction are formed. The content of a certain type of counterion is governed by its valence and concentration in the solution. The experimental data on the influence of ions on the surface tension of aqueous solutions of SDS far from critical micellization concentration (CMC) showed that, with increasing valence of ion, the surface activity of cations increases [12]. For ions of the same valence, the activity is approximately the same. The increase in the probability of penetration into the diffusion layer due to a high concentration of SDS in solution suggests that in foam separation it is necessary to decrease the SDS concentration.

To check this assumption, the foam recovery of copper and nickel cations was carried out as follows. A glass vessel was charged with 700 ml of a 0.001 M solution of copper or nickel sulfate or both salts. The solutions were prepared gravimetrically from crystal hydrates of analytically pure grade; the concentrations of the solutions were checked by EDTA titration. A disc-shaped bubbler presenting a porous plate from microporous plastic with a pore size of 33 μm was placed on the vessel bottom. Air (or nitrogen) was passed through this plate into the solution; the flow rate was controlled with a fine adjustment valve. A 0.05 M SDS solution was fed into the solution in 5-ml portions, so that the highest concentration of surfactant in the solution to be treated did not exceed 0.005 M, i.e., it was lower than the CMC. The next portion of SDS solution was added only after the solution lost the ability to form stable foam as a result of transition of the surfactant to the foam. The resulting foam was subjected to drainage in a glass vertical tube 30 mm in diameter, to avoid the loss of the "outgoing" solution. Due to gravity drainage, the dry transparent foam was withdrawn; in so doing, the solution weight did not change noticeably. With decreasing foam-forming power of the solution, the height of the drainage column was decreased removing its separate units. After addition of SDS to the solution in the equimolar amount relative to the salt in the solution, the solution was analyzed for content of SDS and copper and nickel ions.

The SDS concentration was determined by potentiometric titration with an ion-selective electrode for ionic surfactants. A 1.2×10^{-4} M solution of a cationic surfactant, cetyltrimethylammonium bromide of

pure grade produced by Chemapol, was used as a titrant. The relative titration error was 2%.

The concentration of cations was determined by atomic adsorption spectroscopy (AAS). The measurements were carried out on an AASIN atomic adsorption spectrometer. Lamps with hollow cathodes were used as a source of radiation. The operating wavelength for copper was 324.75 nm, and the sensitivity, 0.1 mg l^{-1}. The wavelength for nickel was 232.0 nm, and the sensitivity, 0.12 mg l^{-1}. The determination error was 15%. The average nitrogen flow rate was 3.3×10^{-4} m^3 h^{-1}. The foaming process was carried out for 60 h.

Since the MPC for nickel is 10 times lower than that for copper, in its recovery we used the double amount of SDS relative to the salt (on the molar scale).

The long duration of the process was caused by the need to lose no solution as a result of foaming, which was provided by prolonged gravity drainage. Compulsory drainage by suction of the liquor from the foam can undoubtedly make the process shorter. The MPC was reached for both copper and nickel. The residual concentration of copper was approximately 1.0 mg l^{-1}, and that of nickel, approximately 0.1 mg l^{-1}. Both concentrations lie at the boundary of applicability of atomic adsorption spectrometry. With a further increase in the concentration of SDS added and in the foaming duration we can reach such concentrations of cations that are governed by their content in the solution used.

As a result of foaming, the solution gets salinized with sodium sulfate. The concentration of this salt in the final solution was not determined. The residual concentration of SDS in this method cannot be lower than the boundary of foaming and was 10 mg l^{-1}. The experiments showed that the expenditure of SDS expressed in moles for recovery of 1 mol of copper was 1.5, and for 1 mol of nickel, 2. The residual concentration of SDS and its expenditure can be undoubtedly reduced using flotation extraction with an organic layer incapable to absorb SDS [13, 14]. In this process, foaming is not required and one portion of SDS is repeatedly used as ion exchanger at the walls of gas bubbles.

The study of surface characteristics and foam separation of the solutions of the mutual system [12]

$$Na^+,\ Co^{2+},\ Ni^{2+} \parallel DS^-,\ SO_4^{2-} - H_2O$$

(DS^- is dodecyl sulfate ion) showed that both surface characteristics and ability to pass into foam for bivalent cobalt and nickel cations do not differ. Foaming did not affect the concentration ratio of cations in the solution. Of course, the concentrations decreased down to the MPC; however, no selectivity of recovery was found. Therefore, in solving problem of selective recovery of nickel, we used a well-known method: masking of one of the cations by complex formation [15].

It is well known that copper cation is able to form complex anion in the reaction with sodium thiosulfate. It was shown previously [15] that copper(II) ions can form with thiosulfate ions three stable complexes of different compositions. The copper thiosulfate complex is stable in the region of pH 4.5. However, when a solution contains a large amount of ammonium chloride or nitrate, the stability of the complex decreases and even at pH 8–9 copper(II) ammoniate is formed and thiosulfate begins to decompose to release sulfur. It was noted that, when borate or ammonium acetate buffer solution is used, the copper thiosulfate complex is stable for several hours.

In one series of the solutions copper and nickel ions were recovered simultaneously without separation. In foaming of other series of the solutions containing copper(II) and nickel(II) ions, we attempted

to recover only nickel ions and retain copper ions in the solution in the form of a thiosulfate complex. Before foaming, ammonium acetate buffer solution (to obtain pH 8.5–9.5) and $Na_2S_2O_3$ were added to the solution. To 650 ml of the solution containing 5×10^{-4} M copper, 33 ml of 540 g l^{-1} $Na_2S_2O_3$ was added. Addition of the buffer solution stabilizes the copper thiosulfate complex. The total amount of SDS added to the column for foaming was 2 times greater than that required for complete recovery of nickel. Foaming was carried out at the average gas flow rate of 3.3×10^{-4} m^3 h^{-1} for 3 days. After foaming, the solutions were analyzed by AAS for the content of copper and nickel ions. The experimental data are listed in the table.

It is evident that the complex formation allows the initial concentration of copper to be kept constant within the limits of experimental error. Without complex formation, both bivalent ions are removed from the solution during foaming.

CONCLUSIONS

(1) The expenditures of surfactant, sodium dodecyl sulfate, required for recovery of copper and nickel cations from dilute aqueous solutions are 1.5 and 2.0 mol per mole of cations, respectively.

(2) Transformation of one of the cations to an anionic complex allows selective recovery of nickel ions by foam separation.

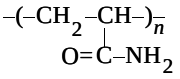
Abstract—The kinetics of sedimentation of kaolin suspension in the presence of coagulants (aluminum polyoxychloride and sulfate) and Praestol anionic flocculant was studied, as influenced by the concentrations of coagulants and flocculant, mode and time of their addition into the suspension, composition of the coagulant mixture, and chemical structure and conformation of flocculant macromolecules.

Simultaneous use of coagulants and flocculants can make the treatment of natural and waste waters much more efficient, and the most common reagents are aluminum sulfate coagulant and polyacrylamide flocculants [1, 2]. As a new aluminum polyoxychloride coagulant becomes commercially available, the data on its performance in water treatment as compared to aluminum sulfate are required. Previously we studied treatment of natural waters using aluminum sulfate and partially hydrolyzed polyacrylamide [3] and copolymers of acrylamide with sodium acrylate [4] and compared the efficiency of water treatment with aluminum sulfate and aluminum polyoxychloride in the presence of polyacrylamide [5]. Here we report on the sedimentation kinetics of kaolin suspension in the presence of aluminum sulfate and polyoxychloride and anionic Praestol as influenced by the concentrations of coagulant (C) and flocculant (F), mode and time of addition of the reagent mixture (C + F), composition of the coagulant mixture, and chemical structure and conformation of the flocculant macromolecules.

EXPERIMENTAL

In the tests we used Akva-Aurat-30 brand aluminum polyoxychloride $[Al(OH)_xCl_y]_m$ (APOC, x = 1.33, y = 1.67) [TU (Technical Specifications) 6-09-05-1456–96] with 30 wt % content of Al_2O_3 and technical-grade aluminum sulfate (AS) [GOST (State Standard) 12966] with 16.4 wt % content of Al_2O_3. We also used anionic Praestols [copolymers of acrylamide (AA) with sodium acrylate (Na-AA)] produced by Moscow–Stockhausen–Perm Russian–German Joint-Stock Company; the properties of Praestol flocculants are listed in the table. The tests were performed with KE-1 brand kaolin (TU 21-5494-310-001–92), because this dispersion system with uniform particle size distribution (average particle size 0.2×10^{-6} m) is widely used to evaluate the flocculation properties of water-soluble polymers. All solutions were prepared in distilled water.



The sedimentation kinetics was studied using 0.15% kaolin suspensions on a sedimentometric unit equipped with a VT-500 torsion balance. The sedi-

mentation rate was determined from the weight of precipitate accumulated on the balance dish in time t after tenfold stirring of the suspension using a perforated disk stirrer.

The content of the ionic units α in AA–Na-A copolymers was determined by potentiometric titration [6]. The intrinsic viscosity [η] of copolymer solutions was measured in a 0.5 M NaCl solution at 30°C on a VPZh-3 viscometer (d_c = 0.56 mm). The [η] values were determined from the experimental linear dependence of the reduced viscosity $\eta_{sp}/c_p = f(c_p)$, where c_p is the copolymer concentration:

$$[\eta] = \lim(\eta_{sp}/c_p) \text{ at } c_p \to 0.$$

The viscosity-average molecular weight $\overline{M}_\eta$ of AA–Na-A copolymer was calculated with the Mark–Houwink equation

$$[\eta] = k\overline{M}_\eta^a,$$

where the factors K and a varied with the concentration of the ionic units in the copolymer; the numerical values K and a were taken from [7].

The effective size of the flocculant macromolecules $(\bar{r}^2)^{1/2}$ was evaluated from the reduced viscosity of solutions η_{sp}/c_p at constant flocculant concentration c_p; in accordance with the Flory–Fox equation $\eta_{sp}/c_p \sim (\bar{r}^2)^{3/2}$ [8].

The effect of concentration of the dispersed phase c_d in the kaolin suspension on sedimentation was evaluated in the 0.1–0.2 wt % range in the absence of flocculant and coagulants. As seen from Fig. 1, with increasing c_d under the conditions of unhindered sedimentation of the kaolin particles the rate of precipitate accumulation on the balance dish increases (Fig. 1, passing from curve *1* to curve *4*). This is obviously due to a decrease in the distances between the kaolin particles, which increases their van der Waals interaction. Since this interaction exceeds the electrostatic repulsion between the negatively charged kaolin particles (–4.2 mV ζ potential), the rates of aggregation and precipitation increase.

The simultaneous effect of coagulant and flocculant on the stability of the kaolin suspension was studied at various modes of their addition. The dependences of the rate of precipitate sedimentation V as influenced by simultaneous and successive (when second coagulant is added 1 min after the first coagulant) addition of the reagents are shown in Fig. 2. As seen, successive addition of the reagents provides higher V as compared to their simultaneous addition into the suspension, and this trend is observed with both APOC (Fig. 2, passing from curves *1*, *2* to curve *4*) and AS (Fig. 2, passing from curves *3*, *5* to curve *6*). The flocculant, when added before the coagulant, hinders coagulation and thus decreases the sedimentation rate. At the same time, when the coagulant is added before the flocculant, the sedimentation rate increases as compared to the above case (Fig. 2, passing from curve *2* to curve *1* for APOC and from curve *5* to curve *3* for AS). This suggests certain differences in adsorption of the flocculant macromolecules on the kaolin particles and irreversibility of the process. When the coagulant is added first, the coagulant hydrolysis is completed before the flocculant addition and the resulting positively charged particles of hydroxo complexes neutralize negatively charged kaolin

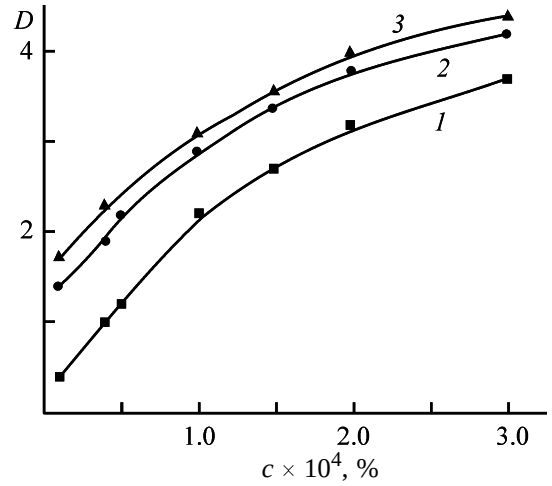

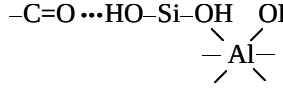

Fig. 4. Flocculation parameter *D* as a function of the concentration of Al_2O_3 *c* in APOC at various concentrations of Praestol 2530. c_p, %: (*1*) 4×10^{-4}, (*2*) 2×10^{-3}, and (*3*) 3×10^{-3}.

particles, causing their sedimentation. The flocculant macromolecules added successively are adsorbed on the precipitated kaolin particles. It is known [9] that the kaolin ($Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O$ with impurities of Fe_2O_3, MnO, Na_2O, K_2O, and TiO_2) particles form hexagons, whose basal surfaces are charged negatively at various pH, whereas lateral faces can be either neutral or positively and negatively charged depending on the solution pH. Obviously, anionic Praestol can be adsorbed due to the formation of the hydrogen bonds between the carbonyl groups of the flocculant macromolecules and hydroxy groups on the lateral faces of the kaolin particles:

Formation of the coarse aggregates accelerates their sedimentation. In all further tests we used the successive C + F mode of the reagent addition, as providing better results.

The effect of the lag between addition of the coagulant and flocculant on the stability of kaolin suspension is shown in Fig. 3. As seen from these data, no changes in the sedimentation rate are observed at time >1 min, and in our further tests the flocculant was added into the suspension 1 min after coagulant addition.

Figure 2 also shows that at c_p = const *V* increases with increasing concentrations of APOC (Fig. 2, curves *1, 2, 4*) and AS (Fig. 2, curves *3, 5, 6*), which is due to acceleration of coagulation of the kaolin suspension, enhancing the resulting flocculation effect. As seen from these experimental data at fixed concentrations of Al_2O_3 in the coagulants, *V* increases on substitution of APOC for AS (Fig. 2, passing from curves *3, 5, 6* to curves *1, 2, 4*); this fact well agrees data in Fig. 3 (passing from curve *2* to curve *1*).

The effect of the flocculant concentration on the kaolin suspension sedimentation was studied in the $(4–30) \times 10^{-6}$% range, the other conditions being constant. The flocculating power of polymers can be evaluated using the parameter *D*:

$$D = (V - V_0)/V_0,$$

where *V* and V_0 are the sedimentation rates of the kaolin suspension in the presence of the flocculant and without it. The dependences of *D* on the concentration of Al_2O_3 in APOC at different c_p are shown in Fig. 4. Comparison of experimental data (Fig. 4) at $[Al_2O_3]$ = const shows that *D* increases with increasing c_p. Apparently, increasing additions of the flocculant increase the concentration of macromolecular bridges between the kaolin particles, providing formation of coarse floccules and thus accelerating their sedimentation.

The dependence of the flocculation parameter *D* on the chemical composition of the flocculant macromolecules is illustrated in Fig. 5. The dependences pass through a maximum (Fig. 5, curves *1, 2*), which agrees with the dependence of η_{sp}/c_p (Fig. 5, curve *3*). These data show that the highest *D* corresponds to the content of ionic units in the flocculant macromolecule of about 30 mol %. We assumed that in this case the macromolecules are characterized by the optimal ratio of the charge density and chain flexibility, providing the highest $(\bar{r}^{-2})^{1/2}$ values. With increasing $(\bar{r}^{-2})^{1/2}$, macromolecules can bind the larger number of the kaolin particles, which increases the flocculation effect. As seen, *D* increases with increasing c_p (Fig. 5, passing from curve *2* to curve *1*), which agrees with the data given in Fig. 4.

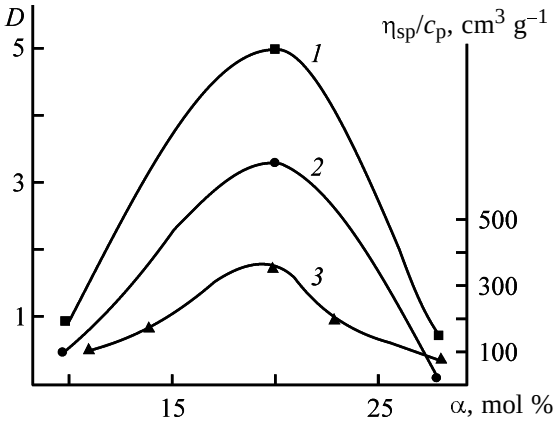

Fig. 5. (*1*, *2*) Flocculation parameter *D* and (*3*) reduced viscosity η_{sp}/c_p as functions of the content of ionic units α in the Praestol flocculant. c_c (APOC) 0.15×10^{-4}%. c_p, %: (*1*) 6×10^{-3} and (*2*, *3*) 2×10^{-3}.

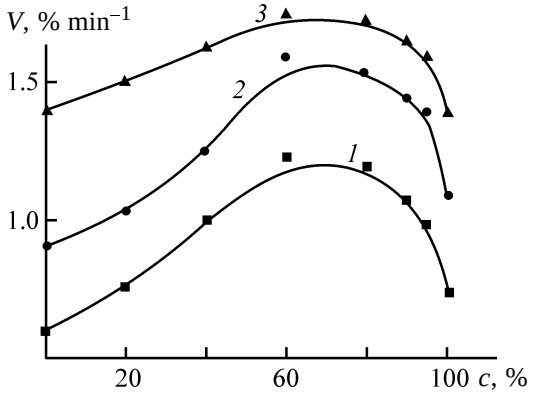

Fig. 6. Sedimentation rate of the kaolin suspension *V* as a function of the APOC content in the mixture [APOC]/[([APOC] + [SA]) *c* at various concentrations of Praestol 2530. c_p, %: (*1*) 1×10^{-3}, (*2*) 2×10^{-3}, and (*3*) 6×10^{-3}.

It is known [10] that polydispersion coagulant aggregates are formed at successive addition of various coagulants and, owing to an increase in the time of their hydrolysis, coagulation is accelerated. We also studied sedimentation of the kaolin suspension as influenced by successive addition of a mixture of APOC and AS coagulants at c_p = const. The results are shown in Fig. 6. As seen, with increasing APOC content in the APOC + SA mixture *V* first increases and then decreases, and the highest sedimentation rates are observed at APOC content of about 60%. Similar dependences of *V* on the composition of the coagulant mixture were determined for various c_p. We found that *V* increases with increasing c_p (Fig. 6, passing from curve *1* to curve *3*), which agrees with the data given in Fig. 4.

CONCLUSIONS

(1) The sedimentation rate increases with increasing concentration of coagulants (aluminum polyoxychloride and sulfate) and Praestol flocculant; it also increases on substitution of aluminum polyoxychloride for aluminum sulfate, on passing from simultaneous to successive addition of coagulants and flocculant, and on passing from flocculant + coagulant to coagulant + flocculant addition modes.

(2) The dependences of the flocculation parameter and reduced viscosity on the chemical nature of the flocculant macromolecules at constant polymer concentration are similar, as both are associated with the effective size of macromolecules in solutions.

(3) The dependence of the flocculation parameter on the content of aluminum polyoxychloride in the mixture of coagulants at their simultaneous use with the flocculant passes through a maximum.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Treatment of Spent Oil-Based Cutting Fluid

V. M. Zarochentsev, A. S. Shvydko, and L. A. Voropanova

North-Caucasian Mining and Metallurgical Institute, Vladikavkaz, North Ossetia, Russia

Received June 16, 2005

Abstract—Treatment of spent oil-based cutting fluid was studied and simulated to identify the optimal treatment conditions.

Units manufactured from very hard and wear-resistant materials prepared from technical stone, e.g., agate, find wide technical application, in particular, in instrument making. The flowsheet for manufacturing such articles includes cutting and abrading. Virtually all the flowsheet operations involve the use of oil-based cutting fluids (CFs). When the radius of the particles based on SiO_2 is small, their gravity sedimentation is very slow. For example, in the system under study, the time of sedimentation of the particle by 1 cm was 3 days. By taking this into account and using the Stockes' law for spherical particles in the form

$$v = \frac{2g(\rho - \rho_0)r^2}{9\eta}, \quad (1)$$

it was possible to estimate the sedimentation rate v at 3.858×10^{-6} cm s^{-1}. Here, v is the particle sedimentation rate; ρ and ρ_0, density of the particle and medium, respectively; r, particle radius; η, viscosity of the medium; and g, acceleration of gravity.

The known procedures for treatment of spent oils, involving sedimentation, filtration, adsorption, treatment with chemicals, distillation of the combustible, centrifugation, pressure variation, etc., involve many operations and are inefficient.

Earlier experiments [1] allowed development of a procedure for treatment of spent oil-based CF, consisting in the following. The pulp is treated with 2–10% aqueous NaOH in amount of 3–17% of the pulp volume under continuous stirring and heating to 313–338 K, which is followed by keeping the warm mixture until degradation of the colloid structure of the gel. Next, phases are separated in accordance with the specific weight, without heating, under intermittent slow stirring of the bottom phase of the silica residue, and the CF after sedimentation is decanted.

Technical and economic calculations showed the promise of a change from alkali to sodium carbonate, which enhances foaming during the pulp aeration. Sodium carbonate is a less expensive chemical; it is widely used in various processes and is less reactive. The use of sodium carbonate in the process of interest is beneficial from both economic and environmental viewpoints and also affords a slightly greater technological effect.

According to the procedure proposed in [2], the pulp is treated at 40–70°C with an aqueous solution containing 0.1–17.7 wt % Na_2CO_3 in the amount corresponding to 3.3–23.3% of the volume of the initial oil-based CF and kept at room temperature, while the oil phase is removed as it separates out.

The table presents the main process parameters of the tests on treatment of the CF. The experiments were run under the following conditions: heating over a period of 1 h and keeping at 293–363 K for 0.5–5.0 h. The spent pulp of the CF was treated with alkaline chemicals NaOH and Na_2CO_3 to remove impurities, and I-20A grade oil served as the initial CF.

Tests of the treated CF in cutting technical stone did not reveal any departures from the ordinary run of the process.

The experimental data were processed using the MathCAD program [3]. The experimental conditions (see table) were set in the form of the $x_{(19.3)}$ matrix, and the degrees of recovery, in the form of the $y_{(19.5)}$ matrix. Block 1 of the program transforms the matrices, taking account of the time of the experiment (0.5, 1.0, 1.1, 3.0, and 5.0 h), and yields matrices of experimental conditions $X_{(95.4)}$ and observations $Y_{(95.1)}$.

We developed a mathematical model describing the recovery of oil from CF as a function of a set of in-

* $V_{Na_2CO_3}$ is the volume of the sodium carbonate solution added, and V_{pulp} is the volume of the initial pulp.

dependent parameters, set in the table:

$$E(X) = a_0 + a_1x_0 + a_2x_1 + a_3x_2 + a_4x_3 + a_5x_0^2 + a_6x_1^2 + a_7x_2^2 + a_8x_3^2 + a_9x_1^3 + a_{10}x_1x_3, \quad (2)$$

where $E(x)$ is the degree of recovery of the oil into solution; x_0, content of sodium carbonate in the solution added; x_1, volume of the Na_2CO_3 solution added; x_2, temperature; and x_3, process time.

The coefficients in the mathematical model were calculated by the least-squares method for a linear combination of arbitrary functions [4]. The matrix X is transformed into the matrix of the $U_{(95.11)}$ functions, corresponding to the form of model (2), in program block II.

The coefficients in regression equation (2) are calculated by the least-squares method in the matrix form [4] (block III).

Technologically preferable option consists in carrying out the process at 333 K (at higher temperatures, thermal degradation of oil becomes more probable) and at the sodium carbonate concentration $c_{Na_2CO_3}$ = 5%. It is convenient to present regression equation (2) in the reduced form as $E = f(V, \tau)$ at fixed $c_{Na_2CO_3}$ and T:

$$E(V, \tau) = s + a_2V + a_4\tau + a_6V^2 + a_8\tau^2 + a_9V^3 + a_{10}V\tau, \quad (3)$$

where $E(V, \tau)$ is the degree of recovery of oil into solution; V, volume of the Na_2CO_3 solution added; τ, process time; and s, sum of the fixed terms in Eq. (2).

Figure 1 presents the response surface for function (3), calculated using MathCAD. It is seen that

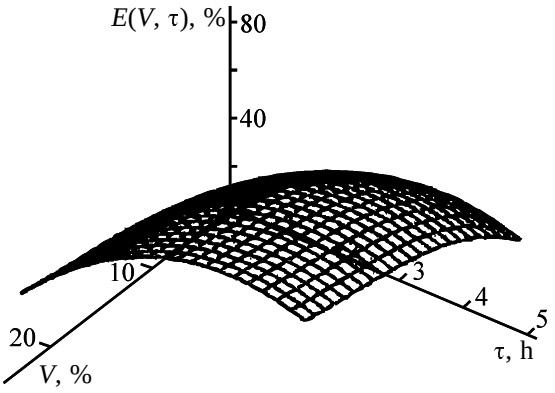

Fig. 1. Response surface for the degree of recovery $E(V, \tau)$, as a function of the reagent volume V and the process time τ.

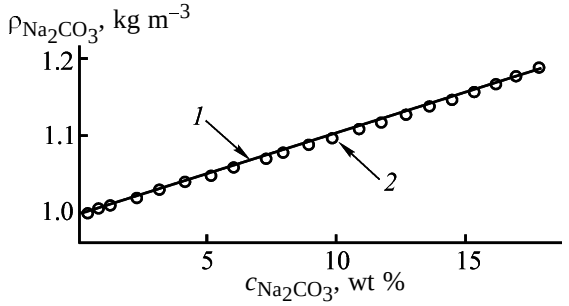

Fig. 2. Sodium carbonate solution density $\rho_{Na_2CO_3}$ as a function of the sodium carbonate content in solution $c_{Na_2CO_3}$. (*1*) (Line) Calculation by Eq. (5) and (*2*) experimental points.

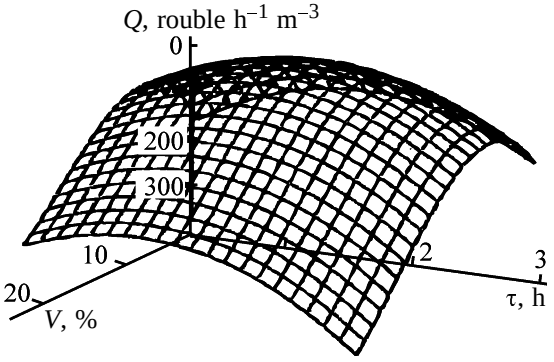

Fig. 3. Response surface of the function of the cost optimization criterion Q with respect to time τ and reagent volume.

the optimal values of the process parameters lie within the region under study. Technologically justified option implies the process time of 1.5–2.5 h and volume of 5% Na_2CO_3 solution of 7–23% relative to the volume of the initial pulp.

To determine the optimal parameters of the process, based on mathematical model (3), we formed a function of the optimization criterion Q, which gives the profit from oil recycling, depending on the operation costs, separation time, and cost of the oil recycled:

$$Q = Eq_0 - G_{Na_2CO_3} q_{Na_2CO_3} - V_r \tau q_v, \quad (4)$$

where q_0 is the cost of the oil recycled; $G_{Na_2CO_3}$, weight of water added during the process; $g_{Na_2CO_3}$, cost of 1 kg of sodium carbonate; V_r, volume of the reactor, required for treatment of 1 m^3 of the CF; and q_v, operation costs for 1 m^3 of the reactor volume in 1 h of the work.

The degrees of recovery in Eq. (4) were calculated by Eq. (3), and the volume of the reactor was composed from those of the CF pulp and the sodium carbonate solution added; the amount of the sodium carbonate added was calculated on the basis of the density and volume of the solution added: $G_{Na_2CO_3} = V\rho_{Na_2CO_3}$.

To estimate the density of the sodium carbonate solution as dependent on the concentration, we determined the $\rho_{Na_2CO_3} = f(c_{Na_2CO_3})$ dependence in the form of the

$$\rho_{Na_2CO_3}(x) = b_0 + b_1 x + b_2 x^2 \quad (5)$$

polynomial, where x is the sodium carbonate concentration in solution.

Coefficients b_0, b_1, and b_2 is Eq. (5) were determined using the linfit (RoNa$^{\langle 1\rangle}$, RoNa$^{\langle 0\rangle}$, FRo) function, processing the concentration vector RoNa$^{\langle 1\rangle}$ and its corresponding density vector RoNa$^{\langle 0\rangle}$ by the least-squares method [4]; the regression equation is set as a linear combination of the functions in the FRo matrix (block IV).

The solution densities were taken from [5] in the concentration range 0.19–17.7 wt %. Figure 2 shows the concentrations calculated by Eq. (5), which agree well with the experimental data.

For transformation of the optimization criterion (4), we substituted the function (3) of the degree of oil recovery and calculated the sodium carbonate solution density by Eq. (5) for the concentration of 5 wt %, which yielded

$$Q(V,\tau) = 10E(V,\tau)q_0 - (Vc_{Na_2CO_3}\rho_{Na_2CO_3}q_{Na_2CO_3}) \times 10^{-1} - (1 + V_r \times 10^{-2})\tau q_v, \quad (6)$$

where $Q(V,\tau)$ is the profit in the separation process (rouble h^{-1} m^{-3} of the CF).

By substituting q_0 = 1.7 rouble l^{-1} and q_v = 280 rouble m^{-3} h^{-1}, as suggested by practical experience, we calculated function (6) in the region of independent parameters studied. The resulting surface has a prominent maximum (Fig. 3).

The region of the optimal values, corresponding to the largest benefit from the CF treatment, was determined using the Maximize function, built in MathCAD, in which the extremum is searched by the Newton method [3] (block V).

The first row in block V sets the initial v and t parameters for the search of the maximum of function (6), which is set in the calculation as $Q(V,\tau)$. We

obtained the following optimal conditions: volume of the sodium carbonate solution added 9.14 l and time of separation 1.63 h (the first and second rows in the P_{opt} matrix); the conditions chosen correspond to the largest profit from the process of 65.6 rouble h^{-1} m^{-3} of the CF.

The experimental data tabulated and the response surface $Q(V, \tau)$ in Fig. 3 confirm that the most economically profitable option is treatment of the CF for 1.5–2 h at the reagent volume of 5% of the volume of the initial pulp and at a temperature no higher than 333 K.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Aminophenols as Inhibitors of Oxidation of Nujol

Donetsk National University, Donetsk, Ukraine

Received May 4, 2005

Abstract—Antioxidant properties of aminophenols in initiated oxidation of Nujol were studied by a chemiluminescence procedure.

Polyfunctional antioxidants (AO) with several reactive groups can be used to stabilize fats and oils. Among these compounds are aminophenols (APs)[1]. To assess practical applicability of APs for inhibition of radical chain oxidation of organic compounds, their antioxidant power (AOP) with respect to model systems should be determined and features of the behavior of APs in complex substrates (liquid fuels, mineral oils, etc.) should be taken into account.

In this study we examined the antioxidant power of aminophenol with respect to Nujol by chemiluminescence (CL) observed during the oxidation.

EXPERIMENTAL

We used Nujol (Merck) as received. Azobisisobutyronitrile (AIBN) (pure grade) double-recrystallized from absolute ethanol was used as the free radical source [2]. CL activator, 9,10-dibromoanthracene (DBA), was prepared and purified by the procedure described in [3]. Aminophenols were prepared by the procedures described in [4, 5]. These compounds were identified and characterized by thin-layer chromatography, IR spectroscopy, and elemental analysis. The CL kinetics in the course of initiated oxidation of Nujol in the presence and in the absence of AO was monitored with a chemiliminesecnce unit described in [6].

The reactivity of aminophenols (InH) in reaction with peroxy radicals of Nujol (ROO) (2) was characterized by the ratio $k_2/k^{1/2}$ and stoichiometric coefficient of inhibition (f).

$$ROO^{\bullet} + ROO^{\bullet} \xrightarrow{k_1} \text{Products}, \quad (1)$$

$$ROO^{\bullet} + PhOH \xrightarrow{k_2} ROOH + PhO^{\bullet}. \quad (2)$$

Since the composition of the substrate being oxidized is complex and variable, the rate constant (k_1) of recombination of peroxy radicals (1) is unknown and hence the quantity $k_2/k^{1/2} = k_{app}$ is apparent.

Oxidation of Nujol initiated by AIBN was performed at 333 K in chlorobenzene at a volume ratio of 1 : 1. The initiation rate (v) of Nujol oxidation was calculated from Eq. (3). For this purpose, the induction period of Nujol oxidation in the presence of a reference inhibitor (Ionol) was determined. The inhibition coefficient (f) of Ionol is 2 [7].

$$v_i = f[InH]_0/\tau, \quad (3)$$

where $[InH]_0$ is the initial Ionol concentration, M.

To determine this parameter, the chemiluminescence kinetic curves were linearized in the coordinates of Eq. (4):

$$(I_0/I)^{1/2} = 1 + 1.1k_2[InH](v_i k_1)^{-1/2}, \quad (4)$$

where I_0 and I are the chemiluminescence intensities in the absence and in the presence of AO, respectively.

The apparent rate constant k_{app} was calculated from the slope of the linearized kinetic curves of CL (φ) (Fig. 1b) by the equation

$$k_{app} = k_2/(k_1)^{1/2} = \tan\varphi\,(v_i)^{1/2}/1.1. \quad (5)$$

The number of radicals decaying on a single AO molecule was calculated from the experimental induction period of oil oxidation (τ) in the presence of AP by Eq. (3).

After addition of the examined AOs into the system, the CL intensity (I) decreases as compared to that

2,6-Di-*tert*-butyl-4-methylphenol (Ionol) (**V**)	4.9	2.0	11	2.0	–	306

in their absence (I_0) owing to a decrease in the concentration of peroxy radicals (Fig. 1a). As seen from Table 1, compounds **I**–**IV** actively react with ROO$^{\bullet}$BM and hence have a high AO power with respect to Nujol oxidation.

As seen from Table 1, the constants k_{app} of the APs are higher than that of the known AO, Ionol, and depend on the structure of these antioxidants. The AOP of the all examined APs in Nujol oxidation is higher than that in ethylbenzene oxidation. This is due to higher oxidation stability of Nujol (which is a mixture of aliphatic and naphthene hydrocarbons) and different reactivity of peroxy radicals of Nujol and ethylbenzene.

The main structural feature of APs affecting their AOP is the presence of two reactive sites (NH and OH groups). Experimental data on the strength of N–H (D_{N-H}) and O–H (D_{O-H}) bonds in the molecules of the APs in question are lacking. We calculated these parameters by AM1 semiempirical quantum chemical method using MOPAC-97 software [8]. The results are presented in Table 1.

Since the strengths of OH and NH bonds in AP molecules differ, the antioxidant activities of these groups should also differ. The amino groups in *ortho* position to each other are directly conjugated and hence the N–H bonds are weakened. Since the electronegativity of an oxygen atom is higher than that of a nitrogen atom, $D_{O-H} > D_{N-H}$. Hence, under the action of peroxy radical the amino group of AP will lose the H atom first. The AOP of *N*,*N*'-bis(2-hydroxybenzyl)-*o*-phenylenediamine is determined by the activity of its amino group. The apparent rate constant k_{app} of the *para* isomer of **II** (Table 1, compound **IV**) is low, since the strength of its N–H bond is comparable with that of the O–H bond. The O–H bond of *N*,*N*'-bis-(4-hydroxy-3-methoxybenzyl)-*o*-phenylenediamine is weakened by the electron-donor methoxy group and can be involved, along with the NH group, in the peroxy radical deactivation.

Compound III is the most reactive (k_{app}) with respect to peroxy radicals of Nujol (Table 1). This is due to the presence in its molecule of two fragments which can be independently involved in chain termination. The reaction sites of this compound are labile OH groups.

Comparison of the AOP of the APs with that of Ionol shows that APs are more reactive AOs with respect to both substrates. The apparent rate constant k_{app} determined from the CL data characterizes the

activity of the group with minimal bond strength. The stoichiometric coefficient of inhibition (f) characterizes the total AOA of a compound under these conditions. This parameter depends on the number and reactivity of all groups involved in oxidation inhibition. Hence, these is no correlation between k_{app} and f (Table 1).

Our study of AOP of APs in initiated oxidation of Nujol showed that Nujol oxidation, unlike that of vegetable oils (sunflower-seed and cotton-seed oils) [10], has no induction period. As shown previously [10, 11], the induction period in Nujol oxidation is due to the presence of AOs added to the oil in the course of its preparation from petroleum. The absence of the induction period in our experiments is due to the fact that we used Nujol of high purity, containing no inhibiting impurities.

We did not observed the CL features in Nujol oxidation found in [10, 11]. These authors reported that, after addition of various inhibitors to Nujol being oxidized, the CL intensity decreases to a definite value I_{mol} which is independent of the concentration and nature of AO at the instant of its introduction. This is caused by the fact that the CL signal consists of two components: the radical constituent (I_{rad}) which is generated in recombined atom of peroxy radicals and is quenched by AO, and the molecular constituent (I_{mol}) which is generated in nonradical reactions and is quenched by AO.

Our study performed under the similar conditions showed that the molecular constituent of CL is absent in oxidation of pure Nujol. This fact agrees with the results of detailed studies [12, 13] where it was found that molecular CL is observed only in oxidation of unsaturated compounds. Molecular CL is generated by electronically excited carbonyl compounds formed in degradation of dioxetanes, oxidation products of unsaturated compounds.

To check this assumption, we added a small amount of unsaturated compound (linoleic acid, LA) to Nujol (Fig. 2a). The CL intensity increased with increasing the LA content in Nujol (Fig. 2b).

To confirm the feasibility of formation of electronically excited species by nonradical degradation of dioxetanes in initiated oxidation of LA, we calculated thermodynamic parameters of reaction (6) by AM1 method.

The enthalpy of this reaction is determined by the following equation:

$$\Delta H_r = (\Delta H^0_{pr.1} + \Delta H^0_{pr.2}) - \Delta H^0_d,$$

where ΔH_r is the standard enthalpy of reaction (6); $\Delta H^0_{pr.1}$ and $\Delta H^0_{pr.2}$ are the standard enthalpies of formation of electronically excited products; and ΔH^0_d is the standard enthalpy of formation of dioxetane.

$$\Delta E_{S_0 \to S_1} = \Delta H^0_{S_1} - \Delta H^0_{S_0},$$

where $\Delta E_{S_0 \to S_1}$ is the transition energy of carbonyl compounds from the ground state to singlet excited state; $H^0_{S_0}$ and $H^0_{S_1}$ are the standard heats of formation of the molecular products in the ground and singlet excited states, respectively.

$$\Delta E_{T_1 \to S_0} = H^0_{S_0} - H^0_{T_1},$$
$$\Delta E_{S_1 \to S_0} = H^0_{S_0} - H^0_{S_1},$$

where $\Delta E_{T_1 \to S_0}$ and $\Delta E_{S_1 \to S_0}$ are the transition ener-

gies of carbonyl compounds from the triplet and from the singlet excited states to ground state, respectively; $H^0_{S_0}$ and $H^0_{T_1}$ are the standard heats of formation of the molecular products in the ground and triplet excited state, respectively.

The results are summarized in Table 2. It is known [6] that electronically excited products can be formed in exothermic chemical reactions. As seen from Table 2, ΔH_r is higher than the transition energy of the carbonyl compounds from the ground to electronically excited states ($\Delta H_r > \Delta E_{S_0 \to S_1}$). Hence, molecular CL ($I_{mol}$) in oxidation of LA is caused by degradation of deoxetanes to form electronically excited products whose transition to the ground state is accompanied by CL.

Transition to the ground state from both singlet and triplet electronically excited states is possible [6]. To determine the type of the excited state of the carbonyl compounds, we calculated from the transition energies ($\Delta E_{S_1 \to S_0}$, $\Delta E_{T_1 \to S_0}$) the wavelengths of emission in the transition to the ground state by the following equations:

$$\lambda_S = \frac{\nu N_A h}{\Delta E_{S_1 \to S_0}}, \qquad \lambda_T = \frac{\nu N_A h}{\Delta E_{T_1 \to S_0}},$$

where v is the velocity of light, N_A is the Avogadro constant, h is the Planck constant, λ_S is the emission wavelength in the transition from the singlet to the ground state, and λ_T is the emission wavelength in the transition from the triplet to the ground state.

The calculated wavelengths λ_S and λ_T are in the visible range, which agrees with the experimental data. Since the maximal spectral sensitivity of the photcathode of FEU-29 photomultiplier of the CL unit lies in the range 420–430 nm, which almost coincides with λ_S, the molecular component of CL of linoleic acid being oxidized is due to the products in singlet electronically excited state.

CONCLUSION

(1) The molecular component of CL appears only in oxidation of unsaturated compounds. This component is absent in initiated oxidation of Nujol (saturated compound) in the presence of aminophenols.

(2) Among examined AOs, *N,N'*-bis(2-hydroxy-3,5-di-*tert*-butylphenyl)-*o*-ethylenediamine and *N,N'*-bis(4-hydroxy-3-methoxybenzyl)-*o*-phenylenediamine are the most efficient in Nujol oxidation.

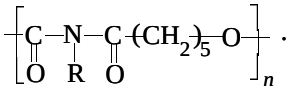
MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Copolymerization of Chlorine-Substituted Monoisocyanates with ε-Caprolactone in the Presence of Sodium Caprolactamate



S. S. Galibeev, A. M. Mukhametzyanova, A. M. Kochnev, V. P. Arkhireev, and O. I. Gnezdilov

Abstract—Copolymerization of ε-caprolactone with a series of aromatic chlorine-substituted monoisocyanates in the presence of catalytic amounts of sodium caprolactamate was performed. The structures of the products obtained and their macromolecular characteristics were determined by IR and ^{1}H NMR spectroscopy and by gel permeation chromatography; kinetic and thermodynamic relationships of the process were found.

Previously we demonstrated the possibility of copolymerization of phenyl isocyanate (PIC) with ε-caprolactone (ε-CLN) in the presence of a catalyst (sodium caprolactamate, Na-CL) and an activator (2,4-toluylene diisocyanate, TDI) [1]. The reaction mainly yielded alternating copolymers, and its rate largely depended on the comonomer ratio, growing with an increase in the content of the isocyanate component. Our IR and ^{1}H NMR study [2] showed that the copolymerization of ε-CLN with isocyanates occurs via cleavage of the N=C bond in isocyanates and acyl bond in the lactone; the resulting copolymer has the following structure:

To extend the range of the isocyanates used and confirm the possibility of preparing alternating copolymers, we performed in this study the copolymerization of ε-CLN with chlorine-substituted monoisocyanates: 3-chlorophenyl isocyanate (3-CPI) and 4-chlorophenyl isocyanate (4-CPI).

EXPERIMENTAL

ε-CLN and 3-CPI (Fluka) were vacuum-distilled before use; 4-CPI (Fluka) was used without additional purification.

As catalyst we used sodium caprolactamate (Na-CL) prepared by the reaction of sodium metal with ε-caprolactam (ε-CL) in the bulk at 110–120°C. The product was stored in a desiccator under an inert gas. The Na-CL content in the product was 25 wt %.

The syntheses of the copolymers were performed in an argon flow in a three-necked flask equipped with a reflux condenser and a stirrer. The polymerization was carried out as follows: 1 wt % Na-CL was dissolved in ε-CLN at 80°C, after which the calculated amount of isocyanate was added with continuous stirring, and 1 wt % activator (TDI) was added. The products were purified by tenfold reprecipitation with hexane from acetone.

The chemical structures of the products formed in the reactions of monoisocyanates with ε-CLN were studied by IR Fourier spectroscopy on a Perkin–Elmer PC-16 spectrometer and by ^{1}H NMR spectroscopy on a Bruker MSL-400 spectrometer (400 MHz) with $CDCl_3$ as solvent and reference.

Gel chromatographic studies were performed with a Waters 150C gel chromatograph equipped with Ultrastyrogel HR 10^3 Å columns; the solvent was DMF, and the reference, polystyrene.

The content of isocyanate groups was determined by potentiometric titration according to [3]. The reaction rate constants and the activation energy and entropy were determined according to [4]. The copolymerization constants were calculated by the Fineman–Ross method [5].

As compared to the spectra of the starting monomers, the ^{1}H NMR spectrum of the product of copolymerization of ε-CLN with 3-CPI contains a signal at 2.4–2.2 ppm corresponding to the α-CH_2 protons relative to the carbonyl group of the opened lactone ring and a signal at 4.3–3.9 ppm corresponding to the α-CH_2 protons relative to the ester oxygen atom. The

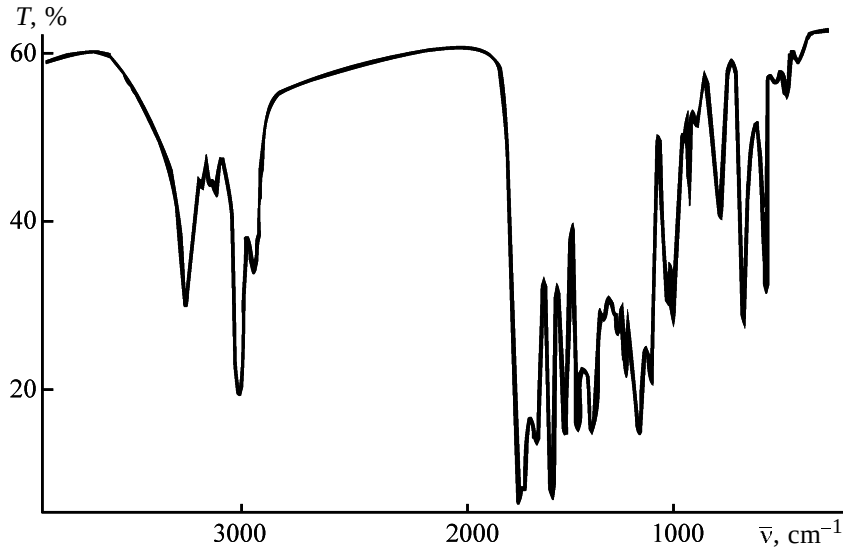

Fig. 2. IR spectrum of ε-CLN–3-CPI copolymer. (*T*) Transmission and ($\bar{\nu}$) wavenumber.

isocyanate component gives rise to sugnals at 7.9–6.9 ppm (benzene ring protons) (Fig. 1). The similar signals are present in the spectra of the copolymers of ε-CLN with 4-CPI and PIC.

The IR spectrum of the ε-CLN–3-CPI copolymer (Fig. 2) contains absorption bands at 1700 (C=O group in amides), 1599 (C=C stretching vibrations of aromatic rings), and 1540 cm^{-1} (C–N stretching vibrations). Also present are bands at 1730 (C=O stretching vibrations in aliphatic esters), 2866, and 2934 cm^{-1} (symmetric and antisymmetric vibrations of aliphatic methylene groups, respectively) [6].

By analytical titration we determined the rates of consumption of isocyanate groups in the course of copolymerization at various ε-CLN : isocyanate ratios (from 90 : 10 to 50 : 50 mol %). Processing of the kinetic data showed that the reaction order was close to 2 at any reactant ratio; therefore, the calculated rate constants were determined with second-order dimensions. We found that the reaction appreciably accelerated with an increase in the isocyanate content in the starting monomer mixture (Table 1). The polymer yield reached a maximum at equimolar ratio of the comonomers (Fig. 3). The same trend was observed with the PIC copolymers [1].

Table 1. Rate constants of copolymerization of ε-CLN with monoisocyanates at various molar ratios of comonomers*

Monomer content, mol %		$k \times 10^3$, l mol^{-1} s^{-1}		
ε-CLN	IC	PIC**	3-CPI	4-CPI
80	20	1.20	0.07	0.07
70	30	1.70	0.10	0.22
60	40	2.70	0.12	0.25

* Temperature: with PIC, 170°C; with 3-CPI and 4-CPI, 80°C.
** Data from [1].

Table 2. Rate constants of copolymerization of ε-CLN with monoisocyanates at various temperatures*

Isocyanate	T, °C	$k \times 10^3$, l mol^{-1} s^{-1}
3-CPI	80	0.12
	100	0.13
	120	0.17
4-CPI	80	0.25
	100	0.39
	120	0.43

* Molar ratio ε-CLN : isocyanate = 60 : 40.

Table 3. Activation energies and entropies of the reaction of ε-CLN with various isocyanates

Isocyanate	E_a, kJ mol^{-1}	ΔS, kJ K^{-1} mol^{-1}
PIC*	21.6	–0.25
3-CPI	35.1	–0.23
4-CPI	22.3	–0.18

* For PIC, data from [1]; the same for Table 4.

Table 4. Copolymerization constants for the system ε-CLN–isocyanate

Isocyanate	r_1	r_2
PIC*	0.67 ± 0.07	0.55 ± 0.06
3-CPI	0.63 ± 0.06	0.61 ± 0.06
4-CPI	0.50 ± 0.05	0.50 ± 0.05

The process was also appreciably intensified by raising temperature. In particular, with increasing temperature from 80 to 120°C, the rate constants of the copolymerization of ε-CLN with 4-CPI increased from 0.25×10^{-3} to 0.43×10^{-3} l mol^{-1} s^{-1} (Table 2).

The activation energy of the process (E_a) was the lowest (21.5 kJ mol^{-1}) with PIC and the highest (35.1 kJ mol^{-1}) with 3-CPI, which is apparently due

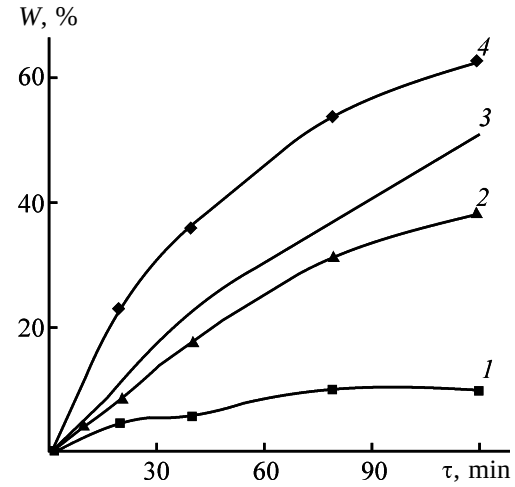

Fig. 3. Copolymer yield W as a function of time τ at various molar ratios of ε-CLN and 4-CPI in the initial mixture: (*1*) 80 : 20, (*2*) 70 : 30, (*3*) 60 : 40, and (*4*) 50 : 50. T = 120°C.

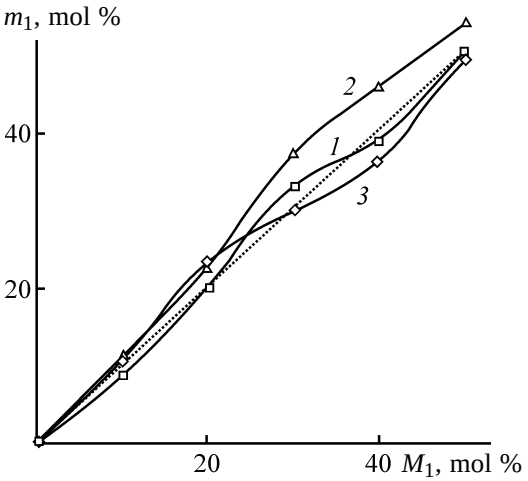

Fig. 4. Content of amide units in polymer m_1 vs. content of isocyanates M_1 in the initial mixture: (*1*) PIC, (*2*) 3-CPI, and (*3*) 4-CPI.

to the lower reactivity of 3-CPI. The negative activation entropies ΔS (Table 3) suggest decreased number of degrees of freedom of the reacting system in the transition state.

As aready noted, with PIC mainly random copolyamido esters were obtained, showing some tendency to alternation of the units, as indicated by the copolymerization constants of 0.67 for ε-CLN and 0.55 for isocyanates. For the copolymers derived from 3- and 4-CPI, r_1 and r_2 are also approximately equal, and their product is less than unity (Table 4). This fact also indicates that the copolymers are mainly alternating. The same conclusion follows from the dependence of the copolymer composition on the monomer ratio in the initial mixture (Fig. 4).

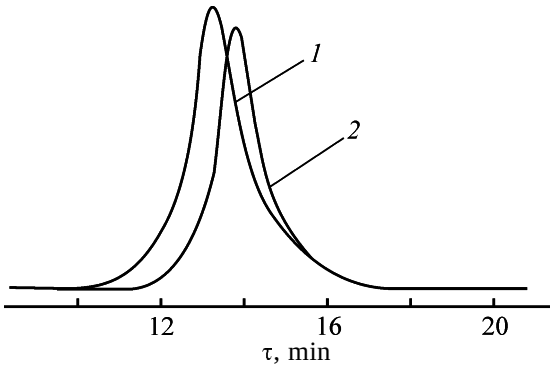

Fig. 5. Gel chromatograms of isocyanate–ε-CLN copolymers. (τ) Retention time. (*1*) 4-CPI–ε-CLN ($\overline{M}_w$ = 7500) and (*2*) 3-CPI–ε-CLN ($\overline{M}_w$ = 3200). Molar ratio isocyanate : ε-CLN: (*1*) 70 : 30 and (*2*) 60 : 40.

In view of the high reactivity of the monoisocyanates and ε-CLN and their tendency to homopolymerization under the reaction conditions, formation of the homopolymers along with the copolymers cannot be ruled out. However, actually the products have unimodal and fairly narrow molecular-weight distribution (Fig. 5) suggesting their uniform composition.

The molecular weights of the copolymers were relatively low. The weight-average molecular weights $\overline{M}_w$ varied in the range 3000–8000 depending on the comonomer ratio and isocyanate used; higher-molecular-weight products were obtained with 4-CPI.

CONCLUSIONS

(1) Copolymerization of ε-caprolactone with chlorinated aromatic monoisocyanates yields copolymers with predominant alternation of units.

(2) The trends revealed previously with phenyl isocyanate are also observed with chlorinated aromatic monoisocyanates.

Abstract—A mixed ether, propyl methyl cellulose with varied number of propyl groups, was synthesized from commercial water-soluble methyl cellulose. The effect of the number of side propyl groups on the dynamics of aqueous methyl and propyl methyl cellulose solutions in longitudinal and convergent flows was studied. The conditions under which solutions transform into the induced anisotropic state were determined.

Environmentally safe and biodegradable polymeric systems based on natural polymers attract a considerable interest of researchers. For example, certain water-soluble derivatives of cellulose, which show reversible gelation and lyotropic mesomorphism, have found wide application in medicine, food and textile industries, some fields of technology, well drilling, and oil production [1–4]. To this group of polymers belong methyl cellulose (MC), hydroxypropyl cellulose (HPC), hydroxypropyl methyl cellulose (HPMC), and some other cellulose ethers. The unique properties of these polymers invite a detailed study of their molecular characteristics.

In [5], gelation conditions of solutions were studied and it was shown that introduction of propyl groups into the MC macromolecule depresses the points of gelation (T_{gel}) and phase separation (T_{tur}) of solutions. Kalinina *et al.* [6] quantitatively described how the supramolecular associative structure of moderately concentrated aqueous solutions of MC and of propyl methyl cellulose (PMC) varies with the number of propyl groups introduced.

In this study we examined the influence of the number of propyl groups on the dynamics of PMC solutions in longitudinal and convergent flows. It should be noted that just flows of this kind are formed in fabrication of polymeric films or fibers, when the solution is forced through spinnerets of various shapes or in those cases when polymer solutions are used to enhance the productivity of oil-bearing strata.

EXPERIMENTAL

Semidilute aqueous MC and PMC solutions (degree of substitution by propyl groups, DS_{pg} = 0.1, 0.25, 0.3), with a polymer concentration C_p = 0.3 g dl^{-1}, were studied.

A mixed cellulose ether was synthesized from a commercial water-soluble MC of MTs-100 brand, with a degree of polymerization (DP) of 830 and degree of substitution (DS) of 1.62 (by methoxy groups). The synthesis of water-soluble PMC was described in [5]. As MC is a cellulose ether, the propylation occurs at free hydroxy groups without elimination of methoxy groups. Therefore, the DS by methoxy groups is constant and equal to 1.62 (DS of the starting MC) for all of the PMC samples synthesized. Both the degree of substitution by propyl groups (DS_{pg}) and the total degree of substitution (DS_{tot}) change during synthesis. The values of DS_{tot} were calculated using the expression $DS_{tot} = 1.62 + DS_{pg}$. The values of DS_{pg} were found by elemental analysis.

The choice of PMC samples is determined by the fact that the solubility of PMC in water becomes zero at $DS_{pg} > 0.30$. At the same time, it is known that trisubstituted MC remains soluble in water [4, 7]. Consequently, introduction of propyl substituents in an amount exceeding 0.30 per monomer unit substantially shifts the hydrophilic–hydrophobic balance of macromolecules toward their hydrophobization, which leads to the loss of PMC solubility in water at $DS_{tot} > 1.92$.

The intrinsic viscosity [η] of the solutions was determined using an Ubbelohde viscometer with a suspended level. The measurements were performed at T = 25°C. The data obtained are listed in the table. It can be seen that [η] grows with an increase in the number of propyl groups in the chain, DS_{pg}.

Parameters and results of an experimental study of MC and PMC solutions

Object of study	DS_{pg}	DS_{tot}	$[\eta]$, dl g^{-1}	$[\eta]c$	g_{cr}, s^{-1}	$\tau \times 10^{-4}$, s
MC	0	1.62	3.8	1.14	3200	1.6
PMC	0.1	1.72	3.95	1.19	4100	1.2
PMC	0.25	1.87	4.25	1.28	5200	0.9
PMC	0.30	1.92	4.4	1.32	8400	0.6

The absorption of light by MC and PMC solutions in the UV and visible ranges was studied with a Specord M-40 spectrophotometer. The dependence of the optical density D on the wavelength λ was used to evaluate the absorption of light by MC and PMC solutions at a varied number of propyl groups in the chain (Fig. 1). It can be seen that the optical densities D are the lowest for the MC solution, and raising the number of propyl groups in the chain leads to an increase in the optical density and, accordingly, to a stronger absorption of light by PMC solutions.

The birefringence method was used to study the dynamics of aqueous MC and PMC solutions with a varied number of propyl groups in a longitudinal flow. The study was carried out on a setup in which the hydrodynamic field is generated in the gap between coaxial capillaries (Frank–Keller method) [8]. When the solution is drawn in the capillaries, an optically anisotropic region in the form of a "filament" appears along their axis at a certain critical velocity gradient g_{cr}. The velocity gradient was found from the flow rate of the fluid, Q, through a capillary:

$$g = Q/\pi r^2 (l/2), \quad (1)$$

where r is the capillary radius, and l is width of the gap between the edge surfaces of the capillaries.

The critical velocity gradient g_{cr}, corresponding to the onset of unfolding of polymer chains and to transition of the solutions to the anisotropic state, was recorded. According to theory of dynamics of macromolecules in a strong longitudinal field, the value of g_{cr} is related to the time τ of orientation-deformation relaxation of the chain as a whole by

$$g_{cr}\tau = 0.5. \quad (2)$$

The effect of the longitudinal flow on the MC and PMC solutions is shown in Fig. 2 in the form of a dependence of g_{cr} on the number of propyl groups in the chain, DS_{pg}. It can be seen that an increase in the number of propyl groups shifts the region in which PMC solutions pass into the anisotropic stage toward larger values of g_{cr}. This result is accounted for by the fact that substitution of a part of hydroxy groups of methyl cellulose with propyl groups makes higher the equilibrium rigidity of macromolecules [9].

To evaluate the resistance of the solutions to longitudinal deformation, the effective viscosity was determined in a convergent flow of the solutions through a short capillary, whose diameter is two times its length (d/l = 2). To stabilize the convergent flow, a cylindrical obstacle was mounted in the entrance zone of the capillary. In the case of such a flow, a unit volume of the solution at the axis of the capillary axis, between its inlet and the obstacle plane, experiences

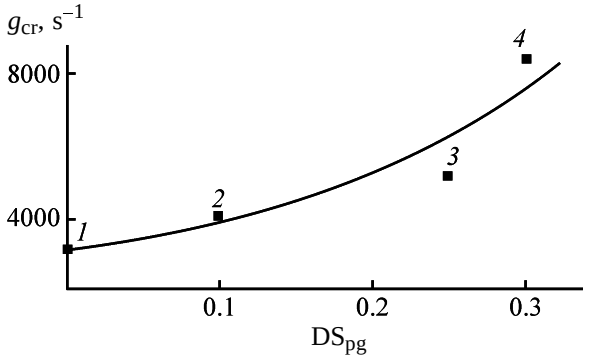

Fig. 2. g_{cr} vs. DS_{pg} for solutions in a longitudinal flow.

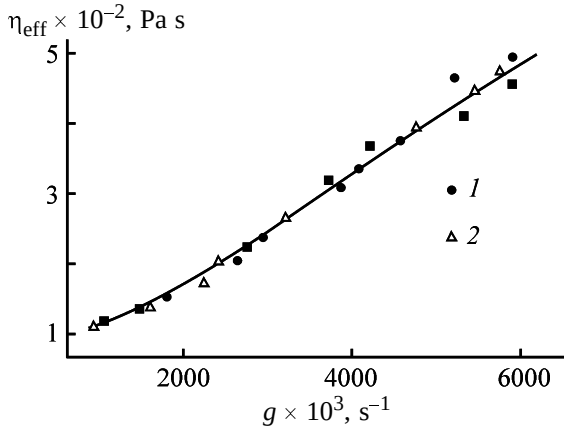

Fig. 3. Effective viscosity η_{eff} of the solutions in a convergent flow vs. the rate gradient *g*. (*1*) MC and (*2*, *3*) PMC; DS_{pg}: (*2*) 0.1 and (*3*) 0.30.

both longitudinal and shear deformations [10]. The effective viscosity η_{eff} in a convergent flow was found using calibration dependences of $\Delta P t$ against η and Re, determined in a flow of water–glycerol solutions through the short capillary. Here, ΔP is the pressure head that causes the flow, and *t* is the time in which a prescribed volume of the solutions flows through.

The gradient dependences of the effective viscosity of MC and PMC solutions in a convergent flow are shown in Fig. 3. It can be seen that, as the velocity gradient *g* becomes higher, η_{eff} grows for all the solutions. The increase in the viscosity is due, in the given case, to unfolding of chains and strengthening of interchain contacts with increasing *g*. The reverse run of the η_{eff} vs. *g* dependence completely repeats the forward run. The viscosities of the solutions, measured before and after the experiment, also coincide. This indicates that there is no degradation of macromolecules and the structure of the solutions under study is stable against the action of both converging and longitudinal flows. It should be noted that variation of the number of propyl groups in the chain does not cause any change in η_{eff} and the gradient dependences of the effective viscosity are approximately the same for all the solutions (Fig. 3). This is due to the fact that the converging flow exerts a weaker influence on polymer chains, compared to the longitudinal flow in coaxial capillaries, because, in the former case, a shear deformation occurs in addition to the longitudinal flow. Extension of a chain periodically alternates with compression, and the deforming action of the flow is weakened. In addition, the results obtained indicate that, in a longitudinal flow, the birefringence method is more sensitive to structural changes in the solution, compared to the rheology of a convergent flow in short capillaries.

CONCLUSIONS

(1) A study of the dynamics of aqueous MC and PMC solutions demonstrated that an increase in the number of propyl groups in the chain shifts the region in which macromolecules pass into the unfolded state toward higher values of the velocity gradient.

(2) A high-intensity longitudinal flow in the space between coaxial capillaries is more sensitive to structural and conformational changes in the polymer chain, compared to a converging flow through a short capillary.

(3) The structure of the solutions studied is stable against the action of both converging and high-intensity longitudinal flows.

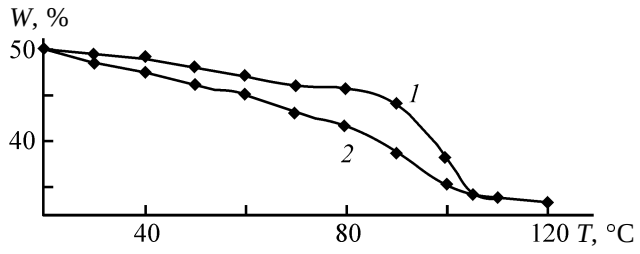
Thermal Treatment of AK-215 Acryl Dispersion in Manufacture of Heat-Insulating Coatings

A. I. Sokol'skii, E. P. Barulin, M. I. Kruchinin, and S. A. Sokol'skii

Ivanovo State University of Chemical Engineering, Ivanovo, Russia

Received March 28, 2005



Abstract—Experimental and theoretical data on thermal treatment of latex in a conductive-infrared drier for manufacture of heat-and-noise insulation for automobiles are presented.

AK-215 acryl dispersion is an aqueous solution of a polymer of the acryl series. The mass transfer in polymeric systems is determined by the intensity of molecular motion, which can be characterized by the mass conductivity coefficient. In colloid capillary-porous materials, a substance being distributed is bound by absorption, adsorption, and capillary forces. The sorption hysteresis covers the whole range of relative humidities of the medium. A latex contains both an osmotic moisture within grains and a capillary-bound moisture, which fills spaces between the grains [1]. In the course of drying, the volume of the latex film changes, with the decrease in the volume of the latex film at $C > C_r$ equal to the volume of evaporated moisture. This can be explained as follows. When the capillary moisture is removed from a latex film in drying, the high elasticity of the skeleton of the body leads to its contraction, to the point of complete coalescence of grains and elimination of the porosity, i.e., the process of drying of this material is accompanied by continuous modification of its porous structure. At a high content of moisture, it is transported by the capillary flow. As the film reaches a certain moisture content in the course of drying, the intergrain free space vanishes and removal of the swelling moisture begins in the already nonporous material. In this case, the process of drying should be performed in two steps; in the first step, heat should by delivered to the film in the conductive way, and in the second, the film should by exposed to IR light with a wavelength corresponding to the maximum absorption of the glue formulation.

EXPERIMENTAL

To determine the influence exerted by the temperature of the heat-transfer surface on the rate of moisture removal from the glue formulation, a latex layer was deposited onto a polyethylene terephthalate film in an amount of 250 g m^{-2}. The sample was weighed on an analytical balance and placed on the heat-transfer surface. The heating time was 15 and 50 s. After that the sample was weighed and the moisture content of the glue formulation was calculated. The figure shows how the humidity of a film depends on the temperature of the heat-transfer surface. Analysis of the curves obtained shows that the removal of the capillary moisture continues until the latex moisture content reaches 33.8% and the optimal temperature of the heat-transfer surface is 105°C. At higher temperatures, the curves merge and moisture removal becomes insignificant, i.e., grains coalesce and the porosity disappears. At a temperature of the heat-transfer surface equal to 120°C, the glue formulation boils up. Consequently, some other type of heat delivery is necessary for further moisture removal.

An analytical calculation of the time necessary for removal of the capillary and adsorption moisture, with the use of the dependence of the mass conductivity coefficient on the moisture content of the latex [2], made it possible to determine more precisely the time of thermal treatment in the conductive- and infrared-heating zones of the installation.

Effect of the temperature of the heat-transfer surface on the final moisture content of a latex film. τ (s): (*1*) 15 and (*2*) 50.

1070-4272/05/7811-1891 © 2005 Pleiades Publishing, Inc.

The mathematical formulation of the problem of the nonstationary mass conductivity of bodies of unlimited dimensions includes a differential equation, as well as initial and boundary conditions:

$$\partial C/\partial\tau = k\partial^2 C(r,\tau)/\partial r^2, \quad \tau > 0, \quad 0 < r < R, \qquad (1)$$

$$C(r,0) = C_0, \qquad (2)$$

$$\partial C(0,\tau)/\partial r = 0, \qquad (3)$$

$$\beta[C_e - C(R,\tau)] = -k[\partial C(R,\tau)/\partial r]. \qquad (4)$$

In these equations, R is the film thickness (m); r, running coordinate; C, concentration of the component being distributed (kg kg^{-1}); τ, time (s); and k, mass conductivity coefficient (m^2 s^{-1}).

The analytical solution to this system of equations has the form

$$\frac{C(r,\tau) - C_e}{C_{in} - C_e} = 2\sum_{m=1}^{\infty} (\mu_m)^{-1}(-1)^{m+1}\cos(\mu_m \bar{r})\exp(-\mu_m^2 \mathrm{Fo}_m), \qquad (5)$$

where $\mu_m = (2m - 1)\pi/2$ are roots of the characteristic equation $\tan\mu_m = \mu_m/(1 - \mathrm{Bi}_m)$; Bi, Biot number; $\mathrm{Fo}_m = k\tau/R^2$, Fourier mass-exchange criterion; and $m = 1, 2, 3, \ldots$, number of terms in the series.

The results of the calculation show that the time necessary for removal of the capillary moisture in the case of a conductive heat supply virtually coincides with experimental data and is equal to 14.25 s. The discrepancy between the experimental and calculated data is within ±5%, i.e., the convergence of the results is fairly good. The calculated residence time in the infrared-heating zone is 91 s.

The main geometric parameters of the drying installation were determined using balance relations with account of the experimental and calculated data. In this way, the lengths of the heat supply zones were found to be 2 m in the case of a conductive heat supply and 10 m for the infrared-heating zone. Also, the necessary power characteristics of electric heaters and their temperatures were calculated. With the calculated values taken, the amount of heat required to remove the capillary moisture is 33 kW. In this case, the calculated temperature of the outer surface of the latex film is 90°C, and that of the heat-transfer surface, 105°C, at an infrared radiator temperature of 800°C.

The amount of heat needed to remove the adsorption moisture in the radiator zone is 29 kW. The temperature of infrared radiators is 400°C, and the calculated distance to the film surface, 113 mm. The experimental and theoretical data obtained were used in designing a conductive-infrared drier for latex drying in manufacture of heat-and-noise insulation for the interior of automobiles at Standartplast Ltd., Ivanovo.

CONCLUSIONS

(1) It was experimentally determined that 15 s is necessary for removal of the capillary moisture from latex at a temperature of the heat-transfer surface equal to 105°C.

(2) The residence time of a latex film in the zone of infrared drying is 91 s, and the temperature of radiator surfaces, 400°C.

(3) The main geometric parameters of the drying chamber were determined.

HISTORY OF CHEMISTRY AND CHEMICAL TECHNOLOGY

Academician Vladimir Aleksandrovich Kistyakovskii (to 140th Anniversary of His Birthday)

Vladimir Aleksandrovich Kistyakovskii is among the prominent Russian natural scientists of the late XIX and early XX centuries. He made a major contribution to the understanding of the nature of electrolyte solutions and to the theory of corrosion and metal protection; he was a versatile physical chemist and electrochemist. In 1904–1905, he organized at St. Petersburg Polytechnic Institute the first Russia's laboratory of physical chemistry and theoretical electrochemistry, which was excellently equipped for that time.

V.A. Kistyakovskii was born on September 30 (October 12), 1865, into the family of a known lawyer, professor of criminal law at Kiev University, Aleksandr Fedorovich Kistyakovskii (1833–1885). A.F. Kistyakovskii descended from a clergyman from Chernigov province. He received his secondary education at Chernigov theological seminary and graduated from the department of law of Kiev University in 1857. In 1970, he became doctor of criminal law and ordinary professor. As more than once evidenced by his contemporaries, he was among outstanding Russia's criminologists.

In 1883, V.A. Kistyakovskii finished Second Kiev Gymnasium and entered the natural department of the physicomathematical faculty of Kiev University. In 1884, the university was temporarily closed because of students' disturbances and the students had to pass again the entrance procedure. In this situation, V.A. Kistyakovskii decided to enter a similar department of St. Petersburg University, where quite a number of known scientists were in the teaching staff at that time [1, 2]. When at senior courses, V.A. Kistyakovskii worked under supervision of Professor M.D. L'vov (1848–1899), an organic chemist and a disciple of A.M. Butlerov (1828–1886). An experimental study of the action of arsenic acid on some organic compounds, reported already in 1889 at a meeting of the Russian Physicochemical Society, was the only V.A. Kistyakovskii's work in the field of organic chemistry. Further, his scientific interests shifted to physical chemistry under the influence of works by West-European scientists J. van't Hoff (1852–1911), M. Planck (1858–1947), and S. Arrhenius (1859–1927). The young V.A. Kistyakovskii accepted with a considerable interest new approaches to the nature of electrolyte solutions and presented as a graduation thesis a review paper "Arrhenius–Planck Hypothesis." This was one of the first papers in Russia in which concepts of dissociation processes in solutions were presented [3]. In the final part of the paper, V.A. Kistyakovskii discussed the possibility of making closer different views concerning the nature of solutions, using the concept of hydration of ions.

At the end of January in 1889, V.A. Kistyakovskii successfully graduated from the natural department of the physicomathematical faculty of St. Petersburg University with a degree of a candidate. After that, in 1889–1890, he continued, on his own initiative, his education at the laboratory of Professor W. Ostwald (1853–1932) in Leipzig (Germany), which, in those years, was a center of newly born scientific disciplines, physical chemistry and electrochemistry. Together with W. Ostwald, W. Nernst (1864–1941) and S. Arrhenius worked at the laboratory during the same period of time. All the three scientists were Nobel Prize winners at different times: in 1909, 1920, and 1903, respectively. In publication of the first

1070-4272/05/7811-1893 © 2005 Pleiades Publishing, Inc.

world's journal specialized in physical chemistry and in studies of solutions, Ostwald had a close associate, van't Hoff. Van't Hoff was a professor of chemistry, mineralogy, and geology at Amsterdam University; later, a professor of Berlin University and one of the first scientists who received the 1901 Nobel Prize in chemistry for the discovery of laws of chemical dynamics and osmotic pressure in solutions [4, 5].

The work at Ostwald's laboratory and personal contacts with prominent physical chemists and electrochemists strongly affected all the subsequent V.A. Kistyakovskii's scientific activities. After his work in Leipzig, the young scientists attended a course of lectures on physics in Paris University. In 1890, V.A. Kistyakovskii summarized the results obtained at Ostwald's laboratory in an important publication on the nature of aqueous solutions of double salts, in which he also considered complicated cases of electrolytic dissociation and introduced the concept of complex compounds into the Russian literature. In November 1890, at the age of 25, V.A. Kistyakovskii returned to Russia.

The last decade of the XIX century was a very difficult time for the young scientist. His attempts to obtain a grant to prepare for professorship at St. Petersburg University failed, and there were no vacant positions at higher-school institutions of the city. V.A. Kistyakovskii had to earn his living in various ways, simultaneously performing experiments as a supernumerary researcher at the chemical laboratory of the university. In 1894–1896, he published in two parts the paper "On Chemical Transformations in a Homogeneous Medium," in which he summarized the results of his experimental studies in the field of kinetics of esterification in aqueous-alcoholic solutions. After having passed his master's examination and delivering test lectures, V.A. Kistyakovskii was allowed to teach at St. Petersburg University as a privatdocent beginning on October 15, 1896. In the same year, he submitted to the Council of the physicomathematical faculty of St. Petersburg University his master's dissertation in chemistry. However, the defense of the dissertation did not take place because rather authoritative chemists, D.P. Konovalov (1856–1929), N.A. Menshutkin (1842–1907), and A.E. Favorskii (1860–1945), and a mathematician K.A. Posse (1847–1928) gave negative referees' comments to the work [6]. From January 1, 1897, till September 1, 1901, V.A. Kistyakovskii taught physics at Peter the Great women's gymnasium in St. Petersburg. Simultaneously he delivered facultative courses of lectures on physical chemistry and photochemistry as a privatdocent of the university. A considerable attention of the scientific community was attracted by V.A. Kistyakovskii's report "Analysis of Objections to the Theory of Electrolytic Dissociation" at the XI Congress of Natural Scientists in 1901 [7]. The scientist emphasized that "it will become possible in the future to find a direct relationship between the chemical nature and electrolytic dissociation."

On August 1, 1902, later than others, after a personal address to Menshutkin, V.A. Kistyakovskii was invited to occupy the position of a senior laboratory assistant at the opening Emperor Peter the Great Polytechnic Institute in St. Petersburg. The institute had, from the time of its foundation, a metallurgical department and electrochemical subdepartment, in whose curricula chemical disciplines occupied the central place. The curricula were composed with the participation of such known chemists as D.I. Mendeleev (1834–1907), P.I. Walden (1863–1957, academician since 1910), and a prominent metallurgist D.K. Chernov (1839–1921). After Walden refused to occupy the position of dean of the metallurgical department, Menshutkin was appointed, and then elected the dean and formed the teaching staff.

Already at the beginning of 1903, V.A. Kistyakovskii submitted to Moscow University a new version of his master's dissertation with a brief title "Physicochemical Studies." The author summarized his previously performed and published studies, largely devoted to substantiation and development of the concept of electrolytic dissociation. The choice of Moscow University was not accidental because I.A. Kablukov (1857–1942), who actively supported ideas of Arrhenius and Ostwald, worked there. In May 1903, V.A. Kistyakovskii's master's degree was approved.

On June 15, 1903, V.A. Kistyakovskii was appointed extraordinary professor of Polytechnic Institute and organized the first Russia's laboratory and chair of physical chemistry and theoretical electrochemistry, which possessed a first-class, for that time, equipment [8, 9]. V.A. Kistyakovskii delivered lectures on physical chemistry and electrochemistry, supervised graduation works, and, in the first years, himself conducted laboratory studies with students. At that time, studies of the electrochemical behavior of metals in aqueous media started to occupy the central place among quite a number of V.A. Kistyakovskii's research areas. Being himself an excellent experimenter, V.A. Kistyakovskii had an opportunity to perform a wide variety of electrochemical studies.

Already in 1901, when determining the electrode potential of magnesium in a solution of potassium cyanide, V.A. Kistyakovskii observed the phenome-

non of passivity for the first time for this metal. The electrochemical behavior of magnesium in various media was studied by him in more detail in 1907. Originally, the passive state of magnesium had been attributed only to formation of an invisible film of the metal oxide. Later, the scientist interpreted this process as formation of magnesium oxide hydrate. This gave rise to examination of thin films from the colloidal-electrochemical standpoint. Beginning in 1909, V.A. Kistyakovskii developed his own original film theory of passivity and corrosion of metals, primarily as applied to magnesium, iron, chromium, and, in part, aluminum. The results obtained were summarized in V.A. Kistyakovskii's doctoral dissertation [10], which was published as a separate book in conformity with the regulations of that time. The concepts of passivity and corrosion of metals, developed by V.A. Kistyakovskii, were put into final shape only in the second half of the 1920s.

Having defended his dissertation for the degree of a doctor of chemistry at Moscow University in May 1910, V.A. Kistyakovskii was elected an ordinary professor at St. Petersburg Polytechnic Institute. In 1912–1916 was, in parts, published the full course of electrochemistry written by the scientist. This course also included the basic concepts of the film theory of passivity of metals. The time from 1903 to 1917 was the most fruitful during the whole period of V.A. Kistyakovskii's scientific activities.

In the summer of 1918, in view of the unfavorable living conditions in Petrograd, V.A. Kistyakovskii went to a long business trip to southern Russia. He first went to Kiev, where his mother and other relatives lived. As is known, German troops were brought into the Ukraine, including Kiev, in early April 1918, in accordance with the Brest peace treaty. On April 29, 1918, the supreme power was handed over to the Ukrainian hetman, to which position was elected P.P. Skoropadskii (1873–1945), a former general of the Russian army. High official positions (Secretary of State, Minister of the Interior) were occupied by I.A. Kistyakovskii (1876–1940), V.A. Kistyakovskii's brother, a prominent lawyer and an active member of the party of constitutional democrats, who later emigrated [11]. After the hetman's rule was established, a group of scientists raised the question of organization of the Ukrainian Academy of Sciences. A Russian academician V.I. Vernadsky (1863–1945, academician since 1912), a prominent natural scientist, geochemist, mineralogist, public figure, and one of leaders of constitutional democrats, who was in the Ukraine at that time, was invited to chair the Commission for organization of the Ukrainian Academy of Sciences. At the ceremony devoted to the beginning of work of the Commission in July 1918, Vernadsky delivered a speech "To organization of the Ukrainian Academy of Sciences." on November 27, 1918, Vernadsky was unanimously elected its president. Among other scientists who was in the Ukraine at that time, V.A. Kistyakovskii and his brother B.A. Kistyakovskii (1868–1920), a lawyer and philosopher, and an ordinary professor of state law at Kiev University, were actively involved in the preparatory work on the draft law concerning foundation of the Academy of Sciences and on its statute [8, 12]. In Vernadsky's opinion, organization of the Ukrainian Academy of Sciences should have promoted the national revival of the Ukraine, rise in its science and culture, and development of economy. It was presumed that intensive exchange of scientific achievements between the Academies of Sciences of Russia and Ukraine would strengthen their union within a common federal state.

In January 1920, V.A. Kistyakovskii's health deteriorated and he went to the North Caucasus for medical treatment. His stay there was described in detail in scientist's autobiography [13]. In view of V.A. Kistyakovskii's departure from the Ukraine, V.A. Plotnikov (1873–1947), a graduate from Moscow University (1895) and a professor of Kiev Polytechnic Institute, who was known for his studies in the field of electrochemistry of nonaqueous solutions, was elected to fill his position as head of the chair of chemistry at the Ukrainian Academy of Sciences. V.A. Kistyakovskii became a supernumerary academician of the Ukrainian Academy of Sciences [14]. Only in the autumn of 1922, he managed to return to Petrograd and resume, after a four years' interruption, his teaching and scientific activities at the Polytechnic Institute, which then continued until he moved to Moscow with Academy's institutions in 1934.

Beginning in 1925, the concepts of the film theory of passivity were fully formulated and its relationship with metal corrosion processes was emphasized in V.A. Kistyakovskii's papers [8, 15–17]. In those years, the film theory of passivity was a major contribution to the theory of electrode potentials and served as a basis for the development of the theory of corrosion of metals [18]. V.A. Kistyakovskii's many-years' comprehensive research activities were highly appreciated in our country and abroad. In 1925, he was elected a corresponding member, and in 1929, an academician of the Academy of Sciences of the USSR. He also was a full member of the Paris Physicochemical Society and Electrochemical Society in New York. It would be incorrect to believe that, beginning in 1907, the whole attention of the scientist was concen-

trated on problems of the electrochemistry of metals, development of the theory of the passive state, and analysis of the nature of passive films. It is clear from V.A. Kistyakovskii's publications and correspondence that in the following years, too, he paid a considerable attention to other issues. In response to a suggestion by Arrhenius to deliver at the Nobel Institute in Stockholm a number of lectures on his works, V.A. Kistyakovskii wrote on September 1, 1923: "... I divided my studies into three series: (1) Theory of heat and the liquid state; here, seven papers were already published in Russian in 1915–1923 and several works remain unpublished. (2) Colloid chemistry and related areas. (3) Miscellaneous. Here belong studies of passivity, periodic phenomena, and motochemical and other observations in the field of electrochemistry" [19].

Already in 1904, V.A. Kistyakovskii established the relationship between the molecular weight of a fluid, its capillary head, and boiling point under atmospheric pressure (Kistyakovskii rule). This relationship was theoretically substantiated in another his work in 1913 and confirmed by a vast body of experimental data. The Kistyakovskii rule can be used to determine the molecular weight of fluids and the degree of their association at the boiling point. In 1923, V.A. Kistyakovskii established an empirical relationship between the molar heat of vaporization of an unassociated fluid and its boiling point at atmospheric pressure (Kistyakovskii formula). The heats of vaporization, calculated by this formula, are in good agreement with experimental data. The scientist's studies in this area are considered in detail in a textbook *Prikladnaya fizicheskaya khimiya* (Applied Physical Chemistry) (part 1, Leningrad, 1926), written by him.

In 1930, V.A. Kistyakovskii organized the Leningrad Colloid-Electrochemical Laboratory of the Academy of Sciences of the USSR (LAKE). Originally, the laboratory had the minimum number of staff members and several postgraduate students. Later, the laboratory was transferred to Moscow, together with a number of other institutions of the Academy. After that the laboratory was, on V.A. Kistyakovskii's initiative, substantially expanded and transformed into the Colloid-Electrochemical Institute of the Academy of Sciences of the USSR (KEIN), where quite a number of prominent scientists worked afterwards [20]. The institute was concerned with a wide variety of problems. In 1939, Academician A.N. Frumkin (1895–1976) became director of KEIN. In 1945, V.A. Kistyakovskii's 80th birthday was celebrated [8].

The more than half a century of V.A. Kistyakovskii's vigorous scientific and pedagogical activities substantially enriched the chemical science with valuable generalizations and laws, new approaches and ideas. V.A. Kistyakovskii luckily combined qualities of a pedagogue, theoretician, experimenter, and organizer. The experimental studies personally carried out by the scientist in the field of physical chemistry and electrochemistry can be rightfully regarded as classical.

For his activities, Academician V.A. Kistyakovskii was decorated with high state awards.

Vladimir Aleksandrovich Kistyakovskii died on October 19, 1952, at the age of 87 after a long illness. The last period of his life was aggravated by the fact that, because of a serious injury, from which he suffered during evacuation to Kazan, he lost, despite prolonged medical treatment, ability to move by himself. Nevertheless, his relationships with the institute and industrial organization survived till the last years of his life [6].

According to recollections of his contemporaries, V.A. Kistyakovskii was a broadly educated scientist, was connoisseur of literature, took interest in theater, and wrote poetry. He was known not only in our country, but also among foreign scientists, and maintained friendly relationships with Arrhenius, Nernst, Bredig, and other colleagues. The scientific and pedagogical activities of V.A. Kistyakovskii constitute an entire epoch in the origination and development of physical chemistry, electrochemistry, and theory of metal corrosion.

An outstanding lawyer Aleksandr Fedorovich Kistyakovskii and his sons were typical representatives of Russian liberal intelligentsia, whose fate is inseparable from the political events in Russia in the first quarter of the XX century. B.A. Kistyakovskii's son, G.B. Kistyakovskii (1900–1982), was educated in Germany and worked in the United States since 1926, at Princeton and Harvard Universities. He was a known physical chemist, special advisor for science and technology of the President of the United States (1959–1968), and bearer of higher scientific and state awards of the United States and other countries [8].

BOOK REVIEWS

Kobayashi, N., *Vvedenie v nanotekhnologiyu* (Introduction to Nanotechnology),

Russian translation from Japanese by Khachoyan, A.V.; Patrikeev, L.N., Ed. of translation; Moscow: BINOM, 2005, 134 pp.

A brief and well-published book in the popular form introduces the reader to advances in nanotechnology in Japan and other countries in the late XX and early XXI centuries. The authors demonstrate the exceedingly wide opportunities of nanotechnologies in such fields of technology as electronics and power engineering, as well as in biology and medicine.

The brief preface by translator and editor (pp. 7, 8) emphasizes that the book is neither a scientific monograph nor a textbook on nanotechnology. Its purpose is to give to a wide audience of readers a notion of the rapid present-day development of nanotechnologies and prospects for their application. The nanoscience develops before our eyes at the interface between quite a number of independent fields of science and technology and has a largely interdisciplinary nature. The preface also notes that the state of development of nanotechnologies in our country was described in an issue of *Rossiiskii khimicheskii zhurnal* (Russian Chemical Journal) (2002, vol. 46, no. 5) devoted to this subject. In recent years, the research in nanotechnology at the leading scientific centers of Russia has become considerably more intensive.

In the introduction of the Japanese edition of the book (pp. 9, 10), its author, N. Kobayashi, notes that the first country that understood the opportunities furnished by nanotechnology and devised a long-term strategy of development of this area was the United States, where an extensive scientific and technological program was adopted already in February 2000.

The material of the book is presented in seven small chapters. Chapter 1 (pp. 11–20) gives a general notion of what is nanotechnology. The author defines it as a set of technologies or methods based on manipulations with separate atoms or molecules on a scale of 1 to 100 nm. Passing to the nanometer scale (to objects less than 10 nm in size) leads to changes in quite a number of highly important parameters of a substance.

Chapter 2 (pp. 21–30) briefly describes the most important scientific achievements that gave rise to nanotechnology. Particularly prominent among these is the idea put forward in 1959 by R. Feynman, an American physicist and Nobel Prize winner, that substances and objects can be created by piece-by-piece "atomic" assembly. Chapter 3, "Nanotechnology World" (pp. 31–70), occupies the central place in the book. The author describes practical applications of the tunneling effect, gives notion of how microscopy develops, traces the transition from optical to electron microscopes, and further to scanning probe microscopes, and explains the principle of their operation. Special attention is given in the chapter to carbon nanotubes and prospects for their use.

Chapter 4 (pp. 71–103) prognosticates economical and social consequences of the introduction of nanotechnologies. The author, in particular, notes that the main difficulty in industrial implementation of nanotechnologies consists in that it is necessary to develop methods for processing of new materials, rather than in their synthesis. The chapter describes methods for measurements, processing, and modeling, to be used to obtain and use nanomaterials. It discusses the relationship between nanotechnologies, on the one hand, and problems of conservation and power engineering, development of science and life, and problems of agriculture, on the other. Also, the possibility of application of nanotechnologies in aerospace engineering and prospects for creation of ultralight and ultrastrong materials are considered.

The small Chapter 5 (pp. 104–115) is devoted to the development of nanotechnologies in the United States, some West-European countries, and Japan. According to the author's prognoses based on budget allocations, the main competition in the field of nanotechnologies will occur in the nearest future between the United States and Japan. In accordance with the Basic plan of development of the Japanese science, the government of the country will spend on the scientific and technological research as a whole 1% of the national income, which will constitute in five years (beginning in 2001) a sum equivalent to about 200 bil-

1070-4272/05/7811-1898 © 2005 Pleiades Publishing, Inc.

lion dollars. To the four research areas that are the most important for Japan belong medicine and public health, information technologies, ecology, and nanotechnology.

Chapter 6 (116–128) is fully devoted to the development of nanotechnologies in Japan. According to the author's prognoses, nanotechnologies will become the base of the industry and will fundamentally change the economy and social life in 10–20 years. In this context, it is necessary to devise a state strategy for development of this field of science. The development of nanotechnologies must improve the competitiveness of Japanese companies and preserve their leadership in key areas of science and technology. The priorities in financing of nanotechnological studies are considered.

Chapter 7 (pp. 129–134) discusses the problems of organization of nanotechnological industries.

The book contains a large number of informative illustrations, schemes, and tables; the presentation is very simple and easily understandable. According to the author's intention, the book will be of use for businesspersons, economists, and sociologists who wish to get an, at least, general notion of the new and rather promising area of science and technology. In the referees' opinion, the audience may be even wider. A popular presentation of the fundamentals of nanotechnology will be of use for teachers of chemistry and physics in senior classes of schools, especially those specialized in physics and mathematics, and teachers of chemical and physical disciplines at junior courses of higher-school institutions.

INFORMATION

11th International Conference on Renewable Resources and Plant Biotechnology NAROSSA 2005

The 11th International Conference on Renewable Resources and Plant Biotechnology was held on June 6–7, 2005 at the head office of the Institute of Natural Fibers (Poznan, Poland). The Conference was organized under patronage of the Department of Agriculture of Saxony-Anhalt (Germany). The sponsors of the Conference were Pilot Pflanzeneöltechnologie Magdeburg e.V. (PPM), Dr. Wiegel, Anlagenbau GmbH (Germany), BMD (BIO Mitteldeutschland GmbH, Halle-Saale, Germany), OHMI-Consulting GmbH (Magdeburg, Germany), and "Cellubast" (Center of Excellence on Natural Lignocellulosic Fibrous Raw Materials, INF). The conference was organized by Innoplanta e.V. (Gatersleben, Germany), INF, BioPro AG (Biological Products, Magdeburg, Germany), Forschungs- und Beratungszentrum für Maschinen- und Energiesysteme e.V. (FBZ), and An-Institut an der Hochschule Merseburg (FH) (Germany).

The conference organizers were Prof. Ryszard Kozlowski (Director of INF) and Dr. Frank Pudel (OHMI, Magdeburg). The members of the Scientific Committee were experts from Belarus, Bulgaria, Canada, Estonia, France, Germany, Hungary, Latvia, Poland, Romania, Russia, the United Kingdom, and the United States (a total of 29 persons). Researchers and industry representatives from these countries and also from Czech Republic, Switzerland, and Vietnam have delivered presentations at the Conference.

The Conference Program covered four plenary lectures and 34 brief presentations, which were delivered at two sections.

At the opening ceremony, Prof. Kozlowski outlined the topicality of the Conference for theoretical and applied chemistry. The ceremony also included speeches by Mr. B. Mackoviak (The Office of the Marshal of Wielkopolskie Voivodeship, Poland), Mrs. Anne-Maria Keding (Ministry of Agriculture and Environment of Saxony-Anhalt, Germany), and Marek Beer (The Wielkopolska Voivodeship Office, Poland).

The plenary lectures covered the most topical areas of science presented at the Conference. Prof. Melvyn F. Askew (Central Science Laboratory, York, England, the United Kingdom) in his lecture considered potentialities and limitations in using bioresources in Europe. The problem of renewable resources and their food and nonfood applications in Poland was analyzed in the lecture given by Ryszard Kozlowski, Maria Mackiewicz-Talarczyk, and Przemyslaw Baraniecki (Institute of Natural Fibres, Poznan, Poland). Dr. Detlef Wilke (Inno Planta e.V., Gatersleben, Germany) told about why we have a need in plant biotechnology. Prof. G.E. Zaikov (Emanuel Institute of Biochemical Physics, Russian Academy of Science, Moscow, Russia) gave a lecture on quantitative prediction of the behavior of polymers in living bodies including human beings.

The presentations delivered at the First Section covered the topics concerning understanding of the strategic potentialities of natural genetic engineering: renewable resources; cultivation of wheat; cultivation of rye for bioethanol production; new quality of potato starch—a novel product produced from the renewable raw material using plant biotechnology; transgenic oil-producing crops as a renewable resource for production of long-chain polyunsaturated fatty acids; interaction of polymers with atmospheric pollutants, utilization of wastes from farming and textile industry; hemp production, processing, and market in the Europe; research on flax in the United States (production and standards); from hemp to textile—some ideas concerning yield, processing, and storage; properties of fibers produced from hail-damaged hemp, recent data on fiber production by biotreatment, and study of the stability of hempseed oil; low-temperature drying of plants in air-fluidized bed; microbial impact on the yield and composition of oils produced from marjoram (*Majorana hortensis*), caraway (*Carum carvi L.*), and common thyme (*Thymus vulgaris L.*); cultivation and production of mulberry-tree (*Bombyx mori L.*); the use of biotechnology in cultivation of flax in Czech Republic; current progress in cultivation of hemp in Poland; *in vitro* methods in production of flax; effect of micro- and macroelements on the yield of flax seed and performance of flax fiber; and some aspects of the effect of sodium ions on flax growing.

The presentations delivered at the Second Section covered the following topics: enzymatic processing in

1070-4272/05/7811-1900 © 2005 Pleiades Publishing, Inc.

fiber production; cotton yarn with high fiber density produced using enzymatic processing; application of hemp fibers obtained by enzymatic processing; protection of flax fabrics against UV rays using natural dyes; new (heterogeneous–heterophase) model for oxidation of carbochain polymers; and improvement of the quality of herbicides using linseed-oil, to meet the European Community standards.

In the Closing Plenary Section, Prof. Ryszard Kozlowski and Dr. Frank Pudel noted that this Conference contributed significantly to both theory and practice. Close interlinks are seen in the Conference contributions between the chemistry, physics, biochemistry, biology, agriculture, and chemical industry.

The next 12th Conference will be held at the University of Magdeburg (Germany) on June 5–7, 2006.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Synthesis of Lanthanide Nitrates from Phosphosemihydrate

E. P. Lokshin, K. G. Ivlev, and O. A. Tareeva

Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Resources, Kola Scientific Center, Russian Academy of Sciences, Apatity, Murmansk oblast, Russia

Received January 26, 2005; in final form, May 2005

Abstract—A technological scheme for the recovery of lanthanides from phosphosemihydrate to obtain a nitrate solution was suggested. This scheme does not violate the balance of sulfuric acid and water, adopted in manufacture of extraction phosphoric acid.

Sulfuric acid leaching-out of lanthanides (Ln) from calcium sulfate semihydrate [technical name, phosphosemihydrate (PSH)] yields solutions containing 0.4–3.25 g l^{-1} Σ Ln_2O_3 [1–3]. Lanthanides are commonly recovered from sulfuric-phosphoric acid leaching solutions by a number of methods. It was shown in [5, 6] that neutralization of leaching solutions with ammonia produces water-enriched, difficultly filterable concentrates containing up to 40 wt % lanthanides. The filtration can be improved as follows: by performing neutralization before the onset of precipitation, with the solutions then evaporated to obtain crystalline precipitates of lanthanide phosphates [7]; by lowering the neutralization rate by using a mixture of gaseous ammonia and air, taken in a 1 : (2–4) ratio [8]; and by using magnesium oxide or carbonate for neutralization [9].

Calculations show that the expenditure for evaporation of solutions may exceed the price of the lanthanide concentrate obtained. No technology has been developed for utilization of low-concentration solutions based on ammonium sulfate and phosphate, contaminated with a number of impurities. Processing of phosphate concentrates of lanthanides is a complicated task involving a gross expenditure.

Lanthanides can be precipitated from sulfuric acid leaching solutions in the form of sparingly soluble fluorides [10, 11]. Upon introduction of hydrofluoric acid into a leaching solution containing 10 wt % sulfuric acid, the fluoride concentrate contains 40–42 wt % lanthanides [10].

Lanthanide fluorides, and especially the most valuable fluorides of yttrium-group lanthanides, are well soluble in sulfuric acid solutions [12]. Therefore, precipitation is commonly carried out using a large excess of hydrofluoric acid, whose main part remains in a solution after the separation of lanthanides. Consequently, it is unlikely that the mother liquor can be used for leaching-out of lanthanides from subsequent batches of PSH. In addition, accumulation of alkaline elements in reused leaching solutions will impair the efficiency of precipitation of lanthanides because of the formation of better soluble double fluorides [13]. Similarly to that of phosphate concentrates, processing of fluoride concentrates of lanthanides is a complicated task involving a gross expenditure. Hydrofluoric acid is expensive and its use can be economically justified only if the resulting fluoride concentrate is used without further processing. However, yttrium and lanthanides of the medium group, which largely predetermine the necessity for recovery of lanthanides from the apatite concentrate, cannot be recovered into separate products in this case.

In [14], it was suggested to recover a lanthanide concentrate from sulfuric acid leaching solutions containing 10–20 wt % sulfuric acid by evaporating a solution to a sulfuric acid concentration exceeding 30 wt %. The thus obtained sulfate concentrates of lanthanides contain up to 25 wt % Ln_2O_3 [1]. Their processing into target products is less expensive and simpler than that in the case of phosphate or fluoride concentrates. However, evaporation of sulfuric acid solutions is expensive. In addition, the possibility of recycling a sulfuric acid solution after recovery of a lanthanide concentrate into leaching of subsequent PSH batches has not been analyzed.

Lanthanides can be extracted from sulfuric acid solutions for PSH leaching with solutions in a hydro-

1070-4272/05/7812-1903 © 2005 Pleiades Publishing, Inc.

carbon stock for manufacture of polyalkylnitrile-phosphoric acid (10% solution). Re-extraction can be done with an aqueous solution of ammonium carbonate to give solid lanthanide carbonates [15]. However, this process cannot be used because there is no industrial manufacture of the extracting agent suggested and its cost is high. The low concentrations of lanthanides and the resulting large volumes of solutions being processed lead to an increased loss of the extracting agent and solvents and to contamination of reused solutions and waste phosphogypsum with hydrocarbon solvents.

Lanthanides can be recovered from sulfuric acid solutions containing ≤20 wt % H_2SO_4 by ionic flotation, with dialkylphosphoric acids as a surfactant, with the subsequent nitric or hydrochloric acid processing of the resulting sublate to regenerate the surfactant and obtain a solution of lanthanide nitrates or chlorides. It has been shown that the surfactant can be introduced without its preliminary dissolution in organic solvents, which makes this method feasible [4]. The implementation of the process is hindered by the necessity for development of a nonstandard industrial equipment for ionic flotation and conversion of the surfactant and by the fact that this surfactant is not manufactured in Russia.

Thus, there still exists no efficient technology for processing of large volumes of lanthanide-containing sulfuric acid leaching solutions with a high content of ecologically hazardous impurities.

In developing methods for recovery of lanthanides from leaching solutions, it necessary to provide their complete utilization and recovery of lanthanides in the form of products convenient for further processing.

The aim of this study was to develop a technique for recovery of lanthanides from sulfuric acid solutions for PSH leaching to obtain conveniently processed lanthanide concentrates and spent sulfuric acid solutions that can be used in manufacture of mineral fertilizers.

EXPERIMENTAL

The solutions used were prepared from waste PSH produced at Ammofos Open-Joint-Stock Company (Cherepovets), which contained 0.56 wt % ΣLn_2O_3 in terms of dry product.

PSH was leached with a sulfuric acid solution for 1 h at 20°C. Then, PSH was separated from the solution and washed with water. A single portion of a sulfuric acid solutions with varied concentration was used to treat successively two batches of the starting PSH, to reach a concentration of ΣLn_2O_3 of about 3 g l^{-1}. Preliminary experiments demonstrated that the optimal leaching conditions are as follows: $c_{H_2SO_4}$ = 20–25 wt %, $V_l : S$ = 2–2.5, temperature 20°C. The concentration of ΣLn_2O_3 and CaO was analyzed by the oxalate gravimetric method, whose relative error for the lanthanide concentrations in the range being analyzed was 0.3 rel % and less [16]. The small amount of SrO, determined together with CaO, was not taken into account separately. The concentrations of individual lanthanides were determined by atomic-emission spectrometry with inductively coupled plasma on a Perkin Elmer Plasma 400 instrument. A good agreement between the results obtained by different methods was observed.

The possibility of precipitation of lanthanides from leaching solutions was analyzed. A 93.5 wt % H_2SO_4 was introduced and its concentration in solution was raised to a prescribed value. The solution was kept with occasional agitation for, as a rule, 12 h. During this time, the rare-earth concentrate crystallized. The mother liquor was separated from the precipitate, diluted to a concentration of 20 wt %, and partly used to process further batches of PSH. The experiments were carried out at $V_l : S$ = 2.5 and 2.0 (Table 1). In determining the recovery, the increase in the solution volume upon addition of concentrated H_2SO_4 was taken into account.

It follows from the data in Table 1 that repeated use of recycled mother liquors obtained upon spontaneous precipitation of the lanthanide concentrate from them provides a satisfactory leaching-out of lanthanides from PSH. A decrease in $V_l : S$ to 2.0 has virtually no effect on the average recovery of lanthanides into a leaching solution. In separate experiments, the concentration of lanthanides in solutions could be raised to $c > 4$ g l^{-1}; however, the significant decrease in recovery in the second stage of each cycle demonstrates that further accumulation of, at least, some of lanthanides in solution is impossible. Although a major part of lanthanides crystallized on raising the H_2SO_4 concentration to 30 wt %, their concentration in the mother liquor remained rather high.

An increase in the initial concentration of lanthanides in solution on lowering $V_l : S$ from 2.5 to 2.0, introducting seed crystals, making longer the crystallization time, and agitating the solutions (Table 1, run nos. 6–10) favored a rise in the completeness of precipitation and, consequently, led to a higher recovery of lanthanides into the concentrate.

However, an insufficient reproducibility of the degree of precipitation of lanthanides was observed.

* Solution nos. 1.2, 2.2, and 4.2 contain a solid phase.

This is probably due to existence of additional factors affecting the process of their crystallization, in addition to the supersaturation by lanthanides, which appears on raising the H_2SO_4 concentration. The most probable of these are fluctuations of the induction period in crystallization or of sodium and potassium concentrations in comparatively small PSH samples used in different experiments. It should be noted that precipitates enriched in lanthanides were formed upon prolonged storage from some solutions obtained in the second stages of leaching and containing, according to a calculation, 20 wt % H_2SO_4.

Table 2 compares the Ln_2O_3/Ce_2O_3 ratio in leaching solutions with that in the apatite concentrate. It can be seen that, in the case of a multiple use of recycled mother liquors, the relative concentrations of most of individual lanthanides that passed into solution are close to those in the apatite concentrate, with, however, a tendency toward accumulation of holmium, erbium, and ytterbium observed.

The Ln_2O_3/Ce_2O_3 ratio in solutions from which precipitates were formed (Table 2, solution nos. 1.2, 2.2, and 4.2) exceeds that in undecomposed solutions. This suggests that precipitates formed in storage are enriched in cerium. However, the fact that there is no noticeable accumulation of lanthanides of the medium group in solutions shows that they also pass in noticeable amounts into concentrates.

The change in the concentrations of ΣLn_2O_3 and CaO in solutions before and after crystallization (Table 1) was used to evaluate their ratio in the concentrates obtained (Table 3).

It can be seen from Table 3 that 71.9–78.6% of lanthanides can be precipitated from leaching solutions obtained at $V_l : S = 2.0$ is. Further increase in the H_2SO_4 concentration markedly raises the completeness of crystallization of lanthanides from leaching solutions (Table 4).

The behavior of individual lanthanides in the course of sulfuric acid precipitation was analyzed using model sulfuric acid solutions containing prescribed concentrations of individual lanthanides. The efficiency of precipitation of yttrium, cerium, and gadolinium was evaluated. The results of the experiments are listed in Table 5, whence it can be seen that raising the H_2SO_4 concentration to 40–42.7 wt % provides precipitation of cerium to an extent of 96% and more; however, an acceptable extent of precipitation was reached for yttrium and gadolinium only at a H_2SO_4 concentration of 50 wt % and more. As can be seen in Table 4, cocrystallization makes greater the extent of precipitation of more soluble lanthanides.

40	39.6	10.4	88.1	120	41.4	9.4	92.0
				180	41.4	9.4	92.1

An analysis of lanthanide concentrates demonstrated (see Table 6) that lanthanides are precipitated in the form of sulfates. The main impurity is calcium sulfate, and the content of P_2O_5 and a number of other impurities in the concentrates is low.

The conversion of sulfate concentrates of lanthanides, recovered by filtration from sulfuric acid leaching solutions, into nitrates by treatment with a solution of calcium nitrate was studied. A concentrate containing (wt %): Ln_2O_3 45 and Ca 12.8, was used in the experiments. The conversion was performed at $V_l : S = 10$. The expenditure of $Ca(NO_3)_2$ exceeded by 5% the amount stoichiometrically necessary for lanthanide nitrates to be formed by the reaction

$$Ln_2(SO_4)_3 + 3Ca(NO_3)_2 = 2Ln(NO_3)_3 + 3CaSO_4. \quad (1)$$

The excess was consumed for the reaction of the mother liquor with sulfuric acid:

$$H_2SO_4 + Ca(NO_3)_2 = CaSO_4 + 2HNO_3. \quad (2)$$

As indicated by the data in Table 7, the conversion is rather fast and complete. A part of "loss" is presumably associated with cocrystallization of lanthanides with $CaSO_4 \cdot 2H_2O$. Calculations show that the content of ΣLn_2O_3 in the $CaSO_4 \cdot 2H_2O$ precipitate is no less than 6 wt %.

To accumulate lanthanides in the nitrate solution, the $V_l : S$ ratio was lowered and the primary nitrate solution was used for conversion of subsequent portions of the sulfate concentrate of lanthanides.

Introduction of additional amounts of $Ca(NO_3)_2$ and a sulfate rare-earth concentrate into a solution containing 41.4 g l^{-1} ΣLn_2O_3 yielded, without any decrease in recovery during 1 h at $V_l : S = 4$, solutions containing 106.5 g l^{-1} ΣLn_2O_3 and 13.9 g l^{-1} CaO.

Conversion of leaner concentrates (35 wt % Ln_2O_3 and 12.8 wt % CaO), performed in the course of 1 h at $V_l : S = 4$ and a 5% excess of $Ca(NO_3)_2$ in two stages, yielded a solution containing 137.1 g l^{-1} ΣLn_2O_3 and 22.0 g l^{-1} CaO at a 83.5% recovery of lanthanides.

The increased content of CaO in the nitric acid solution of lanthanides is due to the noticeable solubility of $CaSO_4 \cdot 2H_2O$ in the nitric acid solution [18] and can be diminished by neutralization of the free nitric acid formed in solution by reaction (2).

If an unwashed PSH is used to recover lanthanides, water spent for its washing to remove extraction phosphoric acid can be delivered to washing of PSH after a sulfuric acid treatment. This will preserve the balance for water of the main production process. Therefore, leaching of PSH with model sulfuric acid solutions, into which H_3PO_4, Na_2SiF_6, and

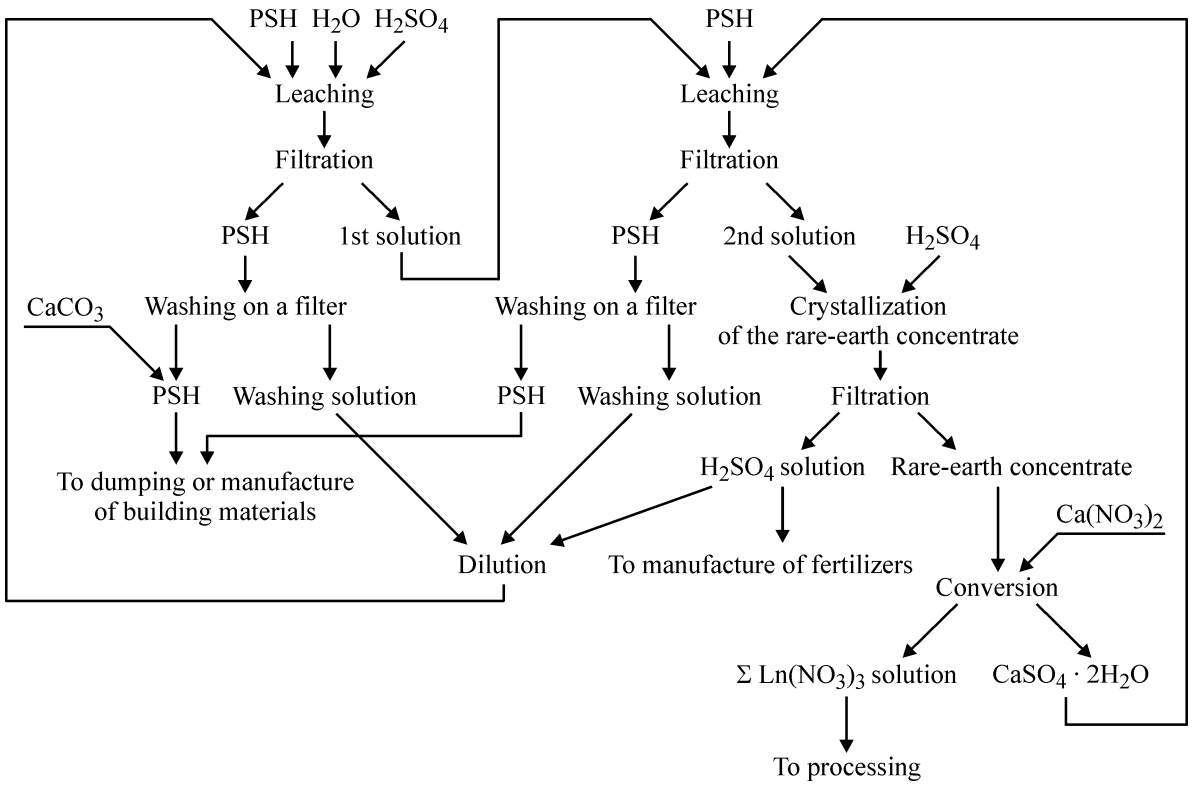
* Numerator, conditions and results of leaching in the first stage; denominator, those in the second stage.

K_2SiF_6 were preliminarily introduced, was studied. The amount of the additives to be introduced was evaluated on the assumption that extraction phosphoric acid remaining in PSH after filtration completely passes, together with Na_2SiF_6 and K_2SiF_6 it contains, into solution.

When the same solution was used for successive leaching of two weighed portions of PSH, the efficiency of leaching in the second stage decreased under any experimental conditions (Table 8). The basic dependences obtained in the case of single-stage leaching were preserved: presence of orthophosphoric acid in a leaching solution improves the efficiency of two-stage leaching-out of lanthanides (run no. 1), presence of Na_2SiF_6 has virtually no effect (run no. 2), and K_2SiF_6 leads to a decrease in the recovery into solution (run no. 3). In the case of a solution with a molar ratio $Na_2SiF_6:K_2SiF_6 = 3$, $V_l:S$ ratio lowered from 2.5 to 2 (run nos. 4 and 5), and leaching time increased to 2 h (run no. 6), the recovery in the second stage decreased.



The results of the study made it possible to suggest [19] a new technological scheme for recovery of lanthanides from PSH (see Scheme). It includes leaching-out of lanthanides with 20–24% sulfuric acid at 20°C and $V_l : S = 2$ for 1 h, crystallization of the lanthanide concentrate by raising the concentration of H_2SO_4 in the leaching solution, separation of the solution from the lanthanide concentrate, and conversion of lanthanide sulfides into nitrates with calcium nitrate. With calcium chloride used for conversion, solutions of lanthanide chlorides can be obtained.

The sulfuric acid solution obtained upon recovery of lanthanides can be used in the main technology of manufacture of extraction phosphoric acid. In the semihydrate process, 0.924 tons of 93.5% H_2SO_4 is consumed per ton of the apatite concentrate [20]. In principle, it can be used to precipitate the lanthanide concentrate from PSH leaching solutions, with the resulting solutions delivered to processing of the apatite concentrate.

Table 9 lists the limiting H_2SO_4 concentrations in recycled solutions in relation to the acid concentration in the solution used to leach PSH, which can

Table 9. Maximum possible H_2SO_4 concentration in recycled solution in relation to acid concentration in the solution used to leach PSH

22	47.4	43.8
24	48.5	45.1

Scheme.

be reached in this case. The calculations disregarded the increase in the concentration of the sulfuric acid solution by the reaction that occurs in PSH leaching:

$$CaSO_4 \cdot 0.5H_2O + 1.5H_2O = CaSO_4 \cdot 2H_2O. \quad (3)$$

As can be seen in Tables 4, 5, and 9, the maximum possible H_2SO_4 concentration in the recycled solution will provide a sufficiently complete precipitation of lanthanides. When necessary to make higher the degree of precipitation, the concentration of H_2SO_4 can be raised if not the whole amount of PSH formed on the technological line is to be processed.

An important issue determining the possibility of application of the technology suggested is to maintain the water balance in manufacture of mineral fertilizers, which is achieved when unwashed PSH is used. In this case, phosphoric acid is not lost and is returned with the recycled sulfuric acid solution into the technological process in which extraction phosphoric acid is manufactured.

The sulfate rare-earth concentrate is converted into a concentrated nitric acid solution, which can be used for extractive production of group concentrates or individual compounds by the known techniques [21] or without processing in manufacture of catalysts. The concentration of lanthanides in a minor amount of gypsum formed in conversion of lanthanide sulfates is rather high, and it is advisable to recycle it into the stage of sulfuric acid leaching.

The direct recovery of lanthanides, achieved in laboratory experiments with a 45% H_2SO_4 solution used for precipitation, will be no less than $0.55 \times 0.9 \times 0.917 \times 100 = 45.4\%$ relative to their content in PSH or 37.8% relative to that in the apatite concentrate. In the calculation, the recovery of lanthanides is taken to be 55% in leaching (the lower recovery in the modeling of leaching from an unwashed PSH is compensated by the higher initial content of $\Sigma\ Ln_2O_3$ in this PSH), 90% in precipitation into a sulfide concentrate, and 91.7% in conversion into a nitric acid solution. In further development of the technology, the recovery may increase because lanthanides are returned with the washing solution into the process for manufacture of extraction phosphoric acid and may pass into PSH, a more complete precipitation of lanthanides into the sulfate concentrate is possible, and additional recovery of a part of lanthanides from gypsum formed in conversion of lanthanide concentration is probable.

Table 10. Content of radionuclides in the apatite concentrate and products of PSH processing*

Product	Activity of radionuclides, Bq kg^{-1}			Content of nuclides, wt % (PSH) or g l^{-1} (solution)		A_{eff}, Bq kg^{-1}
	^{40}K	^{226}Ra	^{232}Th	^{238}U	^{232}Th	
PSH:						
starting	16 ± 13	20 ± 3	54 ± 7	0.00016 ± 0.00002	0.0013 ± 0.0002	92 ± 14
leached	18	12 ± 5	36 ± 6	0.00009 ± 0.00004	0.0009 ± 0.0001	60 ± 4

* Data obtained by N.A. Mel'nik.

A study of the behavior of radionuclides (Table 10) demonstrated that the main part of radionuclides find their way into extraction phosphoric acid. ^{238}U and, especially, ^{232}Th are leached-out to a considerably lesser extent than lanthanides. Analysis of data on the radioactivity of a solution of lanthanide nitrates suggests that the activity A_{eff} of ΣLn_2O_3 recovered from a nitric acid solution will not exceed 250 ± 50 Bq kg^{-1}, i.e., further processing of the lanthanide concentrate or its use are possible without limitations by the radiation factor.

The technology suggested does not produce waste and virtually does not use reagents alien to manufacture of extraction phosphoric acid. Calcium nitrate is converted in the process into gypsum. Typical chemical equipment can be used in all the procedures involved.

CONCLUSIONS

(1) At room temperature, raising the H_2SO_4 concentration in leaching solutions containing 20–24 wt % H_2SO_4 and about 3 g l^{-1} ΣLn_2O_3 to 30 wt % and more causes crystallization of a lanthanide concentrate. The extent of precipitation of lanthanides increases with the H_2SO_4 concentration in solution. It is shown that mother liquors remaining upon crystallization of the lanthanide concentrate can be repeatedly used for effective leaching-out of lanthanides from phosphosemihydrate.

(2) The relative concentrations of lanthanides in the leached-out sum for the most part correspond to those in the starting apatite concentrate; however, there is a tendency toward accumulation of holmium, erbium, and ytterbium. Sulfate concentrations of lanthanides are converted into nitrates by treatment with calcium nitrate solutions to give solutions containing (g l^{-1}): ΣLn_2O_3 137 and CaO 22.

(3) A technological scheme is suggested for recovery of lanthanides from phosphosemihydrate produced from the Khibiny apatite concentrate. The scheme includes sulfuric acid leaching-out of lanthanides with 20–24% sulfuric acid, precipitation of lanthanides in the form of double sulfates with alkali metals by raising the concentration of H_2SO_4 to 30 wt % and more, and conversion of the sulfide concentrate of lanthanides into a nitric acid solution by treating the concentrate with a calcium nitrate solution.

(4) No radioactive products or wastes are formed in recovery of lanthanides by the technological scheme suggested, which is an exceptional situation for the rare-earth production processes.

Abstract—The solubility of $YPO_4 \cdot 2H_2O$, $LaPO_4 \cdot 1.5H_2O$, $CePO_4 \cdot 1.5H_2O$, and $NdPO_4 \cdot H_2O$ 10–60 wt % in sulfuric-phosphoric acid solutions containing 10–60 wt % H_2SO_4 and 13.8–41.4 H_3PO_4 was studied.

The Khibiny apatite concentrate is a promising source of lanthanides. It is mostly processed by the semihydrate sulfuric acid technology, with the main part of lanthanides concentrated in the phosphosemihydrate [1, 2]. It has been shown previously that the main part of lanthanides is present in the phosphosemihydrate in the form of hydrated orthophosphates [3, 4]. The content of yttrium, lanthanum, cerium, and neodymium oxides in the sum of lanthanide oxides in the apatite concentrate is about 90 wt % [5]. Therefore, data on the solubility of their hydrated orthophosphates in mineral acids are particularly important for development of processes for acid leaching-out of lanthanides from the phosphosemihydrate. In addition, data on the solubility of $YPO_4 \cdot 2H_2O$ make it possible to indirectly evaluate the solubility of hydrated orthophosphates of lanthanides of the yttrium group.

The solubility of hydrated lanthanum, cerium, and neodymium orthophosphates in nitric acid solutions containing 1–5 M HNO_3 has been examined [6]. It was found that, for the compounds studied, it increased with the HNO_3 concentration, to reach a value of 70–100 g l^{-1} (in terms of oxides) at 20°C. The solubility varied in the order Ce ≈ Nd > La; however, the solubility of hydrated lanthanum orthophosphate at 100°C markedly exceeded that of hydrated neodymium orthophosphate.

The most promising method for recovery of lanthanides from phosphogypsum and phosphosemihydrate formed in sulfuric acid processing of the apatite concentrate into extraction phosphoric acid is their leaching-out with sulfuric acid [7, 8]. However, the solubility of hydrated lanthanide orthophosphates in sulfuric acid solutions has been insufficiently studied.

It has been found that the solubility of yttrium, lanthanum, and cerium hydrophosphates in sulfuric acid solutions containing 2–10 wt % H_2SO_4 and 2.76 g l^{-1} H_3PO_4 increases with the H_2SO_4 concentration, to reach values of 11.8, 11.1, and 10.7 g l^{-1}, respectively (in terms of Ln_2O_3). In a H_2SO_4 solution with a concentration of 2 wt %, their solubility decreased by a factor of 1.8–2.0 as the H_3PO_4 concentration was raised from 0 to 14 g l^{-1}.

The aim of this study was to determine how the solubility of $YPO_4 \cdot 2H_2O$, $LaPO_4 \cdot 1.5H_2O$, $CePO_4 \cdot 1.5H_2O$, and $NdPO_4 \cdot H_2O$ at 20°C depends on the concentration of sulfuric acid solutions with $c_{H_2SO_4}$ = 10–60 wt % and minor additions of orthophosphoric acid ($c_{H_3PO_4}$ = 13.8–41.4 g l^{-1}).

EXPERIMENTAL

Reagents of analytically pure grade were used in the study. The hydrated phosphates were synthesized by the procedures described in [9–12]. It was established, using thermogravimetric and X-ray phase analyses, that the phosphates synthesized corresponded to $YPO_4 \cdot 2H_2O$ and $LnPO_4 \cdot 1.5H_2O$ (Ln = La, Ce) and $NdPO_4 \cdot H_2O$.

Sulfuric-phosphoric acid solutions were prepared by introducing minor additions of concentrated (85 wt %) H_3PO_4 into a solution with a prescribed concentration of H_2SO_4. In doing so, changes in $c_{H_2SO_4}$ were neglected. The range of variation of $c_{H_3PO_4}$ in solutions corresponded to the possible content of H_3PO_4 in technological solutions produced in sulfuric acid leaching of a waste phosphosemihydrate.

The concentration of lanthanides in solutions was determined by the oxalate gravimetric method [13].

The solubility was studied by the isothermal method. An excess amount of hydrated lanthanides orthophosphates was introduced into starting solutions with a prescribed concentration. The mixtures were kept with agitation in hermetically sealed vessels at 20 ± 0.5°C until equilibrium was established (≥720 h). The attainment of equilibrium was judged from the invariability of the results obtained in analysis of samples of the liquid phase. The experimental data obtained are listed in the table.

As can be seen from the data in the table, the solubility of the hydrated lanthanide orthophosphates studied in sulfuric-phosphoric acid solutions strongly differs from their solubility in nitric acid solutions. An increase in $c_{H_2SO_4}$ first leads to a rise in solubility, but then it markedly decreases for all of the orthophosphates studied. The highest solubility is observed at different $c_{H_2SO_4}$ (wt %): 15 for yttrium and lanthanum orthophosphates, 20 for cerium orthophosphate, and 25 for neodymium orthophosphate. The solubility in sulfuric-phosphoric acid solutions of the same composition decreases in the order Ce > La > Nd, with the exception of solutions with $c_{H_2SO_4} = 10$ wt %, in which the solubility of hydrated lanthanum orthophosphate exceeds that of cerium orthophosphate. The solubility of yttrium orthophosphate exceeds that of cerium orthophosphate at $c_{H_2SO_4} \leq 15$ wt %; however, as $c_{H_2SO_4}$ increases further, it steeply decreases, to become lower than that of orthophosphates of other lanthanides under study at $c_{H_2SO_4} \leq 35$ wt %.

It was found by X-ray phase analysis that the equilibrium phases were $Y_2(SO_4)_3 \cdot 8H_2O$, $La_2(SO_4)_3 \cdot 9H_2O$, $Ce_2(SO_4)_3 \cdot 9H_2O$, and $Nd_2(SO_4)_3 \cdot 8H_2O$. The composition of the solid phase indicates that the hydrated orthophosphates of the lanthanides under study dissolve in sulfuric-phosphoric acid solutions, with their preliminary conversion into sulfates by the reaction

$$2LaPO_4 \cdot kH_2O + 3H_2SO_4 + (m - 2k)H_2O \rightarrow Ln_2(SO_4)_3 \cdot mH_2O + 2H_3PO_4. \quad (1)$$

At the same time, their solubility both in nitric acid and in sulfuric-phosphoric acid solutions is only qualitatively determined (solubility was a maximum as $c_{H_2SO_4}$ becomes higher) by the salting-out action of main acids. This is so because the solubilities of lanthanide nitrates in nitric acid [14] and sulfates in sulfuric acid [15] of about the same concentrations is many times higher. This indicates that presence of phosphate ions in acid solutions noticeably affects the solubility. It should be noted that, because of the occurrence of reaction (1), the $c_{H_2SO_4}$ in equilibrium solutions in fact exceeded that in the starting

solutions and could not be precisely determined because of the variable amount of the solid phase.

An increase in $c_{H_3PO_4}$ in sulfuric acid solutions with lowered $c_{H_2SO_4}$ leads to a decrease in solubility. This is observed at $c_{H_2SO_4} \le 30$ wt % for yttrium and neodymium orthophosphates, ≤ 20 wt % for lanthanum, and ≤ 35 wt % for cerium. The extent of the decrease becomes lower as $c_{H_2SO_4}$ increases. On raising $c_{H_2SO_4}$ further, to 40–45 wt %, making $c_{H_3PO_4}$ higher at a constant $c_{H_2SO_4}$, as a rule, leads to a slight increase in the solubility of hydrated orthophosphates. Finally, upon a further increase in $c_{H_2SO_4}$, introduction of orthophosphoric acid into leaching solutions has virtually no effect on the solubility, whose value becomes rather low.

The decrease in the solubility of hydrated orthophosphates in solutions with a constant comparatively low concentration of H_2SO_4, observed on raising the $c_{H_3PO_4}$, can be attributed to a noticeable decrease in the actual $c_{H_2SO_4}$ because of the occurrence of reaction (1). At higher $c_{H_2SO_4}$, the influence exerted by reaction (1) on the actual value of $c_{H_2SO_4}$ becomes less important, and an increase in $c_{H_3PO_4}$ in solutions of this kind possibly leads to formation of more soluble acid phosphates of lanthanides or of their salts with a mixed sulfate–phosphate anion. The formation of acid phosphates of lanthanides, including those studied here, was observed on raising the concentration of phosphoric acid solutions [6–9]. Raising the concentration of phosphoric acid to ≥75 wt % led to a considerable increase in the solubility of hydrated acid phosphates in this acid at 20–25°C. At low $c_{H_3PO_4}$, the bottom phase was composed of hydrated phosphates. On being kept in more concentrated phosphoric acid solutions these phosphates were converted into $YPO_4 \cdot H_3PO_4 \cdot 2H_2O$ at $c_{H_3PO_4}$ = 44.7–70.2 wt %, $Y(H_2PO_4)_3 \cdot 2.5H_2O$ at $c_{H_3PO_4}$ = 73.1–89 wt %, $3LaPO_4 \cdot H_3PO_4 \cdot H_2O$ at $c_{H_3PO_4}$ = 6.73–77.8 wt %, and $CePO_4 \cdot xH_3PO_4 \cdot yH_2O$ at $c_{H_3PO_4}$ = 1.42–84.8 wt %. Only for hydrated neodymium phosphate in phosphoric acid solutions, no acid phosphate was formed at $c_{H_3PO_4}$ = 8.91–80.50 wt %. Possibly, the less pronounced tendency toward formation of acid salts by hydrated neodymium phosphate predetermines its lowest solubility in sulfuric-phosphoric acid solutions.

To conclude, it should be noted that the hydrated lanthanide orthophosphates studied determine the composition of lanthanides in the apatite concentrate and in phosphogypsum obtained in its processing. Their solubility is sufficiently high and does not limit the accumulation of lanthanides in sulfuric-phosphoric acid solutions for leaching of phosphogypsum at the sulfuric acid concentrations used in this study.

CONCLUSIONS

(1) The dependence of the solubility of $YPO_4 \cdot 2H_2O$, $LaPO_4 \cdot 1.5H_2O$, $CePO_4 \cdot 1.5H_2O$, and $NdPO_4 \cdot H_2O$ at 20°C on the concentration of the acids in sulfuric–phosphoric acid solutions containing 10–60 wt % H_2SO_4 and 13.8–41.4 g l^{-1} H_3PO_4 was determined.

(2) It was established that, for the phosphates studied, the solid phase is composed of hydrated sulfates of the corresponding lanthanide.

(3) It was shown that, as the concentration of sulfuric acid is raised, the solubility of the hydrated lanthanide phosphates studied first increases and then falls.

(4) It was demonstrated that the solubility of the hydrated lanthanide phosphates under study in sulfuric-phosphoric acid solutions is sufficiently high and does not limit the accumulation of lanthanides in sulfuric–phosphoric acid solutions for leaching of phosphogypsum at the sulfuric acid concentrations used in the study.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Synthesis and Thermal Transformations of Hydrated Ammonium Copper(II) Zinc Diphosphate

V. A. Kopilevich, I. D. Zhilyak, and L. V. Voitenko

National Agrarian University, Kiev, Ukraine

Received July 26, 2005

Abstract—Synthesis of hydrated ammonium copper(II) zinc diphosphate was described. Its thermal properties were studied and schemes of thermal transformations were suggested.

Synthesis of phosphates containing cations of various *d*-metals [1–5] with ammonium coordinated to them [6–8] is of potential interest from the viewpoint of their possible catalytic or biological activity [9–11]. We have not found any published information on the synthesis and thermal behavior of ammonium copper(II) zinc diphosphate.

The aim of this study was to prepare hydrated ammonium copper(II) zinc diphosphate and to study its thermal properties.

EXPERIMENTAL

Hydrated ammonium copper(II) zinc diphosphate was prepared by its salting out from an ammonia solution with an organic solvent [8]. As starting reagents we used a mechanical mixture of copper and zinc diphosphates, which were synthesized according to the procedures [12, 13] and taken in a prescribed molar ratio, a concentrated aqueous solution of ammonia (23–25 wt %), and acetone. The mechanical mixture of copper and zinc diphosphates with a prescribed Cu : Zn mole ratio was dissolved in concentrated aqueous ammonia. The resulting solution was poured into acetone. In the process, a bottom phase, i.e., an oily liquid of intense blue color, was separated. The mother liquor was removed by decanting, and the bottom phase was kept in air at 15–25°C to complete solidification and constant weight.

For ammonium copper(II) zinc diphosphate of the composition $CuZnP_2O_7 \cdot 3.0NH_3 \cdot 2.5H_2O$ (**I**)

Found (%): CuO 20.20, ZnO 20.50, P_2O_5 35.30, NH_3 12.72, H_2O 11.28.
Calculated (%): CuO 19.94, ZnO 20.40, P_2O_5 35.58, NH_3 12.80, H_2O 11.28.

The anionic composition of the compound synthesized (in terms of P_2O_5), determined by quantitative paper chromatography [14], is as follows (%): $P_2O_7^{4-}$ 92.30 and PO_4^{3-} 7.70. The starting copper and zinc diphosphates contained 6.00 rel % P_2O_5 in the form of PO_4^{3-}.

The contents of the components were determined as follows: Zn^{2+} by trilonometry [15], with copper masked by thiosulfate; copper(II) by iodometry; P_2O_5 by gravimetry [16]; and ammonia by evaporation on a Seren'ev apparatus [16]. The contents of water and ammonia were determined from the loss of mass upon heating for 2 h at 750°C. The anionic composition of synthesis products was analyzed by quantitative paper chromatography [14].

An X-ray analysis was carried out on a DRON-UM1 diffractometer (Cu_{K_α} radiation). A graphite single crystal placed in the diffracted beam was used as a monochromator. X-ray diffraction patterns were obtained by the step scanning method at angles 2θ = 4°–80°. The scanning step was 0.05°, and the exposure time at a point, 3–9 s. The experimental diffraction peaks were approximated with Voight's pseudo-function, with the K_{α_1} component isolated. The IR spectra were recorded with a Specord 75-IR spectrophotometer. The samples for measurements were fabricated in the form of pellets with KBr, the concentration of a substance under study was 0.2–0.3 wt %.

The transformations of compound **I** upon heating to 20–815C were studied by thermal analysis on a Q-1500D derivatograph. In the dynamic mode of temperature rise, we used cylindrical platinum crucibles with lids; weighed portions of compound **I** were 0.400–0.500 g. The final decomposition prod-

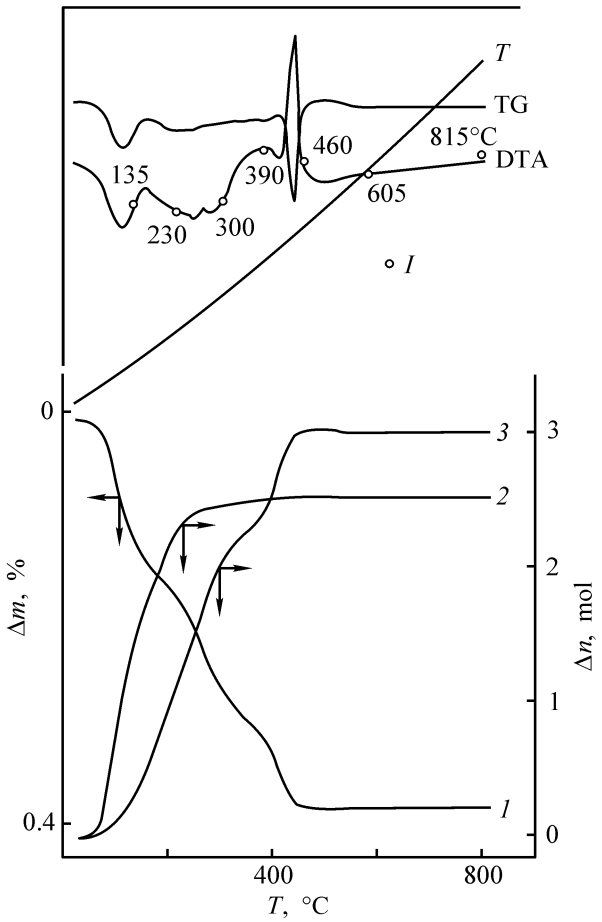

Fig. 1. DTA and TG curves of $CuZnP_2O_7 \cdot 3.0NH_3 \cdot 2.5H_2O$. ($\Delta m$) Change in mass, ($T$) temperature, and ($\Delta n$) change in amount of substance. *I* are sampling points. (*1*) Dynamic heating at a rate of 2.5 deg min^{-1}; (*2*, *3*) loss of (*2*) NH_3 and (*3*) H_2O from the substance on heating.

ucts and all the intermediates were obtained at a sample heating rate of 5 deg min^{-1}.

According to the results of the X-ray analysis, compound **I** has a rhombic crystal lattice with the following lattice constants: a = 6.860(1) Å, b = 15.720(1) Å, c = 18.761(2) Å, and V = 2018.2 Å^3.

According to the results of the thermal analysis (Fig. 1), the thermolysis of the synthesized compound proceeds in the dynamic heating mode in a wide temperature range (70–815°C) and is accompanied (according to the DTA curve) by endothermic effects with dips at 115, 255, 280, and 410°C. At 460°C, a peak associated with an exothermic effect is observed, which is superimposed on an endothermic effect, which is indicated, in particular, by an abrupt change in the weight loss by the sample in the DTG and TG curves.

The TG curve shows a weight loss by the sample at 70–460°C. An analysis of the products formed on heating of compound **I** (Fig. 1, curves *2* and *3*) shows that, in the range 70–135°C, $CuZnP_2O_7 \cdot 3.0NH_3 \cdot 2.5H_2O$ loses 1.43 mol of H_2O and 0.30 mol of NH_3. According to chromatographic data, a sample taken at 135°C, contains 14.00 rel % of P_2O_5 in the form of PO_4^{3-} and 86% in the form of $P_2O_7^{4-}$ (see table). These results indicate that, in the first stage, water is predominantly removed from compound **I** without any essential change of the diphosphate anion:

$$[(CuZn)_2(NH_3)_6(H_2O)_3(P_2O_7)_2] \cdot 2H_2O \xrightarrow{70\text{–}135^\circ C} 2.9H_2O + 0.6NH_3 + [(CuZn)_2(NH_3)_{5.4}(H_2O)_{2.1}(P_2O_7)_2].$$

The results of quantitative chromatography (see table) indicate that a part of diphosphate anions (~45%) are transformed in accordance with the scheme

$$[(CuZn)_2(NH_3)_6(H_2O)_3(P_2O_7)_2] \cdot 2H_2O \xrightarrow{70\text{–}230^\circ C} (CuZn)_2(NH_3)_{3.6}(H_2O)_{0.24}(PO_4)_2(P_2O_7).$$

Variation of the elemental and chemical composition of ammonium zinc diphosphate upon thermolysis in the dynamic mode

T, °C	Composition, as indicated by chemical analysis	Distribution of P_2O_5, rel %			Removed from the starting compound, mol	
		PO_4^{3-}	$P_2O_7^{4-}$	$P_3O_{10}^{5-}$	NH_3	H_2O
Starting	$CuO \cdot ZnO \cdot P_2O_5 \cdot 3.00NH_3 \cdot 2.50H_2O$	7.7	92.3	–	0	0
135	$CuO \cdot ZnO \cdot P_2O_5 \cdot 2.70NH_3 \cdot 1.07H_2O$	14.0	86.0	–	0.30	1.43
230	$CuO \cdot ZnO \cdot P_2O_5 \cdot 1.79NH_3 \cdot 0.12H_2O$	44.9	55.1	–	1.21	2.38
300	$CuO \cdot ZnO \cdot P_2O_5 \cdot 1.00NH_3 \cdot 0.06H_2O$	36.1	52.8	11.1	2.00	2.44
390	$CuO \cdot ZnO \cdot P_2O_5 \cdot 0.59NH_3 \cdot 0.02H_2O$	28.0	60.0	12.0	2.41	2.48
465	$CuO \cdot ZnO \cdot P_2O_5$	9.8	81.2	–	3.00	2.50
605	$CuO \cdot ZnO \cdot P_2O_5$	8.8	91.2	–	3.00	2.50
815	$CuO \cdot ZnO \cdot P_2O_5$	7.8	92.2	–	3.00	2.50

According to the X-ray data (Fig. 2), the substance undergoes amorphization already at 135°C, which points to the active role of water in the crystal structure of the compound. The X-ray-amorphous state of the substance is preserved up to 390°C.

A further increase in temperature in the range 230–390°C results in the condensation of monophosphate and diphosphate ions into tripolyphosphate ions, which is accompanied by removal of additional 2.4 mol of ammonia and 2.5 mol of water. In this case, according to the chromatographic data, the anionic composition of the product of thermolysis at 300–390°C is as follows: 36–28% of P_2O_5 in the form of PO_4^{3-}, 53–60% in the form of $P_2O_7^{4-}$, and 11–12% in the form of $P_3O_{10}^{5-}$. Taking into account the known concepts of thermal transformations of hydrated phosphates [17], we can represent such a distribution of P_2O_5 over oligomeric forms by the following scheme of this stage of thermolysis:

$$(CuZn)_2(NH_3)_{3.60}(H_2O)_{0.24}(PO_4)_2(P_2O_7) \xrightarrow{230–390°C} 2.40NH_3 + 0.20H_2O$$
$$+ (CuZn)_2(NH_3)_{1.20}(H_2O)_{0.04}(PO_4)_{1.12}(P_2O_7)_{1.20}(P_3O_{10})_{0.16}.$$

At 460°C, a new phase is crystallized from the X-ray-amorphous thermolysis products (Fig. 2), and its structure remains unchanged upon further heating up to 815°C. This process is accompanied by a strong exothermic effect and by simplification of the anionic composition of samples, which results from a decrease in the content of tri- and monophosphate ions. The following scheme corresponds to this stage of transformation:

$$(CuZn)_2(NH_3)_{1.20}(H_2O)_{0.04}(PO_4)_{1.12}(P_2O_7)_{1.20}(P_3O_{10})_{0.16} \xrightarrow{460°C} 1.20NH_3 + 0.04H_2O + 2CuZnP_2O_7.$$

According to the X-ray data (Fig. 2), the final thermolysis product is anhydrous copper zinc diphosphate formed at 460°C. According to the results of a full-profile analysis, it has a monoclinic crystal lattice (space group C1 2/*m*1), with the following lattice constants: a = 6.734(1) Å, b = 8.203(4) Å, c = 4.547(2) Å, β = 107.5°, V = 239.53 Å^3, and Z = 2, which is in a good agreement with the known structural data for $CuZnP_2O_7$ [18].

The order in which water and ammonia are removed from the substance is accounted for by the different strengths of H_2O and NH_3 bonds with ions of *d*-metals and by the formation of hydrogen bonds

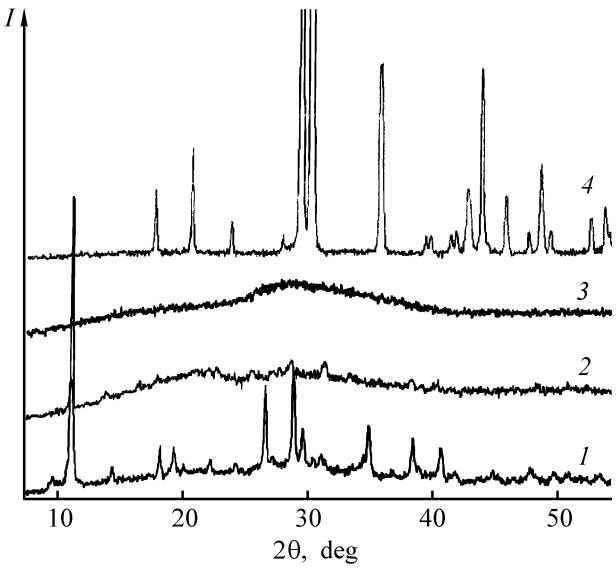

Fig. 2. X-ray diffraction patterns of (*1*) $CuZnP_2O_7 \cdot 3.0NH_3 \cdot 2.5H_2O$ and products of calcination at (*2*) 135, (*3*) 230–390, and (*4*) 815°C. (*I*) Intensity and (2θ) Bragg angle.

in the $M\begin{matrix}\swarrow NH_3 \\ \nwarrow OH_2\end{matrix}\cdots O_3P–O–PO_3$ chain (M = Cu, Zn) with averaging of the electron density [19].

This is confirmed by the results of an IR spectroscopic study of the products formed in thermolysis of the compound, which reveal the presence of bending asymmetric and symmetric vibrations of ammonia molecules at 1595 and 1410 cm^{-1}, respectively, up to 390°C, when vibrations of water molecules are no longer observed.

CONCLUSION

An individual crystalline hydrated ammonium copper(II) zinc diphosphate $CuZnP_2O_7 \cdot 3.0NH_3 \cdot 2.5H_2O$ was isolated from an aqueous ammonia solution. Its thermal properties were studied in the range 20–815°C. It was found that the final product of its thermolysis is anhydrous crystalline copper zinc diphosphate and the process occurs stepwise.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

On the Mechanism of Nickel Recovery from the Sulfide Component in the Ni–Cu–S System in Carbonylation

V. F. Kozyrev, R. A. Shvartsman, and A. S. Mnukhin

Institut Gipronikel' Open Joint-Stock Company, St. Petersburg, Russia

Received July 26, 2005

Abstract—A mechanism of a solid-phase interaction between metallic copper released from the copper–nickel alloy in nickel recovery into the carbonyl gas phase with nickel sulfide in carbonylation of copper-nickel metallurgical half-products is suggested. Experimental data on carbonylation of the magnetic fraction of converter matte in a horizontal rotating reactor at a pressure of 70 gage atm and reaction zone temperature of 180°C are used to determine the coefficient of volume heterodiffusion of copper across a copper sulfide layer.

It is expected that the domestic carbonyl industry will be transferred to synthesis of nickel carbonyl in a horizontal rotating reactor at a pressure of 70 gage atm. In this context, it seems appropriate to consider processes that occur in the course of carbonylation in the Ni–Cu–S system under conditions markedly differing from those in the presently used industrial processes, in which the carbonylation is performed in vertical columns with a fixed bed of a material being carbonylated under a pressure of 200–250 gage atm.

The study was carried out on a laboratory installation, in a horizontal rotating reactor at a pressure of 70 gage atm and reaction zone temperature of 180°C. The magnetic fraction of converter matte, one of the most promising materials for industrial synthesis of nickel carbonyl, was used as the starting raw material. The residue formed in carbonylation, with various techniques used for nickel recovery, was studied by methods of metallography and X-ray fluorescence microanalysis.

One of the main factors governing the rate and extent of nickel recovery in carbonylation of half-products formed in metallurgical processing of sulfide copper-nickel raw materials is recovery of nickel from its sulfide.

This study is concerned with solid-phase interaction of nickel sulfide released from a copper-nickel solid solution after removal of nickel into the gas phase in accordance with the equation

$$Ni_3S_2 + 4Cu = 2Cu_2S + 3Ni. \quad (1)$$

The characteristic structure of a part of a polished section of the residue formed in carbonylation of the magnetic fraction of converter matte produced in solid-phase interaction between metallic copper and nickel sulfide by reaction (1) is shown in Fig. 1. It can be seen that copper sulfide Cu_2S is formed as a continuous fringe at the interface between metallic copper released from grains of a copper-nickel solid solution after removal of nickel from this solution, and grains of nickel sulfide. In this case, copper sulfide reproduces the shape of grains of nickel sulfide it sub-

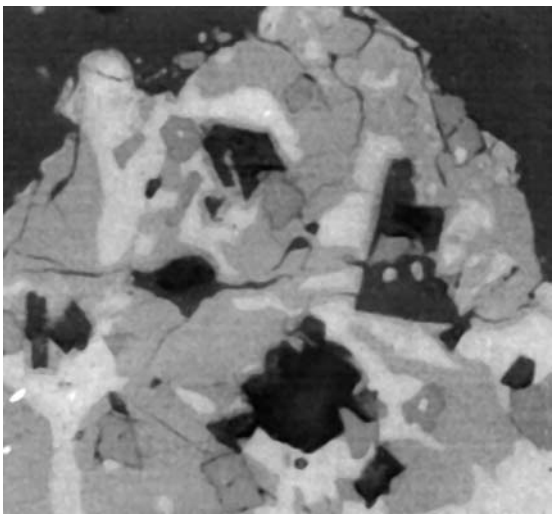

Fig. 1. Formation of Cu_2S at the Cu–Ni_3S_2 phase boundary. *Dark field*, metallic copper released from the Cu–Ni alloy; *light field*, Ni_3S_2; gray fringe at the phase boundary, newly formed copper sulfide Cu_2S.

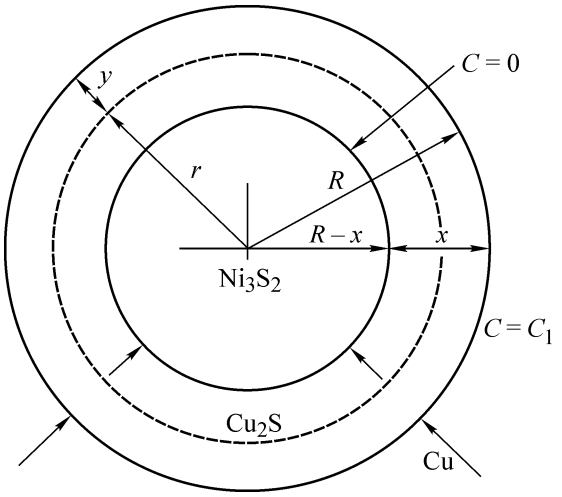

Fig. 2. Model of interaction between metallic copper and nickel sulfide.

stitutes, with the rectilinear contour at the interface between the sulfide and the solid solution, characteristic of nickel sulfide.

In manufacture of nickel from a copper-nickel solid solution, a concentration gradient arises in a layer of the remaining metallic copper. This gradient gives rise to a diffusion flow of its atoms toward the surface of a nickel sulfide grain. The change in the concentration of copper in regions adjacent to nickel sulfide can be rather clearly seen in the same micrograph.

The observed course of the solid-phase reaction of nickel substitution in its sulfide with metallic copper can be understood in terms of the electronic structure of the material being carbonylated. The reactivity of double copper-nickel alloys depends on the number of vacancies in the 3-*d* band of the alloy [1]. The change in the number of vacancies in the 3-*d* band in carbonylation of sulfide copper-nickel materials is due not only to the chemical composition of the metallic phase, which varies as nickel is recovered into carbonyl, but also to contact phenomena that occur at the interface between the solid solution and copper sulfide. A quantitative X-ray fluorescence microanalysis demonstrated that copper sulfide formed by reaction (1) corresponds to a stoichiometry $Cu_{2-x}S$, where $0 < x < 0.22$. This sulfide is a semiconductor with a predominantly *p*-type conduction [2]. The existence of a contact between $Cu_{2-x}S$ and the copper-nickel solid solution in the course of carbonylation leads to redistribution of electrons among the contacting phases because of the different positions of the Fermi level [3]. It may be assumed here that the motion of electrons is directed toward copper sulfide away from the copper-nickel solid solutions, which has a higher lying Fermi level. This is so because, in any system with two condensed phase brought in contact, electrons pass from a subsystem with a higher-lying Fermi level to that with a lower Fermi level. The condition for the attainment of equilibrium is the alignment of the Fermi levels, i.e., equality of the chemical potentials. It is known [4] that, upon chemisorption of gases on ferromagnetic metals and alloys, the magnetic moments of surface atoms change because of the redistribution of the electron density among the adsorbate and adsorbent. Chemisorption of carbon oxide on the surface of ferromagnetic bodies leads to a decrease in the magnetic moments of surface atoms, which is due to filling of holes (vacancies) in the 3-*d* band of the adsorbate by electrons of chemisorbed carbon oxide molecules. The chemisorption capacity of the copper-nickel solid solution for electron-donor species, whose role is played in carbonylation by carbon oxide molecules, grows as the Fermi level moves downwards.

Therefore, the existence of a contact between the copper-nickel solid solution and copper sulfide $Cu_{2-x}S$ in synthesis of nickel carbonyl and the change in the concentration of electrons, which is due to their outflow into copper sulfide, make larger the number of vacancies in the 3*d* band of the metallic alloy and depress the Fermi level. This, in turn, leads to an increase in the chemisorption capacity and reactivity of the copper-nickel solid solution in the near-contact zone.

Copper sulfide Cu_2S is formed as a continuous fringe at the interface between metallic copper released from grains of a copper-nickel solid solution upon removal of nickel. Simultaneously, a concentration gradient arises in a layer of metallic copper. This gradient gives rise to a diffusion flow of its atoms toward the surface of a nickel sulfide grain.

Three main stages can be distinguished when the mechanism of interaction between metallic copper and nickel sulfide by reaction (1) is considered (Fig. 2). The first is migration of copper released from the copper-nickel solid solution after removal of nickel into the carbonyl gas phase toward the surface of nickel sulfide grains (bulk self-diffusion). The second is the bulk heterodiffusion of copper atoms toward the surface of nickel sulfide grains across the copper sulfide layer, which is formed in the course of the reaction and has a continuously growing thickness. The third is bulk heterodiffusion or diffusion along the grain boundaries of nickel released from the sulfide.

If the process of copper migration is considered in terms of the bulk self-diffusion mechanism (stage 1), the diffusion rate can be expressed as

$$\frac{\partial c}{\partial \tau} = \frac{\partial}{\partial x}\left(D\frac{\partial c}{\partial x}\right), \quad (2)$$

whence follows

$$D = \frac{1}{2\tau}\frac{\partial c}{\partial x}\int_{c=c_1}^{c=0} x\partial x, \quad (3)$$

where D is the bulk self-diffusion coefficient of copper ($cm^2\ h^{-1}$).

The rate of nickel migration along crystal faces (stage 3) can be represented as the expression suggested by Hauffe [5]:

$$C_m = \Phi\left(\frac{\eta}{2}\sqrt{D_c t}\right), \quad (4)$$

where $\Phi = \frac{2}{\sqrt{\pi}}\int_0^x e^{-z^2}dz$ is the symbol representing the Gauss error integral.

The problem of bulk heterodiffusion of components in polycrystalline media has been the object of study by domestic and foreign researchers [5–7]. If the model presented in Fig. 2 is adopted as a basis and the Fick equation for spherical coordinates with the boundary and initial conditions

$$C = C_1,\ r = R,\ \tau > 0; \quad (5)$$

$$C = 0,\ r = R - x, \quad (6)$$

is used, the rate of bulk heterodiffusion of copper across the copper sulfide layer (stage 2) can be represented as

$$\frac{\partial x}{\partial \tau} = \frac{D}{B}\left(\frac{\partial c}{\partial r}\right)_{r=R-x}, \quad (7)$$

Here $B = \rho_s/\mu$ is a proportionality factor; ρ_s = 5.7 g cm^{-3}, density of Cu_2S; μ = 159 g mol^{-1}, molecular weight of Cu_2S; c, concentration of metallic copper in the Cu_2S layer; c_1, concentration of copper at the Cu–Cu_2S interface; c_y, concentration of copper on the surface of an arbitrary sphere at a distance of y from the Cu–Cu_2S interface.

Hence, the bulk heterodiffusion coefficient of copper is given by

$$D = \frac{x^2(1 - 2x/3R)B}{2\tau c_1}, \quad (8)$$

Results obtained in measurements of R and x and in calculation of the coefficient D (P = 70 atm, T = 180°C)

Measurement no.	$R\times10^{-4}$, cm	$x\times10^{-4}$, cm	$D\times10^{-8}$, $cm^2\ h^{-1}$
1	9.25	1.85	0.683
2	5.55	0.92	0.173
3	13.90	1.85	0.720
4	6.02	1.38	0.370
5	9.25	1.85	0.638
6	9.25	1.38	0.393
7	2.78	0.92	0.152

and the transformation rate of nickel sulfide grains, by

$$\frac{\partial \varepsilon}{\partial \tau} = K\frac{(1-\varepsilon)^{1/3}}{1-(1-\varepsilon)^{1/3}}, \quad (9)$$

where $K = 2Dc_1/B$.

Experimental data necessary for calculating the bulk heterodiffusion coefficient of copper were obtained by direct measurement of R and x under a microscope at magnification of 1080.

The measurements were made on polished sections of the residues obtained upon carbonylation of the magnetic fraction of the nickel concentrate produced in separation of converter matte, for which the mass recovery of nickel was about 50%.

The results obtained in experiments and in calculating the coefficient D are listed in the table.

Metallographic studies of the x : R ratio in residues formed in carbonylation of various materials at different process durations made it possible to determine the coefficient of bulk heterodiffusion of copper across the newly formed layer of copper sulfide, which was found to be 3.73×10^{-9} $cm^2\ h^{-1}$ at 180°C. For nickel sulfide grains of size not exceeding 10 μm, the rate of their transformation is well comparable with that of nickel recovery from a copper-nickel solid solution.

CONCLUSION

It was shown that, for the recovery of nickel into carbonyl from the sulfide component of the alloy to

be more complete, it is necessary that the structure formed in metallurgical preparation of the material for carbonylation should have grains of the phase constituents of size not exceeding 10–15 μm.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

A Study of the Behavior of Cobalt in Carbonylation of Copper-Nickel Metallurgical Half-Products at Medium Pressure of the Reaction Gas

V. F. Kozyrev, R. A. Shvartsman, and A. S. Mnukhin

Institut Gipronikel' Open Joint-Stock Company, St. Petersburg, Russia

Received July 26, 2005

Abstract—Dependences of the cobalt recovery into the carbonyl gas phase on the content of sulfur and carbon in sulfidized copper-nickel metallurgical half-products subjected to carbonylation were studied at a medium pressure of the reaction gas (70 gage atm). The behavior of cobalt was examined by means of metallographic analysis of the residue formed in carbonylation. A mechanism of solid-phase interaction of cobalt with copper sulfide and a method for calculation of the volume self-diffusion coefficient of cobalt in the crystal lattice of metallic copper deformed after removal of nickel were suggested.

One of the most complicated and capital-intensive conversion techniques in the carbonyl metallurgy of nickel is synthesis of nickel tetracarbonyl. At present, both the technology of this conversion, carried out at a high pressure of the reaction gas (200–250 gage atm) in vertical columns with a fixed bed of the material being carbonylated, and the equipment used in the process have become physically outdated and obsolescent and require a fundamental reconstruction [1].

A new, highly efficient technique for carbonylation of nickel-containing metallurgical half-products formed in processing of sulfide raw materials at a medium pressure of the reaction gas (70 gage atm) in a horizontal rotating reactor has been developed [2, 3]. Industrial implementation of this technology will markedly raise the output capacity of the process, diminish its capital- and energy-intensity, and improve the ecological situation in manufacture of carbonyl nickel.

Of key importance among a number of problems to be solved in developing the new technology was the choice and preparation of a starting raw material for carbonylation that would ensure the maximum selectivity of separation of carbonyl-forming metals, including cobalt.

The behavior of cobalt in the course of carbonylation is largely determined by the ratio of its content in the metallic solid solution to that in the alloy of nickel and cobalt sulfides, because the sulfide cobalt does not react with carbon oxide and its whole amount is preserved in the residue formed in the synthesis [4].

To study the influence exerted by the content of sulfur on the recovery of cobalt in carbonylation, synthetic cobalt-containing sulfur-enriched nickel alloys were prepared. This was done using the most chemically pure materials: carbonyl nickel, electrolytic cobalt, and purified sulfur. The smelting was performed in a corundum crucible placed in a high-frequency induction furnace in a protective argon atmosphere. The compositions of the alloys, recovery of cobalt into carbonyl, and dependence of the cobalt recovery on the content of sulfur in the alloy are listed in Table 1 and shown in Fig. 1a.

Table 1. Chemical composition of cobalt-containing sulfur-enriched nickel alloys

Alloy no.	Mass content in an alloy, %		Mass recovery of Co, %
	Co	S

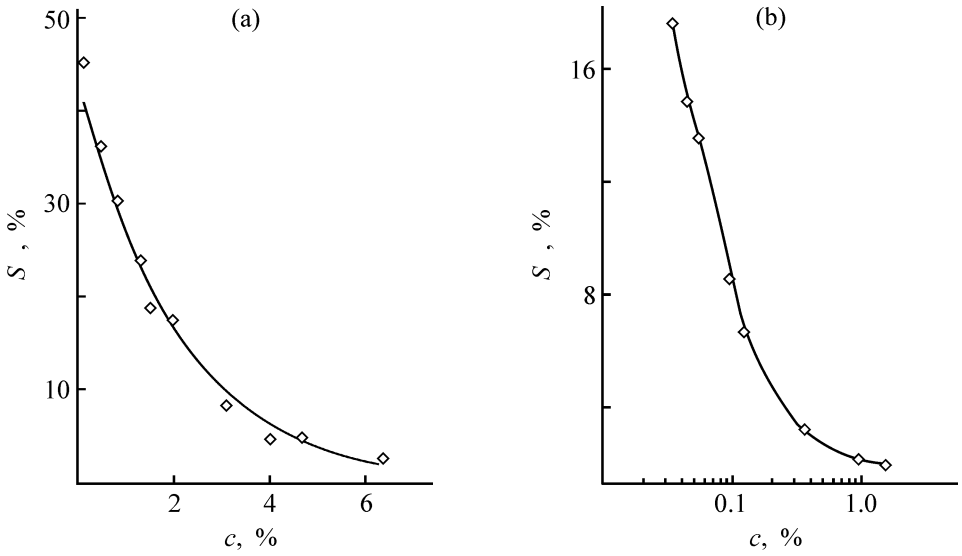

Fig. 1. Mass recovery *S* of cobalt into carbonyl vs. the mass content *c* in the alloy of (a) sulfur and (b) carbon.

Nickel alloys were carbonylated at a pressure of 70 gage atm and temperature of 180°C on a laboratory kinetic installation. The recovery of cobalt was determined from its content in the solid residue formed in the synthesis. The experimental data obtained indicate that, as the mass content of sulfur in the alloy increases from 0.03 to 6.32%, the recovery of cobalt into the carbonyl decreases from 45 to 2%.

Carbon additives introduced to deoxidize the melt in the course of smelting into a raw material to be carbonylated inevitably affect the behavior of cobalt. In order to study the influence exerted by carbon on the recovery of cobalt into the carbonyl, synthetic cobalt-containing carbon-enriched nickel alloys were prepared. Graphite was introduced into the stock as a carbon-containing material. The compositions of the alloys under study, recovery of cobalt into carbonyl, and dependence of the recovery on the content of carbon in the alloy are listed in Table 2 and shown in Fig. 1b.

Table 2. Chemical composition of cobalt-containing carbon-enriched nickel alloys

Alloy no.	Mass content in an alloy, %		Mass recovery of Co, %
	Co	C	
1	2.86	0.035	17.5
2	2.94	0.046	14.8
3	2.54	0.056	12.5
4	2.85	0.098	9.8
5	2.92	0.126	6.7
6	2.68	0.254	2.5
7	2.88	0.368	3.2
8	2.70	0.950	2.2
9	2.43	1.56	2.0

Raising the concentration of carbon in the alloy leads to a dramatic decrease in the cobalt recovery, with this change being the most pronounced when the mass content of carbon is varied within the range from 0.035 to 0.126%. The passivating effect of carbon on the reaction of cobalt carbonylation is accounted for by the overlapping of the "magnetic" band of cobalt in the alloy. In this case, the limited solubility of carbon in cobalt leads, as carbide is formed, to a pronounced decrease in the cobalt recovery just in the range mentioned above, because a carbon atom introduces six electrons into the magnetic matrix of cobalt.

A further increase in the content of carbon has only a slight effect on the recovery of cobalt, which is due to the formation of a separate phase (sooty carbon) at a content of carbon in the alloy that exceeds its solubility limit in both nickel and cobalt. The presence of such a phase does not lead to overlapping of the magnetic band in the ferromagnetic material.

The mass recovery into the carbonyl phase of metallic cobalt contained in the copper-nickel solid solution varies, depending on the composition of the starting raw material and technological parameters of the carbonylation process, from 2 to 40%.

Apparently, the efficiency of the industrial application of the carbonyl process to nickel-containing raw

materials is largely determined by the selectivity of separation of metals. This primarily refers to cobalt and platinum-group metals, because even partial transfer of these metals into the carbonyl phase causes, in further processing, a virtually irrecoverable additional loss.

In order to examine the behavior of cobalt in synthesis of nickel carbonyl, the residue formed in carbonylation of copper-nickel metallurgical half-products was subjected to a metallographic and X-ray fluorescence microprobe analyses. In doing so, a newly formed bright light yellow phase was observed. This phase is formed as a fine fringe at the interface between partly processed grains of the metallic solid solution and copper sulfide. The characteristic appearance of this phase is shown in metallographic micrographs of the residue formed in carbonylation (Fig. 2).

X-ray diffraction and fluorescence microprobe analyses demonstrated that this phase is composed of cobalt sulfide.

Being originally uniformly distributed throughout grains of the solid solution, cobalt concentrates in the course of carbonylation at grain boundaries and forms, after partial or complete removal of nickel into carbonyl, finely dispersed inclusions, now in the form of sulfide in a copper sulfide matrix.

Analysis of the data obtained convincingly demonstrates that the nature of bonds of metallic cobalt in the crystal lattice of the copper-nickel solid solution is of particular importance for the carbonylation process. According to the phase diagrams of the Co–Ni and Co–Cu systems, it can be stated with certainty that, owing to a virtually zero solubility of cobalt in copper, cobalt atoms are associated in the alloy structure exclusively with nickel atoms.

As nickel is recovered into carbonyl, cobalt is liberated from the lattice of the remaining metallic copper and either undergoes carbonylation:

$$2Co + 8CO \rightleftarrows Co_2(CO)_8, \quad (1)$$

or migrates. In the latter case, cobalt migration in the copper lattice may occur in two directions:

(a) from the reaction zone across the layer of metallic copper to the boundary with the newly formed copper sulfide, with the subsequent reaction in accordance with the equation:

$$Co + Cu_2S \rightleftarrows CoS + 2Cu, \quad (2)$$

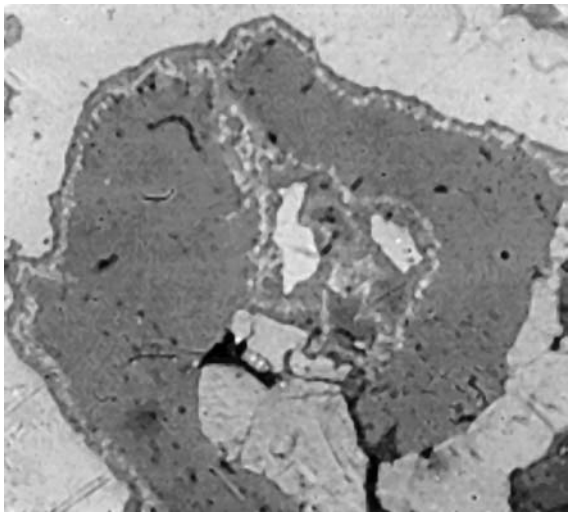

Fig. 2. Characteristic appearance of the residue produced in carbonylation with the formation of a cobalt-containing sulfide phase.

(b) from the reaction zone into as yet unprocessed grains of the copper-nickel solid solution.

The reaction of cobalt sulfide formation goes successfully if copper formed upon removal of nickel is continuously consumed by the reaction with nickel(III) sulfide, which, in turn, is initiated by removal of reduced nickel into the carbonyl phase:

$$Ni_3S_2 + 4Cu \rightleftarrows 2Cu_2S + 3Ni, \quad (3)$$

$$Ni + 4CO \rightleftarrows Ni(CO)_4. \quad (4)$$

Upon the removal of nickel and partial consumption of copper by reaction (3), the crystal lattice is markedly strained and contains a large number of defects. Therefore, the diffusion flux of cobalt across the interface will considerably exceed that in the case of compact metallic copper because of the higher concentration of vacancies and a significant contribution of the surface diffusion.

Let us consider the mechanism of this process for the case of carbonylation of a spherical grain of the copper-nickel solid solution, which has a radius R, contains cobalt, and is embedded in nickel sulfide.

Cobalt released from the crystal lattice after the removal of nickel into carbonyl diffuses from the reaction zone across a layer of metallic copper of thickness $R - \rho = x$. Copper interacts with nickel sulfide and substitutes the latter at the outer contour of the alloy grain, to form a layer of copper sulfide. The scheme of interaction between the phases in

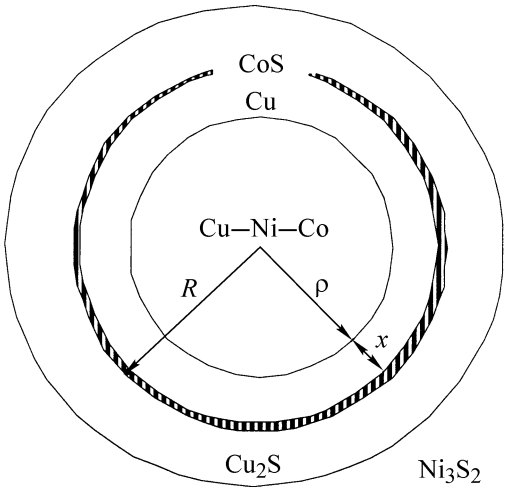

Fig. 3. Scheme of the solid-phase interaction to give cobalt sulfide.

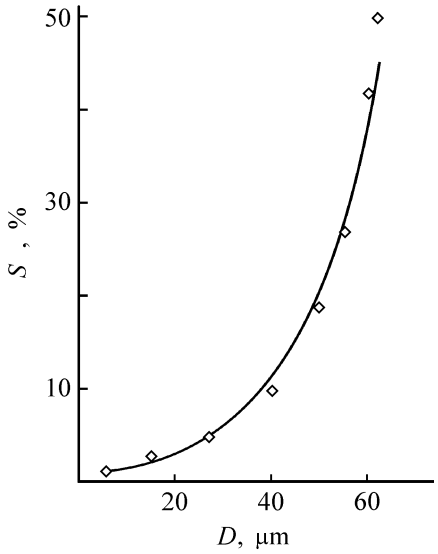

Fig. 4. Mass recovery *S* of cobalt into carbonyl vs. the grain size *D* of the phase constituents of the raw material being carbonylated.

the process under consideration is shown in Fig. 3. The rate of this process is limited by the rate of volume self-diffusion of cobalt across a porous layer of metallic copper. With account of the comparatively low content of cobalt in the initial solid solution, the volume heterodiffusion of cobalt across the layer of its sulfide, formed in the reaction, can be neglected.

To describe the process of cobalt migration across the layer of porous metallic copper, we use the equation of unidimensional spherical diffusion

$$\varepsilon \frac{\partial c}{\partial t} = -D\left(\frac{\partial^2 c}{\partial r^2} + \frac{2\partial c}{r\partial r}\right), \quad (5)$$

where ε is the porosity of the copper layer; *D*, effective diffusion coefficient; and *c*, cobalt concentration at a distance *r* from the particle center, numerically equal to the mass content of cobalt in a unit volume.

We assume that the diffusion process is quasi-stationary, which is justified if the radius of the unprocessed core varies at a sufficiently low rate and the concentration of cobalt in the initial alloy is not high. This assumption can be fully referred to cobalt. Then, integrating the equation

$$\frac{\partial^2 c}{\partial r^2} + \frac{2\partial c}{r\partial r} = 0$$

we obtain

$$\frac{dc}{dr} = \frac{A}{r^2}, \quad (6)$$

where *A* is a numerical coefficient.

Repeated integration yields $c = -A/r + B$.

Taking into account the boundary conditions $r = R$, $r = \rho$, $c = c_r$, and $c = c_\rho$, we find *A*

$$A = \frac{c_\rho - c_R}{1/R - 1/\rho}. \quad (7)$$

Consequently,

$$\frac{dc}{dr} = \frac{c_\rho - c_R}{(1/R - 1/\rho)r^2}. \quad (8)$$

To provide a successful binding of cobalt into sulfide, the diffusion flux across any spherical surface $4\pi r^2$ ($\rho < r < R$) should be no less than the flux of the same metal into the unprocessed core of the metallic solid solution. In view of this fact, we equate both the diffusion fluxes

$$D\frac{c_\rho - c_R}{1/R - 1/\rho} = \gamma_0 \rho^2 \frac{d\rho}{dt}. \quad (9)$$

where γ_0 is the initial mass content of cobalt in a unit volume of the metallic solid solution.

On integrating, we find the time necessary for cobalt released in processing of a grain of the alloy to be bound into sulfide, during which the radius of the grain decreases from *R* to ρ.

$$t = \frac{\gamma_0}{6D(c_\rho - c_R)}[2/R(\rho^3 - R^3) - 3(\rho^2 - R^2)]. \quad (10)$$

The time τ of complete processing of a grain of the cobalt-containing solid solution is found from the condition $\rho = 0$:

$$\tau = \frac{\gamma_0 R^2}{6D(c_\rho - c_R)}. \quad (11)$$

We assume that $c_R = 0$, because cobalt is completely bound into sulfide at the outer surface of the grain and equate c_ρ to the density of cobalt, because being released from the copper-nickel solid solution it virtually does not dissolve in porous metallic copper. Having done so, we can obtain from Eq. (11) the diffusion coefficient of cobalt under carbonylation conditions.

Using the conversion time of a grain of the solid solution of radius R in carbonylation, we calculated the coefficient D_c of volume self-diffusion of cobalt: $D_c = 2.75 \times 10^{-8}$ cm^2 h^{-1} in carbonylation of a granulated nickel alloy at 70 gage atm and a temperature of 180°C.

This value of the diffusion coefficient of cobalt indicates that the diffusion rate and, consequently, the rate of sulfide formation are well comparable with the carbonylation rate of this metal, and the conversion time is directly proportional to the grain size of the phase constituents. The dependence of the recovery of cobalt into the carbonyl phase on the grain size of the phase constituents is shown in Fig. 4.

Thus, an as finely dispersed structure as possible should be formed in the course of a metallurgical preparation of the starting metallurgical half-products for carbonylation in order to improve the selectivity of separation of metals (nickel and cobalt, in particular).

CONCLUSIONS

(1) The behavior of cobalt was studied using methods of metallographic analysis of a residue formed in carbonylation and it was shown that cobalt sulfide appears as a newly formed phase at the boundary between grains of the copper-nickel solid solution and copper sulfide.

(2) An as finely dispersed structure as possible should be formed in metallurgical preparation of the starting metallurgical half-products for carbonylation in order to improve the selectivity of separation of nickel and cobalt in carbonylation.

Abstract—Data on the thermodynamic properties of boundary binary systems were used to calculate the activities of components in liquid alloys of the iron–cobalt–nickel ternary system at a temperature of 1600°C.

Calculational methods have gained wide acceptance in the thermodynamics of liquid three-component metallic systems [1–7]. As rule, the calculations are based on data on thermodynamic properties of boundary binary systems. Using various comparatively simple geometric models, it is possible to describe the surface of an integral thermodynamic property of a ternary system on the basis of the corresponding property of boundary binary systems. Together with geometric models, polynomial expressions for a ternary system are used. The coefficients of these polynomials are found using data on boundary binary systems.

Previously, the integral molar excess Gibbs energy (ΔG^{ex}) and the enthalpy of mixing (ΔH) of alloys of the Fe–Co–Ni system at a temperature of 1600°C were calculated in [8]. The agreement between the results of calculations performed in terms of six different geometric models and those obtained using polynomial dependences reflecting the contribution of binary systems is quite satisfactory. This indirectly confirms that the real shape of the surface of thermodynamic properties of the ternary system is adequately described. The choice of thermodynamic characteristics for the binary boundary systems Fe–Co, Co–Ni, and Ni–Fe was substantiated in detail in [8]. In evaluating the excess Gibbs energy of the binary systems, preference was given to studies carried out using the effusion Knudsen method combined with a mass-spectrometer. Also, the recommendations given in reviews [9–13] were taken into account.

Until recently, data on the thermodynamic properties of the Fe–Co–Ni system have been rather scarce. Velisek and co-authors [13] determined the activities of the components of the ternary system in a limited range of compositions by measuring the saturated vapor pressure at 1227°C, i.e., in the solid state. In [14], the activity of each of the components of the Fe–Co–Ni system was determined at 1200–1650°C, using a Knudsen cell combined with a mass-spectrometer. However, the authors did not intend to make a complete thermodynamic description of the system, and they only studied the Fe–Ni binary system and an adjacent section of the ternary system, with a constant ratio $x_{Fe} : x_{Ni} = 9 : 1$ (x_i, molar fraction of a component in an alloy). In [15, 16], the liquid–vapor equilibrium was studied for eight compositions of the Fe–Co–Ni ternary system at 1600°C. Based on the data obtained and the evidence concerning the boundary binary systems, the authors derived, by means of statistic processing, equations describing how the composition of the vapor phase depends on that of the liquid phase and evaluated the activity coefficients of the components.

Recently, Tomiska studied, using a method modified by him, which employed a Knudsen cell and a mass-spectrometer, the thermodynamic properties of

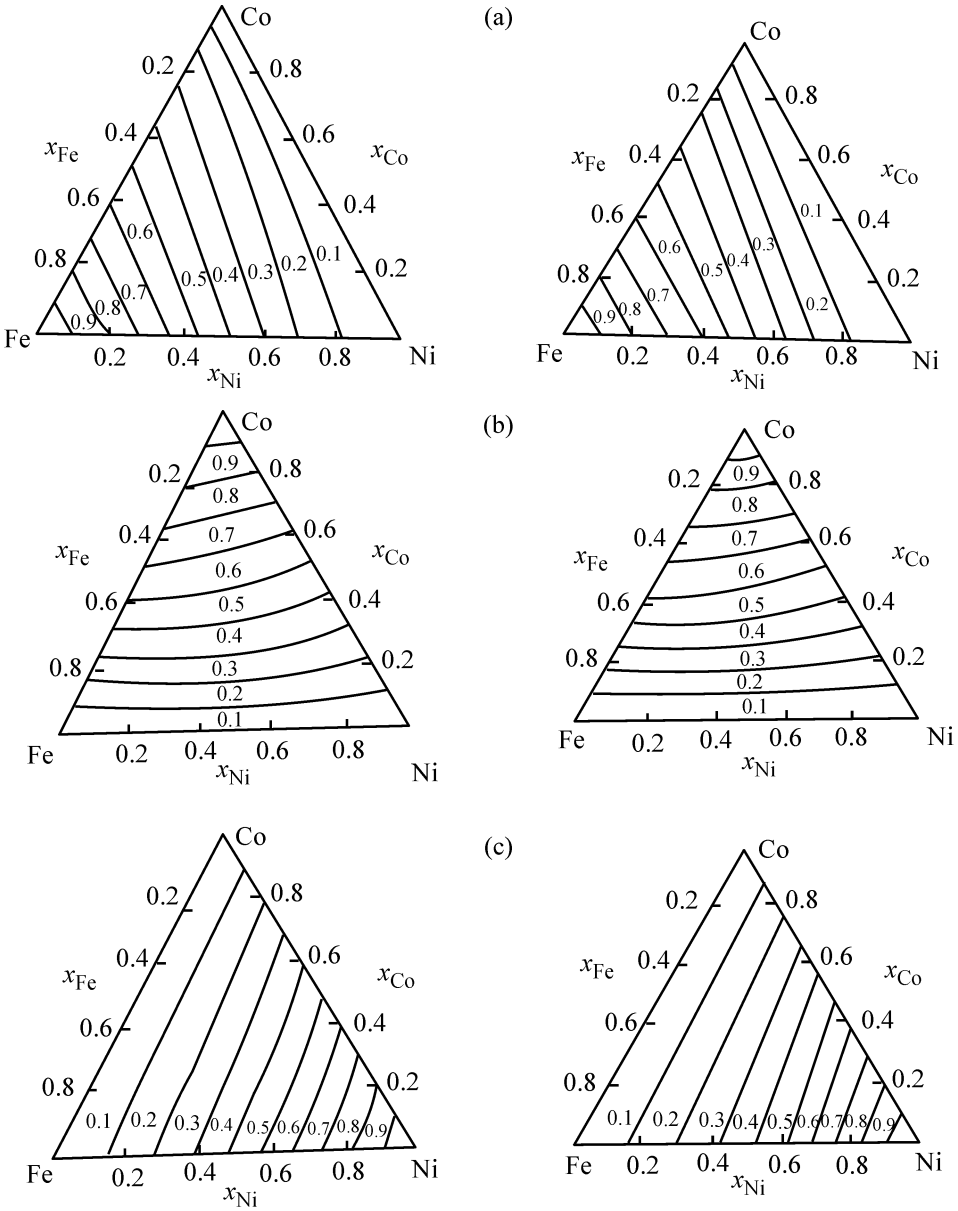

Fig. 2. Isoactivity lines of (a) iron, (b) cobalt, and (c) nickel in liquid alloys in the Fe–Co–Ni system, plotted using experimental (left-hand, 1577°C, data from [18]) and calculated (right-hand, 1600°C) data.

the Fe–Co–Ni system in both the solid (1327°C) [17] and liquid states. Doing so makes it possible to compare the calculated activities of the components in liquid alloys of the Fe–Co–Ni system with the results of an experimental study. As before [19], an equation following from the Toop method was used in calculations. For example, for component 2

$$\log \gamma_2 = \left[\frac{x_1}{1-x_2}\log \gamma_{2(1)} + \frac{x_3}{1-x_2}\log \gamma_{2(3)}\right]_{x_2} + (1-x_2)^2\left[\frac{\Delta G_{13}^{ex}}{2.303\,RT}\right]_{x_1/x_3},$$

where γ_2 is the activity coefficient of component 2 for a composition defined by molar fractions x_1, x_2, and x_3 (Fig. 1, point O); $\gamma_{2(1)}$ and $\gamma_{2(3)}$, activity coefficients of component 2 in boundary binary systems 1–2 and 2–3 at a prescribed value of x_2 (Fig. 1, points M and N); and ΔG_{13}^{ex}, integral molar excess Gibbs energy of the boundary binary system 1–3 at a prescribed $x_1 : x_3$ ratio (Fig. 1, point P).

Similar equations and constructions can be also written for the two other components of the ternary system. The activity coefficients of the boundary binary systems, taken for the calculation, a listed in

* Experimentally determined, from the data obtained by Tomiska [18] (1577°C), activities of one of the components are given for the $x_i : x_j = 1 : 1$ sections. For other sections, no numeric data were presented in the original paper.

Table 1, and values of ΔG^{ex} can be found in [8]. The results of the calculation are listed in Table 2.

Figure 2 compares the isoactivity lines of the componentsin the Fe–Co–Ni system, plotted using experimental and calculated data, and shows a rather satisfactory agreement. In the Fe–Co–Ni system, only very small deviations from ideal behavior are observed for all of the three components.

Received May 12, 2005

Abstract—Kinetics of heat release in thermolysis of mixtures of ammonium nitrate with bis(2,2,2-trinitroethyl) succinate, tetrakis(2,2,2-trinitroethyl) orthocarbonate, technical-grade trinitrotoluene and of the individual polynitro compounds was studied. The temperature dependences of the initial rates of the processes and the time required to attain the maximal rate were determined. A thermolysis mechanism of these mixtures was suggested and the dependence of the thermolysis rate on the properties of the polynitro compounds was accounted for.

Mixtures of ammonium nitrate (AN) with nitro compounds (primarily, with trinitrotoluene [1]) are widely used as industrial explosives. New compositions containing AN are being developed and studied as gas-generating fuels, including those with low combustion temperature. Nitro compounds with low enthalpy of formation show promise in this regard. Fast heat release in these mixtures may result in their self-ignition.

Previously we have studied the kinetic features of heat release in thermolysis of an AN–pyroxylin mixture [2]. Under certain conditions, the reaction between these compounds and their thermolysis products is vigorous and results in a sharp spontaneous acceleration of the thermolysis. As the temperature increases, the process initially accelerates weakly, and then, at a certain temperature, the acceleration becomes sharp. This transition may result in thermal ignition of the mixture if its amount is sufficiently large. The sharp acceleration of heat release is mainly due to fast reaction of AN with nitrogen dioxide liberated in thermolysis of pyroxylin. Nitrogen dioxide oxidizes the ammonium ion to form nitric acid, which, in turn, initiates fast decomposition of pyroxylin to form nitrogen dioxide. Thermolysis of the mixture is sharply accelerated when the steady-state balance between the formation and consumption of nitrogen dioxide is disturbed. Similar reactions should occur in mixtures of AN with other nitro compounds, since their thermolysis also yields large amounts of nitrogen dioxide, which will oxidize AN. However, the catalytic effect of nitric acid on thermolysis of nitro compounds is substantially weaker than that on pyroxylin.

Diverse polynitro compounds are known. The thermal stability of these compounds depends on their molecular structure (primarily, on the number of nitro groups at a carbon atom) and varies widely. Compounds containing the trinitromethyl group exhibit the highest thermolysis rate. The main features of thermolysis of nitro compounds are described in [3].

Here, we studied thermolysis of nitro compound–AN mixtures, direct reactions of these compounds, and reactions of these compounds with their thermolysis products. We studied nitro compounds strongly differing in thermal stability and oxidizing properties. The thermolysis of the individual compounds was examined to a lesser extent; only some quantitative data on their thermolysis were obtained.

EXPERIMNETAL

The critical factor for spontaneous ignition or explosion in chemically reacting systems is deterioration of the thermal balance between the rates of heat release and heat removal. The rate of heat release and its kinetic features determine the possibility of spontaneous ignition of a system under certain conditions of heat removal in any chemical reactor. To study the rate of AN reaction with other components of the mixture, we determined the rate and features of heat

1070-4272/05/7812-1937 © 2005 Pleiades Publishing, Inc.

release (DAK-1-2 calorimeter) [4]. The rate of heat release was measured with a relative error of about 1%. In most of our experiments, we used sealed glass ampules which can be fully accommodated in the working cell of the calorimeter. Their inner volume was about 2 ml. Under these experimental conditions, all the components of the system remain in the ampule and the volatile compounds are in the condensed state. This is of particular importance when studying AN-containing mixtures, since ammonia and nitric acid formed in equilibrium dissociation of AN in the gas phase in an open system can escape from the reaction zone, thus changing the composition of the system. Under these conditions, the pressure of the gaseous products in an ampule may be as high as 1 MPa and more, and the influence of these products on the thermolysis kinetics is usually considerably more significant than that at a pressure lower than 0.l MPa.

We studied the kinetics of heat release in thermolysis of three individual nitro compounds and their mixtures with AN: bis(2,2,2-trinitroethyl) succinate $(NO_2)_3C–CH_2–OC(O)–CH_2–CH_2–C(O)–OCH_2C(NO_2)_3$ (**I**), mp = 125°C; tetrakis(2,2,2-trinitroethyl) orthocarbonate $C(–O–CH_2–C(NO_2)_3)_4$ (**II**), mp = 162°;, and technical-grade trinitrotoluene (TNT) $C_6H_2CH_3(NO_2)_3$, mp ~80°C.

Compounds **I** and **II** were prepared at the Institute of Organic Chemistry by the procedures described in [5, 6]. Ammonium nitrate (analytically pure grade) was dried over P_2O_5, ground in an agate mortar, and mixed manually with an appropriate nitro compound. The AN-to-nitro compound weight ratio was 1 : 1. The weight of each component was about 30 mg.

Liquid trinitrotoluene decomposes at an appreciable rate on being heated to above 190°C. The kinetics of its thermolysis is reviewed in [3]. The thermolysis in the liquid phase is a multistep process which is considerably faster than that in the gas phase. To compare the rate of heat release in TNT and its mixtures with AN, we performed several experiments in the temperature range from 192.7 to 222.5°C. Thermolysis of TNT is an autocatalytic process of approximately the first order. The thermolysis rate increases by a factor of 25–30. The initial thermolysis rates were substantially higher than the published values [3].

Thermolysis of compounds **I** and **II** containing trinitromethyl groups is substantially faster than that of TNT. The rate of heat release in decomposition of compound **I** in the liquid phase at a temperature of 143.3 to 167.1°C was studied. This is a complex autocatalytic process characterized by two rate maximums. However, the rate of the overall process increases by only a factor of 3–6. The total heat of thermolysis of compound **I** is about 3600 J g^{-1}. The experimental initial rates of heat release $(dQ/dt)_{t=0}$ (W g^{-1}) in decomposition of **I** are given below:

T, °C	143.3	155.6	162.5	167.1
$(dQ/dt)_{t=0} \times 10^2$	0.76	2.3	6.5	7.5

The temperature dependence of $(dQ/dt)_{t=0}$ for compound **I** is described by the following equation

$$(dQ/dt)_{t=0} = 10^{17 \pm 2}\exp[(-15 \pm 2) \times 10^4/RT].$$

The kinetics of thermolysis of **II** was studied in the temperature range 145.8–167.1°C. At higher temperatures, the thermolysis is fast and isothermal conditions cannot be provided. At temperatures lower than 162°C, the major portion of the substance is in the solid state. Thus, thermal degradation of **I** in the single-phase liquid state was studied at 162.5–167.1°C. The reaction is autocatalytic and occurs mainly in the liquid phase. The autocatalytic effect is manifested both in acceleration of the reaction and in an increase in the fraction of the liquid phase owing to dissolution of **II** in the thermolysis products. This impairs the true kinetic law for thermolysis rate of liquid **II**, since the thermolysis in the solid state is usually slower than that in the liquid state. In particular, thermolysis, especially at lower temperatures, reaches the maximal rate within a longer time, virtually simultaneously with complete melting of the compound. At 167.1°C, when compounds **I** and **II** are completely in the liquid state, the initial and maximal rates of heat release in thermolysis of compound **II** are higher by factors of 2.5 and 4.5, respectively, than those of compound **I**. The heat of thermolysis of **II** is about 3700 J g^{-1}. The initial rates of heat release $(dQ/dt)_{t=0}$ (W g^{-1}) in thermolysis of **II** are as follows:

T, °C	145.8	155.6	162.5	167.1
$(dQ/dt)_{t=0} \times 10^2$	0.56	3.1	7.7	19.0

The temperature dependence of $(dQ/dt)_{t=0}$ for **II** is described by the following equation:

$$(dQ/dt)_{t=0} = 10^{29 \pm 1}\exp[(-25 \pm 1) \times 10^4/RT]$$

At temperatures lower than the melting point, the system is two-phase owing to partial melting of an eutectic mixture with impurities. The fraction of the liquid phase increases with temperature. Above 162°C the compound is liquid.

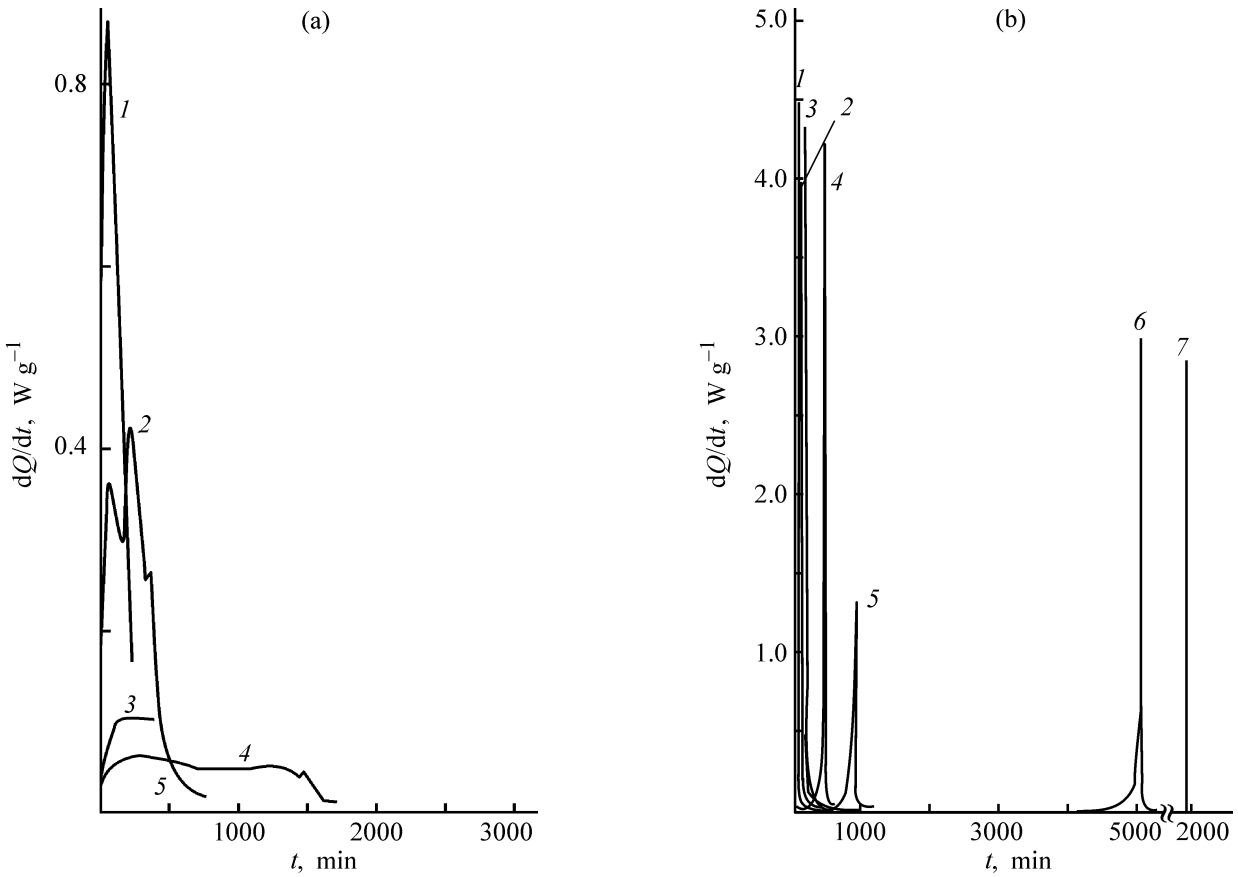

Fig. 1. Rate of heat release, dQ/dt, in thermolysis of mixtures of AN with (a) TNT and (b) compound **I** vs. time t. Thermolysis temperature, °C: (a) (*1*) 222.5, (*2*) 211, (*3*) 192.7, (*4*) 180.7, and (*5*) 144.3 (b) (*1*) 167.1, (*2*) 162.5, (*3*) 155.6, (*4*) 143.3, (*5*) 134.8, (*6*) 121.5, and (*7*) 112.6.

Our study of the kinetics of heat release in thermolysis of mixtures of all the nitro compounds examined with AN showed that the critical factors of this reaction are the thermolysis rate of the nitro compound and the susceptibility to oxidation with nitric acid and nitrogen oxides. Themolysis of AN–TNT mixtures was studied in the temperature range from 143.3 to 222.5°C. The kinetic curves of heat release are shown in Fig. 1a. The initial and maximal rates of heat release are higher by a factor of 10–15 and 1.5–2.5, respectively, than those in thermolysis of individual trinitrotoluene. The overall acceleration is substantially smaller owing to the stronger acceleration in the initial steps. The initial portion of the dependence of the hear release rate on the heat release by this time and proportional to the degree of conversion at $Q <$ 800 J g^{-1} of TNT is fitted by the equation

$$\mathrm{d}Q/\mathrm{d}t = k_1 Q_{\mathrm{tot}} + k_2 Q. \qquad (1)$$

The rate constants of the initial (k_1, s^{-1}) and autocatalytic (K_2, s^{-1}) steps in Eq. 1 are presented below:

T, °C	143.3	180.7	192.7	202.5	211	222.5
$k_1 \times 10^6$	0.19	3.5	5.5	10	17	35
$k_2 \times 10^6$	6.9	83	110	270	300	630

The temperature dependences of k_1 and k_2 are described by the following equations:

$$k_1 = 10^{7.2 \pm 0.4}\exp[(-111 \pm 4) \times 10^3/RT]$$

$$\text{at } Q_{\mathrm{tot}} = 9000 \text{ J g}^{-1} \text{ TNT},$$

$$k_2 = 10^{6.9 \pm 0.5}\exp[(-96 \pm 5) \times 10^3/RT].$$

The mixture is two-phase in the whole temperature range examined. Ammonium nitrate melts at 169.6°C. At higher temperatures, the mixture consists of two liquid phases: AN melt and TNT melt. These liquids are partially soluble in each other. As in the case of AN–pyroxylin mixtures, nitrogen dioxide formed in thermolysis of TNT rapidly oxidizes AN to form nitric acid. As a result, the total enthalpy of thermolysis increases from 3000 for pure TNT to 9000 J g^{-1} for an AN–TNT mixture. The increase in the total

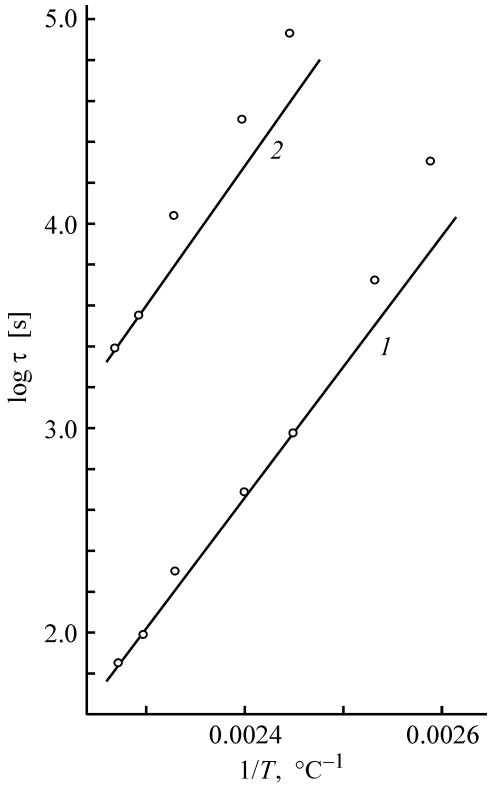

Fig. 2. Logarithm of the time τ required to reach the maximal rate of heat release in thermolysis of compounds (*1*) **I** and (*2*) **II** vs. temperature *T*.

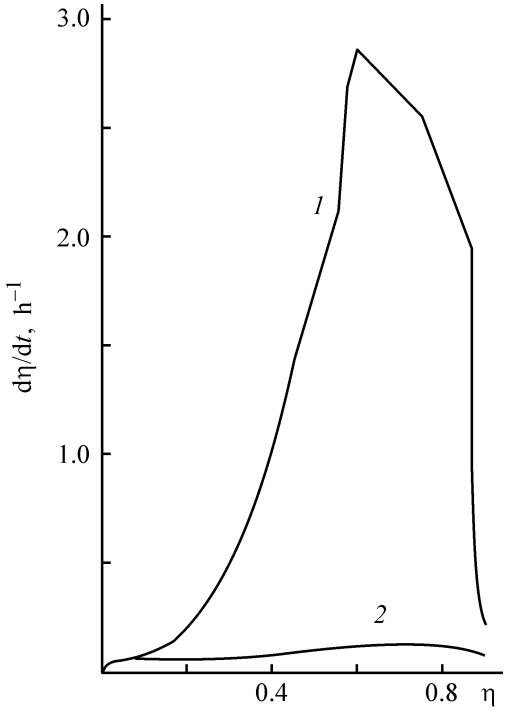

Fig. 3. Thermolysis rate dη/d*t* of (*1*) AN–compound **I** mixture and (*2*) pure **I** at 155.6°C vs. conversion η.

enthalpy of the process accelerates the heat release in the mixture. The increase in the maximal rate of heat release is determined by the growth of the enthalpy of thermolysis. On being heated to above 180°C, liquid AN decomposes at a noticeable rate and the nitric acid released in the process can oxidize TNT. This fact is apparently responsible for the additional increase in the initial rate of heat release. At the same time, it is known [7] that the hydrogen atoms of the benzene ring are difficultly oxidized (especially in the presence of adjacent nitro groups). Hence, the cross influence of thermolysis products of TNT and AN is substantially weaker than that of the products formed in thermolysis AN-pyroxylin mixtures. The sharp maximum of heat release and the jumpwise acceleration of heat release are not observed in thermolysis of AN–TNT mixtures in the temperature range examined. The rate of heat release gradually increases up to a conversion of 0.25–0.3 and then decreases after reaching a maxim (in some cases, two close maxima). It is possible that the sharp acceleration of the thermolysis of an AN–TNT mixture, as in the case of an AN–pyroxylin mixture, will be observed at higher temperatures. This acceleration on heating above 220°C is not of practical importance.

The kinetic features of thermolysis of mixtures of AN with compounds **I** and **II** somewhat differ. The kinetics of thermolysis of an AN–compound **I** mixture was studied in the range 112.6–167.1°C. At these temperatures, thermal decomposition of AN can be neglected. The kinetic curves are shown in Fig. 1b. It is clearly seen that a relatively long period of slow heat release at a rate exceeding by only a factor of 1.5–2 the rate of thermolysis of pure compound **I** is followed by a sharp acceleration of the process. About 30–35% of the total heat of reaction is liberated within 5–10 min. The maximal rate of heat release is higher by a factor of 13–1000 than the initial rate. This ratio decreases with increasing temperature. The temperature dependence of the time τ (s) required to reach the maximal rate at temperatures from 134.8 to 167.1°C, when compound **I** is completely molten, is described by the equation

$$\tau = 10^{-11 \pm 2}\exp[(-119 \pm 5) \times 10^3/RT].$$

This dependence is shown in Fig. 2 in comparison with the similar dependence for solid **I**.

The initial rates of heat release $(dQ/dt)_{t=0}$ (W g^{-1}) in thermolysis of AN–compound **I** mixture are presented below:

T, °C	134.8	143.3	155.6	162.5	167.1
$(dQ/dt)_{t=0} \times 10^2$	0.92	2.4	3.7	18	36

The temperature dependence of $(dQ/dt)_{t=0}$ for a compound **I**–AN mixture is described by the equation

$$(dQ/dt)_{t=0} = 10^{18 \pm 3}\exp[(-16 \pm 3) \times 10^4/RT].$$

The total enthalpy of thermolysis of a compound **I**–AN mixture is about 5400 J g^{-1} of compound **I**. The ratio of the initial rate to the enthalpy of thermolysis of compound **I**–AN mixture is close to that of compound **I**. However, the autocatalytic effect in the mixture is substantially stronger. The dependences of the rate of thermolysis of compound **I** and its mixture with AN $d\eta/dt = (dQ/dt)/Q_{tot})$ h^{-1}) on the conversion $\eta = Q/Q_{tot}$ at 155.6°C are shown in Fig. 3.

At 112.6 and 121.5°C only a small portion of **I** melts owing to the formation of a eutectic with impurities. In the course of the thermolysis, compound **I** melts further owing to its dissolution in the accumulated thermolysis products. The kinetic features of thermolysis under these conditions are considered in [8]. In all cases, the process additionally autocatalytically accelerates owing to an increase in the content of the liquid phase; the maximal rate is attained in the final reaction steps by the end of melting of the compound. In the first steps of the process, compound **I** is only partially in the liquid state, the initial rates of the heat release are lower, and the time required to attain the maximal rate is substantially longer, compared with the values determined from the temperature dependences. The initial rate in the binary mixture at 112.6°C is below the sensitivity limit of the calorimeter. At 121.5°C it is lower by a factor of 2.3 than the rate determined by extrapolation of the temperature dependence of $(dQ/dt)_{t=0}$. The time τ measured at 112.6 and 121.5°C is longer by a factor of 2.6 and 1.6, respectively, than the extrapolated values. This difference confirms our assumption that the thermolysis of the mixture is controlled by thermal degradation of **I** in the liquid phase, since the process is slower in the presence of solid **I**.

The features of thermolysis of AN–compound **II** mixtures are similar. In this case, the rate of heat release in the presence of solid **II** is lower since the melting point of this compound is higher. A sharp acceleration of the heat release is observed on heating to 143°C and higher. The heat release accelerates by only a factor of 5–10 and becomes maximal in the final thermolysis steps. The enthalpy of thermolysis of this mixture is 5700 J g^{-1} of compound **II**. At temperatures below 143°C, the heat is released slowly with slight self-acceleration. The temperature dependence of the time required to reach the maximal rate τ (s), determined from two points in the temperature range 162.5–167.1°C when compound **II** is completely in the liquid state, is described by the equation

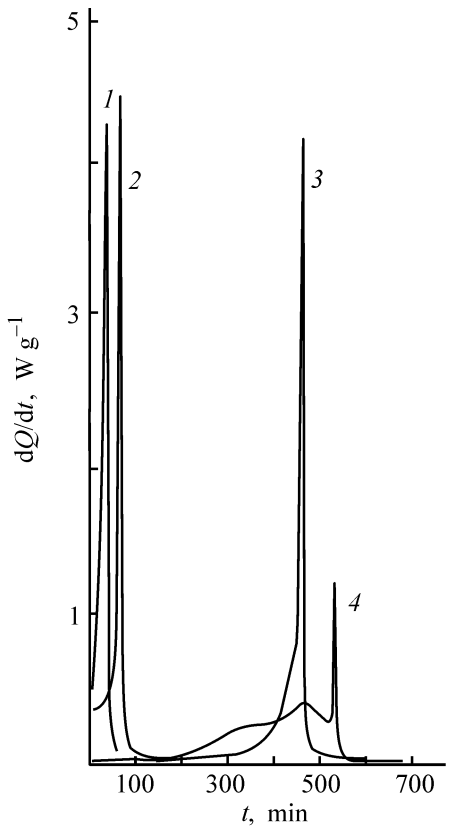

Fig. 4. Rate of heat release, dQ/dt, in thermolysis of mixtures of AN with (*2*, *3*) compound **I** and (*1*, *4*) compound **II** vs. time *t*. Thermolysis temperature, °C: (*1*, *2*) 167.1 and (*3*, *4*) 143.3.

$$\tau = 6 \times 10^{-13}\exp(130 \times 10^3/RT).$$

This dependence in comparison with the similar dependence for solid **II** is shown in Fig. 2.

The initial rates of heat release $(dQ/dt)_{t=0}$ (W g^{-1}) in thermolysis of AN–compound **II** mixture are presented below:

T, °C	134.8	143.3	155.6	162.5	167.1
$(dQ/dt)_{t=0} \times 10^2$	0.33	0.93	5.2	19	54

The temperature dependence of $(dQ/dt)_{t=0}$ for a compound **II**–AN mixture at 134.8–167.1°C is described by the equation

$$(dQ/dt)_{t=0} = 10^{27 \pm 2}\exp[(-23 \pm 2) \times 10^4/RT].$$

At 167.1 °C, when compounds **I** and **II** are completely molten, the initial and maximal rates of heat release for both mixtures are close, but the time in which the maximal rate is attained in the mixture with **II** is shorter by almost a factor of 2 (Fig. 4). In

the case of AN–compound **II** mixture, the maximal rate is higher than the initial rate by only a factor of 12–13. The thermolysis of this mixture in the liquid state is a true autocatalytic process. At lower temperatures, the increase in the fraction of the liquid phase additionally accelerates the process.

To confirm the strong influence of transfer of the nitro compound into the liquid phase on the thermolysis, we studied the kinetics of heat release in the ternary system compound **I** (or **II**)–TNT–AN at 122.1°C. At this temperature, compound **I** is partially molten and melting of **II** is insignificant; at the same time, TNT is liquid at 122.1°C, and nitro compounds are readily soluble in liquid TNT, so that compounds **I** and **II** are completely in the liquid phase. The thermolysis of TNT at this temperature is very slow. Introduction of TNT into an AN–compound **I** mixture shortens the time of attainment of the maximal rate by a factor of 1.75. This value corresponds to the above temperature dependence of this time for a mixture of AN with molten **I**. The thermolysis of the ternary mixture, as well as that of the AN-compound **I** mixture, is characterized by sharp acceleration of the heat release, followed by its deceleration. The maximal rate is higher by a factor of 1000 than the initial rate. Thus, the rate peak is observed in the whole temperature range for the mixture of AN with liquid **I**. The kinetic curve of thermolysis of AN-compound **II** binary mixture at 122.1°C was not measured, since the heat release in this process is very small. In the presence of TNT, the rate of heat release becomes measurable; the initial rate is higher by a factor of 1.5 than that in the ternary mixture with compound **I**. The rate of heat release increases more gradually, reaching a maximum in 67.5 h. The maximal rate is a factor of 18–20 smaller than that with compound **I**. Probably, for a mixture of AN with **II** there may be a sharp jump of the rate of heat release at temperatures from 122 to 143°C; however, an additional study is required to confirm this assumption.

Thus, transition of relatively unstable nitro compounds into the liquid state is a critical factor for thermolysis of their mixtures with AN. To obtain stable mixtures with compounds containing trinitromethyl groups, relatively high-melting compounds should be used. Aromatic nitro compounds like TNT, which are relatively resistant to heat and oxidation, weakly react with AN even after their melting.

Based on our kinetic data and the results of [2], we can elucidate the reaction mechanism in the mixtures in question. As noted above, the first step is thermolysis of the nitro compound or nitrate to form nitrogen dioxide. This is the rate-determining reaction in the initial steps of thermolysis. The rate of thermolysis of aliphatic nitro compounds is determined mainly by the number of nitro groups at the carbon atom and by the influence of adjacent substituents [3] and can vary widely. The thermolysis rate of trinitromethyl-containing compounds in the liquid state is the maximal. The functional groups of **I** and **II** substantially accelerate their thermolysis as compared to aliphatic nitro compounds containing no other functional groups. The liberated nitrogen dioxide rapidly reacts with AN in accordance with the equation

$$4NH_4NO_3 + 3NO_2 = 4HNO_3 + 6H_2O + 3.5N_2.$$

The heat of this reaction is about 1700 J g^{-1} of the equivalent mixture and is higher than the heat of thermolysis of pure AN.

The kinetic features of the final steps of thermolysis somewhat differ. In this case, the fast reaction of the nitro compounds with nitric acid to form nitrogen dioxide plays an important role. This reaction is responsible for the sharp acceleration of the process and the rapid attainment of high heat release rates. The reaction of pyroxylin with nitric acid is the most intense and results in a strong autocatalytic acceleration of the thermolysis. The contribution of this reaction to thermolysis of an AN–TNT mixture is insignificant. In this case, the autocatalytic effect is weaker that that in thermolysis of the initial TNT. The reactivity of the examined esters of 2,2,2-trinitroethanol with respect to nitric acid is intermediate. Compounds **I** and **II** can both be oxidized by nitric acid and undergo acid hydrolysis with subsequent oxidation of the hydrolysis products. These reactions are slower than hydrolysis of cellulose nitrate and oxidation of cellulose with nitric acid. Previously, we have shown that in AN–pyroxylin mixtures nitrogen dioxide is completely taken up by additions of diphenylamine or urea [2]. No autocatalytic effect is observed until these additives are completely spent in reaction with nitrogen dioxide. This fact confirms the proposed thermolysis mechanism. The behavior of these additives in the AN–nitro compound mixtures should be similar.

CONCLUSIONS

(1) The temperature dependences of the specific initial rates of heat release in thermolysis of individual bis(2,2,2-trinitroethyl) succinate and tetrakis(2,2,2-trinitroethyl) orthocarbonate and of their mixtures with ammonium nitrate are described by similar equations. The difference in the initial rates of heat release in

thermolysis of these mixtures and individual bis(2,2,2-trinitroethyl) succinate and tetrakis(2,2,2-trinitroethyl) orthocarbonate is due to different total heats of thermolysis.

(2) The degree of autocatalytic acceleration of thermolysis of mixtures of ammonium nitrate with bis(2,2,2-trinitroethyl) succinate and tetrakis(2,2,2-trinitroethyl) orthocarbonate is higher than that in thermolysis of the individual nitro compounds. The reactive compound of the autocatalytic step is nitrogen dioxide. Nitrogen dioxide rapidly reacts with ammonium nitrate to form an equimolar amount of HNO_3, which catalyzes thermolysis of the polynitro compounds.

(3) The rate of reaction of ammonium nitrate with relatively unstable compounds is controlled by transfer of these compounds into the liquid phase.

Abstract—Carbon-based solid phase containing open and closed multiwalled carbon nanotubes (up to 5% of the total carbon) was found in the waste from industrial production of metallic lithium by electrolysis of lithium chloride melt with graphite electrodes.

The electrochemical method of preparation of carbon nanostructures [1, 2] and, in particular, carbon nanotubes (CNTs) was developed and studied somewhat later than the electric arc method [3] and virtually simultaneously with that CVD method (chemical vapor deposition, i.e., chemical decomposition of volatile carbon-containing substances in the presence of catalysts [4, 5]) and HIPCO [6]. Chen *et al.* [2] studied the structure of a nanomaterial in relation to a salt used in the electrolysis, and Bai *et al.* [7] considered in detail this process with the most readily available salt in the CNT synthesis, sodium chloride. It was found that, under definite conditions, the carbon constituent of the product accumulating in the electrolytic tank may contain up to 50% nanocarbon material. The quality of the thus obtained CNTs may be close to that of nanotubes synthesized in the arc, and their amount is substantially larger than that of multiwalled nanotubes generated in the arc without catalysts [3] and comparable with the CNT content in "cobweb" prepared in the arc, using catalysts. However, in contrast to the latter process, both multiwalled nanotubes (MNT) and single-walled nanotubes (SNT) by electrolysis can be successfully synthesized without catalyst, and hence its subsequent removal is not required.

Unfortunately, the electrolysis as a method of purposeful synthesis of CNTs has not been developed. This is caused by the fact that it is difficult to organize the electrolysis as a continuous process similar to arc synthesis [8]. Coking of an electrolytic tank with the products of graphite electrode degradation rapidly causes breakdown, and tank cleaning is required, so that, e.g., under laboratory conditions, the working time of the electrolyzer (actually, electrochemical cell) was no more than 10–15 min.

In this context, the goal of our study was to examine the possibility of CNT synthesis in the course of industrial production of alkali metals by electrolysis of their salts. In this case, the problem of coking of the electrolytic tank becomes less pressing, because all dimensions of the apparatus are larger by two to three orders in magnitude as compared to the laboratory device. An idea of CNT synthesis under such conditions was published in [1], however, we could find no information on its implementation.

EXPERIMENTAL

In production of alkali metals (lithium), a eutectic melt of lithium and potassium chlorides (Khimkontsentrat plant, Novosibirsk, Russia) serves as a starting material. The anode consisted from four $30 \times 30 \times 180$-cm graphite blocks immersed in the melt approximately to a depth of 1 m. The direct current was 25 kA. The total surface area of the graphite anode was about $2 \times 0.3 \times 1 \times 4 = 2.4$ m^2. The electrolyzer operates for 1–1.5 years. During this time, each graphite block wears out approximately by half.

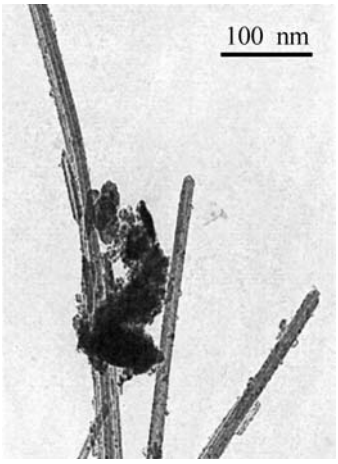

Fig. 1. Electron micrograph of MNT with d = 10–40 nm in a waste from electrolytic production of lithium.

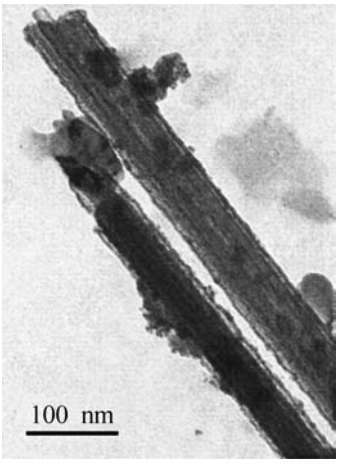

Fig. 2. Electron micrograph of partially open MNTs with d = 50–70 nm in a waste from electroltic production of lithium.

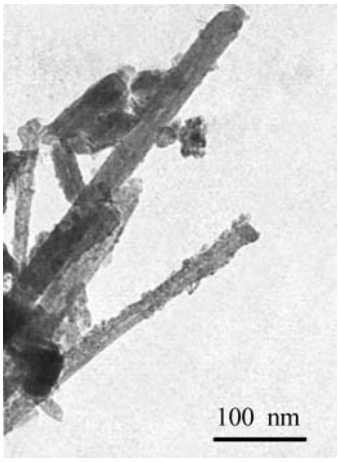

Fig. 3. Electron micrograph of partially open (including "short" tubes) MNTs in a waste from electrolytic production of lithium.

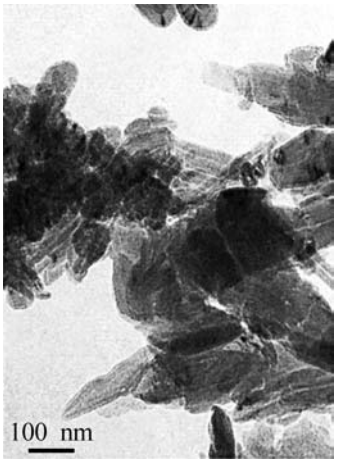

Fig. 4. Electron micrograph of carbon nanobarrels and nanobulbs in a deposit from fullerene production.

A steel cathode is used under the industrial conditions. During the electrolysis, the anode material rapidly converts into a graphitized coke.

We took 5–100-g coke samples from different points of the tank and found that they contain up to 20–30 wt % lithium and potassium chlorides and 30–40 wt % lithium and barium carbonates. To eliminate soluble chlorides, the coke was treated with water for 1 h at 60°C under stirring with a magnetic stirrer and filtered through a "blue tape" paper filter. To separate carbonates insoluble in water, the residue was treated with dilute hydrochloric acid (10 wt %) for 13 h with stirring at room temperature, or boiled in concentrated HCl (36 wt %) for 2h. The weight of the residue thus obtained amounted to 12–20% of the initial slime.

The samples obtained were examined with a JEM-100S (JEOL) transmission electron microscope at 10 000–100 000 magnification after ultrasonic disintegration in toluene.

A typical TEM image of the sample is shown in Fig. 1. MNT bundles 50–70 nm in diameter (d) and separate MNTs 10–40 nm in diameter and 1–2 μm long (L) are clearly seen. In contrast to electron micrographs shown in [1, 2, 7], a substantial part of CNTs have open ends, e.g., MNT with $d \approx 20$ nm projecting from MNT bundle (Fig. 2). The formation of open CNTs is of interest, since, in accordance with reference data, no opening of CNT is observed when a CNT-containing material is treated with dilute acid at room temperature. This fact suggest that at least a part of nanotubes remain open during growth.

The length L of CNTs shown in Figs. 1 and 2 is 1–2 μm. At the same time, short nanotubes with $L \approx$ 100 nm are also seen (Fig. 3). Their number is relatively low. Single-walled CNTs were not observed.

Fig. 5. Electron micrograph of carbon nanobarrels and nanobulbs in modified natural schungites-III.

We did not observe, either, any spiral structures described in [1, 2, 7]. The morphology of nanotubes was similar to that of CNT of crumbled cathodic deposit prepared without a catalyst [3]. The similarity with the crumbled deposit is also observed in the content of nanotubes (~5 wt %) relative to the carbon constituent of the slime. However, in contrast to the deposit[1], we did not observe nanobulbs, nanobarrels, and other concomitant particles in the slim. A typical electron micrograph of the deposit is shown in Fig. 4. The same concerns the nanocarbon constituent of natural schungites (I, II, III, etc.). Schungites always contain, along with nanotubes, noticeable amounts of other hollow and nonhollow nanoparticles (Fig. 5) [11].

Both the properties mentioned above make the carbon constituent of the slimes from alkali metal production (after separation of soluble and insoluble impurities, graphite fraction, and amorphous carbon) fairly precious material for production of emitting coatings, heterogeneous catalysis, etc., when high quality of a separate nanotube and its ideal reproducibility are not required.

The fact that the carbon constituent of the slime from alkali metal production is essentially a waste makes the suggested process commercially attractive. In contrast to a laboratory electrolyzer, the working life of an industrial salt tank into which fresh portions of salts are regularly added can reach 1.5 years. In this time, about 300 kg of the carbon constituent containing several kilograms of nanotubes is accumulated.

[1] Deposit is the product formed on a cathode during recrystallization of carbon that evaporated from the anode surface.

The electrochemical synthesis of CNT is of scientific interest because it proceeds without any catalyst, which is unusual from the viewpoint of the theory. Although iron group metals are inevitably present under conditions of an industrial salt tank (at least at a level of 10–100 ppm), the synthesis of CNT proceeds with the same success as in the chemically pure electrolyte. At the same time, in the case of cathodic deposit, when the CNT synthesis proceeds without the catalyst, the CNTs undoubtedly associated with the cathode [9]. In particular, a model exists in which CNTs are formed by high-temperature solid-phase transformation of fullerenes [10]. In the case of electrolytic CNT with similar morphology, such an association is not obvious.

Another interesting feature (which has not been mentioned in publications devoted to nanotube synthesis) is the formation of a substantial fraction of open tubes. This fact suggests that an unusual mechanism of CNT synthesis under the conditions of the salt tank is operative (this mechanism will be considered in our subsequent paper).

The fact of high CNT content in the electrolytic slime is also of interest. In spite of the apparent similarity of the conditions of laboratory and industrial syntheses, there are substantial differences. In all laboratory experiments, the depth of the electrode immersion into the salt melt was less than 1 cm and substantially affected the nanomaterial structure: at larger immersion depths no CNT or other nanoparticles were formed [1]. In the industrial tank, the depth of electrode immersion was about 1 m.

As for temperature, the conditions of the laboratory device and industrial tank are closer: in the interelectrode area, the temperature in the tank did not exceed 500°C; at this temperature, the CNT yield in the laboratory experiment decreases to several percent relative to the yield at 900°C.

CONCLUSIONS

(1) In the electrolytic tank for the industrial production of alkali metals, small amounts of carbon nanotubes are formed (about 1–2 wt % relative to the total amount of the slime and 5 wt % relative to the slime carbon constituent).

(2) The morphology of nanotubes formed mainly corresponds to that of particles formed in laboratory electrolysis. However, differences also exist: there are no spiral structures and single-walled CNTs, but large amounts of open nanotubes occur.

(3) The latter fact suggests that the growth of open-end CNTs is possible.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Precipitation of Bismuth(III) Oxochloride from Nitrate Solutions

T. V. Daminova, M. N. Novokreshchenova, and Yu. M. Yukhin

Institute of Solid-State Chemistry and Mechanochemistry, Siberian Division, Russian Academy of Sciences, Novosibirsk, Russia

Received June 3, 2005

Abstract—X-ray phase analysis, thermogravimetry, IR spectroscopy, and chemical analysis were used to study precipitation of bismuth from nitrate solutions upon addition of aqueous solutions of hydrochloric acid or ammonium chloride. The conditions in which bismuth(III) oxochloride of BiOCl composition is formed and the possibility of obtaining a high-purity product were determined.

Bismuth(III) oxochloride is used in medicine, for fabrication of polymeric X-ray contrast media, and in cosmetics for imparting pearly luster to lipstick, nail lacquers, and eyeshades. There is evidence that bismuth oxochloride us used for dyeing of lacquers and plastics, in manufacture of paints, in production of light-sensitive photographic films with nonsilver image development, and as a catalyst for cracking of hydrocarbons [1]. This compound is commonly synthesized by precipitation of bismuth from chloride solutions prepared by dissolution of a reagent-pure oxide in hydrochloric acid, with the subsequent ~10-fold dilution of the bismuth-containing solution with water [2, 3]. A method is known for preparing bismuth(III) oxochloride by its precipitation from solutions containing 5–35% nitric acid and 10–400 g l^{-1} bismuth by addition of chlorides of alkali metals or ammonium, or hydrochloric acid in an amount of 70–150% relative to stoichiometry [4].

Compounds of bismuth(III) are, as a rule, prepared from the metal of Vi1 brand, which contains no less than 98.0% bismuth, with lead and silver present as the main impurities (no more than 1.8 and 0.12%, respectively). Metallic bismuth slowly dissolves in hydrochloric acid. For example, in treatment of metal grains at 60°C for 36 h, the bismuth concentration in solution is only 1.88 and 2.85 g l^{-1} when hydrochloric acid with a concentration of 6 and 12 M, respectively, is used. In this connection, compounds of bismuth are commonly synthesized by dissolving its grains in nitric acid with a concentration of 9 M, with the subsequent hydrolytic purification of bismuth to remove impurity metals at pH 1.5–2.0 [5]. Among disadvantages of this method is evolution of toxic nitrogen oxides into the gas phase in the stage of preparation of bismuth nitrate solutions, because the dissolution process occurs in accordance with the equation

$$Bi + 6HNO_3 = Bi(NO_3)_3 + 3NO_2\uparrow + 3H_2O. \quad (1)$$

It has been shown [6] that preliminary oxidation of metallic bismuth to obtain a technical-grade oxide makes it possible to diminish by half the expenditure of nitric acid and to preclude evolution of nitrogen oxides into the atmosphere in the stage of preparation of bismuth nitrate solutions, because, in the given case, the dissolution process is described by the equation

$$Bi_2O_3 + 6HNO_3 = 2Bi(NO_3)_3 + 3H_2O. \quad (2)$$

Together with nitric acid, hydrochloric acid also well dissolves bismuth oxide, and the dissolution reaction has the following form:

$$Bi_2O_3 + 6HCl = 2BiCl_3 + 3H_2O. \quad (3)$$

Of practical interest in this context is a study of the synthesis of bismuth(III) oxochloride directly from solutions obtained upon dissolution of technical-grade bismuth oxide in hydrochloric or nitric acid.

This communication reports the results obtained in a study of how the concentration of chloride ions and process temperature affect the purity and extent of precipitation of bismuth(III) oxochloride from ni-

trate and chloride solutions prepared by dissolving technical-grade bismuth oxide in solutions of these acids.

The metal was oxidized in a stainless steel reactor equipped with a worm for agitation of the melt. A single charge of metallic bismuth into the oxidation reactor was 150–160 kg. The metal was melted at a temperature of 350°C and bismuth oxide from the preceding stage of oxidation of metallic bismuth was added to the melt (20%) under stirring. The temperature was raised to 600°C and the powder was agitated for 6 h. Technical-grade oxide contained 88.4% bismuth, its composition **I** as regards impurity metals is listed in the table. A bismuth(III) nitrate solution of composition (g l^{-1}): Bi(III) 380 and nitric acid 110, was obtained by dissolving technical-grade oxide in 6 M HNO_3. The composition corresponded to that of solutions commonly used in the technology of bismuth compounds. The ratio between the volumes of the initial and final bismuth-containing solutions was 1 : 10. On adding hydrochloric acid or a solution of ammonium chloride to the solution of bismuth nitrate it was adjusted by addition of distilled water. A solution of bismuth chloride, prepared by dissolving technical-grade oxide in 6 M HCl, had the following composition (g l^{-1}): Bi(III) 230 and free hydrochloric acid 70. The bismuth-containing chloride solution was processed by its dilution with distilled water (1 : 9). This was done in fluoroplastic vessels with rabbles. The mixture was agitated for 1 h. After a 1-h settling, the precipitate formed was filtered off in a vacuum, washed with distilled water on a filter, and dried in air. An X-ray phase analysis of the precipitation products was carried out with a DRON-3 diffractometer with Cu_{K_α} radiation, counter rotation rate of 0.5 deg min^{-1}, and I = 4000. Differential-thermal and thermogravimetric analyses of the samples studied were made on an MOM derivatograph (Hungary) at a heating rate of 10 deg min^{-1}. Electron micrographs of the products were obtained on a JSMT-20 scanning electron microscope with a resolution of 200 Å. The specific surface area of the samples obtained was measured by the chromatographic method of thermal desorption of argon. Macroscopic amounts of bismuth(III) in the liquid and solid phases were determined by titration with a solution of Complexone III, with Xylenol Orange as indicator; microscopic amounts were determined by photocolorimetry in the presence of KI. The concentrations of metals (Bi, Pb, Ag, Cu, Fe, Zn) were found by the atomic-absorption method on a Saturn 2M spectrophotometer. The precipitation products were preliminarily dissolved in nitric acid (1 : 1). The concentration of nitrate ions was determined by voltammetry on a renewed copper electrode [7], and that of chloride ions, on a silver electrode [8], after transferring these ions to solution by preliminary treatment of the precipitates with a sodium hydroxide solution (2 M) at 70–90°C.

A study of the hydrolytic processing of bismuth-containing chloride solutions demonstrated that, at their dilution with distilled water (1 : 9) and process temperatures of 25 and 65°C, the recovery of bismuth into oxochloride is 95.2 and 90.1%, respectively. A precipitate obtained at a process temperature of 65°C was washed with a hydrochloric acid solution with a concentration of 0.25 M and twice with water at 65 ± 5°C, with subsequent drying of the product at 110 ± 10°C, to give bismuth(III) oxochloride, whose composition **II** is listed in the table. The results obtained in analyzing this product indicate that processing of bismuth-containing solutions fails to provide an effective purification of bismuth to remove lead and silver. In view of this circumstance, the possibility of obtaining bismuth oxochloride from nitrate

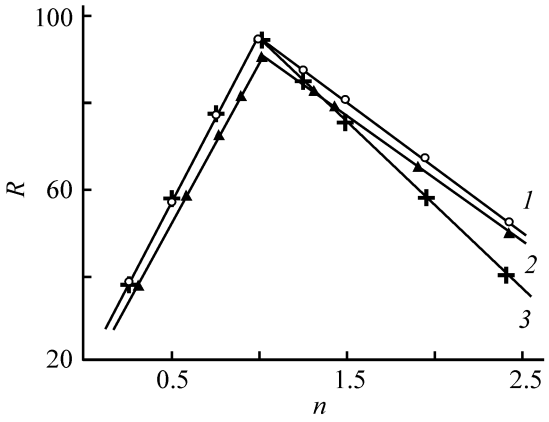

Fig. 1. Degree of bismuth precipitation, *R*, vs. the molar ratio of chloride ions to bismuth (Cl/Bi), *n*, in the system. (*1*, *3*) NH_4Cl and (*2*) HCl. Process temperature (°C): (*1*, *2*) 20 and (*3*) 60.

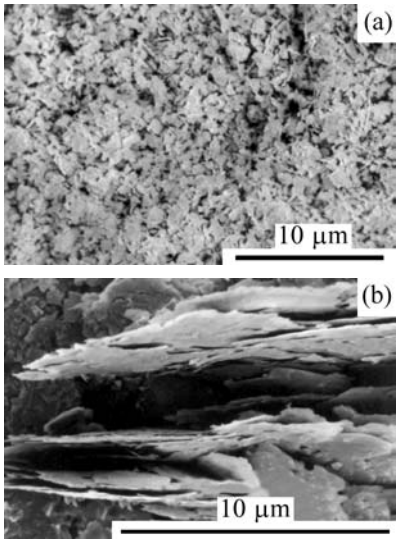

Fig. 2. Electron micrographs of hydrolysis products obtained upon addition of a bismuth-containing nitrate solution to a hydrochloric acid solution. Temperature (°C): (a) 23 and (b) 90.

solutions commonly used in synthesis of bismuth compounds was studied.

In precipitation of bismuth from nitrate solutions by addition of a solution of ammonium chloride or hydrochloric acid, the dependence of the degree of bismuth precipitation, *R*, on the molar ratio of chloride ions to bismuth in solution, *n*, passes through a maximum at 1.0–1.1 (Fig. 1). The decrease in *R* at $n > 1$ is due to the formation in solution of chloride complexes of the type Bi_xCl_{3-x}, which hinders precipitation of bismuth in the form of oxochloride. It can also be seen in Fig. 1 that solutions of both ammonium chloride and hydrochloric acid can be used for quantitative precipitation of bismuth, whereas raising the process temperature leads to a decrease in the degree of bismuth recovery into a precipitate. This is due to the fact that complexation of bismuth with chloride ions mainly occurs via endothermic reactions [9]. As a result, the extent of bismuth complexation with chloride ions in solution increases with temperature, and, accordingly, the degree of its recovery into precipitate decreases. When hydrochloric acid is used as donor of chloride ions, the degree of bismuth recovery into precipitate also somewhat decreases, which is due to an increase in the solubility of bismuth oxochloride as the concentration of hydrogen ions in solution becomes higher.

Bismuth oxochloride shows clearly pronounced characteristic diffraction peaks with d = 7.38, 3.69, 3.442, 2.753, 2.677, 2.205, 1.946, 1.694, and 1.574 Å [10]. It follows from X-ray diffraction analysis that the positions of these peaks remain virtually the same in precipitation of bismuth from both chloride and nitrate solutions upon addition of chloride ions, irrespective of the nature of the solutions used. This fact confirms that bismuth precipitates from these solutions in the pH range studied (0–3) in the form of the oxochloride BiOCl.

The results of differential-thermal and thermogravimetric analyses of bismuth oxochloride samples obtained in processing of bismuth-containing chloride and nitrate solutions indicate that the product has a homogeneous composition and is stable in a wide temperature range. When bismuth oxochloride is heated, loss of mass begins at temperatures above 600°C, which is due to sublimation of bismuth in the form of a chloride to form oxochlorides with a bismuth : chlorine molar ratio exceeding unity [11].

Electron micrographs of hydrolysis products indicate that bismuth oxochloride obtained at 25±5°C by adding water to a hydrochloric acid solution, or a chloride containing solution to a nitrate solution, are, in both cases, aggregates of micrometer microcrystals, presumably of planar-prismatic type, with a poor morphology (Fig. 2a). The product obtained in precipitation of bismuth oxochloride at an elevated temperature, 90±5°C, has the form of aggregates of fine-lamellar crystals with metallic shine and the following dimensions (μm): 20–100 in the basal plane and about 0.1–0.3 in thickness (Fig. 2b). In this case, the specific surface area of bismuth(III) oxochlorides obtained at a process temperature of 25°C varies within 9.6–12.4 $m^2 g^{-1}$, and that of products synthesized at 90°C, within 1.1–1.4 $m^2 g^{-1}$.

To synthesize bismuth oxochloride of increased purity, the possibility of its purification to remove the main impurity metals in precipitation from nitrate solutions was analyzed. The study performed demonstrated that, in precipitation of bismuth from nitrate solutions in the form of oxochloride at a molar ratio of chloride ions to bismuth equal to 1.05, as also in its precipitation from chloride solutions, there is no effective purification of bismuth to remove lead and silver [see table, compositions **III** and **IV**]. In this case, raising the process temperature leads to synthesis of a purer product [**III** at 25°C and **IV** at 65°C]. This result agrees with previously obtained data on bismuth precipitation from hydrochloric acid solutions [12]. The results of the present study demonstrate that, even at a molar ratio of chloride ions to bismuth in solution equal to 0.9, there is no effective purification of bismuth to remove lead and silver at the process temperature of 65°C [product **V**].

Precipitation of bismuth from nitrate solutions in the form of a compound of composition $[Bi_6O_5(OH)_3](NO_3)_5 \cdot 3H_2O$ allows its effective purification to remove impurity metals, and this process is used in synthesis of special-purity bismuth(III) oxide [13]. In this context, it is advisable, in order to obtain high-purity bismuth oxochloride, to preliminarily purify bismuth nitrate solutions to remove accessory metals, with subsequent precipitation of bismuth in the form of oxochloride.

In view of the aforesaid, a variant in which bismuth oxochloride is synthesized by precipitation from oxochloride solutions was chosen for enlarged-scale tests. The advantage of this process is that solutions with a higher concentration of bismuth are obtained in the stage of dissolution of technical-grade oxide and the stainless steel apparatus, used in syntheses of other bismuth compounds, can be used in this case. High-purity bismuth(III) oxochloride was synthesized as follows: metallic bismuth of Vi1 brand was melted at 350°C and 20% bismuth oxide from the preceding stage of oxidation of metallic bismuth was added to the melt with stirring. The temperature was raised to 600°C and the powder was agitated for 6 h. The resulting bismuth oxide was dissolved in a 6 M solution of nitric acid. Bismuth was precipitated from a solution containing 380 g l^{-1} Bi and 110 g l^{-1} free nitric acid by addition, under stirring, of a 2.5 M ammonium carbonate solution at 60°C. The mother liquor was separated by decantation, and the precipitate was washed, under stirring, with a 0.1 M nitric acid solution and then distilled water at 60°C. The filtered-off precipitate of bismuth oxohydroxonitrate was dissolved in 6 M nitric acid, and bismuth was precipitated from the solution in the form of oxochloride by adding a hydrochloric acid solution at a molar ratio of chloride ions to bismuth equal to unity and process temperature of 60°C. The precipitate was washed with a 0.1 M solution and twice with distilled water, and then dried at 100°C. The enlarged-scale tests yielded bismuth(III) oxochloride containing (%): bismuth 80.25 and nitrate ions $<5 \times 10^{-3}$. The content of impurity metals in product (VI) is listed in the table. The degree of bismuth recovery into oxochloride is 89.8%.

CONCLUSIONS

(1) Precipitation of bismuth from both chloride and nitrate solutions upon addition of chloride ions was examined and it was shown that bismuth is precipitated from these solutions in the pH range studied (0–3) in the form of oxochloride BiOCl and the specific surface area of the product decreases from 12.4 to 1.1 $m^2 g^{-1}$ as temperature is raised from 25 to 90°C.

(2) It was demonstrated that, in preparing bismuth-containing chloride solutions from metallic bismuth, it is advisable to preliminarily convert bismuth into oxide by introduction of 20–30 wt % bismuth oxide into its melt at 350 ± 50°C under agitation, with the process temperature subsequently raised to 600 ± 50°C.

(3) It was shown that, to obtain high-purity bismuth oxochloride from technical-grade products, it is necessary to preliminarily purify bismuth to remove accessory metals by its precipitation from nitrate solutions in the form of a compound of composition $[Bi_6O_5(OH)_3](NO_3)_5 \cdot 3H_2O$.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Molybdenum Indicator Electrode for Potentiometric Sensor for Dissolved CO_2

M. S. Turaeva, I. V. Tarasenkova, and V. L. Vasilevskii

Agrophysical Research Institute, St. Petersburg, Russia

Received June 16, 2005

Abstract—Formation of an indicator layer sensitive to dissolved CO_2 on a molybdenum electrode was studied, as influenced by the solution composition, by potentiometry and voltammetry with continuous voltage variation. Kinetic dependences of the potentiometric response and stationary potential of prototype carbon dioxide sensors based on these electrodes were analyzed.

Possible climate changes related to very complex physicochemical and biological processes in the atmosphere, lithosphere, and hydrosphere and to emission of anthropogenic greenhouse gases stimulate studies of indicator structures sensitive to gases. Carbon dioxide is the main climate-affecting gas, and development of compact and reliable CO_2 sensors capable of monitoring an object in its interaction with the environment without damaging the object or affecting the composition of the medium is a topical problem [1, 2].

Since being created, the potentiometric sensor for dissolved CO_2 of the Stone-Severinghaus type [3] has been modified many times. The need for low-resistantce, compact, and mechanically strong devices initiated the use of metal oxide [4–6] and polymeric [7–9] electrodes, instead of glass electrodes, in potentiometric sensors for dissolved CO_2. In most cases, the indicator surface of metal oxide electrodes was prepared by high-temperature oxidation or by chemical or electrochemical oxidation in single-component aqueous solutions [10]. The molybdenum electrode has not been used previously in CO_2 sensors. It has been found [11] that the potential of air-oxidized molybdenum electrode gradually shifts as the solution pH changes and exhibits a hysteresis of the E–pH function. At the same time, molybdenum exhibits stable passivity in aqueous solutions [12–14].

In this study, we examined the formation of an indicator layer sensitive to dissolved CO_2 on a molybdenum electrode and the sensor properties of the indicator electrode for potentiometric CO_2 sensor as influenced by the solution composition.

EXPERIMENTAL

The molybdenum electrode with a front working surface was made of the 99.96% molybdenum wire (0.5 mm in diameter) sealed in molybdenum glass. The inactive surface of the electrode should be reliably insulated, because the contact between the electrolyte and the side surface of the electrode can give rise to additional uncontrollable voltaic cells and cause potential relaxation disturbing the sensor response.

First, the sensor layer on a molybdenum electrode was formed in solutions of various compositions, and then the effect of the preparation conditions on the properties of this layer with respect to H^+ ion exchange and on the stationary potential and potentiometric response to dissolved CO_2 was analyzed. The open-circuit voltage was measured with an I-115 pH-meter (input resistance 10^{12} Ω) or an ITN-7 ion meter (input resistance 10^{16} Ω) and a KSP-4 recording potentiometer. The open-circuit voltage was monitored from the instant of immersion of the molybdenum electrode in the solution of a certain composition until the attainment of the stationary state E_{st}. The measurements were performed with an EVL-3M reference electrode. Before experiments, the working molybdenum electrode was polished, rinsed with water, and dried in air.

The electrolytes for preparing sensor layer were preliminarily selected by analyzing dynamic voltammograms recorded in a three-electrode cell with a Pt auxiliary electrode and a silver chloride reference electrode (with a Luggin capillary), using a PU-1 polarograph and an LKD 4-003 X–Y potentiometer.

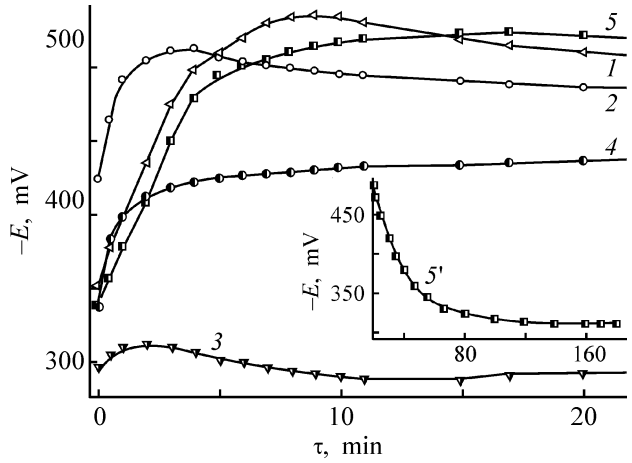

Fig. 2. Open-circuit voltage E vs. time τ of formation of the indicator molybdenum electrode. Solution composition, M: (*1*) 0.1 NaOH, (*2*) 0.1 LiOH, (*3*) 0.1 NaOH + 0.1 $K_3Fe(CN)_6$, (*4*) 0.1 NaOH + 0.1 $K_4Fe(CN)_6$, (*5*) 0.1 NaOH + 1.0 $K_4Fe(CN)_6$ + 0.1 sodium citrate, and (*5′*) the same solution (insert).

Appearance of the area of molybdenum passivation in the voltammogram was a criterion of the solution suitability. It is known that the passivation and corrosion behavior of molybdenum are determined by the composition and pH of the forming solution [15], and stable passive films on the metal surface are formed in alkaline solutions. In our study, we used solutions with pH ≥ 10, because the effect of molecular oxygen is more pronounced in alkaline solutions, compared with that in the acidic medium. An anodic polarization of the molybdenum electrode in alkaline solutions showed that the formation of the surface layer depends on the alkali concentration. For example, the current sharply increases in 1 M NaOH at continuous change in the potential of the molybdenum electrode at a sweep rate V 0.05 V s^{-1}. In the process, the working face of the electrode "sinks" deeper into the glass shell owing to intensive dissolution of molybdenum. In 0.1 M NaOH solutions, the anodic polarization curves recorded in the 0–2.5 V range at a sweep rate V 20 mV s^{-1} can be divided in three portions of (1) slow rise in the current at potentials of 0 to 0.5 V, related to the overvoltage of metal; (2) active dissolution of the metal (from 0.5 to 1.2 V), and (3) passivation (from 1.2 to 2.0 V) (Fig. 1). As the potential increases above 2.5 V, the current grows owing to degradation of the passive layer and pitting. The voltammogram recorded in 0.01 M NaOH shows that, in this case, the passivation potential of the molybdenum electrode shifts toward more positive values.

We found that, at passivation potentials of 2.2 V (0.01 M NaOH) and 1.4 V (1 M NaOH), the electrode surface is coated with a black film. Similar changes in the voltammetric curves were observed in KOH solutions.

The sensitivity $S = dE/d\log[CO_2]$ of the electrodes prepared to dissolved CO_2 and the stability of the stationary potential E_{st} were studied in an open electrochemical system in carbonate-bicarbonate buffers (CBCBs) simulating solutions with a fixed content of carbon dioxide within the 0.998–0.005 vol % range [16], with an EVL-3M silver chloride reference electrode and ESL-43-07 glass pH electrode (to monitor the solution pH). These studies allowed selection of prototype CO_2 sensors.

A study of the potentiometric response showed that the formation of the sensor layers at potentials corresponding to the passivation caused a significant scatter E_{st} of the electrodes (±20 mV), even in the same electrolyte. Initially, the response of freshly prepared electrodes was 55 ± 4 mV per pH unit. However, due to dissolution of the surface film, the sensor electrodes loss their sensitivity.

Stronger films were formed on keeping the molybdenum electrodes in solutions, i.e., when they were prepared by chemical passivation. The changes in the open-circuit voltage after immersion of the molybdenum electrode in 0.1 M NaOH and LiOH solutions are shown in Fig. 2.

In the initial period, the rate of molybdenum dissolution in 0.1 M LiOH is rather high. As the treatment time is rised, mostly passive films are formed after keeping for 3 and 8 min in 0.1 M LiOH and NaOH, respectively. Similar E–t curves are obtained

in passivation of the molybdenum electrode in 0.1 M KOH (with a maximum at ~6 min). The stationary potentials of about –480 mV were attained in 30 (LiOH) or 50 min (NaOH, KOH) after immersion of the electrodes in 0.1 M alkaline solutions.

The electrodes formed in 0.1 M NaOH or KOH in 3 days show a linear E_{st}–pH dependence at pH 2.0–12.5 in various buffer systems, such as oxalate (pH 1.5–2.2), hydrophthalate (pH 2.2–6.0), phosphate (pH 6.8–8.0), tetraborate (pH 8.0–10.6), tris(hydroxy)aminomethane (pH 10.4–11.0), carbonate–bicarbonate (pH 8.5–10.4), and glycine (pH 11.3–12.6) solutions (Fig. 3). The pH dependence of E_{st} of the molybdenum electrode with a deposited sensor layer relative to the silver chloride reference electrode can be described by approximation equations:

$$E_{st} = (0.235 \pm 0.008) - (0.055 \pm 0.005)\text{pH}, \text{ (NaOH 0.1 M)},$$

$$E_{st} = (0.238 \pm 0.009) - (0.052 \pm 0.007)\text{pH}, \text{ (KOH 0.1 M)}.$$

For comparison, we measured the open-circuit voltage (E_{st}–pH) of the molybdenum electrode oxidized in air at 25–60°C. In the pH range 1.0–2.1, the stationary potential remains constant. With the pH increasing to 12.5, linear portions were observed, but, in the case of a hydrophthalate buffer, the linear portion in the pH range 5.50–6.24 shifted by –10 mV, whereas the slope of the dependence increased by +10 mV. On changing the phosphate buffer system for tris(hydroxy)aminomethane in the pH range 7.26–8.40, the stationary potential shifted by –20 mV, whereas the slope dE/dpH remained unchanged.

A study of the time dependence of the open-circuit voltage of the indicator electrodes formed in the alkaline solution and stored in a CBCB (pH 9.4) + KCl (0.001 M) with a CO_2 content of 1.18×10^{-4} M showed that the E_{st} values are unstable. The electrode sensitivity $\Delta E/\Delta$pH changes irregularly (Fig. 4a) with the dependence $E_{st} = f(\text{pH})$ remaining linear. At the same time, the pH function of the indicator electrodes formed in 0.1 M NaOH remains stable in CBCB for more than a month within 50 ± 10 mV. It was found that the reproducibility of the stationary potentials was ±20 mV for a set of 20 electrodes. The function of electrodes formed in 0.1 M NaOH is close to the Nernst dependence, its reproducibility is higher, and the scatter of the stationary potentials is narrower than that of the sensor electrodes formed in 0.1 M KOH (±26 mV for 20 electrodes). Taking these facts into account we used 0.1 M NaOH (S1) as a supporting electrolyte in our further tests of

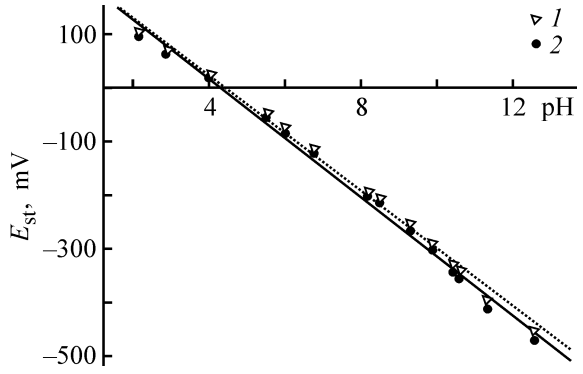

Fig. 3. Potential E_{st} of the molybdenum electrode vs. the solution pH in various buffer solutions after keeping for 3 days in (*1*) 0.1 M NaOH and (*2*) 0.1 M KOH; for explanations see text.

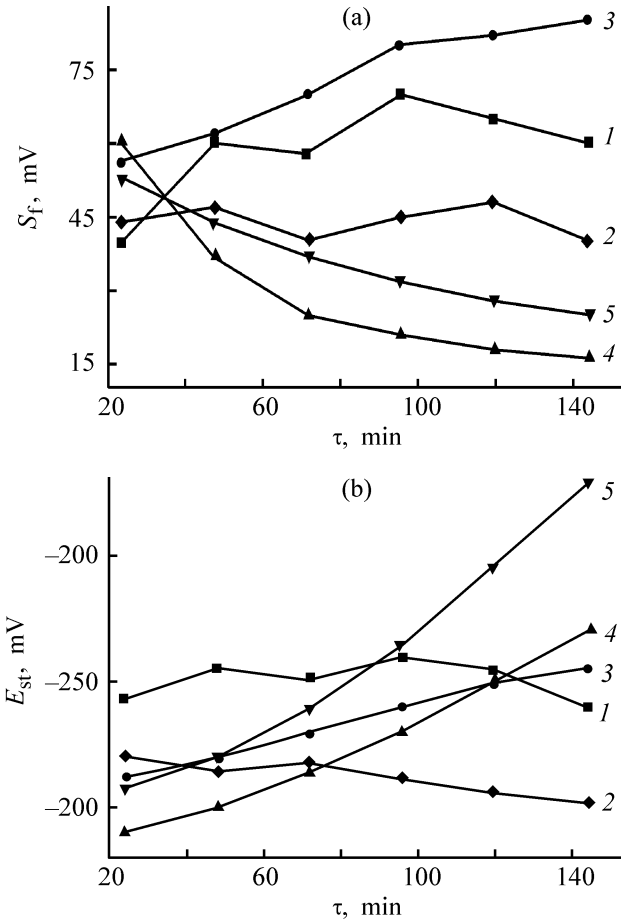

Fig. 4. (a) Changes with time τ in the sensitivity S_f of the molybdenum electrode at various compositions of the forming solution and (b) drift of the stationary potential E_{st} of the molybdenum electrode in the carbonate–bicarbonate buffer with a CO_2 content of 1.18×10^{-4} M after formation of the sensor layer in solutions. Solution composition, M: (*1*) 0.1 NaOH (S1), (*2*) 0.01 NaOH, (*3*) S1 + 0.1 $KMnO_4$, (*4*) S1 + 0.1 $K_3Fe(CN)_6$, and (*5*) S1 + 0.1 $KClO_4$.

the operation solutions for preparing sensitive layers on the electrode surface. In this solution, the electrode surface was coated with a black film. As additional components we used oxidants ($KMnO_4$, $K_2Cr_2O_7$, $KClO_4$), complexes ($K_4Fe(CN)_6$, $K_3Fe(CN)_6$, Na–EDTA), and sodium salts of carboxylic acids (such as aminoacetic, acetylsalicylic, tartaric, malic, oxalic, and citric acids).

The sensor electrodes (SEs) change their properties on being keept in the forming solution in the presence of oxidants, such as $KMnO_4$, $K_2Cr_2O_7$, $KClO_4$, or $K_3Fe(CN)_6$.

Visual monitoring of the films was performed with an SBS-04 optical microscope (×56 magnification). We examined the uniformity of the film and its adhesion to the electrode surface.

We found that the properties of the surface films are determined by the nature of oxidant and its concentration. In the supporting electrolyte containing 0.1 M $K_2Cr_2O_7$, the electrode surface was etched due to the intense dissolution of molybdenum, whereas in 0.01 M $K_2Cr_2O_7$, the electrode surface was coated with a thin semitransparent film, which dissolved in several days.

The variation of the function of the resulting electrodes $dE/d\log[CO_2]$ with time and the shift of the voltage of the open circuit Ag, AgCl, KCl/solution/molybdenum sensor electrode are shown in Fig. 3. The E_{st} values were recorded after keeping the formed electrodes in CBCB (pH 9.4) + KCl (0.001 M) with a CO_2 content of 1.18×10^{-4} M.

The sensor electrodes formed in solutions in the presence of $KMnO_4$, $KClO_4$, and $K_3Fe(CN)_6$ exhibit a linear dependence E_{st}–$\log[CO_2]$ at carbon dioxide concentrations of 10^{-6} to 4×10^{-4} M.

In a 0.1 M $KMnO_4$ solution, the face of the molybdenum electrode was coated with a shining black film. The sensitivity measurements showed that the slope of the E_{st}–$\log[CO_2]$ function is 56 ± 2 mV per tenfold change in the CO_2 concentration (Fig. 4b). Upon a continuous operation of the electrode for 6 days, the slope increases to 80 mV and E_{st} shifts by +40 mV (Fig. 4a); after further keeping, two portions were observed, with slopes of 162 and 80 mV in the CO_2 concentration ranges 3.9×10^{-4}–1.87×10^{-4} and 1.18×10^{-5}–3.13×10^{-6} M, respectively. After keeping for 2 weeks, no film was observed on the electrode surface.

A deeply black film was formed in 0.1 $KClO_4$ solution. In the course of 6-day operation, the slope of the electrode function of the resulting electrodes gradually decreased from 53 to 25 mV (Fig. 4a), and E_{st} shifted by +120 mV, with the film appearance remaining unchanged (Fig. 4b).

In the case of $K_3Fe(CN)_6$, the formation of the film on the electrode surface strongly depends on the concentration of the iron complex. No film was formed in the saturated $K_3Fe(CN)_6$ solution, and the electrode surface was etched in a 1 M solution. Only a thin brownish film was formed in 0.01 M $K_3Fe(CN)_6$, but it disappeared already during the first day of tests. Only in 0.1 M $K_3Fe(CN)_6$ we obtained a black film on the electrode surface, which moved deeper inside the glass holder as the keeping time was made longer. This was to dissolution of the edge surface of the molybdenum electrode. After immersion of the molybdenum electrode in 0.1 M NaOH + 0.1 M $K_3Fe(CN)_6$ solution, the opencircuit voltage in the first two minutes shifted to negative values (Fig. 2, curve *3*) due to the dissolution of the electrode surface, and then the voltage became more positive owing to passivation. A constant $E_{st} = -290$ mV was attained after keeping for 15 min.

The function $dE/d\log[CO_2]$ of the electrodes prepared in 0.1 M $K_3Fe(CN)_6$ solution in the first operation day was 60 mV, and after continuous operation for 6 days it decreased to 20 mV per tenfold change in the CO_2 concentration (Fig. 4a). Measurements of the sensitivity of the resulting electrodes in CBCB showed that, during this period, the stationary potential shifted to the positive values by +70 mV (Fig. 4b).

As can be seen, the sensitivity of the sensor electrodes prepared in solutions containing oxidants [$KMnO_4$, $KClO_4$, and $K_3Fe(CN)_6$] in first operation days was 56 ± 4 mV per tenfold change in the CO_2 concentration. However, in prolonged operation of the sensor electrodes, E_{st} shifts toward positive values (Fig. 4b) with simultaneous changes in the slope of the electrode function (Fig. 4a).

An analysis of our experimental data demonstrated that the electrodes formed in the presence of oxidants show an exponential shift of the output signal with time, which is accompanied by a decrease in the sensitivity to CO_2, whereas in the case of the thin films formed in the presence of $KMnO_4$, E_{st} decreases linearly. This fact is attributable to gradual dissolution of the film coating. For molybdenum electrodes prepared with various oxidants, the exponential drift of E_{st} differs in the characteristic times τ: 110.2 and 141.3 h for $KClO_4$ and $K_3Fe(CN)_6$, respectively. The sensitivity of the electrodes $S_f = dE_{st}/d\log[CO_2]$ also exponentially decreases with a characteristic time τ of 86.2 and 33.7 h for $KClO_4$ and $K_3Fe(CN)_6$, respectively.

The influence exerted by complex compounds used in electroplating to prepare finely crystalline and uniform coatings on the formation of the electrodes and their properties was studied after keeping the molybdenum electrodes in two-component solutions: supporting electrolyte + Na–EDTA and supporting electrolyte + $K_4Fe(CN)_6$. It is known that complex electrolytes enhance the adhesion of the coatings.

In a 1 M Na–EDTA solution, the electrode surface was coated with a black film. The sensor electrodes prepared in the presence of Na–EDTA exhibit linear dependences E–$\log[CO_2]$ with significant differences in E_{st} (±30 mV) and sensitivity $S = 74 \pm 12$ mV (determined for a set of 20 electrodes). A study of the variation of the potentiometric response with time revealed an irregular drift of E_{st} and changes in the electrode sensitivity from 62 to 84 mV. After operation for 2 days, an inflection appeared: at a CO_2 content of 3.9×10^{-4}–1.18×10^{-4} M the electrode sensitivity was 50 ± 3 mV, and at 10^{-4}–3.13×10^{-6} M, 80 ± 5 mV, which is close to the super-Nernst value. Probably, the surface properties of the sensor electrodes change in the course of operation in CBCB.

Keeping in the supporting electrolyte containing 1 M $K_4Fe(CN)_6$ causes formation of the strong black film on the edge surface of the electrode. Upon immersion of the electrodes in 1 M $K_4Fe(CN)_6$ for 20 min, the opencircuit voltage became negative (Fig. 2, curve *4*); however, after keeping for 30 min, it shifted toward positive values, suggesting that the passivation is predominant. The resulting electrodes exhibit linear dependences E–$\log[CO_2]$ with a sensitivity of 64 ± 1 mV per tenfold change in the CO_2 concentration. Changes in E_{st} with time can be described by the dependence $E_{st} = E_1 + A_E \exp(-t/\tau)$ with $\tau = 46.2$ h (Fig. 5a), and the electrode function $dE/d\log[CO_2]$ varied at a rate of +4 mV day^{-1} (Fig. 5b, curve *1*).

The properties of the sensor surface of the molybdenum electrodes as influenced by the organic cations were studied in a 0.1 NaOH + 1.0 $K_4Fe(CN)_6$ supporting electrolyte (S2). The complex $K_4Fe(CN)_6$ is used in electroplating [17] because, when added to the electrolyte, it enhances its throwing power and allows preparation of finely crystalline precipitates.

As can be seen from the dynamic voltammograms, the passivation current of molybdenum electrodes decreases in the presence of $K_4Fe(CN)_6$ and the passivation potential shifts toward negative values (Fig. 1).

The values of E_{st} (Fig. 5a) and S_f of the sensor electrodes formed in the ternary systems containing anions of polybasic hydroxy acids [18] are more reproducible. The open-circuit voltage after immersion of the electrodes into a solution containing S2 + 0.1 M sodium citrate attains stationary potential in approximately 3 h (Fig. 2, curves *5*, *5'*); and passivation becomes predominant after 17-min keeping in the above solution.

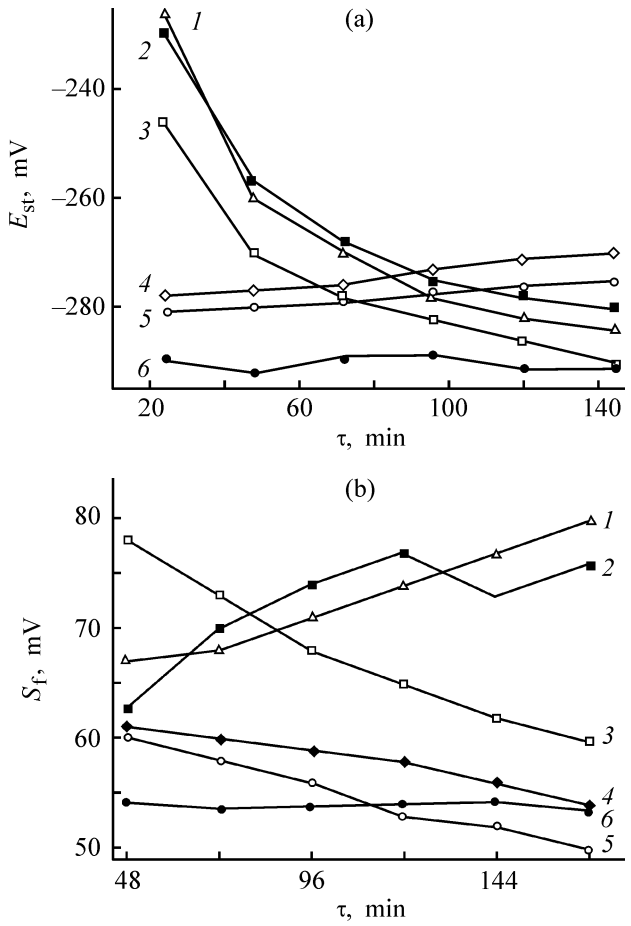

Fig. 5. (a) Drift of the stationary potential E_{st} of the molybdenum electrode in the carbonate-bicarbonate buffer with a CO_2 content of 1.18×10^{-4} M after formation of the sensor layer in given solutions and (b) variation of the sensitivity S_f of the molybdenum electrode at various compositions of the forming solutions with time τ. Solution composition, M: (*1*) 0.1 NaOH + 1.0 $K_4Fe(CN)_6$ (S2) , (*2*) S2 + 0.1 sodium aminoacetate, (*3*) S2 + 0.1 sodium acetylsalycilate, (*4*) S2 + 0.1 sodium oxalate, (*5*) S2 + sodium succinate, and (*6*) S2 + sodium citrate.

A distinctive feature of the sensor electrodes formed in the presence of sodium salts of aminoacetic, acetylsalicylic, malic, oxalic, and citric acids is the linearity of the E–$\log[CO_2]$ dependence in a wider range of CO_2 concentrations. The slopes of the curves depend on the anion (Fig. 5b) and vary from 78 (super-Nernst) to 54 mV per tenfold change in the CO_2 concentra-

tion for electrodes formed in electrolytes S2 + 0.1 M acetylsalicylate and S2 + 0.1 M sodium citrate, respectively. The stationary potentials of the sensor electrodes relative to the EVL-1M silver chloride reference electrode in the pH 8.5–10.5 range (corresponding to the CO_2 concentration from 10^{-3} to 10^{-6} M) can be described by the following equations:

$$E = (0.223 \pm 0.018) - (0.078 \pm 0.006)\text{pH},$$
S2 + sodium acetylsalicylate,

$$E = (0.260 \pm 0.010) - (0.054 \pm 0.002)\text{pH},$$
S2 + sodium citrate.

However, as can be seen from Fig. 5a, the drift of the stationary potential of the electrodes formed in the presence of sodium oxalate, succinate, and citrate is significantly smaller than that for the electrodes formed in solutions containing sodium acetylsalicylate or aminoacetate. The CO_2 function of the sensor electrodes formed in solutions of sodium oxalate, succinate, and citrate is also more stable in the course of time (Fig. 5b).

A statistical analysis of the experimental results was performed to check whether changes observed on varying the electrolyte composition are significant (Tables 1, 2). The results of this analysis by the Cochran test show that the properties of the sensor electrods (stationary potential and sensitivity) regularly change as the electrolyte composition is varied.

Our prolonged studies of the sensitivity of the sensor electrodes to dissolved CO_2 showed that the sta-

tionary potential of the electrode formed in the oxalic acid solution shifts in two months by +70 mV (Fig. 6a) and the slope of the CO_2 function increases to 100 mV per tenfold change in the CO_2 concentration (Fig. 6b). The most stable operation parameters (output signal and sensitivity) were found for sensor electrodes formed in solutions containing sodium citrate, used in electroplating to prepare finely dispersed dense metallic coating strongly adherent to the electrode surface. The trends in the potentiometric response to CO_2 of the sensor electrodes formed in the model solutions of carboxylic acid anions may be due to the formation on their surface of passive films exhibiting a proton conductivity, as in the case of solid solutions.

The stability of the resulting sensor surface is determined by the mechanism of ion transfer in the film in the course of its formation.

It is known that layers covering metallic electrodes contain bound water and its amount increases with pH; the OH^-/O^{2-} ratio in the surface layer is greater than that in the film bulk. Water bound in the form of both H_2O and OH^- groups is a source of highly mobile protons, and, thus, hydrogen ions can penetrate from solution into the crystalline structure of the passivating film. Organic acid anions present in the electrolyte, which control the stoichiometry of the transition metal oxygen in the film and thus affect the film properties, can be also involved in the formation of the structure of the passivating film:

$$H_xMoO_n + pA^- = H_xMO_{n-p}A_p + p/2\,O^{2-},$$

$$H_xMoO_{n-p}A_p + mH^+ + me = H_{x+m}MO_{n-p}A_p.$$

Considering $H_xMoO_{n-p}A_p$ as a solid solution of protons, we can calculate the potential as follows:

$$E = E_{st} + (2.3RT/F)\log a(H^+) - (2.3RT/F)\log a(H_s).$$

This equation suggests the Nernst response to the content of H^+ ions in the aqueous phase at a constant activity of hydrogen atoms in the phase of the solid solution.

CONCLUSIONS

(1) Molybdenum-based electrodes sensitive to dissolved CO_2 were formed in multicomponent solutions. The dependences of the stationary potential on time, sensitivity with respect to CO_2, and operation life of the indicator electrodes are determined by the conditions under which the surface films are formed.

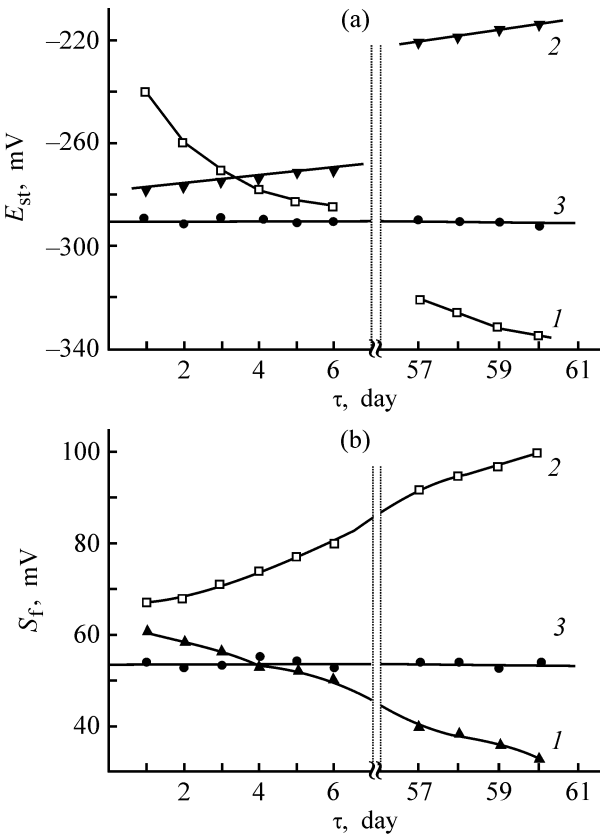

Fig. 6. (a) Drift of the stationary potential E_{st} of the molybdenum electrode in the carbonate-bicarbonate buffer with a CO_2 content of 1.18×10^{-4} M after formation of the sensor layer in given solutions and (b) variation of the sensitivity S_f of the molybdenum electrode at various compositions of the forming solutions with time τ. Solution composition, M: (*1*) S2, (*2*) S2 + 0.1 sodium oxalate, and (*3*) S2 + sodium citrate.

Organic acid anions, being added in the electrolyte, stabilize the operation properties of the electrodes.

(2) The electrolytes containing citrate anions allow preparation of a prototype sensor for dissolved CO_2, which exhibits the Nernst dependence for the open-circuit voltage in the 2×10^{-6}–1.18×10^{-3} M concentration range of carbon dioxide and the output signal remains reproducible for 65 days.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Inhibition of Corrosion and Hydrogenation of Carbon Steel with a Number of Inhibitors in Weakly Acid Media Containing H_2S and CO_2

Abstract—The inhibitive power of AMDOR IK-7 formulation, homologous mixture of alkyl ammonium acetates C_{10}–C_{14} in a specific solvent, and PKU-6 toward corrosion of St. 3 steel in weakly acid media containing 5.8 g l^{-1} NaCl, H_2S, and CO_2 was studied. The influence exerted by the inhibitors on the kinetics of partial electrode reactions and on the hydrogenation of steel was examined. Impedance spectra were recorded and analyzed.

The intensive extraction of oil containing no less than 500 mg l^{-1} hydrogen sulfide [1] makes the protection of building materials against hydrogen sulfide corrosion a matter of current interest. In solving this problem, an important role belongs to corrosion inhibitors. A steadily increasing number of new forms of these inhibitors is being synthesized, because oil companies need inhibitors that would be effective at low concentrations not exceeding 100–200 mg l^{-1}, with the cost of anticorrosion protection thereby reduced and the competitiveness enhanced. It is advisable to develop versatile inhibitors that could retard hydrogen sulfide and carbon dioxide corrosion and hydrogenation of building materials. Such an approach makes it possible to tackle with the presently existing shortage of protective materials, to enlarge the domestic resources of raw materials, and to search for ways to diminish the required amount of imported materials.

This communication presents the results obtained in a comparative study of the efficiency of new corrosion inhibitors for St. 3 steel (AMDOR IK-7 and a formulation composed of alkyl ammonium acetates C_{10}–C_{14} in a specific solvent) and of the known PKU-6 inhibitor (laboratory sample) [2], as versatile inhibitors of the carbon dioxide and hydrogen sulfide corrosion and hydrogenation.

EXPERIMENTAL

The corrosion resistance of St. 3 steel was studied gravimetrically at room temperature on polished samples ($20 \times 12 \times 2$ mm) in solutions containing 5.8 g l^{-1} NaCl, acidified with HCl to pH 2.0–6.0, in the presence of CO_2 and H_2S. Hydrogen sulfide was obtained in the reaction medium by the method reported in [3]. An excess pressure of CO_2 (0.5–2.0 atm) was produced in plastic vessels equipped with nipple valves, as in [4]. CO_2 was pumped from the cylinders, with pressure monitored with a manometer. The exposure time of the electrodes was 24 h. The conventional procedure was used in corrosion tests. The degree of protection, Z (%), by an inhibitor was calculated by the formula:

$$Z = (K_0 - K_{inh})/K_0,$$

where K_0 and K_{inh} are the corrosion rates in a solution with and without inhibitor, respectively.

The following corrosion inhibitors were used: AMDOR IK-7 formulation (c_{inh} = 5–200 mg l^{-1}), which is a 10% solution of higher amines C_{10}–C_{16} in a mixture of aprotic solvents; a formulation composed of alkyl ammonium acetates (AA) C_{10}–C_{14} in a specific solvent; and PKU-6, a product formed

in condensation of urotropin with alkyl chloride C_{12}–C_{15}.

The potentiostatic polarization of the steel was studied with a P-5827M potentiostat in a three-electrode cell with separated anode and cathode spaces, with a 30-s exposure at each potential. A saturated silver chloride electrode served as reference, and Pt, as an auxiliary electrode. The potentials are given relative to a standard hydrogen electrode. The electrochemical measurements under an excess pressure of CO_2 were made using the method described in [5].

The rate of the hydrogen mass-transfer in steel was estimated as in [6], using a Devanathan two-compartment cell (Pyrex) divided in two by a vertical 300-μm-thick steel membrane [7]. Changes in the hydrogen diffusion flux across the membrane were characterized by the coefficient $\gamma_H = i_0/i$, where i_0 and i are the diffusion currents in the supporting solution and in the solution containing additives, respectively.

The mechanism of the inhibiting effect was analyzed by the impedance spectroscopy. The electrochemical impedance of the steel electrodes was studied at frequencies ($\omega/2\pi$) in the range 60 kHz–10 MHz at the amplitude of the ac voltage of 10 mV, using the Solartron system (UK). The working electrode (St. 3 steel, S_{el} = 0.785 cm^2) and auxiliary electrode (Pt, S_{Pt} = 54 cm^2) were coaxial. A silver chloride electrode was used as reference. The potentials were recalculated to the standard hydrogen scale. The samples were polished, degreased, and cathodically activated (ΔE from E_{cor} equal to 0.2 V) for 10–15 min to remove the air-oxide film. After the polarization was switched off, the electrodes were kept in the solution for 10–15 min, until the quasi-stationary potential was attained. The results of the impedance measurement were processed using the software[1] that enabled calculations for any equivalent circuit with up to 12 elements [8]. The program uses complex (real and imaginary) values of the resistance of the electrochemical system and the corresponding frequencies. Preliminarily, arbitrarily chosen initial values are set for all the elements of the equivalent circuit. The calculation is based on a simplex search for an extremum of a function of several variables. To avoid finding a local minimum of the function, the calculation was repeated many times with different initial values of the elements of the circuit. As a criterion for assessment of the circuits was used the root-mean-square deviation s. An equivalent circuit was considered satisfactory at $s \le 5\%$.[2]

In the supporting solutions without gaseous additives, the protective effect of the inhibitors is low. It increases with the solution acidity and inhibitor concentration, to reach the maximum value at c_{inh} = 200 mg l^{-1} (Table 1).

Introduction of CO_2 into the solutions makes K_0 of the steel lower at pH 2.0 and 4.0, in agreement with published data [9, 10], and higher at pH 6.0. Simultaneously, Z of AMDOR IK-7 and AA C_{10}–C_{14} increases in the presence of CO_2, whereas that of PKU-6 decreases (Table 1).

Potentiostatic polarization curves measured on St. 3 steel at pH (a) 2.0 and (b) 6.0 in weakly acid solutions containing 400 mg l^{-1} H_2S (*1*) without and (*2–4*) in the presence of inhibitors c_{inh} = 200 mg l^{-1}; the same for Figs. 2, 3. (*E*) Corrosion potential and (*i*) current density; the same for Fig. 2. Inhibitor: (*2*) AMDOR IK-7, (*3*) AA C_{10}–C_{14}, and (*4*) PKU-6; the same for Fig. 2.

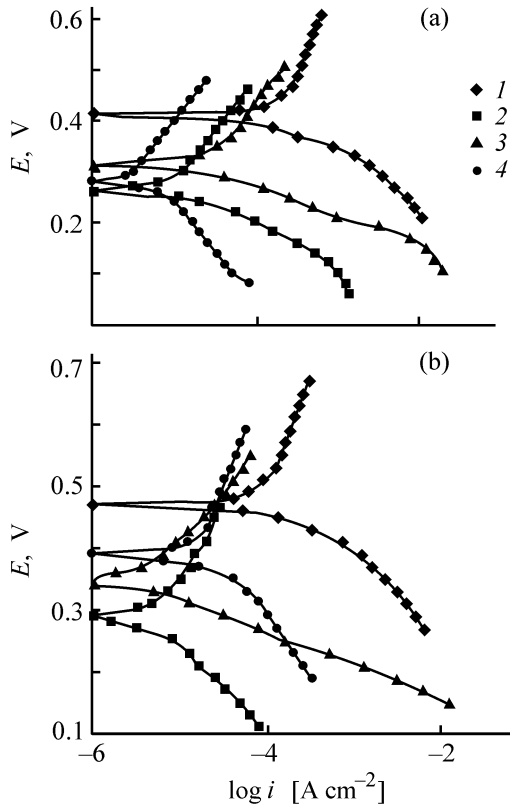

Fig. 2. Potentiostatic polarization curves measured on St. 3 steel at pH (a) 2.0 and (b) 6.0 in weakly acid solutions containing 200 mg l^{-1} H_2S and CO_2 (1 atm) (*1*) without and (*2–4*) in the presence of the inhibitors.

Introduction of H_2S into the supporting solutions makes higher the corrosion rate of the steel and enhances the protective effect of the inhibitors, which depends on pH only slightly (Table 1). However, raising the c_{H_2S} leads to a rise in the corrosion rate K_0 in uninhibited solutions and to an increase in Z at all pH values only to c_{H_2S} = 400 mg l^{-1}. Introduction of an additional amount of H_2S makes K_0 and Z lower. If H_2S and CO_2 are present simultaneously, the corrosion rate increases in comparison with that in solutions containing no hydrogen sulfide or carbon dioxide, and decreases in comparison with purely hydrogen sulfide solutions. The inhibitors produce the most pronounced protective effect at c_{H_2S} = 200 mg l^{-1} and P_{CO_2} = 1 atm (Table 1).

The cathodic polarization curves (CPC) obtained in supporting solutions containing no CO_2 and H_2S show two linear portions with slopes b_c close to 120 and 220 mV. A higher value of b_c indicates that H_3O^+ is reduced at high cathode potentials in the diffusion-kinetic region. The anodic polarization curves (APC) exhibit short linear initial portions with b_a = 60 mV, followed by the region of a higher variable slope.

The presence of CO_2 (P = 1 atm) in the supporting solutions at pH 2.0 and 4.0 inhibits the cathodic process and facilitates the anodic process. The first effect apparently predominates because the corrosion rate K of the steel decreases. In the solutions with an initial pH value of 6.0, both the electrode processes on the steel are accelerated in the presence of CO_2, with pH simultaneously decreasing to 3.9 [11] and K increasing.

Introduction of hydrogen sulfide into the supporting solution at pH 2.0–6.0 and the subsequent rise in its concentration accelerate both the cathodic and the anodic processes, and it is this process that is responsible for the overall increase in the corrosion rate. By contrast, the cathodic reaction at c_{H_2S} = 1000 mg l^{-1} becomes slower in solutions with pH 2.0, and at pH 4.0 and 6.0 the same occurs with the anodic reaction.

The joint introduction of H_2S and CO_2 (P = 0.5, 1 atm) into supporting solutions at pH 2.0 facilitates the cathodic and anodic processes (c_{H_2S} = 200 mg l^{-1}). In the presence of 1000 mg l^{-1} H_2S, the cathodic process is inhibited, whereas the anodic process is stimulated. At pH 4.0 and 6.0, both the processes are

accelerated, and the cathodic curves show short linear portions with b_c = 120 mV in the kinetic region, which rapidly pass into the region of the limiting current.

Introduction of inhibitors into the supporting solutions in the absence of gases and the subsequent increase in c_{inh} lead to a rise in E_{cor}. At all pH values, the cathodic process is accelerated, and the anodic process, decelerated. The same pattern is observed in the presence of CO_2. The inhibitors under study decelerate both the electrode processes in a solution with c_{H_2S} < 1000 mg l^{-1} at pH 2.0 (Fig. 1a) and facilitate the cathodic reaction in a solution with c_{H_2S} = 1000 mg l^{-1}. In the inhibited solutions with pH 4.0 and 6.0, only the ionization of iron is decelerated (Fig. 1b).The joint presence of H_2S and CO_2 in the inhibited solutions decelerates of both the electrode processes at pH 2.0 (Fig. 2a). At pH 4.0 and 6.0, only the anodic reaction is decelerated (Fig. 2b). A study of the diffusion of hydrogen across a steel membrane (Table 2) confirmed the known evidence [10, 12] that H_2S and CO_2 produce a stimulating effect. The decrease in the current i_H of hydrogen diffusion across a membrane upon introduction of CO_2 into a solution containing hydrogen sulfide is presumably due to the concurrent adsorption of CO_2, which is a less efficient stimulant of hydrogenation, compared with H_2S.

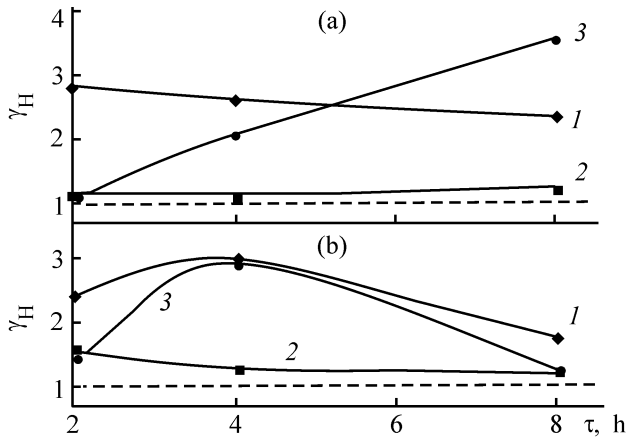

Fig. 3. Effect of the duration τ of an experiment on the coefficient γ_H of change in hydrogen diffusion into a steel in solutions at pH (a) 4.0 and (b) 6.0 containing 200 mg l^{-1} H_2S and 1.7 g l^{-1} CO_2. Inhibitor: (*1*) ANDOR IK-7, (*2*) AA formulation C_{10}–C_{14}, and (*3*) PKU-6.

Raising the duration of an experiment to 4.8 h in the presence of H_2S and CO_2 leads, in virtually all cases, to a decrease in i_H.

According to the results of 2-h tests, AA C_{10}–C_{14} inhibits hydrogenation in the supporting solutions without H_2S and CO_2, whereas ANDOR IK-7 and PKU-6, by contrast, stimulates this process (Table 2). When stimulants are present both separately and simultaneously, the inhibitors decelerate, on the whole, the diffusion of hydrogen into the steel. In this case, i_H is suppressed to the greatest extent by the inhibitors AA and PKU-6 in solutions with pH 2.0, and by ANDOR IK-7 at pH 4.0 and 6.0.

Figure 3 shows how the duration of an experiment affects the coefficient of change in the diffusion of hydrogen into the steel. The dashed line corresponds to γ_H = 1. Above and below this line lie the inhibition and stimulation regions, respectively. Although γ_H

* Without (numerator) and with (denominator) 200 mg l^{-1} inhibitors.

decreases with time, its value remains rather high after 8 h, especially in the presence of ANDOR IK-7 and PKU-6 (γ_H = 1.7 and 1.2, respectively, at pH 6.0 and 2.3 and 2.7 at pH 4.0).

The reason why addition of gases and inhibitors affects the change in the hydrogen diffusion into the steel can be ascertained by analyzing the data in Table 3, which lists selected kinetic parameters of the reaction of hydrogen evolution (RHE) in the solutions under study at pH 2.0–6.0, calculated from the cathodic polarization curves.

The parameters of RHE are considerably smaller than the values corresponding to the delayed discharge theory. This suggests that the discharge is not the limiting stage of the process. Introduction of H_2S and CO_2 into the solutions somewhat increases the kinetic parameters of RHE, with their values approaching those required by this theory. Apparently, the observed increase in i_H is not due to deceleration of the stage of recombination of adsorbed hydrogen or to an increase in γ_H.

The presence of an inhibitor in virtually any of the solutions somewhat decreases the kinetic parameters of RHE, making them approach the values required by the recombination theory, which is inconsistent with the decrease in the hydrogen diffusion flux into the steel. Apparently, the change of the nature of the limiting stage of RHE does not affect the solid-phase diffusion of hydrogen.

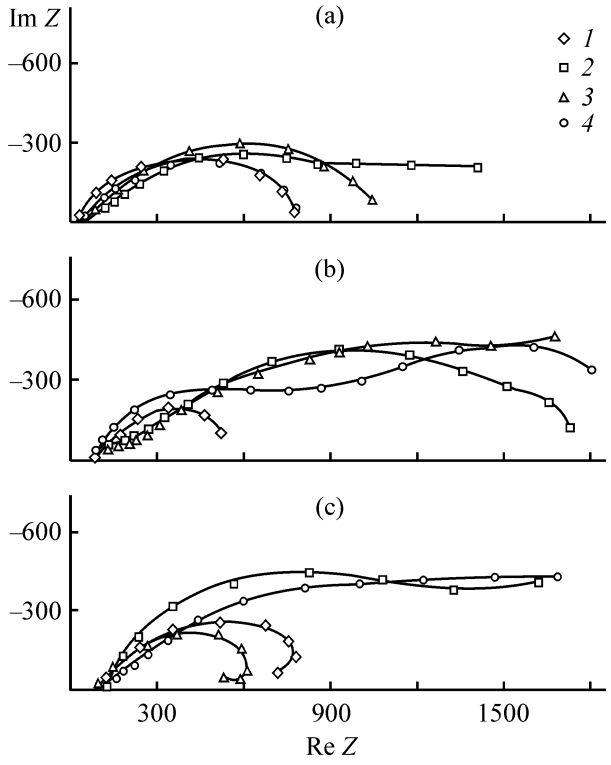

Fig. 4. Nyquist diagrams for steel in weakly acid solutions (a) at pH 2.0, (b) at pH 4.0 in the presence of 50 mg l^{-1} H_2S and (c) at pH 6.0 in the presence of 400 mg l^{-1} H_2S. (*Dots*) experimental data, (*solid lines*) calculation for the equivalent circuit used. Fig. 5. Extended equivalent circuit for a corroding steel electrode in weakly acid solution. R_1 and R_2 are the charge-transfer resistance in the anodic and in the cathodic reaction of O_2 reduction, respectively; $Z_D = R_D th(j\omega\tau)^p/(j\omega\tau)^p$ is the final form of the generalized diffusion impedance; $R_D = RT\sigma/(n^2F^2c_{x=0}D)$, mass-transfer resistance; $\tau = \delta^2/D$, characteristic time of diffusion; δ, thickness of the diffusion layer; D, diffusion coefficient of depolarizer; $c_{x=0}$, the surface concentration of electroactive species; $0 < p < 1$; C_{dl}, capacitance of the double electric layer (DEL); and R_s, solution resistance. The R_a–C_a circuit determines the adsorption of intermediate products (of the anodic process).

On steel and a number of other metals, chemisorbed hydrogen exists in two equilibrium forms, suprasurface (H^r) and subsurface (H^s) [13]:

$$H^r_{ads} \rightleftarrows H^s_{ads}. \quad (1)$$

Therefore, it may be suggested, with account taken of the fact that H^s_{ads} is responsible for the solid-phase diffusion [14], that the increase in $i_{H_{ads}}$ in the presence of H_2S and CO_2 is due to a shift of equilibrium (1) to the right [14]. By contrast, the adsorption of inhibitor onto the steel surface shifts equilibrium (1) to the left.

Nyquist diagrams plotted on a complex plane for steel in weakly acid solutions with different pH values, with and without H_2S and in the presence and absence of an inhibitor, are shown in Fig. 4. Commonly, the hodographs have two overlapping arcs in the capacitance half-plane. The equivalent electrical circuit (EC) was obtained using that suggested in [15] for a corroding electrode made of low-carbon steel (neutral medium) (Fig. 5).

It is noteworthy that the EC in [15] contains no elements R_a and C_a, and $p = 0.5$.

The EC is suitable for description of the impedance spectra of steel electrodes [16] in model stratal water, which is virtually neutral. It can also be used in weakly acid solutions, because here, as in neutral media, oxygen reduction is a major cathodic process at pH 6.0. At pH 2.0, the hydrogen over-voltage is due to the deceleration of the electrochemical or heterogeneous chemical stage, rather than being the diffusion overvoltage [17]. To a first approximation, RHE can be modeled with a resistance connected in parallel with the impedance of O_2 reduction and with that of the anodic process. In this case, the resistance associated with charge transfer in RHE is combined with that associated with charge transfer in the anodic reaction into a single resistance R_1, i.e., an EC is obtained (Fig. 5). Only at pH 4.0 it may be expected that the above EC will describe experimental data with poorer precision, because, in this case, the concentration polarization caused by the low rate of delivery of H^+ ions to the electrode cannot be neglected. However, the data processing demonstrated that, as regards the criterion of a weighted sum of root-mean-square deviations, the experimental impedance graphs at pH 4.0 are described in terms of the chosen model with a precision that is not worse than that at pH 2.0 and 6.0.

The EC in Fig. 5 satisfactorily describes the experimentally observed impedance spectra in weacly

acid solutions inhibited and uninhibited with ANDOR IK-7, AA, PKU-6, and (or) hydrogen sulfide. The values of the EC elements, obtained by data processing, are listed in Table 4.

The effect of inhibitors on the kinetics of the cathodic and anodic reactions is manifested upon adsorption of their molecules onto the electrode surface. As in the case of neutral solutions [16], the inhibitors

Table 5. Values of *Z*, obtained from impedance data

Inhibitor	c_{H_2S}, mg l^{-1}	*Z*, %, at indicated pH		
		2.0	4.0	6.0

under study are adsorbed in a weakly acid medium onto the steel electrode, thereby lowering C_{dl} by one and a half or two orders of magnitude (at an inhibitor concentration of 200 mg l^{-1}) both in the absence and in the presence of H_2S. Presumably, the fact that $C_{dl} < 1$ μmF cm^{-2} in some cases indicates that there occurs a multilayer adsorption of the inhibitor.

As the pH of the supporting solutions (without H_2S and inhibitors) is raised, R_2, C_a, R_a, and C_{dl} decrease, R_1, R_D, and τ increase, and *p* remains approximately constant. The closest correlation with *K* is observed for R_1. Its increase with the solution pH corresponds to a decrease in the corrosion rate, in agreement with the results of gravimetric measurements (Table 1). In supporting solutions with pH in the range 2.0–6.0, $\partial \log R_2/\partial \mathrm{pH} \approx -0.2$. Iron without an oxide film belongs to the group of electrode materials for which $\partial E/\partial \mathrm{pH} \approx -2.3RT)/F$ in the region of oxygen reduction [18], and the derivative $\partial \log R_2/\partial \mathrm{pH}$ must have a value on the order of unity. The value $\partial \log R_2/\partial \mathrm{pH} < 0$ is apparently due to a shift of E_{cor} into the negative region on raising the pH. Therefore, the following two factors affect R_2: (1) an increase in R_2, in accordance with [18], and (2) a decrease in R_2, caused by the lowering of the corrosion potential. Presumably, the effect of the second factor predominates in the solutions studied, with the result that negative values of $\partial \log R_2/\partial \mathrm{pH}$ are also obtained in H_2S-containing solutions (both with and without inhibitors). The only exception are solutions containing inhibitors in the absence of H_2S, in which R_2 increases as pH decreases.

As the pH of the supporting solutions is raised, the parameters of the diffusion impedance vary in the following manner: on passing from pH 2.0 to pH 6.0, the characteristic time $\tau = \delta^2/D$ increases to the greatest extent, and the resistance R_D, which is proportional to $\delta/(c_{x=0}D)$, to the least extent. The extent to which the τ/R_D ratio, which is proportional to $c_{x=0}\delta$, increases is intermediate between those for τ and R_D. Hence follows that, as the pH of the supporting solution increases, $c_{x=0}$ and δ grow, with the increase in δ presumably exceeding that for $c_{x=0}$.

As the hydrogen sulfide concentration in the uninhibited solution increases, R_2 and R_D decrease at all pH values (with R_D decreasing to the greatest extent at pH 2.0), *p* somewhat increases, and R_1 decreases (to a greater extent at pH 6.0). C_{dl} depends on c_{H_2S} only slightly. Thus, H_2S somewhat accelerates the cathodic and anodic reactions, in a qualitative agreement with the results of polarization measurements. The action of H_2S on the surface of a steel electrode results in the development of its surface profile, as indicated by an increase in *p*.

It is noteworthy that, as the concentration of the inhibitors grows, the impedance parameters increase in a manner common to all the inhibitors. In the absence of H_2S, R_2 decreases at pH 2.0 and increases at pH 6.0, and the resistance R_1 grows. The value of *p* tends to decrease (which reflects a partial activation of the electrode surface [16]). R_D decreases solely in the presence of ANDOR IK-7; R_D changes insignificantly in the case of PKU-6 and somewhat increases in the presence of AA. In the presence of H_2S, R_1, R_2, and R_D increase, and p = const.

The degree of protection (%) by the inhibitor can be calculated by substituting the impedance data into the relation [19]:

$$Z = \frac{R_{1,\,\mathrm{inh}} - R_{1,\,\mathrm{sup}}}{R_{1,\,\mathrm{inh}}} \times 100.$$

The results of this calculation (Table 5) are in a qualitative agreement with the gravimetric data. For example, the results of impedance measurement show that the protective effect is weak in solutions without H_2S and becomes stronger as the solution pH and inhibitor concentration increase. Introduction of H_2S enhances the protective effect. The values of *Z* are at a maximum at $c_{H_2S} = 50$ mg l^{-1}. However, the values of *Z*, calculated from the impedance data, are, as a rule, lower than those obtained from gravimetric measurements. This is apparently due to the different times of exposure of the samples to a solution.

CONCLUSIONS

(1) A high efficiency of protection of St. 3 steel by such inhibitors as ANDOR IK-7, homologous mixture

of alkyl ammonium acetates C_{10}–C_{14}, and PKU-6 in chloride solutions containing H_2S and CO_2 (pH 2.0–6.0) was demonstrated. The protection efficiency increases as the pH value is raised and H_2S and CO_2 are introduced.

(2) The inhibitors studied effectively suppress the hydrogen diffusion into steel in solutions containing H_2S and CO_2.

(3) The inhibitors decelerate the anodic reaction of iron ionization in solutions with pH 4.0 and 6.0 and cause retardation of both the electrode processes at pH 2.0.

(4) An equivalent electrical circuit is suggested for describing the impedance spectra of a corroding steel electrode in weakly acid solutions in both absence and presence of inhibitors and (or) hydrogen sulfide. The influence exerted by inhibitors and H_2S on the corrosion rate and on the kinetics of the anodic and cathodic reactions is considered in terms of this model.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Design of Large-Volume Agitators for Polydisperse Suspensions

A. I. Mil'chenko, I. V. Domanskii, and N. V. Vorob'ev-Desyatovskii

Received July 7, 2005

Abstract—Specific features of designing of large-volume agitators for mechanical agitation of concentrated polydisperse suspensions are considered. Mathematical models and results of model experiments are applied to obtain calculational relations that can be use to determine technical parameters of industrial agitators. The designing procedure is confirmed by the experience of industrial use of agitators with a capacity of up to 1000 m^3.

Processes of mechanical agitation in fluid–solid and fluid–solid–gas systems are widely employed in chemical and mining-and-smelting industries. As examples of processes of this kind can serve leaching-out of gold and silver from ores with sodium cyanide and of sodium aluminate from bauxites with an alkali, biooxidation of sulfide ores, manufacture of extraction phosphoric acid in sulfuric acid treatment of apatite, and many others. It should be noted that many processes are not only large-tonnage, but also require a long time (up to 4 days). All these factors make necessary development of cascaded agitators or chains of agitators working in the rotary mode. The capacity of single agitators in such cascades or chains has reached a value of 5000 m^3 [1]. A specific feature of agitators of this kind is also that the solid phase is a polydisperse medium (Fig. 1), whose particle size, as a rule, does not exceed 200 μm, and the agitation process is performed at a nearly zero excess pressure in the agitators.

Designing of such unconventional large-volume agitators meets certain difficulties, which have been insufficiently discussed in the special literature [2–4].

The influence exerted by centrifugal forces on the distribution of the solid phase along the agitators radius in agitation of finely dispersed suspensions is insignificant. Therefore, it is advisable to use for this purpose low-energy-intensive smooth-walled agitators. The scheme of the agitators we recommend, with account of the minimum expenditure for its fabrication and use, is shown in Fig. 2. This is an ap-

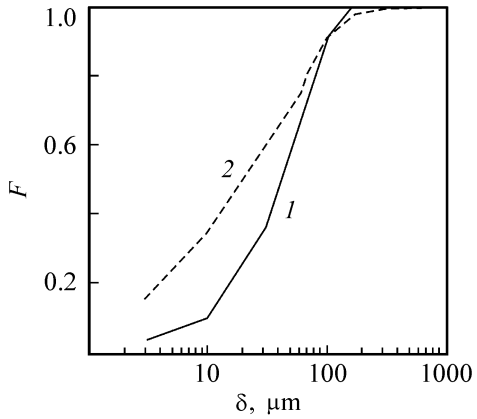

Fig. 1. Integral dispersion composition of the ore (*1*) before and (*2*) after leaching. (*d*) Particle diameter.

paratus with flat cover and bottom. The latter has a conical fillet along its perimeter for eliminating the stagnant zone and a small collector with a pipe for discharging the suspension at the center, with the height H of agitators filling approximately equal to its diameter D.

A preferable type of impeller is that of the standard three-blade design with a diameter d_2 and angle of blade inclination of 24°–30° [3], which provides an intense three-dimensional motion of the slurry throughout the working volume of the agitators. The size of such a impeller and the height at which it is mounted, to ensure economical and accident-free operation, is calculated from the inequality

$$\Gamma_{D_2} = D/d_2 = 2.5\ldots4, \quad H_{sed} < h_2 \le d_2. \qquad (1)$$

As shown by studies and industrial tests of the agitators used for the purpose in question [5–7], the rotor of the mechanical agitating devices (MAD) should be supplemented [especially in those cases when $H_{sed} = (0.2–0.5)H$] with another standard impeller, a closed turbine of diameter d_1 [3], for which

$$\Gamma_{D_1} = D/d_1 = 6\ldots7, \quad h_1 = 0.5d_1. \qquad (2)$$

This impeller rapidly suspends the sediment formed after a prolonged standstill of an MAD and provides a nearly complete discharge of the solid phase from the agitators, after the suspension level becomes lower than the impeller d_2.

In the stationary mode, i.e., in prolonged operation, when all the technological parameters have stabilized, the power expended for agitation can be calculated by the formula [2–4]

$$N = K_N \rho_{susp} n^3 d_2^5, \qquad (3)$$

where K_N is the power factor; n rotation rate of the impeller; and ρ_{susp}, suspension density.

To diminish the power consumption, it is necessary to perform the agitation process at the lowest (determining) rotation rate n_0, which ensures that, on the bottom, there is no sediment of particles whose diameter is chosen in accordance with the inequality

$$\delta \le \delta_{lim}, \qquad (a)$$

where δ_{lim} is the diameter of the limiting grain, whose being suspended in agitation of a polydisperse suspension is guaranteed.

It is planned beforehand that, to save energy, a minor fraction of particles (1–2%) (Fig. 1) with diameters

$$\delta > \delta_{lim}, \qquad (b)$$

is to be precipitated and collected in the central collector, with their subsequent delivery to additional grinding.

The problem of finding the value of n_0 has been studied extensively [8–11]. However, the solutions obtained are only for particular cases, because they refer to a limited range of variation of variables and fail to take into account in full measure the effect of design features of an agitators, concentration and granulometric composition of the dispersed solid phase, shape of particles, and their tendency to cake.

Therefore, the most reliable way to design and calculate such unique industrial agitators is scaling [12] based on physical modeling. The method consists in the following. A model installation geometrically similar to the agitators being designed is used to experimentally find the determining rotation rate n_m and power N_m, which correspond to the instant of when the whole sediment of the solid phase of the industrial slurry becomes suspended. The resulting n_m and N_m can be used to calculate with a sufficient accuracy n_P and N_P for the industrial agitators being designed. For this purpose, it is necessary to preliminarily determine how the agitators diameter D_m affects the rotation rate n_m by using a mathematical description of the model of suspension of solid particles.

It follows from [13] that the shear model [14] can be adopted as such a mathematical model of particle suspension from the sediment surface or from the horizontal surface of the agitators bottom. In accordance with [14], the condition for the onset of suspension of a monolayer of particles in a turbulent flow can be written as

$$\tau_b = (\rho_s - \rho_{fl}) g \delta_{lim} (1 - \varepsilon_{sed}) f, \qquad (4)$$

where f and ε_{sed} are the experimentally found friction factor and porosity of the sediment.

Condition (4) for a smooth-walled agitators with a flat bottom can be represented [14] as

$$n = 10.4 \frac{D}{d_2^2} \left[\frac{(\rho_s - \rho_{fl}) \delta_{lim} (1 - \varepsilon_{sed}) f \Gamma_{D_2}}{\rho_{susp} K_N} \right]^{0.5}. \qquad (5)$$

As shown in [14], the shear model is well confirmed by experimental data of numerous domestic and foreign researchers [11, 15].

Thus, the similarity condition (τ_b = idem), which characterizes the onset of particle motion over the bottom, can be written, with account of the invariability of suspension properties and the geometrical similar-

ity of the model and industrial agitators and in accordance with Eq. (5), as

$$nDK_N^{0.5} = \text{idem.} \quad (6)$$

In the turbulent mode of mixing, the power factor in equality (6) can be represented as a power monomial

$$K_N = a_2\left(\frac{\rho_{susp} n d_2^2}{\mu_{susp}}\right)^{-a_1}, \quad (7)$$

in which, e.g., $a_1 = 0.18$ and $a_2 = 1.5$ for a three-blade impeller at $\Gamma_{D_2} = 2.4$ [3]. The viscosity of low-concentrated Newtonian suspensions (at $\varphi < 0.1$) can be found using the known equality [4]:

$$\mu_{susp} = \mu_{fl}(1 + 2.5\varphi). \quad (8)$$

If, however, $\varphi \geq 0.1$, the suspension frequently has the form of a non-Newtonian fluid, whose behavior depends on the shear rate $\dot{\gamma}$ and can be described by Ostwald's power rheological equation [3]:

$$\tau = K\dot{\gamma}^m, \quad (9)$$

In this case, the effective viscosity is calculated by the equation

$$\mu_{susp} = K\dot{\gamma}^{m-1}, \quad (10)$$

with the constants K and m found experimentally [16].

For example, $K = 0.46$ and $m = 0.14$ were obtained on a rotation viscometer for an aqueous suspension with $\delta = 74$ μm, $\rho_s = 2640$ kg m^{-3}, and $\varphi = 0.16$.

In scaling of agitators of non-Newtonian suspensions, it is necessary, to ensure that particles are suspended in accordance with the shear model, to create tangential stresses equal to the stresses in the model agitators at the bottom of the industrial agitators. With account of Eqs. (9) and (10), this is equivalent to equality of the shear rates and effective viscosities at the bottom of the model agitators and that being designed. It is also noteworthy that, in the case of a developed turbulent agitation and turbulent flow around the blades, the viscosity only slightly affects the resistance characteristics of the impeller. Therefore, the scaling of agitators in a turbulent mode of mixing of non-Newtonian suspensions should be performed following the same recommendations as in the case of agitation of Newtonian suspensions.

Substituting (7)–(10) into condition (6) and excluding from consideration the invariable parameters of the suspension, we obtain the first condition for scaling of the industrial agitators

$$nD^b = n_m D_m^b = n_P D_P^b = \text{idem}, \quad (11)$$

with the exponent b found using the formula

$$b = \frac{1 - a_1}{1 - 0.5a_1}. \quad (12)$$

In a particular case of agitation with three-blade impellers ($a_1 = 0.18$), the exponent $b = 0.9$, in accordance with formula (12), and the rule (11) takes the form

$$nD^{0.9} = \text{idem}. \quad (13)$$

The other three scaling conditions, which are frequently used in the special literature [8–11] for calculating the power N, specific power $P = N/V$, and specific torque $T = M/V$, can be readily derived from (11) with account of formula (3):

$$N/D^{3-b} = \text{idem}, \quad (14)$$

$$PD^b = \text{idem}, \quad (15)$$

$$TD^0 = T = \text{const}. \quad (16)$$

The last rule (16) was noted previously in a study [17] of specific features of agitation of highly concentrated suspensions: the thick sediment of aluminum hydroxide particles was completely suspended at one and the same specific torque T for three-blade impellers with different diameters and rotation rates. It is also noteworthy that, when studying the dissolution of oxalic acid fixed in the form of a bulky pellet at the flat bottom of an agitators with changeable rabbles, professor Gzovskii found [18] that its dissolution rate is the same at T = const (for 12 different types and sizes of impellers). As the mass-transfer coefficient in a turbulent flow of a fluid is proportional to the dynamic velocity $U_* = \sqrt{\tau_b/\rho_f}$ [19], we can conclude that the tangential stresses at the bottom remained constant in these experiments, irrespective of the type and size of a impeller. This circumstance indirectly confirms the applicability of the shear model to a wide variety of impeller designs.

In impeller operation in the stationary mode, the quality of agitation is commonly evaluated by the deviation of the running concentration φ at a height z

($z = 0$ at the bottom and $z = H$ at the slurry surface) from its prescribed average value φ_{av}. As is known [12], this distribution follows from a solution to the equation of the circulation-diffusion model and has the form

$$\frac{\varphi}{\varphi_{av}} = \frac{\mathrm{Pe}\exp\left(-\mathrm{Pe}\dfrac{z}{H}\right)}{1-\exp(-\mathrm{Pe})}. \quad (17)$$

This equation contains a single generalized coefficient, the Peclet number

$$\mathrm{Pe} = w_i H/D_s, \quad (18)$$

where w_i is the velocity of hindered sedimentation of particles with diameter δ_i.

The similarity condition for concentration fields in agitators scaling has the form

$$\mathrm{Pe} = \text{idem}. \quad (19)$$

It is recommended [4] to calculate the longitudinal diffusion coefficient D_s in formula (18), averaged along the agitators height, using the semiempirical dependence

$$D_s \sim nD^2. \quad (20)$$

Substitution of (20) into (18) and (19) yields (with account of H/D = const and invariability of w_i in the model and industrial agitators) the following scaling condition

$$nD = \text{idem} \quad (21)$$

and, accordingly,

$$ND^{(a_1-2)} = \text{idem}, \quad PD^{(1+a_1)} = \text{idem}, \quad TD^{a_1} = \text{idem}. \quad (22)$$

For example, for the above-mentioned three-blade impeller, i.e., at $a_1 = 0.18$, the scaling conditions take the form

$$nD = \text{idem},\ N/D^{1.82} = \text{idem},\ PD^{1.18} = \text{idem},\ TD^{0.18} = \text{idem}.$$

As follows from the solution (17), deviations of the running concentration from its average value become well practically acceptable (15% and less) already at Pe = 0.3.

Equation (17) makes it also possible to evaluate the average residence time of the solid phase, compared with the average residence time of the suspension in the agitators,

$$\tau_s = (\varphi_{out}/\varphi_{av})\tau_{susp}, \quad (23)$$

where

$$\tau_{susp} = V/Q_{susp}, \quad (24)$$

φ_{out}, concentration of particles in the agitators at the height of the suspension outlet point [Eq. (17)]; and Q_{susp} is the volumetric flow rate of the suspension through the agitators.

Thus, to evaluate the agitation quality in accordance with formula (17) and the residence time of particles in the agitators in accordance with formula (23), it is necessary to know the velocity w_i of hindered sedimentation of solid particles with a prescribed limiting diameter δ_{lim} in the suspension.

The velocities w_i for each fraction δ_i of the polydisperse suspension can be calculated using the equation derived in terms of the model of mutually penetrating continuums [19]

$$\left[\left(\frac{2\delta_i S_{susp}}{\varphi_{fl}} + \frac{3}{\zeta}\right)\mathrm{Re}_i^{-1} + 0.45(\mathrm{Re}_i\zeta)^{-4/9} + 0.042\right]\frac{w_i^2}{g\delta_i} = \frac{(\rho_s-\rho_{fl})\rho_{fl}}{6\rho_{fl}\zeta^3}. \quad (25)$$

In Eq. (25), which takes into account the interaction forces of all the particle fractions with the fluid, the following designations are used:

$$\mathrm{Re}_i = \frac{\delta_i w_i \rho_{fl}}{\mu_{fl}},\ S_{susp} = \sum_{i=1}^{m}\frac{6\varphi_i}{\delta_i},\ \zeta = 1 + \left(\frac{\pi}{2}-1\right)\varphi_{fl}.$$

The volume fraction of the solid phase and the fluid are related by apparent expressions

$$\varphi_s = \sum_{i=1}^{m}\varphi_i,\ \varphi_s + \varphi_{fl} = 1.$$

Figure 1 shows the dispersion composition of solid particles of an ore in an industrial suspension before and after leaching-out of silver, and Fig. 3 presents the sought-for dependences $w_i = f(\delta_i)$ for the dispersion composition in Fig. 1, divided into 100 fractions. As shown by special-purpose experiments, the accuracy of calculation of the velocities of hindered sedimentation of particles is within 4.2–7.4%.

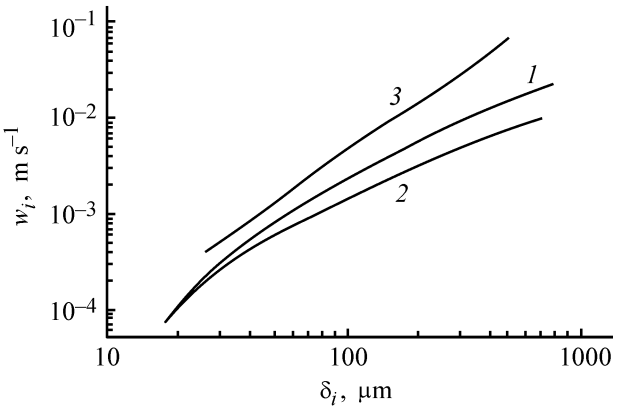

Fig. 3. Velocities w_i of hindered sedimentation vs. particle diameter δ_i. (*1*) Before leaching {Eq. (25)], (*2*) after leaching [Eq. (25)], and (*3*) before leaching (calculation by the Todes formula [13]).

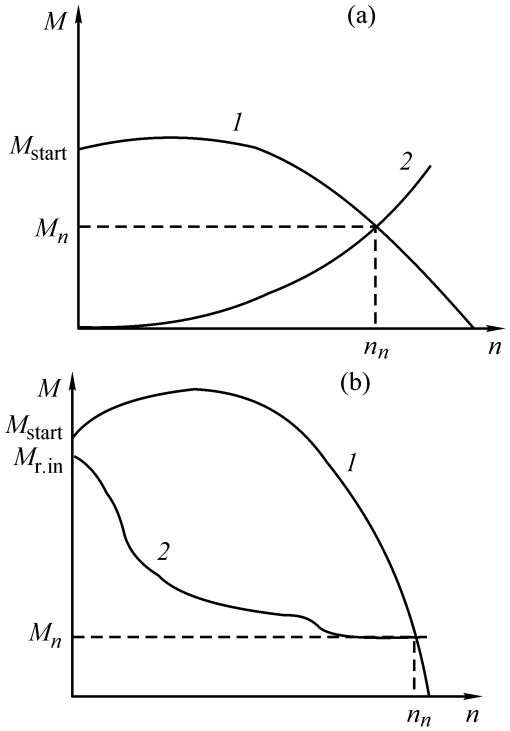

Fig. 4. Experimental dependence of the moment M of resistance of the medium on the rotation rate n of the impeller for a two-stage MAD. (n_n) Nominal rotation rate of the impeller. Rotation: (a) in water and (b) in the sediment from the suspension. $M(n)$ dependence: (*1*) for motor-gearbox and (*2*) for impeller [20].

Figure 3 shows for comparison data on the velocities of hindered sedimentation of monodisperse particles, calculated using the Todes formula [13], which is frequently used in practice. This comparison shows that the velocities of hindered sedimentation of particles of mono- and polydisperse suspensions are strongly different.

Of particular interest is the nonstationary operation mode of a two-stage MAD, e.g., that when the MAD is started after a shutdown and subsequent sedimentation of the slurry to form a many-ton sediment layer (Fig. 2). To prevent failure of rotor elements under an overload, we use the experimental dependence of the resistance momentum of the medium for a two-stage MAD (Fig. 4b):

$$M_{r.in} < M_{start}, \quad (26)$$

where M_{start} is the starting (passport) drive shaft torque, and $M_{r.in}$ is the initial momentum of the force of resistance by the sediment to the turbine rotation during 2–3 s after the switch-on of the drive.

In the course of time, the resistance momentum of the sediment falls from $M_{r.in}$ to M_n because of the fast dilution of the sediment by the pure fluid pumped in by the impeller of the second stage (Fig. 4b). As shown by tests on pilot stands and industrial agitators [5–7, 20], the value of $M_{r.in}$ for the standard turbine impeller can be found using the following formula:

$$M_{r.in} = 0.29\tau d_1^3, \quad (27)$$

in which the tangential stresses in the sediment are determined by Coulomb's law for the shear resistance of water-saturated soils

$$\tau = \tau_0 + \sigma_0 \tan\phi = \tau_0 + (\rho_s - \rho_{fl})(1 - \varepsilon_{sed})(H_{sed} - h_1)gf. \quad (28)$$

The constants τ_0, ε_{sed}, and f can be determined for a particular sediment experimentally, using the standard procedures of engineering geology [21]. Then, the power consumed for agitation will be as follows:

(i) in the starting period, in accordance with formula (27):

$$N_{start} = M_{r.in} 2\pi n = 1.8\tau n d_1^3, \quad (29)$$

(ii) in the stationary mode:

$$N_{st} = K_{N1}\rho_{susp} n^3 d_1^5 + K_{N2}\rho_{susp} n^3 d_2^5, \quad (30)$$

where K_{N1} and K_{N2} are found as in [2–4].

Using the results of calculation by formulas (11)–(16) and (28–30), we can choose the rotation rate and power of the standard motor-gearbox, which, in addition, should satisfy the inequality

$$N_{m\text{-}g} \geq \max(N_{start}, N). \quad (31)$$

To conclude, we present the results of a practical verification of the specific features of calculation of large-volume agitators, described above.

A cascade of seven 1000-m^3 agitators (Fig. 2), designed for the first time in accordance with [2–4], but having no central collector of coarse particles for leaching-out of precious metals from hydrometallurgical slurries [22] has been in industrial exploitation for more than four years. Numerous measurements of electrical parameters, laboratory analyses of a multitude of samples of the suspensions and sediment, observation of how the cascade operates, and, finally, special-purpose model experiments revealed the following.

(1) The agitators of the cascade mostly fulfill their technological purpose. At the same time, their design and technical and economical parameters can be markedly improved using the design procedures described above.

(2) The principles of scale-up of the results of model tests to industrial agitators according to relations (11)–(16) are correct at a scaling factor $D_p/D_m \leq 35$.

(3) The agitators require an expensive periodic cleaning, because they are filled, even though slowly, by settling particles whose size approximately corresponds to inequality (b) at $\delta_{lim} = 160$ μm. The working rotation rate of MAD is lower by 20% than that required by condition (13). The experimentally measured power consumed for agitation exceeds that given by the design by 50% and more. This is due to the friction of the lower impeller against the sediment, which is indicated by the erosion wear of its elements and of the central part of the bottom.

(4) The experimentally measured particle distribution nonuniformity at depths of 9 and 1 m is within 4%. This is considerably better than the value of 21% in the design calculation and shows a good agreement with relations (17)–(22) of the circulation-diffusion model based on the results of measurements and calculations of the velocity of hindered sedimentation of real polydisperse particles (Fig. 3).

(5) The average residence time of the solid phase in the cascade, with account of the sediment accumulated by the instant of measurement, is about 62 h, instead of 72 h in accordance with the design, which corresponds to the results of calculations by formula (23).

(6) Even after a prolonged sedimentation of the slurry (19 h) the agitators can be safely started, which has been tested as yet only at a halved rotation rate of the MAD rotor. This quantitatively verifies the procedure used to calculate the startup power and the method for evaluation of the physicomechanical properties of the sediment [formulas (26)–(29)].

Successful tests of a similar agitators with a volume of 400 m^3 (Fig. 2), which confirmed the above-suggested calculation procedure for a suspension of aluminum hydroxide, were previously reported in [7].

CONCLUSIONS

(1) An integrated method for design of large-volume agitators for mechanical agitation of concentrated polydisperse suspensions was developed.

(2) The method is based on the following: a new shear model which makes it possible to lift the particles from the agitator's bottom, confirmed by published data; known circulation-diffusion model based on the experimentally confirmed new procedure for calculation of the velocity of hindered sedimentation of particles of the polydisperse suspension; and model of washing-off of the sediment at MAD startup, based on new experimental data of physicomechanical parameters of sediments formed from ore slurries.

(3) The method is verified by experimental data obtained in industrial exploitation of agitators with a volume of up to 1000 m^3.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Convective-Infrared Drying of a Polyamide-based Composite in a Fluidized Bed

Yu. K. Sudarushkin, V. V. Pavlyuk, and A. N. Makhov

Saratov State University, Saratov, Russia

Received April 28, 2005

Abstract—The effect of convective-infrared drying of a glass-filled polyamide in a fluidized bed on the diffusion properties of the material and physicomechanical properties of the articles obtained is considered.

An increasingly wide use in fabrication of articles for construction, electric insulation, and special purposes is found by the following polyamide-based thermoplastic cast composites possessing a set of valuable mechanical, thermal, and dielectric properties [1, 2]: PA 6-210KS [OST (All-Union Standard) 6-11-498–79], PA 6-210-DS (OST 6-11-498–79), PA 6-211-KS (OST 6-11-498–79), PA 6-211-DS (OST 6-11-498–79), PA SV-30-2T (2243-015-11378612–97), PA SV-30-3M (2243-015-11378612–97).

The wide-scale introduction of the progressive polyamide-based composites requires a further improvement of the technology of their processing, in which one of the most important stages is drying. This stage affects formation of bubbles, "silver" cracks, delaminations, and inclusions (in products of thermooxidative destruction of polymers) in construction articles made of polyamide.

In the course of drying of thermoplastics, a humid body tends to attain equilibrium with the environment, and, therefore, its moisture content Δ and temperature T depend on time and the coordinates of a point of the body (x, y, z):

$$\Delta(x, y, z, \tau), \quad (1)$$

$$T = T(x, y, z, \tau). \quad (2)$$

The time dependence of temperature can be disregarded if the temperature of a material reaches equilibrium considerably faster than its moisture content does.

The above dependences describe the dynamics of drying and heating of a material. According to [3–5], the variation with time of the average (over the body volume) moisture content Δ and temperature characterizes the kinetics of drying and heating of thermoplastics:

$$\Delta = \Delta(\tau), \quad (3)$$

$$T = T(\tau), \quad (4)$$

$$\Delta = \iiint_V \Delta(x, y, z, \tau)\,dx\,dy\,dz, \quad (5)$$

$$T = \iiint_V T(x, y, z, \tau)\,dx\,dy\,dz. \quad (6)$$

The strongest influence on the drying process is exerted by factors defining the thermoplastic being dried as an object of drying. To these factors belong the microstructure of the materials, their thermal properties and geometric dimensions (grains, beads, crumb), and the content and nature of a filler.

The process of drying of thermoplastics is also affected by parameters of the heat-carrying agent: temperature, pressure, relative humidity, flow velocity of air and motion velocity of the material, and also the possible use of radiant energy.

The presently used method of drying of thermoplastics in shelf-type drying ovens (SNOL, VG-0.35A, VSh-0.05, ShSSU, VN-5805, ShSV-16-KU, and TShch-903), both evacuated and not, involves a considerable expenditure of time (up to 36 h) and is not always effective.

Drying of thermoplastics in a fluidized bed with the use of a USPE installation [6, 7] fails to always provide the residual humidity required by regulations (State Standard, All-Union Standard, Technical Spe-

Diffusion flux, mol $m^{-2}\ s^{-1}$	–	–	-0.998×10^{-6}

cifications). This is due to the fact that, in convective-radiant heat exchange, moisture is only removed from the surface layer of the fractions of the material (grains or beads) that are processed.

In order to improve and intensify the technological process, a procedure for drying a material in a fluidized bed, with a simultaneous infrared irradiation, on a TIS installation has been developed [8–10]. The use of temperatures elevated to 100°C and of infrared light ensured a rapid, and uniform throughout the volume, removal of the residual moisture from the thermoplastics being processed, which are in the state of continuous circulation and fluidization.

For unfilled thermoplastics, the use of convective-infrared drying in a fluidized bed made it possible to intensify the technological process by a factor of 9–11 (compared with convective drying in a fixed bed) or 1.35–1.5 (compared with convective drying in a moving bed). Moreover, use of IR irradiation precludes overheating of thermoplastic grains and thereby diminishes the destruction of the material [11].

EXPERIMENTAL

Experiments on drying of a glass-filled polyamide of PA 6-210-KS brand (OST 6-11-498–79) were performed in a TShch-903 shelf-type drying oven and a TIS-50 installation at a varied temperature and time of drying (at fixed air pressure of 0.3–0.4 MPa). Thus, the group of variable parameters P_c includes temperature T and treatment time τ:

$$P_c = f(T, \tau). \quad (7)$$

For the glass-filled polyamide mentioned above, the effect of various drying technologies on the rate of moisture removal, diffusion coefficients (molecular and turbulent), diffusion flux, and main physicomechanical parameters was studied.

The molecular diffusion coefficient D was determined experimentally, using the relation

$$D = \frac{r^2 \tan \alpha}{\pi^2}, \quad (8)$$

where r is the radius of grains of the material; tan α, slope ratio of the dependence $\ln(1 - M_t/M_\infty) = f(t)$; M_t, amount of moisture in polyamide at instant of time t; and M_∞, that in equilibrium [12].

The turbulent diffusion coefficient E_m can be found from

$$E_m = E_t - D, \quad (9)$$

where E_t is the total diffusion coefficient [12].

The diffusion flux J is given by

$$J = -E_t \frac{dc_A}{dy}, \quad (10)$$

where dc_A is a change in water concentration in a time t (mol dm^{-3}), and dy is the pathway of the flow in a grain (m).

The calculated values of the parameters are listed in Tables 1–3.

It can be seen from Tables 1–3 that the convective-infrared drying of the PA 6-210-KS polyamide in a fluidized bed intensifies the drying process by a factor of 2.14–2.5, compared with convective drying in a fixed bed.

The following physicomechanical parameters were studied for a material dried at 100°C: tensile strength, relative elongation at break, bending stress at fracture,

Table 4. Physicomechanical parameters of articles fabricated from PA 6-210-KS polyamide with the use of various drying technologies

Parameter	Required by regulations	Convective drying	Convective-infrared drying	Convective-infrared drying in a fluidized bed
Tensile strength, MPa	118–122	119–123	122–124	136–138
Relative elongation at break, %	3–4	3.4–3.5	3.3–3.4	4.2–4.4
Bending stress at fracture, MPa	167–170	166–170	142–146	172–178
Impact viscosity, kJ m^{-2}	24.5–27.0	25–26	25–27	34–35

and impact viscosity without notch. The results obtained are listed in Table 4.

CONCLUSIONS

(1) Use of convective-infrared drying of a glass-filled polyamide leads to an increase in its bending stress at fracture, tensile strength, relative elongation at break, and impact viscosity.

(2) Making the time of drying shorter diminishes the thermo-oxidative destruction of a material. The residual internal stresses are lowered, which improves the longevity of articles. Formation of bubbles, "silver" cracks, delaminations, and inclusions is totally precluded.

(3) Thus, the developed drying technology with convective-radiant heat exchange on a TIS-50 installation eliminates the basic defects, improves the performance and mechanical parameters of the articles fabricated, and intensifies the technological process.

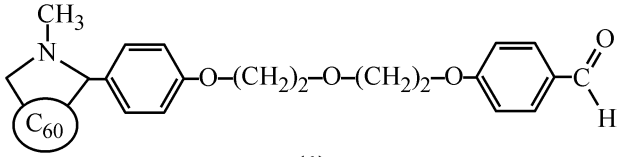
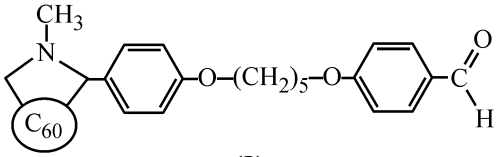
Abstract—Water-soluble methanofullerene and fulleropyrrolidine derivatives were synthesized by the reactions of methanofullerenes (MFs) and fulleropyrrolidines (FPs) with poly(*N*-vinylpyrrolidone) (PVP) bearing one terminal amino group. The products contain MF or FP covalently bound to the polymer, corresponding polymeric complexes, and unreacted PVP. Large aggregates of the polymeric MF and FP derivatives are found in aqueous solutions. The electrooptical properties of the products differ considerably from those of the initial polymer. The phosphorus-containing MF and FP derivatives are capable of cleaving the molecule of plasmid DNA.

Water-soluble fullerene derivatives are of great interest for biomedical use [1].



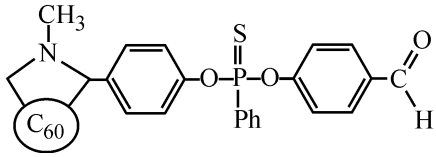
Previously, we have synthesized water-soluble star-like polymeric fullerene (C_{60}) derivatives of PVP bearing one terminal amino group (PVP–NH_2) and examined their molecular-weight and electrooptical characteristics [2–5].

In this study, starting from PVP–NH_2, we synthesized a series of metallofullerene (MF) and fulleropyrrolidine (FP) derivatives and examined their physicochemical properties. The products were also characterized by their ability to interact with biopolymers, such as DNA.



EXPERIMENTAL

MFs and FPs are stable monoadducts of fullerene C_{60}. They are readily soluble in many organic solvents, and their physical and chemical properties are reported in [6–9]. The structures of MFs and FPs used for modification of PVP–NH_2 are shown in Fig. 1.



The starting PVP–NH_2 was prepared by radical polymerization of *N*-vinylpyrrolidone in the presence of an amino derivative of mercaptan, cysteamine hydrochloride [10]. The reactions of PVP–NH_2 with MFs or FPs were carried out at $[NH_2]:[MF(or\ FP)] = 6:1$ molar ratio in a DMF/toluene mixed solvent for

24 h. The reaction mixture was then filtered and concentrated in a vacuum. The dry residue was dissolved in water and filtered. The products were isolated by freeze drying.

The products were characterized by gradient step TLC on Sorbfil plates, PTSKh-AF-B-UF (Sorbpolimer, Krasnodar, Russia), with toluene, chloroform, and CCl_4 as eluents. To develop the chromatograms we used UV light (254 nm) or iodine vapor.

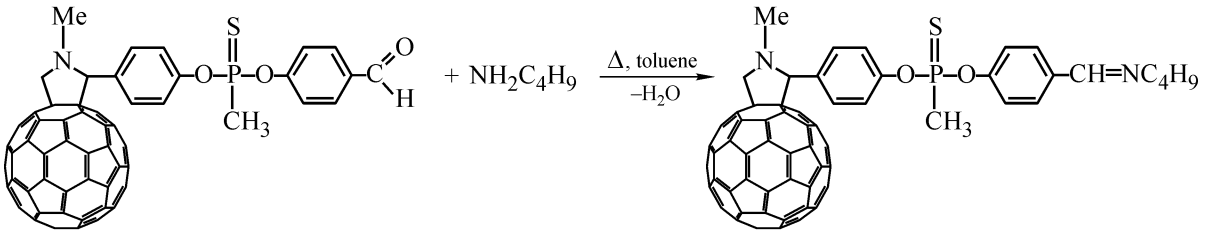
The sedimentation velocity of the polymer solutions was studied in 0.2 M NaCl on a Beckman XL-I analytical ultracentrifuge at a rotor speed of 42 000 rpm and, in the case of fast sedimentation, at 10 000 rpm. The interference and absorption (λ = 250 nm) scans were performed to monitor the sedimentation boundary mostly at the concentration $c = 0.17 \times 10^{-2}$ g cm^{-3}. For some of the samples we studied the concentration dependence over the range $(0.02–0.2) \times 10^{-2}$ g cm^{-3}. In these experiments we observed no significant concentration effects.

To study the electrooptical properties of the fullerene derivatives of PVP, we measured the electrooptical Kerr effect in a rectangular-pulse electrical field. The experiments were carried out in chloroform at 21°C. The experimental setup and conditions were reported elsewhere [5]. The Kerr constant K was estimated by the relation

$$K = \lim_{E \to 0} {}_{c \to 0} (\Delta n - \Delta n_0)/E^2 c,$$

where $(\Delta n - \Delta n_0)$ is the difference between the optical birefringence under the electric field in the test solution with a concentration c and in the solvent, and E, the electric field strength.

The interaction of the polymeric MF and FP derivatives with DNA was studied as follows. Aqueous polymer solutions (c = 0.4–10 mg ml^{-1}, V = 10 μl) were mixed with a solution of plasmid DNA pUC 19 (0.1 mg ml^{-1}, 2 μl). The interaction was evaluated by using electrophoresis in 0.8% agarose gel at a current of 90 mA.



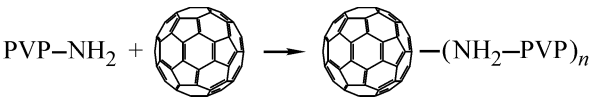
The products of the reactions of compounds **1**–**8** with PVP–NH_2 (PVP-1–PVP-8) are soluble in water. However, in contrast to the initial polymer PVP–NH_2, they are brown. The UV spectra of PVP-1–PVP-8, like those of the initial MFs and FPs, have the form of steadily descending curves with weak features near 260 nm, which is typical of covalently bound C_{60} [11, 12].

The formation of polymeric derivatives with the MF and FP covalently bound to the polymer matrix was confirmed by TLC. In chromatography on Sorbfil silica gel plates, the eluent (toluene, chloroform, CCl_4), C_{60}, MFs, and FPs move along with the solvent front, while PVP–NH_2 is irreversibly adsorbed, remaining at the start zone. Under these conditions, the complex of C_{60} with PVP decomposes [2, 3], and two zones are observed in the chromatograms, namely, those of C_{60} and PVP. In the cases of previously described covalent C_{60} derivatives of PVP–NH_2 (PVP–C_{60}) [2, 3], C_{60} is not eluted, and the only colored zone at the start is observed. This zone shows absorption in the UV(254) range and also dark brown fluorescence in the UV(366) range, which is atypical of the initial PVP–NH_2 samples and can be attributed only to the presence of covalently bound C_{60} [2, 3].

Similarly to PVP–C_{60}, in the cases of PVP-1–PVP-8 products, the zones of the corresponding PVP–MF or PVP–FP derivatives is found at the start. How-

ever, for PVP-1–PVP-8, in contrast to PVP–C_{60}, the zones of the initial MFs or FPs are also observed in the chromatograms. As mentioned above, all the products obtained are water-soluble, unlike the initial MFs and FPs. Evidently, the products also contain, along with the covalent derivatives PVP–MF (or FP), water-soluble complexes of MFs or FPs with PVP.

To confirm the structure of the polymeric MF and FP derivatives, we studied the reaction of the aldehyde-containing compound with a model low-molecular-weight amine, *n*-butylamine. It was found that this reaction yields the corresponding Schiff bases. For example, a mixture of **4** and *n*-bytylamine (1 : 1 molar ratio) was refluxed in toluene for 7 h with a Dean–Stark trap. The precipitated compound **4'** was dried and characterized by the mass and IR spectra. The filtrate contained minor amounts of unreacted compound **4**, as demonstrated by HPLC. The yield of **4'** was 77.8% (recalculated to the reacted fulleropyrrolidine **4**).



(4) **(4')**

The mass spectra of **4'** show a peak of the molecular ion with *m*/*z* 1121.95 (calculated *m*/*z* 1122.81). No absorption band of the aldehyde group of the initial compound **4** at 1700 cm^{-1} was found in the IR spectrum, but the characteristic band of the C=N bond appears at 1648 cm^{-1}.

Therefore, in the case of fulleropyrrolidine **4**, the addition of PVP–NH_2 occurs essentially at the aldehyde group.

At the same time, it is known that both low-molecular-weight amines and polymers containing primary amino groups are capable of readily reacting with the fullerene core [11, 12]. In this case, if macromolecules of the polymer contain a single terminal amino group, star-like derivatives with the fullerene molecule as a branching site are formed [2, 3].

Evidently, this is the case for the reactions of MFs and FPs containing no aldehyde group with PVP–NH_2. As noted above, in the case of aldehyde-containing compounds, the addition of PVP–NH_2 occurs essentially at the aldehyde group.

For compounds **3**–**8**, the addition of PVP–NH_2 could occur via the phosphorus atom to give salt-like structures [16].

The sedimentation data were processed using Sedfit software [17] by direct fitting with numerical solutions of the Lamm equation for the sedimentation velocity in a dilute solution of ideally sedimenting macromolecules.

The sedimentation velocity data obtained using the interference optics show that the initial PVP–NH_2 shows a peak at 1.0 Sv, which corresponds to MW 10 000 [18]. The sedimentation coefficient distributions of the fullerene derivatives show the peak practically coinciding with the sedimentation coefficient of the initial PVP–NH_2, i.e., these samples contain a considerable fraction of the unreacted initial polymer. The sedimentation analysis allows estimation of the composition of PVP-1–PVO-8. The fraction of the fullerene-containing macromolecules in PVP-1, PVP-2, PVP-5–PVP-8 is 19 ± 2 wt %, whereas that in PVP-3 and PVP-4 is less than 10 wt % (see table).

The interference scan system of a Beckman XL-I analytical ultracentrifuge provides the sedimentation coefficient distribution for the sample as a whole, while the absorption scan system records the fullerene-containing fraction of the sample, as the only

fraction having UV absorption. Comparison of the sedimentograms obtained with both recording systems (Fig. 2) shows that the absorption optics reveals higher sedimentation coefficients, providing a clear evidence in favor of the fact that larger fullerene derivatives are formed as compared to the initial polymers. The results show that the fullerene fraction of the samples is nonuniform. It contains fullerene-containing macromolecules whose sedimentation coefficients are higher on the average, by an order of magnitude, than those of the initial PVP–NH_2, and also still larger water-soluble molecular aggregates. The occurrence of such aggregates has been reported previously for other fullerene-containing polymers [3, 15].

Let us estimate from the experimental sedimentation data the extent to which the volume occupied by the fullerene-containing macromolecules/clusters in the solution is larger than that occupied by the initial PVP macromolecule, using the equivalent hydrodynamic sphere model and taking into account that the measured partial specific volumes of the initial PVP–NH_2 and fullerene derivatives are similar. It may be demonstrated that, in our case, $V_f/V_b = (s_f/s_b)^{3/2}$, where V_b and s_b, and V_f and s_f are the volumes and

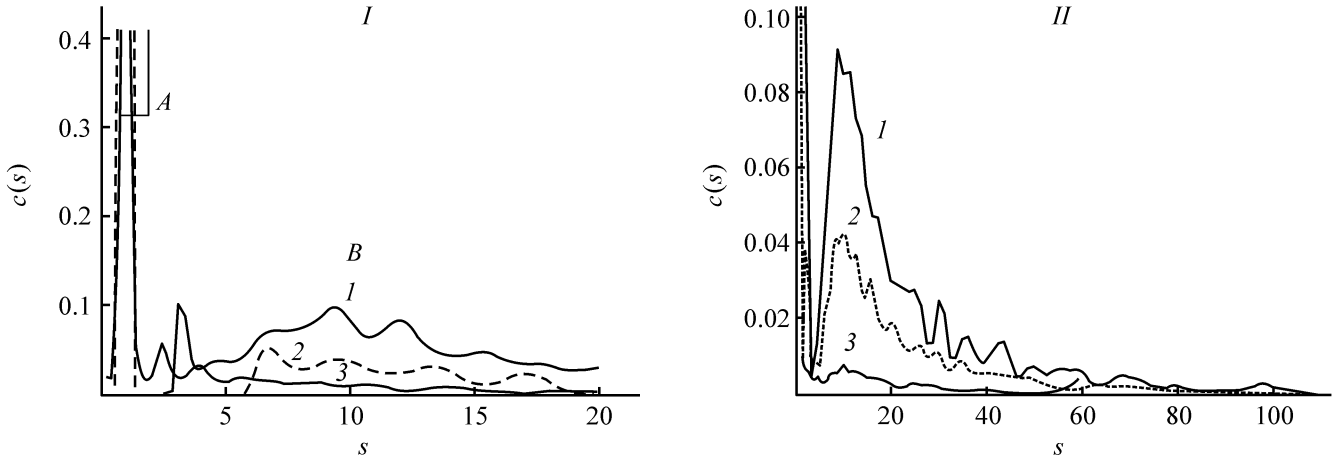

Fig. 2. Sedimentation coefficient distribution for PVP-7 at various solution concentrations ($c \times 10^{-2}$ g cm^{-3}): (*1*) 0.199, (*2*) 0.099, and (*3*) 0.019. (*I*) Distributions obtained using the interference optics: (*A*) slow sedimentation range corresponding to the sedimentation coefficient of the initial linear PVP (see table) and (*B*) fast sedimentation range corresponding to the fullerene-containing fraction of the sample. (*II*) Distributions obtained using the absorption optics, corresponding to the fullerene-containing fraction of the sample.

sedimentation coefficients of the initial PVP macromolecule and fullerene-containing macromolecules/clusters, respectively. The estimates listed in the table suggest that the volume occupied by the fullerene-containing macromolecules/clusters is, as a rule, larger by an order of magnitude than that occupied by the PVP macromolecule corresponding to a branch of the star-like dendrimer.

One of the fulleropyrrolidines (compound **2**) has been studied previously [20]. It was demonstrated that, in contrast to the nonpolar and optically isotropic (by virtue of high symmetry) fullerene C_{60}, the molecules of **2** form polar nanoparticles with high dipole moment (μ = 5.4 D) and optical anisotropy ($\Delta a \sim 20 \times 10^{-24}$ cm^3). Their Kerr coefficient in chloroform was found to be $\pm 5.3 \times 10^{-10}$ cm^5 g^{-1} (300 V)$^{-2}$. Covalent or coordination incorporation into PVP macromolecules of polar carbon nanoparticles having different polarization, dielectric, and optical characteristics, compared to the polymer, alters significantly the properties of the polymer, as we have been previously demonstrated for the example of star-like PVP-based dendrimers with C_{60} as a branching site [4, 5].

Figure 3 shows the results of a comparative study of the electrooptical Kerr effect in chloroform for samples of starting compounds **2** and PVP–NH_2 and also for the synthetic derivative PVP-2. The solutions of PVP-2 and PVP-1 in chloroform, in contrast to PVP-3–PVP-7, were molecular-disperse, which was reflected in that the optical birefringence Δn was a linear function of the squared electric field strength, E^2. For products PVP-3–PVP-7, such a dependence was distinctly nonlinear. Furthermore, they demonstrated considerable difference in Δn (by two orders of magnitude and more) as compared to the initial PVP, which is typical of the cases when charged aggregates or strongly polarizable molecular species are present in a solution. As clearly seen from Fig. 3, PVP-2 exhibits strongly different behavior as compared to the initial polymer. Its Kerr coefficient K differs significantly by the sign and absolute value from the initial PVP, exceeding that of the fullerene adduct, even though the weight fraction of the latter in the polymer is small. Generally, the above-mentioned alterations of the molecular properties of PVP-2 are consistent with the previous results obtained for the pairs constituted by a star-like PVP–C_{60} and linear PVP having similar molecular weight [4, 5].

As is known [1, 21, 22], some fullerene derivatives exert a destructive influence on DNA molecules. Therefore, we studied the interaction of the MF and FP polymeric derivatives (PVP-1–PVP-7) and also of

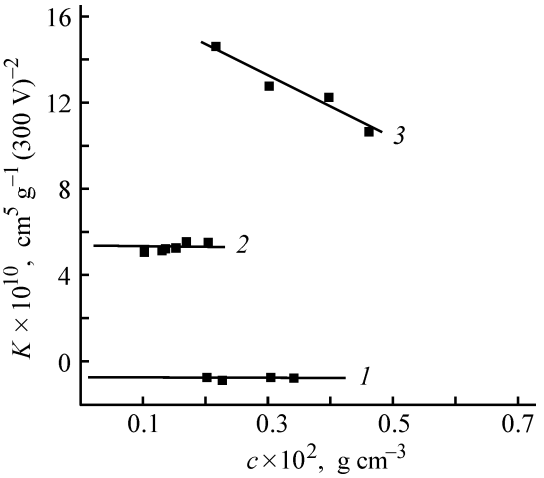

Fig. 3. Concentration dependences of the electrooptical Kerr coefficient K for (*1*) initial PVP–NH_2, (*2*) compound **2**, and (*3*) PVP-2.

the previously described PVP–C_{60} [2–5] with plasmid DNA pUC 19. The destructive effect was evaluated by the change in the DNA component ratio, using electrophoresis in agarose gel. In the reference electrophoregram of the initial DNA we found two bands corresponding to circular and supercoiled DNA conformations [21]. For PVP–C_{60}, PVP-1, and PVP-2, we obtained similar electrophoregrams. In the cases of PVP-3–PVP-7, the fraction of the circular conformation increased with the polymer : DNA ratio at the expense of the supercoiled conformation, the effect being particularly clearly pronounced for PVP-3 and PVP-7. For these samples, the band of the supercoiled DNA vanished at the polymer concentration of 2 mg ml^{-1} and higher. Furthermore, in the case of PVP-7, this effect was accompanied by the appearance of the band of linear DNA. These results suggest that DNA molecules are cleaved under the action of PVP-3–PVP-7 by the single-strand cleavage mechanism, which results in DNA conversion from the supercoiled to circular form [21]. In the case of PVP-7, the appearance of the band of linear DNA can be attributed to two-strand cleavage.

The toxicity of the MF and FP polymeric derivatives synthesized in this study was examined using the microtetrazolium test (MTT) [23]. The results showed that, when taken in concentrations of up to 100 mg ml^{-1}, these fullerene derivatives are not cytotoxic with respect to T 98G cells.

CONCLUSIONS

(1) Water-soluble polymeric derivatives of a series of methanofullerenes (MFs) and fulleropyrrolidines

(FPs) were synthesized starting from poly(*N*-vinylpyrrolidone) with a terminal amino group.

(2) It was established that the resulting products are multicomponent. They contain the initial polymer, MF or FP covalently bound to the polymer, complexes polymer–MF (or FP), and also large aggregates.

(3) It was shown that the electrooptical properties of the products differ significantly from those of the initial PVP–NH_2 by virtue of the presence of chemically bound polar and optically anisotropic FPs or MFs.

(4) It was demonstrated that incorporation of phosphorus-containing MF and FP derivatives in PVP enhances the capability of the PVP–MF(or FP) derivatives to cleave plasmid DNA pUC 19.

Abstract—A simple technology is described for preparing latexes with core–shell particles, in which the composition of the shell copolymer regularly varies from the inner layers of the shell to the particle periphery. Equations are suggested for calculating the instantaneous and integrated compositions of the shell copolymer and for analyzing how the composition of the copolymer varies along the particle radius. Specific examples of synthesis of emulsion copolymers intended for preparing plastisols and latexes with hollow particles demonstrate the benefits from application of the technology suggested.

The principles of formation of polymeric latex particles with complex morphology are widely used now in development of processes for preparation and application of synthetic latexes and emulsion copolymers [1, 2]. We restrict the consideration to particles with the core–shell morphology, implying that the interior and exterior of the polymer sphere are built of different, typically thermodynamically incompatible, (co)polymers. This approach has a number of advantages over the technologies utilizing latexes with homogeneous particles. One of them consists in that the same monomer raw material can be used for preparation of various polymeric materials, sometimes with opposite properties. As an example can serve ABS emulsion plastics (with butadiene (co)-polymer as the core and random acrylonitrile–styrene copolymer as the shell) and reinforced elastomers (a polybutadiene shell and a core formed from a rigid polymer, e.g., polystyrene). The shell on the core particles imparts novel properties to the material. This principle is applied, e.g., in preparing polymer powders whose particles do not stick together during spray drying and in storage [3]. Also, many applied problems can be solved by introducing functional groups into the shell polymer, and, in this case, functionalization requires a substantially smaller amount of typically expensive components. As an example can serve antistatic coatings prepared from latexes whose particles contain amine monomer units in their shells [4, 5].

The technology of preparing latexes with core–shell particles seems fairly simple. First, a latex is synthesized by emulsion polymerization of monomer **1**. Next, monomer **2** is introduced into the latex acting as seed and is polymerized. However, implementation of this technology is troublesome because of the specific thermodynamic and kinetic features of preparation of the core–shell latex particles. If the process is run under close-to-equilibrium conditions, the structure of the resulting particles is characterized by the lowest surface free energy. Since water typically serves as the dispersion medium, formation of particles with the shell composed of a more hydrophilic polymer seems the most probable. In some cases, this structure is formed even with hydrophilic particles as seeds, since hydrophobic monomer diffuses into the bulk of the seed particles [6]. The situation is improved to a certain extent when the process is carried out under nonequilibrium conditions, i.e., when monomer **2** is introduced into the seed latex at a rate not exceeding that of its polymerization ("monomer starvation") [7]. However, complications may arise in this case as well if the core and shell polymers differ too strongly in their thermodynamic properties; the resulting particles may have a hemispherical structure, with the shell polymer incompletely covering the core polymer [8]. This problem can be solved by creating an intermediate shell exhibiting affinity for both the core polymer and the shell polymer [9, 10].

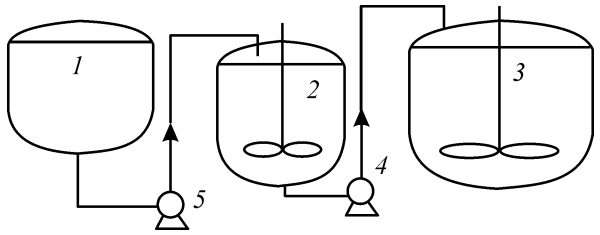

Fig. 1. Flowsheet of dosing of the monomer mixture with variable composition into the reactor. (*1*) Tank for monomers, (*2*) intermediate tank, (*3*) reactor, and (*4*, *5*) pumps.

It should be noted that this technique complicates the entire technology. At the same time, a polymer equally compatible with thermodynamically dissimilar polymers is hardly conceivable.

In this paper, we describe a simple technology for making compatible the core and shell polymers by gradually varying the chemical composition of the shell when going from the core–shell interface to the particle periphery. The properties of the inner layers of the shell are chosen in such a way that the core and the shell polymers exhibit the greatest affinity for each other.

EXPERIMENTAL

The technology described was implemented by dosing into the seed latex a monomer mixture with variable composition. At the initial moment, the monomer mixture being dosed forms a polymer having a high thermodynamic affinity for the core polymer. In an ideal case, the shell and core polymers can have identical compositions in this stage of the process. Gradual variation of the composition of the monomer mixture being dosed radically modifies the properties of the peripheral layers of the shell, thereby ensuring the desired properties of the latex.

Two requirements should be satisfied in implementation of the process. First, the monomer mixture being dosed into the seed latex should not be accumulated, i.e., the process should be run under monomer starvation conditions. Under these conditions, the instantaneous composition of the monomer mixture is identical to that of the copolymer being formed. Second, the monomers being dosed into the reaction mixture should be polymerized only on the seed particles, with formation of new particles precluded. This requirement is easily satisfied when there is no free surfactant in the dispersion medium. In other words, the seed latex should have adsorption-unsaturated particles.

As is known, the adsorption saturation is calculated on the basis of the characteristics of the latex (particle diameter and content of the polymer in the latex) and the parameters of the surfactant used (area occupied by one surfactant molecule in the saturated adsorption layer and the critical micelle concentration). The adsorption saturation can be experimentally monitored by measuring the surface tension of the latex being formed. It should be noted that the probability of particle formation by the homogeneous mechanism is sharply reduced when the dispersion medium contains seed particles [11]. As the volume of the particles increases, their adsorption saturation is reduced, and if the latex stability is endangered, it is necessary to add additional amounts of the surfactant during the process, taking into account that the increase in the total surface area of the particles is proportional to their growing volume raised to power 2/3.

Figure 1 presents the flowsheet of the process, which provides dosing of the monomer mixture with variable composition into the reactor containing the seed latex and, if the above-stated requirements are satisfied, ensures formation of particles whose chemical composition regularly varies along the shell thickness. We consider the simplest version of this process, when monomer **1** (M_1) contained in tank *1* is transferred by pump *5* into intermediate tank *2* containing monomer **2** (M_2) at a flow rate w_1, and the resulting monomer mixture $M_1 + M_2$ is dosed into reactor *3* by pump *4* at a flow rate w_2. The change in the amount of M_1, mass units, in tank *2* can be expressed by the differential equation

$$dq_1 = w_1\rho_1 dt - w_2\frac{q_1}{V}dt. \quad (1)$$

Here, ρ_1 is the density of M_1, and V, volume of $M_1 + M_2$ in tank *2* at the instant of time t.

Since the volume of the monomer mixture in tank *2* and its change are determined by the difference in the dosing rates w_1 and w_2,

$$V = V_0 + w_1 t - w_2 t, \quad (2)$$

holds. Here, V_0 is the volume of M_2 in tank *2* at $t = 0$, and

$$dV = (w_1 - w_2)dt. \quad (3)$$

The amount of M_1, occurring at any moment in tank *2*, is described by the equation

$$q_1 = [M_1]V. \quad (4)$$

Here, $[M_1]$ is the running concentration of M_1 in tank *2*, expressed as the mass of the monomer per unit volume. Then

$$dq_1 = d[M_1]V + Vd[M_1]. \quad (5)$$

By combining (1)–(5), we obtain the equation

$$\frac{1}{w_1}\int_0^{[M_1]}\frac{d[M_1]}{[M_1]-\rho_1} = \frac{1}{w_2-w_1}\int_0^t\frac{dt}{t-\frac{V_0}{w_2-w_1}}, \quad (6)$$

whose solution yields the running concentration $[M_1]$

$$[M_1] = \rho_1 - \rho_1\left(1 - \frac{w_2-w_1}{V_0}t\right)^{\frac{w_1}{w_2-w_1}}. \quad (7)$$

A simplified version of this flowsheet can be implemented at $w_1 = w_2$. We practically implemented it by eliminating pump *4* from the flow sheet and filling tank *2* to full capacity ($V = V_0$). Solution of Eq. (1) under these conditions yields

$$[M_1] = \rho_1[1 - \exp(w_1/V_0)]. \quad (8)$$

Thus, the instantaneous composition of the monomer mixture in tank *2* and, hence, the instantaneous composition of the copolymer formed in reactor *3* can be controlled by varying the dosing rates, the initial volume of M_2 or, in the simplified version, the volume of the intermediate tank.

Taking into account the need for running the process under the monomer starvation conditions, there can be only limited possibilities for varying the dosing rates. As to the intermediate tank, it is not always expedient to replace it on a pilot or commercial plant in order to change V_0. It is more convenient to vary the composition of the monomer mixtures in tanks *1* and *2* by introducing into them both monomers and varying their concentration ratio to achieve a desired distribution of the components in the shell of a particle. Basically, the reaction system can contain any amount of the monomers. Then Eqs. (7) and (8) for monomer M_i can be represented as:

$$[M_i] = c_i + \left([M_i]_0 - c_i\right)\left(1 - \frac{w_2-w_1}{V_0}t\right)^{\frac{w_1}{w_2-w_1}}, \quad (9)$$

$$[M_i] = c_i + \left([M_i]_0 - c_i\right)\exp[-(w/V_0)t] + c_i. \quad (10)$$

In Eqs. (9) and (10), the density of the monomer is replaced with its concentration in tank *1*, c_i, and integration is carried out for the concentration going from the initial concentration of M_1 in tank *2*, $[M_i]_0$, rather than from 0. The instantaneous content of the units of M_1 in the copolymer containing n types of monomer units is described by the expression

$$m_i = \frac{[M_i]}{\sum_{i=1}^{n}[M_i]}. \quad (11)$$

To calculate the integrated composition of the shell copolymer at any instant of time t, it is necessary to determine the amounts of each of the monomers Q_i, charged into the reactor by this instant of time, by solving the equation

$$\int_0^{Q_1} dQ_i = \int_0^t w_2[M_i]\,dt. \quad (12)$$

In this equation, we substitute $[M_i]$ from Eqs. (9) or (10), depending on the chosen version of the process. At $w_1 \neq w_2$,

$$Q_i = c_i w_2 t + \left([M_i]_0 - c_i\right)V_0\left[1 - \left(1 - \frac{w_2-w_1}{V_0}t\right)^{\frac{w_1}{w_2-w_1}}\right]. \quad (13)$$

At $w_1 = w_2 = w$,

$$Q_i = (c_iV_0 - [M_i]_0V_0)\exp[-(w/V_0)t] + c_iwt + [M_i]_0V_0 - c_iV_0. \quad (14)$$

As a result, the content of the M_i units in the shell copolymer, accumulated by the instant of time t, is described by the expression

$$q_i = \frac{Q_i}{\sum_{i=1}^{n}Q_i}. \quad (15)$$

The equations presented above show that, in the shell of the particle, both ascending and descending gradient of the content of the monomer units of the given type along the particle radius can be basically obtained. The nature of this gradient can be changed by varying the monomer concentrations in tanks *1* and *2* and the dosing rates w_1 and w_2. Figure 2 presents the calculated plots describing the variation of the content of monomer 1 along the particle radius for a hypothetical case of copolymerization of two monomers M_1 and M_2. The initial composition of the monomers in tank *2* precisely corresponded to the composition of the core copolymer. When constructing the plots, we calculated the shell radius r_s in various stages of the process by the equation

$$r_s = \left(r_c^3 + \frac{3kw_2t}{4\pi N}\right)^{1/3}. \quad (16)$$

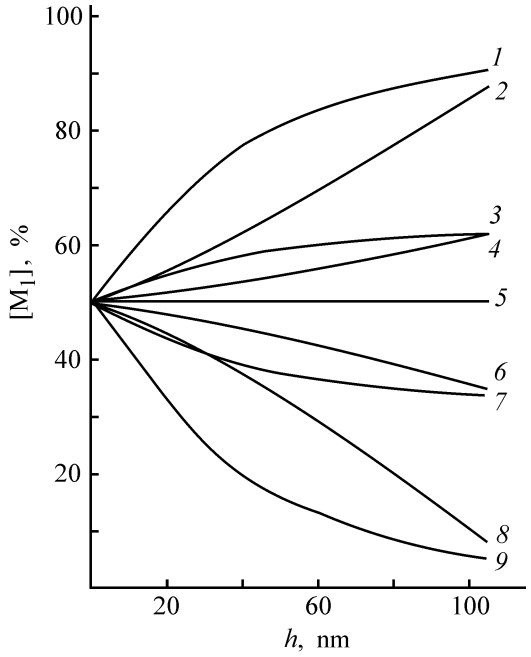

Fig. 2. Calculated plots describing the variation of the composition of the shell copolymer along its thickness *h*, expressed via the content of the M_1 monomer units for a hypothetical copolymerization of two monomers M_1 and M_2. Copolymerization conditions: core, $M_1 + M_2$ (50 : 50 wt %) copolymer; $N = 2.386 \times 10^{16}$, $r_c = 100$ nm; parameters of the monomers: $\rho_1 = 0.9$, $\rho_2 = 1.0$ g cm^{-3}, $k = 0.85$; tank *2*: $V_0 = 500$ cm^3, $[M_1]_0 = [M_2]_0 = 0.474$ g cm^{-3} (mass ratio $M_1 : M_2 = 50 : 50$), $w_2 = 3$ cm^3 min^{-1}; copolymerization time 300 min. c_1, g cm^{-3}: (*1, 2*) 0.9; (*3, 4*) 0.6; (*5*) 0.474; (*6, 7*) 0.3; and (*8, 9*) 0. w_1, cm^3 min^{-1}: (*1, 3, 7, 9*) 9 and (*2, 4–6, 8*) 2.

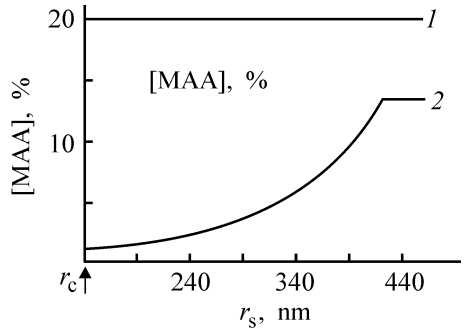

Fig. 3. Calculated plots describing the variation of the content of the MAA units in the shell copolymer along the particle radius r_s in synthesis of the emulsion copolymer for plastisols. Copolymerization at (*1*) constant and (*2*) variable composition of the monomer mixture dosed; the same for Fig. 4. For copolymerization conditions, see Table 1.

Here, r_c is the core particle radius; *k*, coefficient describing the decrease in the volume of the reaction system, associated with conversion of the monomers into the copolymer; and *N*, total number of the particles in the reaction system.

Our data suggest that the surface zone of the particles of the final latex can contain approximately the same number of the M_1 units, and the integrated composition of the copolymer can be varied within fairly wide limits by varying w_1 only.

Let us consider two specific cases of preparation of latexes with core–shell particles by the procedure we suggest. The first example concerns preparation of emulsion polymers for plastisols, i.e., dispersions of polymer particles in a plasticizer. One of the major problems in preparation and application of plastisols stems from their low stability in storage. Fast premature gelation is due to thermodynamic instability of plastisols even under ordinary conditions. It is known [12] that dissolution of the polymer particles in a plasticizer can be decelerated by coating the polymeric particles with a shell composed of a polymer having a lower thermodynamic affinity for the plasticizer that the core polymer. We synthesized latexes with particles of such type. The core of the particles was formed from a styrene–methyl methacrylate (ST–MMA) copolymer, and the shell copolymer included, along with the monomer units mentioned, methacrylic acid (MAA) units. We used two versions: In the first version, the shell copolymer had a homogeneous composition, and in the second, there was an ascending gradient of the concentration of the MAA units from the core copolymer–shell copolymer interface to the periphery of the particle.

Table 1 lists the formulations and preparation conditions of the latexes, as well as the characteristics of the plastisols thereof. Figure 3 shows how the concentration of the MAA units varies along the particle radius. It is seen that the technology we suggest makes it possible to reduce the total amount of the functional monomer, but, at the same time, provides a high content of the MAA units in the surface zone of the shell of the particle and, eventually, stable plastisols.

The second example concerns preparing latexes with hollow polymer particles. These particles, owing to a high light-scattering power, are applied as white pigment in preparation of coatings and paint and varnish materials [13]. The most promising technology of synthesis of latexes with hollow particles includes the following stages: (1) preparation of latexes with highly hydrophilic particles, e.g., consisting of weakly cross-linked MMA–MAA copolymers; (2) creation of core–shell particles by emulsion seed (co)polymerization of ST or others monomers; and (3) neutralization of the carboxy groups of the core at a temperature close to T_g of the shell (co)polymer, accompanied by ionization of the functional groups, sharp enhance-

ment of their hydration, swelling of the core copolymer, and expansion of the shell, which is responsible for formation of cavities in the particles.

The most difficult-to-implement is stage 2 involving creation of particles with the hydrophilic core/hydrophobic shell morphology, which is extremely unfavorable from the thermodynamic viewpoint. We succeeded in solving this problem by enhancing the hydrophilicity of the shell copolymer through introduction of acrylonitrile (AN) units into its composition [14]. The desired effect is achieved by introducing no less than 25 wt % AN units into the copolymer. However, creation of a descending gradient of the concentration of the AN units (we used a simplified version, $w_1 = w_2$) from the surface of the core to the periphery of the particle (Fig. 4) decreases the AN content in the shell copolymer to 7 wt% without deteriorating the properties of the resulting latexes, characterized by the contrast factor of the coatings prepared using hollow pigments (Table 2). A probable reason is that, at a high content of the AN units in the inner layers of

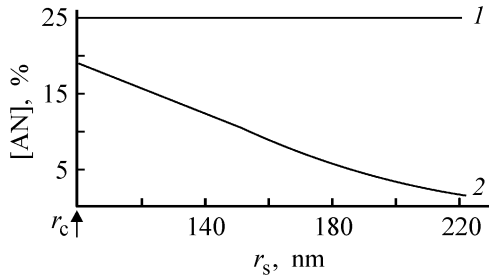

Fig. 4. Calculated plots describing the variation of the content of the AN units in the shell copolymer along the particle radius r_s in stage 2 of the synthesis of the latex with hollow particles. For copolymerization conditions, see Table 2.

the shell, adjacent to the core copolymer, conditions making compatible the core and shell copolymers are preserved or even improved.

For techniques of synthesis of the latexes and their characteristics, as well as for the properties of the plastisols and coatings, see [14–16].

CONCLUSIONS

(1) Specific examples demonstrated that it is expedient to synthesize latexes with core–shell particles in which the chemical composition of the shell varies along the particle radius. The content of the units of the functional monomer in the shell copolymer, which provides the desired properties of the latex, can be reduced severalfold without deteriorating the characteristics of the resulting products.

(2) The variable composition of the shell copolymer is provided by a very simple procedure. It can be recommended for preparation of synthetic latexes, especially with the use of highly reactive monomers whose emulsion polymerization by semicontinuous technologies, i.e., in the monomer dosing mode, is a common practice at the present time.

(3) To implement the processes that we suggest, it is sufficient to insert, between the dosing tank with the monomer mixture and the reactor in the conventional flowsheet, an intermediate tank containing a monomer mixture whose composition differs from that of the monomer mixture in the dosing tank. The equations that we derived allow the required composition of the monomer mixtures and monomer dosing modes to be easily calculated.

Abstract—Conducting composite systems containing polypyrrole layers were prepared by *in situ* polymerization of pyrrole on the surface of porous polyethylene films. The polymerization was performed in the gas phase, in a monomer solution, and in supercritical CO_2. The chemical structures, electrical conductivities, and mechanical, thermodeformational, and morphological characteristics of the composites obtained were compared.

Conducting polymers, such as polypyrrole (PPyr), polyaniline, polythiophene, and their derivatives, have been extensively studied recently because of the wide prospects for their application. Thanks to a combination of electrical, magnetic, optical, and electrochemical properties, these polymers are widely used as membranes, electrochemical sensors, electrode materials, etc. [1, 2]. Among conducting polymers, polypyrrole attracts particular attention owing to its relatively high chemical stability [3]. However, this polymer has a low mechanical strength and is very brittle, which substantially restricts its potential applications. One of the best ways to solve this problem is to prepare composite systems in which an elastic support would provide the required mechanical properties and the conducting polymer would be the active component.

We have shown previously [4–6] that porous polyethylene (PE) films can be efficiently used as supports for PPyr layers. These films exhibit high adhesion to various coatings, including layers of conducting polymers. We found that the high adhesion is due to the developed profile of the film surface and to the presence of a large amount of through flow channels, providing a tight fixation of the coating.

Numerous procedures for preparing PPyr are known [7]. As the structure and, hence, the properties of a conducting polymer largely depend on the procedure and conditions of its preparation [8, 9], it is of particular interest to compare the characteristics of conducting composite systems with the active component prepared by different procedures.

In this paper, we compare the electrical, mechanical, thermodeformational, and morphological properties of PE/PPyr composite systems prepared by both well-known and new procedures, one of which is the polymerization in supercritical CO_2. The last procedure is also attractive from the environmental viewpoint, as involving no toxic solvents and initiators.

The porous films were prepared from HDPE with $M_w = 1.4 \times 10^5$, $M_w/M_n = 6–8$, and $T_m = 132°C$. The porous structure was formed by uniaxial extension of films prepared by the melt extrusion followed by annealing [10, 11]. The film thickness was 12 μm, and the overall porosity, 48%. The porous films contained through flow channels of size 180–500 nm [11].

An important feature of these films is the strongly developed surface profile (Fig. 1) produced by uniaxial extension of annealed films at the stage of pore formation. The profile scale increases with the degree of orientation of the support, ranging in the interval examined from 0.2 to 0.8 μm.

To prepare PPyr by polymerization of the monomer in solution and in the gas phase, we used pyrrole (Fluka), $FeCl_3$ (Vekton) as oxidant, and methanol (Vekton). For the synthesis in supercritical CO_2, we used 99.998% pure CO_2 [BKZ Linde Gas AGA, Balashikha; GOST (State Standard) 8050–85] and pyrrole-2-carboxylic acid (Aldrich).

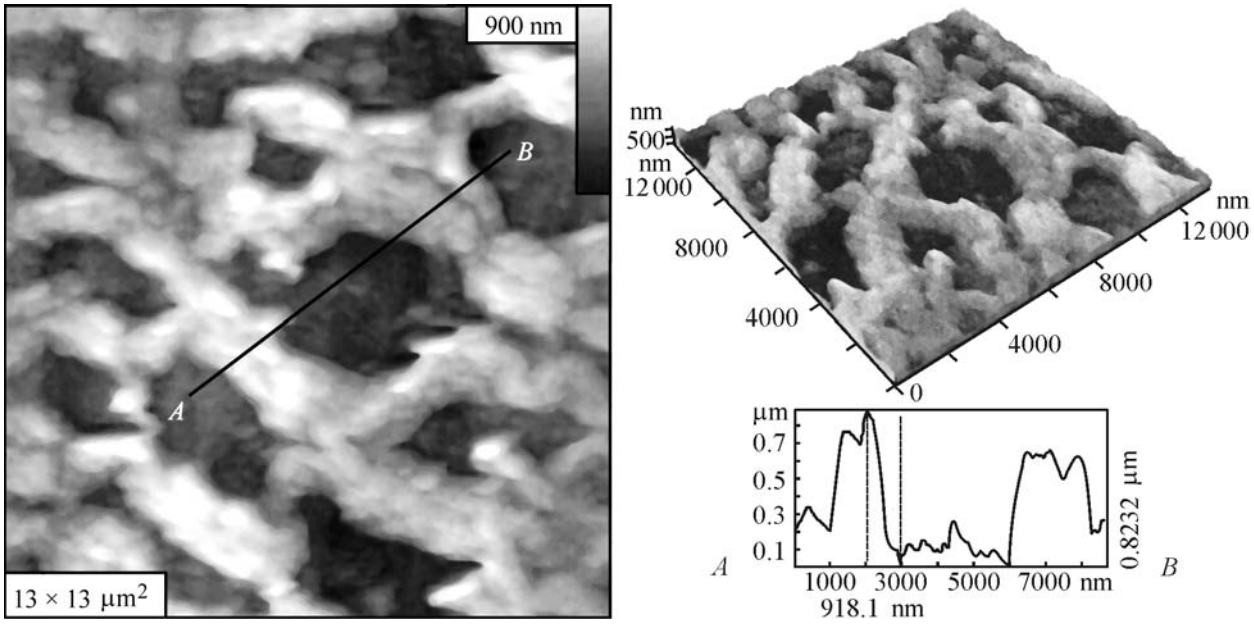

Fig. 1. AFM patterns of the surface of a porous PE film.

Composite PE/PPyr systems were prepared by, *in situ* polymerization directly on the porous PE film from the monomer gas phase [4], from a monomer solution [12], or in supercritical CO_2 [13]; the products obtained are denoted as PE/PPyr(g), PE/PPyr(s), and PE/PPyr(c), respectively.

To prepare PE/PPyr(g) systems, porous PE films impregnated with a 1 M solution of $FeCl_3$ in methanol were exposed to a pyrrole vapor. After a PPyr layer was formed (the reaction was performed for 1 day), the resulting composite material was washed with methanol and dried in air at room temperature.

Systems PE/PPyr(s) were prepared as follows. A porous support was placed in a solution of pyrrole in methanol, and an aqueous solution of $FeCl_3$ was added. The concentrations of pyrrole and the oxidant were 0.2 and 0.5 M, respectively. The polymerization was performed at 0°C; the methanol : water ratio in the reaction mixture was 3 : 7. The reaction was performed for 1 h, after which the film was withdrawn, cleaned to remove excess PPyr, washed with water, and dried in air.

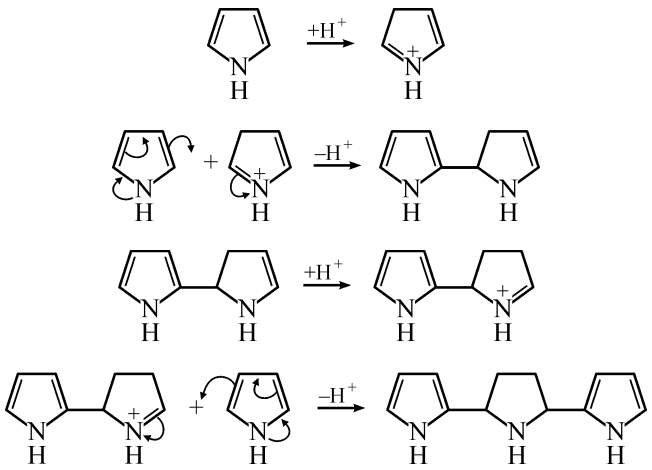
To prepare PE/PPyr(c) samples, a porous PE film impregnated with a 0.5 M solution of $FeCl_3$ in methanol was placed, together with a weighed portion of pyrrole-2-carboxylic acid, in a stainless steel vessel filled with CO_2. The CO_2 was brought to the supercritical state (20 MPa, 75°C) with a pressure generator (Company for Production of High-Pressure Equipment, the United States) and a thermostat. Under these conditions, pyrrole-2-carboxylic acid decomposed to give pyrrole, which polymerized when contacting with $FeCl_3$ on the surface of the porous PE film. The samples thus prepared were also washed with methanol and dried in air.

The content of PPyr in the samples was determined gravimetrically.

The surface conductivity of the composite systems (conductivity in the direction parallel to the film surface) was measured by the standard four-probe method, and the bulk conductivity (between the surfaces), by the two-disk method.

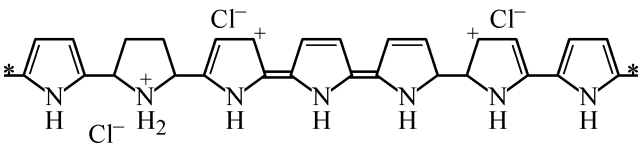
The mechanical properties of porous PE films and composite systems were studied with an R-5 tensile-testing machine (Ivanovo). The strength, elastic modulus, and relative elongation at break were determined from the stress–strain curves in the course of uniaxial extension of 30 × 2-mm specimens at a rate of 100% min^{-1}. The strength was calculated as the ultimate (breaking) force per initial cross section of the specimen. The elastic modulus was determined at a 0.5% strain.

Thermomechanical tests were performed in the uniaxial extension mode at a heating rate of 10 deg min^{-1} and applied loads of 0.02 to 0.2 MPa. The tests were performed in a vacuum to prevent oxidation.



The elemental analysis was performed with a Vario El elemental analyzer (Germany).

The IR spectra were recorded on a Nicolet Impact 400 FTIR spectrometer in the attenuated total internal reflection mode.



The TG and DTA curves were recorded with a C-1500 derivatograph (Hungary) in the course of heating of 50-mg samples in a self-generated atmosphere at a rate of 10 deg min^{-1}.

Chemical structure of PE/PPyr composite systems. Polymerization of pyrrole is a complex multistep process accompanied by a set of side reactions. Both the chemical and supramolecular structure of PPyr depends on many parameters, such as the synthesis temperature, composition of the polymerization medium, type and concentration of the oxidant, etc. Hence, the service properties of the polymer, such as the electrical conductivity and mechanical characteristics, will also depend on the polymerization conditions.

Published data [2, 3, 14–16] show that PPyr is chemically and structurally nonuniform, which is due to the occurrence of side reactions in the course of the polymerization. One of the most known reactions is that leading to incorporation of pyrrolidine rings into the conjugated polypyrrole chain. It has been found [14–16] that, under the action of Brønsted acids, pyrrole undergoes transformations yielding products that show no conductivity because of the lack of the conjugation system. The acid-catalyzed formation of nonconjugated compounds from pyrrole can be described by the following scheme:

This process is also possible under common conditions of the oxidative synthesis of PPyr, because Fe(III) salts frequently used as oxidants are strongly susceptible to hydrolysis with the formation of basic salts [$Fe(OH)_nCl_{3-n}$, where n = 1, 2] and rise in the solution acidity [14, 17]. Thus, because the main process (oxidative polymerization) is usually accompanied by the side reaction, PPyr contains a certain amount of saturated units making lower the electrical conductivity of the polymer. The scheme below shows how a saturated unit breaks the conjugation chain in polypyrrole:

The content of saturated units can be estimated, in particular, by elemental analysis from the C : H atomic ratio. In the "ideal" PPyr, this ratio should be 4.00 : 3.00, and incorporation of saturated rings should cause the relative content of hydrogen to increase. In PPyr prepared in a monomer solution, the C : H atomic ratio (4.00 : 3.17) was the closest to the ideal value; in the sample prepared from the gas phase it was 4.00 : 3.23, and in the sample prepared in supercritical CO_2, 4.00 : 3.80.

The differences in the chemical structure of the composite systems prepared by different methods are also manifested in the IR spectra (Fig. 2). Comparison of the IR spectra of the PE/PPyr(g) and PE/PPyr(c) samples shows that both these samples contain PPyr. The spectra exhibit all the bands characteristic of PPyr (Table 1) [18, 19]. However, some other bands are also present. The spectra of the systems PE/PPyr(g) and PE/PPyr(c) contain a weak band at ~1700 cm^{-1}, assignable to C=O vibrations. The peak position of this band is different for PE/PPyr(c) (1705 cm^{-1}) and PE/PPyr(g) (1680 cm^{-1}). This pattern suggests that the ketones are conjugated with a double bond in PE/PPyr(g), being not conjugated in PE/PPyr(c). Both the spectra also contain bands at about 1100 cm^{-1}, assignable to the C–O stretching vibrations in enols,

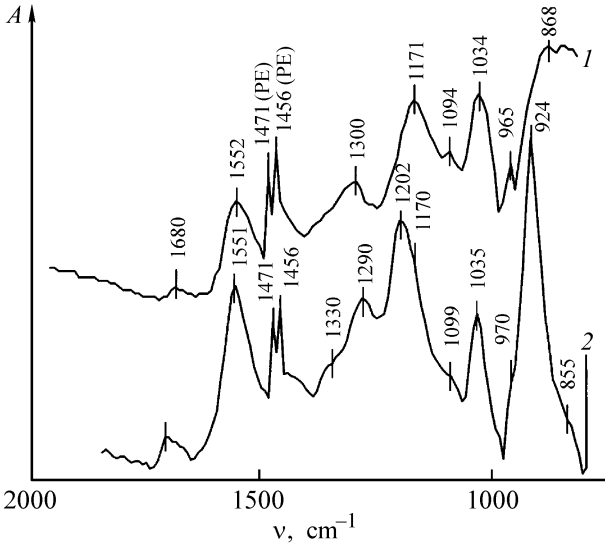


Fig. 2. IR spectra of composites (*1*) PE/PPyr(g) and (*2*) PE/PPyr(c). (*A*) Absorption and (ν) wave number.

868	855 sh	860, bending vibrations of C–H bonds

which occur in equilibrium with C=O [20]. Presumably, these groups are formed by a nucleophilic attack of water molecules at cations in the chain of oxidized PPyr, which occurs both in the course of polymerization and during the subsequent storage of the composite in air. Also, the spectrum of PE/PPyr(c) contains a number of peaks absent in the spectrum of PE/PPyr(g): 1330, 1202, and 920 cm^{-1}, which can be assigned to the C–C skeleton vibrations in saturated fragments [16]; the presence of such fragments follows from the elemental analysis.

The PE/PPyr(s) sample shows 100% absorption throughout the examined IR range. Such a pattern is characteristic of substances in which electronic transitions between the valence and conduction bands have a low energy (i.e., in which the band gap is narrow). In PPyr, the band gap depends on the length of the conjugation chain. The longer the conjugation chain, the lower the electronic transition energy and the larger the wavelength of light that can be absorbed. In the PE/PPyr(g) and PE/PPyr(c) samples, the conjugation chain length is sufficient for absorption of the visible light (all these samples are black) but insufficient for the IR absorption. At the same time, the PE/PPyr(s) sample strongly absorbs the IR radiation, i.e., the conjugation chain in this sample is longer than that in the other samples; accordingly, its electrical conductivity is higher.

Thus, in the order PE/PPyr(s)–PE/PPyr(g)–PE/PPyr(c), the content of incorporated saturated rings increases, and hence the length of the conjugation chain decreases. This trend is caused by different relative rates of the side reaction under different synthesis conditions.

The side reactions occur to the least extent in solution, which is due to the optimal reactant ratio and to their uniform distribution in the reaction volume. In the gas-phase synthesis, first an oxidant solution is applied to a porous PE film, and then the monomer is gradually supplied to the film surface. In this case, $FeCl_3$ with the residual solvent is in excess relative to the monomer. The acid formed by hydrolysis of $FeCl_3$ is also in excess, which results in an increased content of the saturated units.

A similar pattern is observed in the synthesis in supercritical CO_2, but, along with the presence of excess oxidant in the reaction zone, there is another negative factor: elevated temperature (75°C), which accelerates both the formation of saturated fragments and other side reactions (e.g., deamination [14] and overoxidation of polypyrrole). Furthermore, the source of pyrrole in the polymerization in supercritical CO_2, is pyrrole-2-carboxylic acid, which also favors acceleration of the acid-catalyzed side reaction.

Morphological features of PE/PPyr composites. To reveal morphological features of the composites prepared by different methods, we examined the structure of their surface by electron microscopy (Fig. 3). As reported previously [4], in formation of composites by gas-phase polymerization of the monomer, the PPyr layer "inherits" the specific character of the surface of the porous PE support (Fig. 3a). When the polymerization is performed in a monomer solution, the PPyr layer has its own morphology, but with the preserved character and orientation of the support surface (Fig. 3b). In polymerization in supercritical

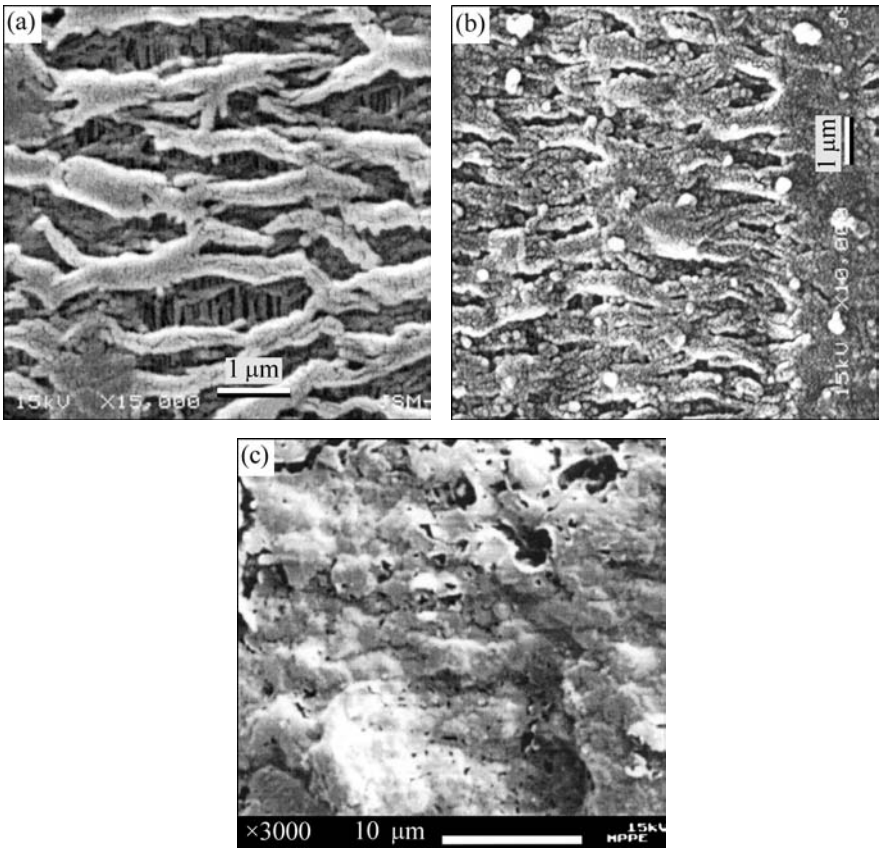

Fig. 3. Electron micrographs of the surface of (a) porous PE support, (b) PE/PPyr(s) composite, and (c) PE/PPyr(c) composite.

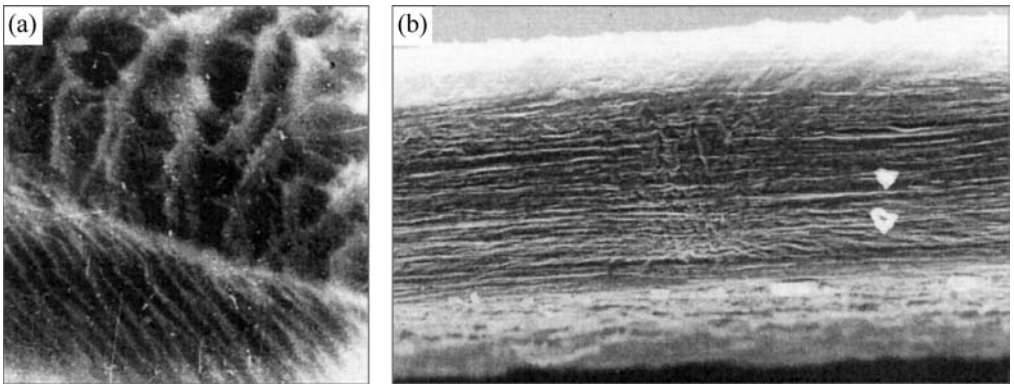

Fig. 4. Cross-sectional electron micrographs of (a) porous PE film and (b) PE/PPyr composite prepared by gas-phase polymerization.

CO_2, the layer of the conducting polymer fully masks the structure of the support surface, which can be traced only in certain areas (Fig. 3c); the structure of the PPyr layer exhibits no orientation characteristic of the PE support. Figure 3c also shows that the polymerization at high pressure yields a smoother and less structured polypyrrole layer, compared to the PE/PPyr(g) and PE/PPyr(s) samples prepared under atmospheric pressure, but this layer has visible defects disturbing its continuity.

Electrical characteristics of the composites. In the synthesis of PPyr on porous supports, the polymerization is preceded by penetration of reactant molecules into the support, and PPyr is formed not only on the film surface but also in pores and intercrystallite areas, which results in that a spatially continuous conducting phase of PPyr is formed both on the surface and in the bulk of the support. This is seen from the images of the cross sections of the porous support and composite (Fig. 4). It is seen that the

Table 2. Electrical conductivity of PE/PPyr composites (thickness of the porous support 12 μm)

Sample	Thickness, μm	PPyr content, %	Surface conductivity, S cm^{-1}	Bulk conductivity, S cm^{-1}
PE/PPyr(g)	14	40	10^0	10^{-6}
PE/PPyr(s)	14	40	10^2	10^{-3}
PE/PPyr(c)	13	18	10^{-3}	10^{-8}

Table 3. Mechanical characteristics of porous PE films and PE/PPyr composites*

Sample	Breaking strength, MPa	Elastic modulus, MPa	Elongation at break, %
Porous PE film	150	700	50
PE/PPyr(g)	143	1400	40
PE/PPyr(s)	147	2000	48
PE/PPyr(c)	145	800	47

* The mechanical characteristics were determined in the direction of orientation of the porous support.

whole volume of the support is filled with the conducting polymer, fully masking the porous structure of the support. Such a spatial structure of the conducting phase allows the composites obtained to be characterized by the sheet and volume conductivity (Fig. 2). The essential difference between these quantities is due to the fact that the volume conductivity is determined by the amount of through channels filled with the conducting polymer.

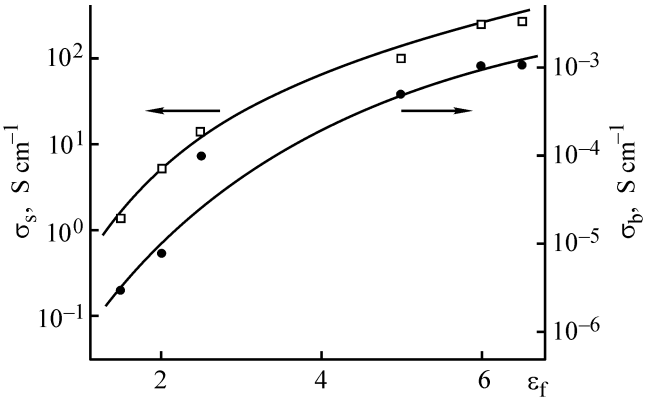

Fig. 5. Surface conductivity σ_s and bulk conductivity σ_b of PE/PPyr(s) samples vs. degree of orientation of the support ε_f.

Table 2 shows that the electrical conductivity of the samples correlates with the length of the conjugation chain in PPyr. Even despite high pressures in the synthesis in supercritical CO_2, which may favor closer packing of the PPyr chains and hence increase the conductivity, the measured conductivity of the samples prepared under these conditions is very low, because of the large content of the incorporated saturated rings. An additional factor decreasing the conductivity of these samples is the above-mentioned lack of orientation in the polypyrrole layer.

At the same time, according to our measurements (Fig. 5), the conductivity substantially increases with the degree of orientation; this also follows from the considerably higher conductivity of the PE/PPyr(g) and PE/PPyr(s) composites containing the PPyr layers with an oriented structure, compared to the PE/PPyr(c) samples.

It should be noted that the conductivities that we attained with PE/PPyr(s) are the highest among the values reported for composites and are close to the conductivity of pure PPyr.

Mechanical properties. Introduction of PPyr into a composite, as a rule, decreases its strength and results in the loss of elasticity. Therefore, we examined the mechanical properties of PE/PPyr samples (Table 3). All the samples exhibited high deformation and strength characteristics: The strength and elasticity of all the composites were comparable with those of the porous PE supports.

Table 3 shows that the mechanical properties of the composites depend on their preparation procedure: The sample prepared by polymerization in solution shows the best properties. Its electrical conductivity is also the highest (Table 2). Furthermore, the elastic modulus of PE/PPyr(g) and PE/PPyr(s) is higher than that of the support by a factor of 2 and 3, respectively, whereas the elastic modulus of PE/PPyr(c) is only slightly higher than that of the support. The increased elastic modulus of the composites is due to the appearance of a spatially continuous phase of the conducting rigid-chain polymer, which is formed on the stretched support and "inherits" its oriented character. Figure 3 shows that the degree of orientation of the PE/PPyr(c) samples is considerably lower than that of the PE/PPyr(g) and PE/PPyr(s) samples, which may be due to the fact that the conditions of the all-round compression at high pressure prevent arrangement of the forming PPyr molecules in one preferential direction. Thus, the elastic modulus of the PE/PPyr(g) and PE/PPyr(s) samples is determined by the oriented structure of the rigid-chain PPyr layer in which the degree of ori-

entation of the molecules can be higher than that in the PE support (flexible-chain polymer), whereas the PE/PPyr(c) samples contain a weakly oriented polypyrrole phase, and their elastic modulus is determined by the support.

Thermal stability. The thermal stability of the PE/PPyr composites and their components was studied by TGA and DTA. Heating of PE films to 200–250°C is not accompanied by any noticeable weight loss (Fig. 6a, curve *1*). The endothermic peak at 132°C (Fig. 5b, curve *1*) corresponds to PE melting, and the thermal effects at about 200°C, as shown in [21], to its oxidation. Active weight loss starts at 200–250°C; it is caused by the release of volatile thermal degradation products and is accompanied by exothermic effects (Fig. 6b, curve *1*).

PPyr shows weight loss from the very beginning of the heating (Fig. 6a, curve *2*); the weight loss is uniform throughout the examined temperature range. At 800°C, when the sample transforms into a carbonized residue, the weight loss is about 65% [22].

The TGA curves (Fig. 6a) show that the degradation patterns of the PE/PPyr composites are intermediate between those of the pure components and differ from each other insignificantly. Similarly to the PE support, the PE/PPyr composites show a sharp weight loss above 400°C, but it is considerably less pronounced because of the fixing effect of the PPyr layer.

The DTA curves of PE (Fig. 6b, curve *1*) exhibit pronounced thermal effects caused by melting, oxidation, and thermal degradation. The thermal degradation of PPyr is not accompanied by thermal effects; its heat capacity first steadily increases and then, above 300°C, steadily decreases (Fig. 6b, curve *2*). The DTA curves of the composites (Fig. 6b, curves *3*, *4*) mainly reflect the transformations of the PE support, but the effects are less pronounced, compared to the straight support, because of the effect of the rigid-chain component, polypyrrole. The three-dimensional PPyr framework is "fused" into the bulk of PE, which loses the porous structure upon melting, and this rigid framework prevents complete melting of PE (the heat of melting of the composites is considerably lower than that of PE [22]), restricting the motion of its chains. Thus, PPyr affects all the structural changes occurring above T_m of PE.

Thermodeformational behavior of PE/PPyr composites. We have shown previously [6, 22] that the oriented structure of the porous PE support is responsible for the shrinkage of the composite systems

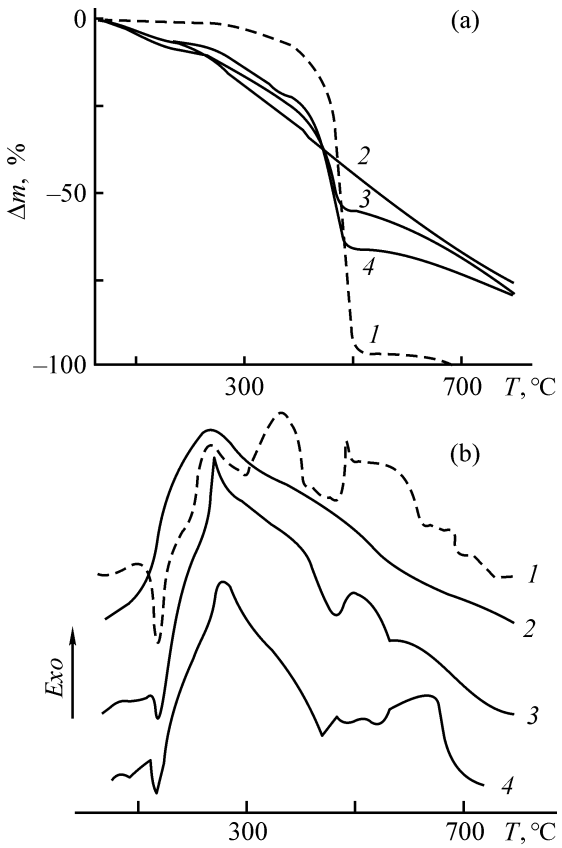

Fig. 6. (a) TGA and (b) DTA curves of (*1*) PE film, (*2*) PPyr prepared by gas-phase polymerization, (*3*) PE/PPyr(g) composite, and (*4*) PE/PPyr(s) composite. (Δ*m*) Weight loss and (*T*) temperature.

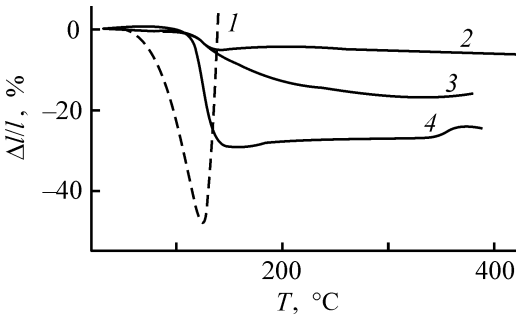

Fig. 7. Deformation Δ*l*/*l* vs. temperature *T* (thermomechanical curves) for (*1*) porous PE films and composites (*2*) PE/PPyr(s), (*3*) PE/PPyr(g), and (*4*) PE/PPyr(c). Load 0.02 MPa.

on heating. The thermomechanical curves of porous PE films (Fig. 7, curve *1*) are typical of oriented systems of flexible-chain polymers: In the vicinity of T_m of PE, the shrinkage is maximal, and above this temperature the film undergoes sharp elongation followed by break. The thermomechanical curves of the composite systems are strongly different (Fig. 7,

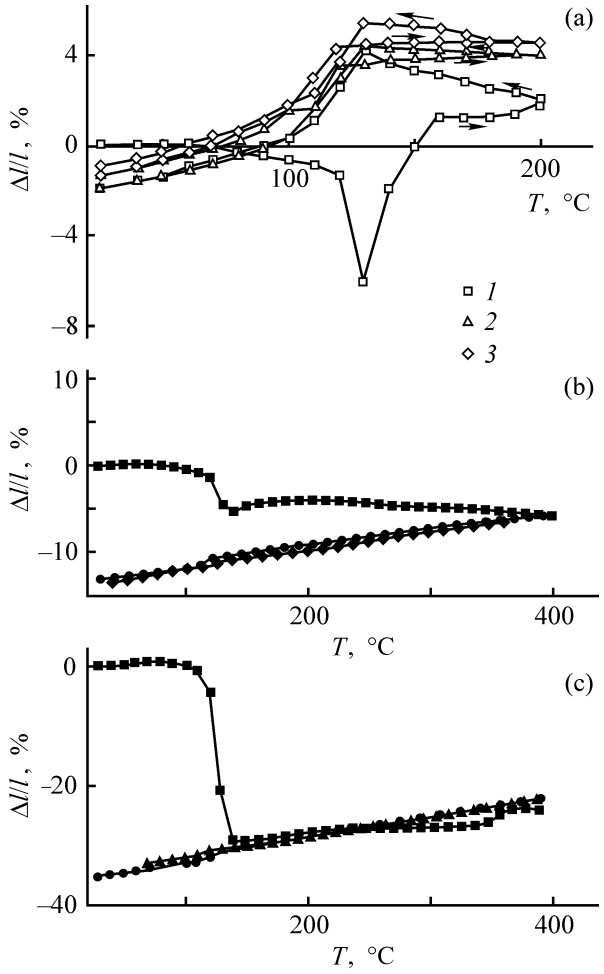

Fig. 8. Deformation $\Delta l/l$ vs. temperature T (thermomechanical curves) for PE/PPyr composites in cyclic heating. System, load (MPa): (a) PE/PPyr(g), 0.2; (b) PE/PPyr(s), 0.02; and (c) PE/PPyr(c), 0.02: Cycle: (*1*) first, (*2*) second, and (*3*) third.

curves *2*–*4*). Their major feature is a plateau in a wide temperature range above T_m of PE. In this range, the samples not only keep a load, but even do not change size on heating. It is important that the composite systems studied preserve their integrity on heating up to 400°C, i.e., to temperatures much higher than T_m of PE. This result is caused by the fact that, in these systems, the load is taken over by the three-dimensional framework of the rigid-chain conducting PPyr, rather than by the PE support.

Figure 7 illustrates noticeable differences in the behavior of PE/PPyr samples prepared by different methods. All these samples undergo shrinkage in the vicinity of the PE melting point, but the extent of this shrinkage is varies: about 30% for PE/PPyr(c) and only 5% for PE/PPyr(g) and PE/PPyr(s). As the temperature is raised further, the smallest changes in size are observed with the PE/PPyr(s) composite. Thus, the strongest fixation of the porous structure of the support by the PPyr layer is ensured by preparing this layer from the monomer solution, owing to the denser structure of the PPyr layer thus obtained. Indeed, measurements of the density of the composites by hydrostatic weighing gave the following results (g cm^{-3}): PE/PPyr(s), 1.102; PE/PPyr(g), 1.088; and PE/PPyr(c), 1.009 (the density of PE is 0.950 g cm^{-3}). The density of the PPyr component can be estimated taking into account its content in the composites; in PE/PPyr(s), PE/PPyr(g), and PE/PPyr(c), it is 1.33, 1.30, and 1.29 g cm^{-3}, respectively.

The limiting temperatures above which the samples fail are also somewhat different. The PE/PPyr(s) composites under the conditions of the thermomechanical experiment fail at temperatures exceeding 420°C, whereas the PE/PPyr(g) and PE/PPyr(c) samples do so at 380–400°C. This is due to the fact that the PPyr layer formed from the monomer solution contains less structural defects (cracks, inhomogeneities) and is considerably more oriented and ordered than the layers prepared by gas-phase polymerization or in supercritical CO_2.

To reveal changes that occur in PE/PPyr samples on heating in a vacuum, we performed repeated heating–cooling cycles under the same conditions (Fig. 8). It is seen that all the samples undergo irreversible changes in the first cycle of heating, as indicated by different runs of the heating and cooling curves; the run of the cooling curve is typical of cross-linked systems.

In the repeated cycles, the heating and cooling curves are fully reproduced for all the samples, i.e., the structural changes are complete in the first cycle. This fact can be accounted for by the cross-linking of polypyrrole at about 200°C, as found by mechanical relaxation studies [23]. As a result, the mechanical properties of the composites change after the first cycle: The elastic modulus increases, and the elongation at break decreases, although the samples preserve certain elasticity. Gas permeability measurements show that the samples become considerably denser after heating (the gas permeability decreases by more than two orders of magnitude, compared to the initial samples), which is due to collapse of pores in the support upon melting and to cross-linking of the polypyrrole layer.

CONCLUSIONS

(1) New composites were prepared by polymerization of pyrrole in solution, in the gas phase, and

in supercritical CO_2 on porous polyethylene films. The polymerization in solution yields the conducting polymer phase of a more uniform chemical structure, compared to the products obtained by polymerization in the gas phase and in suprecritical CO_2.

(2) In the composites obtained, the conducting properties of polypyrrole are combined with the high mechanical characteristics of the porous support.

(3) The composites prepared by polymerization in the monomer solution show a higher conductivity, compared to the samples prepared by polymerization in the gas phase and in supercritical CO_2.

(4) Preparation of conducting composite systems in an environmentally safe medium (supercritical CO_2) is, in principle, possible.

(5) At temperatures considerably exceeding the melting point of polyethylene, the composite systems preserve mechanical stability owing to the presence of a spatially continuous rigid framework of the conducting polymer.

Abstract—Anionic copolymerization of 2,4-toluene diisocyanate with γ-butyrolactone in the presence of triethylamine was performed. The chemical structure of the copolymer obtained was determined by IR and ^{1}H NMR spectroscopy, and some kinetic features of the process were revealed.

Lactones are valuable monomers for preparing polyesters with unique properties, showing promise both as structural materials and as biologically active substances in medicine [1–3].

The capability of various lactones to undergo polymerization strongly depends essentially on the ring strain. In particular, β-propiolactone spontaneously polymerizes under mild conditions [4]; ε-caprolactone undergoes ring opening under the action of organometallic catalysts at 60–80°C; γ-butyrolactone (γ-BL) does not undergo homopolymerization even in the presence of Ziegler–Natta catalysts but copolymerizes with a wide variety of monomers (vinyl monomers, cyclic acetals, amines, amides, ketenes, carboxy hydrides of amino acids) [5].

In this study, we examined the possibility of copolymerization of γ-BL with 2,4-toluene diisocyanate (TDI) in the presence of triethylamine (TEA). The choice of TDI as comonomer was governed by the fact that, in the presence of TEA, it can induce ring opening of some heterocyclic compounds [6–8] that do not undergo homopolymerization under these conditions.

EXPERIMENTAL

The copolymers were prepared in a solvent (acetone) at 20°C. The catalyst (TEA) concentration was 0.02 mol %. The amount of the unchanged monomer was determined by extraction with acetone in a Soxhlet apparatus for 8 h.

The reaction of TDI with γ-BL was studied by ^{1}H NMR spectroscopy with a Tesla-100 spectrometer operating at 100 MHz. Acetone-d_6 was used as solvent and reference. The mid-IR spectra of the copolymers were recorded on a Bruker FT-IR spectrophotometer. Samples were pelletized with KBr, using a hydraulic press. The molecular mobility of the polymers was studied by pulsed NMR spectroscopy on a relaxometer operating at 20 MHz.

The thermal analysis was performed with a Q-1500 derivatograph (MOM, Hungary) at a heating rate of 3 deg min^{-1}.

To determine the physicomechanical characteristics, we obtained films of TDI–γ-BL copolymers from acetone solutions by casting. The breaking stress σ_b was determined on an MR-500T-2 tensile-testing machine at 20 ± 2°C. The velocity of mobile clamps was 100 mm min^{-1}.

The reaction rate constants were determined as described in [10].

The IR spectra of TDI–γ-BL copolymers contained new bands absent in the spectra of the starting monomers (Fig. 1): at 3490–3400 (N–H stretching vibra-

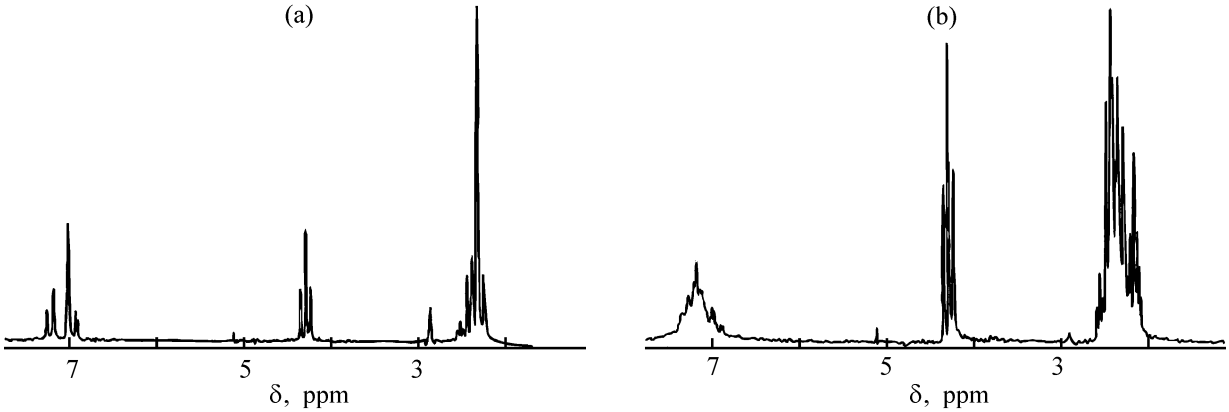

Fig. 2. ^{1}H NMR spectrum of the system γ-BL–TDI (a) before and (b) after the reaction performed for 30 min at 25°C. Solvent acetone-d_6; equimolar ratio of the monomers. (δ) Chemical shift.

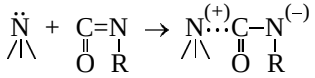
tions in secondary amides and O–H stretching vibrations), 1706 (C=O stretching vibrations in tertiary amides), 1508 (N–C stretching vibrations in secondary amides), ~1404 (C–N stretching vibrations), and 1211 cm^{-1} (ester stretching vibrations). The bands at 2860 and 2920 cm^{-1} (stretching vibrations of methylene groups) are indicative of the presence of γ-BL units [10].

The chemical transformations in the system can also be monitored by ^{1}H NMR spectroscopy (Fig. 2).

The copolymerization in acetone-d_6 for 30 min results in an appreciable broadening of the aromatic proton signals at 7.2–6.9 ppm, suggesting growth of the molecular weight; the singlet at 2.8–2.7 ppm (TEA protons) virtually disappears. The signals at 2.5–2.0 ppm belonging to the protons of the TDI methyl group and methylene groups of the lactone ring get appreciably broadened, i.e., the environment of these protons changes.



Using near-IR spectroscopy, we calculated from the absorption at 5310 cm^{-1} (vibrations of the isocyanate group) the reaction rate constant k and the rate of consumption of isocyanate groups V in the course of the copolymerization at various monomer ratios (Table 1). It is seen that the consumption rate is the highest at the equimolar ratio of the comonomers in the starting mixture.

This result suggests that, taking into account that γ-BL does not undergo homopolymerization under the synthesis conditions, the reaction of γ-BL with TDI may involve formation of an alternating copolymer in the initial steps. With an excess of the isocyanate component, it may subsequently depolymerize at active anionic centers. The IR spectra show that only γ-BL remains unchanged, and TDI is converted virtually completely at any comonomer ratios.

This suggestion is confirmed by the fact that the copolymer yield decreases with an increase in the γ-BL content in the starting mixture.

Our results suggest the following mechanism of the reaction of TDI with γ-BL.

(1) As γ-BL itself is incapable of ring opening, the first step apparently involves nucleophilic addition of the tertiary amine to the electrophilic center of the isocyanate groups to give a quasiammonium complex:

(2) The chain propagation in this case can occur via nucleophilic addition of either TDI or γ-BL to the anion formed by opening of the isocyanate group:

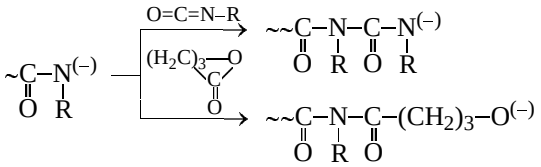


Table 1. Rate of consumption of isocyanate groups and rate constants of the reaction of TDI with γ-BL

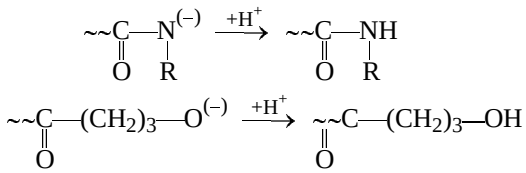
γ-BL/TDI molar ratio	$V \times 10^6$, mol l^{-1} s^{-1}	$k \times 10^2$, l mol^{-1} s^{-1}
1.0/5.0	0.81	1.0
1.0/3.0	1.13	2.2
1.0/1.0	4.11	25.0
1.0/0.5	2.29	2.4
1.0/0.4	1.72	0.6
1.0/0.2	1.67	0.2
1.0/0.1	1.58	0.1

Table 2. Spin–lattice relaxation time T_1 of TDI–γ-BL copolymers

γ-BL/TDI molar ratio	T_1, ms
1.0/20.00	116
1.0/4.00	122
1.0/0.25	132
1.0/0.20	142
1.0/0.10	151

Table 3. Heat resistance of TDI–γ-BL copolymers (DTA data)



γ-BL/TDI molar ratio	$T_{\Delta m = 5\%}$, °C
1.0/3.0	310
1.0/1.0	292
1.0/0.3	284
1.0/0.1	270

Table 4. Breaking tensile stress σ_b of TDI–γ-BL copolymers

γ-BL/TDI molar ratio	σ_b, MPa
1.0/0.62	37.3
1.0/0.42	35.0
1.0/0.34	33.1
1.0/0.25	22.6
1.0/0.17	5.7

With excess isocyanates, the chain end can contain tertiary amide blocks.

(3) The termination in such polymerizing systems may occur [11] via exchange reactions of the propagating macroanions with compounds containing a labile hydrogen atom or by the chain transfer to the monomer; both hydroxy and amino groups can be formed, depending on the nature of the active center:

It is also necessary to take into account the possible presence of triisocyanurate and uretidinedione rings in the polymer, as it is known [12] that isocyanates can form such structures in the presence of tertiary amines, and certain heterocyclic compounds (oxiranes, lactones) activate the dimerization and cyclotrimerization reactions.

We examined some physicomechanical, processing, and service properties of the copolymers.

In particular, we found that they dissolve only in strongly polar organic solvents (formic acid, dimethylformamide, dimethyl sulfoxide) at high temperatures. The solubility decreases with an increase in the TDI content in the starting monomer mixture.

Such a behavior may be associated with enhanced branching and cross-linking of the macromolecules due to the bifunctional structure of TDI. This is confirmed by the NMR relaxation data (Table 2).

The copolyamido esters obtained have a high $T_{\Delta m =}$ 5% (temperature of 5% weight loss, Table 3), decreasing with an increase in the γ-BL content, which indicates that the tertiary polyamide fragments are more stable than the polyester fragments.

From the starting mixture containing excess γ-BL, we prepared polymer films by casting. The breaking stress σ_b of these films appeared to be essentially dependent on the monomer ratio, varying from 5 to 37 MPa (Table 4).

The materials obtained with excess TDI were very brittle, apparently because of the high degree of cross-linking (due to the bifunctional structure of TDI) and of the presence of polycyclic triisocyanurate structures. A decrease in σ_b with decreasing content of TDI in the starting mixture is due to the presence of a large amount of the unchanged lactone, adversely affecting the strength of the material.

CONCLUSIONS

(1) 2,4-Toluene diisocyanate undergoes anionic copolymerization with γ-butyrolactone in the presence of triethylamine. The reaction mechanism is suggested.

(2) The copolyamido esters obtained exhibit high strength, reaching a maximum at a certain excess of γ-butyrolactone in the starting mixture.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of Natural Polysaccharides on Aggregation of Aqueous Protein Dispersions

I. N. Konovalova and N. V. Stepanova

Murmansk State Technical University, Murmansk, Russia

Received January 26, 2005; in final form, April 6, 2005

Abstract—The kinetics of aggregation of aqueous protein dispersions under the action of flocculants, natural polysaccharides (cationic chitosan and anionic sodium alginate), were studied turbidimetrically in relation to the protein : polysaccharides ratio in the solution and the pH value. Sodium alginate and chitosan were tested in treatment of wastewater from the flotation processing of hydrobiontics.

Anionic and cationic macromolecular flocculants are widely used to intensify treatment of natural water and industrial wastewater to remove colloid and dispersed substances [1, 2]. One of the methods to remove organic pollutants and, in particular, proteins from water is flotation preceded by aggregation of protein particles with inorganic electrolytes and synthetic macromolecular flocculants. Inorganic flocculants have a number of drawbacks and, above all, large consumption and enhancement of the corrosion activity of water. Synthetic macromolecular flocculants hinder further utilization of the organic waste as nutritive additives. Inorganic electrolytes and synthetic macromolecular flocculants can be replaced in exhaustive treatment of water to remove protein substances with nontoxic biodegradable natural macromolecular polyelectrolytes (PEs), sodium alginate and chitosan.

EXPERIMENTAL

We examined natural macromolecular PEs, cationic chitosan and anionic sodium alginate (AlgNa). Chitosan had the degree of deacetylation of 66% {TU (Technical Specifications) 6-9-5591 [3]}. Sodium alginate was of medical grade {FS (Pharmacopoeia Item) 42-3383–97 [4]}. Food gelatin [GOST (State Standard) 11293–89)], a water-soluble degradation product of collagen, as well as an aqueous extract from a fish tissue, served as the protein component. Solutions of AlgNa and gelatin were prepared by preliminary swelling and dissolution in water. Chitosan solutions were prepared using 1% acetic acid. To prepare an aqueous extract of fish, a weighed portion of the tissue was shredded and left for 30 min in a small volume (20–25 ml) of distilled water for extraction of water-soluble components. The resulting solution was twice filtered to remove suspended matter. Flotation treatment of the wastewater was carried out on a pilot pressure-flotation setup.

The concentration of the protein substances, c_{protein}, in the extract and in the wastewater was estimated turbidimetrically, by the modified Lawry method [5].

The aggregation power of the PEs was estimated turbidimetrically [6, 7]. We constructed plots of the optical density of the solution against the time of addition and the concentration of the aggregating substances. The aggregation rate was calculated as the change in the optical density D per unit time τ in the initial linear portion of the $D = f(\tau)$ plot. The optimal flocculating concentration of the polysaccharides (OFC) was determined as the minimal concentration of the polysaccharides, required for achieving the maximal flocculation rate of the protein substances.

The conformation of the polysaccharide and gelatin macromolecules in solution was determined by plotting the pH dependences of the relative viscosity of the corresponding solutions [8]. Based on the viscometric data, we graphically estimated the intrinsic viscosity and calculated the hydrodynamic volume of the macromolecules [9], which made it possible to estimate the degree of their "folding." Using the Mark–Kuhn–Houwink equation, we calculated the viscosity-average molecular weight of the PEs under study by the procedure described in [10, 11]. The viscosity-average molecular weight of chitosan and sodium alginate was 40 000 and 4500, respectively.

1070-4272/05/7812-2006 © 2005 Pleiades Publishing, Inc.

Table 1 lists the gelatin aggregation rates at various concentrations of the PEs in solution.

Table 1 shows that, in the case of sodium alginate, the gelatin aggregation rate attains a maximum at 0.75 g_{PE}/g_{gel}. The flocculation activity of chitosan corresponds to 0.0005 g_{PE}/g_{gel}. The fact that the gelatin aggregation rate is higher in the presence of sodium alginate is most likely due to the electrostatic interaction of alginate with positively charged functional groups of gelatin, predominantly situated at the ends of the protein macromolecule chains [12]. This interaction is responsible for conformational transformations of the macromolecular chains of gelatin, which decreases the degree of ordering, as noted in [13, 14]. The negatively charged functional groups of gelatin are predominantly situated in the middle of the macromolecular chain and are less easily accessible to cationic flocculant; in this case, gelatin aggregation follows mostly the bridging mechanism.

Figure 1 (curves *1*, *2*) shows the OFC of chitosan and sodium alginate as dependent on the gelatin concentration. It is seen that, in the concentration range examined, this dependence is virtually linear. Baran [15] and Vincent [16] noted that such a dependence is typically observed in the case when the reagent added is fully involved in the interaction with the dispersed phase.

The mechanism of aggregation of dispersions containing solid negatively charged particles with synthetic cationic flocculants is discussed in [17–20]. In this case, aggregation is due to neutralization of the surface charge of the dispersed phase, which decreases the aggregation resistance, thus leading to aggregation of the particles. Also, interaction of the PE macromolecule with the surface of several particles yields a kind of "bridges" between individual particles of the dispersed phase.

This mechanism seems to be applicable to aggregation of protein macromolecules with polysaccharides, since the protein macromolecules contain both positively and negatively charged functional groups. In this case, however, we have to take into account the conformation of the macromolecules and their hydrophilic-hydrophobic properties. Evidently, the factors enhancing the hydrophobicity of the protein macromolecules via conformational changes should intensify their flotation and extraction from aqueous dispersions [21]. These factors include, above all, pH of the solution, strongly affecting the conformation of both the PE and protein macromolecules. A study of the conformation of the substances as influenced by pH is also of interest, since the protein-

containing process wastewater delivered to flotation treatment should be neutral. Even a minor shift of pH toward acid or alkaline region can interfere with aggregation, thus deteriorating the water treatment quality [11].

Figure 2 and Table 2 show how the conformation of the polysaccharide macromolecules varies with pH.

Figure 2 shows that, at pH > 8, the viscosity of the chitosan solution is at a minimum. Most likely, the PE macromolecules occur as dense coils, irrespective of pH. In an acidic medium (pH < 4), the viscosity of the solution significantly increases, evidently, due to "unfolding" of the macromolecular coils. Sodium alginate shows an opposite trend: The degree of fold-

ing of the macromolecules decreases in alkaline medium (pH > 8), and compact structures are formed in the acidic medium (pH < 4), in agreement with the nature of the PEs under study [22].

Table 2 shows how the hydrodynamic radius of the polysaccharides under study varies with pH.

Table 2 shows that chitosan forms larger structures compared to sodium alginate, which can be due to a higher molecular weight of this PE. The hydrodynamic volume V_0 of the macromolecules of ionic PEs varies, as the pH of solution increases, in accordance with the chemical nature of the macromolecular substances. Figure 2 and Table 2 suggest that, at pH 5.5, the hydrodynamic volume of the macromolecules of both sodium alginate and chitosan is intermediate between that at pH at which the functional groups of the PE are ionized and the macromolecules are "unfolded" to the greatest extent, and that at pH at which ionization of the functional groups is completely suppressed, and the macromolecules have the conformation of compact structures. Such an intermediate state of the PE macromolecules is, most likely, the most favorable for aggregation of the protein particles.

Flocculation of the protein particles by polyelectrolytes can be regarded as a result of aggregation of the protein particles occurring in a close-to-isoelectric state (under the experimental conditions, pH was 5.5–6) owing to neutralization of the functional groups of the protein macromolecules and to the "bridging" mechanism of binding of the protein particles by the polysaccharide macromolecules. These processes, evidently, result in the formation of peculiar interpolymeric hydrophobic complexes, composed of protein particles bound by polymeric bridges of polysaccharide macromolecules. Evidently, such complexing makes the protein macromolecules more hydrophobic, which facilitates their aggregation and subsequent flotation [11].

Table 3 and Fig. 1 (curves *3*, *4*) show how sodium alginate and chitosan affect the aggregation of the protein substances contained in the aqueous extract from the fish.

A preliminary microelectrophoretic study [7] showed that the aqueous extract from the fish contained virtually identical amounts of positively and negatively charged particles.

Table 3 shows that, under the experimental conditions, aggregation of the protein substances with sodium alginate is observed at an alginate concentration of 0.01 $g_{PE}/g_{protein}$. The maximal rate of aggregation of the protein particles with chitosan is observed at a chitosan concentration of 0.07 $g_{PE}/g_{protein}$, which significantly exceeds both the aggregation rate of protein particles with sodium alginate and the rate of gelatin aggregation with PE throughout the PE concentration range studied. In aggregation of the fish extract, chitosan performs better than alginate: Table 3 shows that a high aggregation rate is observed in a wide range of the aggregating concentrations of chitosan. In this case, the aggregation is most likely affected by lipids that are structurally related to the protein macromolecules and react with the chitosan macromolecules [23].

In aggregation of the proteins extracted from fish, the OFCs of the PEs under study are virtually identical throughout the examined concentration range of the protein substances (Fig. 1, curves *3*, *4*). This is

evidently due to the presence of both positively and negatively charged particles in the dispersion. Similar to aggregation of gelatin, the OFC-vs.-$c_{protein}$ dependence is nearly linear, which suggests that the PE has completely reacted with particles of the dispersed phase [15, 16].

The data presented below show how the removal of the protein substances by flotation is influenced by the wastewater pretreatment with sodium alginate and chitosan (Table 4).

As is known, the wastewaters from hydrobiontic processing is a complex dispersed system consisting mainly of protein substances, lipids, and inorganic electrolytes. Table 4 confirms that sodium alginate and chitosan favor removal of protein substances from wastewater: In the case of sodium alginate and chitosan, the treatment efficiency is 89.6 ± 3.4 and $50.8 \pm 2.8\%$, respectively, against $19.4 \pm 2.3\%$ in water treatment without polysaccharides.

CONCLUSION

Natural polyelectrolytes sodium alginate and chitosan exhibit an aggregation power with respect to protein substances. They favor removal of protein substances from wastewater resulting from flotation processing of hydrobiontics. The efficiency of removal of the protein substances (in percent relative to the initial content of protein) after wastewater pretreatment with sodium alginate or chitosan was 89.6 ± 3.4 and 50.8 ± 2.8, respectively.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Radical Copolymerization of Allyl and Vinyl Monomers Derived from 1,4-Benzoquinone with Acrylic Acid

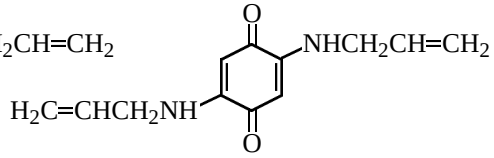
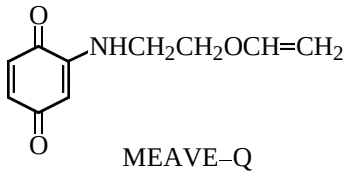
Received March 16, 2005

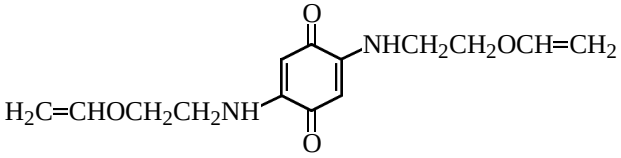


Abstract—Radical copolymerization of allyl and vinyl redox monomers derived from 1,4-benzoquinone with acrylic acid in dimethylformamide was studied.

Allyl compounds are difficultly polymerizing monomers; therefore, they are mostly used as comonomers in combination with other vinyl monomers [1]. Monoethanolamine vinyl ether (MEAVE) also polymerizes under rigorous conditions [2]. Copolymerization with carboxyl-containing monomers and, in particular, acrylic acid acquires growing importance for modification of polymeric materials as a way to enhance their heat resistance, hydrophilicity, adhesion, and also thermoreactive, ion-exchange, and other properties.



The reactions of allylamine (AlA) and MEAVE with 1,4-benzoquinone (Q) yield both mono- and disubstituted derivatives of the following structures [3, 4]:



AlA–Q

AlA–Q–AlA

MEAVE–Q

MEAVE–Q–MEAVE

Owing to the presence of a quinoid ring responsible for the redox properties and to activation of the double bond, these compounds can be used for preparing redox ion exchangers. Their copolymerization with acrylic acid (AcA) allows, thanks to introduction of carboxy groups, preparation of resins combining the redox, ion-exchange, and adsorption properties. The choice of AcA as comonomer is governed by its ready copolymerization with monomers of all kinds, including even monomers whose homopolymerization is difficult [5].

In this study, we examined the radical copolymerization of mono- and disubstituted quinoid derivatives of allylamine and MEAVE with acrylic acid.

EXPERIMENTAL

Allylamine and MEAVE derivatives of 1,4-benzoquinone were prepared according to [3, 4]. Dimethylformamide (DMF) was purified by the standard procedure [6]. Benzoyl peroxide (BP) and azobis(isobutyronitrile) (AIBN) were recrystallized from absolute methanol [7], mp 106–108 and 102–103°C, respectively. Acrylic acid was purified by vacumm distillation, bp 64°C (25 mm Hg), ρ 1.062, n_D^{20} 1.421.

Copolymerization of redox monomers was performed by the ampule method in DMF in the course of 0.5 h. Copolymerization conditions: allyl derivatives, 7 wt % BP, 87°C; vinyl derivatives, 6 wt % AIBN, 68°C. The copolymerization was studied in the range of monomer ratios from 80 : 20 to 20 : 80, at a redox monomer concentration of 20 g l^{-1}. The degree of conversion was judged from the variation of

the monomer concentrations, determined polarographically (redox monomers) and by titration (AcA).

The polarograms were recorded with a phosphate buffer solution (pH 7.4) as supporting electrolyte in 25% DMF in a temperature-controlled cell at 25 ± 0.5°C on a PU-1 polarograph, using a mercury dropping electrode (capillary characteristic at open circuit $m^{2/3}t^{1/6}$ = 4.38 $mg^{2/3}\,s^{-1/2}$ (m, mercury outflow rate, mg s^{-1}; t, dropping period, s). As reference electrode we used saturated calomel electrode. The solutions were deoxygenated by bubbling with argon.

The reactivity of the mono- and disubstituted quinoid monomers derived from AlA and MEAVE was evaluated toward a well-known and extensively studied monomer, AcA.

The copolymerization constants r_1 and r_2 of AlA–Q, AlA–Q–AlA, MEAVE–Q, and MEAVE–Q–MEAVE with AcA were calculated by the Shtraikhman graphical method based on the Mayo–Lewis integral equation [8]. From these constants, we determined the intrinsic specific activities (Q_1) and polarities (e_1) of the new redox monomers (for AcA, we took Q_2 = 1.15 and e_2 = 0.77 from [5]). The results of the calculation are listed in Table 1.

In the systems AlA–Q/AcA, MEAVE–Q/AcA, and MEAVE–Q–MEAVE/AcA, $r_1 > 1$ (Table 1), i.e., the polymeric radicals of the redox monomers react with the "own" monomers faster than with AcA; in the system AlA–Q–AlA/AcA, the pattern is the opposite. All the monomer pairs show a weak tendency toward alternation of units, since the product $r_1r_2 \approx 1$, which is usually characteristic of ideal copolymerization yielding a random copolymer. This is also suggested by small differences in polarity (Δe) between the redox monomers and AcA.

The reactivity of a monomer in copolymerization mainly depends on the polarity of the double bond, stability of the free radical formed by addition of this monomer to the propagating chain, and steric hindrance in the transition state [5]. The parameter Q is the measure of the reactivity determined by the resonance stabilization of the radical, whereas the quantity e characterizes the polarity of the double bond in the monomer. The conjugation in allyl compounds is insignificant; in most of them, Q is within 0.011–0.052 [9]. In the monosubstituted derivative AlA–Q, Q_1 increases by two orders of magnitude (Q_1 = 2.19) owing to the electron density redistribution caused by introduction of Q into the AlA molecule; therefore, this monomer should be more reactive. Its reactivity is higher than that of AlA–Q–AlA (Q_1 = 0.66). The mono- and disubstituted deriva-tives AlA–Q and AlA–Q–AlA appreciably differ in the activity in copolymerization with AcA, whereas the difference in the reactivities of MEAVE–Q and MEAVE–Q–MEAVE is less significant, with the disubstituted derivative being somewhat more reactive.

Another significant factor in copolymerization, along with the resonance factor Q, is the polarity of the monomers, determined by the electron-donor or electron-acceptor power of substituents at the double bond. The quinoid derivatives of AlA and MEAVE are considerably more reactive than the initial compounds because of the influence exerted by the quinone on the electron density in the allyl and vinyl groups which are good electron donors but weak electron acceptors [5]. Quinones are, by contrast, good electron acceptors [10]. Their high electron affinity is due to the low LUMO energy.

The homo- or copolymerization rate is influenced by the activities of both the monomer and the polymeric radical. Since the reactivity of the monomer grows and that of the polymeric radical decreases with an increase in the polarization e [11], the increase in the relative activity of the redox monomers ($1/r_2$) in their copolymerization with AcA, observed with a decrease in e, shows that the process is mainly governed by the properties of the polymeric radical, rather than of the monomer molecule. The $1/r_2$ values (Table 1) show that the vinyl compounds are appreciably more active than the allyl compounds. The reactivity of

	21	79	36.65	63.35	0.096	0.246	0.411	1.39	2.6

* Data from [12].

the redox monomers studied toward the AcA radical decreases in the following order:

MEAVE–Q–MEAVE > MEAVE–Q > AlA–Q > AlA–Q–AlA

e	0.11	0.37	0.49	0.56
$1/r_2$	2.44	1.75	1.67	0.62

Thus, we demonstrated the possibility of copolymerization of the new redox monomers with AcA and found that the structure of the redox monomer affects its reactivity.

Then we studied how the activities and ratio of the comonomers affect the distribution of the monomeric units in the copolymer macromolecules. From the copolymerization constants found and data on the content of both monomers M_1 and M_2 in the starting mixture (Tables 1, 2), we calculated the probability of formation of various diads ($f_{M_1-M_1}$, $f_{M_1-M_2}$, $f_{M_2-M_2}$), mean block lengths (L_{M_1}, L_{M_2}), and Harwood parameters of the block structure R [12, 13]. Using these parameters (Table 2), one can estimate the distribution of units in the macromolecular chain, which determines the properties of the copolymers.

As can be seen from Table 2, the mean block lengths L_{M_1} and L_{M_2}, calculated by different methods [12, 13], essentially coincide. The largest block length is observed with an excess of one of the monomers. The Harwood parameter R is maximal when the copolymer consists of short blocks, i.e., copolymers of more regular structure are formed at the largest R. By choosing appropriate compositions of monomer mixtures, it is possible to control the microstructure of the forming copolymers, which is one of the most promising ways to modify their properties.

CONCLUSIONS

(1) Radical copolymerization of mono- and disubstituted allyl and vinyl redox monomers with acrylic acid was studied. The copolymerization constants and Alfrey–Price Q–e parameters of the redox monomers were determined; the microstructural characteristics of the copolymers obtained were calculated.

(2) It was found that the monosubstituted derivative of 1,4-benzoquinone and allylamine is involved in the radical copolymerization with acrylic acid more readily than the disubstituted redox monomer. By contrast, the disubstituted derivative MEAVE–Q–MEAVE is more reactive than the monosubstituted monomer MEAVE–Q. The copolymers show no tendency toward alternation of the monomeric units.

ACKNOWLEDGMENTS

The study was supported by ISTC (project K-604).

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis of Carboxymethyl Cellulose Based on Short Fibers and Lignified Part of Flax Pedicels (Boon)

L. I. Kutsenko, A. M. Bochek, E. N. Vlasova, and B. Z. Volchek

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received October 12, 2005

Abstract—The conditions under which carboxymethyl ethers of cellulose with various degrees of substitution can be prepared from wastes formed in production of flax fibers were studied. The structure of the cellulose ethers synthesized was studied by IR Fourier spectroscopy and physicochemical methods.

The rise in production of textile materials based on flax fibers, observed in recent years, is accompanied by an increase in the amount of wastes formed in flax production, such as short fibers and lignified part of flax pedicels (boon). In comparison with cotton goods, textile materials based on flax fibers have higher consumers', hygienic, and sanitary characteristics, which is caused by specific features of the fine structure of fibers, their morphology, and chemical composition.

The present-day environmental problems require development of a waste-free process for flax utilization. Flax fibers differ in their chemical composition from cotton by smaller content of cellulose, and flax pedicels are close in their composition to coniferous wood. At present, there is no procedure of waste-free utilization of the lignocarbohydrate complex of flax, including short flax fibers and flax pedicels. The possibilities of using short flax fibers and boon as a raw material, instead of cotton linter and purified wood pulp, for synthesis of sorbents and cellulose ethers are being examined [1, 2].

Among cellulose derivatives, its water-soluble ethers are used the most widely: for drilling muds in oil industry; in production of varnishes, paints, and detergents in textile industry; and also in food industry, cosmetics, and perfumery. These cellulose derivatives are methyl cellulose (MC), hydroxypropyl cellulose (HPC), hydroxypropyl methyl cellulose (HPMC), methyl ethyl cellulose (MEC), and other cellulose ethers.

Among cellulose ethers containing carboxy groups, carboxymethyl cellulose (CMC) produced in the form of a sodium salt (NaCMC) is the most widely used in practice. CMC exhibits properties typical of polyelectrolytes [3, 4]. Of scientific and practical interest is synthesis of NaCMC from large-capacity wastes formed in flax production: short fibers and boon.

This study is aimed to examine the conditions under which NaCMC can be prepared from short flax fibers and lignified part of flax pedicels and also to analyze the factors affecting the kinetics of carboxymethylation of flax cellulose.

EXPERIMENTAL

As a starting material we used short fibers and the lignified part of flax pedicels from the Nevel plant. The degree of polymerization (DP) of cellulose in the initial short flax fibers was 3000. The degree of polymerization of cellulose in flax pedicels was determined viscometrically from the viscosity of cellulose nitrate in acetone solutions (Mitchell method) [5]. The DP of cellulose in flax pedicels was 2600. Samples of flax fibers and pedicels were tentatively characterized by the component composition (Table 1). The chem-

Table 1. Chemical composition of flax fibers and pedicels

Component	Content, wt %	
	flax straw (flax pedicels)	short fibers
Ash	2.1	1.3

ical composition of the samples was determined using the procedures described in [6].

In contrast to cotton, flax fibers contain a larger amount of fats, waxes, pectins, and hemicelluloses, which affect the rate of cellulose carboxymethylation. Therefore, the starting materials were prepurified to remove concomitant substances: fats, waxes, and pectins. The flax fibers were treated by the procedure described in [7]. Fats and waxes were removed by treatment with a benzene–ethanol mixture in a Soxhlet apparatus. Pectins were removed by treatment of degreased fibers with aqueous solutions of HCl and ammonium citrate [8]. Flax boon was preliminarily milled in a knife mill. CMC was synthesized by two commercially used procedures: of solid-phase and suspension types [9, 10].

The solid-phase carboxymethylation of flax fibers and boon involved treatment of the starting material with 30% aqueous sodium hydroxide at room temperature for 3 h. After the alkaline treatment, the sample was squeezed to threefold weight and mixed with monochloroacetic acid (MCAA). The carboxymethylation was performed at 55°C with stirring of the reaction mixture for various periods of time. The reaction products were purified with 70% ethanol, with 90% acetic acid added to neutralize excess alkali. The final product was extracted with 70% ethanol to remove sodium chloride and sodium acetate, washed with methanol, and dried at 60°C, after which the product yield and its solubility in water were determined.

The suspension carboxymethylation of flax fibers and boon was performed as follows. The cellulose material was stirred with isopropanol for 30 min. Then, 30% aqueous sodium hydroxide was added to the reaction mixture with stirring for various periods of time. After stirring at room temperature, a calculated amount of MCAA was added. The reaction with MCAA was performed at 20 and 55°C for various periods of time. The subsequent work-up procedure was similar to that in the solid-phase carboxymethylation.

The degree of substitution (DS) of the NaCMC samples synthesized was determined from the content of carboxy groups by the formula

$$DS = 162m/(4500 - 58m), \quad (1)$$

where m is the content of carboxy groups (wt %).

The content of carboxy groups was determined by conductometric titration of the samples with 0.1 N NaOH.

The IR spectra of cellulose ethers were recorded in KBr pellets on a Bruker FS-88 IR Fourier spectrometer.

The conditions of carboxymethylation of flax fibers and boon are presented in Table 2. It is seen

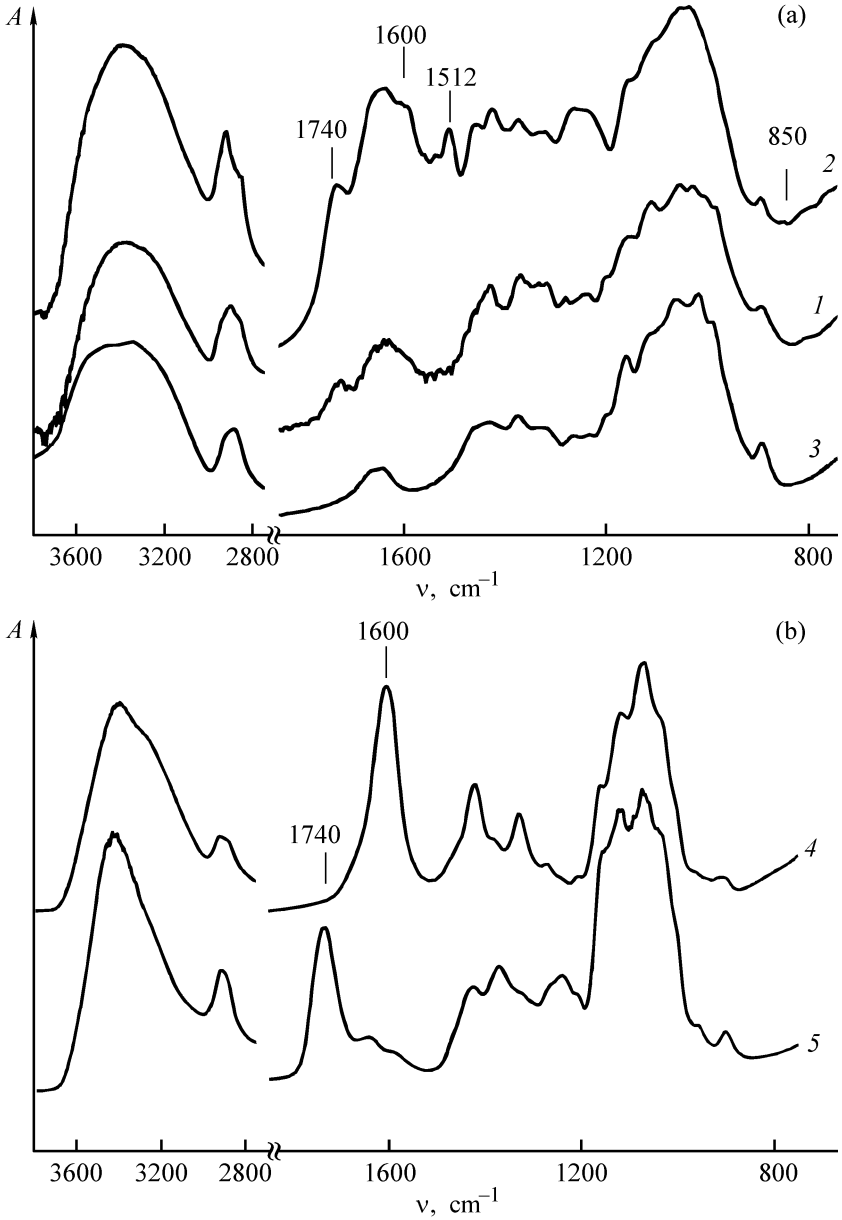

Fig. 1. IR Fourier spectra of (a) (*1*) initial flax fibers, (*2*) boon, (*3*) cotton linter, (b) (*4*) NaCMC, and (*5*) HCMC prepared from short flax fibers. (*A*) Absorption and (*ν*) wave number.

that the solid-phase and suspension procedures allow preparation of CMC partially or completely soluble in water.

To qualitatively confirm the structure of the resulting cellulose derivatives, we recorded IR spectra of the carboxymethylation products. The IR Fourier spectra of the initial short flax fibers and boon and of the resulting cellulose ethers are shown in Figs. 1a and 1b. For comparison, the IR spectrum of purified (bleached) cotton linter is shown in Fig. 1a.

The following absorption bands are typical of purified cotton cellulose: a broad band in the range 3000–3700 cm^{-1} belonging to free and H-bonded OH groups of the polymer and the band in the region of 2900 cm^{-1} corresponding to vibrations of the CH_2 and CH groups of the polymer. The absorption band at 2900 cm^{-1} in the spectrum of free cellulose is virtually symmetrical [11].

The IR spectra of crude wood pulp contain characteristic absorption bands at 1600, 1500, and 850 cm^{-1}, which are assigned to lignin [11]. Figure 1a shows that the IR spectrum of the lignified part of flax pedicels contains an absorption band appearing as a shoulder at 1600 cm^{-1}, which suggests that lignin is present

in the sample of flax pedicels (boon) in an amount comparable that in wood pulp (Table 1). In the IR spectrum of boon, there is also an absorption band in the region of 1512 cm^{-1}, typical of the aromatic structures of lignin. This band is absent in the IR spectrum of flax fibers, which may be due to a significantly smaller amount of lignin.

The characteristic bands of pectins are those at 1740 (free COOH groups of polygalacturonic acid), 1615, and 1410 cm^{-1} (symmetric and antisymmetric vibrations of ionized COO^- groups). In the range 2850–2950 cm^{-1}, there is one broad band or two bands assignable to CH_2 and CH groups [12]. It is seen that in the initial samples there is an absorption band of carboxy groups of pectin substances at 1740 cm^{-1} (Fig. 1a).

In activation of cellulose with alkali solution and carboxymethylation, hemicelluloses, pectin substances, and lignin partially dissolve, i.e., cellulose is whitened and refined. It has been shown previously [13] that, with removal of fats and pectin substances from the surface of flax fibers, the intensity of the absorption band corresponding to carboxy groups of pectins decreases. After treatment of flax fibers with a surfactant solution, the absorption band virtually desappears.

In the IR spectra of NaCMC prepared on the basis of flax fibers (Fig. 1b), there is a band in the range 1597–1605 cm^{-1}, assigned to antisymmetric vibrations of ionized carboxy groups COO [11]. In passing from NaCMC to its H form, the absorption band of COOH groups appears in the spectrum at 1740 cm^{-1}; its intensity is comparable to that of the band of residual unsubstituted OH groups of the polymer (2700–3200 cm^{-1}). In addition, in passing from ionized form to H form of CMC, an absorption band appears in the range 1200–1300 cm^{-1}, which is due to changes in the system of hydrogen bonds in the polymer [11].

It should be noted that a significant amount of lignin remains in the CMC samples synthesized on the basis of boon, which is suggested by the absorption band at 1512 cm^{-1}, observed in the spectrum of the carboxymethylated sample, as in the case of the initial sample (Fig. 1a). The presence of the residual lignin results in incomplete solubility of the CMC samples with high DP in water.

The IR data are confirmed by the results of a quantitative determination of carboxy groups in the samples by conductometric titration.

The content of carboxy groups in the water-soluble fraction of the resulting products depends on the activation time of the initial material with an alkali solution and also on the reaction time and temperature. A longer solid-phase synthesis of CMC results in an increased amount of carboxy groups and a higher DS in the resulting products. A similar trend is observed for the CMC samples synthesized by the suspension procedure. With increasing reaction temperature, the DS of the samples grows from 0.84 to 1.02 for short fibers (Table 2, run nos. 4 and 5) and from 0.36 to 1.12 for boon (run nos. 9 and 10). An increase in the amount of reagents per mole of cellulose also results in acceleration of carboxymethylation (run nos. 5, 6, 9, and 11). It should be noted that the suspension synthesis of CMC yields products with a more uniform distribution of carboxy groups in polymer macromolecules.

It is well known that NaCMC with DS ≥ 0.45–0.50 is completely soluble in water [4, 10]. Table 2 shows that the content of the water-soluble fraction in the samples synthesized by the solidphase procedure at DP = 0.56 is 60.0% (run no. 1, short fibers). The incomplete dissolution of the sample in water is due to nonuniform carboxymethylation of cellulose, caused by the presence of lignin and other concomitant substances in cellulose (Table 1). The effect of impurities (other components) on the solubility of the synthesized products is manifested to a greater extent for boon. The presence of significant amounts of lignin results in that, even at a high DS the solubility in water does not exceed 60.0%, which correlates well with the amount of lignin in the initial sample.

For a comparative estimation of how the DP of cellulose varies in carboxymethylation of flax fiber we determined the intrinsic viscosity of the NaCMC samples in 6% aqueous sodium hydroxide and evaluated the DPs of the cellulose ethers. The DP of carboxymethyl cellulose was evaluated by the expression [10]

$$[\eta] = 7.3 \times 10^3 DP^{0.93}. \quad (2)$$

It was found that, in synthesis of NaCMC from short flax fibers, the DP of the polymer decreases by 30–50%, which is caused by oxidative degradation of polymer macrochains in alkaline medium.

Thus, according to IR Fourier spectroscopy and analysis by physicochemical methods (conductometry), carboxymethyl ethers of cellulose with various degrees of substitution were synthesized from short flax fibers and lignified part of flax pedicels (boon).

CONCLUSIONS

(1) Experiments on synthesis of carboxymethyl ethers of cellulose with various degrees of substitution

from wastes formed in production of flax fibers demonstrated that the degree of substitution of the resulting cellulose ethers and their solubility depend on the activation time of the initial materials with alkali solution, temperature and duration of carboxymethylation, molar ratio of the reactants, and presence of lignin in the starting lignin materials.

(2) The study confirmed the possibility of using wastes from flax production to prepare carboxymethyl cellulose.

Abstract—Methods of preparation and purification of nanocarbon materials (nanotubes, nanobarrels, nanobulbs) from deposits formed in fullerene production were developed.

Since the beginning of extensive studies of carbon nanotubes (CNTs) and other nanostructures in 1991 [1, 2], the separation of CNTs from concomitant products (amorphous carbon, graphite, and sometimes catalyst metal particles) has become an increasingly topical problem, strongly affecting the CNT cost.

At present, the purest CNTs (< 90%) are prepared by their CVD growth in the presence of catalysts on special supports [3, 4]. In this case, the amount of amorphous carbon is relatively small, graphite is virtually absent, and catalyst metal particles can be eliminated by comparatively brief treatment with an acid. Various pathways of purification of CNTs prepared by CVD are described in [5–7] and depend on CNT type (single- or multiwalled). However, only small CNT amounts can be prepared by CVD, and, therefore, this method is not widely used today. Nevertheless, a CVD method for preparation of single-walled nanotubes containing no impurities was described in [8].

The HIPCO method [9], which is essentially similar to CVD and involves preliminary synthesis of catalyst particles in the gas phase, gives CNTs with a high content of excess catalyst, which requires a complex purification procedure [10].

Very complex treatment is required for CNT-containing raw material obtained by electric arc synthesis, which is the most productive now [11, 12]. According to [13], the purification procedure in the arc synthesis of single-walled CNT with a catalyst must be multistep. However, this method (arc + catalyst) is also inefficient and is claimed only when just single-walled CNTs are required.

When multiwalled CNTs with varied size and orientation are applicable (e.g., as catalysts, hydrogen accumulators, etc.), a common noncatalytic arc method of CNT preparation is used [11]. In this case, a deposit formed on the cathode during recrystallization of the carbon evaporated from the anode surface is the source of CNTs. An apparatus for fullerene generation, produces during continuous work for one day, up to 1 kg of soot and 200–300 g of a deposit containing up to 10 g of CNTs [14].

These amounts of the deposit require that strongly different treatment procedures should be used to separate amorphous carbon and graphite constituents. For example, it was shown in [15] that selective oxidation in air at 700°C proceeds slowly. The deposit ground to 50–100-nm particles loses no more than 50% of the initial weight upon a 12-h treatment. Other gaseous oxidants were also ineffective. Rotation of the working volume of a tubular furnace substantially accelerates the treatment of the ground deposit [13]. However, this technology is suitable only for a small volume of the material treated. Treatment with acids [16] is only efficient at continuous addition of fresh portions of the acid and small amounts of the deposit (a few grams per 100 ml of working volume). Treatment of larger amounts is possible in a countercurrent

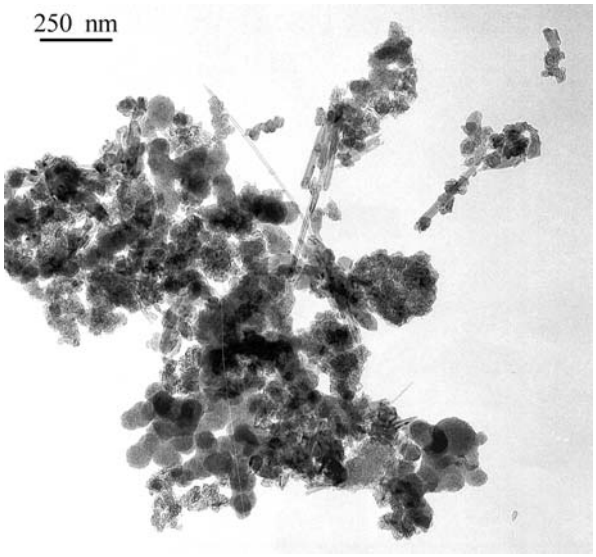

Fig. 1. Electron micrograph of the ground initial deposit.

Soxhlet apparatus. However, the acid is rapidly deactivated in this case. In our experiments, boiling of 10 g of the deposit in a tenfold excess $HClO_4$ under atmospheric pressure decreases the deposit weight by no more than 20% in the first 3 h, and then the weight loss stops completely (5 h of treatment). Oxidation through intercalation of the graphite component of the deposit with a KCl + $CuCl_2$ aqueous solution described in [17] is also time consuming (4–6 days). A hydrothermal method of CNT purification has also been described [18]. It is known that superheated steam exhibits fairly strong oxidizing properties at the near-critical pressures (~400 atm) [19, 20]. Unfortunately, the required high-pressure apparatus is very complex, and, as it follows from [18], the weight of the material being treated cannot be large (no more than 1 g per 100 ml).

Here we describe several simple and unconventional methods for purification of the cathodic deposit containing CNTs, which are based on selective decomposition of its amorphous and graphite constituents.

The initial cathodic deposit was obtained as a by-product in the synthesis of a fullerene-containing soot on a device developed at Innovations of Leningrad Institutes and Enterprises Closed Joint-Stock Company, described in [14, 21]. This device is mainly intended for fullerene production (up to 4.5 kg of fullerene-containing soot per day; content of fullerene mixture in soot 12–15 wt %). The conditions were not optimal with respect to production of the deposit and CNTs: the pressure in the working chamber was lower than optimal 300 torr and the current density was about 320 A cm^{-2}. The device productivity for the deposit is 800–1200 g per day, and the content of the carbon nanostructures in the deposit (various nanotubes, nanobarrels, and nanobulbs) is 3–5 wt %. A typical electron micrograph of the ground deposit, obtained on a JEM-100S transmission electron microscope (JEOL, Japan) at a 10^4–10^5 magnification, is shown in Fig. 1. Spheroid particles of nanocarbon phases, single- and multiwalled nanotubes nanobarrels, and nanobulbs, soldered in nonnanocarbon structures, are seen.

The cathodic deposit ground in a ball mill (50–100-μm fraction) was soaked in 20 wt % aqueous solution of $(NH_4)_2MoO_4$. Carbon particles were well wetted with this solution and formed a stable suspension. A further study showed that the same result, complete wetting of the cathodic deposit, is attained in aqueous solutions of NH_4NO_3 and NH_4Cl. However, these solutions were less technologically effective. The suspension was treated (up to 3 times) as follows: freezing in a Peltier refrigerator to –35°C and thawing at 20°C in order to cleave graphitic layers in the graphite component of the deposit through expansion of the ice formed, after which the deposit was washed in water to neutral pH and dried at 100°C. This material is oxidized more readily than the initial deposit. The material obtained was oxidized with atmospheric oxygen at 700–800°C. Annealing in air for 3–5 h gave a weight loss of 50 to 95% relative to the initial deposit. The residue contained nanostructures (mainly multiwalled nanotubes and a small amount of single-walled nanotubes, nanobarrels, and nanobulbs). The content of nanostructures increased by an order of magnitude and reached 50 to 90 wt %. An electron micrograph of a sample enriched with CNT after oxidation in a furnace of 80% of the initial deposit is shown in Fig. 2. The content of the sum of nanomaterials was about 60 wt % (40% multiwalled CNT and 60% nanobarrels and nanobulbs; single-walled nanotubes were virtually absent).

Along with intercalation (and subsequent oxidation) of the graphite constituent of the deposit, selective dissolution can be used. Similarly to intercalation, the latter should initially dissolve,during reaction with the liquid oxidant, the more reactive part of the deposit, graphitic and amorphous carbon, and only then structurally regular nanotubes, nanobarrels, and nanobulbs. The oxidant can be taken in deficiency with account of the relative content of nanotubes in the deposit. This idea was implementeded with two efficient solvents of carbon: a mixture of $KClO_3$ (10 wt %) with concentrated nitric acid (65 wt %) and a mixture of CrO_3 (5 wt %) with concentrated sulfuric acid (70 wt %). During treatment of the ground deposit

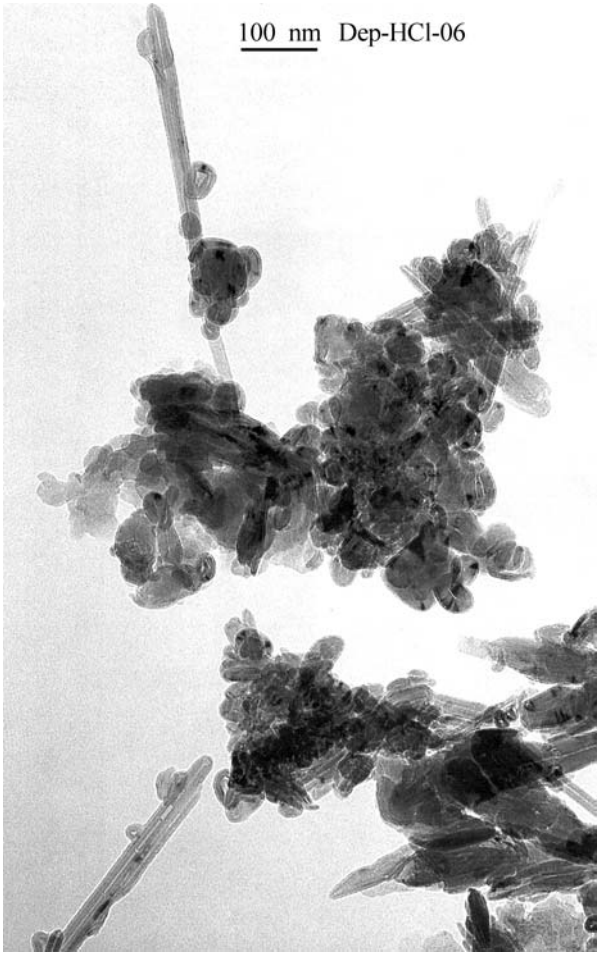

Fig. 2. Electron micrograph of the deposit prepared by intercalation of the graphite constituent with water followed by gas-phase oxidation with air.

with the above oxidants at 80–85°C, the nonnanocarbon part of the deposit is oxidized to carbon monoxide and is eliminated from the reaction zone. Despite that a small part of nanocarbon material is also decomposed (mainly the most brittle single-walled CNTs), the deposit material is substantially enriched with carbon nanostructures. The enrichment level is close to that obtained by intercalation followed by gas-phase oxidation, and the method is somewhat more technologically effective. Electron micrographs of samples prepared by this method are virtually the same as that in Fig. 2.

Abstract—Samples of a continuous series of $Ba_{3-x}Sr_xSm(BO_3)_3$ solid solutions ($0 < x < 3$), crystallizing in the trigonal crystal (system, space group $R\bar{3}$) were synthesized by solid-phase reactions. Formation of a continuous series of solid solutions in the system was confirmed by X-ray phase analysis. The X-ray characteristics of phases of variable composition were determined.

Complex borates $M_3R(BO_3)$, where M is alkaline-earth element Ba or Sr and R is rare-earth element (REE) [1–6], are of interest as materials for microelectronics and nonlinear optics. Variation of the cationic composition allows purposeful synthesis of phases and makes it possible to elucidate the influence exerted by the composition and structure on their characteristics. Since double borates $Ba_3Sm(BO_3)_3$ and $Sr_3Sm(BO_3)_3$ crystallize in the same structural type [3, 4], formation of a continuous series of solid solutions would be expected.

In this study, we examined the possibility of formation of solid solutions based on double borates of alkaline-earth elements and samarium, with the composition $Ba_{3-x}Sr_xSm(BO_3)_3$, by isovalent substitution of Sr^{2+} for Ba^{2+}. The x value was varied from 0 to 3 with a step of 0.5.

EXPERIMENTAL

Polycrystalline samples were synthesized by solid-phase reactions from Sm_2O_3 (content of the main component no less than 99.99%), $BaCO_3$ and $SrCO_3$ of ultrapure grade, and H_3BO_3 of chemically pure grade. Mixtures of stoichiometric amounts of the initial reagents were calcined in platinum crucibles in air with repeated intermediate grindings. Barium and strontium carbonates were preliminarily annealed at 400°C, and samarium oxide, at 800°C, for 5 h. The synthesis temperature was gradually raised from 600°C to 1000°C, with a step of 100°C, over a period of 70–80 h. Single-phase samples were prepared by annealing at 1000°C for 20–25°C. The phase composition of the compounds studied and the attainment of equilibrium were monitored by X-ray phase analysis (Bruker D8 Advance diffractometer, Cu_{K_α} radiation, graphite monochromator).

The X-ray patterns diffraction of all the compounds obtained (Fig. 1) are similar in the positions and rela-

tive intensities of the reflections. The powder X-ray patterns of the variable-composition phases were indexed using X-ray data for $Ba_3Sm(BO_3)_3$ (trigonal crystal system, space group $R\bar{3}$) [3] on the assumption that these phases are isostructural. The results of indexing of the powder X-ray pattern of $Ba_{1.5}Sr_{1.5}Sm(BO_3)_3$ are presented in the table. The unit cell parameters were refined by the least-squares method in the range of angles 2θ 10°–60°, using the LATTIC software.

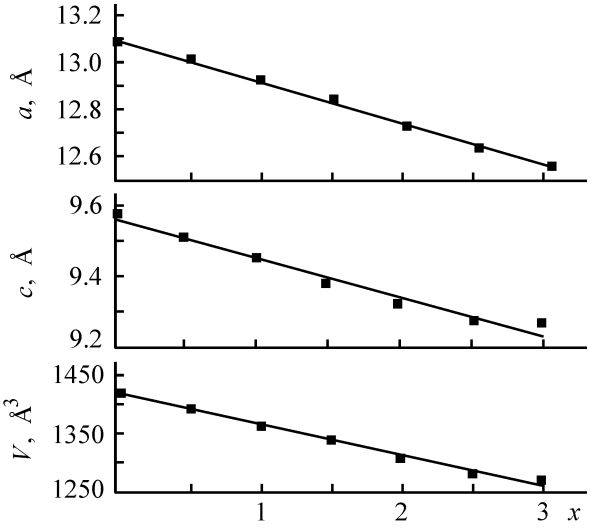

Fig. 2. Parameters a and c and unit cell volume V vs. the degree of Sr substitution for Ba, x, in $Ba_{3-x}Sr_xSm(BO_3)_3$ ($0 < x < 3$).

According to published data [7], the ionic radii of bivalent cations Ba^{2+} and Sr^{2+} for the coordination number 9 realized in this structural type are 1.47 and 1.31 Å, respectively. Analysis shows that the triple phases obtained are substitutional solid solutions based on the double borate $Ba_3Sm(BO_3)_3$ crystallizing in the trigonal crystal system (space group $R\bar{3}$). The concentration dependences of parameters a and c of the rhombohedral units and also unit cell volumes V for $Ba_{3-x}Sr_xSm(BO_3)_3$ are shown in Fig 2.[1] It is seen that, with increasing degree of Sr substitution for Ba, x, in the solid solutions studied, parameters a, c, and V decrease linearly.

The similarity of the X-ray diffraction patterns of all the samples and linear dependences of the unit cell parameters on the composition suggest that a continuous series of solid solutions is formed.

CONCLUSIONS

(1) Previously unknown phases of variable composition, $Ba_{3-x}Sr_xSm(BO_3)_3$ ($0 < x < 3$), were synthesized by solid-phase reactions from barium and strontium carbonates, samarium oxide, and boric acid.

(2) An X-ray phase analysis showed that the resulting ternary phases are isostructural and form a continuous series of substitutional solid solutions.

Oxidative Degradation of Neonol AF 9-12

Yu. N. Kozyreva, E. N. Kolesnikova, N.A. Glukhareva, and O.E. Lebedeva

Belgorod State University, Belgorod, Russia

Received August 22, 2005

Abstract—The oxidative degradation of a difficultly degradable surfactant, oxyethylated isononylphenol (Neonol AF 9-12), with aqueous hydrogen peroxide containing iron(III) chloride was studied tensimetrically.

The wide application of surfactants, primarily, household chemicals, leads to wastewater pollution with these agents. As a rule, surfactant-containing municipal wastes of large cities are treated at wastewater treatment plants in combination with some industrial wastes. However, biodegradation of some surfactants is not sufficiently fast to decrease their content in decontaminated wastewater to the level of the maximum permissible concentration (MPC). Oxyethylated alkylphenols, the only type of nonionic surfactants produced in Russia, belong to extremely slowly degradable "biologically hard" surfactants. To remove these surfactants from wastewater, local treatment facilities and specific physicochemical technique are required [1].

Published methods for water treatment to remove oxyethylated alkyphenols are few. The degradation of Igepal CA 520 commercial product mainly consisting of oxyethylated octylphenol with varied degree of oxyethylation was studied in [2]. It was found that UV light (365 nm) decomposes this surfactant in the presence of iron(III).

The oxidative degradation of oxyethylated alkylphenols shows much promise in view of the fact that this procedure has been successfully used for degradation of other chemically resistant xenobiotics. The Fenton reagent [mixture of hydrogen peroxide with iron(II) or iron(III) salts] is one of the most efficient oxidants [3]. The iron cations present in this reagent induce the hydrogen peroxide decay by a radical mechanism.

The oxidative degradation of oxyethylated isononylphenol with hydrogen peroxide in the presence of iron(III) was studied in [4]. It was found that this surfactant is effectively decomposed by hydrogen peroxide. In this study, with Neonol AF-9-12 as an example, we attempted to evaluate the extent of its oxidative degradation under the action hydrogen peroxide and to find the optimal conditions of this process.

EXPERIMENTAL

In our experiments, we used oxyethylated isononylphenol with an average degree of oxyethylation of 12 (Neonol AF 9-12, Neonol) produced by Nizhnekamskneftekhim Limited Liability Company in accordance with TU (Technical Specifications) 38.507-63-300–93.

Neonol was subjected to oxidative degradation by its treatment with aqueous hydrogen peroxide in the presence of iron(III) at varied concentrations of these reagents. The oxidant solutions were prepared in twice-distilled water.

The Neonol oxidation was monitored by surface tension measured by the ring detachment technique on a Kruss tensimeter at room temperature (23°C).

In all the experiments, the Neonol concentration was 6.7×10^{-5} M. This value is lower than the critical micelle concentration (CMC) of Neonol. Therefore, even minor variations in the Neonol concentration give rise to noticeable changes in the surface tension. In contrast, at the surfactant concentration exceeding CMC, the surface tension is insensitive to the surfactant concentration.

The surface tension at the initial Neonol concentration was 38 mN m^{-1}. On adding hydrogen peroxide to aqueous Neonol, the surface tension did not change significantly: the surface tension was 37.5 mN m^{-1} in 1 h, and 34 mN m^{-1} after 1 day. On keeping aqueous Neonol without adding hydrogen peroxide for 1 day, the surface tension decreases to a similar extent owing to attainment of the equilibrium sorption of Neonol at the interface between the aqueous surfactant and air.

A different pattern is observed after adding H_2O_2 in combination with a Fe(III) salt to aqueous Neonol. In this mixture, the surface tension noticeably increases after 15 min (see Fig. 1a), and this increase

1070-4272/05/7812-2024 © 2005 Pleiades Publishing, Inc.

reaches a maximum after approximately 1 h. We believe that this increase in the surface tension is caused by a decrease in Neonol concentration due to its oxidative degradation.

In the initial experiments, the iron(III) chloride concentration was kept constant (10 mM), while the hydrogen peroxide concentration was varied. Figure 1a shows that the maximum surface tension substantially depends on the H_2O_2 concentration. At a H_2O_2 concentration of 16.5 mM, Neonol degrades only partially. At a H_2O_2 concentration 66.0 mM, the surface tension reaches 67–68 mN m^{-1}, suggesting a high degree of Neonol degradation.

Further studies showed that the degree of Neonol degradation is also influenced by the Fe(III) concentration. Figure 1b demonstrates how the surface tension changes in the system with a constant H_2O_2 concentration (56 mM) and variable Fe(III) content.

We found that the initial rate of Neonol oxidation increases with the iron(III) content. After the completion of the experiment, the surface tension of the final solution was 71 mN m^{-1}. Comparison of this value with the surface tension of twice-distilled water (72.5 mN m^{-1}) shows that, in our experiments, the Neonol degradation was virtually complete, because, otherwise, the surface tension whould decrease.

With increasing iron(III) concentration, the initial rate of Neonol oxidation grows but the surface tension of the solution decreases after the completion of the experiment (see Fig. 1b). It is possible that the Neonol oxidation was incomplete under these conditions.

It is known that, in oxidation of Neonol with H_2O_2 in the presence of Fe(III), radicals are generated by the reaction

$$Fe^{3+} + H_2O_2 = Fe^{2+} + HOO^{\cdot} + H^+.$$

In accordance with the stoichiometry of this reaction, the most efficient oxidation of Neonol should be reached at an approximately equimolar ratio of H_2O_2 and Fe(III) in the reaction mixture. In the first step of Neonol oxidation, the $HOO^{\cdot}$ radical ruptures one of bonds in the Neonol molecule by the scheme

$$HOO^{\cdot} + RH \rightarrow H_2O_2 + R.$$

To reach complete oxidation of oxyethylated nonylphenol, a large amount of these radicals is required.

CONCLUSIONS

(1) The oxidative degradation of Neonol with hydrogen peroxide in the presence of Fe(III) allows efficient removal of this surfactant from wastewater.

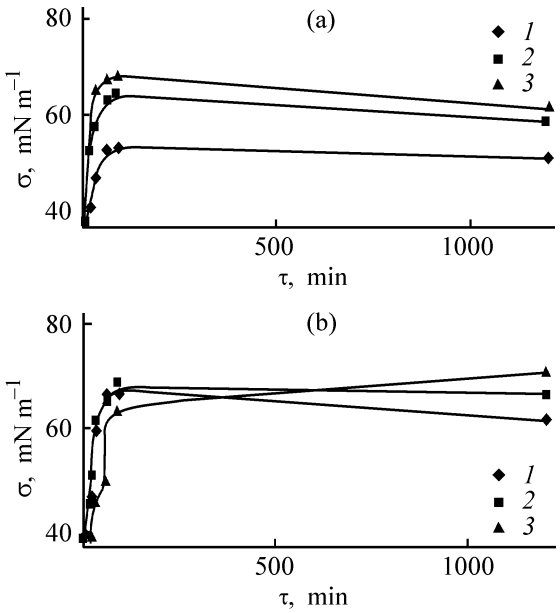

Fig. 1. Variation of surface tension σ with time τ in the course of oxidative degradation of Neonol. (a) $FeCl_3$ concentration 10 mM; H_2O_2 concentration, mM: (*1*) 16.5, (*2*) 33, and (*3*) 66. (b) H_2O_2 concentration 56 mM; $FeCl_3$ concentration, mM: (*1*) 10, (*2*) 2.5, and (*3*) 1.25.

(2) The rate and completeness of surfactant oxidation can be controlled by varying the oxidant content. At optimal ratio of hydrogen peroxide and iron(III) chloride, the surface tension of solution contaminated with the surfactant becomes approximately equal to that of twice-distilled water, which indicates that the surfactant degradation is virtually complete.

(3) Oxidative degradation of surfactants can be used instead of biodegradation technique or in combination with it to rupture the strongest bonds in the surfactant molecules. The development of an efficient technique for water treatment to remove Neonol can prolong the commercial use of surfactants of this kind until new softer nonionic surfactants is developed.

BRIEF COMMUNICATIONS

Synthesis of 1-Alkoxy-3-*N*-succinimido-2-propanols

R. A. Gasanov and M. A. Allakhverdiev

Institute of Chemistry of Additives, National Academy of Sciences of Azerbaijan, Baku, Azerbaijan

Received June 22, 2004; in final form, October 2005

Abstract—Procedures for preparing 1-alkoxy-3-chloro-2-propanols, with their subsequent transformation to 1-alkoxy-*N*-succinimido-2-propanols, were developed.

N-Substituted succinimides show a wide spectrum of pharmacological properties [1, 2]. They are effective against convulsions caused by Metrazole and electric shocks; some of them have also proved to be effective against epilepsy. Many *N*-aryl-substituted succinimides have been tested for activity and toxicity; among these compounds, *N*-*p*-xylylsuccinimide is the most promising as anticonvulsant [1–3]. 2-Ethyl-3-methyl-3-phenylsuccinimide exhibits sedative, anticonvulsive, and tetragenic properties [4]. Other nontoxic highly active anticonvlusants for treating apoplectic shocks are *N*-methyl-2-phenyl-2-ethylsuccinimide and *N*-methyl-2-phenyl-3-methylsuccinimide [5]. *N*-Methyl-2-phenylsuccinimide (Milontin) is an antiepileptic drug and is used as a reference for comparing the anticonvulsive activities [6].

In this context, synthesis of *N*-substituted succinimides by the reaction of sodium succinimide with 1-alkoxy-3-chloro-2-propanols is a topical problem. The first step is to prepare sodium succinimide **III** by the reaction of sodium isopropylate **I** with succinimide **II**:

$$\underset{\mathbf{I}}{(CH_3)_2CHONa} + \underset{\mathbf{II}}{\begin{matrix}CH_2—CO\\|\\CH_2—CO\end{matrix}>NH} \xrightarrow{-(CH_3)_2CHOH} \underset{\mathbf{III}}{\begin{matrix}CH_2—CO\\|\\CH_2—CO\end{matrix}>NNa.}$$

Reactions of sodium succinimide with 1-alkoxy-3-chloro-2-propanols **IV**–**IX** are carried out at 70–75°C in the course of 3 h and yield the corresponding *N*-substituted succinimides **X**–**XV** (see table):

$$\underset{}{\begin{matrix}CH_2—CO\\|\\CH_2—CO\end{matrix}>NNa} + \underset{\mathbf{IV}–\mathbf{IX}}{ClCH_2CH(OH)CH_2OR} \xrightarrow{-NaCl} \underset{\mathbf{X}–\mathbf{XV}}{\begin{matrix}CH_2—CO\\|\\CH_2—CO\end{matrix}>NCH_2CH(OH)CH_2OR,}$$

where R = CH_3 (**IV**, **X**); C_2H_5 (**V**, **XI**); C_3H_7 (**VI**, **XII**); C_4H_9 (**VII**, **XIII**); C_5H_{11} (**VIII**, **XIV**); C_6H_{13} (**IX**, **XV**).

Yields, boiling points, refractive indices, and elemental analyses of substituted succinimides **X**–**XV**

1070-4272/05/7812-2026 © 2005 Pleiades Publishing, Inc.

The starting 1-alkoxy-3-chloro-2-propanols **IV**–**IX** were prepared by reactions of epichlorohydrin with aliphatic alcohols in the presence of $ZnCl_2$ (yield 80–90%). It should be noted that alternative procedures are also known [7, 8]. In particular, Floress Gallardo and Pollard [7] reacted epichlorohydrin with aliphatic alcohols in the presence of H_2SO_4; the yield of the target products did not exceed 55%. With $BF_3 \cdot OEt_2$ used as acid catalyst [8], the yield of the target products did not exceed 55%, either.

In both the studies cited, the yield of the target product was relatively low, and one of the reactants was taken in a large excess (threefold or sixfold excess of aliphatic alcohol, or sixfold excess of epichlorohydrin). Furthermore, $BF_3 \cdot OEt_2$ used in [8] is expensive and toxic.

We tested as acid catalysts in the reactions of epichlorohydrin with aliphatic alcohols both Brønsted (H_2SO_4, $HClO_4$) and aprotic Lewis acids ($AlCl_3$, $SnCl_4$, $ZnCl_2$). The best result was obtained with $ZnCl_2$. When the reaction was performed at the equimolar ratio of the alcohol and epichlorohydrin in the presence of 1.2 wt % $ZnCl_2$ (relative to the sum of the reactants) at the boiling point of the alcohol for 2.5–3 h, the yield of 1-alkoxy-3-chloro-2-propanols **IV**–**IX** reached 80–90%. Thus, the procedure is improved by eliminating the excess of one of the components, using a cheaper catalyst, and making shorter the reaction time.

The reaction course and the accumulation of 1-alkoxy-3-chloro-2-propanols were monitored by gas–liquid chromatography on a Tsvet-104 device (flame ionization detector; 200×0.03-cm column packed with 5% polyethylene glycol adipate on Porapak; sample volume 0.1 μl; P_{He} 0.8 kg cm^{-2}; paper feed velocity 240 mm h^{-1}; column temperature 140°C; vaporizer temperature 200°C).

The composition and structure of substituted succinimides **X**–**XV** were confirmed by elemental analysis, IR and NMR (^{1}H, ^{13}C) spectroscopy, and TLC.

The IR spectra of substituted succinimides **X**–**XV** contain bands at 3604–3598 (free OH groups), 3537–3532 (intramolecular hydrogen bond), and 1715–1705 cm^{-1} (C=O).

The highest-field signal in the ^{1}H NMR spectra of **X**–**XV** is the triplet of the terminal methyl group (3H) at 0.9–1.0 ppm. The OCH_2 protons give a multiplet at about 2.9 ppm. A broad singlet centered at 4.15–4.20 ppm belongs to the hydroxyl proton. The methine proton appears as a multiplet at about 3.71 ppm. Two methylene groups of the succinimide ring give a singlet at 4.8–5.7 ppm. In the ^{13}C NMR spectrum, the C=O signals are observed at 178–237 ppm.

EXPERIMENTAL

The ^{1}H NMR spectra were measured on a Bruker spectrometer operating at 300 MHz, and the IR spectra, on a Specord 75-IR spectrophotometer (thin films).

The purity of the products and the reaction progress were monitored by TLC on Silufol UV-254 plates, with isopropyl alcohol–heptane (1 : 5) as eluent.

1-Propoxy-3-chloro-2-propanol. A three-necked flask was charged with 6 g of 1-propanol, 9.3 g of epichlorohydrin, and 0.2 g of $ZnCl_2$. The mixture was heated at 90–95°C for 3 h, after which the product was cooled and vacuum-distilled. Yield 13 g (85%), bp 95–96°C (20 mm Hg), n_D^{20} 1.4391. Published data [7]: bp 97–98°C (20 mm Hg), n_D^{20} 1.4378.

Other 1-alkoxy-3-chloro-2-propanols **IV**–**IX** were prepared similarly; their constants agree with published data [7, 8].

1-Propoxy-3-*N*-succinimido-2-propanol XII. A three-necked flask equipped with a reflux condenser, dropping funnel, thermometer, and stirrer was charged with 50 ml of 2 propanol, after which 4.6 g of finely divided sodium metal was added with vigorous stirring. When the whole amount of sodium dissolved, the mixture was cooled, 19.8 g of succinimide was added, and the mixture was stirred on a water bath at 70–75°C for 1 h. After that, 1-propoxy-3-chloro-2-propanol was added dropwise over a period of 20 min. The resulting mixture was heated on a water bath at 90°C for 3 h and then cooled; the NaCl precipitate was filtered off. The 2-propanol was distilled off in a water-jet-pump vacuum, and the product was vacuum-distilled. Yield of the substituted succinimide 23 g (53%), bp 168°C (20 mm Hg), n_D^{20} 1.4847.

Found, %: C 55.39, H 8.13, N 6.52.
$C_{10}H_{17}NO_4$.
Calculated, %: C 55.80, H 7.96, N 6.51.

N-Substituted succinimides **X**–**XV** were prepared similarly.

CONCLUSIONS

(1) The optimal conditions of the reaction of epichlorohydrin with aliphatic alcohols in the presence of

$ZnCl_2$ were found, and 1-alkoxy-3-chloro-2-propanols were obtained in 80–90% yields.

(2) A procedure was developed for preparing 1-alkoxy-3-*N*-succinimido-2-propanols in 48–60% yield from 1-alkoxy-3-chloro-2-propanols and sodium succinimide.

Abstract—Heat of solution of salsoline salsolinodithiocarbamate (SS) at 1 : 18000, 1 : 36000, and 1 : 72000 dilution (mol per mol H_2O) was determined on a DAK-I-IA calorimeter, and the standard heat of solution at infinite dilution was estimated. The temperature dependence of the heat capacity of SS was studied over the range 173–348 K. The heats of combustion and fusion, and the standard heat of formation of liquid (molten) and crystalline SS were estimated by indirect methods.

Sulfur-containing alkaloids, among them dithiocarbamates, are of practical interest for developing highly effective domestic drug preparations from plant raw materials [1–4].

Determination of the fundamental thermodynamic characteristics of natural alkaloids and their synthetic derivatives is of considerable theoretical and practical interest for physicochemical simulation of their reactions and for standardization of drug substances on their basis.

Therefore, the goal of this study, was to measure by calorimetry the heat of solution of salsoline salsolinodithiocarbamate (SS) in water, to examine the temperature dependence of its heat capacity over the range 173–348 K, and to characterize its thermodynamic properties.

The heat of SS solution was measured on a DAK-I-IA automatic differential isothermal calorimeter at 25°C. The theory and procedure of the calorimetric experiment were described in detail in [5–8]. The performance characteristics of the calorimeter were as follows: temperature range 25–200°C, ampule volume 8 ml, sensitivity in the direct mode of measurement of the thermoelectric voltage less than 0.012 μV, and uncertainty of the measured thermal effects within 2.0%. Thermal effects were recorded on a KSP-4 potentiometer and then quantified using an IP-4 high-precision integrator. The preliminary thermostating time was 2 h. The sample was placed into a metallic ampule, which was inserted in a metallic cylinder with a solvent.

The system was tested by measuring the heat of solution of triple-recrystallized KCl at dilutions of 1 : 1600, 1 : 2400, and 1 : 3200 (mol per mol H_2O). The value we measured, $\Delta H_s = 17780 \pm 262$ J mol^{-1} (25°C), is well consistent with that recommended in [9, 10].

The errors of the experiments and the homogeneity of their variances were estimated using the Student and Bartlett tests [11].

The heat capacity of SS was measured over the range 173–348 K on an IT-S-400 dynamic calorimeter. It took about 2.5 h to carry out measurements over the entire experimental temperature range and to process the data. According to the equipment certificate, the upper limit of the error of the calorimeter is 10%. To calibrate the calorimeter, we measured its thermal conductivity K_T [12, 13]. For this purpose, we carried out a series of blank experiments with a copper sample and empty ampule. The thermal conductivity was estimated by Eq. (1)

$$K_T = C_{Cu}/(\bar{\tau}_{Cu} - \bar{\tau}^0), \quad (1)$$

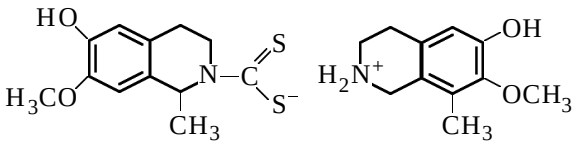
348	1.3085 ± 0.0392	605 ± 40

where C_{Cu} is the total heat capacity of the copper sample (J mol^{-1} K^{-1}); $\bar{\tau}_{Cu}$, mean delay time of the calorimeter in the blank experiments (s); and $\bar{\tau}^0$, mean time.

The specific heat capacity was measured at 25 K intervals.

The sample was placed in a metallic ampule of the measuring cell and heated by a continuous heat flux through the calorimeter. The time delay of the sample temperature relative to the base temperature was measured at 25 K intervals.



As in the case of calibration, five replicate runs were carried out with the samples investigated, and the experimental data were processed statistically [8].

At each temperature, we estimated the root-mean-square deviation $\bar{\delta}$, for the averaged specific heat capacity and the random error $\mathring{\Delta}$ for molar heat capacity.

The combustion heat was estimated by the Karash–Frost method [14], and the enthalpy of melting, by the equation recommended in [15]. The enthalpy of SS formation, $\Delta_f H^0_{298.15}$, was estimated using the Hess cycle from ΔH^0_{comb} and reference data on the heats of formation of the reagents.

EXPERIMENTAL

The crystals of SS ($C_{23}H_{30}N_2O_4S_2$) were prepared at the Institute of Organic Synthesis and Coal Fuel Chemistry (Karaganda, Kazakhstan). The quality of the product corresponded to chemically pure grade (mp 160°C). The structural formula of SS is given below.

A calorimetric determination of the heat of solution of SS was carried out in water at the 1 : 18 000, 1 : 36 000, and 1 : 72 000 dilutions (mol per mol H_2O). The results are listed in Table 1.

From the averaged data on the enthalpies of SS solution at various dilutions ($\Delta\bar{H}_1^m$, $\Delta\bar{H}_2^m$, $\Delta\bar{H}_3^m$), using the known relationship $\Delta H_s^m = f\sqrt{m}$ (m is the molal concentration), we derived Eq. (2) [16]:

$$\Delta H_s^m = 98.58 + 2918.5\sqrt{m},\ \text{kJ mol}^{-1}. \quad (2)$$

From this linear expression we determined the standard enthalpy of SS solution at infinite dilution (98.58 ± 1.48 kJ mol^{-1}). It should be pointed out that the enthalpy of solution decreases linearly with increasing dilution. As mentioned above, the heat capacity of SS was measured on an IT-S-400 calorimeter over the range 173–323 K, since the melting point of SS is 433 K. As a coolant we used liquid nitrogen.

The experimental specific and molar heat capacities are listed in Table 2.

From these data we derived a polynomial expression for the temperature dependence of the heat capacity (J mol^{-1} K^{-1}):

$$C_p^0 = (604 \pm 40) + (144 \pm 9) \times 10^{-3}T - (60.1 \pm 4.0) \times 10^5 T^{-2}. \quad (3)$$

To determine the standard enthalpy of formation of $C_{23}H_{30}N_2O_4S_2$, we estimated the heats of combustion and fusion, using the empirical methods [14, 15]. The mean heat of combustion, estimated by the Karash and Frost equations [14], is $\Delta H^0_{comb} = -12\,889 \pm 395$ kJ mol^{-1}. The standard enthalpy of SS formation in the liquid (molten) state was determined by Eq. (4) using the $\Delta_f H^0_{298.15}$ values for $CO_{2(g)}$, $H_2O_{(l)}$, and $SO_{2(g)}$ from [17].

$$C_{23}H_{30}N_2O_4S_{2(l)} + 53.5O_{2(g)} = 23CO_{2(g)} + 15H_2O_{(l)} + N_{2(g)} + 2SO_{2(g)} - \Delta H^0_{comb}. \quad (4)$$

To determine $\Delta_f H^0_{298.15}$ of crystalline SS, we estimated its heat of fusion ΔH_m, using the Gambill equation [15] (283.0 kJ mol^{-1}).

$$\Delta_f H^0_{298.15,\, C_{23}H_{30}N_2O_4S_{2(cr)}} = \Delta_f H^0_{298.15,\, C_{23}H_{30}N_2O_4S_{2(l)}} - \Delta H_m. \quad (5)$$

The standard enthalpy of formation of crystalline SS, estimated by Eq. (5), is –1330.0 kJ mol^{-1}.

CONCLUSIONS

(1) The first calorimetric study of the alkaloid derivative, salsoline salsolinodithiocarbamate, was made to determine the standard heat of solution in water at infinite dilution, heats of combustion and melting, and also the standard heats of formation of $C_{23}H_{30}N_2O_4S_2$ in the liquid (molten) and crystalline states.

(2) The temperature dependence of the heat capacity of $C_{23}H_{30}N_2O_4S_2$ was studied over the range 173–348 K. The C_p^0(298.15 K) was determined and an equation for the temperature dependence was derived.

Separation of Titanium from Niobium and Tantalum via Complexation of Titanium with Fluoride Ions

V. N. Lebedev

Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Raw Materials, Kola Scientific Center, Russian Academy of Sciences, Apatity, Murmansk oblast, Russia

Received March 25, 2005

Abstract—Conditions in which niobium and tantalum can be separated in the presence of fluoride ions from titanium-containing products formed in processing of loparite were studied.

In decomposition of a loparite concentrate with nitric or hydrochloric acid, titanium(IV), niobium(V), and tantalum(V) are recovered into a combined concentrate, which is for the most part a hydrated cake [1–3]. In the sulfuric acid technology of loparite, titanium(IV) is recovered as a binary salt and, in the extraction separation of niobium(V) and tantalum(V), a fluoride is expended virtually only for these elements. At the same time, in processing of the overall product, the fluoride is also required for formation of fluorotitanic(IV) acid, which results in an increased expenditure of hydrofluoric acid and a stronger operating load on the equipment.

Previously, the possibility of recovering titanium(IV) by its selective transfer to solution upon introduction of fluoride ions has been considered [4–6]. A prerequisite in this case is that niobium(V) and tantalum(V) form readily soluble stable complexes with titanium(IV), which decompose in the presence of fluoride ions, because titanium(IV) is a stronger fluoride-acceptor [7]. The destruction of the complexes results in precipitation of the less soluble niobium(V) and tantalum(V). Positive results were obtained in [4] in selective hydrolytic precipitation of niobium(V) and tantalum(V) from model sulfate solutions in the presence of 2 mol of fluoride ions per 1 mol of TiO_2. A poorer separation of titanium(IV) and niobium(V) was achieved in [5], with the optimal results obtained at the molar ratio F^-:Ti(IV) = 3. There is a US patent [6] on selective leaching-out of titanium(IV) from precipitated hydroxides by introduction of fluoride ions.

The separation of titanium from technological products obtained in large-scale experiments with various versions of the hydrochloride technology of loparite was studied in [2, 3].

EXPERIMENTAL

A hydrated cake (74, 14.8, and 1.1 wt % TiO_2, Nb_2O_5, and Ta_2O_5, respectively) and acid chloride solution (40.8, 5.8 and 0.27 g l^{-1} of TiO_2, Nb_2O_5, and Ta_2O_5, respectively) were used in the experiments. The chloride solution was a re-extract obtained in separating the sum of titanium(IV), niobium(V), and tantalum(V) from rare-earth elements by extraction with octanol. The proportion of the components points to loss of niobium(V) and, to a greater extent, tantalum(V) during the extraction.

The hydrated cake was treated with various acids in fluoroplastic beakers under reflux at 85°C for 3 h. The precipitates formed were separated on a vacuum filter and analyzed by the X-ray fluorescence method. The data obtained are listed in Table 1. It follows

Table 3. Precipitation of niobium(V) and tantalum(V) from acid chloride solutions

$F^-:TiO_2$ mole ratio	Phase	Content of the sum of Ti, Nb, and Ta oxides, g	HCl concentration, M	Content of indicated oxide, wt %, in the phases		Recovery, %	
				TiO_2	Nb_2O_5	TiO_2	Nb_2O_5
2.0	Solution	1.9	1.9	61.6	1.7	29.0	5.3
	Precipitate	3.9		74.8	13.9	71.0	94.7
2.5	Solution	3.9	2.75	88.0	0.5	85.5	3.9
	Precipitate	1.15		50.8	43.5	14.5	96.1
3.0	Solution	4.1	2.7	87.0	1.08	87.5	6.9
	Precipitate	1.19		42.7	45.4	12.5	93.1

from the experimental results that, under all the conditions tested, the leaching-out of titanium(IV) from the hydrated precipitate is insufficiently complete and selective. Apparently, this occurs because of the low solubility of hydrated oxides.

The solubility of the hydrated cake increases upon addition of fluoride ions, and niobium(V) and tantalum(V) pass into solution owing to the excess of these ions, since the amount added is calculated for the entire sample weight. A gradual introduction of fluoride ions has virtually no effect on the selectivity of isolation.

The acid sulfate solution was prepared by decomposition of the hydrated cake with a 93% acid at 220°C, with the subsequent leaching of the sulfate mass with water. The total concentration of titanium(IV), niobium(V), and tantalum(V) was 75 g l^{-1} (in terms of oxides). A calculated amount of NaF was added to the solutions, which were heated until the onset of hydrolysis. The results obtained in hydrolysis of the sulfate solution are listed in Table 2.

It follows from Table 2 that the separation of titanium(IV) from niobium(V) and tantalum(V) is not complete; however, hydrolysis in the presence of 2.5 mol of F^- per 1 mol of TiO_2 makes it possible to diminish the mass of the precipitate being processed by nearly a factor of 3, with insignificant loss of niobium. As the solution acidity increases, niobium(V) and tantalum(V) are precipitated more selectively.

Similar results were obtained in hydrolysis of chloride solutions (Table 3). The optimal norm of fluoride ions for both the sulfate and chloride solutions is the mole ratio $F^-:TiO_2 = 2.5$. In all the cases, tantalum is contained almost completely in a precipitate.

CONCLUSIONS

(1) A study of the separation of niobium(V) and tantalum(V) from titanium(IV) by their precipitation in the presence of fluoride ions from products formed in processing of loparite demonstrated that the dissolution of hydrated oxides is nonselective, irrespective of the type and amount of an acid and the amount of fluoride ions.

(2) It is possible to isolate 96% of niobium(V) and 99% of tantalum(V) with coprecipitation of 14.5–20% of titanium(IV) by hydrolysis from solutions with the mole ratio $F^- : TiO_2 = 2.5$. The best separation is achieved at an acidity of 2–3 mol-equiv l^{-1}.

Abstract—Extraction of phenol from aqueous solutions containing NaCl, K_2CO_3, and $(NH_4)_2SO_4$ as salting-out agents with hexane–2-propanol binary mixtures was studied, and conditions of determining the phenol concentration in the organic phase were optimized.

Organic solvents are widely used for extracting phenols from aqueous solutions [1]. Extractive preconcentration of phenols is performed with organic solvents of various polarities, used in high-performance liquid chromatography as mobile liquid phases [2].

In this study, we examined the extraction of phenol from aqueous sodium chloride, potassium carbonate, and ammonium sulfate with binary polar organic mixtures. An extraction-chromatographic technique for determining phenol in binary organic extracts was developed.

EXPERIMENTAL

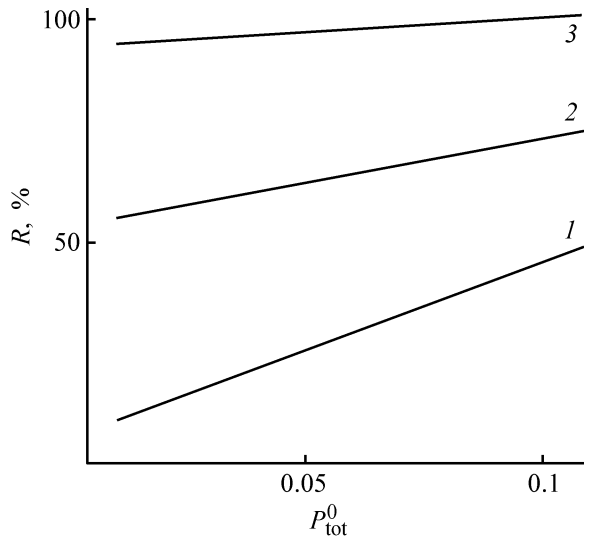
In experiments, we used phenol (pure grade) and prepurified extractants hexane and 2-propanol [3]. The extraction power of the binary mixture was estimated by its total polarity [4]. The polarity of hexane–2-propanol binary organic mixtures was evaluated using the rational polarity criterion P_i^0, which takes into account the normalized Snyder polarity index, Hildebrand criterion, and solvatochromic Dimroth-Reichardt parameter [5]. The total polarity of the binary mixture was calculated by the equation

$$P_{tot}^0 = \Sigma \varphi_i P_i^0,$$

where φ_i is the volume fraction of the solvent of *i*th kind.

Since 2-propanol is unlimitedly miscible with water [6], the extraction of phenol was performed in the presence of salts. The phenol concentration in the equilibrium phases was determined spectrophotometrically on an SF-46 spectrophotometer. The fields of a two-phase equilibrium in the ternary system water–salting-out agent–2-propanol were found by constructing its phase diagram [7]. Taking into account that the solubility of the salting-out agent is temperature-dependent, we performed all the experiments at $22 \pm 2°C$.

The phenol content was determined on a Milikhrom-4 liquid chromatograph under the following conditions: eluent (hexane–2-propanol mixture with hexane to 2-propanol volume ratio 92.5 : 7.5); eluent flow rate 100 μl min^{-1}; Silasorb 600 sorbent with grain size of 7 μm; column size 2 × 64 mm; analytical wavelength λ = 270 nm; and phenol retention time 2.75 min.



The efficiency of extractive recovery of phenol with the binary solvent was evaluated using the distribution factor *D* of phenol and its degree of recovery *R*, %. Table 1 shows that the distribution factor of

Degree of extraction of phenol, *R*, from aqueous solutions containing (*1*) NaCl, (*2*) K_2CO_3, and (*3*) $(NH_4)_2SO_4$ with the binary organic mixture vs. its total polarity P^0_{tot}.

phenol increases with the total polarity of the binary solvent at a constant volume ratio of the organic (V_o) and aqueous (V_{aq}) phases.

The salting-out power of salts is dependent not only on the cation and anion but also on the solubility of a salt in water [6]. The mostl soluble in water is K_2CO_3. However, the solution of this salt has pH ~10, which considerably hinders transfer of phenol from the salt solution to the organic phase. As a result, the efficiency of extraction of phenol from aqueous K_2CO_3 is considerably lower than that in the presence of $(NH_4)_2SO_4$ (Table 1).

The interaction of organic solvents with phenol occurs via van der Waals forces and hydrogen bonding [8]. It is known that extraction of phenol from aqueous solution with hexane occurs at the interface [1]. In our experiments, the content of the hydrophilic solvent 2-propanol in the binary organic mixtures was varied. The higher was the total polarity of a binary extractant, the more probable was the transfer of phenol to the organic phase not only across the macroscopic interface, but also in the bulk across the interfaces of numerous small bubbles at their nucleation. In extraction of phenol with binary mixtures, its molecules are solvated not only with organic molecules, but also with water to form hydrate solvates. The figure shows that the maximum extractive recovery of phenol is reached at the total polarity of the binary extractant equal to 0.117.

Table 2. Determination of phenol extracted from aqueous solution containing $(NH_4)_2SO_4$ with hexane–2-propanol mixture (n = 5, P = 0.95)

Added	Found	$S_R \times 10^{-2}$	W, %
μM			
1.0	0.99 ± 0.075	3.2	7.6
10.0	9.80 ± 0.234	9.1	2.4
100.0	99.95 ± 1.530	59.5	1.5

The phenol concentration in the aqueous solution was determined as follows. A phenol-containing water sample (500 ml) to be analyzed for phenol was placed in a separatory funnel and acidified with H_2SO_4 to pH ~2. Thereafter, solid $(NH_4)_2SO_4$ was added in an amount sufficient to form an approximately saturated solution, and then the binary organic extractant hexane–2-propanol (5 ml) was added. The resulting mixture was shaken on a vibromixer for 15 min. After the phase separation, the organic phase was separated and its chromatogram was obtained on a Milikhrom-4 liquid chromatograph. The phenol content in water was calculated from the chromatogram by the formula

$$c_{aq} = c_o \times 100/Rr,$$

where c_{aq} is the chromatographically determined phenol concentration in the organic extract (g cm^{-3}); R, degree of phenol recovery in the system constituted by an aqueous salt solution and binary organic mixture (%); and r, the volume ratio of equilibrium organic and aqueous phases.

The statistically processed results of phenol determination in aqueous solutions are listed in Table 2, where S_R is the standard deviation, and W, relative total error, %.

The error in determination of phenol in aqueous solutions by our express extraction-chromatographic technique does not exceed 10%.

CONCLUSION

The distribution factors of phenol in the systems constituted by a hexane–2-propanol mixture and an aqueous solution of salting-out agents [$(NH_4)_2SO_4$, NaCl, K_2CO_3] were determined. The maximal distribution factor (500 ± 46) and the maximal degree of recovery (~98%) of phenol were reached with the binary organic mixture with a total polarity of 0.117. An express extraction-chromatographic technique for determining phenol in binary organic extracts on a Milikhrom-4 chromatograph was developed. The total determination error of phenol does not exceed 10%.

Professor Nikolai Nikolaevich Baraboshkin (To 125th Anniversary of His Birthday)

Nikolai Nikolaevich Baraboshkin is widely known as one of founders of the domestic platinum industry. He also made a major contribution to the organization of higher-school metallurgical education in Sverdlovsk (Yekaterinburg) and to the development of a number of branches of nonferrous metallurgy in the Urals.

N.N. Baraboshkin was born on October 24 (November 6), 1880. He descended from peasants of Moscow province. Having finished a village school, he educated at nonclassical secondary schools at towns of Syzran' and Samara. In 1899, he finished his secondary education and entered the Mining Institute in St. Petersburg. In view of the financial difficulties and the necessity to maintain his family, his education at the institute was prolonged and repeatedly interrupted, and was complete only in April 1915. A detailed list of a diversity of works in which Baraboshkin took part during his education at the Mining Institute can be found in the scientist's biography, prepared by S.S. Naboichenko [1]. Particularly noteworthy are geological expeditions that surveyed the gold-fields and platinum deposits in the Urals (1906, 1907), umpire analysis of raw platinum from Ural deposits (1911), development and improvement of methods for platinum refining (1914, 1915), and works at plants of nonferrous metallurgy (1908, 1910, 1912). Baraboshkin, in particular, took part in an inspection of Ural copper plants, which was commenced in 1914 by the decision of the Scientific Council of the Mining Institute.

Among Baraboshkin's teachers at the Mining Institute, who should be primarily mentioned, are chemists I.F. Shreder (1857–1918) and N.S. Kurnakov (1860–1941, academician since 1913), and metallurgist N.P. Aseev (1871–1952). Other teachers also included quite a number of known scientists: crystallographer E.F. Fedorov (1853–1919), mathematician I.P. Dolbnya (1853–1912), and metallurgist V.N. Lipin (1858–1930). Already in 1901, Baraboshkin started to work at Shreder's chemical laboratory; in 1902, he moved to the analytical laboratory headed by Kurnakov and worked there till 1913, with an interruption in 1908–1910. In 1913–1914, Baraboshkin was a not-on-the-staff assistant of professor Aseev.

When working at the laboratory headed by Kurnakov, together with Kurnakov's closest associate N.I. Podkopaev (1872–1930), Baraboshkin did a great deal in the field of analytical chemistry of platinum metals. A known Russian chemist-analyst, chairman of the Analytical Commission of the Institute of General and Inorganic Chemistry (Academy of Sciences of the USSR), B.G. Karpov (1870–1940) highly appreciated Baraboshkin's activities and regarded him as "... one of the most outstanding representatives of Kurnakov's analytical school" [2].

At the beginning of 1915, Baraboshkin graduated with success from the institute to become a mining engineer. He presented as his graduation thesis the results obtained in a study of the phase diagram of the binary system constituted by antimony oxide and antimony sulfide. Later, this study was awarded the prize named after Professor K.I. Lisenko (1836–1903) [1, 3]. Simultaneously, a design of a plant for processing of copper ore was presented. Having graduated from the Mining Institute, Baraboshkin continued to work there as an assistant.

In 1914, Russia's Government made a concession contract with the joint-stock company of the Nikolae-Pavdinskii mining district in the Urals for construc-

1070-4272/05/7812-2038 © 2005 Pleiades Publishing, Inc.

tion of Russia's first plant for refining of raw platinum and manufacture of platinum articles. Baraboshkin was invited to supervise the construction process. The technology to be used in platinum purification was based on the method that had been suggested by Russian inorganic chemist K.K. Klaus (1796–1864) and was modified by Baraboshkin and Podkopaev. In November 1915. Baraboshkin took the office of director of the plant being constructed.

At the beginning of 1916, a temporary laboratory for refining and production of spongy platinum started to work in Yekaterinburg. In October of the same year, the construction of the plant was, for the most part, complete. The commonly accepted official data of its starting is October 10 (23), 1916, when the Ministry of commerce and industry approved a special instruction regulating all aspects of operation of the new plant. From November 1916 till November 1917, 900 kg of platinum was refined [4]; by the beginning of 1918, the monthly output capacity reached a value of 400 kg and continued to gradually increase. However, the plant was nationalized on February 6 (19) and closed soon after. During the Civil war, the work on refining of platinum was suspended, but the plant was not evacuated and the equipment was intact. Baraboshkin's public and political activities were considered in detail in [1].

In the spring of 1920, the refining plant resumed its work, largely due to Baraboshkin's efforts, and soon started to manufacture, in addition to platinum, other metals: palladium (1922), iridium (1923), rhodium (1925), osmium (1927), and ruthenium (1930). Manufacture of platinum of extra brand was organized in 1928, platinum was smelted into ingots beginning in 1923; platinum alloys and articles made of platinum and its alloys started to be manufactured in 1928. The purity of the resulting platinum and its accessories was as good as, and in some cases considerably exceeded, that of the metals produced by foreign companies [5, 6].

Beginning in 1915, Baraboshkin was engaged in the development of higher-school metallurgical education in Yekaterinburg. Being an organizer of the Ural Mining Institute, he was elected a docent (1913), professor (1919), and dean of the metallurgical faculty at this institute. He was a professor of the Ural University in 1922–1925 and a professor of the Ural Polytechnic Institute in 1925–1935. The permanent reorganizations of higher-school institutions, faculties, chairs, and research institutions, which were characteristic of that time, give no way of briefly describing Baraboshkin's diverse pedagogical and scientific activities during this period. The Refining plant remained the scientist's main working place, where he was a technical director till 1930, and a scientific advisor later. As noted in Baraboshkin's biography [1], he was directly involved in the organization of the chairs of metallurgy of precious and nonferrous metals and theory of metallurgical processes at the Ural Polytechnic Institute and headed these chairs during several years.

Baraboshkin was among the organizers of the first in the Urals research institute of nonferrous metallurgy (1930) and was a deputy director for research work at this institute.

On July 27, 1935, when taking a rest, Baraboshkin tragically lost his life under unclear circumstances. The Russian science was deprived of one of the most talented representatives: an engineer, researcher, pedagogue, and organizer and head of industrial and research collectives. Papers devoted to Baraboshkin's memory have been published by his colleagues and pupils [5, 7, 8].

Kubrakova, N.I. and Vasil'eva, O.M., Compilers, Gagarin, A.V. and Zibareva, I.V., Foreword, Bakibaev, A.A., Ed., Tomsk: Tomsk. Politekhn. Univ., 2005, 76 pp.

Istoriya kafedry fizicheskoi i analiticheskoi khimii (1900–2004) [History of the Chair of Physical and Analytical Chemistry (1900–2004)],

Bakibaev, A.A., Ed., Tomsk: Tomsk. Politekhn. Univ., 2005, 67 pp.

All the three publications are devoted to 95th birthday of a prominent Russian scientist, founder of a large scientific school in the field of electroanalytical chemistry, honored professor of Tomsk Polytechnic University, Honored Chemist of the Russian Federation, honored Soros professor, and doctor of chemical science, Armin Genrikhovich Stromberg. One of the oldest Russian electrochemists, Stromberg was the first in our country who widely used polarographic methods in studies of various objects, in research work, and in industrial conditions. A particular prominent contribution was made by the scientist to the theory and practice of amalgam polarography. In 1951, he defended his doctoral (chem. sci.) dissertation "Theory and Practice of Polarography, and Amalgam Polarography in Particular." In 1956, Stromberg was elected head of the chair of physical and colloid chemistry at Tomsk Polytechnic Institute. In 1962, he initiated the organization of "Problem-solving laboratory for physicochemical of microimpurities in semiconductors and high-purity materials." Stromberg's talent not only as a theoretician, experimenter, and pedagogue, but also as a head and organizer of a large research team, was displayed in full measure at the chair and the problem-solving laboratory. The laboratory was directly headed by Stromberg during 24 years, after which he remained there as a scientific advisor. All the staff members of the laboratory, who included teachers of the chair, research workers, and postgraduate students, were engaged in comprehensive development of the method of inversion voltammetry: the theory of the method, development of apparatus and practical procedures for determination of microimpurities. During the 40 years of existence of the problem-solving laboratory under Stromberg's supervision, near 100 candidate dissertations were defended and a number of his pupils became doctors of science and headed research teams in other cities of the country.

The main results obtained at the problem-solving laboratory were summarized in the previously pub-

1070-4272/05/7812-2040 © 2005 Pleiades Publishing, Inc.

lished collection of works *Tomskoi elektrokhimicheskoi shkole i problemnoi laboratorii mikroprimesei sorok let. 1962–2002* (Tomsk Electrochemical School and Problem-solving Laboratory of Microimpurities Are Forty, 1962–2002) (Tomsk, 2004). In recollections of Stromberg's pupils, they emphasize his talent and self-discipline, remarkable working capacity, and devotedness to science.

The bibliography of Stromberg's works presents the results of a detailed sciencemetric analysis of the activities of the Tomsk electrochemical school and its head. The analysis was based on the databases Science Citation Index and Chemical Abstracts. In the ranked list of 20 world's most active authors in the field of voltammetry, Stromberg is the third, with three of his pupils also appearing in this list. According to the Chemical Abstracts database, Stromberg is an author of 372 publications that have appeared since 1935, 92% of these being journal articles. All the publications are in Russian in domestic journals and books. It should be noted that, together with being actively engaged in works in the field of voltammetry, Stromberg paid a considerable attention to sciencemetric studies and was the first in our country who understood their importance. The bibliographic list gives 471 references to scientist's works carried out in 1930–2005.

Stromberg (together with D.P. Semchenko) is the author of the textbook *Fizicheskaya khimiya* (Physical Chemistry) for higher-school institutions, which has already run into five editions. The three last of these (in 1999, 2001, and 2003) were supplemented by Stromberg with new important sections: "Introduction to the Theory of Self-Organization of Matter. Elements of Synergetics" and "Introduction to the Theory of Fractals." In 1999 was published an original textbook *Sinergetika. Primenenie v khimii* (Synergetics. Application to Chemistry), written by Stromberg.

The third of the books discussed is devoted to the history of the chair of physical and analytical chemistry. Studies at the chemical department of the Tomsk Polytechnic Institute (now Tomsk Polytechnic University) commenced in 1900. However, independent chairs of analytical chemistry and of physical and colloid chemistry appeared much later, in 1930 and 1934, respectively. In 1999, these chairs were amalgamated into the chair of physical and analytical chemistry. The book presents evidence concerning the teaching staff and research areas from their organization to amalgamation, and further until the present.

All the three small publications are of interest for a wide audience of readers interested in the development of science and higher-school education in our country.

INFORMATION

21st Annual Meeting of the Polymer Processing Society, 2005

The 21st Annual Meeting of the Polymer Processing Society was held in Leipzig (Germany) on June 19–23, 2005. The first such conference was organized seventeen years ago and held in Germany, too.

The participants of the Conference were about 500 scientists from 230 research centers of 41 countries. Leipzig was selected as a place for holding the Conference because the region of Germany around this city is characterized by a concentration of chemical industry and research centers specialized in processing of polymers.

The Conference Program included seven plenary lectures, fifteen symposia, and a workshop.

The first plenary lecture entitled Innovative Methods of Injection Molding for Automotive Components was presented by H. Eckardt (Meinerzhagen, Germany). In the second lecture, L.J. Lee (Columbus, the United States) reported on polymer processing at the micro/nanoscale. The third lecture was devoted to modeling of extrusion chain processes [H. Potente (Paderborn, Germany)]. P.D. Coates (Bradford, the United Kingdom) presented his concept of metrology as a science. The following plenary lectures were devoted to indicator products as a new tool for prediction of long-term properties of degradable polymers [A.-C. Albertsson (Stockholm, Sweden)]; extrusion, injection molding, and technological parameters of fibers reinforced with composites [P. Oswald (Munich, Germany]; and recent advances in silicon-containing polymeric nanocomposites [Maurice Lambada Award Lecture, M. Okamoto (Nagoya, Japan)].

The scientists participated in the Workshop "Rheology and Processing of Polymers" and discussed practical aspects of polymer processing.

Recent data covering various areas of polymer research were presented in fifteen Symposia.

Symposium 1. Extrusion and Coating (Chairmen: W. Michaeli, C. Rauwendaal, and T. Sakai). The following topics were considered: microwave-mediated plasticizing of PVC, effects of various catalysts on the reaction of 1,3-acetidine-2,4-dione with hydroxy groups, UV study of the kinetics of radical polymerization of methylmethacrylate with azobisisobutyronitrile and benzoyl peroxide in toluene, and extrusion of polyolefins.

Furthermore, there were presented results on blow extrusion to give a foam of polyesterimide used as a low-molecular-weight thermoplastic substrate, effect of extrusion on mechanical properties of polyethylene, and interfacial instabilities that occur in preparation of multilayer films.

Symposium 2. Injection Molding and Molds (S.-J. Liu, G. Mennig, and G. Titomanlio). Problems concerning the development of new injection molding machines, in particular, those for manufacture of hybrid Microsystems were considered. It was demonstrated that mechanical stress occurring in injection molding affects the mechanical characteristics of the products.

Symposium 3. Blow and Rotational Molding and Thermoforming (E. Harkin-Jones, J. Vlachopoulos, and J. Wortberg). Two presentations were made: (1) Thermomechanical Analysis of Protective Coating for Automotive Parts, Prepared by Thermoforming and Polymer-Polymer Diffusion, and (2) Interfacial Reactions in Multilayer Moldings.

Symposium 4. Reactive Processing (E. Haberstroh, M. van Duin, and M. Xanthos) (eight reports). Among others, such topics were discussed as oxidation of molten polypropylene, preparation and properties of high-performance ion-exchange acryl fibers, continuous process for production of polyurethane-based adhesives by reactive extrusion, and properties of reactive polypropylene for use as an elastomer in manufacture of rubber powders.

Symposium 5. Mixing and Compounding (M. Bousmina, T. Osswald, and C.L. Tucker, III). Four reports were delivered; they concerned determination of the electrical conductivity as a method for study of mixing processes that occur in carbon black rubbers, conditions for the attainment of homogeneity through a decrease in the number of ingredients, and stabilization of mechanical characteristics of low-density polyethylene with cyclohexylphosphonic acid.

Symposium 6. Rheology and Rheometry (E. Mitsoulis, P. Moldenaers, and M. Wagner). Among the

1070-4272/05/7812-2042 © 2005 Pleiades Publishing, Inc.

topics were the effect of acrylate polymers on properties of asphalt, deformation and fluidity of long-chain branched polypropylene prepared by the reaction of propylene with nonconjugated dienes, comparison of parameters obtained in studying the fluidity by vibrational and extrusion methods, fluidity of filled polymers, and analysis of the deformation and fluidity of paper fibers.

Symposium 7. Process Modeling (A. Hrymak, T. Kajiwara, and I. Manas-Zloczower). In this section, such questions were considered as processes in segmented polyurethane fibers, adhesion in layers, simulation of fiber break in textile materials, and quantitative *3D* simulation of processing.

Symposium 8. Morphology and Structure Development (J.-M. Haudin, S.C. Kim, and H. Muenstedt). The following topics were discussed: supramolecular structure of isotactic polypropylene obtained by the thermal reaction, X-ray study of the morphology and structure, anion-exchange resins, formation of solid phases, glassy and crystalline states in various polymers, and morphology and its correlation with mechanical properties of polymers.

Symposium 9. Polymer Blends and Composites (W. Hufenbach, H.E.H. Meijer, and R.D. Paul): synthesis and properties of polymer blends and composites; effect of various, particularly nanoscale fillers; optimization of the component proportion in preparation of composites; effect of pressure on the thermal conductivity in filled and unfilled powdered polymers; thermal and rheological characteristics of various polymers and polymer articles; and chemorheological study of phase separation and gelation.

Symposium 10. Natural Based and Biodegradable Polymers (A.-C. Albertsson, A. Bledzki, and A. Cunha): kinetics and mechanism of biodegradation of a wide variety of natural-based biodegradable polymers and sorption/desorption of water and saline solutions on these polymers.

Symposium 11. Elastomers and Elastomer Processing (A. Limper, W. Rzymski, and S. Thomas): morphology of elastomers and elastomer chains with and without fillers, and also of elastomers obtained from natural renewable raw materials. A special attention was paid to the injection molding and the construction of molding machines. Furthermore, synergistic and antagonistic effects in elastomer processing were considered, including vulcanization.

Symposium 12. Nano-Structured Materials (V. Altstaedt, S. Bhattacharya, and L.J. Lee). This section attracted special interest of the participants, particularly as regards flame retardants. It was demonstrated that nanocomposite flame retardants show promise for considerable decrease in the flammability of polymer and composite materials; they also reduce the volume of toxic compounds formed in pyrolysis and combustion of various polymers. Use of these nanocomposites allows alteration of the pyrolysis route toward formation of low-toxic products.

Symposium 13. Process Monitoring, Control, and Sensors (P.D. Coates, M. Stephan, and H. Yokoi). In this section, special attention was paid to small-angle scattering methods.

Symposium 14. Sustainable Development, Reprocessing, and Recycling (M. Kozlowski, C.D. Papaspyrides, and R. Renz). In this section, the main topics were environmental protection and collection, grading, and recycling of polymer wastes to obtain polymer blends and composites with acceptable properties.

Symposium 15. Foams, Novel Processes, and Applications (P. Eyerer, C.B. Park, and P. Saha). This section was devoted to foamed polymers, new processes for their preparation and processing, and practical applications. Part of the foams were prepared on the basis of rubbers, using nanocomposites. Particular attention was paid to blowing agents, foam extrusion, and polymer foams. Of special interest were reports on the development of bioactive foams and biocompatibility.

In addition to oral reports, the Symposia included more than 100 poster presentations.

The Conference showed how theoretically and practically important is the problem of polymer processing.

The next, 22nd Conference will be held in Yamagata (Japan) on July 2–6, 2006, and the 23rd Conference, in Salvador (Brasil) on May 27–31, 2007. It is anticipated that about 700–800 researchers and industry representatives from 50 countries will participate in these Conferences.

G.E. Zaikov, M.I. Artsis, and L.L. Madyuskina
