Abstract—Polymer electrolytes for lithium and lithium–ion chemical power sources are described.

INTRODUCTION

Lithium chemical power sources (CPSs) have high specific electrical characterisitcs and show promise for power supply to diverse autonomous objects [1–4]. The use of Li, which has a high negative potential and a low electrochemical equivalent (0.259 g A^{-1} h^{-1}), allowed an increase in the working voltage and specific energy of such power sources.

Success in development of lithium CPSs was stimulated by a suggestion to use melts of lithium-containing salts and solutions of lithium salts in aprotic dipolar organic solvents (ADSs) as electrolytes. However, power sources with a lithium-based anode and a molten electrolyte have not found wide use because of problems with structural materials, design, and service. At the same time, lithium power sources (and later lithium–ion batteries) with a nonaqueous (aprotic) electrolyte, despite certain drawbacks, became commercially available. The most widely used organic solvents in such electrolytes are propylene carbonate (PC), ethylene carbonate (EC), diethyl carbonate (DEC), dimethyl carbonate (DMC), or their mixtures; as lithium salts are used perchlorate ($LiClO_4$), hexafluorophosphate ($LiPF_6$), hexafluoroarsenate ($LiAsF_6$), and tetrafluoroborate ($LiBF_4$). The electrical conductivity of the nonaqueous electrolytes is within 10^{-2}–10^{-3} S cm^{-1}.

Comparative analysis of the characteristics of various electrochemical systems [5] demonstrates advantages of the new generation of batteries: lithium–ion batteries with liquid (Li–IB) and polymer solid or thickened electrolyte (PLi–IB). Such systems provide voltages of 2.7–3.7 V and have a specific energy of 150–200 W h^{-1} kg^{-1}, which is 2–2.5 times higher compared to the well-known nickel–cadmium and nickel–metal hydride batteries.

Experts engaged in development and production of lithium–ion batteries believe that, by 2010, virtually all the autonomous power sources used in military equipment will be based on the technology of a lithium–ion battery [5].

Studies aimed at development of new and improvement of existing working bodies for lithium power sources are being performed during the whole period since the development of the first lithium voltaic cell (more than three decades).

One of promising lines in improvement of lithium and lithium–ion CPSs is the use of polymer electrolytes (PEs), which allows improvement of their energy and service characteristics and simplification of the production process. Studies of PEs are being performed since 1970s, and today the electrochemistry of polymer electrolytes is one of the most actively developing fields of the modern electrochemistry [6]. Polymer electrolytes to be used in lithium CPSs should exhibit good physicomechanical properties, high ionic and low electronic conductivity, and wide range of electrochemical stability; they should be inert toward the electrode materials.

Polymer electrolytes are subdivided into two large groups with respect to the component composition. The first group includes PEs that contain no low-molecular-weight solvent; they contain a high-molecular-weight polymer, a lithium salt, and (in some cases) finely dispersed inorganic fillers. Polymer electrolytes of this type are termed polymer solid electrolytes (PSEs). The second group includes electrolytes containing, along with polymers, lithium salts, and fillers, also low-molecular-weight solvents. Electrolytes of

1070-4272/05/7801-0001 © 2005 Pleiades Publishing, Inc.

this group are further subdivided into microporous, gel, and plasticized polymer electrolytes [7].

Microporous PEs are microporous polymer films prepared from chemically resistant polymers (e.g., polyethylene or polypropylene) and impregnated with solutions of lithium salts in dipolar aprotic solvents. These electrolytes exhibit good mechanical properties and high ionic conductivity approaching that of liquid nonaqueous electrolytes (10^{-2}–10^{-3} S cm^{-1}).

Gel PEs (GPEs) are multicomponent systems consisting, at least, of a film-forming polymer, an aprotic dipolar solvent, and a lithium salt. The solution of the salt in ADS is distributed in a three-dimensional GPE network formed by macromolecules or their aggregates. These electrolyte systems have a relatively high ionic conductivity (up to 10^{-3}–10^{-4} S cm^{-1}) and, in some cases, also fairly good mechanical properties.

The solvent content in plasticized polymer electrolytes is considerably lower than in gel polyelectrolytes; their electrical conductivity, as a rule, is also appreciably lower.

An essential disadvantage of PEs containing a low-molecular-weight solvent (except microporous PEs) is the possible thermodynamic instability of their phase composition. Also, a common drawback of PEs of the second group is the possibility of solvent evaporation during storage and service of CPSs. Finally, the presence of a solvent is responsible for the drawbacks characteristic of liquid nonaqueous electrolytes: chemical activity toward lithium and the possibility of undesirable cointercalation of solvent molecules into the cathode matherial. All these processes may result in degradation of electrode materials and deterioration of the characteristics of CPSs based on such polymer electrolytes.

From the viewpoint of safety and convenience in production and service, PSEs in lithium CPSs are preferable. However, certain problems restrict today the use of PSEs. First, they have low ionic conductivity at common temperatures (10^{-5}–10^{-8} S cm^{-1}); second, not only lithium ions but also anions participate in the charge transfer, which may lead to concentration polarization; third, similarly to liquid electrolytes, PSEs can form a transition layer with a high resistance in contact with electrode (both cathode and anode) materials [7–9].

Therefore, development of lithium-conducting polymer electrolytes exhibiting high electrical conductivity in a wide temperature range, chemical and electrochemical stability, and good physicomechanical properties remain an urgent problem.

POLYMER SOLID ELECTROLYTES

Interactions in Polymer–Lithium Salt Systems

Organic polymers used for preparing PEs are dielectrics. Their low conductivity (10^{-12}–10^{-10} S cm^{-1}) is due, as a rule, to the presence of impurities. Therefore, fairly good polymer ionic conductors can be obtained by introducing ionogenic or ionophoric groups into the polymer molecule, or ionophores into the polymer system as a whole. Ionization of ionogens and ionophores is possible in the case if the polymer system exhibits sufficiently high dielectric permittivity and solvating power toward various ions. Such properties are exhibited by systems based on functional polymers, i.e., polymers whose molecules contain electron-donor or electron-acceptor groups. Interaction of macromolecules with low-molecular-weight ionophores (e.g., lithium salts) is possible owing to solvation of cations, anions, or both with functional groups of the polymers.

Anions are usually solvated by hydrogen bonding with relatively "acidic" hydrogen atoms, i.e., with hydrogen atoms directly bonded to electronegative atoms of the polymer molecule, e.g., with oxygen atoms in polyalcohols or hydrogen atoms in polyamides. However, the interchain interaction in such polymers is relatively strong, resulting in high cohesion energy. Therefore, such polymers are unfavorable media for diffusion of ions in the absence of protic solvents having high dielectric permittivity (water). Furthermore, the mobile hydrogen atom may be electroactive in a wide range of chemical potentials, which excludes the use of such polymers in lithium power sources. Anions can also be solvated by Lewis acids, e.g., by organoboron compounds R_3B, but stable macromolecules containing such fragments are unknown [10].

It should also be noted that one of the major problems in development of lithium-conducting polymer electrolytes is elimination of the undesirable contribution of the anionic conductivity [11, 12]. Because of binding of the cations with polar groups of the polymer molecule, the anion makes a significant contribution to the conductivity. The mobility of the anions usually decreases with an increase in their size. The undesirable anionic conductivity can also be eliminated by using polyelectrolytes, i.e., polymers in which the negative ion is chemically bound to macromolecules. The electrical conductivity of such systems usually does not exceed 10^{-5} S cm^{-1}.

The cations are solvated via interaction with lone electron pairs of heteroatoms in functional groups of

the polymer molecules [13]. The most typical functional groups are ether (–O–), sulfide (–S–), amino (–N<), phosphino (–P<), carbonyl (>C=O), and cyano (–C≡N) groups.

According to Pearson's concept of hard and soft acids and bases, the electron-donor properties of heavy heteroatoms (S, P) are realized most efficiently in the presence of soft acids, i.e., cations with polarizable *d* orbitals (e.g., Ag^+, Pb^{2+}) [14]. Cations of alkali and alkaline-earth metals strongly interact with oxygen and nitrogen atoms.

The possibility of polymer–salt complexation depends on the cohesion energy of the polymer and crystal lattice energy of the salt [15, 16]. Complexes with the above-mentioned types of macromolecules are formed only by salts with a low lattice energy. Such salts generally contain large anions with the delocalized charge.

Polyethers [in particular, poly(ethylene oxide), PEO] were the first macromolecular compounds considered as candidate materials for PSEs [17, 18]. In particular, Papke *et al.* [19] showed that with PEOs, indeed, the crystal lattice energy of the salt determines the possibility of the polymer–salt complexation. The complexation of PEO with lithium salts $LiClO_4$, $LiPF_6$, $LiBF_4$, and others was proved in [20–22]. Robitaille and Fauteux [23], based on the conductivity and X-ray diffraction data, confirmed the results obtained for the system PEO–$LiCF_3SO_3$ and constructed the phase diagrams for the systems PEO–X, where X = LiI, $LiAsF_6$, and $LiClO_4$. In the latter case, also, at least one crystalline complex is formed, $(PEO)_6$–$LiClO_4$. Poly(ethylene oxide) forms mixed crystals of the pure polymer and complex at temperatures below T_m, and above T_m the salt-containing melt (elastomer) is in an equilibrium with the complex. For the majority of crystalline polymers, the crystalline phase, as a rule, occupies only about 70–85% of the volume of the polymer body because of entanglement of the polymer chains. The remaining volume is occupied by the amorphous phase. Such phase equilibria govern the properties of such polymers as poly(ethylene succinate) $(–C_2H_4–O–CO–C_2H_4–COO–)_n$, polyaziridine $(–CH_2–CH_2–NH–)_n$, poly(ethylene adipate) $(–C_2H_4–O–CO–C_4H_8–COO–)_n$, and polypropiolactone $(–C_2H_4–COO–)_n$ [10].

The DSC and NMR studies made by Berthier *et al.* [24, 25] showed that the crystalline phase of the complex (three monomer units per mole of salt) starts to dissolve in PEO at temperatures above T_m of PEO. It is assumed that the crystalline phase of the complex has a helical structure with the cations located inside, and the ion motion occurs in the elastomer phase, with the crystalline complex acting only as a salt reservoir.

Armand [10] summarized data on interaction of PEO and poly(propylene oxide) (PPO) with the most commonly used alkali metal salts. It was noted that the complexing power of PEO considerably exceeds that of PPO, despite the fact that the electron-donor properties (*DN*) of both polymers are comparable. A decrease in the stability of polymer–salt complexes is due to steric hindrance caused by the methyl groups in PPO. In amorphous polymers above their glass transition points and in polymers incapable of crystallization because of structural disordering, the salts bound in a complex form continuous solutions up to saturation.

When studying ionic association of PPO–$LiClO_4$ complexes, Schantz [26] noted that the amount of the dissociated ions remained constant with variation of the polymer/salt ratio from 1000 to 30 [26]. With an increase in the salt concentration in PPO, the intensity of ion pair formation decreased. The major contribution to an increase in the PE conductivity at low $LiClO_4$ concentrations is made by an increase in the number of dissociating ions, rather than in their mobility. The IR and polarized Raman spectra of the PPO–$LiCF_3SO_3$ complexes suggest existence of three types of associates: two differently coordinated ion pairs and a ternary ion. Manning and Frech [27] state that the free ions which were believed previously to exist in these polymer–salt complexes are actually the cation–anion pairs in which the cation weakly interacts with the terminal CF_3 group of the anion.

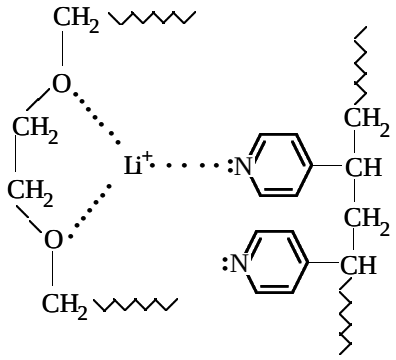
It was found that polymers with the crystalline structure, tending to form crystalline complexes with dissolved lithium salts, do not ensure the electrical conductivity acceptable for PSEs. The conductivity of PSEs, including those based on PEO, can be increased by decreasing the crystallinity of the polymer, because the high ionic conductivity is mainly provided by the amorphous part of the polymer electrolyte.

Therefore, the majority of studies involve choosing amorphous polymers for PSEs, forming the network structure (cross-linking), and introducing additives that render the system amorphous.

Polymer Solid Electrolytes Based on PEO and Its Modifications

As a rule, solid inorganic electrolytes have a unipolar conductivity. It was initially expected that PSEs would also exhibit unipolar conductivity. Indeed, the

preliminary results were encouraging: For the PSE based on $LiCF_3SO_3$, the lithium transport number was ~0.8 [28]. However, it was found soon that the transport numbers of the positive ions t^+ for the majority of salts in PSEs are within 0.3–0.5.



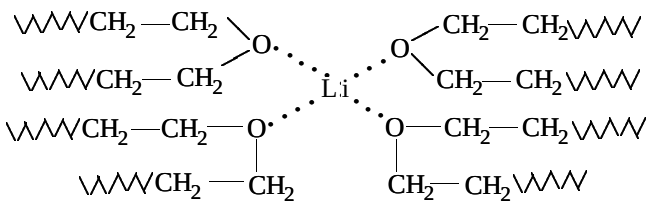
The transport numbers in PSEs are usually determined by impedance spectroscopy [29, 30], Tubandt method [31], dc electrolysis [32], potentiometry [33], and NMR spectroscopy [34]. For the lithium salts with such anions as SCN^-, ClO_4^-, and BF_4^-, all these methods give similar values characteristic of these salts in liquid electrolytes. An apparent exception is the $CF_3SO_3^-$ ion for which independent measurements give $t^- \approx 0.3–0.4$ [33, 34]. Presumably, synthesis of polymer electrolytes with unipolar lithium conductivity will lead to a considerable progress in this field.

Bruce and Vincent [35] studied by the emf method the ion transport in amorphous complexes PEO–$LiClO_4$ of various compositions. In potentiostatic polarization, the steady-state current was attained in several hours and was determined by the mobility of both Li^+ and ClO_4^- ions, and at high salt concentrations, also by the mobility of the ion pairs [36]. According to [37], at a given temperature the conductivity depends on the lithium perchlorate concentration in a complex manner. At low concentrations, with an increase in the salt content, the specific molar conductivity σ rapidly decreases. Then, as the salt concentration is increased further, σ increases, reaches a maximum (whose position depends on temperature), and then decreases again. The shape of the dependences of σ on the temperature and lithium perchlorate concentration suggests the transfer of the electricity not only by the simple ions Li^+ and ClO_4^-, but also by ion clusters $Li(ClO_4)_2^-$ and $Li_2(ClO_4)^+$.

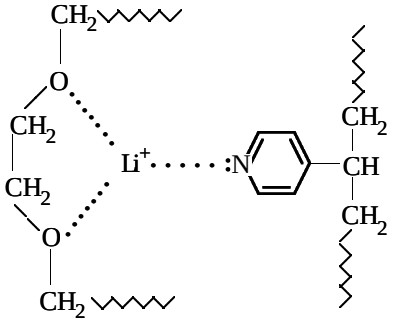
Studies by Brillouin and photon-correlation spectroscopy [38] showed that the cooperative motion of approximately 20 monomeric units of the polymer is required for the ionic transport. At $n > 4$, short-lived ion–polymer cross-links arise in the electrolyte, limiting the mobility of polymer segments. The density of the cross-links abruptly decreases with increasing temperature because of formation of ion pairs exerting a plasticizing effect of PSE.

Arumugam *et al.* [39] determined the diffusion coefficients of Li^+ and PF_6^- in the amorphous electrolyte PEO–$LiPF_6$ by ^7Li and ^{31}P NMR spectroscopy with pulse field gradient in a wide temperature range (25–100°C) at a salt concentration of up to 0.25 mol dm^{-3}. Their results suggest different mechanisms of transfer of the cation and anion at low and high concentrations of the salt. The diffusion coefficients of the cation appeared to be weakly sensitive to the salt concentration; the system showed a deviation from the Nernst–Einstein relationship. To interpret the results obtained, Arumugam *et al.* suggested hopping of the cation between ion clusters and diffusion of neutral ion pairs.

Blending of two or several polymers is widely used to decrease the crystallinity of polymer electrolytes. Li and Khan [40] studied an interesting type of polymer electrolytes with a conductivity of 10^{-5} S cm^{-1} at 25°C. The electrolytes were prepared by blending PEO with poly(2-vinylpyridine) (P2VP) or poly(4-vinylpyridine) (P4VP) with $LiClO_4$ in solution. In these composite electrolytes, $LiClO_4$ behaves as agent improving the compatibility of the polymers, as it was shown previously that PEO and P4VP are immiscible and PEO–P2VP (40/60 by weight) blends are only slightly miscible [41], as indicated by independence of T_m of PEO and T_g of P2VP from the blend composition. Ueda *et al.* [41] believe that increased miscibility in the PEO–polyvinylpyridine system is most probably due to the fact that the lithium ion interacts simultaneously with the PEO oxygen atoms and nitrogen atom of the pyridyl unit. The probable structure of the complexes formed by this type of ion–dipole interactions is shown below:

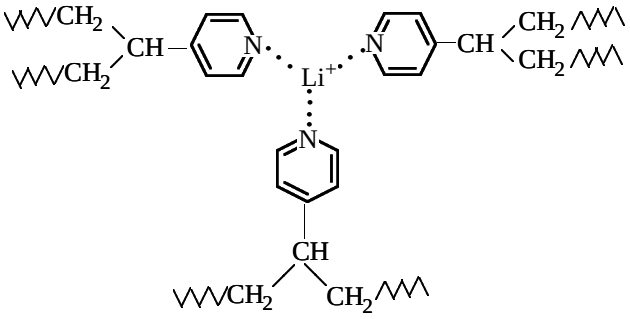


It was shown that the ion–dipole interactions improve the miscibility of polystyrene ionomers with poly(alkylene oxide) systems [42] and of polyamide-6 with lithium or sodium salts of sulfonated polystyrene [43, 44]; $LiCF_3SO_3$ improves the miscibility of poly(methyl methacrylate) and poly(propylene glycol) [45]. The increased miscibility is explained by simultaneous interaction of Li^+ with the carbonyl oxygen atoms of poly(methyl methacrylate) and ether oxygen atoms of poly(propylene glycol). Furthermore, it was shown that the blends have a phase-segregated structure with $LiCF_3SO_3$ acting as an emulsifier stabilizing the two-phase microstructure [46].



Mani *et al.* [46] explained the conductivity and

thermal transitions assuming the existence of three different types of ion–dipole complexes:



Complex of type 1

Complex of type 2

Complex of type 3

Complexes of type 1 are present in the pure PEO phase, and complexes of type 3, in the pure P2VP or P4VP phase. Complexes of type 2 stabilize the two-phase microstructure and are present at the phase boundary. Mani *et al.* suggested that the ions incorporated in complexes of types 1 and 2 are mobile and hence participate in the ionic transport. Complexes of type 3 form a rigid phase with a low segmental mobility at room temperature. Therefore, the ions in these phases are mostly immobile and do not make a significant contribution to the ionic conductivity. Preferential formation of complexes of types 1 and 2 increases the amount of charge carriers, increasing the ionic conductivity. However, the larger the amount of complexes of type 1, the weaker the segmental motion and the higher T_g [47]. As the segmental motion becomes less intense, the mobility of charge carriers and hence the ionic conductivity decrease. Wintersgill *et al.* showed that the amplitude of segmental motion plays an important role in the ion transport in polymer–salt complexes [48].

Zhukovskii *et al.* [49] blended two polymers to prepare an electrolyte based on PEO and amorphous poly(vinyl acetate) (PVA). The PEO crystallinity decreased with increasing PVA content and fully disappeared at a PVA content of about 30 wt %. The highest conductivity at room temperature was 10^{-5} S cm^{-1} at 10–20% PVA content.

Carre and Hamaid [50] succeeded in suppressing PE crystallization by adding to PEO an elastomer (butadiene–acrylonitrile copolymer) and a macromonomer derived from styrene. The polymer electrolyte consisting of a blend of a poly[bis(methoxyethoxyethoxidophosphazene)] complex salt (I) and PEO (II), doped with $LiCF_3SO_3$ or $LiClO_4$, was cast from a solution of I + II in acetonitrile and vacuum-dried at 100°C [51]. At a I : II ratio of 1 : 1, the specific conductivity of the electrolyte was 2×10^{-4} (at 20°C) and 5×10^{-2} S cm^{-1} (at 100°C).

Sehlenoff *et al.* [52] suggested a PE based on poly(*p*-phenylenevinylene) (PPV). Films were prepared from a mixture of aqueous solutions of the polymers, a PPV precursor (water-soluble sulfonium salt) and a water-soluble polymer such as PEO, methyl cellulose, or hydroxypropyl cellulose, taken in 1 : 1 ratio. To prepare PPV, the salt precursor was subjected to heat treatment. The best results were obtained with PPV–PEO blends doped with $LiClO_4$. Such blends are resistant to thermal degradation (up to 225°C) and have good mechanical properties.

Bannister *et al.* [53] reported on the conducting properties of PEO alloys with a polymer containing sulfonate or perfluorocarboxylate groups. The conductivity obtained was relatively low ($\sigma = 10^{-5}$ S cm^{-1} at 100°C), probably because the initial monomeric salts either were insoluble or dissociated only slightly in the polyether phase.

In [54], the polymer matrix was PEO in which each monomeric unit of the backbone contained a pendant $-(CH_2-CH_2-O)_x-R$ chain ($1 < x < 20$, R is alkyl). The backbone and pendant chains in the polymer were linked via ether groups. The molecular weight (MW) of the backbone was 10^4–5×10^6, and that of the pendant chain, 50–2000. Such a PSE has a high conductivity at 20°C and can be used in lithium batteries.

PEs derived from PEO can be modified by introducing lithium salts of various fluorinated monobasic acids. The complex of PEO with $LiCF_3SO_3$ shows the highest conductivity among the complexes studied

($\sigma = 4 \times 10^{-4}$ S cm^{-1} at 100°C). With an increase in the size of the anion in these salts, the conductivity decreases, which is attributable to changes in the interaction and mobility of the ions. With a mixture of $LiCF_3SO_3$ and NaI, the electrical conductivity of a PE based on PEO substantially increases, and the microviscosity decreases [55]. Presumably, this effect is associated with a considerable increase in the content of the amorphous elastomer phase and to nonuniform distribution of different cations and anions in different phases.

Zapol'skikh *et al.* [56] studied the properties of PSEs based on poly[poly(ethylene glycol) dimethacrylate] (PPEGDM) and lithium salts of fluorinated sulfonic acids CF_3SO_3Li and $CF_3CF_2CF_2SO_3Li$. They found that the anion does not participate actively in the salt–polymer intermolecular interaction. The structure of the anion affects the solubility and degree of dissociation of the salt in cross-linked PPEGDM and exerts no direct influence on the flexibility of the polymer chains and mobility of the cations. As the anion size increases, the salt solubility decreases, but the electrical conductivity of the PSE increases.

To enhance the ionic conductivity of polymer electrolytes and improve the service characteristics of power sources based on them, many researchers [57–62] introduced into PSEs organic and inorganic additives decreasing the degree of crystallinity of the formulations. Chervakov *et al.* [62] synthesized and tested as additives certain nitrogen-containing compounds. Organosilicon derivatives of 4,4'-bipyridine appeared to be among the best additives; they increased the PE conductivity by a factor of 2.

Relatively high conductivity and good mechanical properties are exhibited by PSEs of the composition $(PEO)_8LiClO_4$ filled with finely divided (<5 μm) β-Al_2O_3 by mixing with a solution of PEO and $LiClO_4$ in acetonitrile [57]. Addition of Al_2O_3 [58] and $LiAlO_2$ ceramic microspheres 1 μm in diameter [59] (to 10–30% content) positively affects the mechanical properties and conductivity of PSEs. The conductivity increases by an order of magnitude on adding to PEO-based PEs such fillers as β-Al_2O_3, Li_2O–B_2O_3–SiO_2 ionic glasses, and ion-exchange resins in the lithium form [60, 61]. Assuming that the relationship between the preexponential term in the conductivity equation and the activation energy obeys the Meyer–Neldel rule in the entire range of the filler concentrations, Wieczorek and Florjanczyk [60, 61] concluded that the ionically conducting fillers do not participate in the charge transport through the solid electrolyte; their only role is that they make the composite more amorphous.

An increase in the PE conductivity on mixing with Al_2O_3 powder was reported in numerous papers. Such PEs were studied by impedance spectroscopy, X-ray diffraction, and NMR. It was shown that the conductivity of the PEO–NaI polymer electrolyte increases on mixing with Al_2O_3, exceeding 10^{-5} S cm^{-1} at room temperature [63].

One more method for preventing crystallization of amorphous polymers is cross-linking, e.g., cross-linking of PEO induced by irradiation with γ-rays or an electron beam [64]. The PEs thus obtained have increased lithium ion conductivity at low temperatures. The mechanisms of radiation-induced degradation and cross-linking of PEO in the solid state and in aqueous solution were studied by ESR [65]. A decrease in the crystallinity of cross-linked polymer materials and enhancement of their mechanical properties and conductivity at 20°C show that γ-irradiation is a simple and efficient procedure for preparing highly conducting and mechanically stable PEs. However, Kronfli *et al.* [66] have not confirmed the effect exerted by γ-irradiation of PE samples based on PEO and lithium salts ($LiClO_4$, $LiCF_3SO_3$).

Cross-linking of PEO containing the terminal groups CO–CH=CH–C_6H_4R (R = NO_2, Cl, OCH_3), CO–CH=CH–CH=CH–C_6H_5, CO–C(CN)=CH–C_6H_5, and CO–C(CN)=CH–CH=CH–C_6H_5 was described in [67]. The cross-linking occurs under irradiation with accelerated electrons or UV light. A thin-film PE sample (in a mixture with lithium salts) with 90% degree of cross-linking was obtained; its ionic conductivity was 1.7×10^{-4} S cm^{-1} at 20°C.

A polymer solid electrolyte with good mechanical properties and fairly high electrical conductivity, 5×10^{-5} S cm^{-1} at 25°C, was prepared from lithium perchlorate and cross-linked PPEGDM with a low cross-linking density [68]. The behavior of the boundary between the lithium electrode and PSE based on PPEGDM and lithium perchlorate was studied by impedance Fourier spectroscopy [69, 70]. It was shown that the behavior of a passivating film on the lithium electrode at anodic and cathodic polarization is unsymmetrical. A dc polarization decreases the resistance of the electrode|PSE boundaries, probably owing to enrichment of the passivating film with charge carriers.

Methods for chemical cross-linking of the polymer matrix were described in [71–73]. For example, a film PE with satisfactory conductivity at 30°C [71] and a

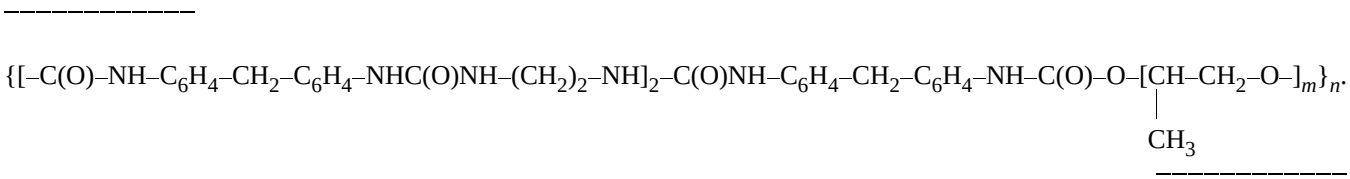
strong and elastic PE with $\sigma = 6 \times 10^{-5}$ S cm^{-1} at 25°C [72] were prepared by mixing of a product of copolymerization of polyglycerol with ethylene oxide, or of a mixture of ethylene and propylene oxides, with a polyfunctional cross-linking agent (polyisocyanate) at 50–200°C and $P > 10$ atm. Procedures for preparing PEs based on lithium salts and poly(ethylene glycols) cross-linked with siloxane tetraisocyanate were described in [73].

Hu and Wright [74] reported on cross-linking of PEO-based resins with vinyl monomers. Lithium perchlorate was added to PEO-400 maleate isophthalate resins prior to cross-linking with styrene (I), vinylpyrrolidone (II), or vinylpyridine (III). At the ratio [PEO]/[Li^+] = 50, the conductivity of the resulting PEs increased in the order III < II < I, inversely correlating with the strength of Li^+ binding, which increases in going to more polar comonomers.

Wieczorek *et al.* [75] prepared composite electrolytes from amorphous PEO copolymer cross-linked with oxymethylene groups (OMPEO), with additions of poly(*N*,*N*-dimethylacrylamide) (NNPAAM); these electrolytes showed a room-temperature conductivity of 4×10^{-4}–10^{-5} S cm^{-1}. There is no hydrogen bonding in such systems, which allowed the interactions of both polymers with the Li^+ ions to be studied in a wide range of temperatures and NNPAAM concentrations. Three types of complexes were revealed in the OMPEO–NNPAAM–$LiClO_4$ system: polyether–Li^+–polyether (type 1), polyether–Li^+–NNPAAM (type 2), and NNPAAM–Li^+–NNPAAM (type 3). Wieczorek *et al.* suggest that, above T_g, the ion motion is associated with the segmental motions of polymeric chains. Below T_g, the ion motion is a result of activated hoppings and is associated with the segmental motion of chains to a minor extent.

In parallel with the attempts to reduce the crystallinity of known PSE matrices, some researchers chose another approach: preparation of polymers with intrinsic amorphous structure by copolymerization of different monomers, one of which, as a rule, was oxirane [76]. In particular, amorphous single-phase solid electrolyte with enhanced ionic conductivity, no crystallinity, and good elasticity at 20°C was prepared by copolymerization of ethylene oxide and other oxides of the type –CH_2–CH(R)–O–, where R is alkyl, alkenyl, or alkynyl group containing 1 to 12 carbon atoms, or –CH_2–O–R'–R, where R' is a polyether –$(CH_2$–CH_2–O–$)_p$ (p is an integer from the range 0–10) or a cyclic ether containing more than three carbon atoms in the ring [77]. The oxides are chosen from the group of tetrahydrofuran, dioxolane, and their derivatives. Short cross-links in the electrolyte are provided by additions of silicon, cadmium, boron, titanium, zinc, magnesium, or tin compounds. The polymer electrolyte contained 1.5 to 25 wt % $LiClO_4$ or $LiCF_3SO_3$. A PE with $LiClO_4$ was prepared from an amorphous copolymer of ethylene and propylene oxides and alkyl glycidyl ether (98% amorphous phase). Its maximal conductivity at 25°C was 7.5×10^{-5} S cm^{-1} at a lithium to oxygen ratio of 0.05 [78].

It was suggested in [79, 80] to use as a base of a polymer electrolyte for a lithium battery a cross-linked copolymer of ethylene and propylene oxides. In a combination with a lithium salt, such a PE ensures the specific conductivity of the order of 10^{-5} S cm^{-1} at 25°C. The product of the copolymerization of the vinyl ether R(O–$CH_2CH_2)_n$–O–CH=CH_2 (R = Me or Et, n = 1–16) with the divinyl ether CH_2=CH–(O–$CH_2CH_2)_n$–CH=CH_2 (n = 1–16) is a cross-linked polyether with a glass transition point of about 60–80°C; this polymer was used as a matrix for preparing solid PE.



A procedure for preparing PE by mechanical mixing of acrylic poly(alkylene oxide) and a lithium salt with polyurethane (PU) or polyurethane–urea in a solvent at room temperature, followed by a heat treatment of the resulting mixture, was suggested in [81]. The resulting solid electrolyte had a conductivity of 1.5×10^{-5} S cm^{-1} and satisfactory mechanical properties. On adding $LiClO_4$ to PU, the ionic conductivity at 20°C increased to $\sigma = 4 \times 10^{-4}$ S cm^{-1} at PU : $LiClO_4$ = 8 : 1 [82]. At a high $LiClO_4$ content, the conductivity decreased because of growing viscosity. The difference between the conductivities of the PEs based on PU and PEO is especially significant below 80°C, since, as the temperature is decreased, the conductivity of PEO drastically (by a factor of about 10) decreases because of structural rearrangement. Experiments with lithium electrodes showed that the transport numbers of lithium cations at 50–100°C were 0.5–0.8. To prevent deterioration of the PE in prolonged storage, it was suggested to use as a polymer matrix a urethane-like polymer with the hydrogen atoms substituted by alkali or alkaline-earth metal atoms [83].

A polymer electrolyte having the structure of a modified polyurethane network was prepared from poly(dimethylsiloxane) with grafted PEO, cross-linked with an aliphatic diisocyanate and containing 10 wt % $LiClO_4$. Its ionic conductivity was 10^{-5} S cm^{-1} at 30°C. This electrolyte was used in solid-state lithium batteries. The voltammetric data showed that, after the completion of the formation of the polyurethane net-

work, the unchanged cross-linking agent can prevent the diffusion of lithium ions at the electrode–electrolyte phase boundary. The limiting currents were determined from the cathodic branches of the voltammogram. The internal resistance of the RuO_2/Li battery with the PE, 5 kΩ, was determined from the discharge curves taken at 60–80°C. After two discharge cycles with 95 and 73% degree of discharge, the adhesion of the PE film on RuO_2 and on Li remained unchanged [84].

The morphology and physical properties of the electrolytes from linear segmented polyurethanes based on PEG and alkali metal salts are described in [85]. Systems based on siloxane polymers can be prepared by mixing in a common solvent lithium salts and organopolysiloxane containing more than two COOH groups [86]. The conductivity of such PE at 25°C is 5.6×10^{-5} S cm^{-1}.

Another way to retain PE in the amorphous state is formation of segmented block copolymers in which the chain order is distorted and hence the crystallization is hindered. Watanabe *et al.* [87, 88] studied a series of materials in which this principle is followed, especially the system with segmented polyether–urethane–urea as primary crystal. This substance has an $(A–B)_n$ structure, where A is a rigid polyurethane–urea segment (~30 wt %) and B is a flexible polyether segment:

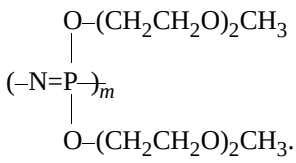
The polyurethane–urea segments tend to aggregate by hydrogen bonding with the formation of a two-phase microstructure, which imparts to the electrolyte excellent mechanical properties. Salts such as $LiClO_4$ selectively dissolve in the polyether. The relationships between the morphology, dynamic and mechanical properties, and ionic conductivity of these materials are given in [88, 89].

Liu *et al.* [90] suggested a related matrix polymer, polyurethane–urea (PUU) derived from 4,4'-methylenebis(phenyl isocyanate), ethylene diamine, and poly(ethylene glycol). The molecular weight of the flexible (polyether) segment was 1000, the weight fraction of the rigid (polyurethane–urea) segment, 35, and the melting point of the polymer, 180°C. A film prepared from the complex of a lithium salt with polyurethane–urea had the ionic conductivity $\sigma = 10^{-5}$ S cm^{-1} at 33°C; its mechanical strength was sufficiently high. To extend the assortment of polymer matrices, oligo(ethyleneoxy)polyphosphazene (OPP) containing alkyl groups was prepared in [91]. The procedure involved transformation of hexachlorotriphosphonitrile into dichlorophosphonitrile followed by its reaction with appropriate alcoholates. Up to 5 wt % $LiClO_4$ is introduced into OPP in the course of the synthesis, which ensures sufficiently high lithium ion conductivity of the PE.

Nagaoka *et al.* [92] prepared polymers with a very low glass transition point by polycondensation of dimethyldichlorosilane with poly(ethylene glycol):

$$[–Si(CH_3)_2–O–(CH_2–CH_2–O–)_n]_m.$$

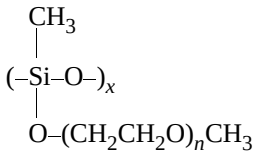
The high flexibility of the backbone and the absence of crystallinity (because of irregular chain structure) provide relatively high conductivity of such polymers: 10^{-4}–10^{-5} S cm^{-1} (considerably higher than that of MEEP, see below).



Zapol'skikh *et al.* [93] studied the PSEs based on poly(ethylene glycols) of various molecular weights, cross-linked with methyl- and phenyltrichlorosilanes. The polymers were transparent elastic heat-resistant materials. The highest room-temperature conductivity, 5×10^{-5} S cm^{-1}, was shown by the PSE prepared by cross-linking of PEG-300 with methyltrichlorosilane. However, the use of such systems is restricted by high susceptibility of siloxanes to hydrolysis.

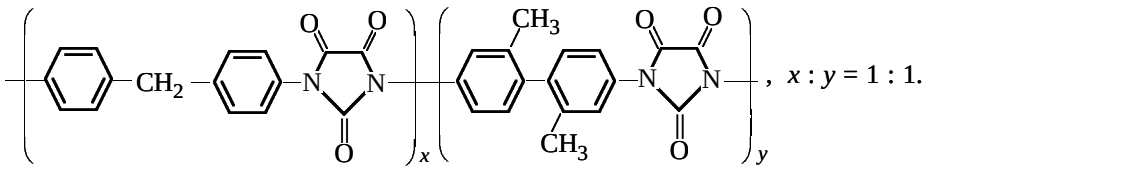
Polymer Solid Electrolytes Based on Other Polymer Matrices

Numerous attempts to improve PSEs based on the traditional poly(ethylene oxide) matrix failed, which stimulated search for new polymer materials with low crystallinity and low glass transition point. Such properties are exhibited, e.g., by comb-shaped branched polymers.



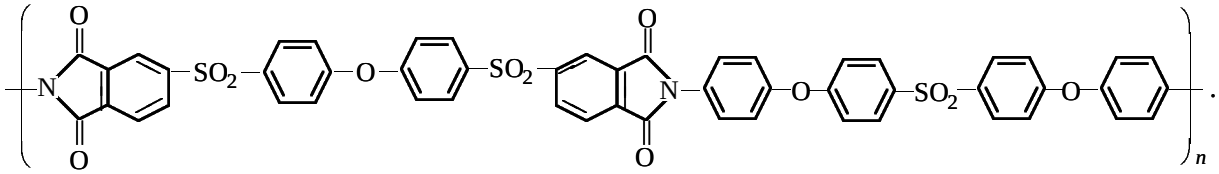
Flexible comb-shaped branched systems can be prepared from polymers whose backbone has a low

glass transition point [94]. With the aim to prepare such PEs, Allcock *et al.* [95–97] studied systems based on phosphazene and siloxane polymers. One of the best polymers for PEs was prepared by replacement of chlorine atoms in poly(dichlorophosphazene) with alkoxy groups under the action of sodium 2(2-methoxyethoxy)ethylate in the presence of tetra-*n*-butylammonium bromide to obtain the compound



This polymer, poly[bis(methoxyethoxyethoxy)-phosphazene] (MEEP), forms single-phase amorphous electrolytes with salts of various uni-, bi-, and trivalent metals [95]. The complexes of some lithium salts with this inorganic polymer are PEs with a high conductivity. For example, the room-temperature conductivity of MEEP–$(LiBF_4)_{0.25}$ is 2×10^{-5} S cm^{-1}. However, the mechanical properties of these electrolytes are unsatisfactory, and they cannot be cast as free films to be used in solid-state lithium CPSs. Several approaches are used to enhance the mechanical stability of MEEP-based electrolytes [98]. One of them is blending of MEEP with PEO, PPO, polyvinylpyrrolidone, or poly(tetraethylene glycol diacrylate). The resulting composite electrolytes can be cast as free films. Their conductivity is somewhat lower than that of MEEP–$(LiX)_n$ but considerably higher than that of PEO–$(LiX)_n$. The dependences of the ionic conductivity of solid-phase polymer complexes of the oligo(ethylene oxide)–polyphosphazene graft copolymer on the temperature and salt concentration were studied by Hara [99]. The highest conductivity ($\sigma_{max} = 10^{-4}$ S cm^{-1}) of the complexes was observed at 25°C and 15 wt % content of $LiClO_4$. For the complexes of $LiClO_4$ (7.5 wt % salt content) with polyphosphazene modified by grafting of oligooxyethylene with the degree of oligomerization of 7, σ was as high as 3.5×10^{-4} S cm^{-1}. For the systems of polycyclotriphosphazene of a complex structure with $LiClO_4$, $\sigma = 1.2 \times 10^{-4}$ S cm^{-1} (at 90°C); with increasing temperature, the conductivity maximum shifted toward higher salt concentrations [100].

It was shown in [101] that liquid comb-shaped branched polymers of the structure



can be additionally cross-linked by heating to 150°C (to obtain rubber-like films). The length of the pendant chain in this case affects the conductivity insignificantly. For the PE containing $LiClO_4$ as an ionic additive, the conductivity was 10^{-4} S cm^{-1} at 25°C. Liquid curable organosiloxanooxyalkylene copolymer formulations with acrylate functional groups, containing $LiCF_3SO_3$ and azobis(isobutyronitrile), were patented. After curing at 85–90°C for 30 min, 1-mm-thick elastic films with a conductivity of 1.6×10^{-5} S cm^{-1} were obtained.

Yamamoto *et al.* prepared and studied polymer solid electrolytes based on polyvinyl alcohol (PVAl, MW 25 000, degree of saponification 88%) and heat-resistant polyarylene(1,3-imidazolidine-2,4,5-trione-1,3-diyl) (polyparabanic acid, PPA) [102]. These polymers dissolve large amounts of alkali metal salts such as $LiCF_3SO_3$, $LiBF_4$, $LiClO_4$, and $NaBF_4$ (1–1.5 g g^{-1} polymer) to form homogeneous films. Dissolution of lithium salts renders the polymers amorphous.

A DSC study of the pure polymers and polymer–salt compounds showed that T_g and T_m decreased on introducing salts into the polymer matrix. This contradicts the usually observed trend that formation of polymer electrolytes from commonly used polymers causes T_g and T_m to increase. Yamamoto *et al.* attribute a decrease in T_g and T_m to decreased degree of crysrtallinity and, correspondingly, to facilitated micromotions of the chain. It was suggested that a decrease in T_g facilitates motion of ions in polymer solid electrolytes. These results indicate that low T_g is important for migration of ions in a polymer electrolyte.

At the same time, ions can also migrate even in a polymer matrix containing relatively rigid domains. A polymer electrolyte can consist of amorphous domains with a high concentration of a lithium salt and domains with a relatively rigid structure and lower salt concentration; the ions mainly migrate through amorphous domains. Yamamoto *et al.* also examined the possibility of using as polymer electrolyte water-soluble and highly heat-resistant polysulfone–ether–imide (PSEI, $[\nu] = 0.5$ g dl^{-1}):

In contrast to PPA, this polymer gave only heterogeneous and brittle films on introducing $LiCF_3SO_3$ (0.16–0.5 g g^{-1} PSEI), despite the presence of a large amount of electron-donor atoms theoretically capable of solvating Li^+ cations.

Zapol'skikh *et al.* [103] studied the properties of PSEs based on poly(piperylene sulfone) and lithium perchlorate. They found that the room-temperature electrical conductivity of the PSE was 10^{-6} S cm^{-1} and explained this relatively high value by the presence of residual solvent, which could not be fully removed upon preparation of the films from a solution of the polymer and salt in dimethylformamide. An IR study showed that the lithium ion was coordinated with three oxygen atoms of sulfone groups and nitrogen atom of dimethylformamide. This results in displacement of the perchlorate ion from the inner coordination sphere of the lithium ion and thus in higher degree of electrolytic dissociation of the salt in the polymer matrix.

The goal of Smirnov *et al.* [104] was to develop new highly conducting PEs free of aprotic solvent. The formulation for preparing a PE consisted of an amorphous rigid-chain polymer (polyheteroarylene) and a lithium salt ($LiClO_4$ or $LiBF_4$). The polymer solid electrolytes exhibited high elasticity, mechanical strength, and acceptable adhesion to the electrode materials. Their conductivity at 20–60°C reached about 10^{-3} S cm^{-1}. The polarization at the PSE|Li phase boundary was 30–60 mV, and it gradually decreased in the course of charging–discharge, which was due to mutual adjustment of the components of the Li–PSE system. The photomicrographs of the surface of the lithium foil before and after the cycling revealed no significant changes.

Studies of the structure and mechanisms of the ion transfer in PE showed that the required set of transport properties can be attained in PSEs based on noncrystallizing polymer matrices, acrylonitrile–butadiene copolymers. Lirova *et al.* [105] used a 40 : 60 acrylonitrile–butadiene copolymer (SKN-40 rubber) containing highly polar CN groups capable of coordination interaction with the metal salts. The electrolyte films 40–120 μm thick were prepared by a modified casting procedure, with introduction of $LiClO_4$, $LiCF_3SO_3$, or $LiAsF_6$. The interaction of the lithium ions with the CN groups was studied by IR spectroscopy. By analogy with the well-studied interaction of Li^+ with acetonitrile, it was found that the solvation of the cations in SKN-40 is due to formation of coordination bonds with the cyano groups: $-C\equiv N^{\delta-}\cdots Li^+$. Lirova *et al.* [105] conclude that the solvation of the cation with the polar groups of the polymer is the factor ensuring solubility of the salt both in the low-molecular-weight solvent and in the chemically related polymer, and formation of a macromolecular ionic solution ensures high ionic conductivity of the electrolytes.

As a continuation of these studies, Dusheiko [106] prepared films from copolymers of acrylonitrile with styrene and vinyl acetate as PSEs. The solid electrolyte films prepared with these polymer matrices showed a conductivity of 10^{-5}–10^{-6} S cm^{-1} and high physicomechanical properties. Bushkova *et al.* systematically studied the ion solvation in PSEs in wide temperature and concentration ranges. As polymer matrices they used amorphous acrylonitrile copolymers (SKN-40, SKN-26, SKN-50) and polyacrylonitrile, into which $LiClO_4$, $LiAsF_6$, and $LiCF_3SO_3$ were introduced. The measurements of the temperature and concentration dependences of the PSE conductivity suggested that, in the range of maximally high salt concentrations, a specific mechanism of ion transport is realized, involving higher ionic associates.

In some cases, the conductivity of such electrolytes reached about 10^{-3} S cm^{-1}. However, stabilization of the highly conducting structure in the concentrated electrolytes was not yet attained.

Amorphous polymer electrolytes can be obtained from a copolymer of acrylonitrile with sulfoalkyl methacrylate [109]. The conductivity of various salt species of PE varies in the order Li salts > Na salts > K salts and increases as the oxygen to lithium ratio is increased from 20 to 100. The new PEs based on copolymers with polyvinyl alcohol, PVA, and polyacrylamide exhibit high heat resistance at fairly high conductivity [110].

Novakov *et al.* [9] tested as polymer matrices aliphatic polycarbonates: poly(ethylene carbonate) (PEC) and poly(propylene carbonate) (PPC), with lithium perchlorate introduced in various molar ratios. The electrical conductivity of the best formulations varied from 10^{-6}–10^{-5} at 293 K to 10^{-3} S cm^{-1} at 393 K. *Ab initio* quantum-chemical calculations of the PEC–$LiClO_4$ and PPC–$LiClO_4$ system showed that the lithium ion preferentially coordinates with the carbonyl oxygen atom, in agreement with the IR data.

Dusheiko *et al.* [111] used as PEs copolymers of acrylonitrile with butyl methacrylate (1 : 1), vinylpyridine (1 : 1), and vinyl fluoride (2.3 : 1). The copolymers were amorphous white nonhygroscopic powders. From their solutions, elastic transparent films 30–60 μm thick, doped with lithium perchlorate, were prepared. The highest conductivity, with preservation of the required physicomechanical properties, was attained at a $LiClO_4$ content of 15–20 wt %.

PLASTICIZED POLYMER ELECTROLYTES

Attempts to develop PSEs based on polymer–lithium salt systems, exhibiting acceptable electrochemical characteristics (in particular, room-temperature conductivity), were yet unsuccessful. Despite the optimism expressed in [104, 108, 112, 113], the results obtained with true PSEs are mainly inferior to those obtained with plasticized PEs. Therefore, much efforts were focused in the recent years on the development of plasticized or gel-polymer electrolytes (GPEs) containing, along with a polymer and a lithium salt, also plasticizers (solvents) and other components. The requirements to the plasticized PEs are mainly the same as those to PSEs: high electrical conductivity, satisfactory physicomechanical properties, chemical stability toward electrode materials, and wide range of electrochemical stability. However, in development of plasticized PEs, it is necessary to take into account also other factors: compatibility of the polymer matrix with the organic solvent, necessary for retention of the solvent in GPE; phase stability and efficiency in a wide temperature range. Otherwise, the GPE film can lose the solvent and the mechanical strength.

The above properties are largely determined by the kind of the polymer, composition of the plasticized PE, and temperature. Complex physicochemical processes involving the components and governing the characteristics of plasticized PEs occur in the system. The mechanisms of these processes are not fully understood. Presumably, donor–acceptor, ionic, and van der Waals interactions occur in the system [114].

The problem of enhancing the conductivity of PEO-based polymer electrolytes was solved in [115–119] by introducing crown ethers. Measurements of the electrical and electrochemical properties of PE films consisting of PEO and $LiCF_3SO_3$, $LiBF_4$, or $LiClO_4$ and containing 12-crown-4 (12C4) or free of it showed that, with each salt, the conductivity at a given temperature depends on the crown ether concentration and reaches a maximum at [12C4] : [Li] = 0.003 [116].

Eyring [117] studied the kinetics of complexation of alkali metal cations with macrocyclic ligands: 12-crown-4, 18-crown-6, and 15-crown-5. The crown ether groups (16-crown-5) were also introduced into polyphosphazenes (PPs) as pendant groups [120, 121]. The temperature dependence of the conductivity of such PEs containing $LiClO_4$ or $NaClO_4$ was studied. The $\log\sigma$–T^{-1} dependence was linearized using the VTF equation. The highest conductivity was attained in the system PP–$NaClO_4$, which was due to higher degree of ionization of the salt bound by the macrocyclic moiety of the polyphosphazene.

Introduction of 12-crown-4 both into a solid PE consisting of PEO and $LiBF_4$ and into the cathodic formulation enhances the ionic conductivity [119]. The electrolyte has a very low leakage current. Addition of the crown ether improves the cell performance, decreases the resistance to charge transport, increases the current, and makes the cell operation more reversible (with CoO_2 and TiS_2 cathodes). Along with crown ethers, a suitable additive is cryptand, a bicyclic compound also forming a complex with lithium ions [122].

Yarmolenko *et al.* [123] prepared and studied a series of new polymeric electrolytes based on $LiClO_4$ and PEO with additions of finely divided β-$LiAlO_2$,

γ-$LiAlO_2$, or Al_2O_3 powder and of 2,4-dioxo-16-crown-5. Measurements by impedance spectroscopy showed that the room-temperature conductivity of the samples was as high as 10^{-4}–10^{-5} S cm^{-1}; the compatibility with the cathodes based on thermally crosslinked polyacrylonitrile (TCPAN) and lithium anode was good. Introduction of 2,4-dioxo-16-crown-5 into PEO-based PSE improved its parameters owing to complexation of the lithium salt with the crown ether. In a later work [124], Yarmolenko *et al.* studied a series of new PSEs based on $LiClO_4$ and PEO with additions of 15-crown-5, benzo-15-crown-5, and 2,4-dioxo-16-crown-5. A series of the samples obtained exhibited high (10^{-4}–10^{-3} S cm^{-1}) room-temperature conductivity, good compatibility with the lithium anode, and stability in prolonged storage. Yarmolenko *et al.* found that introduction of 15-crown-5 and 2,4-dioxo-16-crown-5 into PEO-based PSE enhances its conductivity by two orders of magnitude, whereas introduction of benzo-15-crown-5 exerts no effect on the conductivity of this electrolyte.

Additions of 15-crown-5 and benzo-15-crown-5 to polymer electrolytes based on polyacrylonitrile, lithium perchlorate, and propylene carbonate allowed preparation of PEs with the conductivity at 20°C as high as 10^{-3} S cm^{-1} [118].

To enhance the electrical conductivity of films based on acrylonitrile copolymers, Clericuzio and Parket [125] added a mixture of propylene carbonate and dimethoxyethane as plasticizer; their content in the copolymer did not exceed 10 wt %. The conductivity of the PEs obtained was within 10^{-6}–10^{-4} S cm^{-1}.

Addition of low-molecular-weight plasticizers such as ethylene and propylene carbonate to electrolytes based on PEO [126, 127], polyacrylonitrile (PAN), poly(tetraethylene glycol diacrylate), or polyvinylpyrrolidone [128], and also to hybrid films based on poly(methyl methacrylate), polystyrene, poly(vinyl chloride) (PVC), PVA, PAN, and poly(vinylidene fluoride) in amounts of up to 30 mol % increased the electrical conductivity to 10^{-5}–10^{-3} S cm^{-1} [129]. The stable voltage of a Li|PE|MnO_2 voltaic cell, which operated for more than 70 h without electrolyte degradation, shows that hybrid films are suitable as PEs for solid-state batteries. The possibility of plasticizing PEO-based compounds by adding poly(propylene glycols) of various molecular weights was examined in [130, 131]. Such plasticization enhances the conductivity owing to an increase in the content of the amorphous phase in the electrolyte, with a simultaneous increase in the salt concentration in this phase.

The properties of gel polymer electrolytes based on PVC and solutions of lithium salts in sulfolane were studied in [132, 133]. An electrolyte solution in a polymer matrix acts as an intra- and interstructural plasticizer. The distribution of an electrolyte solution in a polymer matrix is determined by the kind and concentration of the electrolyte salts. In some cases, structural nonuniformity of GPEs results in dendrite formation in the course of prolonged dc polarization [134].

To obtain an amorphous polymer with PVC as a PE matrix, Chervakov *et al.* [135] performed a chemical modification by chlorination. As a result, the chlorine content increased from 56.8 (initial PVC) to 65%. The other electrolyte components were a salt and a plasticizer (aprotic solvent).

Polishchuk *et al.* [112] studied the system Li|Li^+|PE|FeS_2. The polymer matrix for the electrolyte was modified PVC. The modification of the polymer electrolyte was performed by additional chlorination, which afforded a more amorphous material. The conductivity of the polymer electrolytes prepared by this procedure was as high as 10^{-3} S cm^{-1}; it depended on the kind of the low-molecular-weight plasticizer and lithium salt.

The problem of development of a GPE based on PVC, which is insoluble in EC and PC, was solved by using tetrahydrofuran as solvent, in which all the components (PVC, EC, PC, $LiClO_4$) are soluble. Films with a conductivity of 1.2×10^{-3} S cm^{-1} at 20°C were prepared by casting [136].

A procedure for preparing new plasticized and microporous PEs based on poly(vinylidene fluoride) and chlorinated poly(vinyl chloride), with a room-temperature conductivity of 10^{-4}–10^{-3} S cm^{-1} and electrochemical stability in the range from 0.5 to 4.5 V (vs. lithium electrode), was suggested by Chervakov *et al.* [137]. A characteristic feature of the procedure developed is the possibility of preparing a polymer matrix with the required pore structure morphology and specific interaction with solutions of lithium salts in aprotic solvents. This is attained by a proper choice of a plasticizing system and a process for forming PE. It was shown that the nature and composition of the plasticizing system for PE essentially influence the formation of passivating films on metallic lithium and graphite anode and govern the specific characteristics of the cathode materials, stability in cycling, and self-discharge of the electrochemical systems. A process for preparing PEs for the systems Li|PE|$LiCoO_2$ and Li–MnO_2 involves preparation of a microporous polymer material and its subsequent

activation with a solution of a lithium salt in an aprotic solvent.

Kelly and Owen [138–140] enhanced the low-temperature conductivity of the systems PEO–$LiClO_4$ and PEO–$LiCF_3SO_3$ by adding low-molecular-weight polyethers $CH_3(OCH_2CH_2)_nOCH_3$. The materials obtained behaved similarly to solutions of the salts in poly(ethylene glycol) dimethyl ether ($\sigma = 10^{-4}$ S cm^{-1} at 40°C); however, the mechanical properties of the products appeared to be unsatisfactory.

An X-ray diffraction study showed that the unit cell of the PEO crystal remained monoclinic on adding the elastomer and macromonomer. The diffraction patterns and conductivities remained unchanged during a period of 15 months. The conductivity was also stabilized by partial replacement of PEO by oligo(ethylene oxide) with terminal styrene groups, with the weight ratio of ethylene oxide units to Li^+ kept unchanged [141]. The best results ($\sigma = 2 \times 10^{-4}$ S cm^{-1}) were obtained with $LiCF_3SO_3$ on adding 20 to 50% low-molecular-weight oligo(ethylene oxide) with MW 550.

Xia *et al.* [142] studied how the conductivity of solid polyelectrolyte complexes of alkali metal salts NaSCN, $NaCF_3SO_3$, and $LiCF_3SO_3$ with polymers derived from methoxypoly(ethylene glycol) methacrylate $CH_2{=}C(CH_3)COO(CH_2–CH_2O)_nCH_3$ [n = 8 (PMG-8) and n = 22 (PMG-22)] depend on the temperature and salt concentration. The systems based on copolymers of PMG-22 with polystyrene, like the systems plasticized with propylene carbonate, showed considerably higher conductivity than the systems based on the homopolymers. A highly conducting formulation based on a blend of alkylacrylate (alkyl C_1–C_8) and/or alkoxyacrylate (alkoxy C_2–C_5) polymer with 5–100% (relative to the weight of the acrylate polymer) of $LiClO_4$ or a lithium salt of a polymeric acid (polystyrenesulfonic, polyethylenesulfonic) was described in [143] as a thin-film electrolyte. The plasticizer and solvent was an organic solvent with a high dielectric permittivity.

Polymers derived from phosphazene with various alkyl ether and alkoxy pendant groups were prepared. The room-temperature ionic conductivity of the electrolytes consisting of such polymers and $LiCF_3SO_3$ was 10^{-4}–10^{-3} S cm^{-1} [144]. Villarreu [145] studied the behavior of polymer electrolytes formed by a blend of PEO and perfluorinated polyphosphazene and filled with γ-$LiAlO_2$ or propylene carbonate. It was found that the filler appreciably increases the ionic conductivity of the polyelectrolyte, whereas propylene carbonate decreases it; these effects were attributed to structural changes in the formulation.

Kicheev *et al.* [146] suggested aromatic polymers as the polymeric components, in view of the high thermal, chemical, and electrochemical stability of these polymers. As plasticizer they used a 1 M solution of $LiClO_4$ in a mixture of propylene carbonate and dimethoxyethane. The best of the polyelectrolytes studied showed the conductivity of 2.25×10^{-2} S cm^{-1} (298 K). An XPES study of the lithium anode showed that the polyelectrolyte was chemically inert.

Siling *et al.* [147] suggested a highly conducting gel-polymer electrolyte for lithium power sources, based on poly(phenylene oxide) prepared by a special procedure. The gel-polymer electrolytes were prepared by impregnation of the polymer with a solution of $LiClO_4$ in a mixed solvent. The electrical conductivity of the GPE was $(1.25–7) \times 10^{-2}$ S cm^{-1} at room temperature and $(4.1–7) \times 10^{-3}$ S cm^{-1} at 30°C; it was chiefly determined by the conditions of the synthesis of the polymeric component.

No oxide film is formed on lithium in the course of operation of Li–MnO_2 and Li–LiV_3O_8 cells with the GPE developed. No dendrites are formed either.

Yarmolenko and Efimov [148] found that oligo(urethane–methacrylates) derived from polytetrahydrofuran of molecular weight 1400–1600 (SKU–PFL) and poly(ethylene glycol monomethacrylate) (PPMBE) of molecular weight 370 can be used for preparing gel-polymer electrolytes for lithium batteries by introduction of liquid organic electrolytes (e.g., 1 M $LiClO_4$ in a 1 : 1 mixture of propylene carbonate and dimethoxyethane) into the oligomer, followed by film forming and photochemical or thermal curing. The conductivity of the film electrolytes is increased by formation of a branched network copolymer with a methacrylic comonomer in combination with addition of organic solvents for alkali metal salts; these solvents also act as plasticizers. Gel-polymer electrolytes based on SKU–PFL + PPMBE (1 : 1 by weight) and 1 M solution of $LiPF_6$ in EC + dimethyl carbonate (volume ratio 1 : 1) showed a conductivity of 2.5×10^{-3} S cm^{-1} (at 20 wt % content of the polymer in the system). The resulting thin-film electrolyte was a structured gel rather than a monolithic film. Therefore, a special procedure was developed to enhance the mechanical stability of PE. It involved introduction of the electrolyte formulation into a porous polypropylene separator, followed by photocuring. The highest conductivity (2.8×10^{-4} S cm^{-1}) was attained with the GPE containing 20 wt % SKU–PFL + PPMBE (1 : 1) and 80 wt % organic electrolyte (1 M $LiClO_4$ in γ-butyrolactone), applied to a fibrous polypropylene separator (99% porosity).

Gel-polymer electrolytes can also be prepared on the basis of anion- and cation-exchange polyelectrolytes [149–151]. Such electrolytes exhibit fairly high electrical conductivity (10^{-4}–10^{-3} S cm^{-1}) and selectivity with respect to the transported ion.

Papers concerning development of solid and plasticized polymer electrolytes show that it is very promising to search for nontraditional ways to improve the electrochemical and service properties of PEs. Among such ways are synthesis and use of new lithium salts with hyperlarge anions and chemical modification of electrolytes of lithium power sources with the aim to optimize the current transport in liquid and solid polymer media [5, 137, 152].

In particular, Chervakov *et al.* [137] develop procedures for preparing new lithium salts of *N,N'*-disubstituted alkyliminosulfinic acid amides. These resinous substances are readily soluble in aprotic solvents and are electrochemically stable in the range 1.1–4.6 V. By optimizing the structure of the anion, Chervakov *et al.* prepared lithium salts acting in PE not only as conducting additives but also as plasticizers. The following ionic salts with large anions were involved recently in PE studies: lithium tris(trifluoromethanesulfonyl)methide $LiC(CF_3SO_2)_3$, lithium bis(trifluoromethanesulfonyl)imide $LiN(CF_3SO_2)_2$, and lithium bis(perfluoroethanesulfonyl)imide $LiN\cdot(C_2F_5SO_2)_2$ [5].

CONCLUSION

Although a large body of data have been accumulated on lithium-containing polymer composites, search for new formulations of polymer electrolytes for lithium and lithium–ion batteries is being continued. The interest in basic and applied research in the field of development of new polymer electrolytes and high-capacity CPSs based on them undoubtedly grows.

Abstract—Reactions of crushed wastes from lithium tantalate (niobate) production with lithium carbonate were studied by thermal and X-ray analyses. Conditions for their most complete conversion into lithium orthotantalate (orthoniobate) were determined.

In modern production of lithium metatantalate (metaniobate) single crystals, which are widely used in electronics, large amounts (70–80% in many cases) of the rare metals pass into wastes. Because of shortage and high cost of tantalum and niobium raw materials, and also of a substantial demand for the products of their conversion, development of the methods for the waste regeneration is an urgent problem.

Lithium metatantalate and metaniobate are very stable compounds, and their breakdown is a complex problem. In contrast to $LiNbO_3$, lithium orthoniobate was found [1] to react easily with H_2SO_4, HCl, and HNO_3; in the process, lithium passes into a solution and niobium is converted to complex compounds. Their calcination yields amorphous niobium pentoxide. However, the degree of Li_3NbO_4 decomposition depends not only on the acid in use, but also on the degree of $LiNbO_3$ conversion into Li_3NbO_4 by the reaction of $LiNbO_3$ with Li_2CO_3. At present, procedures for preparing lithium orthotantalate and its properties have not been adequately studied. At the same time, this problem is important for the technology of compound production and waste processing.

In this work we studied of the mechanism of the solid-state reaction between lithium tantalate (niobate) and lithium carbonate with the aim to find conditions of their most complete conversion into other less stable compounds.

We studied the Li_2CO_3–$LiTaO_3$ and Li_2CO_3–$LiNbO_3$ systems by differential thermal (DTA), differential thermal gravimetric (DTG), and thermal gravimetric analyses (TG), and also by X-ray diffraction and crystal-optics methods.

We studied the sintering process on an MOM Q-1500D derivatograph (Hungary) in platinum crucibles. We used calcined Al_2O_3 as a reference. The temperature was measured with a platinum/platinum–rhodium thermocouple. The heating rate was 10 and 20 deg min^{-1}.

We performed the X-ray analysis of the reaction products on a DRON-2 diffractometer with CuK_α radiation.

As starting substances we used predried ultrapure grade lithium carbonate; crushed wastes of $LiNbO_3$ and $LiTaO_3$ with particle size less than 160 μm (d > 50 μm, 40%; d < 50 μm, 60%), and also the 30–60-μm fractions.

The melting points of Li_2CO_3 reported by numerous researchers are inconsistent, because in the vicinity of the melting point of the compound (or simultaneously with melting) it starts to dissociate to give Li_2O. The following melting points are given for Li_2CO_3 in different papers: 618, 699, 710, 720, and 723°C. Plyushchev and Stepin [2] believe that these results are underestimated and the value of 735°C recommended in the handbook [3] and confirmed in numerous studies is the most reliable. The data characterizing the range of temperatures at which the dissociation of Li_2CO_3 starts and becomes noticeable are not always consistent either: 580–1000, 610–1010, and 777–1113 °C [2]. In this range, the CO_2 pressure increases from 1 mm Hg at 610°C to the atmospheric pressure (760 mm Hg) at 1270°C.

The experimental derivatogram of Li_2CO_3 is given in Fig. 1. It shows that the weight loss (the TG curve) starts at a temperature higher than 678°C. We assign this temperature to the onset of the stepwise dissociation of lithium carbonate. A sharp endothermic effect is observed in the DTA curve at 730°C; we assign it to the onset of Li_2CO_3 melting. The most reliable

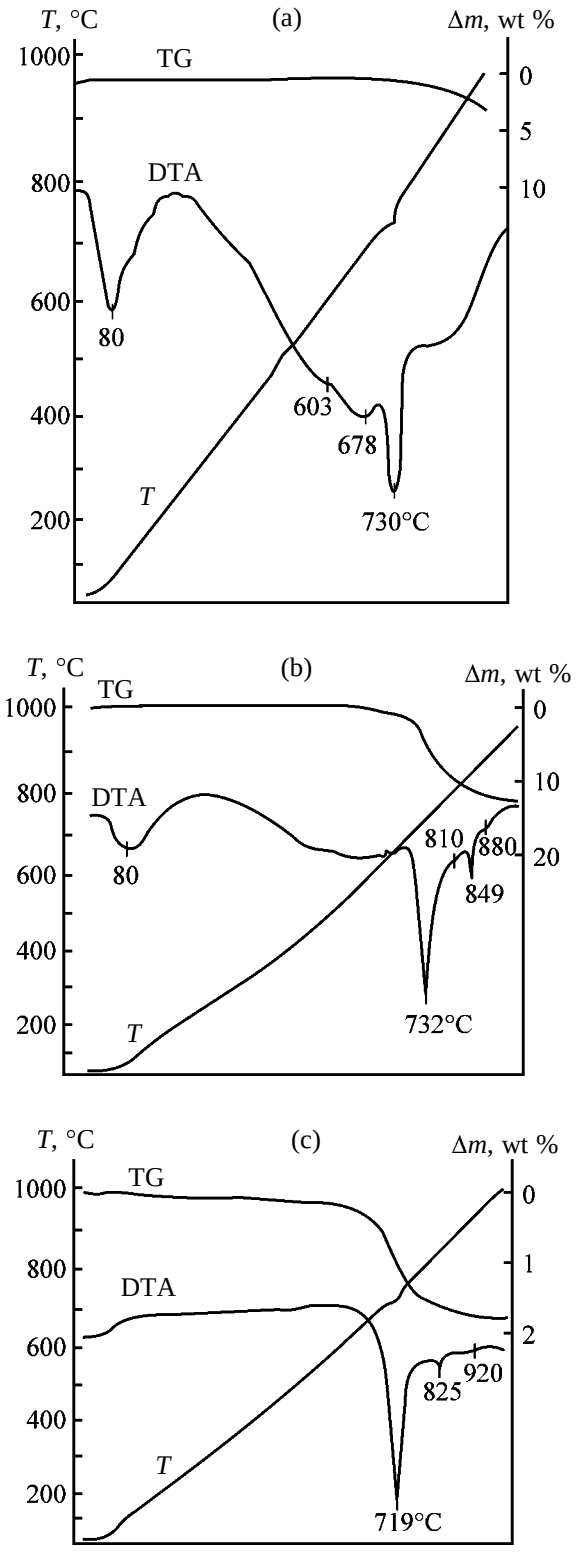

Fig. 1. Derivatograms of (a) Li_2CO_3, (b) mixtures $LiTaO_3 : Li_2CO_3 = 1 : 1$, and (c) mixture $LiNbO_3 : Li_2CO_3 = 1 : 1$, recorded in the dynamic mode. (*T*) temperature and (Δm) weight loss.

results can be obtained by visual polythermal analysis.

Reaction of Li_2CO_3 with $LiTaO_3$. The formation of lithium metatantalate in the Li_2CO_3–Ta_2O_5 system has been thoroughly studied in the literature. No clear steps can be distinguished in the reaction. In the DTA curve, one endothermic effect is always observed at different heating rates [4]. This effect coincides in temperature with the Li_2CO_3 melting. Starting from 550–600°C, lithium metatantalate appears to be the main reaction product at the ratio $Li_2CO_3 : Ta_2O_5 = 1 : 1$. Other possible phases are found only in trace amounts in definite temperature ranges: $LiTa_3O_8$, after annealing the mixture at 600°C; Li_7TaO_6, at 700°C; and α-Li_3TaO_4, at 900°C. However, the X-ray phase analysis shows that $LiTaO_3$ actively reacts with Li_2CO_3 even at 550°C. In this case, up to 700°C, the first and main product of the reaction is $LiTa_3O_8$, and only at 800°C β-Li_3TaO_4 appears, which transforms into α-Li_3TaO_4 at 900°C. At 1000°C, α-Li_3TaO_4 is the main phase. In turn, $LiTa_3O_8$ and α-Li_3TaO_4 react considerably less actively with Li_2CO_3, Ta_2O_5, and each other. According to the IR spectra, a certain amount of Li_2CO_3 is retained in the reaction mixture up to at least 900°C, which is also proved by a certain minor weight loss above 900°C.

We have recorded the derivatograms of sintering in the Li_2CO_3–$LiTaO_3$ system (Fig. 1b). The weight of a portion of jointly ground Li_2CO_3 and $LiTaO_3$ (<160 μm) was $m = 0.4988$, and their molar ratio was 1 : 1. The weight of the resulting cake was 0.4254 g. It follows from the DTA curve that at 732°C lithium carbonate melts. The endothermic effect at $T \sim 810$°C corresponds to the formation of a phase which we failed to identify by X-ray phase analysis. The next endothermic effect observed at $T \sim 850$°C can be assigned to the formation of the low-temperature β-phase of lithium orthotantalate Li_3TaO_4, which begins to transform into α-Li_3TaO_4 at $T \sim 880$°C. Figure 2b gives the X-ray diffraction pattern of the reaction products corresponding to the final state of the $LiTaO_3$–Li_2CO_3 system at 1000°C. The peaks of the high-temperature modification of Li_3TaO_4 in the X-ray pattern were assigned according to [5]. The weight loss in the TG curve ceases at the temperatures higher than 900°C, with the theoretical and experimental weight losses being in good agreement. Hence, we can believe that in the range 900–1000°C, when the Li_2CO_3 dissociation is completed, the α-phase of lithium orthotantalate is formed by the following reactions occurring simultaneously:

$$Li_2CO_3 = Li_2O + CO_2\uparrow, \quad (1)$$

$$Li_2O + LiTaO_3 = Li_3TaO_4. \quad (2)$$

Thus, the complex thermal analysis shows that sufficiently complete conversion of lithium metatantalate to orthotantalate by sintering with lithium carbonate requires the temperature of 900–1000°C. Further trials showed that this process should be carried out for 1–2 h. When studying the sintering of lithium tantalate and carbonate at the $LiTaO_3$ particle size of 30–60 μm, we obtained similar results.

Reaction of Li_2CO_3 with $LiNbO_3$. It follows from the total phase diagram of the Li_2O–Nb_2O_5 system [6] that there exist four lithium niobates: $Li_2Nb_{28}O_{71}$, $LiNb_3O_8$, $LiNbO_3$, and Li_3NbO_4. At 700–730°C, lithium metaniobate reacts with lithium carbonate to give Li_3NbO_4 [7]. At higher temperatures (higher than 1000°C), Li_3NbO_4 decomposes to $LiNbO_3$ and Li_2O, the latter evaporating.

The shapes of CO_2 pressure polytherms and DTA curves and the data of the X-ray phase analysis given in [4] suggest stepwise reaction between lithium carbonate and niobium compounds. We can choose temperature ranges corresponding predominantly to the reactions with gas evolution and without it. At 680–730°C, Li_3NbO_4 starts to appear in the mixture. As it is accumulated, the reaction with CO_2 evolution somewhat decelerates and the reactions without gas evolution starts to dominate. As a result of these reactions, of lithium carbonate melting, and of increasing temperature, the possibility of more active chemical reaction with CO_2 evolution appears again. Recrystallization of the products of this reaction, which occurs in the range 775–805°C, results in a strong increase in the amount of lithium orthoniobate. The IR data [4] point to the presence of lithium carbonate in the mixture up to at least 780°C.

Lithium orthoniobate was first described in [8] as an individual phase with the congruent melting point of 1408°C. Kulifeev *et al.* [1, 8] prepared Li_3NbO_4 by the reactions

$$3Li_2CO_3 + Nb_2O_5 = 2Li_3NbO_4 + 3CO_2, \quad (3)$$

$$Li_2CO_3 + LiNbO_3 = Li_3NbO_4 + CO_2 \quad (4)$$

and studied its thermodynamic characteristics and resistance to various acids.

The derivatogram of sintering in the Li_2CO_3–$LiNbO_3$ system is shown in Fig. 1c. The weight of jointly crushed Li_2CO_3 and $LiNbO_3$ (<160 μm) was m = 0.4806, and the weight of the resulting cake was 0.3856 g. The Li_2CO_3 : $LiNbO_3$ molar ratio was 1 : 1. An endothermic effect in the DTA curve is observed at T ~ 825 °C. This temperature may correspond to

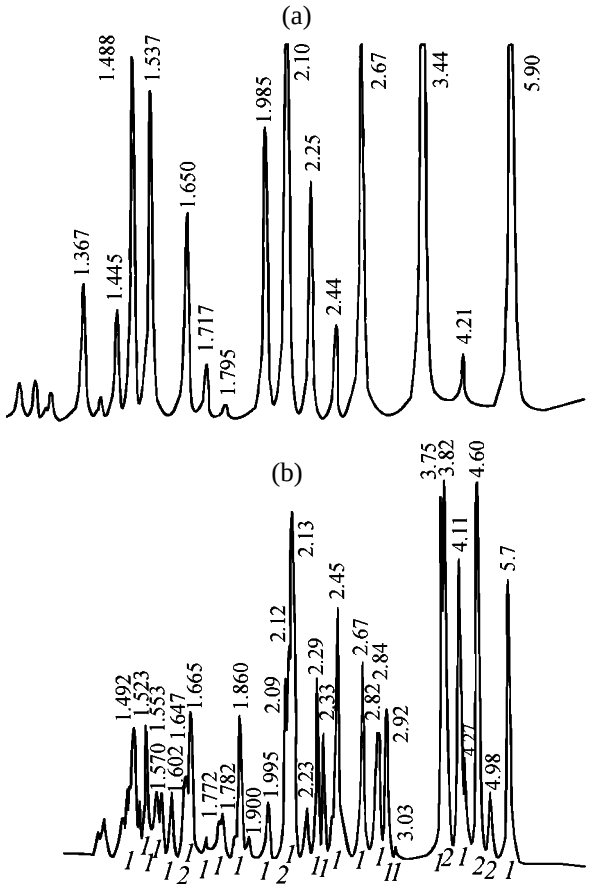

Fig. 2. X-ray diffraction patterns of the reaction products formed in the mixtures (a) $LiNbO_3$–Li_2CO_3 and (b) $LiTaO_3$–Li_2CO_3. Synthesis temperature, °C: (a) 950 and (b) 1000. Peak assignment: (*1*) Li_3TaO_4, high-temperature modification; (*2*) low-temperature modification. Interplanar spacings are given in Å.

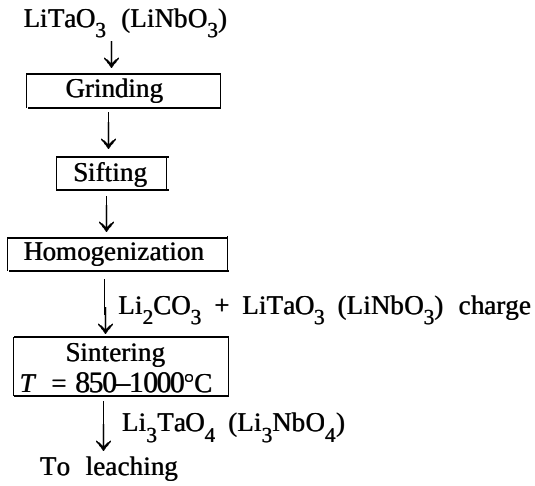

stepwise dissociation of lithium carbonate. However, by analogy with endothermic effects in the tantalum system, the peak at 825°C can be assigned to the formation of the ortho compound, the more so since, according to the X-ray diffraction data, sintering for 1–2 h under these conditions gives two phases, one of which corresponds to lithium orthoniobate and the other, to lithium niobate. The second endothermic effect is in the region of 920°C. Since at this temperature the weight loss is still observed, we can suggest that the formation of lithium orthoniobate is complete at T ~ 950 °C. For simplicity sake, the process may be considered to follow Eq. (4). This result is confirmed by the X-ray diffraction data (Fig. 2a) indicative of the presence of the single Li_3NbO_4 phase.

Thus, according to the results of the complex thermal analysis, it was found that sufficiently complete conversion of lithium metaniobate to orthoniobate by

sintering with lithium carbonate requires a temperature of 950°C.

Based on these studies, a process scheme was suggested for the conversion of lithium metatantalate (metaniobate) to lithium orthotantalate (orthoniobate). The scheme includes grinding of the wastes on a vibrational mill, their sifting through a sieve to obtain particles with $d < 160$ μm, homogenization of Li_3TaO_4 (Li_3NbO_4) with a 2–10% excess of Li_2CO_3, and subsequent fusion of the resulting charge at 900–1000°C for 1–2 h.

Scheme of production of lithium orthotantalate (orthoniobate)

The lower limit of the temperature range was chosen from the thermographic data, and the higher was specified with regard to the operating characteristics of thermal equipment and also to the kinetic (diffusion) limitations and decrease in the sintering time. The synthesis of tantalum (niobium) compounds can be carried out on standard equipment used in the production of $LiTaO_3$ ($LiNbO_3$) single crystals.

CONCLUSIONS

(1) The reactions of $LiTaO_3$ ($LiNbO_3$) with lithium carbonate were studied by complex thermal analysis, and the temperatures of their most complete conversion into orthotantalate (orthoniobate) were determined.

(2) A process scheme was proposed for the conversion of wastes from the production of $LiTaO_3$ ($LiNbO_3$) single crystals into compounds readily decomposing under the action of acids (HCl and H_2SO_4).

Received March 18, 2004

Abstract—Compounds $M_3Sc(BO_3)_3$ (M = Ba, Sr) were prepared by solid-phase reactions and studied by X-ray diffraction (XRD) analysis and IR spectroscopy. The structural type of the compounds was determined and their unit cell parameters were refined.

Mixed borates $M_3RE(BO_3)_3$ (M = Ba, Sr; RE = rare-earth elements) are promising as laser, luminescence, and nonlinear-optical materials [1, 2]. Double borates $M_3RE(BO_3)_3$ (M = Ba, Sr; RE = La–Lu) were prepared previously [2–5] using $MO–RE_2O_3–B_2O_3$ three-components systems, and their crystal structure and some physicochemical properties were determined.

Published data on similar double borates with scandium concern preparation of single crystals and determination of their crystal structures. Centrosymmetrical $Sr_3Sc(BO_3)_3$ crystallizes in the trigonal system (space group $R\bar{3}$, Z 6) [1]. This structure is built of two types of scandium octahedra forming chains along the c axis; in turn, these chains are linked through nonahedra of Sr atoms to form a rhombohedral framework. The octahedra of Sc atoms are strongly distorted depending on the type of junction with the oxygen polyhedra of the Sr cations. For example, Sc octahedra linked with Sr nonahedra are trigonally extended, whereas the octahedra sharing triangular faces with Sr polyhedra are trigonally compressed. The BO_3 groups are isolated and arranged along the threefold axis. The isomorphic substitution of Sr cations by larger Ba cations destabilizes the rhombohedral framework to form the compound of a new structural type.

As seen from XRD data and results obtained by the second-harmonic generation (SHG) procedure, $Ba_3Sc(BO_3)_3$ crystals contain no center of symmetry [6]. Double borate $Ba_3Sc(BO_3)_3$ crystallizes in the hexagonal system (space group $P6_3cm$, Z 6). This cell contains two structurally independent Sc atoms occurring in distorted octahedral environment, and Ba atoms of four types occupy nonahedra. Boron cations of three types have trigonal planar oxygen surrounding. Large Ba cations form alternating layers in the (001) plane and each of these layers contains the atoms of similar type. These layers are linked in a three-dimensional framework through Sc octahedra and discrete BO_3 groups arranged perpendicularly to the c axis.

The aim of this work was to study the synthesis of $M_3Sc(BO_3)_3$ compounds and to determine their XRD characteristics.

EXPERIMENTAL

The compounds $M_3Sc(BO_3)_3$ (M = Sr, Ba) were prepared by annealing of the stoichiometric amounts of ultrapure grade $BaCO_3$, analytically pure grade $SrCO_3$, and chemically pure grade H_3BO_3 and Sc_2O_3 at 600–1000°C for 60 h.

The reaction completeness was checked with a DRON-UM-1 diffractometer (CuK_α radiation). The individual phases were identified by XRD analysis and IR spectrometry. The intensity data were collected on an FR-552 focusing camera-monochromator (CuK_α radiation, Ge internal reference). The unit cell parameters were refined by the least-squares method. The IR spectra were recorded on a UR-20 spectrometer in the 1500–400 cm^{-1} range using KBr pellets.

The XRD patterns showed that barium scandium double borate crystallizes in the hexagonal system (space group $P6_3cm$), whereas in the case of strontium the trigonal unit cell is formed (space group $R\bar{3}$).

The experimental data on the powder XRD patterns of these compounds are listed in Table 1. The unit cell

ration ν_2 of the borate anion splits in two bands at 860 and 790 cm^{-1} for the strontium compound. Similar splitting of the band at 590 cm^{-1} into three components at 640, 600, and 570 cm^{-1} is observed for the in-plane bending vibrations ν_4. The IR spectrum of $Sr_3Sc(BO_3)_3$ also showed rather complex splitting of the stretching absorption bands of the B–O bonds. This splitting is probably due to a decrease in the symmetry of the boron environment on passing from barium to strontium borate.

CONCLUSIONS

(1) With the aid of XRD analysis of the intermediate and final products, the conditions of formation of double borates $M_3Sc(BO_3)_3$ (M = Sr, Ba) from the initial carbonates, scandium oxide, and boric acid were determined.

(2) The powder XRD patterns showed that $Ba_3Sc(BO_3)_3$ and $Sr_3Sc(BO_3)_3$ crystallize in hexagonal (space group $P6_3cm$) and trigonal (space group $R\bar{3}$) systems, respectively.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Hydrothermal Synthesis of Magnesium Silicate Montmorillonite for Polymer–Clay Nanocomposites

O. Yu. Golubeva, E. N. Korytkova, and V. V. Gusarov

Grebenshchikov Institute for Silicate Chemistry, Russian Academy of Sciences, St. Petersburg, Russia

Received September 7, 2004

Abstract—Conditions of hydrothermal synthesis of magnesium silicate montmorillonite $Mg_3Si_4O_{10}(OH)_2 \cdot nH_2O$ with a particle size of 50–100 nm are optimized, including the temperature, initial chemicals, reaction medium, and run duration.

At present, synthesis of hybrid polymer–inorganic nanocomposites appears to be one of the most effective ways in developing novel structural materials. A steadily growing interest in nanocomposites is stimulated by their improved physical and mechanical characteristics as compared to micro- and macrocomposites containing the same or even larger amounts of an inorganic filler.

Interest in polymer–inorganic nanocomposites based on layered silicates has quickened since 1987, when a series of works on Nylon–clay hybrids were published by the Toyota Research Center [1]. It was demonstrated that small additions of layered minerals, particularly montmorillonite, significantly enhance the thermal resistance and mechanical characteristics of the polymer.

Later on polymeric nanocomposites with layered silicates as fillers were intensively studied [2–6]. Polymer–silicate nanocomposites were found to be characterized by increased strength, thermal and chemical resistance, and ionic conductivity and by lower thermal expansion coefficient and gas permeability as compared to the initial polymer. Several characteristics were also improved, such as the flame propagation resistance and barrier action, which could not be realized with any other filler [7]. It is significant that such improvements of properties were not accompanied by noticeable increase in the density or decrease in the light transmission [8].

The possibility of improvement of a series of performance characteristics stimulated more extensive applications of polymer–inorganic materials in such areas as motor-car construction, light industry, electronics, and aerospace industry [9].

In the works devoted to synthesis and characterization of polymer–inorganic nanocomposites, such polymers as polyester, polyurethane, polystyrene, polypropylene, polyethylene, polybutadiene resin, polyaniline, and many others were used [10]. However, in all cases, practically the only material, montmorillonite, representing a layered silicate, was used a filler.

Layered silicates are very convenient materials for fabrication of nanocomposites (nanocomposite is a composite material in which a filler dispersed in the polymer matrix has at least one dimension of nanometer size). Silicate layers, being about 1 nm thick and 100–1000 nm wide, have highly developed surface capable of interacting with the polymer matrix. The particle size distribution and interaction of the silicate layers with the polymer matrix control the performance characteristics of the resulting composite. Minerals belonging to the montmorillonite group, in their turn (by virtue of their structural features), are the most suitable layered silicates for nanocomposites.

Montmorillonites are natural clay minerals with the general formula $(Na, Ca, K)_{x+y}(Si_{y-x}Al_x)(Al_{2-y}Mg_y) \cdot O_{10}(OH)_2$, $x = 0.05–0.45$; $y = 0.05–0.65$. The montmorillonite group includes about 20 different minerals, among them the title mineral, montmorillonite, being the most abundant. The crystal structure of these minerals is characterized by layered arrangement of cations and anions (Fig. 1). Montmorillonite stacks have a plane of symmetry. They are faced to each other by similarly charged oxygen layers, thus stabilizing the aluminum(magnesium)–oxygen–hydroxo layers by the van der Waals forces.

Water and other polar liquids can easily penetrate into the interlayer space of the montmorillonite lattice, expanding the layers to the extent depending on the

1070-4272/05/7801-0026© 2005 Pleiades Publishing, Inc.

amount of absorbed liquid. This structural feature promotes the use of montmorillonite as a filler for nanocomposites, since, to attain the required characteristics, a layered filler should be totally exfoliated in the polymer matrix.

At the same time, natural montmorillonite as a filler for polymer–inorganic nanocomposites demonstrates some drawbacks. For example, natural clay minerals represent mostly a mixture of several natural compounds, being, therefore, inhomogeneous in the chemical, phase, and disperse compositions. This makes the task of directed synthesis of functionalized nanocomposites more complicated.

To our best knowledge, in all the works on polymer–clay nanocomposites with montmorillonite as a filler, natural clay minerals were used, and the authors mostly gave no indication of their composition, rarely specifying the particle size. This does not allow establishment of the relationship between the composition and particle size of the filler and the properties of the resulting nanocomposite on the basis of published data. Establishment of such a relationship appears to be even more significant in view of the fact that no concept has been offered by now to explain the observed abrupt changes in characteristics of the polymers occurring with even small (2–3%) additions of montmorillonite.

Therefore, synthesis of montmorillonite of a fixed composition with a narrow particle size distribution is of considerable scientific and practical interest in view of its application as a filler in polymer–inorganic nanocomposites.

EXPERIMENTAL

The goal of this work was hydrothermal synthesis of magnesium silicate montmorillonite $Mg_3Si_4O_{10}\cdot(OH)_2\cdot nH_2O$ (analog of natural saponite) with a particle size of about 100 nm.

Optimization of the synthetic procedure was aimed at preparation of a single-phase product of a fixed composition with a narrow particle size distribution. Therefore, we studied the effects of such factors as the temperature, initial chemicals, reaction medium, and run duration on the yield and quality of the product.

As starting materials for the synthesis we used dry and ground silica gel $SiO_2\cdot nH_2O$, MgO, and $Mg(OH)_2$ precipitated from a $MgCl_2$ solution.

A stoichiometric mixture of the starting chemicals was treated with NaOH solutions of various concentrations under hydrothermal conditions (250–350°C, 70 MPa) for 0.5–7 h.

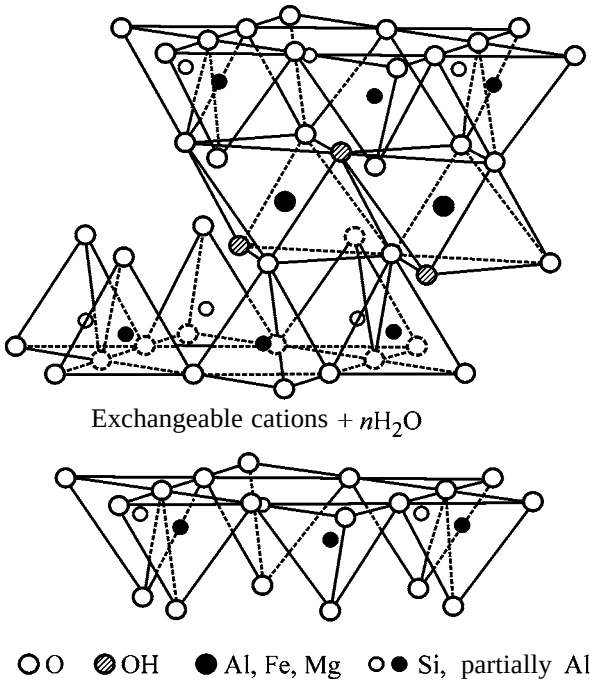

Fig. 1. Crystal structure of montmorillonite.

The resulting products were examined by X-ray diffraction (DRON-3 diffractometer, CuK_α radiation), crystal optics (MIN-8 microscope), and transmission electron microscopy (EM-125 electron microscope; U_{acc} = 75 kV).

The synthesis conditions and characteristics of the resulting products are summarized in the table.

The results show that, in hydrothermal synthesis of montmorillonite, brucite $Mg(OH)_2$ is the major impurity phase. Under certain conditions, the final product contains also other impurities such as magnesium oxide, quartz, and chrysotile (Fig. 2).

At 250 and 300°C, increasing alkalinity of the hydrothermal solution results initially in decrease in the montmorillonite content in the final product and increase in the brucite content (see table, experiment nos. 2, 3, and 7–9), and, with further increase, in a change montmorillonite/brucite ratio in the direction of increasing montmorillonite fraction (experiments nos. 4 and 5). In experiment no. 15 (350°C; 1 wt % NaOH), the product also contains MgO, which was not the case in experiment no. 14 performed with 3 wt % NaOH, all other conditions being equal. MgO was also found in the products obtained with 2.5 wt % NaOH at 250 and 300°C, but at a run time of 2 h (experiment nos. 1 and 6). Synthesis under the same

* (I_{MMT}/I_{br}) Montmorillonite (MMT) to brucite (br) ratio in the products. It was estimated from the X-ray diffraction data as the intensity ratio of the characteristic peaks of montmirillonite (2θ = 60.5°, I_{rel} = 100%) and brucite (2θ = 38°, I_{rel} = 100%).
** Characteristics of as-prepared (not subjected to acid treatment) products, determined by the crystallooptical method.

conditions, but for 4 h produces only montmorillonite and brucite (experiment nos. 2, 8). The use of more alkaline solutions (4 wt % NaOH) results in formation of brucite in considerable amount, and with increasing run time to 5 h, chrysotile is also formed (experiment no. 10).

According to the thermodynamic data (IVTAN–THERMO), magnesium hydroxide is stable over the experimental temperature and pressure ranges. Therefore, MgO that was found in the reaction products can be considered, most likely, as an unreacted initial component, but not as a decomposition product of brucite formed in the reaction.

It is known [11, 12] that the solubility of silica in a hydrothermal solution strongly increases in the presence of an alkali metal oxide, i.e., increase in the solution pH results in transfer of a considerable part of SiO_2 into the liquid phase. Dissolution of silica in the system Na_2O–SiO_2–H_2O may produce three phases: quartz, sodium silicate solution, and aqueous silicic acid. The latter two phases are liquids, and their compositions are temperature- and pressure-dependent [11]. Therefore, in performing the synthesis in alkaline solutions, the solid phase may be silica-deficient (relative to the fixed stoichiometry of montmorillonite). As a result, in addition to montmorillonite, other solid phases with a lower SiO_2 content can be formed, e. g., chrysotile (see table, experiment no. 10), and the final product will contain unreacted brucite.

According to the known classification of layered silicates [13] based on the layer structure, two major groups of minerals belong to the 1 : 1 and 2 : 1 types. In layered silicates of the 1 : 1 type, e.g., in chrysotile, a two-dimensional network built by SiO_4 tetrahedra is jointed to a two-dimensional network of MgO_6 octa-

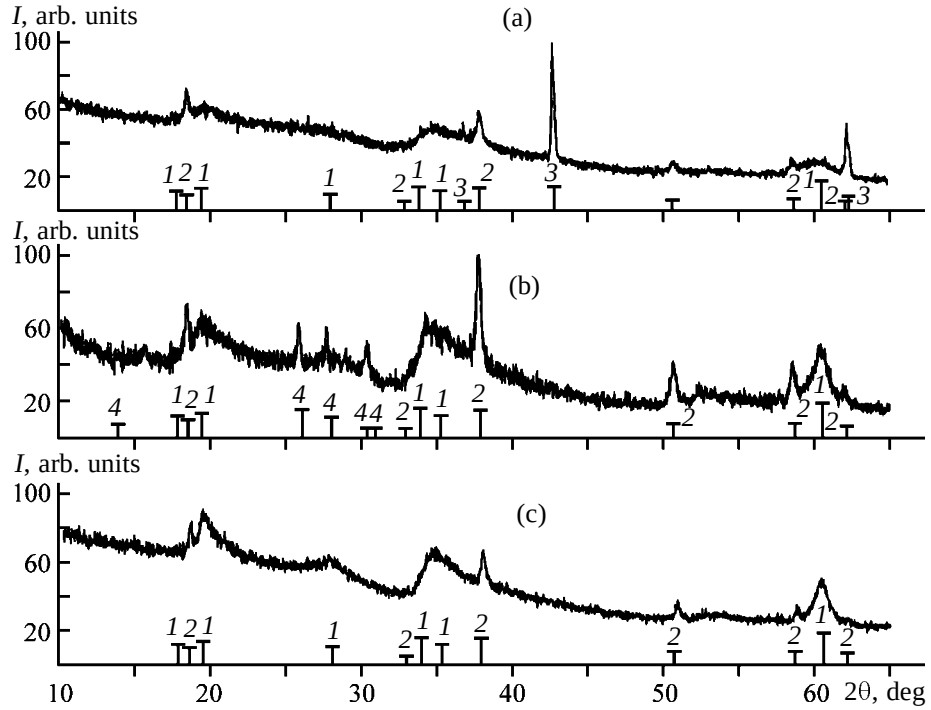

Fig. 2. X-ray diffraction patterns of montmorillonite samples obtained under different synthetic conditions together with XRD data for reference compounds. (*I*) Intensity and (2θ) Bragg angle; the same for Figs. 3, 5, and 6. (a) 250°C, 2 h, 2.5% NaOH; (b) 350°C, 0.5 h, 3.0% NaOH; and (c) 300°C, 4 h, 3.5% NaOH. (*1*) $Mg_3Si_4O_{10}(OH)_2 \cdot nH_2O$, (*2*) $Mg(OH)_2$, (*3*) MgO, and (*4*) SiO_2.

hedra. Montmorillonite is classed with layered silicates of the 2 : 1 type. In its structure, the octahedral layer is arranged between two tetrahedral layers (Fig. 1). Therefore, partial dissolution of silica may promote formation of chrysotile $Mg_3Si_2O_5(OH)_4$ whose structure contains smaller amount of SiO_2 than in montmorillonite $Mg_3Si_4O_{10}(OH)_2$.

Analysis of the effect of the alkalinity of the hydrothermal solution on crystallization of montmorillonite shows that increase in the NaOH concentration, first, increases the solubility of SiO_2, resulting in formation of chrysotile and brucite. At the same time, after formation of the nucleation centers, e.g., magnesium–oxygen octahedra in brucite, crystallization of montmorillonite is controlled by SiO_2 transfer to the reaction zone. Therefore, increase in the NaOH concentration and the corresponding increase in the solubility of SiO_2 in the hydrothermal solution should enhance the mass transfer of SiO_2 and, therefore, the montmorillonite formation rate.

Furthermore, increasing alkalinity of the solution produces silicates with highly associated silicon–oxygen complex polyanions such as $[SiO_3]^{2-}$ and $[Si_2O_5]^{2-}$ [11]. Entering the reaction, these silicates promote formation of silicates with infinite silicon–oxygen radicals, i.e., of layered silicates. This trend is supported by the data on the effect of the NaOH concentration in the hydrothermal solution: the yield of montmorillonite decreases on passing from 2.5 to 3.5 wt % NaOH (250°C; run time 4 h; see table, experiment nos. 2–4), and then increases as the NaOH concentration increases to 4 wt % (experiment no. 5; 4 wt % NaOH).

Finally, in low-alkaline solutions (1–2.5 wt % NaOH) and at small run time (2 h), the reaction between the starting components is incomplete. Increasing alkalinity to 3–4 wt % may result in stabilization of chrysotile. The maximal yield of montmorillonite was obtained at an alkalinity of 2–2.5 wt % NaOH at 350°C and run time of 2 h.

Increasing temperature from 250 to 300°C (4 h; experiment nos. 5 and 9) slightly increases the yield of montmorillonite and decreases the fraction of $Mg(OH)_2$ in the final product. Therefore, increasing temperature activates reactions between the initial components, promoting initially formation of brucite and then, of montmorillonite.

Similar trend was observed with respect to the run time. Increasing run time from 2 to 4 h at 250 and 300°C (2.5 wt % NaOH; experiment nos. 1, 2, 6,

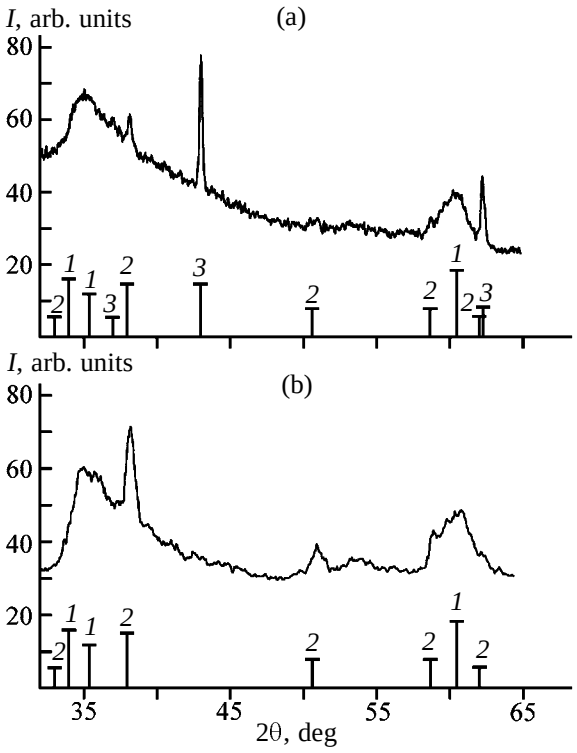

Fig. 3. XRD patterns of montmorillonite samples synthesized using (a) MgO and (b) $Mg(OH)_2$ (experiment nos. 6 and 17). T = 300°C, τ = 2 h, and c_{NaOH} = 2.5 wt %. (*1*) Montmorillonite $Mg_3Si_4O_{10}(OH)_2 \cdot nH_2O$, (*2*) $Mg(OH)_2$, and (*3*) MgO.

and 8) increases the yield of montmorillonite and decreases the fraction of $Mg(OH)_2$ in the product with formation of single-phase montmorillonite (experiment no. 8; 300°C; 2.5 wt % NaOH; 4 h).

The following conclusions could be made on the formation mechanism of montmorillonite under hydrothermal conditions. In alkaline solutions, initial stages of the process involve hydration of MgO with formation of brucite and partial dissolution of SiO_2. In the next stage, $Mg(OH)_2$ reacts with silica with formation of magnesium hydrosilicates, particularly, montmorillonite. Thus, the formation of $Mg(OH)_2$ precedes the formation of montmorillonite, which can be attributed to structural effects. Brucite has layered structure with the layers representing a magnesium–oxygen network [13]. Structurally these layers are similar to the magnesium–oxygen octahedral network arranged between the tetrahedral layers in the structure of montmorillonite. Evidently, $Mg(OH)_2$ plays a role of a nucleating center in crystallization of montmorillonite, which can be thought as formation of silicon–oxygen layers between still existing brucite layers through deposition of the silicon-containing component from the hydrothermal solution onto the layers of magnesium–oxygen octahedra.

Increasing run time, on the one hand, results in decreasing brucite fraction in the product, and, on the other hand, in increasing particle size.

Insofar as the goal of the work was synthesis of montmorillonite not of only the desired composition, but also with the optimal particle size distribution, we performed a series of experiments at higher temperature (350°C) and shorter run times (0.5–1 h) in hydrothermal solutions of various concentrations. Analysis of the resulting products revealed that synthesis in 3 wt % NaOH (experiment nos. 12, 13) affords products containing two impurity phases, $Mg(OH)_2$ and SiO_2. According to the XRD data, the latter product represents a labile intermediate phase SiO_2–X_2. It is known [14, 15] that hydrothermal crystallization of amorphous silica into quartz is a complex process involving formation of a series of intermediate phases. Introduction of a sufficient amount of the alkali into the reaction medium causes formation of intermediate phases representing cation-filled polymorphs of silica (SiO_2–X, kenyaite, SiO_2–Y, and magadiite). Further hydrothermal treatment converts the intermediate crystalline phases to quartz.

When performing the synthesis in 2 wt % NaOH (350°C; 1 h), we obtained montmorillonite with the minimal content of $Mg(OH)_2$ and dominating finely disperse fraction (up to 90%). This result is well consistent with the above considerations on the effects of the NaOH concentration in the hydrothermal solution, temperature, and run time on the characteristics of the resulting montmorillonite.

As mentioned above, brucite serves as a nucleation center in crystallization of montmorillonite. Therefore, it appeared desirable to use $Mg(OH)_2$ instead of MgO as an initial component, to increase the yield of the final product and also to accelerate the process (experiment nos. 17 and 18). The crystallooptical data show that the samples prepared using $Mg(OH)_2$ contain relatively larger amount of the coarse fraction even at a shorter run time (1 h, experiment no. 18), which can be attributed to agglomeration of the initial $Mg(OH)_2$ particles. This conclusion is supported by the mean size of $Mg(OH)_2$ particles in the product, estimated from the XRD data by the Scherrer equation [16]. For the sample obtained in experiment no. 17 (2.5 wt % NaOH, 300°C, 2 h), the mean size of $Mg(OH)_2$ particles was estimated to be 46 nm. In conducting the reaction under the same conditions, but using MgO as a starting reagent (experiment no. 6), we obtained $Mg(OH)_2$ particles with a mean size of 90 nm, i.e., twice that obtained in the experiment with MgO. Figure 3 shows the XRD patterns of montmoril-

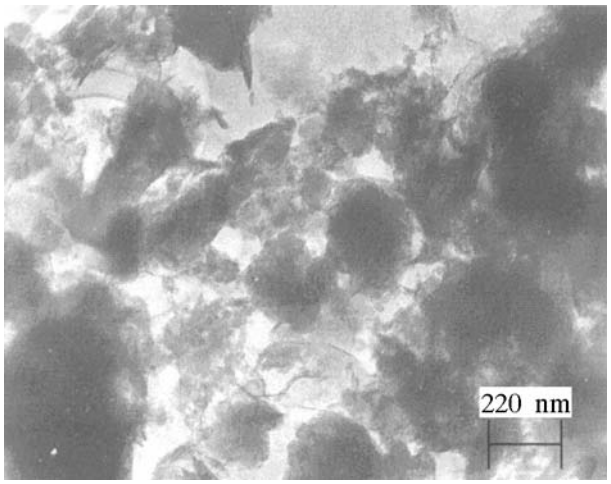

Fig. 4. Electron micrograph of montmorillonite prepared by hydrothermal synthesis.

lonite samples obtained from MgO and $Mg(OH)_2$.

To obtain single-phase finely dispersed montmorillonite, the samples were treated with 1 M HCl. Such a treatment allows removal of impurity phases, if they formed. At the same time, it is known [17] that acid treatment decreases the mechanical strength of clays through weakening the interparticle interactions and also interlayer interactions in the structure of clay minerals, realized with participation of the adsorbed water molecules. Such a disaggregation of the particles favors their dispersion in the polymer matrix in preparation of nanocomposites.

Using acid treatment of montmorillonite samples prepared under different conditions, we obtained single-phase samples of magnesium silicate montmorillonite with a particle size of 50–100 nm (Fig. 4).

As mentioned above, the authors of studies devoted to preparation and characterization of polymer–inorganic nanocomposites used either natural montmorillonite or modified clay materials [2–10]. In both cases, the starting materials represented mixtures of several natural compounds.

Figures 5 and 6 show XRD patterns of natural montmorillonite, of MMT–Na^+ modified montmorillonite (Southern Clay Products, Inc.), which is most often used in preparation of nanocomposites [4, 5], and also of the samples synthesized in this work (Figs. 5b, 6). Comparison of the XRD patterns (Figs. 5, 6) reveals that synthetic montmorillonite differs advantageously from its natural analogs in that it contains no impurity phases. Furthermore, it follows from electron microscopic data that the particles of

CONCLUSIONS

(1) Synthesis of magnesium–silicate montmorillonite in alkaline solutions proceeds through the stage of formation of brucite [$Mg(OH)_2$], which may be considered as a nucleation phase in the formation of montmorillonite layers.

(2) The montmorillonite formation rate is controlled by the NaOH concentration in the hydrothermal solution. Increase in the NaOH concentration and correspondingly in the solubility of SiO_2 in the hydrothermal solution increases the montmorillonite formation rate. At the same time, increase in the SiO_2 concentration in the solution may distort the fixed stoichiometry of montmorillonite, resulting in formation of chrysotile and brucite. The optimal NaOH concentration providing the maximal yield of montmorillonite is 2–2.5 wt %.

(3) Increasing temperature activates reactions of the initial components, promoting, first, formation of brucite and then, montmorillonite.

(4) The optimal parameters of hydrothermal synthesis of magnesium silicate montmorillonite with the desired composition and grain size are as follows: c_{NaOH} = 2.5–3.0 wt %; temperature 300–350°C; and run duration 0.5–1 h, followed by treatment of the reaction products with 1 M HCl.

Abstract—Physicochemical processes that occur in mechanical activation of kaolinite in centrifugal-planetary mills in the presence of concentrated sulfuric acid were studied. A scheme of formation of aluminum sulfate in the course of acid activation was analyzed.

The constant rise in the consumption of metallic aluminum, alumina, and other products formed in processing of aluminum-containing raw materials results in an increase in the share of unconventional, secondary, and technological kinds of raw materials involved in the processing procedures [1]. Kaolinites have long attracted the researchers' attention as a promising raw material, which can be successfully processed with mineral acids and, in particular, sulfuric acid [2].

Sulfuric acid methods for processing of layered aluminum-containing silicates have been intensively developed since the middle of the last century as a promising area of research. The common feature of various kinds of these techniques is the stage of preliminary activation of a raw material, which is performed in autoclaves or by a thermal or thermochemical method.

In the course of a thermal activation, kaolinite loses the most part of its structural water and passes into a metastable state, which makes it possible to extract Al(III) with hot H_2SO_4 solutions. The thermochemical activation of kaolinite is performed by its treatment with sulfuric acid at elevated temperatures, which leads to disintegration of the structure of the mineral and to formation of $Al_2(SO_4)_3$ crystal hydrates [3].

The elevated pressures and temperatures used in these kinds of activation are technologically and environmentally dangerous, impose strict requirements to the equipment employed, and lead to an increase in the number of process procedures and, in the end, to a higher cost of the product [4, 5].

The mechanical activation of kaolinite in centrifugal-planetary mills with high specific energy supplied to a substance being activated has demonstrated a high efficiency. This method yields, at a short time of activation, a product with a high reactivity, whose processing with acid solutions under moderate heating results in virtually complete recovery of Al(III) in the form of a sulfate [6].

Previously, a method has been suggested for mechanochemical activation of kaolinite in AGO mills in the presence of concentrated H_2SO_4 [7, 8]. The method provides virtually complete extraction of Al(III) from the product in the form of a sulfate with water without heating. This technique ensures environmental safety of processing of the raw materials because the amount of solid products formed is at a minimum and the acidity of wastewater is low.

In this work we studied physicochemical processes occurring in dry mechanical activation of kaolinite and its combined mechanochemical activation in the presence of concentrated H_2SO_4.

EXPERIMENTAL

White kaolinite from the Puzla deposit, Komi Republic, was used in the study. According to the results of elemental analysis, the kaolinite contains the following components (wt %): 37.2 Al_2O_3, 43.4 SiO_2, 2.5 TiO_2, 0.56 Fe_2O_3, 0.04 FeO, 0.17 MgO, 0.28 CaO, 0.16 Na_2O, 0.03 K_2O; calcination loss 14.47. The composition of the mineral is close to the empirical formula of aluminum silicate $Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O$.

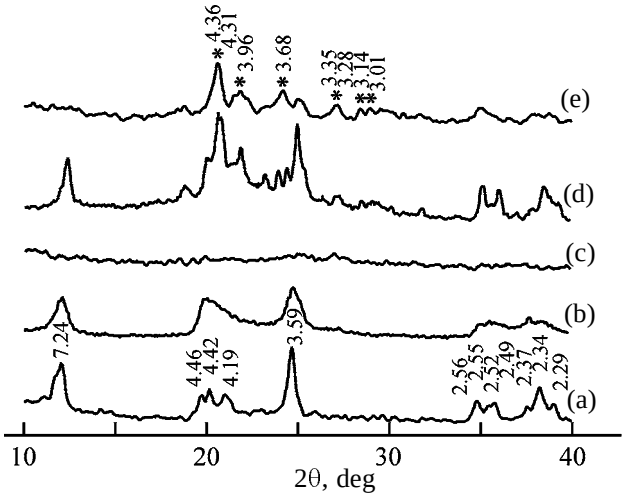

Fig. 2. X-ray diffraction patterns of (a) starting kaolinite; products formed upon mechanical activation of kaolinite for (b) 60 and (c) 390 s; and products of mechanochemical activation of kaolinite for (d) 60 and (e) 390 s in the presence of H_2SO_4. (2θ) Bragg angle.

The mechanical activation of the kaolinite was performed in AGO-2 centrifugal-planetary mills [9] with a ball diameter of 8 mm, the mass ratio of balls and weighed portion of kaolinite was 20 : 1, and the time of activation was varied within the range 0.5–10 min. The mechanochemical activation was carried out after preliminary mixing of kaolinite with a certain amount of concentrated H_2SO_4.

The structure of the starting kaolinite was studied by X-ray phase analysis (XPA) on a DRON-3M instrument with CuK_α radiation. IR absorption spectra were recorded on a Specord M-80 spectrometer in the range 4000–400 cm^{-1} in a thin layer of Vaseline oil on a KBr substrate.

Similarly to most of layered silicates, kaolinites have been sufficiently well studied [10–13]. The structural unit of minerals belonging to the group of kaolinites is the kaolinite layer (Fig. 1). There are no water molecules or metal cations in the interstack space, with the result that kaolinite shows no swelling and has a low exchange capacity.

The X-ray diffraction pattern of the starting kaolinite used in the study (Fig. 2a) is typical of the typomorphic varieties of the mineral. The X-ray diffraction pattern of the starting kaolinite contains high-intensity lines at Bragg angles 2θ of 12°, 20°, 25°, 34°–36°, and 38°–40°. The Hinckley crystallinity index of the starting kaolinite is 1.10, which characterizes it as a structurally ordered typomorphic variety [14]. The IR spectrum of kaolinite (Fig. 3, curve *1*) contains a set of absorption bands associated with the stretching vibrations of surface OH groups (3708, 3688, and 3668 cm^{-1}) and internal OH groups (3636 cm^{-1}) bound by weak hydrogen bonds. The spectral index of kaolinite is 3.5, which corresponds to its medium-ordered typomorphic variety [15]. The discrepancy in the estimates of the degree of ordering of the structure of the starting kaolinite is due to the fact that the evaluation procedures are based on different criteria.

The X-ray diffraction pattern of the product formed in dry mechanical activation of kaolinite shows broadened diffraction lines with a significantly lower intensity already after 60 s of treatment (Fig. 2b). Extending the treatment duration to 390 s leads to complete disappearance of lines from the diffraction pattern, which may be due either to a small size of kaolinite particles produced by intensive mechanical treatment or to complete disordering of the initial structure of kaolinite, in agreement with the results of [6].

Analysis of the IR spectra of the products formed in dry mechanical activation of kaolinite confirms the results of XPA. The IR spectra clearly demonstrate a change in the intensities of the absorption bands in the spectral range associated with stretching vibrations of surface and internal OH groups. As a result of activation for 60 s (Fig. 3, curve *2*), the bands at 3688 and 3668 cm^{-1} disappear and the intensity of the bands at 3708 and 3636 cm^{-1} decreases. Extending the time of activation to 390 s (Fig. 3, curve *4*) results in that the above bands merge into a broad band at 3700–2800 cm^{-1}, shifted to longer wavelengths, i.e., into the range of stretching vibrations of molecular water. Simultaneously, bands at 968 and 920 cm^{-1} decrease in intensity and then completely disappear. These bands are associated with bending vibrations of structural OH groups bound to the aluminum atom from the octahedral network of the kaolinite layer. A

similar behavior is exhibited by the band at 548 cm^{-1}, associated with mixed bending vibrations of Si–O and Al(III)–O. The disordering of bonds between the tetrahedral and octahedral networks of the kaolinite layer leads to merging of a doublet band of stretching vibrations of Si–O– (1038, 1012 cm^{-1}) into a broad unresolved peak [16].

The disordering of the structure of surface and internal OH groups of kaolinite and their condensation yield molecular water, which is confirmed by the fact that a broad low-intensity band peaked at 1630 cm^{-1} appears in the spectrum of the product formed upon activation for 180 s (Fig. 3, curve *3*). This band is associated with bending vibrations of H_2O in the polymer hydrate form. With increasing time of activation, the intensity of this band grows and its peak is shifted to shorter wavelengths (1660 cm^{-1}). A theoretical calculation demonstrated that absorption associated with bending vibrations of the H_3O^+ ion must be observed in this spectral range [17, 18]. The shift of the peak of the band under consideration to shorter wavelengths indicates that H_3O^+ ions are present in the product formed upon mechanical activation of kaolinite. Thus, it can be stated that the disordering of the structure of OH groups in kaolinite under intensive mechanical activation is accompanied by the appearance of water and hydroxonium ions in the activation product.

The appearance of protons in the course of mechanical activation of layered silicates of various types has been termed prototropy [19]. In the course of dry grinding, free protons appear through rupture of the O–H bond in structural OH groups in the octahedral network of the kaolinite layer. Recombination of protons in the structural OH groups leads to additional structural disordering.

The influence of protons on the disordering of the structure of kaolinite is well manifested in mechanical activation of kaolinite in the presence of concentrated H_2SO_4, when H_3O^+ ions are introduced into the system with the acid from the very beginning. The X-ray diffraction patterns of products formed under this kind of activation reflect not only the strong disordering of the initial structure of kaolinite, which is indicated by the disappearance of the diffraction lines at 2θ 12°, 45°–50°, and 54°–60° and by a decrease in the intensity of broad lines at 2θ 25°, 34°–36°, and 38°–40°. Also, new diffraction lines appear at 2θ 20°–22°, 24°, and 26°–29° (Figs. 2d, 2e), which confirms that the "alunogen" phase [$Al_2(SO_4)_3$ crystal hydrate] is formed in the course of activation.

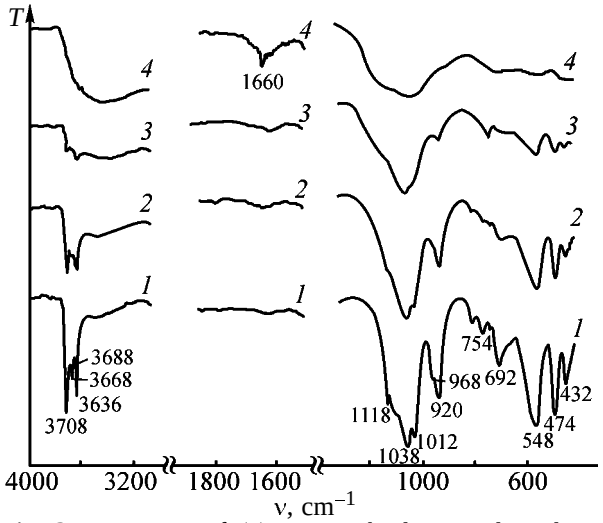

Fig. 3. IR spectra of (*1*) starting kaolinite and products formed upon mechanical activation of kaolinite for (*2*) 60, (*3*) 180, and (*4*) 390 s. (*T*) Transmission and (ν) wave number: the same for Fig. 4.

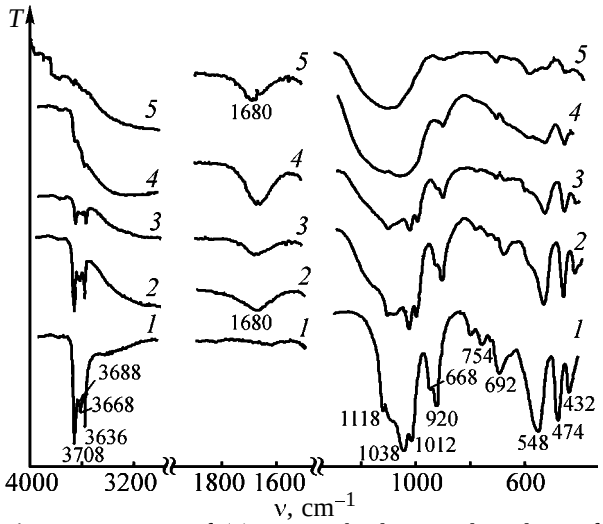

Fig. 4. IR spectra of (*1*) starting kaolinite and products of mechanochemical activation of kaolinite in the presence of sulfuric acid for (*2*) 60, (*3*) 150, and (*4*) 390 s and (*5*) in the presence of a stoichiometric amount of H_2SO_4 for 390 s.

The IR spectra of products formed in mechanochemical activation of kaolinite (Fig. 4, curves *2–5*) are similar in the set and positions of absorption bands to the spectra of products formed in dry mechanical activation. In the spectra of the products formed in mechanochemical activation, the absorption bands associated with structural OH groups completely disappear in the short-wavelength region when the activation time is made longer. The set and positions of the absorption bands at 1200–400 cm^{-1} are identical to those in the spectra of the products formed upon mechanical activation, which is due to the presence of SiO_2 in both types of products. However, the ab-

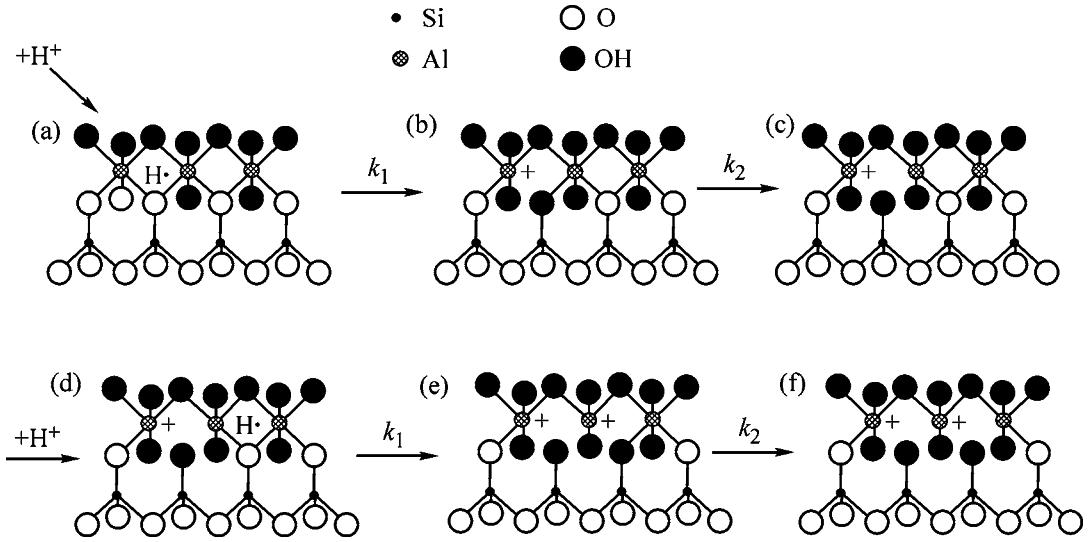

Fig. 5. Scheme of interaction of a proton with the structure of kaolinite [21].

sorption bands in the spectra of products formed in mechanochemical activation are markedly broadened in this spectral range, which gives no way of resolving the absorption bands associated with the sulfate ion. In addition, a clearly pronounced band peaked at 1680 cm^{-1} is present in all spectra of products formed upon mechanochemical activation. In the spectra obtained upon mechanical activation, this band appears after activation for 3 min and more.

The intensity of this band grows in the first stages of activation (Fig. 4, curves *2–4*), which indicates that the concentration of protons increases in the course of activation of kaolinite. The degree of structural disordering of kaolinite in the course of mechanochemical activation grows in proportion to the content of acid (protons) in a mixture being activated, which confirms that protons are strongly involved in the process of structural disordering of the mineral. It is noteworthy that the IR spectra of concentrated H_2SO_4 and an unactivated mixture of kaolinite and concentrated H_2SO_4 also contain a broad band at 1800–1600 cm^{-1} without any pronounced peak. This band is presumably due to the presence of H_2SO_4 hydrates [20].

A possible scheme of the structural disordering of kaolinite by protons was reported by Ganor *et al.* [21], who studied the dissolution of kaolinite in $HClO_4$ solutions. It was assumed that a hydrated proton penetrates into the octahedral network and, stage-by-stage, polarizes and ruptures bonds between the octahedral and tetrahedral networks of the kaolinite layer (Fig. 5).

In the case of activation of kaolinite in energy-intensive mills in the presence of concentrated H_2SO_4, ideal conditions are created for intercalation of protons into the crystal lattice of the mineral. Recombination of protons at bonds disrupts the structure of the kaolinite layer, which must lead to formation of amorphous aluminum and silicon oxides.

The capacity of sulfate ions for specific adsorption on the surface of aluminum and silicon oxides containing silanol and aluminol groups [22] leads to quantitative synthesis of alunogen in deformation-induced agitation of the mixture in the course of activation. The final products of mechanochemical activation of kaolinite in the presence of concentrated H_2SO_4 are $Al_2(SO_4)_3$ and a solid residue of the composition $ySiO_2 \cdot xH_2O$, which is low-temperature hydrated X-ray amorphous silicon dioxide.

CONCLUSION

A study of the mechanical and mechanochemical activation of kaolinite in the presence of sulfuric acid made it possible to substantiate and confirm the involvement of protons of the acid in physicochemical processes of structural disordering of the kaolinite layer and the formation of aluminum sulfate and X-ray amorphous hydrated silicon dioxide.

Abstract—Experimental data on the equilibria Fe^{2+}/Fe^{3+} and SO_3^{2-}/SO_4^{2-} in the system $Fe(OH)_3(H_2SO_4)$–Na_2SO_3–H_2O are presented. The quantitative relations between the reduction of Fe(III) and the precipitation of $FeSO_3 \cdot 2.5H_2O$ as a Fe_2O_3 precursor have considered graphically.

An urgent problem for hydrometallurgical enterprises is the utilization of ferriferous dump cake, which is formed when solutions are purified to remove iron. The problem consists in recycling of valuable components coprecipitated with iron and in production of commercial iron oxide.

Ferriferous cake, which precipitates from industrial solutions as pH is increased, is amorphous iron(III) hydroxide resistant toward acids and alkalis [1]. Its mother liquor contains ions of impurity components, which cannot be removed by multiple repulpation. An efficient procedure of iron cake utilization is based on transformation of iron(III) hydroxide into another compound, e.g., into slightly soluble iron(II) sulfite, by its sulfitization, i.e., by treatment of $Fe(OH)_3$ with sodium sulfite followed by thermolysis of the suspension and preparation of hydrated iron(II) oxide. In the course of filtration and washing, $FeO \cdot nH_2O$ is separated from impurity components, and upon subsequent oxidation in air it is converted to Fe_2O_3, which is a commercial product (e.g., in the form of red iron oxide pigment).

The aim of this work was to study Fe^{2+}/Fe^{3+} and SO_3^{2-}/SO_4^{2-} redox equilibria in the system $Fe(OH)_3 \cdot (H_2SO_4)$–Na_2SO_3–H_2O with graphic representation of the precipitation of iron(II) sulfite from the aqueous solution as a phase capable of transforming to iron(II) oxide and then to iron(III) oxide, i.e., as a precursor of Fe_2O_3.

EXPERIMENTAL

The system $Fe(OH)_3(H_2SO_4)$–Na_2SO_3–H_2O was studied at 25°C. Ferriferous cake was used as the $Fe(OH)_3$ component. It was activated by sulfuric acid and transformed to the lyosol form by a treatment with a $FeCl_3$ solution as a peptizing agent, which was added to the cake at the molar ratio $FeCl_3 : Fe(OH)_3 = 1 : 30$. Sulfuric acid was added in the amount required for $Fe(OH)_3$ activation [molar ratio $H_2SO_4 : Fe(OH)_3 = 1 : 1.56$]. Chemically pure grade sodium sulfite was used in the form of aqueous solution. Its concentration was varied from 0.5 M to saturated solution (2.17 M) at 0.25 M intervals. The thermal hydrolysis of the suspension after the precipitation of iron(II) sulfite was carried out by boiling at a residual pressure of 30.4 kPa. Hydrated iron(II) oxide was separated from the mother liquor by filtration with washing and then was kept at 400°C in air.

The system was studied in eight sections, each corresponding to a certain sodium sulfite concentration and including 10 points in the pH range of 1.8–3.6 at the interval of 0.2 unit.

Iron(III) hydroxide peptization was accompanied by the formation of micelles and liquefaction of the amorphous precipitate by the reaction

$$n\mathrm{Fe(OH)_3} + \mathrm{FeCl_3} \rightarrow \{[\mathrm{Fe(OH)_3}]_n \cdot \mathrm{Fe^{3+}} \cdot (3 - x)\mathrm{Cl^-}\}^{x+} \cdot x\mathrm{Cl^-}.$$

It was shown experimentally that n is within the range 25–45 and x varies from 0.2 to 2.8.

In the course of the reaction with $Fe(OH)_3$, a part of sodium sulfite is consumed for the Fe(III) reduction and the other part, for the formation of the precursor, namely, of iron(II) sulfite precipitate. To reveal the redox equilibria accompanying the precipitation of iron(II) sulfite, we processed the experimental data

1070-4272/05/7801-0038 © 2005 Pleiades Publishing, Inc.

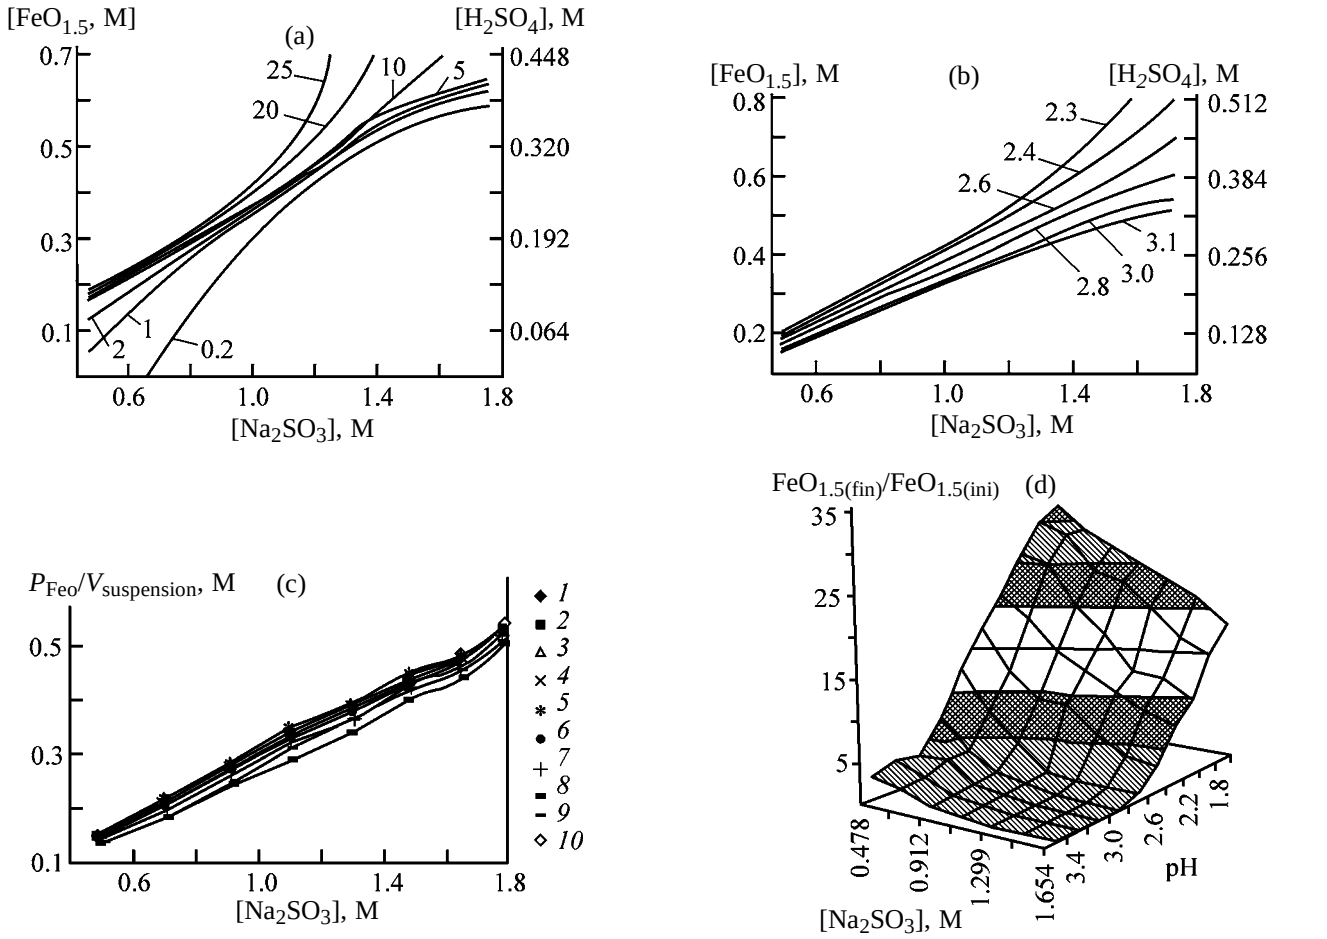

Fig. 1. Iron(III) reduction in the system $Fe(OH)_3(H_2SO_4)$–Na_2SO_3–H_2O at 25°C at various ratios of $FeO_{1.5}$, Na_2SO_3, and H_2SO_4 concentrations (M). (a) Isoreducts $FeO_{1.5(fin)}/FeO_{1.5(ini)}$; (b) isorelates $Na_2SO_3/Fe(OH)_3$; (c) specific yield $P_{FeO}/V_{suspension}$; and (d) dependence of the degree of iron(III) reduction $FeO_{1.5(fin)}/FeO_{1.5(ini)}$ on the sodium sulfite concentration and suspension pH. (c) pH: (*1*) 3.6, (*2*) 3.4, (*3*) 3.2, (*4*) 3.0, (*5*) 2.8, (*6*) 2.6, (*7*) 2.4, (*8*) 2.2, (*9*) 2.0, and (*10*) 1.8.

according to [2]. The system was presented graphically by two response functions: lines of equal degree of reduction $FeO_{1.5(fin)}/FeO_{1.5(ini)}$ (%) (isoreducts) (Fig. 1a) and lines reflecting the molar ratio of the reacting components $Na_2SO_3/FeO_{1.5}$ (isorelates) (Fig. 1b). The isorelates allowed us to determine the ratio of components in the system corresponding to the sufficient extent of the redox process. A combination of both isolines allowed us to suggest a mechanism of the reaction between sulfite ions and Fe(III) and to find the operation range corresponding to a high degree of iron(III) reduction at the optimal concentrations of the reacting components.

It follows from Fig. 1 that three molecules of Na_2SO_3 react in the system with one molecule of $Fe(OH)_3$ to provide almost complete precipitation of Fe(II) sulfite. The reaction can be expressed by the scheme [3]

$$Fe(OH)_3 + 3HSO_3^- \rightarrow [Fe(SO_3)_3]^{3-} + 3H_2O,$$

$$[Fe(SO_3)_3]^{3-} \xrightarrow{h\nu} [Fe(SO_3)_2]^{2-} + \dot{S}O_3^-,$$

$$[Fe(SO_3)_2]^{2-} \rightarrow FeSO_3\downarrow + SO_3^{2-}.$$

Iron sulfite is precipitated in the form of $FeSO_3 \cdot 2.5H_2O$, whereas sulfite radicals form $S_2O_6^{2-}$ dimers, i.e., the anions of dithionic acid.

The maximal yield of iron(II) sulfitization per unit volume of the suspension (Fig. 1c) corresponds to the pH range 3.0–2.8. Addition of excessive sulfuric acid suspension of $Fe(OH)_3$ results in decreased pH and increased iron(III) content.

The three-dimensional representation of the $Fe(OH)_3(H_2SO_4)$–Na_2SO_3–H_2O system (Fig. 1d), which shows the dependence of the Fe(II) content after sulfitization on both the concentration of sodium

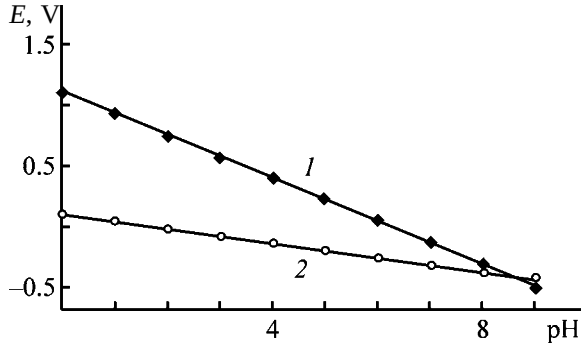

Fig. 2. *E*–pH dependence for the sulfitization process. Line numbers correspond to equation numbers.

sulfite and the pH of suspension, allows us to determine the boundary of the working region, which corresponds to the onset of ascent from the flat part of the diagram.

The redox equilibrium $Fe^{2+} : Fe^{3+}$ in the system can be described using the Nernst equation

$$E = E^0 + \frac{RT}{F}\ln(a_{Fe^{3+}}/a_{Fe^{2+}}).$$

Iron(III) ions are hydrolyzed in weakly acidic solutions; therefore, $a_{Fe^{3+}}$ is determined by the solubility of $Fe(OH)_3$. Taking the solubility product under standard conditions to be $K^0_{S[Fe(OH)_3]} = a_{Fe^{3+}}a^3_{OH^-} = 10^{-37.4}$, we find

$$a_{Fe^{3+}} = \frac{K^0_S[Fe(OH)_3]}{a^3_{OH^-}} = \frac{K^0_S[Fe(OH)_3]a^3_{H^+}}{K^3_w} = 10^{4.59}a^3_{H^+}.$$

Substituting the $a_{Fe^{3+}}$ values in the Nernst equation, we obtain

$$E = E^0 + \frac{RT}{F}\ln\frac{10^{4.59}a^3_{H^+}}{a_{Fe^{2+}}}.$$

At 298 K, the equation takes the form

$$E = 1.044 - 0.178\text{pH} - 0.059\log a_{Fe^{2+}}.$$

For $a_{Fe^{2+}} = 0.1$ M, we obtain the expression

$$E = 1.103 - 0.178\text{pH}. \quad (1)$$

Sulfite ions are oxidized according to the equation

$$SO_3^{2-} + H_2O - 2e \rightarrow SO_4^{2-} + 2H^+,\ E^0 = 0.104\ \text{V},$$

and the Nernst equation for the equilibrium SO_3^{2-}/SO_4^{2-} takes the form

$$E = E^0 + \frac{RT}{2F}\ln\frac{a_{SO_4^{2-}}a^2_{H^+}}{a_{SO_3^{2-}}}.$$

The dependence of the potential on pH for an aqueous solution with $a_{SO_3^{2-}} = a_{SO_4^{2-}} = 0.1$ M is described by the equation

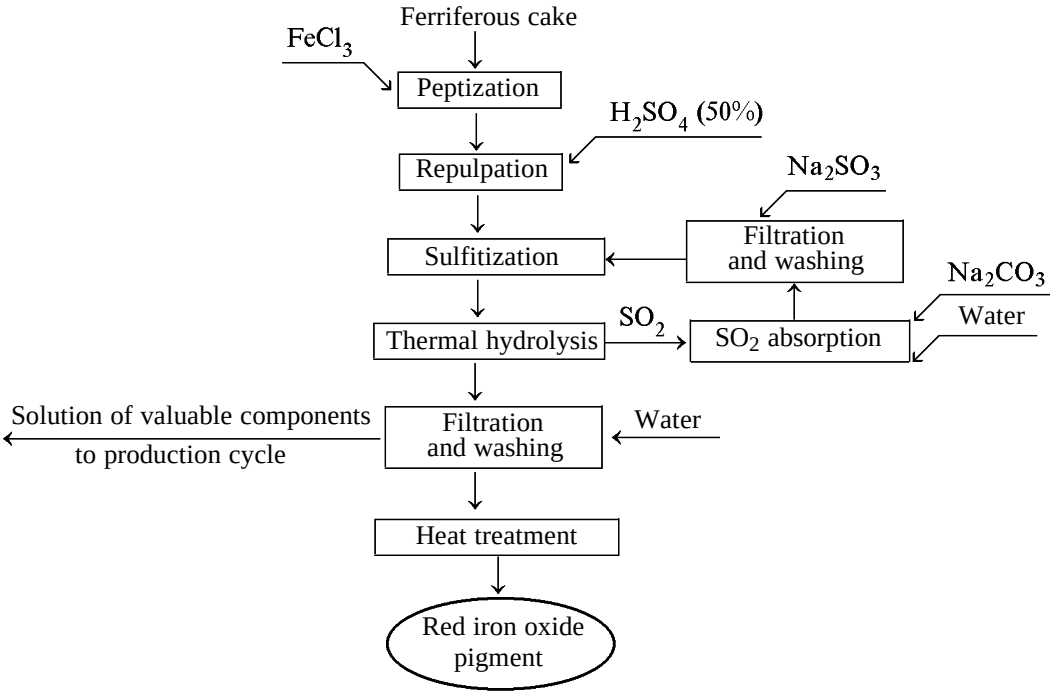
$$E = 0.104 - 0.059\text{pH}. \quad (2)$$

The plots of $E = f(\text{pH})$ are expressed as the Pourbaix diagram (Fig. 2), which shows that the difference of the redox potentials decreases as pH increases, and consequently, the reducing power of sulfite ions decreases. The maximal yield of iron(II) and $\Delta E = 0.64$–0.67 V are observed in the pH range 3.0–2.8; in this range, sulfitization occurs spontaneously.

A single solid phase, $FeSO_3 \cdot 2.5H_2O$, is precipitated in the redox reaction of sulfite ion with $Fe(OH)_3$. Its solubility in water was determined by direct conductometric technique at 298–328 K [4]. At 298 K, the solubility is 1.87×10^{-3} M.

If the solubility product $K^0_{S(FeSO_3 \cdot 2.5H_2O)}$ is considered as a heterogeneous equilibrium constant, we can determine the pH corresponding to the onset of the $FeSO_3 \cdot 2.5H_2O$ precipitation at various concentrations of reactants in the solution:

$$\text{pH} = -\log a_{Fe^{2+}} + \log K^0_{S(FeSO_3)} - \log a_{HSO_3^-} - \log K_{2(HSO_3^-)}.$$



The pH of precipitation decreases as the concentrations of reactants increase. The substitution of the constant of the second ionization step of sulfurous acid $K_{2(HSO_3^-)}$ and the solubility product of iron(II) sulfite $K^0_{S(FeSO_3)}$ leads to the dependence

$$\text{pH} = 1.71 - \log a_{Fe^{2+}} - \log a_{HSO_3^-}.$$

The working region of the sulfitization process is limited, on the one hand, by the pH value of the onset of $FeSO_3 \cdot 2.5H_2O$ precipitation, and on other hand, by the difference of redox potentials, which tends to zero on reaching pH 8.39.

Within the estimated pH range, iron(II) sulfite can undergo thermal hydrolysis with the evolution of SO_2 and formation of crystalline iron(II) hydroxide, which can be readily filtered off, allowing high degree of recycling of valuable components into the solution. The liberated sulfur dioxide is absorbed by a sodium

Flowsheet of ferriferous cake processing

carbonate solution to recycle sodium sulfite to the sulfitization stage. The subsequent heat treatment of iron(II) oxide results in its oxidation with the formation of finely dispersed product utilizable as red iron oxide pigment.

The developed flowsheet involving iron(II) sulfite as precursor includes the following stages: peptization with iron(III) chloride, cake repulpation in a sulfuric acid solution, and sulfitization with the conversion of $Fe(OH)_3$ to $FeSO_3 \cdot 2.5H_2O$. This precursor is converted to Fe_2O_3 by thermal hydrolysis of the suspension, filtration and washing of hydrated iron(II) oxide, and its subsequent thermal treatment to obtain iron(III) oxide as a commercial product used as red iron oxide pigment.

CONCLUSIONS

(1) Graphic representation of the multicomponent system $Fe(OH)_3(H_2SO_4)$–Na_2SO_3–H_2O revealed a relationship between the redox processes occurring in this system and the concentration ratio of the reacting components.

(2) Joint plotting of isoreducts and isorelates in the same coordinates made it possible to suggest a redox reaction mechanism and to find optimal conditions for the precipitation of $FeSO_3 \cdot 2.5H_2O$ in the process of the conversion of ferriferous cake to iron sulfite, a precursor of Fe_2O_3, which, in turn, is used as red iron oxide pigment.

Abstract—A dielectric study of triglycine sulfate crystals was carried out and the phase transition temperatures were determined for samples grown at temperatures below 0°C. The influence exerted by a single-crystal silicon substrate treated by various methods on the shape of triglycine sulfate crystals was examined.

Crystals of triglycine sulfate, $(NH_2CH_2COOH)_3 \cdot H_2SO_4$ (TGS), are primarily known as classical ferroelectrics [1, 2]. Their ferroelectric properties are mainly determined by hydrogen bonds between atoms of nitrogen, hydrogen, and oxygen [1, 3].

Commonly these crystals are grown from aqueous solutions at temperatures of 20–60°C. The Curie point (T_c) of crystals of this kind (49°C) in a certain way characterizes the strength and rigidity of those bonds, which, undergoing transformations under the action of external factors (electric field, temperature), lead to formation and transformations of the domain structure of the crystals. Pyro-, piezoelectric, and other electrical properties of TGS crystals, which determine their practical importance and possible applications, depend on hydrogen bonds. Studies of the composition, structure, and properties of TGS crystals, which contain an amino acid (glycine), in relation to methods and conditions of their synthesis, with TGS used as a model material, yield valuable information about properties of various amino acids and their compounds. At the same time, it is of interest to study the possibility of directed modification of the properties of these TGS crystals in order to expand the area of their practical application. As an example, mention can be made of investigations devoted to doping of these crystals with various organic and inorganic components [1] and to their radiation treatment.

The properties of TGS crystals largely depend on the state of water both in their synthesis and growth and under the action of various external factors. With account of this fact, the range of variation of these factors was significantly expanded, primarily via a shift of the temperature range of crystal growth to below 0°C, where water can undergo phase transformations together with TGS. Simultaneously, it was decided to examine the effect of water vapor on the properties of the crystals. Finally, a study of TGS crystals grown on the surface of silicon single crystals pretreated by various methods was commenced with account of the fact that silicon is the basic material of solid-state electronics.

To find the conditions for growth of TGS crystals from aqueous solutions below 0°C, the eutectic point was determined in the phase diagrams of the systems water–glycine and water–TGS [4]. For this purpose, a method based on analysis of the kinetics of fractional melting of ice ingots crystallized from aqueous solutions with different initial concentrations has been developed [5] in view of the fact that attainment of a thermodynamic equilibrium in aqueous solutions at $T < 0$°C is hindered and requires a long time. The temperature and concentration of components at the eutectic point of the systems under study was found by determining the time necessary for the onset of melting of an ingot upon its heating from the temperature of complete crystallization of the solution and finding the type of distribution of the substance dissolved in water among fractions of the melt. A comparison of the eutectic points determined using the method developed with published data obtained for systems studied by the classical techniques, e.g., for water–salt systems [6], demonstrated good agreement.

The method of fractional melting is convenient for aqueous systems with a complex ionic-molecular composition, such as aqueous solutions of amino acids and their compounds. The data furnished by this

1070-4272/05/7801-0042 © 2005 Pleiades Publishing, Inc.

method make it possible to find the optimal conditions of synthesis and growth of single crystals of these substances and, simultaneously, to reveal specific features and fundamental aspects of their properties governed by interaction with water. The method of fractional melting was used to determine the eutectic points in the systems mentioned above, as well as in systems constituted by water and lysine and by water and lysine hydrochloride. This, on the one hand, made it possible to develop methods for low-temperature growth of crystals of these amino acids and their compounds, and on the other, confirmed the efficiency of the fractional melting in growth of crystals with varied nature of chemical bonding and different properties.

A study of the electrical properties of TGS crystals grown at $T < 0$°C revealed that their most important dielectric parameter, Curie point, shifts to higher temperatures [7], with the entire set of their electrical properties significantly changing.

In this work we further studied the dielectric properties of the crystals prepared and the influence exerted by properties of the silicon surface on the conditions of nucleation and growth of TGS crystals and on their properties. Also we report the results of X-ray phase analysis of these crystals.

EXPERIMENTAL

TGS crystals were grown from aqueous solutions saturated at different temperatures. Two methods were used: (i) lowering of the temperature of a saturated solution and (ii) slow evaporation of the solvent (water).

In the "classical" temperature range 20–50°C, "standard" crystals were grown and their properties were compared with those of crystals grown by the original technique at $T < 0$°C. The crystals were grown in Petri dishes without any special seeds. In parallel, crystals were grown in Petri dishes on whose bottom were placed standard wafers of single-crystal silicon, 76 mm in diameter and 400 μm thick, used in the planar silicon technology: KEF-20 (*n*-Si : P) (100), KEF-0.8 (111), and KDB-10 (*p*-Si : B) (111). The diameter of the silicon wafers was somewhat smaller than that of the Petri dishes. Before the experiments, the surface of single-crystal wafers was pretreated by various methods. Some of the wafers remained coated only with a layer of silicon oxide SiO_2 of thickness about 3 nm, which is commonly formed on the surface of silicon single crystals stored in air. Other wafers were coated with a SiO_2 layer with a thickness of about 300 nm, purposefully formed by thermal oxidation (thermal SiO_2) or pyrolytically by the standard procedures of silicon microelectronics. In addition, part of the wafers was coated with layers of specially deposited polycrystalline silicon of thickness ~100 nm and (separately) layers of metallic Ti (~100 nm); finally, layers of porous silicon were formed on the surface of part of the wafers [8].

It is known that the state of the silicon surface predetermines the type of its interaction with water. The surface of a clean single crystal is hydrophobic; its oxidation makes it hydrophilic; formation of a polycrystalline or porous structure on the surface changes its sorption properties. At the same time, lowering the temperature of water and aqueous solutions to below 0°C also significantly changes their structure and properties and, consequently, the type of interaction between the components of aqueous systems. A combination of these two, surface- and volume-related factors may make it possible to control the nucleation and growth of crystals of widely diverse substances (TGS, in the case in question) with prescribed properties.

Crystals with growth faces characteristic of TGS were chosen. The dimensions along the *X*, *Y*, and *Z* axes were the same as those for the standard TGS crystal and did not exceed 14, 17, and 6 mm, respectively. The samples prepared for study were in the form of rectangular wafers of polar *Y*-cut (thickness of about 1 mm and area of 3×5 mm^2). A conducting layer was deposited on these samples by vacuum evaporation of silver. The capacitance of the samples studied was measured with a Tesla-VM-484 semiautomatic bridge at a frequency of 1.59 kHz and amplitude of the measuring field of about 3 V cm^{-1}. Dielectric hysteresis loops were measured using the standard Sawyer–Tower scheme at a frequency of 1 kHz. Pyroelectric measurements were carried out in the quasistatic mode with a UT-6801A coulometer with a current sensitivity of 10^{-17} A, and temperature measurements, with a UTU-4 universal thermostat. The temperature was monitored with a mercury thermometer with an accuracy of ± 0.05°.

An X-ray diffraction analysis of the crystals on a DRON-4 diffractometer (CuK_α radiation, λ = 1.54178 Å) revealed a noticeable shift of reflections and a pronounced change in their intensity, compared with an ordinary TGS crystal as a control (Fig. 1). Preliminary calculations of the lattice constants demonstrated that the lattice constants *b* and *c* remain unchanged and the parameter *a* tends to increase. To analyze the influence exerted by low growth tempera-

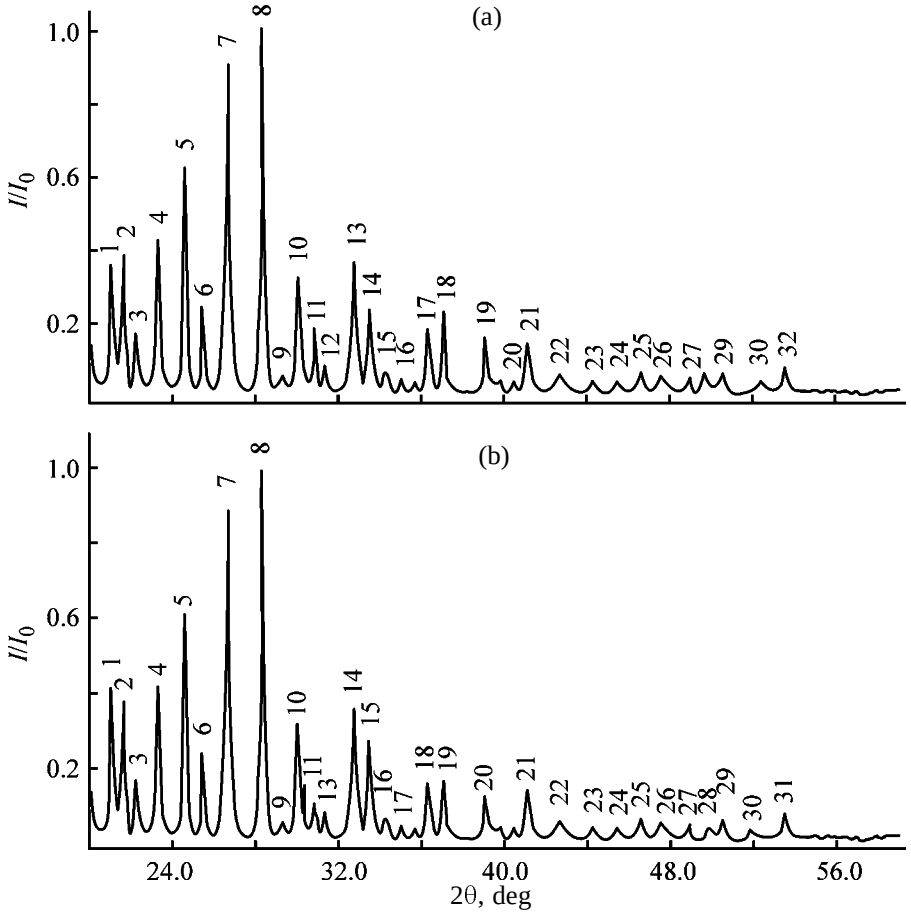

Fig. 1. X-ray diffraction patterns of (a) ordinary TGS crystal and (b) TGS crystal grown at $T_{gr} < 0$°C. (I/I_0) Relative intensity and (2θ) Bragg angle; the same for Fig. 5.

tures on the properties of TGS crystals, their main ferroelectric properties were studied.

The dielectric studies performed demonstrated that the phase transition temperature T_c increases for TGS samples grown at temperatures lower than 0°C by 0.5–0.7°C. For an ordinary TGS crystal, T_c is 49°C,

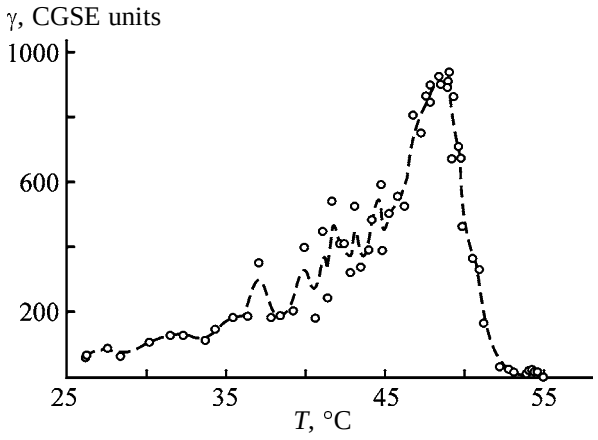

Fig. 2. Pyroelectric coefficient γ vs. temperature T for a TGS crystal grown below 0°C.

and the maximum values of the dielectric constant ε are as high as 50 000. TGS crystals grown at temperature lower than 0°C show a certain broadening of the phase transition; the maximum values of ε for different crystals are in the range from 800 to 2000. However, the type of the phase transition remains unchanged: both the "pair" and Curie–Weiss law are observed.

Pyroelectric studies of TGS crystals grown below 0°C demonstrated rather high values of the pyroelectric coefficient both at room temperature ($\gamma \cong 70$–100 CGSE units for different crystals) and at the maximum ($\gamma \approx 600$–1000 CGSE units). A specific feature of these crystals is that the pyroelectric effect vanishes at temperatures exceeding the Curie point of ordinary TGS crystals by 2–3°C (Fig. 2). The values of the macroscopic polarization P, calculated from the pyroelectric data ($P \approx 1.7$–2.3 μC cm^{-2}), are close to values of spontaneous polarization, found from dielectric hysteresis loops.

Figure 3 shows the temperature dependence of the

macroscopic polarization, determined from the results of pyroelectric measurements for one of the low-temperature samples. It is noteworthy that the polarization extends into the paraelectric phase. Commonly, such a behavior is observed for heavily doped crystals, whereas in the case in question, the TGS crystal is nominally undoped, but is grown at negative (on the centigrade scale) temperatures.

The dielectric hysteresis loops have a common shape with a minor bias field of 10 to 100 V cm^{-1} for different crystals. It should be noted that the hysteresis loops disappear at 50°C, which exceeds the phase transition temperature for ordinary TGS crystals (49°C). The hysteresis loops are saturated in sufficiently strong fields (~2–3 kV cm^{-1}). The coercive fields are about 400 V cm^{-1}.

The extension of the pyroelectric effect into the paraelectric phase and high values of coercive fields indicate that the domain structure of TGS crystals grown below 0°C is rigid.

The results obtained may be due to changes in the structure of water at 0°C. At this temperature, the network of hydrogen bonds in water and aqueous solutions becomes more rigid and the number of unruptured hydrogen bonds increases, which leads to fixing of domains and, consequently, to an increase in T_c.

The properties of TS crystals grown on the surface of silicon single crystals preliminarily subjected to various treatments were studied. The influence exerted by a single-crystal silicon wafer placed in the starting aqueous solution on the general characteristics of the crystallization process (shape and size of crystals, their number and distribution in the solution bulk) was determined. Under the same conditions, TS crystals were grown in a Petri dish in the absence of silicon and on the surface of single-crystal silicon coated with a layer of thermal SiO_2.

If a silicon wafer occupies part of the bottom of a Petri dish, the majority of the TGS crystals are formed beyond the bounds of the wafer or on its periphery (it is known that the number of ruptured bonds in the covalent silicon crystal is large in this region) [9]. Crystals formed on the surface of the wafer are arranged on it nonuniformly and have a more regular shape (rhombohedral crystals); all the crystals grown have approximately the same dimensions, shape, and crystallographic orientation and differ from those formed on the bottom of a Petri dish without a silicon wafer.

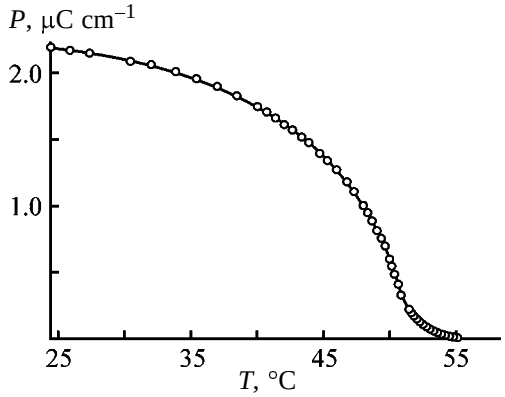

Fig. 3. Macroscopic polarization P vs. temperature T for a TS crystal grown below 0°C.

The dimensions of the crystals grown without silicon, as well as their shapes and orientations, differ more widely as compared to crystals grown in the presence of silicon. The coarsest crystals grow on the surface of single-crystal silicon, whereas the finest crystals are formed in a vessel without silicon. Thus, the very presence of single-crystal silicon in solution noticeably affects the growth of TGS crystals.

Similar results were obtained for TGS crystals grown at a temperature lower than 0°C on polished single-crystal wafers of KDB-10 (111) silicon.

Further, the patterns of TGS crystallization on the surface of identical single crystals of silicon, coated with thermal or pyrolytic silicon oxide, polycrystalline silicon, or having no coating, were compared. The crystals grown are shown in photographs in Figs. 4a–4d. It can be seen that the coarsest crystals are obtained on the surface of silicon coated with pyrolytic SiO_2 (Fig. 4c), with their dimensions varying from 7–8 to 4–5 mm. The crystals most frequently have the shape of a parallelepiped. Similar, but finer (6–5 to 4–5 mm) crystals were grown on the surface of silicon coated with thermal SiO_2 (Fig. 4b). The smallest number of TGS crystals was formed on the surface of silicon coated with polycrystalline silicon (crystals were mostly formed in the Petri dish beyond the bounds of the silicon wafer). The number of TGS crystals having the shape of rhombohedra and parallelepipeds is about the same. It can be seen that silicon treated in various ways affects the shape of TGS crystals by predetermining a predominant growth of crystals along some crystallographic direction.

It was established that the orienting effect of silicon varies with the type of a coating, but not disappears completely. This means that it is "translated" across the layer of amorphous SiO_2 or polycrystalline silicon.

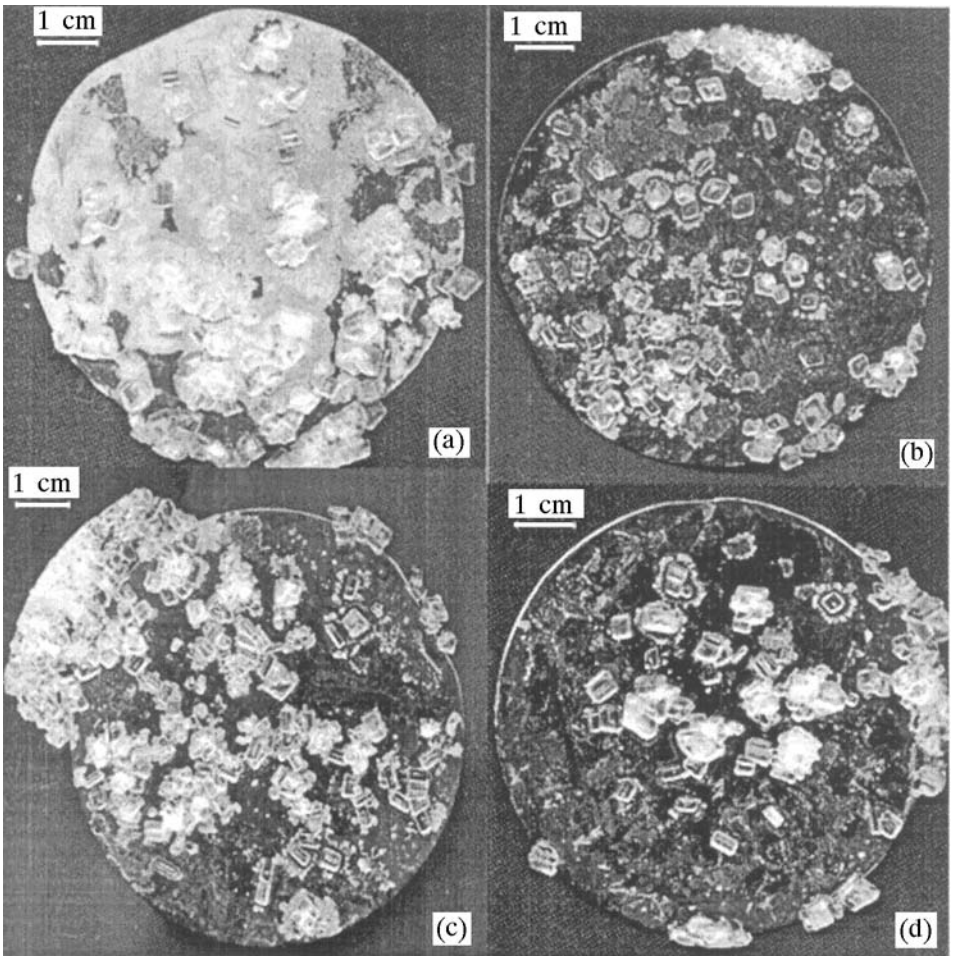

Fig. 4. Photographs of TGS crystals grown on single-crystal wafers: (a) KEF-20-500 (100), d = 380 nm; and (b–c) KDB-10 (111) silicon coated with: (b) thermal SiO_2, d = 85 μm; (c) pyrolytic SiO_2; and (d) layer of polysilicon.

Characteristically, this influence regularly varies along the surface of a silicon wafer from its center toward periphery. It is also important that, at this stage of the study, there is no reason to speak about any epitaxial relationships between single crystals of silicon and TGS, which are commonly expressed in term of crystal lattice parameters.

When speaking about the orienting influence of silicon single crystals on the growth of TGS crystals in the experiments in question, it is, in all probability, necessary to keep in mind the effect of silicon on the state of that initial medium (aqueous solution) in which TGS crystals nucleate and grow. For example, the predominant growth of crystals on the periphery of a silicon wafer can be attributed to the fact that the "long-range" field of silicon (gradient of the crystal-lattice potential) is the strongest at the edge of the wafer. In this region, the orienting influence of silicon first leads to a change in the structure of water and the aqueous solution, which, in turn, favors homogeneous nucleation of TGS crystals. Closer to the wafer center, the effect of silicon has another nature. The strict periodicity of the crystal field of silicon makes lower the contribution of the homogeneous, bulk component to the nucleation process, which leads to a decrease in the number of TGS crystals growing on its surface, but makes higher the probability of predominant orientation of these crystals. To confirm the results obtained, the crystals were subjected to X-ray phase analysis.

It was found that part of the crystals grown on KEF-20-500 (100) Si are single crystals with a [101] orientation (Fig. 5a). The rhombohedral crystals grown on silicon coated with thermal (Fig. 5b) or pyrolytic SiO_2 (Fig. 5c) have a polycrystalline structure with a clearly pronounced texture in the [101]

direction. Crystals grown under the same conditions in the form of a parallelepiped on polycrystalline silicon or on silicon coated with pyrolytic SiO_2 have also a polycrystalline structure, but with a [041] texture (Fig. 5d). This is, in all probability, accounted for by the orienting effect of polysilicon on the growth of TGS crystals.

Particularly noteworthy is the nature of TGS crystal growth on porous silicon (Fig. 6a), whose initial layer was grown of KEF-0.8 (111) Si by means of electrochemical etching [8]. Some of the wafers with such a layer were subjected to additional treatment: (a) additional anodic etching for 10 min (J = 15 mA cm^{-2}, pore size 10 μm), (b) etching in HCl (c = 30%, τ_{et} = 5 min), and (c) etching in HF (c = 20%, τ_{et} = 5 min). For comparison, ground silicon wafers were used (Fig. 6f).

The wafers were kept at 20°C in a saturated TGS solution for 12 days. Micrographs of TGS structures formed on the silicon surface are shown in Figs. 6b–6f. The crystals grown on the surface of porous silicon are coarser and have a more regular shape (Fig. 6c) than those formed on the surface of ground silicon (Fig. 6f). No coarse TGS crystals are formed on the surface of porous silicon subjected to additional anodic etching (Fig. 6c) or etching in HCl (Fig. 6d) or HF (Fig. 6e). The surface of silicon is decorated with microcrystals of TGS. Experiments show that the effect of silicon on the nucleation and growth of TGS crystals depends on the dispersity of its surface.

IR reflection spectra of these structures virtually coincide with one another and with the reference IR reflection spectrum of a single crystal of TGS. The characteristic lines of OH and NH_3^+ groups are somewhat shifted to longer wavelengths as the concentration of the initial solutions of TGS, brought in contact with silicon, becomes higher.

The results obtained make it possible to assess the prospects for further studies with the use of recent achievements of the planar silicon technology. It is known that, to fabricate microelectronic devices and solid-state integrated circuits, complex heterostructures containing layers and regions of single- and polycrystalline silicon, silicon oxide, and various metals and their compounds with silicon (titanium silicide being one of these) are created on the surface of silicon. The layers having a strictly prescribed shape and dimensions are formed in strictly specified order. We found how each of these layers affects the

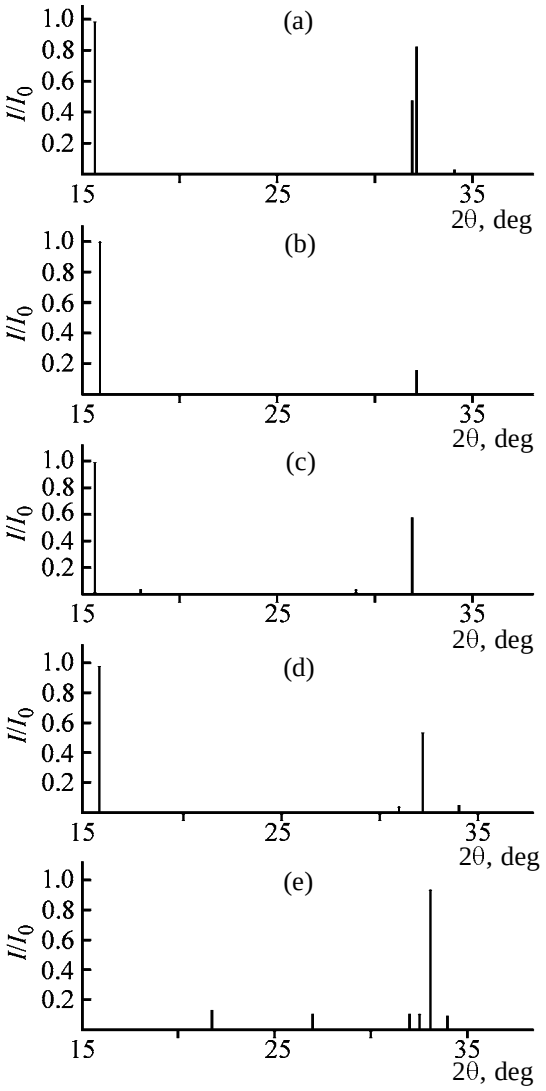

Fig. 5. X-ray diffraction patterns of TGS crystals (a) grown without silicon and those obtained on the surface (b) of KEF-20-500 (100) Si, and (c–e) of KDB-10 (111) Si coated with (c) thermal SiO_2, (d) pyrolytic SiO_2, and (e) polysilicon.

conditions of nucleation and growth of TGS crystals as a model material containing simultaneously organic (amino acid) and inorganic (sulfo groups) components. It is hoped that a prescribed "technological" pattern formed, e.g., by photolithography (a method widely used in microelectronics) on the silicon surface will make it possible to "array," e.g., various amino acids or their compounds on separate micro- or even nanoelements of solid-state circuits. Thereby, complex structures, including those of biological origin, will be formed with the use of the latest achievements of solid-state electronics and incorporated into solid-state electronic circuits.

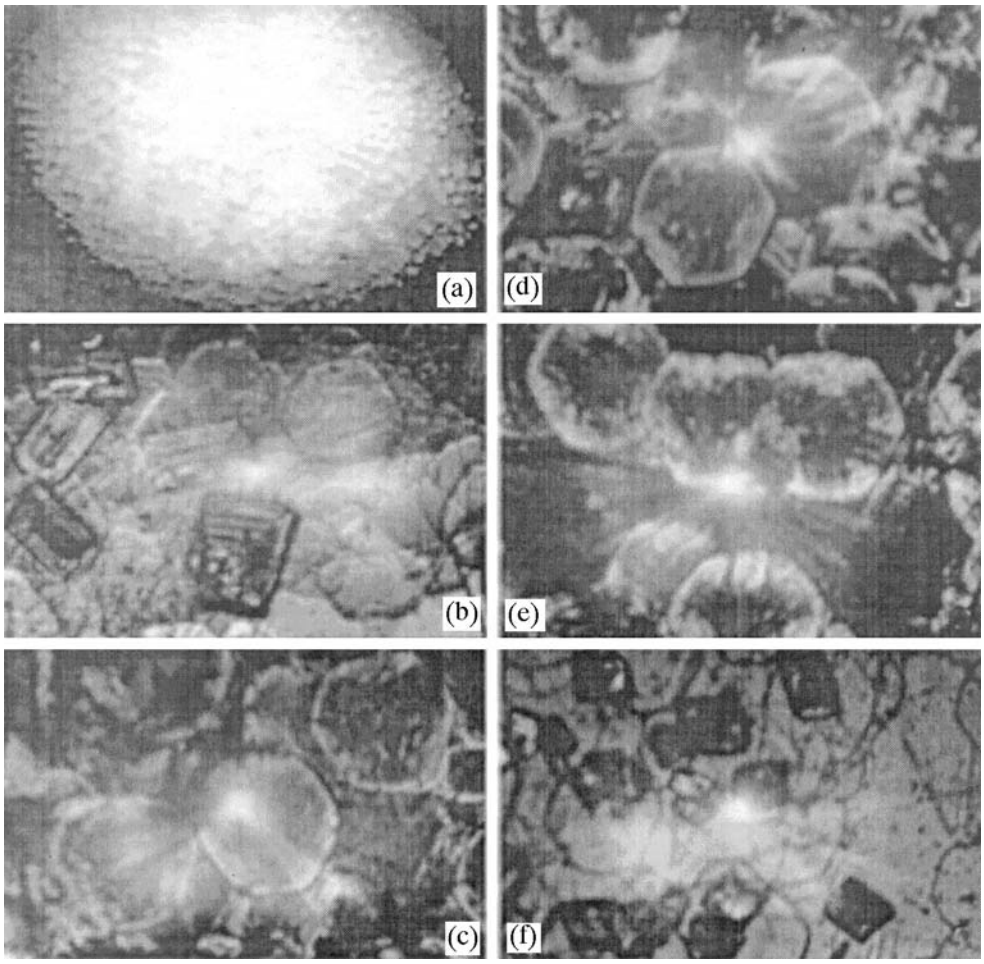

Fig. 6. Micrographs of crystalline structures on the surface of silicon: (a) porous Si, (b) porous Si + TGS, (c) porous Si + anodic etching + TGS, (d) porous Si + etching in HCl + TGS, (e) porous Si + etching in HF + TGS, and (f) ground Si + TGS.

CONCLUSIONS

(1) The extension of the pyroelectric effect into the paraelectric phase and the high coercive fields indicate that the triglycine sulfate crystals grown below 0°C have a rigid domain structure. The results obtained may be due to changes in the structure of water at 0°C: the network of hydrogen bonds becomes more rigid and the number of unruptured hydrogen bonds increases, which fixes the domains and, as a consequence, leads to an increase in T_c.

(2) Silicon affects the conditions of nucleation and growth of triglycine sulfate crystals in aqueous solutions because a silicon wafer present in a solution changes the number of triglycine sulfate crystals, their dimensions, and type of their arrangement in the bulk of the solution.

(3) Silicon treated in different ways affects the shape of triglycine sulfate crystals by predetermining a predominant growth of the crystals along some crystallographic direction.

Abstract—Alcoholic solution of tetraethoxysilane was studied IR-spectroscopically. The compositions with various ratios of a binder and thermochromic substance were prepared, and their structure and thermal stability were studied. Mixtures of cobalt phosphomolybdate with tetraethoxysilane alcoholic solutions show promise for obtaining thermochromic compositions with the range of the working temperatures 350–400°C.

Phosphomolybdates of iron-like metals are materials for obtaining thermochromic compositions used for visual temperature monitoring of out-of-the-way places of devices, furnaces, etc., working at high temperatures. As a rule, thermochromic substances are applied onto the monitored surface as the compositions with various organic binders. However, the organic component rapidly loses its performance under the periodical impact of high temperatures. The binders based on inorganic compounds are more promising. In this work, we propose to use alcoholic solutions of Group IV element compounds as binders. Thermolysis of such compounds gives thermostable oxides as a matrix in which the thermochromic component is distributed.

In this work, we studied alcoholic solutions of tetraethoxysilane (TES) and oxyzirconium chloride as binders for obtaining thermochromic materials based on cobalt phosphomolybdate.

Cobalt phosphomolybdate was prepared from chloride solutions by the method described in [1]. The quantitative ratio of the initial components and the solution pH (pH < 1) were strictly controlled, which ensured formation of compounds with the Keggin structure. The crystalline form was prepared by the prolonged evaporation of the mother liquor. Cobalt phosphomolybdate obtained is a yellow powder readily soluble in water and ethanol. Phosphomolybdate and its compositions were identified by chemical, X-ray phase (a DRON-UM1 diffractometer, filtered Co radiation), and thermal (a Q-1500 derivatograph, MOM, Hungary) analyses and IR spectroscopy within the 4000–400 cm^{-1} range (a Specord M-80 spectrometer; samples were prepared as KBr pellets). Color transitions were determined visually at heating of the compositions in a furnace; the temperature was monitored with a Chromel–Copel thermocouple. The alcoholic solutions of tetraethoxysilane (20 vol % TES) and zirconium(IV) oxychloride (0.4 M) were used as binders [2]. The contents of the components were selected so that the solutions could be used for a long time. The compositions were prepared by mixing of the heteropoly compound (HPC) and the correspond-

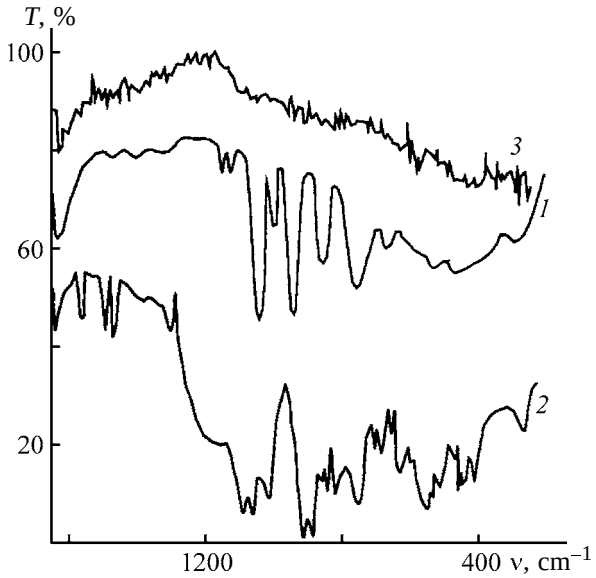

Fig. 1. IR spectra of (*1*) cobalt phosphomolybdate and its compositions with alcoholic solutions of (*2*) tetraethoxysilane and (*3*) zirconium oxychloride. (*T*) Transmittance and (ν) wavenumber.

ing alcoholic solutions in various ratios. During mixing of the cobalt 12-phosphomolybdate powder with an alcoholic solution of TES or zirconium(IV) oxychloride, the solution–gel transition was observed, which favored formation of a handy spread. This spread was applied onto glass supports by a thick-film method using a template and dried in air, with the subsequent heat treatment at 400°C. The minimal HPC content in the composition amounted to approximately 0.5 wt % and was determined by the threshold of visual determination of the color transition. The HPC content higher than 10 wt % favors accelerated gelation, which makes difficult applying the spread onto the support.

The structure of the initial cobalt 12-phosphomolybdate was determined IR-spectroscopically (Fig. 1). The IR spectrum of cobalt 12-phosphomolybdate, $CoH[PMo_{12}O_{40}]\cdot nH_2O$, contained the absorption bands characteristic of Keggin structures with stretching ν(P–O), ν(Mo=O), and ν(Mo–O–Mo) vibrations at 1080, 980, and 890 cm^{-1}, respectively, and bending δ(P–O) vibrations at 530 cm^{-1}. Vibrations of the bridging oxygen (–O–) lie at 800 cm^{-1}. Vibrations ν(OH) at 3680 cm^{-1} and δ(OH) at 1430 and 1030 cm^{-1} of the OH groups bound with the cation (Co) [3, 4] were also observed. A broad absorption band at 400–600 cm^{-1} indicates that the substance contains an impurity of cobalt chloride or hydrophosphate, which is caused by their coprecipitation at evaporation of the mother liquor. Weak bands at 1170 and 1260 cm^{-1} are assigned to vibrations of $[HPO_4]^{2-}$ groups. Absorption at 3200–3600 cm^{-1} (broad band) and 1640 cm^{-1} belongs to stretching and bending vibrations of water molecules, respectively [5, 6].

During mixing cobalt 12-phosphomolybdate with the TES solution (pH 4–5), the color changes from yellow to light blue, which is caused by conversion of $[PMo_{12}O_{40}]^{3-}$ into $[H_xPMo_{11}O_{39}]^{7-x}$ by the scheme

$$[PMo_{12}O_{40}]^{3-} + (5 - x)OH^- \rightleftarrows [H_xPMo_{11}O_{39}]^{7-x} + HMoO_4^- + (2 - x)H_2O.$$

In the process, the ν(P–O) band at 1080 cm^{-1} characteristic of HPC with the Keggin structure splits into two components at 1085 and 1060 cm^{-1}, suggesting formation of lacunary phosphomolybdate structure, $[H_xPMo_{11}O_{39}]^{7-x}$ [7]. In addition, a broad shoulder at 1250–1150 cm^{-1} caused by ν(SiO) vibrations and bands at 1100 and 720 cm^{-1} belonging to vibrations of the bridging Si–O–Si bonds [5, 7–9] appear. Absorption bands at 1580 and 1330 cm^{-1} suggest formation of the ethoxy groups $Me–OC_2H_5$ [10].

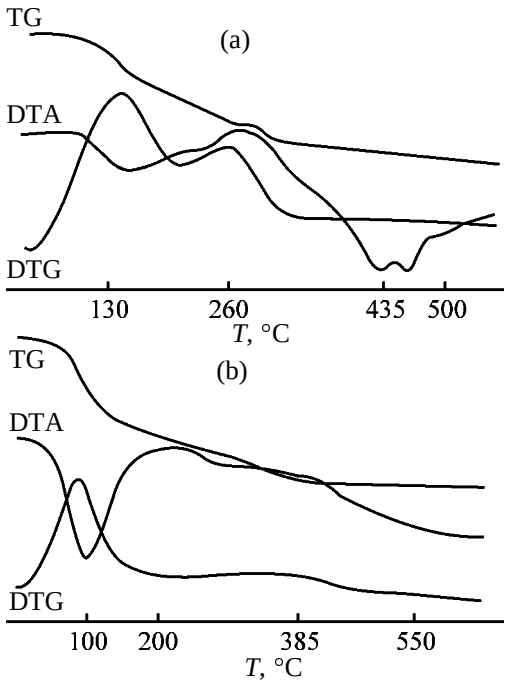

Fig. 2. Thermograms of decomposition of the spreads containing solutions of (a) tetraethoxysilane and (b) zirconium oxychloride. (*T*) Temperature.

To provide stability of zirconium oxychloride, pH 1–2 is required, which is reached at salt dissolution in ethanol. At mixing cobalt phosphomolybdate with an alcoholic solution of zirconium oxychloride, the color of the composition changes from yellow to green. The IR spectrum of the latter contains no bands of the phosphomolybdate ion (Fig. 1).

Processes in zirconium oxychloride solutions are less studied. The initial zirconium oxychloride is a tetramer with the composition $[Zr_4(OH)_8(H_2O)_{16}]Cl_8\cdot 12H_2O$ [11]. On dissolution, the initial salt dissociates with formation of a cyclic zirconium tetramer containing Zr–O–Zr bonds [12]. Ethanol converts into acetates on these groups [10, 13]. The IR spectra of the dried binders contain characteristic bands of the acetate groups. Introduction of HPC prevents formation of acetate on the zirconium ion, owing to decomposition of the heteropoly anion with the release of protons, molybdate, and phosphate ions. The reaction proceeds by the acid–base mechanism between the heteropoly anion and complex hydroxy cation exhibiting amphoteric properties. Water formation promotes hydrolysis and HPC decomposition.

To form thermochromic materials, the spread was subjected to the heat treatment. To study thermolysis, we measured thermograms of both the initial components and spreads within the 20–600°C range. The results showed (Fig. 2a) that the thermal decomposi-

tion of the spreads based on TES is accompanied by complex processes connected with the presence of HPC structures. In the course of the thermolysis, the weight of the spread decreases, suggesting formation of the silicon oxide framework. The thermal decomposition of cobalt phosphomolybdate starts above 430°C. The derivatograms of spreads based on TES show heat effects caused by structural changes in HPC, described previously [14]. This confirms once again the existence of the lacunary structure in these compositions. The X-ray phase analysis of the samples annealed at 600°C shows that the compositions studied are multiphase systems. The most intense reflections in the powder patterns belong to molybdenum, silicon, and cobalt oxide phases.

The composition containing zirconium oxychloride decomposes in two stages, which is characteristic of the thermal decomposition of the products of zirconium oxychloride hydrolysis (Fig. 2b).

The compositions prepared were tested for the thermochromism. The color of the composition based on TES changes at 375–380°C from light blue to dark blue. The thermogravimetric studies showed that, to obtain a thick-film thermochromic material based on silicon, the sample heating for 90–120 min at 400°C is required.

CONCLUSIONS

(1) The alcoholic solutions of tetraethoxysilane can be used as a binder for preparing thermochromic materials based on cobalt phosphomolybdates. In the reaction of the heteropoly compound with an alcoholic solution of tetraethoxysilane, $[PMo_{12}O_{40}]^{3-}$ transforms into the lacunary structure, $[H_xPMo_{11}O_{39}]^{7-x}$. The hydrolysis in the compositions including zirconium oxychloride prevents stabilization of the structure of the heteropoly compound responsible for the thermochromic color transitions.

(2) The optimal procedure for obtaining thick-film thermochromic materials is heating of the spread for 90–120 min at 400°C.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Interactions in the Silver Selenide–Water System

G. V. Petrov and A. M. Belen'kii

Plekhanov State Mining Institute, St Petersburg, Russia

Received May 26, 2004

Abstract—Interactions in the Ag_2Se–H_2O system in the whole pH range was studied by thermodynamic calculations and polarization measurements. Refined Pourbaix diagrams at 25 and 80°C were constructed.

Chemical reactions in aqueous solutions find expanding application in metallurgy and chemical industry. An important process of this type is hydrochemical oxidation of chalcogens (sulfur, selenium, and tellurium) and their most stable compounds, metal chalcogenides. These reactions are involved in formation of natural minerals, in particular, in secondary transformations of earth's crust. The processes for recovering chalcogenides and non-ferrous and noble metals from both natural ores and various intermediate reprocessing products are usually based on these reactions. Development and industrial application of hydrometallurgical processing of copper electrolytic refining slimes containing noble metals substantially depends on the behavior of silver and gold chalcogenides in various solutions.

It is known that Ag_2Se is oxidized in alkaline solutions to selenate anion which is highly stable and can be reduced to elemental selenium only at a high pressure. Selenium(VI) is reduced with HCl only at elevated temperatures and high acid concentrations. In addition, liberation of Cl_2 complicates the industrial application of this process. Selenium(VI) can be reduced in acidic solution at room temperature in the presence of a catalyst (e.g., titanium salts). The catalytic reduction expands the possibility of oxidative acid breakdown of chalcogen-containing materials, but the problem of selenium recovery from alkaline solutions remains unsolved [1–3].

To develop new methods for breakdown of chalcogen-containing materials enriched with noble metals, we studied in this work the interactions in the Ag_2Se–H_2O system in the whole pH range by thermodynamic calculations (construction of Pourbaix diagrams) and potentiostatic measurements.

EXPERIMENTAL

Polarization curves were recorded on a P-5827 potentiostat using a KSP-4 electronic potentiometer and a three-electrode cell with separated electrode compartments. A silver plate coated with Ag_2Se by immersion in a sodium polyselenide solution immediately prior to the measurements was used as the working electrode. Platinum and silver chloride electrodes were used as auxiliary and reference electrodes, respectively. The polarization curves were recorded at a current sweeping rate of 75 A m^{-2} min^{-1} and the time providing attainment of the stationary potentials. The current density was varied in the range 1.0–1500 A m^{-2}.

In the examined system, silver can be formed by both the reduction and oxidation of Ag_2Se. The Pourbaix diagram for the Ag_2Se–H_2O system at pH < 6 and $\varphi > 0.4$ [2] shows that Ag_2Se is oxidized directly to selenate ions. However, this conclusion is not quite correct, since the solubility of Ag_2SeO_4 (SP = 5.6×10^{-8}) in acidic and neutral solutions [$K_2(H_2SeO_4) = 8.9 \times 10^{-3}$] was not taken into account. We calculated and constructed the refined φ–pH diagram for the Ag_2Se–H_2O system at 25 and 80°C (Figs. 1a, 1b).

The activity of all components except for hydrogen ions were taken as 1.

The stability region of Ag_2Se in the diagram of the Ag_2Se–H_2O system at 25°C (Fig. 1a) in the whole pH range (except for pH < 1) is bounded from the top by lines *1–3* corresponding to the equilibrium potential of reduction of Ag^+ to Ag^0 and oxidation of Se^{2-} to SeO_3^{2-}. The stability region of SeO_3^{2-} is narrow: Se(IV) can be oxidized to Se(VI) at the overvoltage as low as 0.1–0.2 V. At pH 1, Ag^+ is not reduced to Ag^0 and goes into the solution as Ag^+ cation. Above lines *7–11*, silver is mainly in the ionic or oxide form. On heating to 80°C, the Pourbaix diagrams of the Ag_2Se–H_2O system insignificantly changes (Fig. 1b). Thus, the electrochemical behavior of Ag_2Se is almost independent of temperature in the whole pH range.

The anodic polarization curves of Ag_2Se oxidation in an alkaline solution (NaOH concentration 80–

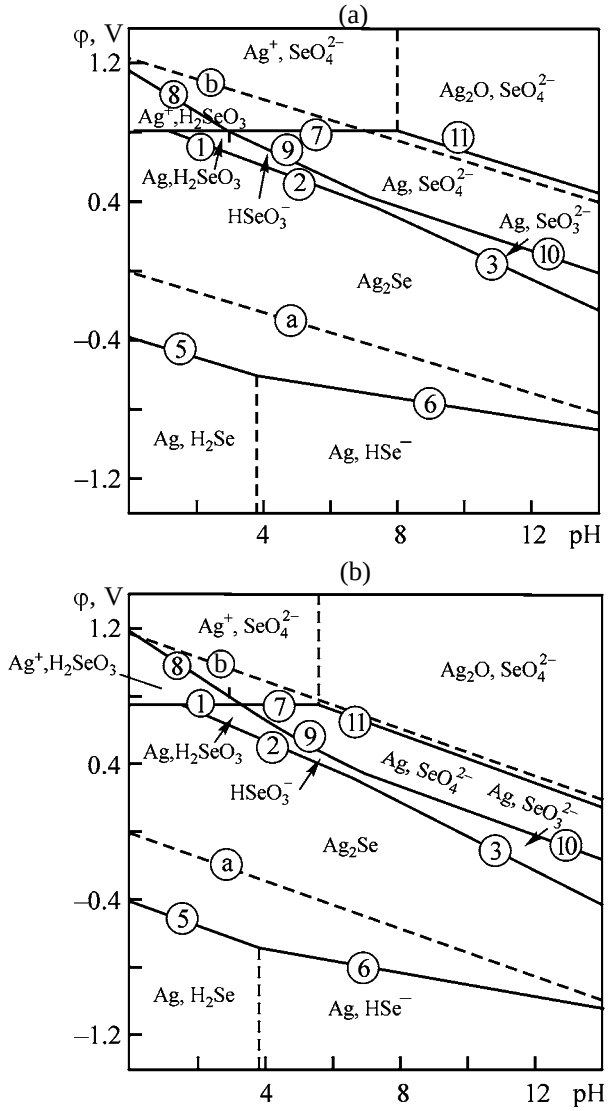

Fig. 1. Refined Pourbaix diagrams for the Ag_2Se–H_2O system at (a) 25 and (b) 85°C. (φ) Potential.

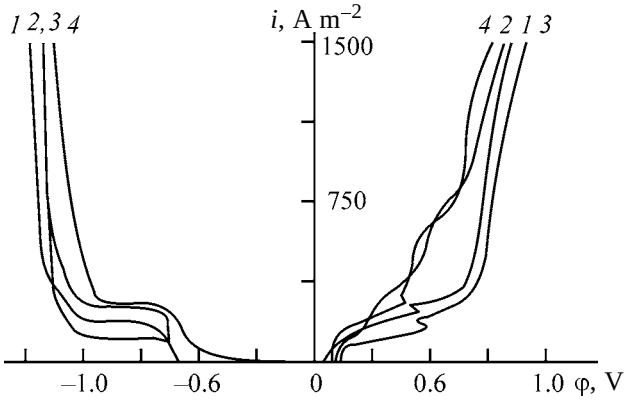

Fig. 2. Polarization curve of Ag_2Se at NaOH concentration of (*1*) 80, (*2*) 120, (*3*) 160, and (*4*) 200 g l^{-1} and the current sweeping rate of 75 A m^{-2} min^{-1}. (*i*) Current density and (φ) potential; the same for Fig. 4.

200 g l^{-1}) contain three typical waves (Fig. 2). The first wave appears at 0.3 V and the current density of 170 A m^{-2}. In accordance with the Pourbaix diagram (Fig. 1b), this wave is due to formation of Ag and SeO_3^{2-}. The second wave is observed in the potential range 0.4–0.5 V and is assigned to oxidation of SeO_3^{2-} to SeO_4^{2-}. The third wave at 0.55–0.6 V is due to oxidation of Ag^0 to silver oxide. At higher potentials, both hydroxide and selenium-containing anions are discharged to form O_2. Hence, to prevent formation of stable SeO_4^{2-} anions, the electrolysis should be performed at low current densities (Fig. 2).

As seen from the Pourbaix diagrams, Ag_2Se is reduced to elemental silver and Se^{2-} anions in the potential ranges from –0.4 to –0.8 (25°C) and from –0.5 to –0.9 V (80°C). Liberation of H_2Se from the solution with pH <4.0 (25°C) or 2.5 (80°C) is possible. At higher pH, hydrogen selenide is not liberated from solutions.

The hydrogen overvoltage decreases with increasing temperature (the boundary of H_2Se existence is moved away from the region of water stability), which complicates the reaction

$$HSe^- + 2Ag \rightleftarrows Ag_2Se + H^+ + 2e. \quad (1)$$

However, since the hydrogen overvoltage on silver is high, Ag_2Se can be reduced to elemental Ag and Se^{2-} in a wide temperature range at pH substantially lower than 14.

To transfer selenium into the gas phase, the electrolysis should be performed in acidic solution (pH < 3.8), and to transfer selenium into the solution, the process should be performed in neutral or weakly acidic solution (pH > 4).

The cathodic polarization curves of Ag_2Se in alkaline solution have several inflection points (Fig. 2). In the course of polarization the solution in the electrode compartment turns brown-red owing to formation of selenide and polyselenide anions. The color of the cathodically polarized electrode is grayish-metal owing to deposition of metallic silver. The standard potential of one of the potential-determining cathodic reactions,

$$Ag_2Se + 2e \rightleftarrows Se^{2-} + 2Ag, \quad (2)$$

is –1.06 V at 80°C. However, the other cathodic reactions yielding polyselenide ions are possible:

$$2Ag_2Se + 2e \rightleftarrows Se_2^{2-} + 4Ag, \quad \varphi^0 = -0.54 \text{ V}; \quad (3)$$

$$4Ag_2Se + 2e \rightleftarrows Se_4^{2-} + 8Ag, \quad \varphi^0 = -0.44 \text{ V}. \quad (4)$$

At high overvoltage observed in the range of saturation currents, hydrogen can be formed:

$$2H_2O + 2e \rightleftarrows H_2 + 2OH^-, \quad \varphi^0 = -0.83 \text{ V}. \quad (5)$$

Taking into account the calculated standard potentials and the polarization shift of the cathodic potential to the negative region, we suggest that various selenium oxide films adsorbed on the cathode in the course of synthesis of the initial Ag_2Se (Fig. 2) are reduced at the current densities of up to 30 A m^{-2} and cathodic potential of up to –0.6 V. The section of the cathodic curves at current densities from 30 to 60 A m^{-2} is characterized by constant potential of –0.65 V caused by cathodic reactions (3) and (4) yielding polyselenide ions.

The stationary cathodic potential at low current densities is affected by a low concentration of selenide ions in the solution. At the current density of 100 A m^{-2}, the cathodic potential reaches –0.95 V and is in the range of formation and existence of sodium monoselenide [reaction (2)]. As the current density increases to the maximal value (1300 A m^{-2}), the cathodic potential slightly changes to the value from –1.0 to –1.1 V. Under these conditions, the main electrode process is reaction (2).

The cathodic reaction not involving hydroxyl ions is independent of the alkaline concentration varied from 80 to 200 g l^{-1}. Since the polarization curves measured in these solutions at the stationary potentials virtually coincide, selenide ions are not hydrolyzed in this concentration range. When the potential sweeping is lower than the stationary potentials, the cathodic polarization is slightly higher and increases with increasing alkali concentration (Fig. 2). The calculated apparent activation energy E^* of the cathodic process at 20–80°C is 6.28 kJ mol^{-1}. The fact that the activation energy is independent of the redox potential suggests diffusion overvoltage of the electrode reaction (Fig. 3).

Since chalcogens and metal chalcogenides are hydrophobic, we studied cathodic polarization of Ag_2Se in alkaline solutions containing surfactants. In the presence of Na_2S, the shape of the polarization curve does not change (Fig. 4) except for the initial section. In this step, the reduction starts at more negative potentials since oxidized selenium films adsorbed on the electrode are probably reduced with sulfide ions. Formation of monosulfo- and disulfoselenides along

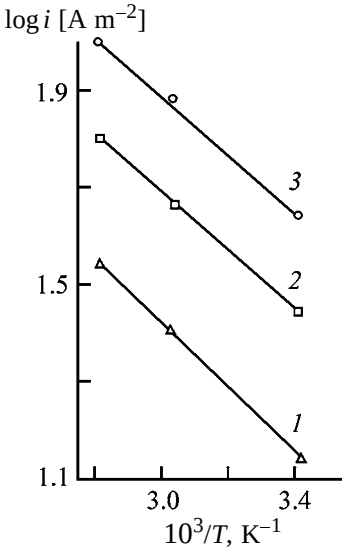

Fig. 3. Rate of cathodic reduction of Ag_2Se at φ (*1*) –0.7, (*2*) –0.8, and (*3*) –0.9 V in alkaline solution as a function of temperature *T*. (*i*) Current density.

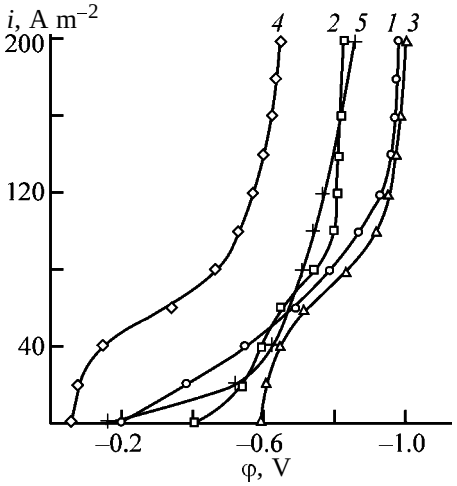

Fig. 4. Cathodic polarization curves of Ag_2Se in alkaline solution (80 g l^{-1} NaOH) at 80°C (*1*) without surfactant; in the presence of surfactant (g l^{-1}): Na_2S (*2*) 5 and (*3*) 100; C_2H_5OH (*4*) 5 and (*5*) 100.

with selenide ions is also possible:

$$2Ag_2Se + S^{2-} + 2e \rightleftarrows SSe^{2-} + Se^{2-} + 4Ag, \ \varphi^0 = -0.6 \text{ V}; \quad (6)$$

$$4Ag_2Se + S^{2-} + 4e \rightleftarrows SSe_2^{2-} + 2Se^{2-} + 8Ag, \quad \varphi^0 = -0.63 \text{ V}. \quad (7)$$

Ethanol, unlike Na_2S, strongly affects the cathodic polarization (Fig. 4). All typical inflection points in the cathodic curves are shifted to the positive potentials, which is due to stabilization of polyselenide

ions. In other words, introduction of ethanol decreases the reduction potential of Ag_2Se.

Thus, about 95–98% of selenium can be converted into water-soluble polyselenide species by electrochemical decomposition or hydrochemical reduction of deleaded copper slime in alkaline solution containing surfactant.

CONCLUSIONS

(1) In oxidation of silver selenide in the whole pH range, selenide ions exist in a narrow potential range. Extremely stable selenate anion, which can be reduced to elemental selenium only at elevated pressure or in the presence of catalyst, is formed at the redox potentials slightly exceeding this range.

(2) In the presence of surfactants (sodium sulfide or ethanol), reduction of silver selenide is accelerated and polyselenide anions are stabilized, which shifts the cathodic potential to the electropositive range and suppresses hydrogen liberation.

(3) Introduction of surfactants in electrochemical breakdown or chemical reduction of chalogenide-containing materials enriched with noble metals provides almost quantitative transfer of selenium into an alkaline solution.

Received December 8, 2004

Abstract—The integral thermodynamic characteristics and copper activity in liquid alloys of the system nickel–copper–cobalt at 1600°C were calculated by various methods from data on boundary binary systems.

For analysis of systems and processes involved in the main pyrometallurgical procedures in nickel and copper production, it is necessary to know the thermodynamic properties of various combinations of elements constituting the complex system Cu–Ni–Co–Fe–S–O at high temperatures. It is impossible today to estimate the thermodynamic characteristics of formation of a liquid alloy from pure components from data on their properties even for binary systems, to say nothing of more complex systems. The use of phase diagrams requires, as a rule, certain assumptions for calculating the thermodynamic characteristics of the system does not always affords reliable thermodynamic data. At the same time, a variety of pure geometrical and analytical models allow integral and partial thermodynamic characteristics of ternary and more complex systems to be estimated sufficiently reliably using only data on the corresponding properties of the boundary binary systems.

The suitability and reliability of the calculation methods, depending on the features of interactions in a particular multicomponent system, was confirmed for a great variety of liquid metallic systems, which are relatively fusible and convenient for experimental study [1–11]. For ternary and more complex systems formed by the above components, fairly reliable and comprehensive data are virtually lacking. In such cases, the extent to which the calculation results are close to true thermodynamic characteristics of mixing can be largely judged from the coincidence of the integral thermodynamic characteristics of ternary and more complex system calculated using different geometrical models (6–8 versions are possible) and polynomial methods, Redlich–Kister polynomials [12] in particular. The partial molar properties, activities, and activity coefficients of components in ternary system can be estimated both from the calculated integral characteristics and directly from the corresponding partial molar characteristics of binary systems. The second way seems more preferable, since it does not require to differentiate the equation expressing the dependence of the corresponding integral property on the composition of a ternary system along one or another section.

The choice of appropriate values for binary systems, based on detailed analysis of data available from the original literature, is important in calculating the thermodynamic properties of ternary and more complex systems. Presently, the thermodynamic characteristics (component activities, Gibbs energies, enthalpies and entropies of formation from elements) are available for a large number of binary metallic systems and systems metal–sulfur. They were obtained by different methods and different authors and are far from being consistent in all cases. Practical thermodynamic calculations require reliable and consistent values of thermodynamic functions, and choosing them is sometimes a problem of no less importance than obtaining new results. First of all, the preliminary expertise of thermodynamic functions should be based on the laws of chemical thermodynamics. Also, it should take into account the regular trends or dependences reliably established for more or less wide classes of systems and involve the assessment of the reliability of the applied experimental method and of the skill and experience of a specific experimental team, as well as of the results obtained by this team in studying other systems [13]. Such expertise can be also useful for characterizing the reliability of single thermodynamic data.

Previously, we used data on boundary binary systems to calculate the thermodynamic characteristics of

liquid alloys of the systems Ni–Cu–Fe [14, 15] and Fe–Ni–Co [16]. As noted above, quite satisfactory agreement of the results obtained in calculation of the integral molar excess Gibbs energies ΔG and enthalpies of mixing ΔH of ternary systems by various geometrical models and analytical Redlich–Kister equation gives grounds to consider that they are described rather reliably. The calculation was preceded by the detailed analysis of the available experimental data on thermodynamic properties of boundary binary systems.

The thermodynamic properties of liquid alloys of the system Ni–Cu were repeatedly studied by various methods, such as the emf measurements with molten or solid electrolyte, the saturated vapor pressure measurement by the transfer method and with a Knudsen's cell as a source of the molecular beam, and the high-temperature calorimetry. According to a calorimetric study [17], the enthalpy of mixing is positive over the entire composition range (1480°C), its maximum value does not exceed 2.5 kJ mol^{-1}, and the curve maximum is slightly shifted to the nickel-rich region of compositions. Kulkarni and Johnson [18] studied the system by the emf method with solid anion-conducting electrolyte (ZrO_2 + MgO) at 1400°C ($0.0 \le x_{Ni} \le 0.77$, where x is the mole fraction of nickel in the alloy). In calculation of the thermodynamic functions, nickel in the solid state and copper in the liquid state were standard states. According to [18], the isotherms of component activities in the system Ni–Cu exhibit moderate positive deviations from the ideality over the composition range studied.

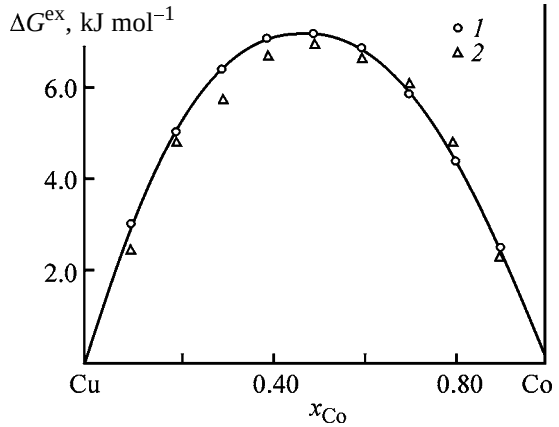

Fig. 1. Integral molar excess Gibbs energy ΔG^{ex} vs. Co mole fraction in liquid alloys in the system Cu–Co. References: (*1*) [27] (1600°C, extrapolation) and (*2*) [26] (1550°C).

The thermodynamic properties of liquid alloys of the system Ni–Cu were studied, analyzed, and optimized in a number of other studies [19–23]. Based on the comparison of the whole set of the experimental data used for calculating the thermodynamic properties of the ternary system Ni–Cu–Co at 1600°C, we have taken as input data the results from [21, 23]. The same data are recommended for the system Ni–Cu in a reference book [24]. The values accepted for calculation are validated in more detail in [25].

The interaction between the components in liquid alloys of the system Cu–Co has been studied less extensively. Timberg *et al*. [26] used the mass spectrometry with a Knudsen's cell as a source of the molecular beam ($0.060 \le x_{Co} \le 0.949$, 1422–1597°C) to study the thermodynamic properties of liquid alloys of copper with cobalt. The standard state was the liquid state of pure components. The copper and cobalt activities were calculated from the values of the ion currents at 1550°C. The system shows considerable positive deviations from the ideal behavior. The close results were obtained by Taskinen [27] who studied the thermodynamic properties of the Cu–Co system by the emf method with a solid oxygen-containing electrolyte ZrO_2 + MgO ($0.030 \le x_{Co} \le 0.700$, 1097–1457°C). The cobalt activity was determined directly from the results of the emf measurements. The calorimetric study and calculation of the phase diagram from the thermodynamic data of [28–30] were also performed. The ΔG^{ex} and ΔH values obtained by different authors for the Cu–Co system are compared in Figs. 1 and 2. The data on the copper alloys with cobalt in the liquid state, accepted as input data for thermodynamic calculation of the ternary sys-

tem (Table 1), are based on the results of [26, 27].

Cobalt and nickel show unlimited mutual solubility in both liquid and solid states. The liquidus and solidus temperatures are so close that virtually merge into one line. Data on the thermodynamic properties of liquid Co–Ni alloys have been considered previously [16].

Table 1 summarizes the data on the integral molar excess Gibbs energy and enthalpy of mixing in liquid binary alloys, which were used for calculating the corresponding integral characteristics of the ternary system Ni–Cu–Co. The calculation of ΔG^{ex} and ΔH for the ternary system involves a number of geometrical models, which were analyzed in detail in a monograph [12] and applied in previous studies [14–16]. The symmetric geometrical models (Kohler's and Muggiani's methods and various versions of Colinet's method) and asymmetric models (Toop's method and two versions of Hillert's method) yield reasonably consistent results. For all the 27 considered compositions of the ternary system, the values calculated by the four main models (Toop, Kohler, Muggiani, and Colinet's methods) commonly deviate from the average value by no more than 1.5%, the deviation attaining 3% only in some cases. The average results of the ΔG^{ex} and ΔH calculation are presented in Table 2. The lines of the equal values of these functions are plotted in Figs. 3 and 4. The degree of consistency of the results obtained using various simple geometrical models is to a certain extent a criterion of reliability in description of the thermodynamic property of a ternary system.

The problem of expressing analytically the concentration dependence of integral thermodynamic functions of binary alloys is important for estimating the

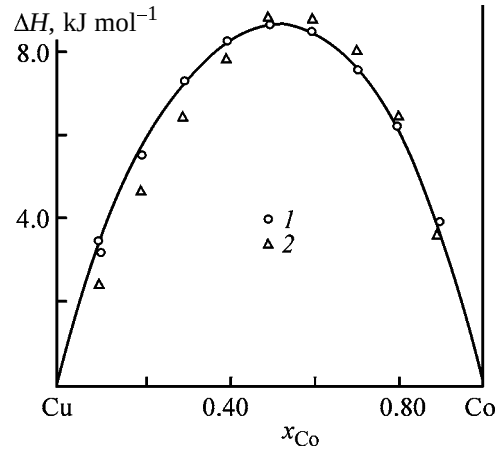

Fig. 2. Integral molar enthalpy of mixing ΔH vs. Co mole fraction in liquid alloys in the system Cu–Co. References: (*1*) [27] (1600°C) and (*2*) [26] (1550°C).

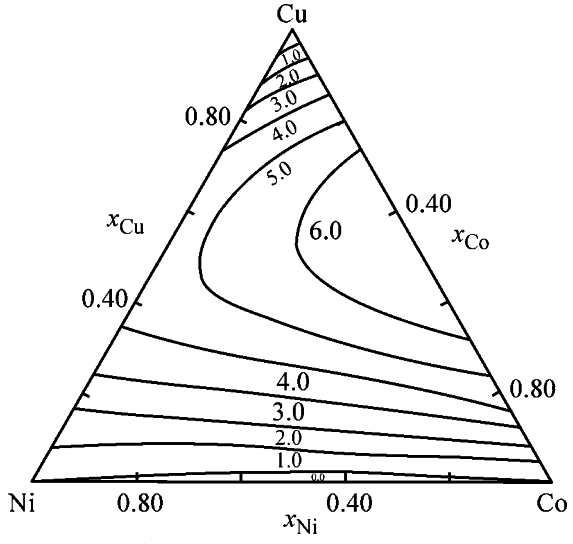

Fig. 3. Lines of equal integral molar excess Gibbs energies ΔG^{ex} (kJ mol^{-1}) for liquid alloys in the system Ni–Cu–Co at 1600°C.

Table 3. ΔG^{ex} and ΔH values for the ternary system Ni–Cu–Co at 1600°C, calculated by polynomial equations

x_{Cu}	$x_{Ni} : x_{Co} = 3 : 1$		$x_{Ni} : x_{Co} = 1 : 1$		$x_{Ni} : x_{Co} = 1 : 3$	
	ΔG^{ex}	ΔH	ΔG^{ex}	ΔH	ΔG^{ex}	ΔH
	kJ mol^{-1}					
0.2	2.92	3.52	3.27	4.50	3.76	5.24

0.6	5.36	4.87	5.94	6.02	6.48	7.12
0.8	3.82	3.23	4.12	4.11	4.66	4.95

integral thermodynamic characteristics of ternary system without using geometrical models. As in study of other ternary systems [14–16], we applied the Redlich–Kister method [12, 25]. In this method, the analytical expression of the ΔG^{ex} (kJ mol^{-1}) and ΔH (kJ mol^{-1}) dependences on the composition in ternary system involves the polynomials

$$\Delta G^{ex} = x_1(1 - x_1)[b + c(2x_1 - 1) + d(2x_1 - 1)^2], \quad (1)$$

$$\Delta H = x_1(1 - x_1)[b' + c'(2x_1 - 1) + d'(2x_1 - 1)^2]. \quad (2)$$

It was shown previously [31] that it is unnecessary for liquid metallic systems to use higher degrees of polynomials. For the binary systems discussed here, the following coefficients were obtained:

	Ni–Cu	Cu–Co	Co–Ni
b	18.8829	28.2676	–2.5158

In Eqs. (1), (2), x_1 corresponds to the component indicated first for all the three binary systems. As noted previously [14, 16], the polynomial dependences for boundary binary systems allow the integral molar excess Gibbs energy and enthalpy of mixing to be calculated with reasonably simple expressions:

$$\Delta G^{ex} = x_1x_2[b_{12} + c_{12}(x_1 - x_2) + d_{12}(x_1 - x_2)^2] + x_2x_3[b_{23} + c_{23}(x_2 - x_3) + d_{23}(x_2 - x_3)^2] + x_3x_1[b_{31} + c_{31}(x_3 - x_1) + d_{31}(x_3 - x_1)^2], \quad (3)$$

$$\Delta H = x_1x_2[b'_{12} + c'_{12}(x_1 - x_2) + d'_{12}(x_1 - x_2)^2] + x_2x_3[b'_{23} + c'_{23}(x_2 - x_3) + d'_{23}(x_2 - x_3)^2] + x_3x_1[b'_{31} + c'_{31}(x_3 - x_1) + d'_{31}(x_3 - x_1)^2], \quad (4)$$

where x_1–x_3 characterize the composition of a ternary system ($x_1 + x_2 + x_3 = 1$); the subscripts 12, 23, and 31 in the polynomial coefficients refer to the binary systems Ni–Cu (1–2), Cu–Co (2–3), and Co–Ni (3–1), respectively.

The results of a calculation by Eqs. (3) and (4) are presented in Table 3 for a number of compositions of the ternary system. The calculated ΔG^{ex} and ΔH values reasonably agree with the results obtained using the geometrical models (Table 2).

A characteristic feature of the ternary system considered is that liquid alloys in the system Co–Ni show quasi-regular behavior and those in the system Ni–Cu and, especially, in the Cu–Co system exhibit rather significant positive deviations from the ideal behavior. The copper content in liquid alloys of the given ternary system determines the value of its integral and partial thermodynamic functions. Based on this fact, the thermodynamic functions of copper (ΔG^{ex}_{Cu}, γ_{Cu}, and α_{Cu}) were chosen to verify various methods used for direct estimation of the partial molar functions of a component from data on boundary binary systems.

The following dependence can be derived from Toop's equation [32–34]:

$$G_2^{ex} = [x_1(1 - x_2)^{-1}\Delta G^{ex}_{2(1)} + x_3(1 - x_2)^{-1}\Delta G^{ex}_{2(3)}]_{x_2} - (1 - x_2)^2[\Delta G^{ex}_{13}]_{x_1/x_3}, \quad (5)$$

where ΔG_2^{ex} is the partial molar excess Gibbs energy of component 2 in the ternary alloy of a composition determined by mole fractions of the components x_1–x_3; $\Delta G^{ex}_{2(1)}$ and $\Delta G^{ex}_{2(3)}$ are the partial molar excess Gibbs energies of component 2 in the boundary binary systems 1–2 and 2–3 at a given x_2; and ΔG^{ex}_{13} is the integral molar excess Gibbs energy of the system 1–3 at a given $x_1 : x_3$ ratio.

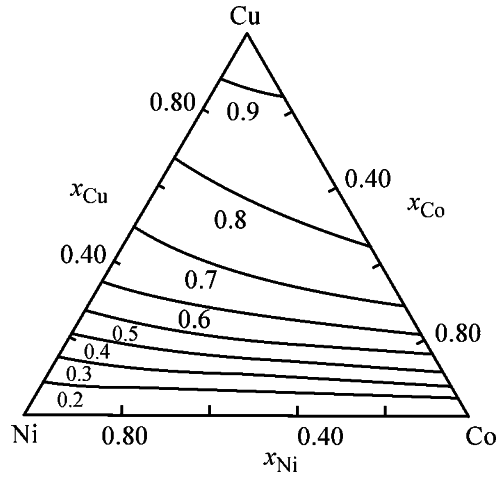

Fig. 5. Lines of equal copper activities in liquid alloys of the system Ni–Cu–Co at 1600°C.

In the given case, as in the subsequent expressions, components 1, 2, and 3 are nickel, copper, and cobalt, respectively. The results of the calculation are given in Table 4. The lines of the equal activities of copper in the concentration triangle are plotted in Fig. 5. The reliability of the results obtained was verified by taking Darken's integral [12] along one of sections of the ternary system ($x_1 : x_3 = 3 : 1$).

$$\Delta G^{ex} = (1 - x_2)\left\{\int_0^{x_2} [\Delta G_2^{ex}/(1 - x_2)^2]dx_2 + \Delta G^{ex}_{x_2=0}\right\}_{x_1/x_3}. \quad (6)$$

The integrand includes the ΔG_2^{ex} function along the section considered and the integral molar excess Gibbs energy $\Delta G^{ex}_{x_2=0}$ of the system 1–3 at a given $x_1 : x_3$ ratio, which were calculated by the above-indicated method. To the left, the integral molar excess Gibbs energy of the ternary system corresponding to the values calculated by Toop's method should be obtained. The integrand vs. composition is a continuous dependence without any singularities, which ensures highly accurate graphical integration. For a number of compositions, the ΔG^{ex} values obtained by the integration are compared below with the previously calculated values (Toop's method, $x_{Ni:Co} = 3 : 1$; ΔG^{ex}, kJ mol^{-1}, 1600°C).

x_{Cu}	$\Delta G^{ex}_{(i)}$*	$\Delta G^{ex}_{(T)}$*
0.2	2.80	2.82
0.4	4.77	4.79
0.6	5.13	5.16
0.8	3.71	3.73

* $\Delta G^{ex}_{(i)}$ was obtained by integration of Eq. (5), and $\Delta G^{ex}_{(T)}$ was calculated by Toop's method.

Table 5. Partial molar excess Gibbs energies, activity coefficients, and activities of copper in liquid alloys of the system Ni–Cu–Co at 1600°C

Composition, mole fraction			ΔG_{Cu}^{ex}, kJ mol^{-1}	$\ln\gamma_{Cu}$	γ_{Cu}	a_{Cu}
x_{Cu}	x_{Ni}	x_{Co}				
0.200	0.600	0.200	13.38*/14.09	0.859/0.905	2.36/2.47	0.472/0.494
0.500	0.375	0.125	6.29/6.85	0.404/0.440	1.50/1.55	0.750/0.775
0.600	0.300	0.100	4.30/4.51	0.276/0.290	1.32/1.34	0.791/0.802
0.600	0.100	0.300	5.18/5.35	0.333/0.344	1.39/1.41	0.837/0.846
0.800	0.100	0.100	1.41/1.50	0.091/0.096	1.09/1.10	0.876/0.881

Note: Numerator and denominator correspond to calculations by Toop's and Kohler's equations, respectively.

The dependence allowing calculation of ΔG_2^{ex} from data on boundary binary systems (component numbering is the same) can also be obtained from the main equation of Kohler's method [33, 35]:

$$G_2^{ex} = [(1 - x_1)\Delta G_{2(3)}^{ex} + x_1(1 - x_1)\Delta G_{2(3)}^{ex}]_{x_2/x_3} + [(1 - x_3)\Delta G_{2(1)}^{ex} + x_3(1 - x_3)\Delta G_{1(2)}^{ex}]_{x_2/x_1} - (1 - x_2)^2[\Delta G_{13}^{ex}]_{x_1/x_3}.$$

The partial molar excess Gibbs energies of copper, obtained by the two above methods, and the corresponding copper activities and activity coefficients of copper are compared in Table 5 for a number of compositions of the ternary system. For such kind of thermodynamic estimations, the observed deviation lies within the admissible limits.

CONCLUSIONS

(1) Calculations of the integral molar excess Gibbs energy and enthalpy of mixing in liquid alloys of the system nickel–copper–cobalt at 1600°C, using a number of geometrical models and Redlich–Kister polynomials, yield the consistent results.

(2) The copper activity in liquid Ni–Cu–Co alloys at 1600°C was calculated. The positive deviations of the copper activity from Raoult's law continuously increase as nickel is replaced by cobalt at the constant content of copper.

SORPTION AND ION-EXCHANGE PROCESSES

Preparation of Titanium Phosphate Sorbents from Products of Processing Sphene Concentrate and Properties of These Sorbents

V. I. Ivanenko, E. P. Lokshin, V. V. Vladimirova, and Kh. B. Avsaragov

Received March 1, 2004

Abstract—Procedures for the preparation and granulation of sorbents based on $TiO(HPO_4)\cdot nH_2O$ from the products of processing of sphene concentrate were developed. The sorption and hydrodynamic characteristics of the sorbents were determined.

Titanium(IV) phosphates are of a great interest as sorption materials. Depending on synthesis conditions they can have the composition $TiO(OH)_{2x}(HPO_4)_{1-x}\cdot nH_2O$, $TiO(HPO_4)\cdot nH_2O$, or $Ti(HPO_4)_2\cdot nH_2O$, with $TiO(HPO_4)\cdot nH_2O$ being prepared more easily. Hydrated oxotitanium hydrophosphate can be produced both as a fine amorphous powder and as a granulated product. It was shown in numerous studies that this sorbent efficiently absorbs cations of radionuclides [1–8] and also of nonferrous metals and iron [9–14] from very dilute aqueous solutions. This sorbent can be used for efficient decontamination of liquid radioactive wastes, which are aqueous solutions with a high content (the studies covered concentrations of up to 32 g l^{-1}) of salts present in seawater [15–17]. Known procedures for preparing granulated sorbents are complicated and expensive [7, 18].

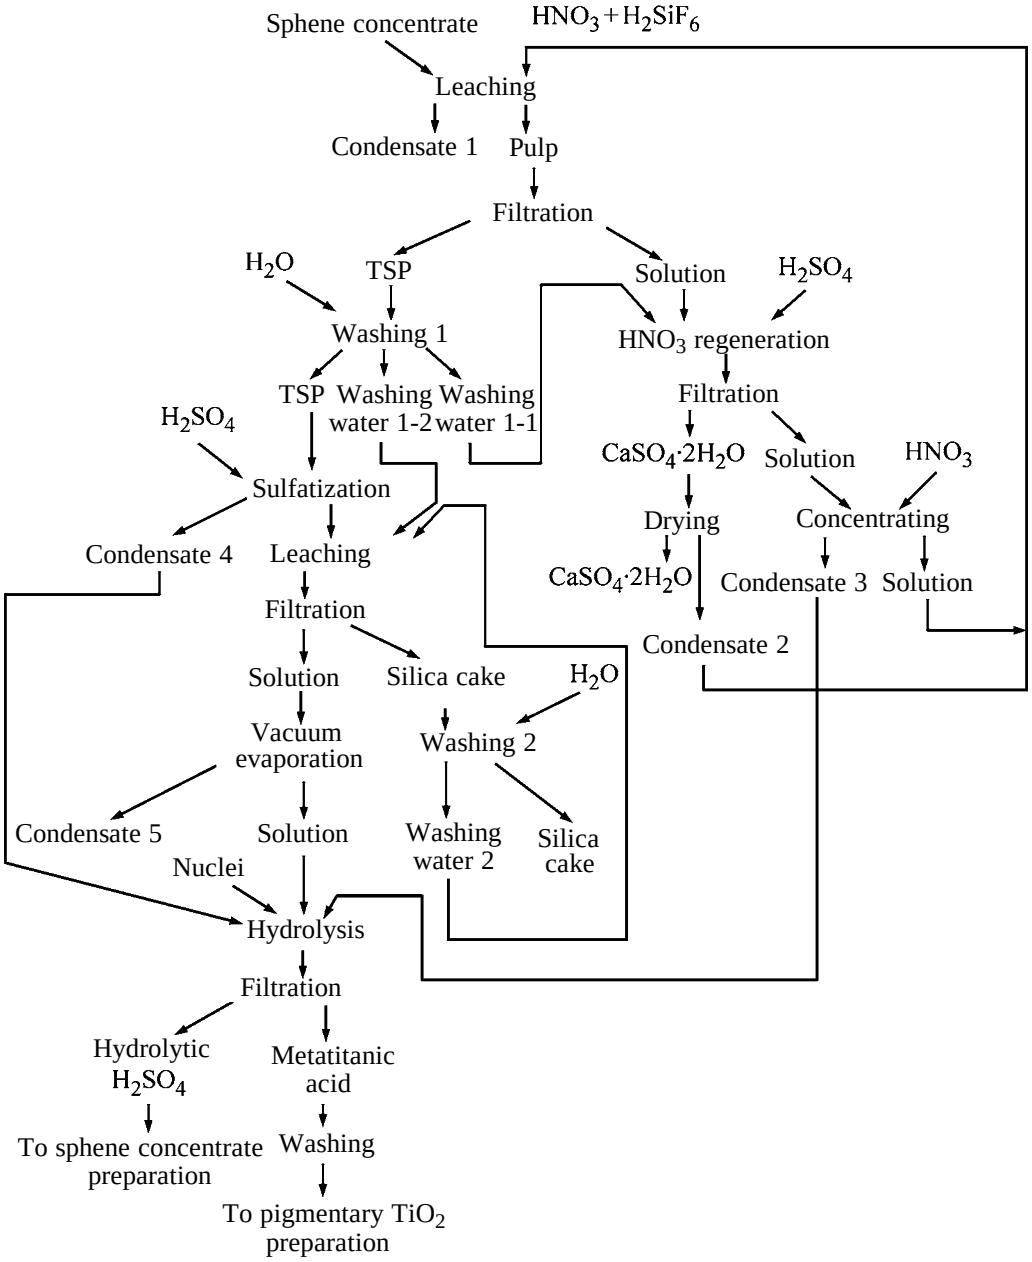
The developed technology of processing sphene concentrate for the synthesis of titanium phosphate sorbent (see scheme) can use titanium sulfate process solutions containing, g l^{-1}: TiO_2 160–340, H_2SO_4 280–570, CaO 1.6–5.6, F 4.4–7.7, Fe_2O_3 1.7–7.4, SiO_2 <0.05, and TR_2O_3 <0.20 (solution after sulfatization in the scheme); titanium–silica product (TSP) containing, wt %: TiO_2 48, SiO_2 37, CaO 0.56–3.00, Ln_2O_3 <0.018, Fe_2O_3 <0.64, Al_2O_3 <0.25, F <2.2, and NO_3^- 3.60; and hydrolytic sulfuric acid containing, g l^{-1}: TiO_2 12–13.5, Fe_2O_3 up to 7.4, and F 4.4–7.7.

In this work we studied the conditions of the synthesis of powdery titanium-phosphate sorbents based on $TiO(HPO_4)\cdot nH_2O$ from titanium-containing products obtained in processing of sphene concentrate using simple granulation procedures, and also the sorption and hydrodynamic characteristics of these sorbents.

EXPERIMENTAL

Titanium(IV) was precipitated from titanium sulfate process solutions by a stoichiometric amount of orthophosphoric acid according to the reaction

$$TiOSO_4 + H_3PO_4 + nH_2O = TiO(H_2PO_4)(HSO_4)\cdot nH_2O. \quad (1)$$



The further washing with water yields the desired product:

$$TiO(H_2PO_4)(HSO_4)\cdot nH_2O = TiO(HPO_4)\cdot nH_2O + H_2SO_4. \quad (2)$$

The product (sorbent 1) contains 45–46.7 wt % water, which corresponds to $n = 6.60 \pm 0.25$. A comparison with sorbents synthesized from Ti(IV) sulfate solutions in the absence of fluoride ions shows that their presence in the titanium sulfate solution had no effect on the composition and properties of the product, because fluoride ions remained in the highly acidic mother liquor.

A sort of such sorbent is the product obtained by the precipitation of residual Ti(IV) present in hydrolytic H_2SO_4 after thermohydrolytic isolation of hydrated Ti(IV) oxohydroxide. After adding a stoichiometric amount of H_3PO_4 with respect to Ti(IV) and heating the resulting solution to 90°C, more than 98% of Ti(IV) contained in the solution passes into

1070-4272/05/7801-0064 © 2005 Pleiades Publishing, Inc.

Flowsheet of processing sphene concentrate into titanium dioxide pigment.

this product. The resulting precipitate trapped the mother liquor (moisture content up to 84%), but after washing with water its moisture content decreased to 39% (sorbent 1-1).

To prepare titanium phosphate sorbent, we used also a titanium–silica product forming as an intermediate in processing of sphene concentrate. The titanium–silica product is synthetic leucoxene with a particle size of 0.07–0.15 mm, in which TiO_2 (about 47 wt % in the titanium–silica product) is uniformly dispersed in SiO_2 in an approximately equimolar proportion. It differs from natural leucoxene by the following features: TiO_2 is present there as anatase, whereas in natural leucoxene it is in the form of rutile; SiO_2 is hydrated (15–18 wt % of water is removed at high-temperature calcination of the product); chemically stable minerals, such as aegirines and feldspars, are present in it as impurities (5–10 wt %).

The interest in the sorbent based on a titanium–silica product is due to the fact that, in spite of the presence of "ballast" silica and sorption-inactive extrinsic minerals in it, its preparation does not

require preliminary sulfuric acid breakdown of the titanium–silica product, which can decrease the cost of the sorbent.

In this work we prepared the sorbent by the reaction of a titanium–silica product with H_3PO_4 at 140–150°C according to the reaction

$$TiO_2 + 2H_3PO_4 + (n - 2)H_2O = Ti(HPO_4)_2 \cdot nH_2O. \quad (3)$$

Then the forming titanium(IV) hydrophosphate was hydrolyzed by washing in water according to the reaction

$$Ti(HPO_4)_2 \cdot nH_2O + H_2O = TiO(HPO_4) \cdot nH_2O + H_3PO_4. \quad (4)$$

The resulting sorbent (sorbent 2) was $TiOHPO_4$ uniformly distributed in a matrix of hydrated silica. The particle size of such product substantially depended on the particle size of the sphene concentrate.

Granulated sorbents were prepared by two procedures. According to the first procedure, a titanium sulfate process solution was added dropwise to an H_3PO_4 solution, the mixture was held for 1–2 h, and the resulting granules were separated and washed with water. The product obtained consisted of hollow lenticular particles with a typical size of 3–5 mm. The granules were separated from the solution and subjected to heat treatment at various temperatures. We have found heat treatment conditions providing the preparation of granules stable in an aqueous medium (sorbent 3). According to the second procedure, the granulated sorbent was prepared from sorbent 1. Finely divided $TiO(HPO_4) \cdot nH_2O$ powder was separated from the solution by filtration and was then dried, also at various temperatures. The "monolithic" product was crushed and sieved into classes (sorbent 4). It was found that, depending on the heat treatment conditions, we can obtain both particles of the required coarseness that are stable in an aqueous medium, exhibit sufficient strength, and are not destroyed in solution, and particles that are broken down to the finest powder, which, however, preserved the sorption activity.

Finally, we made experiments aimed to obtain coarser particles of sorbent 2. When studying the possibility for coarsening of particles of phosphate-containing titanium sorbent based on silica, we also considered two approaches: preliminary coarsening of particles of titanium–silica product in both alkaline and acid media, followed by treatment of the solid phase with orthophosphoric acid; and direct treatment of the titanium–silica product with phosphoric acid followed by coarsening of particles.

An increase in particle size was observed in both cases. However, the sorbent aggregation in the acid solution was more intense than in alkaline solution.

The possibility for coarsening of product particles with the formation of granules stable in an aqueous medium can be associated with polymerization processes and can be rationalized on the following basis.

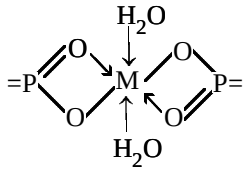
When $TiOHPO_4$ is formed, we should expect formation of oxo or phosphate bridging bonds between Ti(IV) atoms of different particles. The polymerization of Ti(IV) compounds in aqueous media with the formation of oxo-bridged compounds results from successive processes of hydroxylation, olation, and oxolation [19–21]. In the coarsening of particles based on TSP, it is not improbable that similar oxygen bridging bonds can also be formed between Si(IV) atoms. Interparticle oxotitanium or oxosilicon bonds are hardly formed through interaction between separate surface TiOH or SiOH groups of the approaching particles. Most likely, the primary stage consists in the activation of the particle surface (its hydroxylation) and in the formation of interparticle hydrogen bonds with more or less uniform distribution of Ti(IV) and Si(IV) oxohydroxides in the intermicellar liquid.

The formation of particles of Ti(IV) and Si(IV) oxohydroxides with activated surface can promote the formation of fairly large fragments of the solid phase. As Ti(IV) and Si(IV) in oxide compounds have vacant 3*d* orbitals and oxygen atoms have lone pairs of 2*p* electrons at oxygen, the dehydroxylation and polymerization process can yield oxotitanium or oxosilicon groups owing to the increased bond flexibility and the occurrence of d_π–p_π interaction [22]. Unlike p_π–p_π bonds with *p* orbitals having a rigid orientation relativen to σ bonds, d_π–p_π bonds are less sensitive to the deviations of the molecular geometry from planarity, owing to specific features of the symmetry of *d* orbitals. Therefore, even in nonplanar systems 3*d* orbitals can appreciably overlap with adjacent 2*p* orbitals. The increased flexibility of Ti–O–Ti and Si–O–Si bonds allows formation of diverse types of packing of titanium–oxygen octahedra and silicon–oxygen tetrahedra. Such d_π–p_π interaction of Ti(IV) or Si(IV) atoms with oxygen should result in increased bond multiplicity and additional strengthening of particles.

In near-neutral solutions, the mechanism of particle coarsening based on the amphoteric character of Ti(IV) oxohydroxide is the most probable. In this

case, different hydroxy groups of the same molecule or of different molecules of Ti(IV) oxohydroxide can exhibit both basic and acidic properties.

In acid solutions, a proton can add to a lone pair of oxygen electrons in OH groups of a part of Ti(IV) oxohydroxide molecules, increasing the positive charge and electrophilic power of titanium. The interaction of protonated and nonprotonated $TiO(OH)_2$ by the donor–acceptor mechanism results in particle coarsening. In the presence of electron–donor acido ligands of orthophosphoric acid in an aqueous medium, the particles should be coarsened more efficiently because of possible formation of bridging phosphate groups.



The results obtained may be due to the fact that the coarsening of sorbent particles and their mutual linking occurs through multiple repetition of the formation of oxo or phosphate bonds between Ti(IV) atoms, which requires time and can take place if the sample is dehydrated slowly. At fast drying, the amount of forming oxo-bridging bonds between various particles seems to be insufficient. It should be noted that the strength of particles increased with an increase in the acidity of the solution in which the particles were formed, which may be due to an increase in the rate of particle aggregation.

The synthesized sorbents were tested for chemical stability. All of them are stable in acid and neutral media. In the alkaline medium, partial hydrolysis of the titanium phosphate sorbent takes place to deplete it of phosphate groups and to convert a part of $TiHPO_4$ to $TiO(OH)_2$. At pH 9–10, a part of phosphate ions is "washed out" from oxotitanium hydrophosphate $TiO(HPO_4)\cdot nH_2O$ (Ti : P = 1 : 1), which is stable in acid and neutral solutions, and a solid phase with a Ti : P ratio close to 3 : 2 is formed. Such composition probably corresponds to the compound $(TiO)_3(HPO_4)_2(OH)_2\cdot nH_2O$. It is possible also that the solid phase formed by the hydrolysis is a hydroxide–phosphate matrix of variable composition. The further increase in the pH of the medium results in even greater depletion of the solid phase in phosphate groups. Apparently, the hydrolysis in alkaline solutions can be prevented or reduced by adding phosphate ions competing with hydroxide ions in heterogeneous anion exchange.

The heterogeneous sorption of alkali metal ions (M^+) in oxotitanium hydrophosphate can be presented by the reaction

$$TiOHPO_4\cdot nH_2O + M^+ \rightleftarrows TiOMPO\cdot nH_2O + H^+. \quad (5)$$

It was shown [11] that, in the course of the sorption, a double-charged metal ion combines with two hydrophosphate functional groups to form preferably chelates of the type

The sorption of double-charged metal ions (M^{2+}) is described by the reaction

$$2(TiOHPO_4\cdot nH_2O) + M^{2+} \rightleftarrows (TiOPO_4\cdot nH_2O)_2M + 2H^+. \quad (6)$$

We determined the static exchange capacity (SEC) of the samples at 20°C. A weighed portion of a sorbent was added to a 1 M solution of chloride of the corresponding metal, which was stirred to reach an equilibrium. The concentration of hydrogen ions, which were released by substitution with metal cations, was adjusted by potentiometric titration to pH 6. The pH was measured with an I-130.2M.1 ion meter with an accuracy of ± 0.02, and its values that did not change in time were considered as equilibrium values. As an indicator electrode we used a proton-selective ESL-43-07 electrode with the coordinates of the isopotential point pH_i 7 ± 0.3, and as an auxiliary electrode, an EVL-1M3 silver chloride electrode (Ag|AgCl, saturated KCl solution) with the potential of 202 ± 2 mV at 20°C relative to normal hydrogen electrode.

The experimental SEC values for various sorbents with respect to cations of some alkali and alkaline-earth metals, and also to Co^{2+} cations measured in solutions with pH 6 are given in Table 1.

The theoretically possible static exchange capacity of $TiO(HPO_4)\cdot nH_2O$ containing 45–46.7 wt % water (sorbent 1) is 3.33–3.44 mg-equiv g^{-1}. It is seen from Table 1 that SEC of sorbent 1 was no less than 85% of the theoretically possible value for cations of light (Na^+, Ca^{2+}), and 92–98%, for those of heavy (Cs^+, Sr^{2+}) alkali and alkaline-earth elements. The static exchange capacity for Co^{2+} ions appeared to be much lower. This may be due to the fact that, at pH 6, cobalt(II) salts are apparently hydrolyzed to form a poorly sorbable cobalt cation of a complicated composition [23]. In fact, when pH was reduced to 4.93, SEC of sorbent 1 with respect to Co^{2+} increased to 2.46 mg-equiv g^{-1}, though, according to reaction (6), the increase in the solution acidity should make the sorption worse.

Table 1. Static exchange capacity of sorbents at pH 6

Cation	Sorbent SEC, mg-equiv g^{-1}						Ratio of SECs of sorbents 2 and 1
	1	1-1	2	3	4		
					+0.7–2.0 mm	+0.2–0.7 mm	
Na^+	2.9	1.75	1.93	2.63	1.74	2.24	0.652
Cs^+	3.37	N/d*	2.14	3.02	2.24	N/d	0.635
Ca^{2+}	2.98	N/d	1.83	2.76	1.65	N/d	0.614
Sr^{2+}	3.17	N/d	2.08	2.93	2.11	2.36	0.656
Co^{2+}	1.89	N/d	1.52	1.67	1.26	N/d	0.804

* (N/d) Not determined.

The static exchange capacity of sorbent 1-1 with respect to Na^+ ions appeared to be much lower than the theoretical value, which may be due to capture of iron ions, which are present in hydrolytic H_2SO_4 in a concentration comparable with that of Ti(IV) and can be sorbed even at pH <1 [13]. However, the reached SEC of sorbent 1-1 is sufficient for some applications, especially if we take into account that it is obtained using Ti(IV) irrevocably lost in hydrolytic H_2SO_4.

For the majority of the cations under study, the SEC of sorbent 2 obtained on the basis of the titanium–silica product corresponded to the content of oxotitanium hydrophosphate in it, and for Co^{2+} it appeared to be even higher. Presumably, hydrated SiO_2, being a support of oxotitanium hydrophosphate, does not participate appreciably in the sorption of cations of alkali and alkaline-earth elements.

The static exchange capacity of granulated sorbent 3 is lower by only 7.6–11.6% than that of the powdery sorbent, whereas in the case of sorbent 4 it decreases to the level of sorbent 2. This is caused by diffusion limitations which inhibit penetration of sorbed cations into the depth of particles and release of protons from sorbent particles into the solution. In fact, the reduction in the sorbent particle size to 0.2–0.7 mm noticeably increased SEC with respect to Na^+ and Sr^{2+} ions.

Table 2. Distribution coefficients of radionuclides (α = 60) for sorbents 1 and 2

Radionuclide	K_d, $cm^3\ g^{-1}$, for indicated sorbent	
	1	2
^{134}Cs	1256	3080
^{90}Sr	1422	300
^{60}Co	332	128

The distribution coefficients K_d of cesium, strontium, and cobalt radionuclides in suspensions containing sorbents 1–3 are given in Tables 2 and 3. The distribution coefficients of the cations were determined by the formula

$$K_d = A_s/(A_{sol}\alpha), \quad (7)$$

where A_s is the fraction of metal ions sorbed by the solid phase; A_{sol}, fraction of metal ions remaining in the solution; and α, ratio of the sorbent weight (g) to the solution volume (cm^3).

The starting solutions contained (Bq kg^{-1}) ^{134}Cs 1×10^5, ^{90}Sr 2.2×10^4, and ^{60}Co 1×10^4. In the experiments, the ratio of the solution volume to the weight of the air-dry sorbent α was 60. The specific activity was measured in integral and differential modes on certified instrumentation: a Progress-G γ-ray spectrometer with a scintillation detecting block; PSO2-08 and DRG-01 T radiometers. The processing of spectra and the calculation of the activity and errors were carried out with a Progress software package. The exposure time was up to 1800 s depending on the activity of samples and their weight. The error of the determination of radionuclides for the confidence level of 0.95 was 11% on average. The β-radioactivity was determined on a UMF-1500D low-background installation.

Sorbent 3-1 was preliminarily heat-treated under optimal conditions; and the resulting granules, as noted above, were not destroyed in solutions, whereas sorbents 3-2 and 3-3 got dispersed on stirring in solutions.

As seen from Table 2, finely dispersed sorbents 1 and 2 were characterized by fairly high K_d values for

Table 3. Distribution coefficients and sorption percentages of radionuclides (α = 60) for sorbent 3 heat-treated at various temperatures

* Obtained by interpolation of experimental data.
** Obtained by extrapolation of experimental data.

all the radionuclides under study. The distribution coefficients of ^{134}Cs and ^{90}Sr for sorbent 1 were close to each other. Higher K_d for ^{134}Cs in the case of sorbent 2 as compared to sorbent 1 cannot be satisfactorily accounted for at present, as the sorption of ^{134}Cs by hydrated silica contained in sorbent 2 is improbable [in this case the static exchange capacity of sorbent 2 with respect to ^{134}Cs should be higher (Table 2)]. Probably, this is associated with the breakdown of the sorbent particles during sorption with the formation of active centers, as it took place in the case of sorbent 3 (samples 3-2 and 3-3 showed very high K_d values for ^{134}Cs).

As the size of sorbent granules increases, K_d for all the radionuclides under study decreases, which is especially noticeable in the case of double-charged cations. This can be accounted for as follows. First, large granules of sorbents can trap acidic mother liquor, and it is practically impossible to wash it out completely. As pH of solutions was not determined and adjusted when determining K_d, the increase in the solution acidity resulted in the K_d reduction. This can be overcome by maintaining the optimal pH value [15, 16]. Second, when the size of sorbent particles increases, diffusion limitations arise.

As crystallographic radii of Cs^+, Sr^{2+}, and Co^{2+} ions are 1.69, 1.13, and 0.74 Å, respectively [24], lower K_d values for Sr^{2+} and Co^{2+} ions are attributable to a higher charge and a smaller ionic radius of these latter, which results in the appearance of a developed hydration shell. It should be expected that the activity of the sorbents under consideration toward Sr^{2+} and Co^{2+} cations will increase upon partial hydrolysis of the sorbent in alkaline solutions, resulting in an increase in the hydroxide component exhibiting the high affinity for hydrated cations [13].

To determine the hydrodynamic resistance ΔP of the sorbent, we measured the volume of water passing through the sorbent in a specified time interval at various fixed heights of the liquid column above the sorbent. The experiment has shown that the amount of the passing liquid linearly correlates with the height (pressure) of the column, which allows us to extrapolate or interpolate experimental data to determine the pressure (which is equal to the hydrodynamic resistance of the sorbent bed) ensuring a specified rate of the liquid flow through the sorbent bed. The experiments were carried out at the sorbent bed height H_b = 100 mm and the ratio of the sorbent bed height to its diameter H_b/d_c = 10.

Experimental data on the filtration rate and hydrodynamic resistance for the filtration through samples of sorbents 2–4 are given in Table 4. The bulk weight of the sorbents was 0.826, 0.484, and 0.784 g cm^{-3}, respectively.

The hydrodynamic resistance of sorbent 2, which is

the most finely dispersed among the sorbents under study, substantially increased (by a factor of 2–3) when it came in contact with water during the first 0.5 h owing to spontaneous compaction of the sorbent bed.

The particles of the sorbent based on the titanium–silica product were made coarser by pretreatment in an alkaline medium followed by interaction of the titanium silicate matrix with phosphoric acid. We have found that the sorbent resistance to filtration can be thus reduced by a factor of 1.4–1.7 as compared to sorbent 2, and pretreatment in an acid medium (HCl or H_2SO_4) ensures the 1.9–2.4-fold reduction. The filtration characteristics remain poor in spite of appreciable coarsening of particles of the titanium phosphate sorbent prepared on the basis of the titanium–silica product.

Table 4 shows that sorbents 3 and 4 have low hydrodynamic resistance and can be considered promising for the use in sorption columns. Sorbent 2 and, the more so, sorbent 1 have high hydrodynamic resistance and are promising for the use in batch processes.

CONCLUSIONS

(1) Sorbents based on $TiO(HPO_4)\cdot nH_2O$ can be obtained from products of sphene concentrate processing using simple granulation procedures.

(2) The sorbents obtained are chemically stable in acid and neutral media, but in an alkaline medium (pH ≥ 9) they gradually lose a part of phosphate groups.

(3) The static exchange capacity of powdery materials based on oxotitanium hydrophosphate obtained from sphene concentrate processing solutions is close to the theoretically possible capacity corresponding to the content of hydrophosphate groups in the sorbent.

(4) Simple granulating techniques ensure the preparation of a material with a low hydrodynamic resistance, suitable for use in columns. Powdery sorbents can be recommended for wide use in batch processes.

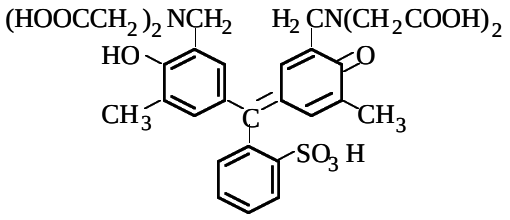
SORPTION AND ION-EXCHANGE PROCESSES

Physicochemical and Sorption Properties of Silica Gel with Immobilized Xylenol Orange Surface Groups

S. V. Korneev and Yu. V. Kholin

Karazin National University, Kharkov, Ukraine

Received October 22, 2004



Abstract—Organomineral sorbents were prepared by sorption immobilization of Xylenol Orange on the surface of two different samples of silica gel from aqueous solutions with pH 1.68 under static conditions. The diffusion coefficients of Xylenol Organe in the near-surface layer of silica gel and the equilibrium sorption constants were determined. Wash-out of the dye from the sorbent was studied. Sorption of Cu(II), Zn(II), and Pb(II) on the sorbents from aqueous solutions with pH 5.8 was studied.

Organomineral materials combining the complexing properties of the organic ligand with the mechanical and morphological properties of the inorganic matrix are being intensively developed. These materials find expanding application in sorption, solid-phase extraction, and prompt analysis. Sorption immobilization of an organic compound on the silica surface, usually in the presence of a surfactant [1–3], is the simplest procedure for preparing organomineral materials. To determine the best conditions of synthesis and application of these materials, the sorption kinetics, sorption equilibria, and physicochemical and analytical properties of the sorbents should be studied.

In this work we studied sorption modification of silica with Xylenol Orange dye (XO) and sorption of some metal cations on the resulting materials. Since XO forms strong intensely colored complexes with metal cations, we used this compound to modify the silica surface with the aim of preparing new sorbents for solid-state spectrophotometric and prompt visual analysis of the sum of heavy metals.

EXPERIMENTAL

Xylenol Orange [3,3'-bis-*N*,*N*-di(carboxymethyl)-aminomethyl]-*o*-cresol sulfophthalein, H_6L (XO) (Table 1)

(analytically pure grade, Voikov Plant of Chemicals, Moscow) was purified by the procedure in [5]. The purity of distilled water was assessed by its electrical conductivity. The presence of impurity metals in the metal salts was checked by X-ray fluorescence spectroscopy. Acetate buffer was prepared from CH_3COONa (analytically pure grade) and CH_3COOH (chemically pure grade) [6]. The stock XO solutions were prepared by dissolving an accurately weighed portion of the dye in the buffer with pH 1.68 [GOST (State Standard) 8.135–74] and the stock solutions of $Cu(NO_3)_2$ (chemically pure grade), $Zn(NO_3)_2$ (ultrapure grade), and $Pb(NO_3)_2$ (chemically pure grade), by dissolving accurately weighed portions of these salts in an acetate buffer (pH 5.8). The metal concentrations in the initial solutions were determined by titration with EDTA [7]. A 0.01 M EDTA solution was prepared from the reference solution and standardized with metallic bismuth [7]. All working solutions were prepared by dilution of the stock solution with the same buffer.

Table 2. Morphological properties of silica gels

Sample	Specific surface area, S_{sp}, $m^2\ g^{-1}$	Pore volume, V_{pore}, $cm^3\ g^{-1}$
SG I(450)	117 ± 6*	0.87 ± 0.01
SG II(450)	510 ± 12	1.64 ± 0.05
SG II(900)	444 ± 9	1.29 ± 0.02

* Here and hereinafter, the confidence level of the measurements is 95%.

Silica gel SG I prepared from hydrogel of methyl silicate (Sorbi Research and Production Association, registry no. P.05.99/00646) was washed with 0.01 M HCl and water to the negative reaction for chloride ions and dried at 120°C. We also used commercial silica gel L 5/40 (Chemapol, Czech Republic) (SG II). To activate the silica gel surface, SG I was calcined at 450°C for 3 h [SG I(450)], and SG II was calcined at 450°C for 3 h [SG II(450)] and at 900°C for 2 h [SG II(900)]. The specific surface area of the samples was determined by thermal desorption of argon in accordance with GOST 23401–90. The specific pore volume of the sorbents was calculated from the true density which, in turn, was determined pycnometrically [8]. The morphological properties of the samples are summarized in Table 2. We recorded IR spectra of the samples pressed in conventional micropellets. The XO sorption was studied under the static conditions. Flasks containing accurately weighed portions of the sorbents (0.03–0.09 g) were filled with 25–50 ml of 4.0×10^{-5} to 2.8×10^{-4} M XO solutions. The current XO concentration was measured spectrophotometrically by the absorption at 432 nm (pH 1.68).

Modified silica gel (MSG) was separated from the solution by centrifuging, washed with water to the negative reaction for oxalate anions (pH of wash waters is 5.5–5.8), and dried at 105°C for 12 h. To determine the wash-out of XO from MSG, suspensions of accurately weighed portions of the samples (0.1–0.15 g) in 25 ml of hydrochloric acid (pH 1.0–3.0) or acetate buffer (pH 4.0–6.0) were mechanically stirred. The XO concentration in the solutions was determined at regular intervals by the absorption at 432 nm. The XO concentration became constant after stirring for 30–45-min.

Sorption of metal ions on MSGs from aqueous solutions was studied under the static conditions. Preliminary experiments on the determination of the best conditions of sorption of Cu(II), Zn(II), and Pb(II) showed that the sorption equilibrium was attained within 15 min and the optimal pH range for sorption of Cu(II) and Zn(II) and Pb(II) was 5.6–6.0 and 5.3–5.8, respectively. Therefore, the sorption experiments were performed at pH 5.8. Working solutions of the metal salts were placed in flasks containing precisely weighed portions of the samples (0.07–0.08 g). The initial metal concentration ranged from 6 to 300 μM. After the sorption completion, the sorbent was separated from the solution and dried at 105°C for 12 h. The diffuse reflectance spectra of the resulting materials were recorded. The equilibrium metal concentration in the solution was determined by the atomic absorption spectroscopy. The measurements were performed on an AAC-3 spectrophotometer (Carl Zeiss, Jena, Germany) using a conventional lamp with hollow cathode. The nonspecific absorption was compensated with a deuterium lamp. All measurements were performed with acetylene–air flame [9].

All sorption experiments were performed at 20 ± 1°C. The sorbent was separated from the solution by centrifuging at 7000 rpm for 5 min on an MLW centrifuge (Germany). The IR spectra were recorded on a Specord M-80 spectrophotometer (Carl Zeiss, Jena, Germany). The absorption spectra of XO solutions were recorded on a Specord M-40 spectrophotometer (Carl Zeiss, Jena, Germany).

The diffuse reflectance spectra were recorded on a Specord M-40 spectrophotometer with a $R\ 8°/d$ unit. The MgO reflection was used as the reference. The Kubelka–Munk function was calculated from the reflection intensities by the equation

$$F(R) = (1 - R)^2/2R.$$

The sorption kinetics was described in terms of the model of the sorption from a semi-infinite solution [10]. The initial sorption steps are described by the equation

$$c(\tau) = c(0)(1 - 2b\tau^{1/2}), \quad (1)$$

where $c(0)$ is the initial concentration of the adsorbate in the solution and $c(\tau)$ is the concentration of the adsorbate in time τ (s):

$$b = g[\rho D\pi^{-1}(1 + \beta)]^{1/2}.$$

Then

$$D = \frac{b^2\pi}{g^2\rho(1 + \beta)}, \quad (2)$$

where g is the geometrical factor [11]; ρ, porosity coefficient; β, constant of the sorption equilibrium; and

D, diffusion coefficient of the adsorbate in the near-surface layer.

The dye adsorption was determined from the difference between its initial n_a (mol) and equilibrium n_s (mol) amounts in the solution:

$$N_f = (n_a - n_s)/m,$$

where N_f is the adsorption (mol g^{-1}) and m is the sorbent weight (g).

The sorption isotherms were described by the Langmuir equation[1]

$$N_f = t\frac{\beta[X]}{1 + \beta[X]}, \quad (3)$$

where t is the concentration of the sorption sites (mol g^{-1}) and [X] is the equilibrium concentration of the adsorbate (XO or metal ion) in the solution (M).

The Langmuir isotherm can be readily transformed into the linear equation (4)

$$\frac{1}{K} = \frac{1}{N_f} = \frac{1}{\beta t} + \frac{[X]}{t}, \quad (4)$$

where K is the distribution coefficient (l g^{-1}).

Both the equilibrium constant β and the concentration of the sorption sites t can be determined by the mathematical treatment of the K^{-1} vs [X] dependence.

The estimation of these parameters by the linearized Langmuir equation (4) violates two principles of the least-squares (LS) method: (a) the lack of correlation of the independent variables and responses and (b) the absence of the random errors of the independent variables.

Estimation by the nonlinear weighted LS method is more precise. The parameters of the sorption equilibria were estimated by this method from the composition–property dependences. The criterial function

$$\chi^2_{exp} = \sum_{k=1}^{n} w_k \xi_k^2,$$

where $\xi = [X]_k^{calc} - [X]_k^{exp}$ and w_k is the statistical weight of the kth measurement, was minimized by the CLINP 2.1 program [10].

The statistical weights were set as $w_k = 1/\sigma_k^2$, where

[1] This equation is valid for ideal monolayer adsorption on the energetically uniform surface.

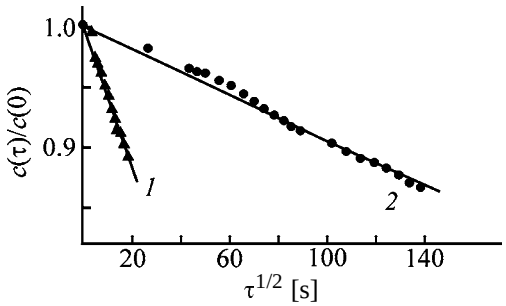

Fig. 1. Initial sections of the $c(\tau)/c(0)$ vs. $\tau^{1/2}$ dependence for adsorption of XO on (*1*) SG I(450) and (*2*) SG II(900).

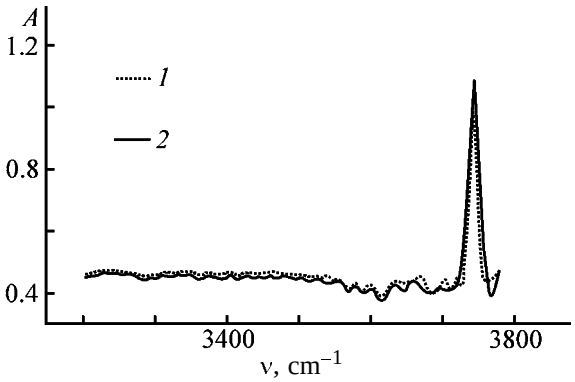

Fig. 2. IR spectra of (*1*) SG II(900) and (*2*) SG II(450). (*A*) Absorption and (ν) wave number.

$\sigma_k = [X]_k^{exp}\sigma_r$, σ_k is the random error of $[X]_k^{exp}$, σ_r is the relative error taken as 0.05.

Coefficient b was determined by linear LS treatment of the initial sections of the dependences plotted in the coordinates of Eq. (1) (Fig. 1). The diffusion coefficients of XO in the near-surface layer of SG I(450) and SG II(900), calculated by Eq. (2), were $(6 \pm 2) \times 10^{-9}$ and $(1.1 \pm 0.7) \times 10^{-9}$ $m^2\ s^{-1}$, respectively. The diffusion coefficients of XO are less by several orders of magnitude than those of H^+ and Cu^{2+} in the near-surface layer of slilicas containing amino groups [11, 12]. Clearly, the mobility of large XO molecules in both solution and sorbent pores is low. As determined by IR spectroscopy, physically sorbed water molecules are almost completely removed (the absence of broad band at 3450–3680 cm^{-1}) and the strong band of stretching vibrations of free silanol groups appears at 3742 cm^{-1} (Fig. 2) after activation of the surface of SG I and SG II at 450°C for 3 h [13]. However, the XO sorption on SG II is so low (~10^{-7} mol g^{-1}) that the sample becomes only light yellow after the sorption. Activation of SG II at 900°C increases its sorption capacity for XO to 2.8×10^{-5} mol g^{-1}. The modified samples are light orange. Activation at higher temperatures decreases the specific surface area and the pore volume. This is probably

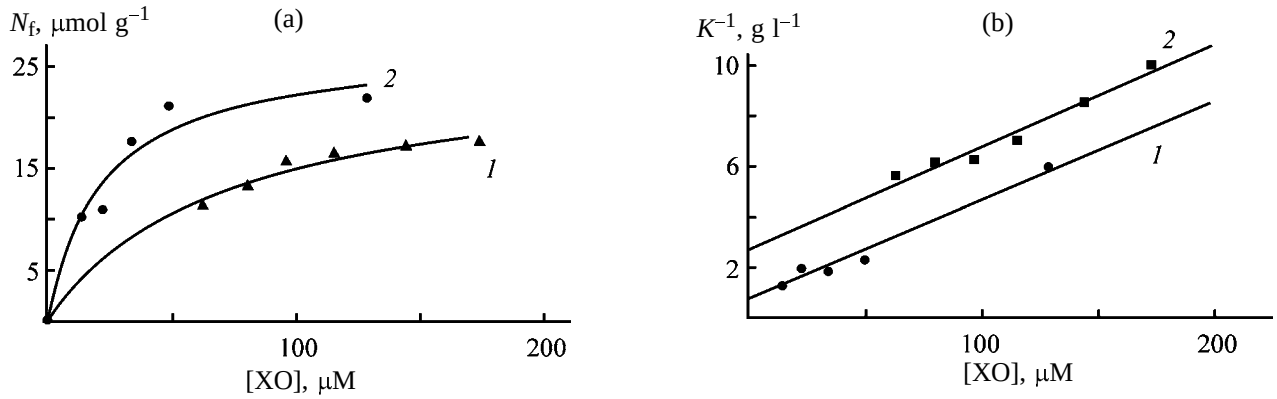

Fig. 3. (a) Sorption isotherms and (b) linearized sorption isotherms of XO on the surface of (*1*) SG II(900) and (*2*) SG I(450). (N_f) Adsorption, (K) distribution coefficient, and ([XO]) equilibrium XO concentration in the solution.

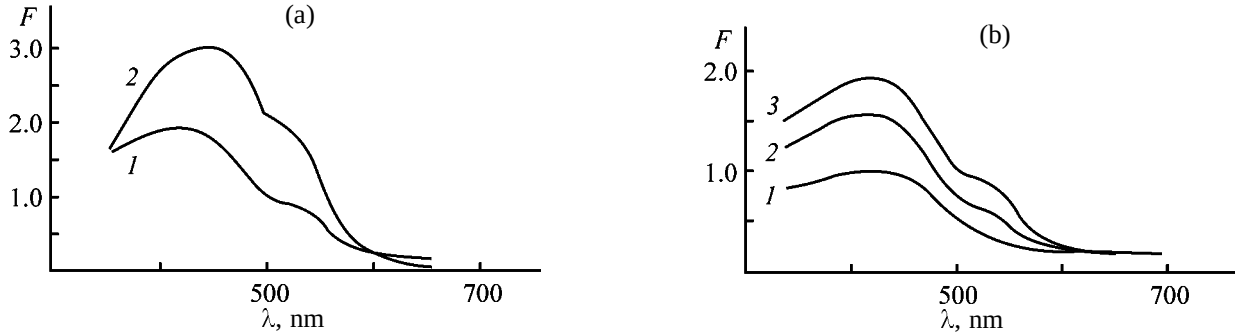

Fig. 4. Absorption spectra of (a) (*1*) MSG I(450) and (*2*) MSG II(900) and (b) MSG I(450). XO concentration (mol g^{-1}): (*1*) 1.3×10^{-5}, (*2*) 1.5×10^{-5}, and (*3*) 1.7×10^{-5}. (F) Kubelka–Munk function and (λ) wavelength; the same for Fig. 6.

due to enlargement of pores by dehydroxylation of the surface. As a result, the XO diffusion is simplified. It should be noted that the structure of silica surface subjected to high-temperature dehydroxylation and subsequent rehydroxylation differs from that of both initial and thermally dehydroxylated surface [14]. Although the intensity of the band at 3742 cm^{-1} decreases with increasing the activation temperature because of partial dehydroxylation of the surface, the concentration of the surface silanol groups remains high.

Table 3. Parameters of equilibrium sorption of XO

Sample	$t \times 10^{-5}$, mol g^{-1}	log β	r*	χ^2_{exp} ($\chi^2_{f=n-1}$)**
Eq. (4), linear LS treatment				
SG I(450)	2.5 ± 0.2	4.2 ± 0.2	0.97	–

** 5% distribution point of χ^2 with $f = n - 1$ degrees of freedom.

The results of the linear LS treatment of the linearized sorption isotherms [Eq. (3)] and those of weighted nonlinear LS treatment of the isotherms of XO sorption on SG I(450) and SG II(900) (Fig. 3) are presented in Table 3. The fact that K^{-1} vs. [XO] dependence is almost linear and the results presented in Table 3 suggest that XO sorption on the surface of both samples is ideal, the lateral interactions are absent, and the surface sorption centers are energetically uniform.

We studied wash-out of XO from the modified SGs. In the pH range 1.0–6.0, no more than 10% of the dye is washed out depending on its concentration in the sample. Hence, unlike the previous opinion [1, 3], materials highly stable to wash-out of the organic modifier can be obtained without introduction of surfactants.

The Kubelka–Munk functions for the modified silica gels with different XO concentrations are shown in Fig. 4. The single broad absorption band at 415 nm

is observed at the XO concentration lower than 1.3×10^{-5} mol g^{-1}. Clearly, in this case the dye is sorbed in the form of H_3L^{3-} prevailing in the solution at pH 4.5–6.5. The absorption maximum of H_3L^{3-} and H_4L^{2-} species in aqueous solution is observed at 432–435 nm [5]. As the surface concentration of XO increases, a shoulder appears at 525–540 nm. Resolution of the spectra into the Gaussian components shows the presence of two bands. The first band is located at 405–415 nm in the spectrum of MSG I(450) and at 425–430 nm in the spectrum of MSG II(900). The second band in the spectra of both materials has a maximum at 520–525 nm. This band is tentatively assigned to H_4L^{2-} which absorbs in aqueous solutions at 578–580 nm [5]. The strong shift of the band to the short waves is due to formation of hydrogen bonds with surface groups of the silica gel. The appearance of the H_4L^{2-} band suggests partial neutralization of the silanol groups in the course of the dye sorption. The intensity of this band is maximal in the spectrum of SG II(900) in which the XO concentration is the highest. The fact that spectra of the sorbents prepared from silica gels with different morphological properties and activated at different temperatures are similar (Fig. 4) suggests similar mechanism of XO immobilization.

Since XO forms stable complexes with a number of transition metals, it is widely used in analytical chemistry [7]. We studied sorption of metal ions on MSG II(900). The XO concentration in this sorbent is the highest (2.8×10^{-5} mol g^{-1}). The sorption isotherms of Cu(II), Zn(II), and Pb(II) are shown in Fig. 5. The results of mathematical treatment of the sorption equilibrium are presented in Table 4. The sorption of metal ions is described well by the Langmuir equation, i.e., it is ideal as in the case of XO. The color of the sorbent brought into the contact with solutions of the metal salts changes within 3–5 min to purple-red. After the sorption, a strong band at ~600 nm appears in the spectrum (Fig. 6). The concentration of metal ions is stabilized in 10–15 min, i.e., the sorption kinetics is fast. Resolution of the absorption spectra into the Gaussian components gives two bands at 425–430 and 576–582 nm. As the metal sorption increases, the first band is weakened and the absorption at 576–582 nm increases (Fig. 6). This is probably due to a decrease in the concentration of free dye molecules and an increase in the concentration of the metal complexes on the surface. In aqueous XO solutions containing Cu(II), Zn(II), or Pb(II) cations (pH 5.0–7.0), the MH_3L^- complex prevails [15, 16]. These complexes absorb at 580, 570, and 580 nm, respectively.

Table 4. Parameters of equilibrium complexation, obtained by mathematical modeling

Metal ion	$t \times 10^{-6}$, mol g^{-1}	$\log \beta$	r	χ^2_{exp} ($\chi^2_{f=n-1}$)
Linear LS treatment, Eq. (4)				
Cu(II)	7.1 ± 0.6	4.36 ± 1.4	0.99	–
Zn(II)	3.7 ± 0.7	4.71 ± 1.4	0.99	–
Pb(II)	0.50 ± 0.03	4.7 ± 1.2	0.97	–
Weighted nonlinear LS treatment, Eq. (3)				
Cu(II)	7.1 ± 0.6	4.42 ± 0.20	–	3.8 (12.6)
Zn(II)	3.7 ± 0.7	4.65 ± 0.20	–	4.3 (12.6)
Pb(II)	0.50 ± 0.03	4.72 ± 0.18	–	4.0 (12.6)

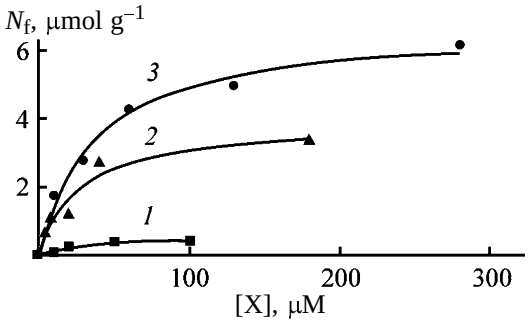

Fig. 5. Sorption isotherms of (*1*) Pb(II), (*2*) Zn(II), and (*3*) Cu(II) on SG II(900). (N_f) Metal adsorption and ([X]) equilibrium concentration of the metal ion in the solution.

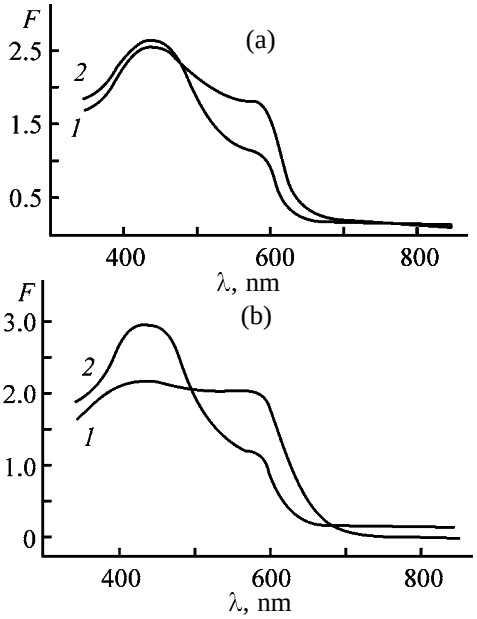

Fig. 6. Absorption spectra of MSG II(900) containing (a) Zn(II), and (b) Cu(II) and Pb(II). Metal concentration (mol g^{-1}): (a) (*1*) 3.4×10^{-6} and (*2*) 1.2×10^{-6}; (b) (*1*) 6.2×10^{-6} and (*2*) 4.2×10^{-7}.

High affinity of the sorbents for Cu(II), Zn(II), and Pb(II) ions, good sorption kinetics, and contrast color change in formation of the surface metal complexes make these sorbents promising for visual prompt analysis.

ACKNOWLEDGMENTS

The authors are grateful to N.V. Borisenko (Institute of Surface Chemistry, National Academy of Science of Ukraine) for measuring specific surface area of the silica gel.

CONCLUSIONS

(1) New organomineral materials were prepared by sorption immobilization of Xylenol Orange dye on the surface of two silica gel samples activated at different temperatures and having different morphological properties. No more than 10% of the dye is washed out from the sorbents at pH 1.0 – 6.0 under the static conditions.

(2) The initial steps of Xylenol Orange sorption on the silica gel surface can be described in terms of the sorption from a semi-infinite solution; the maximal diffusion coefficient of Xylenol Orange in the near-surface layer is $(6 \pm 2) \times 10^{-9}$ $m^2 s^{-1}$.

(3) The modified silica gel has high affinity for Cu(II), Zn(II), and Pb(II) in aqueous solutions. The complexes of these ions with immobilized dye absorb in the range 576–582 nm.

(4) The sorption equilibria of Xylenol Orange on silica gel and those of the metal cations on the modified silica gel surface are described well by the Langmuir equation, which suggests the ideal monolayer sorption on the energetically uniform surface.

SORPTION AND ION-EXCHANGE PROCESSES

Extraction of Aromatic Sulfonic Acids in the Presence of a Surfactant

Ya. I. Korenman, A. S. Gubin, and P. T. Sukhanov

Voronezh State Technological Academy, Voronezh, Russia

Received July 19, 2004

Abstract—Extraction of phenol- and naphtholsulfonic acids from aqueous salt solutions in the presence of a surfactant, *N*-cetylpyridinium chloride, with hexane, ethylbenzene, and acetone–diacetone alcohol is studied.

Determination of carcinogenic organic substances, particularly, naphthols, phenol, and their derivatives is of a great significance in analysis of waters. Occurring in trace amounts, they cannot be detected by the existing methods. Determination of trace amounts of aromatic compounds involves preconcentration, for example, by liquid extraction.

The most efficient extractants for naphthol- and phenolsulfonic acids are hydrophilic solvents and their binary mixtures; in the presence of a salting-out agent they provide practically quantitative (95%) recovery [1, 2].

To increase the efficiency of extraction of naphthol- and phenolsulfonic acids, we suggested to use hydrophobic (hexane, ethylbenzene) and mixed hydrophilic (acetone–diacetone alcohol) solvents in the presence of a cationic surfactant, *N*-cetylpyridinium chloride, at 37°C.

In this work we studied the extraction of napthol-sulfonic [1-naphthol-4-sulfonic acid (1N4SA), 1-naphthol-5-sulfonic acid (1N5SA), 2-naphthol-6-sulfonic acid (2N6SA), 1-naphthol-3,8-disulfonic acid (1N38SA), and 2-naphthol-6,8-disulfonic acid (2N68SA)], phenolsulfonic [phenol-2-sulfonic acid (Ph2SA), phenol-4-sulfonic acid (Ph4SA), phenol-2,4-disulfonic acid (Ph24SA), phenol-2,4,6-trisulfonic acid (Ph246SA), 2-methylphenol-5-sulfonic acid (2MPh5SA), 4-methylphenol-5-sulfonic acid (4MPh5SA), and 2-ethylphenol-4-sulfonic acid (2EPh4SA)], aminophenol- and naphtholsulfonic [1-amino-2-naphthol-4-sulfonic acid (1A2N4SA), 2-aminophenol-4-sulfonic acid (2APh4SA), 2-amino-4-chlorophenol-6-sulfonic acid (2A4ClPh6SA), 1-amino-8-naphthol-2,4-disulfonic acid (1A8N24SA), 1-amino-8-naphthol-3,6-disulfonic acid (1A8N36SA), and 1-amino-8-naphthol-4,6-disulfonic acid (1A8N46SA)], and carboxy-substituted phenolsulfonic acids [sulfosalicylic acid (SSA) and 5-aminosulfosalicylic acid (5ASSA)].

EXPERIMENTAL

Naphthol- and phenolsulfonic acids in aqueous solutions were determined photometrically: naphtholsulfonic acids (except for 1N38SA and 1A2N4SA) by the reaction with diazotized sulfanilic acid; phenolsulfonic acids, with the same reagent in the presence of Na_2CO_3; 1N38SA, with 4-aminoantipyrine in the ammonia buffer solution in the presence of an oxidant, ammonium persulfate [3]; 1A2N4SA, by diazotization in the presence of Cu^{2+} [4, 5]; and SSA and 5ASSA, by the reaction with $FeCl_3$. The calibration curves were linear over the concentration ranges (M): $10^{-3.4}$–$10^{-6.7}$ for 1N38SA, $10^{-3.0}$–$10^{-5.5}$ for 1A2N4SA, and $10^{-2.8}$–$10^{-5.8}$ for other acids. The optical density was measured on a KFK-2MP photoelectric colorimeter.

To determine the distribution coefficients, to 10 ml of 10^{-4} M sulfonic acid solution we added *N*-cetylpyridinium chloride to obtain a $(1.0-4.0)\times10^{-4}$ M concentration, ammonium sulfate to obtain a saturated solution, and 1 ml of the acetone–diacetone alcohol mixture or of a hydrophobic solvent, hexane or ethylbenzene. Extraction was carried out with a mixture of the hydrophilic solvents at 20–37°C or with the hydrophobic solvents at 20°C; pH was varied from 0 to 12 by adding HCl or aqueous ammonia solutions. After extraction on a vibroshaker for 7–10 min, the extract was separated, and the optical density of the aqueous phase was measured at 400 nm (except for 1N38SA, SSA, and 5ASSA). The path length was 0.5 and 5 cm for the samples before and after extraction, respectively. In the case of 1N38SA, the measure-

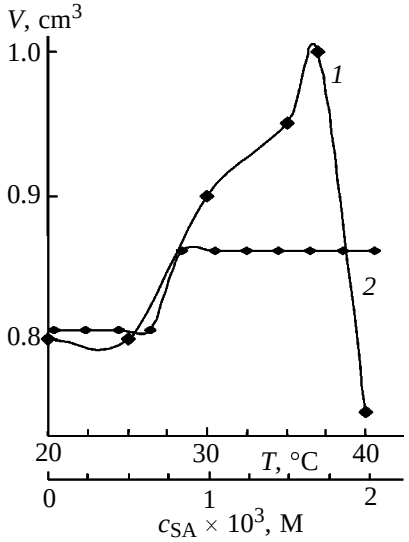

Fig. 1. Effects of (*1*) surfactant concentration c_{SA} and (*2*) temperature T on the efficiency of separation of the organic phase V in the system acetone–diacetone alcohol.

ments were performed at 540 nm, and with SSA and 5ASSA, at 490 nm.

The distribution coefficients D were estimated by Eq. (1):

$$D = [(A - A_{eq})/A_{eq}](V_w/V_o), \quad (1)$$

where A and A_{eq} are the optical densities of the solutions before and after extraction; and V_o and V_w, equilibrium volumes of the organic and aqueous phases (ml).

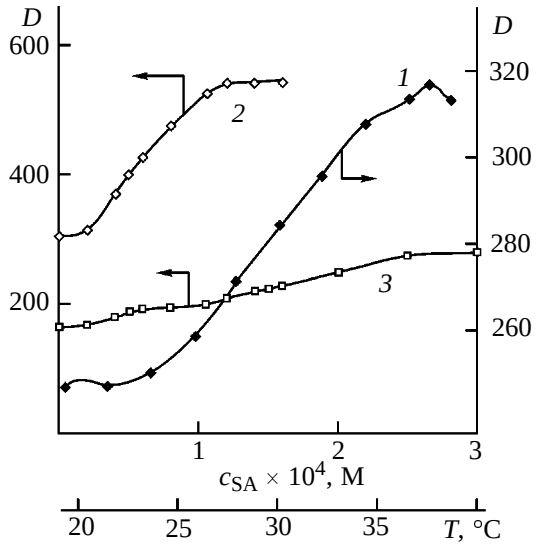

Fig. 2. Distribution coefficient D of naphtholsulfonic acids in the acetone–diacetone alcohol system as a function of the temperature T (*1*) in the absence and (*2, 3*) in the presence of the surfactant at 37°C: (*1, 2*) 1-naphthol-4-sulfonic acid and (*3*) 1-naphthol-3,8-disulfonic acid. pH: (*2*) 4 and (*3*) 7.

We studied extraction in the presence of *N*-cetylpyridinium chloride (NCPC) of twenty sulfonic acids with acetone–diacetone alcohol mixtures and of four sulfonic acids, with hexane and ethylbenzene.

In extraction with the hydrophilic extractants, the surfactant does not significantly influence the completeness of separation of the organic phase (Fig. 1). In the systems with hydrophobic solvents, at an NCPC concentration above $10^{-3.5}$ M, emulsions were formed, which could not be separated by centrifugation.

It is known that some hydrophilic solvents can form an equilibrium phase at a temperature increased to 35–40°C [3]. Acetone forms an individual phase at 37°C (Fig. 1). In extraction with acetone–diacetone alcohol mixtures, this allows an increase in the distribution coefficient of, for example, 1N4SA from 250 at 20°C to 310 at 37°C (Fig. 2).

Combination of these two factors, temperature and the presence of a surfactant in the aqueous solution, produces considerable increase in the distribution coefficient.

The effect of the number of the sulfonate group in a sulfonic acid on the distribution coefficient in the presence of NCPC suggests the formation of ion associates (Figs. 2, 3): the efficiency of extraction of monosulfonic acids is maximal at an NCPC concentration of $(1.2–1.5) \times 10^{-4}$ M; that of disulfonic acids, at 2.5×10^{-4} M; and that of trisulfonic acids and acids containing other ionic groups, at up to 4.0×10^{-4} M.

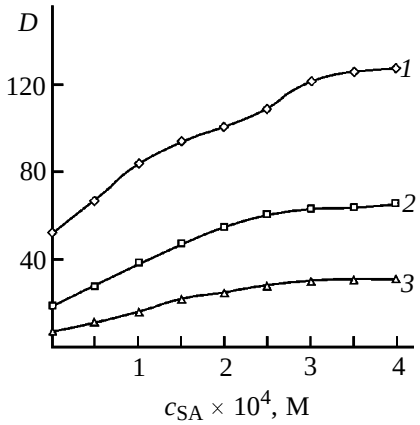

Fig. 3. Distribution coefficient D of (*1*) 5-aminosulfosalicylic, (*2*) sulfosalicylic, and (*3*) phenol-2,4,6-trisulfonic acids as a function of the surfactant concentration c_{SA} in extraction with acetone–diacetone alcohol mixtures.

In routine use, in extraction of ion associates, hydrophobic solvents (benzene, toluene, and, more rarely, hexane) are used in the presence of associate-forming agents such as positively or negatively charged dye species [6]. In this work, we used NCPC as an associate-forming agent.

In the presence of NCPC, the distribution coefficients of sulfonic acids between a hydrophobic solvent and water increased by a factor of 15 and more as compared to extraction in the absence of the surfactant (Table 1). To interpret the experimental results, we suggest the following extraction mechanism. A nonpolar hydrocarbon radical (hydrophobic fragment) of the surfactant, displaced from the polar phase (water), is oriented in the direction of the less polar phase (hexane or ethylbenzene). The extraction proceeds through absorption of ion associates on the surface of the hydrophobic solvent by van der Waals interaction.

In extraction with the hydrophilic solvents in the presence of NCPC, the organic phase is enriched with water. The extraction proceeds primarily through H bonding between the solvent and a sulfonic acid. The increased distribution coefficients are caused by higher hydrophobicity of the ion associates as compared to the sulfonic acids, which favors their transfer to the organic phase.

We studied the effect of pH on the extraction of sulfonic acids in the presence of NCPC (Figs. 4, 5). Based on the results obtained, the sulfonic acids studied can be divided in three groups as follows.

(1) Naphtholmono- and disulfonic acids; phenolmono-, di-, and trisulfonic acids; and alkylphenolsulfonic acids. The distribution coefficients of these acids remain unchanged over a wide pH range. Increasing pH from 0 to 8 has practically no effect on the degree of ionization of the hydroxy and sulfonate groups. In the pH range 8–11, the OH groups ionize, and the distribution coefficients of the sulfonic acids gradually decrease. At pH >11, D abruptly decreases, which is a resultant of two factors, practically full ionization of the OH groups and impossibility of formation of ion associates because of decreased solubility of NCPC in strongly alkaline solutions.

(2) Aminosulfonic acids. The highest distribution coefficients are obtained in neutral and weakly alkaline solutions (pH 7–8) (Figs. 4, 5). In acidic solutions, the NH_2 group of the acid is protonated and, therefore, it cannot be involved in H bonding. As pH increases from 1 to 7, the distribution coefficients strongly increase, reaching a maximum at pH 7–8,

which is caused by deprotonation of the NH_2 group, making H bonding with the extractant possible.

The distribution coefficients of the aminosulfonic acids remain practically constant as pH increases to 11. In this case, the NH_2 group forms H bonds, and the ionized OH group is involved in formation of an ion associate with NCPC.

(3) Sulfosalicylic and 5-aminosulfosalicylic acids. These acids are efficiently extracted in a narrow pH range. At pH 3–4, the sulfonate groups are fully ionized, and the carboxy groups are partially ionized, so that ion associates with NCPC are formed, and the distribution coefficients increase. The maximal D values are observed at pH 7. In this case, a combined extraction mechanism is realized: the ionized

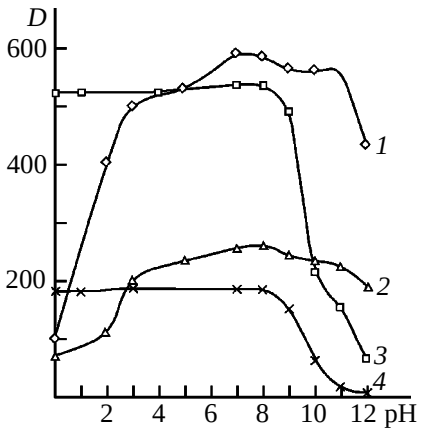

Fig. 4. Distribution coefficients of naphtholsulfonic acids as functions of pH of the aqueous phase in extraction with the acetone–diacetone alcohol mixture: (*1*) aminonaphtholmonosulfonic acid, (*2*) naphtholmonosulfonic acid, (*3*) aminonaphtholdisulfonic acid, and (*4*) naphtholdisulfonic acid. $C_{SA} \times 10^4$ (M): (*1*, *2*) 1.5 and (*3*, *4*) 2.5.

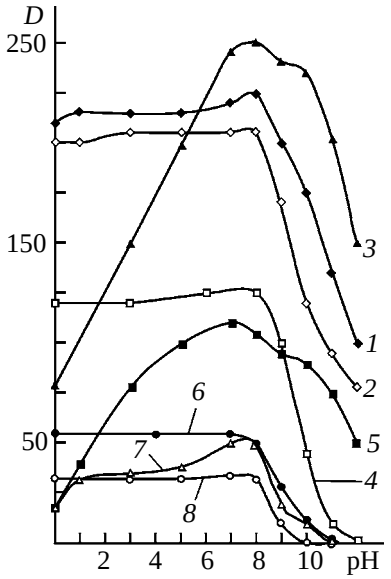
carboxy groups form ion associates with NCPC, and the nonionized OH and (or) NH_2 groups form H bonds with the extractant.

The equilibria in 5ASSA solutions can be described by the scheme shown below.

Table 2 shows the distribution coefficients of the sulfonic acids in extraction with the acetone–diacetone alcohol mixture and also the factors of their increase on passing from 20 to 37°C and in the presence of the cationic surfactant.



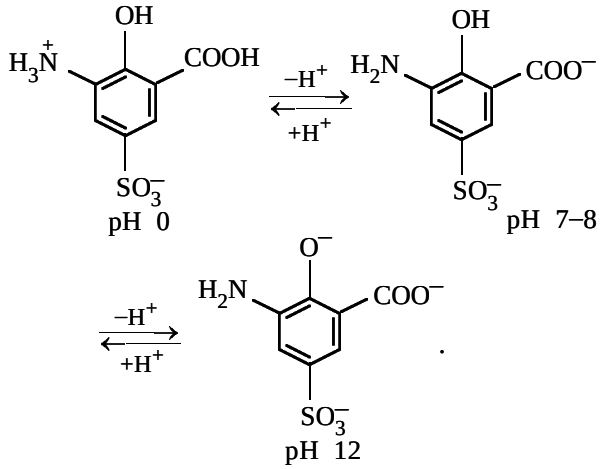


Fig. 5. Distribution coefficients *D* of phenolsulfonic acids as functions of pH of the aqueous phase in extraction with acetone–diacetone alcohol mixtures (37°C): (*1*) ethylphenolsulfonic acid, (*2*) cresolsulfonic acid, (*3*) 2-aminophenol-4-sulfonic acid, (*4*) phenolsulfonic acid, (*5*) 5-aminosulfosalicylic acid, (*6*) phenol-2,4-disulfonic acid, (*7*) sulfosalicylic acid, and (*8*) phenol-2,4,6-trisulfonic acid. $C_{SA} \times 10^4$ (M): (*1–4*) 1.5, (*5, 7, 8*) 4, and (*6*) 2.5.

Simultaneous increase in the temperature and addition of CNPC to the aqueous phase result in increasing *D* of the naphtholsulfonic acids by a factor of 2–3. The increase factor increases in the order aminonaphtholsulfonic acids < aminonaphtholdisulfonic acids < naphtholmonosulfonic acids = aminosulfosalicylic acid < naphtholdisulfonic acids < phenolsulfonic acid < sulfosalicylic acid. This order corresponds to the hydrophilicity order in the series of the sulfonic acids studied.

CONCLUSION

Extraction of 20 aromatic sulfonic acids from saturated ammonium sulfate solutions in the presence of *N*-cetylpyridinium chloride with hydrophobic solvents (hexane, ethylbenzene) and acetone–diacetone mixtures at 20–37°C is studied. Effects of the surfactant concentration, pH of the aqueous phase, and nature of the acids on the characteristics of the extraction systems are analyzed. Increasing temperature to 37°C and addition of the surfactant significantly increase

the distribution coefficients of strongly hydrated aromatic sulfonic acids.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electroless Deposition of Nickel Coatings with High Phosphorus Content

V. F. Makarov, Yu. V. Prusov, and I. O. Lebedeva

Nizhni Novgorod State Technical University, Nizhni Novgorod, Russia

Received March 22, 2004

Abstract—Acid hypophosphite solution for electroless deposition of a Ni–P alloy containing up to 12 wt % phosphorus was developed and recommended for practical use. The possibility of repeated use of the solution developed was examined.

Nickel–phosphorus coatings formed by electroless deposition exhibit important functional and high protective properties. Among them, coatings deposited from acid solutions have the highest corrosion resistance [1], owing to increased phosphorus content and considerably lower porosity [2]. The melting point of the alloy containing 7.9 wt % P is 890°C and that of pure Ni, 1455°C, i.e., it decreases with increasing phosphorus content in the alloy [3]. This result is important for welding, soldering, and other operations with nickel–phosphorus coatings, which are widely used in electronic engineering [3]. The freshly deposited nickel–phosphorus alloys containing more than 8 wt % P are virtually resistant to magnetization [4]. The single use of a nickel-plating solution, with discharge of a large amount of hazardous and often rather valuable substances, is inadmissible from both the environmental and economical standpoints. Therefore, the subject of this study is rather urgent.

The coatings were deposited onto Cr18Ni10Ti steel plates in a temperature-controlled cell with a load of 1 $dm^2\ l^{-1}$ at 90°C for 1 h. Prior to coating deposition, the samples were subjected to the standard pretreatment. The deposition rate was calculated from the gain in the sample mass. The P content in the coatings was determined analytically [5]. The solutions were analyzed for the content of phosphite and hypophosphite ions and for the nickel content by the methods described in [6]. The pH value of nickel-plating solutions was measured with a pH-121 ionometer. All solutions were prepared from chemically pure and analytically pure grade chemicals. The automated correction was performed in a lab model of an AkNAR automated electroless nickel-plating installation [7].

The hypophosphite nickel-plating solutions used today contain organic ligands and buffer additives in relatively high concentrations [8], which increases the cost of these solutions and makes them more environmentally hazardous. Therefore, in development of a hypophosphite solution, attempts were made to avoid, as far as possible, the use of various organic compounds. The starting solution contained (g l^{-1}) $NiSO_4$ 20–30, $(NH_4)_2SO_4$ 20–30, NaH_2PO_2 20–30, and $NaNO_2$ (stabilizer) 0.02–0.03. The temperature was 80–85°C. The required pH of the solution was adjusted with 30% ammonia.

The P content in the coatings deposited from such solution varied from 18.4 to 14.5 wt %, depending on solution pH (Fig. 1). However, the deposition rate of the coatings was inadmissibly low (2.3–3.4 μm h^{-1} depending on solution pH). This is probably due to the fact that the buffer effect exerted by the above solution lies at pH ~ 3.4, which can be judged from the solution pH after coating deposition (Fig. 1). As known [9], at such pH values the coating deposition

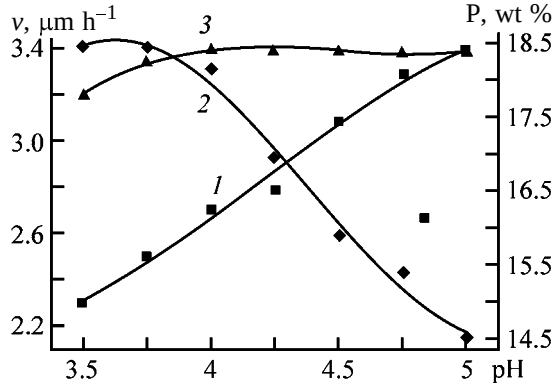

Fig. 1. Influence of pH of the initial electroless nickel-plating solution on the (*1*) coating deposition rate *v*, (*2*) P content in the coating, and (*3*) solution pH after the coating deposition.

1070-4272/05/7801-0082 © 2005 Pleiades Publishing, Inc.

virtually does not occur. Furthermore, in the course of the deposition, sparingly soluble nickel phosphite precipitated from the solution, making it turbid.

To avoid the above drawbacks, a part of the solution was modified. For example, to shift the region where the solution exerts the buffer effect toward necessary pH values and to increase the buffer capacity of the solution, the $(NH_4)_2SO_4$ concentration was increased to 50 g l^{-1} and acetic acid (20 ml l^{-1}) was added into the solution. Moreover, this prevents the nickel phosphite precipitation owing to its binding into the ammonia complex. The pH of the given solution was adjusted by varying NH_4OH concentration. In the pH range studied here (4.8–5.6), quality lustrous coatings containing 12.5–8.5 wt % P were deposited from the solution at a rate of 12–23 μm h^{-1} (Fig. 2). Both before and after the coating deposition, the solution was always stable and transparent.

Thus, the phosphorus content in the coating, and, consequently, its functional properties can be controlled using the dependences shown in Fig. 2. It was established that the pH range 5.0–5.2 (12–15 ml l^{-1} NH_4OH) is optimal. In this case, the rate of the coating deposition and the P content are fairly high, 15–18 μm h^{-1} and 12–11 wt %, respectively.

The suggested nickel-plating solution was used repeatedly under laboratory conditions. The solution was corrected nine times (ten deposition runs). The content of the main solution components (nickel salt and sodium hypophosphite) was adjusted according to the results of the analysis. The solution pH was adjusted to the initial value with 25% NH_4OH. The results are given in Table 1.

The results obtained made it possible to calculate the average consumption of the main components of a nickel-plating solution in one deposition run. In calculations, allowance was made for the consumption of components for coating deposition, their entrainment by parts, and evaporation. The component consumption in one deposition run was the following (g l^{-1}): $NiSO_4 \cdot 7H_2O$ 5.5, $(NH_4)_2SO_4$ 0.05, $NaH_2PO_2 \cdot H_2O$ 7.0, and $NaNO_2$ 0.015; CH_3COOH 1.0 and NH_4OH 4.0 ml l^{-1}. These values served as basis for the development of correcting solutions.

In an AKhNAR installation, the pH of the coating solution was adjusted automatically by adding equal portions of correcting solutions. Therefore, the ratio of the component concentrations in the correcting solutions must correspond to the given condition and their values must be reasonably large to prevent dilution of the coating solution. Moreover, the composition of the correcting solutions must ensure their prolonged stability. Taking into account these facts, we tested the correcting solutions containing $NiSO_4 \cdot 7H_2O$ 550 g l^{-1}, (solution no. 1); $NaH_2PO_2 \cdot H_2O$ 700 g l^{-1} and $NaNO_2$ 1.5 g l^{-1} (solution no. 2); $(NH_4)_2SO_4$ 5.0 g l^{-1}, NH_4OH 400 ml l^{-1}, and CH_3COOH 100.0 ml l^{-1} (solution no. 3).

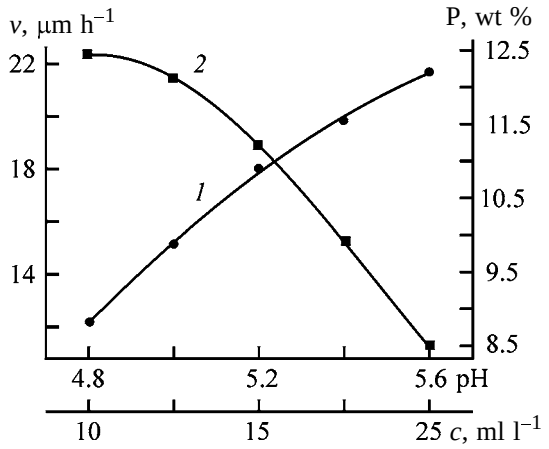

Fig. 2. Influence of pH of the modified electroless nickel-plating solution and NH_4OH concentration *c* on the (*1*) deposition rate *v* and (*2*) phosphorus content in the coating.

These solutions were tested for the correction of the developed nickel-plating solution in an automated AKhNAR installation. The results are given in Table 2.

The solution was stable and transparent over the entire working time (ten deposition runs). The deposited coatings were smooth, lustrous, and strongly adherent to the support. The deposition rate and the P content in the coatings varied within 15–18 μm h^{-1} and 12–14 wt %, respectively.

Table 1. Results of repeated use of electroless nickel-plating solution. pH of the solution before loading 5.0

Run no.	Solution pH after loading	Coating thickness, μm	P content, %
1	4.95	15.5	11.8
2	4.9	16.8	12.7
3	4.95	13.7	12.7
4	4.9	14.7	12.7
5	4.7	13.8	13.7
6	4.85	15.7	13.5
7	4.9	15.2	12.8
8	4.8	16.3	12.8
9	4.9	14.4	12.7
10	4.9	15.6	12.8

Table 2. Results of repeated use of electroless nickel-plating solution in automated mode

Run no.	Solution pH		Coating thickness, μm	P content, %
	before loading	after loading		
1	5.0	4.9	18.1	–
2	5.0	4.9	14.9	11.9
3	4.95	4.85	14.6	–
4	5.0	4.9	17.1	–
5	5.05	4.95	16.1	–
6	5.05	4.9	14.7	12.7
7	5.1	4.95	14.9	–
8	5.15	5.05	15.3	–
9	5.1	5.05	14.9	12.3
10	5.15	5	15	–

Manual correction of the suggested solutions is also possible. This involves addition of solution no. 3 after each deposition run to adjust pH of the coating solution, followed by addition of the same volumes of solution nos. 1 and 2 into the coating solution.

CONCLUSION

A process for electroless deposition of nickel–phosphorus coatings with a high phopshorus content was developed. The nickel-plating solution containis (g l^{-1}) $NiSO_4 \cdot 7H_2O$ 20, $NaH_2PO_2 \cdot H_2O$ 25, $(NH_4)_2SO_4$ 50, $NaNO_2$ 0.03; CH_3COOH 20 ml l^{-1}; NH_4OH 12–15 ml l^{-1}; pH 5.0–5.2. It withstands at least ten deposition runs with intermediate corrections in automated or manual mode.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Kinetics and Mechanism of Reactions Occurring in Electrodeposition of Silver from Thiosulfate Solutions

N. A. Shvab, I. A. Gur'yanova, and A. A. Omel'chuk

Vernadsky Institute of General and Inorganic Chemistry, Ukrainian National Academy of Sciences, Kiev, Ukraine

Received June 23, 2004

Abstract—The kinetics and mechanism of processes occurring in reduction of silver thiosulfate complexes on stationary and rotating disc electrodes and on fluidized glass-bead electrode were studied voltammetrically.

Owing to depletion of natural resources of nonferrous and noble metals, their recovery from various wastes acquires growing importance. Utilization of production waste is necessary not only from the standpoint of saving raw materials but also from the environmental standpoint. Among wastes contaminating the environment are spent thiosulfate fixing solutions from treatment of X-ray films and photographic materials used in printing industry. These solutions contain a considerable amount of silver (to 9–10 g l^{-1}) and sulfur compounds (up to 250 g l^{-1}). Only in the United States, up to 1/3 of the total industrial consumption of silver is spent for preparation of photographic materials [1], with approximately 1000 t of silver passing annually to fixing solutions. The spent fixing solutions, even those free of silver, are environmentally hazardous, since in water reservoirs they decompose with the release of toxic sulfur compounds.

Silver is present in spent fixing solutions mainly in the form of a complex compound $Na_3Ag(S_2O_3)_2$, whose instability constant is $K = 3.5 \times 10^{-14}$ [2]. The standard potential of the silver electroreduction from this complex is 0.017 V [3].

Various chemical and electrochemical methods of silver recovery from spent fixing solutions are known [1, 4–8]. Nevertheless, silver recovery from fixing solution has not received wide acceptance. The traditional electrolysis methods are suitable for recovery of pure silver only at very low current densities, hardly acceptable for commercial processes. Silver sulfide, which is reduced to silver with high specific consumption of chemicals and electric power, is deposited on the cathode at higher current densities. In this case, the electrochemical processing of silver-containing thiosulfate solutions is, in essence, a combination of the electrochemical and electroless methods. Also, the electroless methods do not allow recovery of pure silver in one stage and are labor-consuming.

The lack of data on the features of the cathodic reduction of silver thiosulfate complexes does not allow purposeful control of this process, optimization of the electrolysis conditions, and development of the corresponding processes. Therefore, study of the reactions proceeding on the cathode during electrolysis of silver-containing thiosulfate solutions is an urgent scientific and practical problem.

In this work we studied the reduction of a silver thiosulfate complex on stationary and rotating disc electrodes and in a fluidized bed of glass beads.

EXPERIMENTAL

The processes occurring on the cathode in reduction of silver thiosulfate complexes under the static conditions without stirring the electrolyte and with active transfer of electroactive species toward the cathode and removal of intermediate reduction products from the cathode surface were studied in a universal cell with a fluidized bed of glass beads [9]. The cathode and anode compartments of a poly(methyl methacrylate) cell had rectangular shape and were separated with a semitransparent diaphragm made of thermally densified Khlorin fabric. A 4 cm^2 platinum plate coated with silver and pressed into a flat poly(methyl methacrylate) holder, which was arranged normally in the cathode space using guiding slots, was the working electrode. Silver chloride reference electrode was fed closely to the surface of the working electrode using a Haber capillary. An electrolyte-flow distributor made of stacked polyethylene grids with

Electrode: (*1*) Stationary without stirring electrolyte, (*2*) fluidized bed of glass beads, and (*3*) rotating (1000 rpm) disc electrode; the same for Fig. 2.

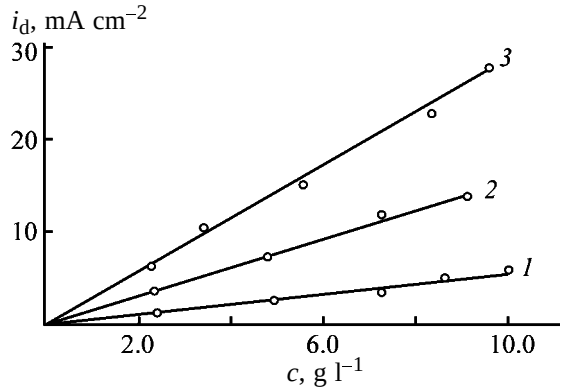

Fig. 2. Limiting current density i_d in reduction of the silver thiosulfate complex as a function of its concentration *c* under different conditions.

small windows was located on the bottom of the cathode space. The platinum anode was mounted in the anode space in the vertical direction after the semitransparent diaphragm. The cell contained an additional reservoir with the solution and was equipped with a centrifugal pump, which ensured fluidization of spherical glass beads 0.08–0.1 cm in diameter by electrolyte circulation through the electrode spaces [10]. The cathodic processes under the steady-state conditions were studied in this cell without electrolyte circulation and without addition of glass beads.

The additional information on the cathodic processes was obtained on an installation equipped with a rotating silver disc electrode of 1.9 cm^2 area. The rate of the electrode rotation was controlled with an ATT-6001 digital tachometer. The volt–ampere curves were taken with a PI-50-1 potentiostat and a two-coordinate self-recorder. The potential scan rate was 10 mV s^{-1}. The study was performed at 20–23°C. As test object was chosen a 1 M sodium thiosulfate solution containing varied amounts of silver in the form of the thiosulfate complex, which was obtained by addition of freshly prepared silver chloride to this solution. All the chemicals used were of chemically pure grade.

The study showed that only one wave is always recorded in the voltammograms of reduction of the silver thiosulfate complex (Fig. 1), with the characteristic current peak revealed on the stationary electrode without stirring the electrolyte. The current densities at a potential of –0.33 V are maximal and linearly increase with increasing silver concentration in the solution (Fig. 2, line *1*). The voltammograms show that the current sharply increases again at potentials more negative than –1.0 V.

The analysis of the cathodic deposits showed that the light gray silver deposit is formed with a 100% current efficiency at current densities not exceeding the maximum value. Further cathodic shift of the potential results in darkening of the silver deposit, which turns black at potentials from –0.8 to –0.9 V. At potentials more negative than –1 V, the deposition is accompanied by hydrogen evolution. Figure 3 shows how the composition of the electrolysis products on the cathode varies with the current density. The results obtained show that, at current densities corresponding to the maximum values, the silver thiosulfate complex and thiosulfate ions start to discharge jointly, since the difference of the standard potentials of these redox systems is as small as ~23 mV [3].

The rate of electroreduction of the anions is controlled by the slow discharge stage; it depends on the zero-charge potential of the electrode and is not controlled by transport limitations [11]. Data on the reduction of thiosulfate ions are lacking; it may be suggested that the rate of their electroreduction is also controlled by the slow discharge stage and is potential-dependent. Owing to the fact that the discharge of the silver thiosulfate complex occurs at the limiting diffusion current, the concentration of the silver ions on the electrode surface is equal to zero. The sulfide ions formed upon reduction of thiosulfate ions are accumulated in the near-electrode space and interact with the silver ions to form sparingly soluble silver sulfide. As a result, the concentration of the silver

ions in the near-electrode space decreases. The low electrical conductivity of silver sulfide (owing to blocking of a part of the cathode surface) and a decrease in the silver concentration in the near-electrode space are responsible for the appearance of a maximum in the discharge wave of $[Ag(S_2O_3)_2]^{3-}$ ions on the stationary electrode.

Taking into account the fact that the silver thiosulfate complex is moderately stable (instability constant is $K = 3.5 \times 10^{-14}$ [2]), the shape of the voltammograms, and the fact that the maximum current density is a linear function of the concentration of the complex in the solution, we may state that the discharge of the complex is accompanied by the concentration polarization and that the maximum current densities correspond to the limiting diffusion currents.

The above suggestion on the limiting diffusion currents of reduction of the silver thiosulfate complex is confirmed by the results of studying the cathodic process in a fluidized bed of glass beads and on a rotating disc electrode.

In this case, there is no current peak on the wave of reduction of the complex silver anions (Fig. 1, curves *2*, *3*). Low-conducting silver sulfide is not deposited on the cathode under the given hydrodynamic conditions. This ensures more intense delivery of the silver-containing ions toward the cathode. The limiting current densities are directly proportional to the concentration of the complex silver ions in the solution (Fig. 2) and to the square root of the electrode rotation rate (Fig. 4). These results show that the currents are limited by diffusion.

Thus, the mechanism of the reduction of silver thiosulfate complexes can be presented as follows. Depending on the current density, different processes occur at the cathode. At low current densities, not exceeding the limiting values, the silver thiosulfate complex is reduced at the cathode with the deposition of pure silver.

$$[Ag(S_2O_3)_2]^{3-} + e = Ag + 2(S_2O_3)^{2-}. \quad (1)$$

After the limiting current is attained, the simultaneous discharge of thiosulfate ions starts:

$$S_2O_3^{2-} + 2e = S^{2-} + SO_3^{2-}, \quad (2)$$

which is followed by the chemical deposition of silver sulfide:

$$2[Ag(S_2O_3)_2]^{3-} + S^{2-} \rightarrow Ag_2S + 4S_2O_3^{2-}. \quad (3)$$

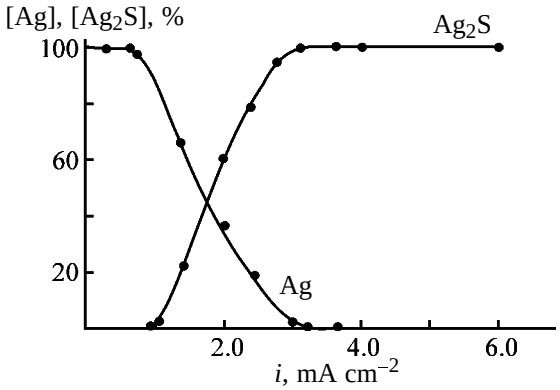

Fig. 3. Influence of the cathodic current density i on the composition of the deposit formed on stationary electrode without stirring the electrolyte. ([Ag], [AgS]) Contents of the components in the deposit.

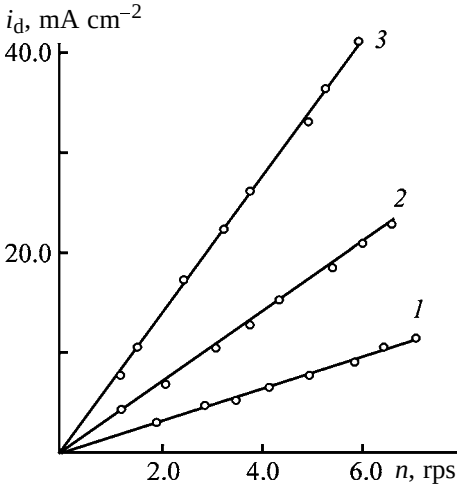

Fig. 4. Limiting current density i_d in reduction of the silver thiosulfate complex on a disc electrode vs. rotation rate n at various concentrations of the complex in the solution. Concentration of the silver complex (g l^{-1}): (*1*) 2.3, (*2*) 5.4, and (*3*) 9.6.

Thus, the reduction of the silver thiosulfate complex is a diffusion-controlled process. Pure silver can be obtained solely at the current densities not exceeding the limiting values. To increase the electrolysis intensity, it is necessary to make the diffusion limitations weaker. The electrolysis in a fluidized bed of glass beads is the best suited for this purpose [10]. A fluidized bed of glass beads not only increases the electrolysis rate, but also improves the quality of the cathodic deposit, even when the electrolysis current is close to the limiting diffusion currents. The latter is very important in selective recovery of silver. This electrolysis method is the best suited for recovery of metals from the solutions of arbitrary concentration and, from the economic standpoint, is more efficient than other electrolysis methods [12]. To use the elec-

trolysis in a fluidized bed of glass beads in selective recovery of silver from thiosulfate solutions, it is necessary to know the limiting diffusion currents, which would allow development of a program for controlling the current with time. From the data obtained, the necessary calculations can be done.

Study of the silver electrodeposition from thiosulfate solutions during electrolysis in a fluidized bed of glass beadse showed [13] that light gray finely crystalline silver deposits can be obtained at current densities exceeding by an order of magnitude those used in traditional electrolysis.

CONCLUSIONS

(1) A study of processes occurring in electrolysis of silver-containing thiosulfate solutions showed that the rate of the electroreduction of the silver thiosulfate complex is described by the laws of diffusion kinetics. At the current densities not exceeding the limiting values, pure silver is deposited on the cathode at a current efficiency close to the theoretically predicted value. At higher current densities, the joint discharge of $[Ag(S_2O_3)_2]^{3-}$ and $(S_2O_3)^{2-}$ ions, followed by the chemical reaction to yield silver sulfide, takes place.

(2) The composition of the reduction products as a function of the current density was determined. When the transport limitations for the delivery of discharging particles to the cathode and removal of intermediate reduction products (sulfite ions) are eliminated, the current density range ensuring deposition of pure silver can be extended. These conditions can be realized either in an electrolyzer with a fluidized bed of glass beads or on a rotating disc electrode.

Abstract—Application of chemometric methods to processing of the dynamic response of a flow-injection multiple-sensor system of the "electronic tongue" type is described. A through flow-injection multiple-sensor system of a new type is developed. The data processing is carried out using the method of projection to latent structures and the *n*-variate method of projection to latent structures (in processing of three-dimensional data). The results obtained in determining ions of lead and zinc in the case of their simultaneous presence in solution and comparative characteristics of various calibration models are presented.

Chemometrics is widely used at present in processing of experimental data obtained with various analytical instruments [1, 2]. In particular, chemometric methods are used to process signals produced by multiple-sensor systems in analyzers of the "electronic nose" and "electronic tongue" types [3, 4]. Multiple-sensor systems of this kind have been developed using organization principles of sensor systems, and primarily the sense of smell in mammals. By analogy with their biological prototypes, electronic tongues and noses include a large number of weakly selective or cross-selective sensors that can respond to several components of a multicomponent medium simultaneously, with the sensor signals processed by means of chemometric methods. Because the response of cross-sensitive sensors contains information about several components of a solution, use of chemometric methods to obtain analytical information from results of measurements with multiple-sensor systems is necessary and highly important.

Various chemometric methods have been suggested for processing of results of measurements with multiple-sensor systems, including the electronic tongue [4–6]. The choice of a particular method is primarily determined by an analytical task, as well as by the structure of the data obtained. In particular, principal component analysis (PCA) has been used for study of the structure of data and for recognition, and the self-consistent projection method of classification (SIMCA), as follows from its name, for classification. The multiple linear regression analysis (MLRA) and principal component regression analysis (PCRA), as well as the method of projection to latent structures (PLS) (other names can also be found in the literature: fractional or partial least squares), can be used both in multivariate regression analysis and in classification, and various types of artificial neural networks (ANN), for all of the above-mentioned purposes.

Previously, multiple-sensor systems of two types: static and flow-injection, have been developed and used to solve various analytical problems [4, 7]. In static systems, measurements are carried out similarly to those with separate sensors: sensors are submerged in a liquid being analyzed and the equilibrium potential of each sensor relative to a reference electrode is recorded. In flow-injection systems, sensors are brought in contact with a liquid being analyzed when flowing through a measurement cell, and the difference between the sensor signals in a background solution and the solution being analyzed serves as an analytical signal. Data obtained using both methods have been processed using the same techniques, despite the difference in how the analytical signal was obtained. It may be assumed that, in the flow-injection system, useful information can be contained not only in the difference between responses in a background solution and that being analyzed, but also in the temporal, or dynamic response of sensors.

In this study, an attempt was made to apply various chemometric methods to processing of the dynamic response of a flow-injection multiple-sensor system of the type of electronic tongue for the example of

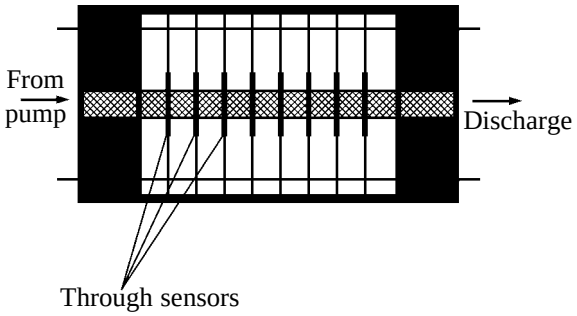

Fig. 1. Schematic of a flow-through cell.

determining the content of zinc and lead in mixed solutions.

EXPERIMENTAL

Measurements were performed using a flow-injection multiple-sensor system with a through cell. The flow-through cell is constituted by a set of poly(methyl methacrylate) discs, between which polymeric membranes are squeezed in the course of assembly. Each membrane has an aperture 3 mm in diameter at its center. These apertures form a channel along which a solution flows. All the membranes were fabricated with a solid inner contact. A silver chloride reference electrode was placed directly downstream of the cell. The flow-through cell is shown schematically in Fig. 1.

The array comprised seven sensors with plasticized polyvinyl chloride membranes of three different types. Sensors sensitive to both lead and zinc ions and having a low sensitivity were chosen for measurements. This choice was based on experimental data previously obtained in laboratory. The compositions of membranes in the sensors used, as well as data on their sensitivity and selectivity toward cations of transition metals were published in [8, 9].

Table 1. Compositions of mixed solutions containing simultaneously lead and zinc nitrates

Solution no.	*c*, M	
	Zn(II)	Pb(II)
1	10^{-5}	5×10^{-6}
2	10^{-4}	10^{-4}
3	10^{-5}	10^{-5}
4	10^{-4}	5×10^{-6}
5	5×10^{-6}	5×10^{-6}
6	10^{-5}	10^{-4}
7	5×10^{-6}	10^{-5}
8	10^{-4}	10^{-5}
9	5×10^{-6}	10^{-4}

Potentiometric measurements with the array of sensors were carried out using a multichannel voltmeter with a high input resistance. The process of measurements was controlled and data files were recorded with a personal computer. The sensor responses were measured at 4-s intervals during 2 min after injection of a sample into the system. Thus, 30 potentials were obtained for each sensor in each solution being analyzed. The sample volume was 500 μl, and the flow rate, 1.44 ml min^{-1}.

Preliminarily, calibration measurements were performed with an array of sensors in individual solutions of lead and zinc nitrates in the concentration range 10^{-7}–10^{-3} M. Then, measurements were carried out is solutions simultaneously containing cations of lead and zinc in the concentration range 5×10^{-6}–10^{-4} M. Nine mixed solutions with compositions listed in Table 1 were prepared. A 0.1 M solution of potassium nitrate served as a background. The calibration solutions of lead and zinc nitrates, both individual and mixed, were also prepared with 0.1 M potassium nitrate as background. All the solutions were prepared with double-distilled water.

The data processing consisted in a multivariate calibration and prognostication of lead and zinc concentrations. The PLS method was used for multidimensional calibration, and *n*-variate PLS, for modeling of 3D data. The calibration models were verified using test data, i.e., data not used for calculating the calibration model. The Unscrambler v.7.8 software was used for calculations by the PLS method, and Multiway matlab toolbox, for calculations by the *n*-vector PLS method [10].

The analytical signal in static measurements with potentiometric chemical sensors (ion-selective electrodes) is the equilibrium potential of a sensor, measured relative to a reference electrode in a solution being analyzed. Apparently, the result of measurements with an array of potentiometric sensors for a set of samples is a 2D matrix of data of dimension equal to the number of samples multiplied by the number of sensors. In this matrix, each row is formed by responses of each of the sensors of the array for a sample. The flow-injection system assumes that the dynamic response of a sensor is measured continuously: in the background solution, when passing a sample through the cell, and in washing of sensors and returning of the sensor potentials to the base line. A typical

form and basic parameters of the response of a sensor in the flow-injection system are shown in Fig. 2.

Traditionally, only a single parameter, the peak height H or the maximum difference between the sensor potentials in the background solutions before injecting a sample and in the sample, is used as an analytical signal (Fig. 2). However, the shape of the response of a sensor in the flow-through system may bear additional information. It is known from experiments that the time in which the potential of the sensor returns to the base line and the peak shape depend both on the concentration and on the nature of a component in a sample. This is due to differences in the interaction of the sensitive membrane of the sensor with ions of varied nature. It may also be assumed that the additional information contained in the dynamic response of the sensor will be of particular interest in measurements with an array of cross-sensitive sensors in multicomponent solutions.

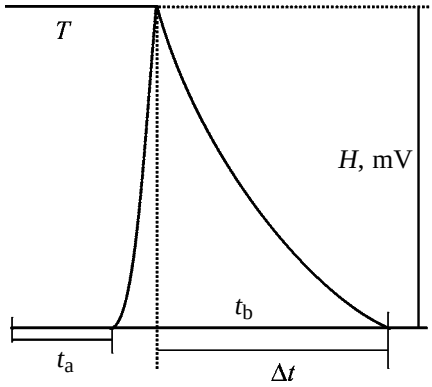

Fig. 2. Typical shape and parameters of the response of a sensor in a flow-injection system. (t_a) Time elapsed from the instant of injection of a sample into the system till its entry into the measuring cell, (T) time of residence of a sample in the flow-through cell, (t_b) width of the peak base, (Δt) time in which the sensor response returns to the base line, and (H) peak height.

The result of measurements with a flow-injection multiple-sensor systems is a 3D data array of dimension equal to the number of samples multiplied by the number of sensors and by the measurement time ($T + \Delta t$). Various methods for analyzing data arrays of dimension exceeding two have been described in the literature. One approach consists in the reduction of a multidimensional data array into a 2D array. In particular, the reduction of data obtained with a multiple-sensor flow-injection system yields a matrix of dimension equal to the number of samples multiplied by the number of sensors and measurement time. After that, any multivariate regression method, e.g., multiple linear regression analysis, PCRA, PLS [1, 2], neural networks [11], etc., can be used in data processing and analysis.

An alternative approach consists in that the initial dimension of the data array is preserved and the so-called multilinear statistical methods are used for their processing. By now, quite a number of methods of this kind have been suggested, including PARAFAC, Tucker model, trilinear PLS, etc. [12–14]. Although some of these methods started to be developed as far back as the 1960s [15], their application to mathematical processing of the results of chemical analysis was commenced only in recent years [16–18]. An advantage of application of multilinear methods to processing of high-dimension data consists in that the thus obtained calibration models are simpler, including the simplicity of interpretation, and more stable to presence of noise and, consequently, to overtraining. This is accounted for by the smaller number of parameters to be evaluated in the calibration model when using undeveloped data and multilinear processing methods, which can be illustrated by the following example.

Let us assume that experimental data form an array of dimension $2 \times 10 \times 100$. The reduction of such a data array yields a matrix of dimension 2×1000. In this case, the load vector of dimension 1000 is to be calculated for two samples. Apparently, such a solution cannot be stable; moreover, the increase in the number of variables makes rather complicated assessment of their contribution to the model. Two hundred samples are accessible if data undeveloped in the second dimension are used for calculating a load vector of dimension 10, and 20 samples in the case of data undeveloped in the third dimension and a load vector of dimension 100.

In this study, the multilinear PLS was used for mathematical processing of a 3D data array obtained in measurements with a flow-injection multiple-sensor system. This method was chosen among other multilinear methods because it takes into account (as also does the ordinary PLS), in data modeling, the covariance between the independent and dependent variables. As the aim of data processing in this study was to obtain a multivariate calibration model, this property of PLS may be of value. In addition, algorithms of other multilinear methods are rather slow and calculations take a long time even when carried out on modern computers.

Let us consider the basic principles of the trilinear PLS-1 algorithm used for data processing in this study. Here, the notion "trilinear" means that the method is used to process 3D data, and the index 1

refers to the number of dependent variables (component concentrations). As the algorithm of the multilinear PLS, suggested in [12], is an extension of the ordinary PLS algorithm to a larger number of dimensions, we first consider a bilinear PLS. In what follows, we use the following designations: X, matrix of independent variables (instrumental responses) of dimension $I \times J$ or $I \times J \times K$ for the 2D and 3D cases, respectively; y, vector of dependent variables (concentrations) of dimension $I \times 1$; T and W, matrices of markers and weights X, respectively; and A, number of components. The bilinear PLS consists in decomposition of the input data into a "model" and an "error," with the modeling performed with two matrices of markers and weights, which are also named bilinear factors. The model X has the following form for each of the components:

$$\hat{x}_{ij} = t_i w_j. \quad (1)$$

The algorithm of the bilinear PLS consists of two main parts. First, a new component (new variable) is calculated for X and y, and then the resulting model is subtracted from the input data and the remainder is used to calculate the next component, etc. If the weight vector w is known and has a unity length, markers t_i are calculated by the least-squares method, i.e., by projection of X to w:

$$t = Xw \text{ or } t_i = \sum_{j=1}^{J} x_{ij} w_j, \quad (2)$$

The problem consists in that it is necessary to find a vector w that would maximize the covariance between the markers t and the dependent variable y:

$$\max_w \left[\operatorname{cov}(t, y) = \sum_{j=1}^{J} x_{ij} w_j \Lambda \, |w|_A^2 = 1 \right]. \quad (3)$$

For centered data, the covariance between t and y can be expressed as a sum:

$$\max_w \left[\sum_{i=1}^{I} t_i y_i = \sum_{j=1}^{J} x_{ij} w_j \Lambda \, |w|_A^2 = 1 \right]. \quad (4)$$

In Eq. (4), the number of degrees of freedom is dropped, but it is constant and thus does not affect maximization. Combining the expressions for calculation of the covariance (4) and for least-squares calculation of loads (2), we obtain

$$\max_w \left[\sum_{i=1}^{I} \sum_{j=1}^{J} y_i x_{ij} w_j \Lambda \, |w|_A^2 = 1 \right]. \quad (5)$$

As X and y are known beforehand, a preliminary summation over i can be performed. This summation yields a vector z of dimension $J \times 1$:

$$\max_w \left[\sum_{j=1}^{y} z_j w_j \Lambda \, |w|_A^2 = 1 \right]. \quad (6)$$

As the weight vector w is normalized to unit length, expression (6) is maximized if w is a unit vector with the same direction as z. Thus, the weight vector can be calculated using the following equation:

$$w = \frac{z}{\|z\|} = \frac{X'y}{\|X'y\|}. \quad (7)$$

As in the case of the bilinear PLS, the aim of the algorithm of the trilinear PLS is to decompose the initial 3D data matrix X into "triads," which are analogs of bilinear factors in the ordinary PLS. A triad is constituted by a marker vector t and two weight or load vectors w^J and w^K for the second and third dimensions, respectively. Thus, the model X has, for each component, the form:

$$x_{ijk} = t_i w_j^J w_k^K. \quad (8)$$

Using (8), we can calculate markers t:

$$t_i = \sum_{j=1}^{J} \sum_{k=1}^{K} x_{ijk} w_j^J w_k^K. \quad (9)$$

As also in the case of the bilinear PLS, the problem consists in finding a set of unit weight vectors w^J and w^K that would maximize the covariance between the markers t and the dependent variable y. The expression for optimization has the following form

$$\max_{w^J w^K} \left[\sum_{i=1}^{I} t_i y_i = \sum_{j=1}^{J} \sum_{k=1}^{K} x_{ijk} w_j^J w_k^K \right]$$

$$= \max_{w^J w^K} \left[\sum_{i=1}^{I} \sum_{j=1}^{J} \sum_{k=1}^{K} y_i x_{ijk} w_j^J w_k^K \right] = \max_{w^J w^K} \left[\sum_{j=1}^{J} \sum_{k=1}^{K} z_{jk} w_j^J w_k^K \right]. \quad (10)$$

In the given case, Z is a matrix of dimension $J \times K$, rather than a vector. The weight vectors can be found by means of a singular decomposition:

$$\max_{w^J, w^K} [(w^J) Z w^K] \longrightarrow (w^J, s, w^K) = SVD(Z, 1). \quad (11)$$

A more detailed description of the algorithm of multilinear PLS was given in [12].

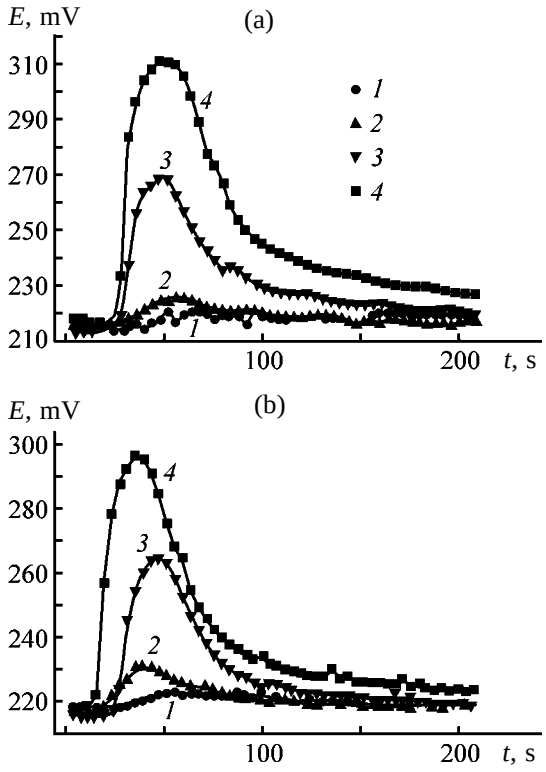

Fig. 3. Response of a sensor of the flow-injection system in individual solutions of ions of (a) lead and (b) zinc. (*E*) Potential and (*t*) time; the same for Fig. 4. pM: (*1*) 6, (*2*) 5, (*3*) 4, and (*4*) 3.

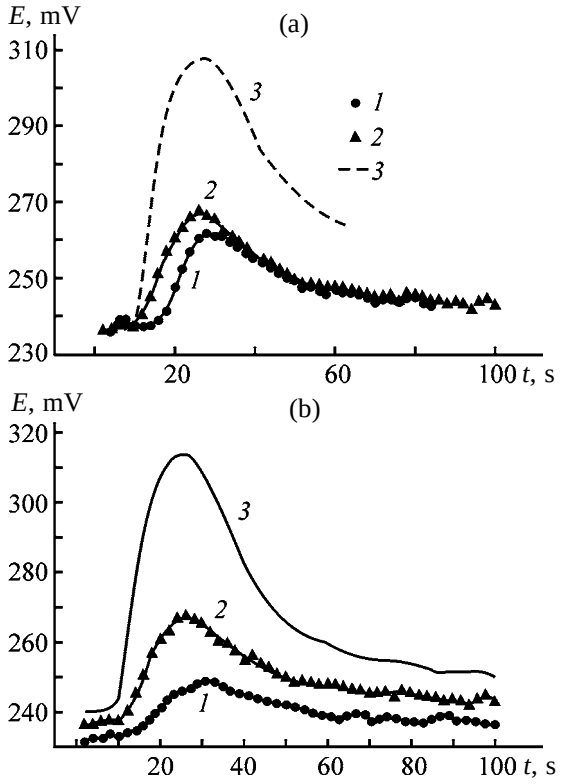

Fig. 4. Response of a sensor in the flow-injection multiple-sensor systems in mixed solutions. Response: (a) to zinc ions in the presence of a constant concentration of lead (pZn = 5) and (b) to lead ions in the presence of a constant concentration of zinc (pPb = 5). pM: (*1*) 5.3, (*2*) 5, and (*3*) 4.

Prior to measurements in mixed solutions, the sensitivity of sensors of the flow-injection multiple-sensor system to lead and zinc ions was studied in their individual solutions. The response of a sensor of the array to lead and zinc ions is shown in Fig. 3. It was established that the sensors of the array are sensitive to lead and zinc in the concentration range 10^{-6}–10^{-3} M, with the slope of the electrode function equal to 42 ± 1 and 33 ± 2 mV/pM, respectively. These results are in agreement with the data previously obtained in static measurements with sensors for these compositions. Interestingly, not only the magnitude, but also the shape of response of the sensor depends on concentration in the flow-injection system (Fig. 3).

Measurements with a flow-injection multiple-sensor system were carried out in mixed solutions containing simultaneously lead and zinc ions. The compositions of the solutions are listed in Table 1. A typical response of a sensor of the array in mixed solutions is shown in Fig. 4. The response of the sensor contains information about both cations. As also in the case of measurements in individual solutions, not only the magnitude, but also the shape of

* (I) Only peak height, (II) developed dynamic data, (III) 3D dynamic data: parameters of the introduced/found curve (slope, offset, and correlation) for the calibration and test data arrays.

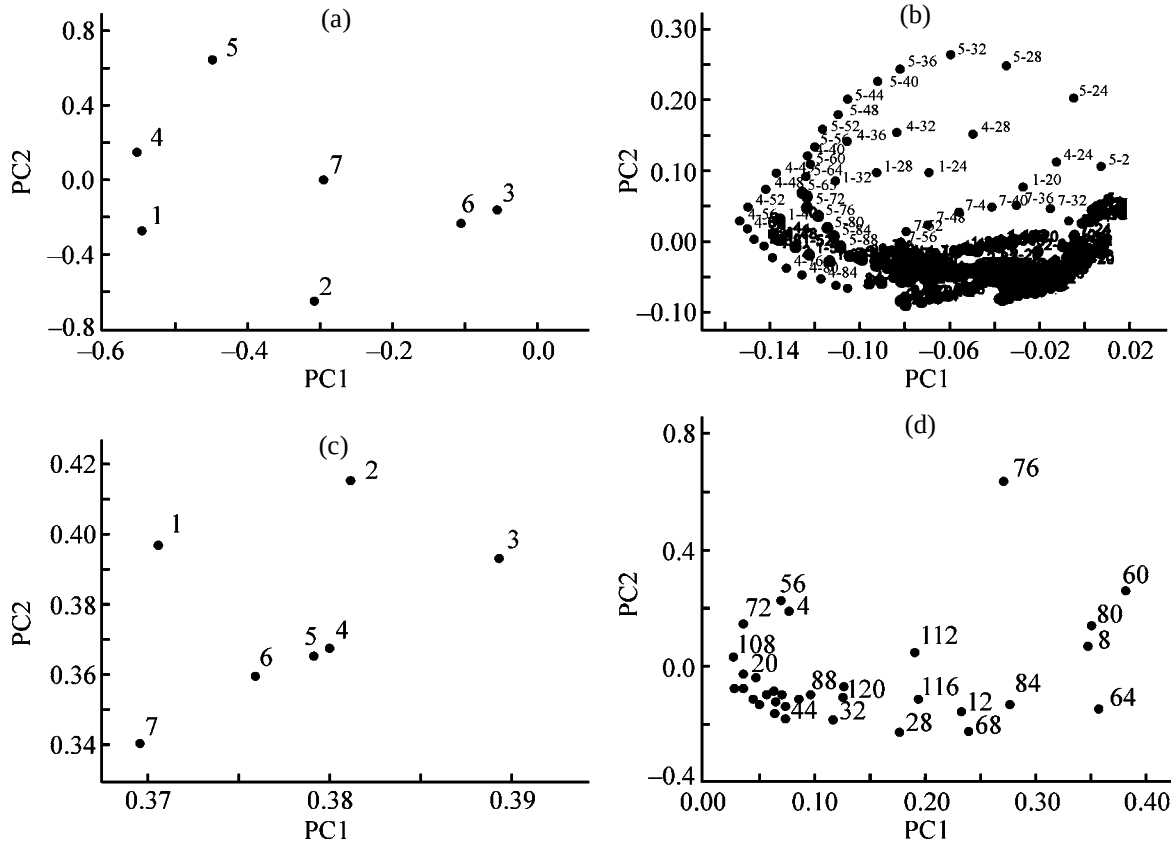

Fig. 5. Load plots for different types of data files. (a) Only peak height, (b) developed dynamic data, (c) 3D dynamic data in the direction of sensors, and (d) 3D dynamic data in the direction of time. Result of analysis for principal components in the form of load plots: PC1 and PC2 are the first and second principal components, respectively [principal components are new variables obtained in data processing in the form of a linear combination of the input variables, i.e., sensor potentials; the first two of these new variables, principal components, contain a major part of information about the system (account for the most part of variance in the data)]. Digits at points: (a, c) sensor number and (b) sensor number–time (s), and (d) time (s).

the dynamic response of the sensors varies with concentration. In particular, Fig. 4a can be regarded as an illustration of the fact that the dynamic response of sensors in the flow-injection system contains additional information about the solution components. Three types of data were used in calculations, and, accordingly, three multivariate calibrations were obtained for determining the concentrations of lead and zinc. The data array constituted by values of the maximum response H (I) and a "dimension-reduced" array of dynamic responses of the sensors (II) were processed using the ordinary PLS regression analysis. The 3D array of dynamic responses of the sensors (III) was processed using a trilinear PLS regression analysis. The parameters of the introduced/found curve for all the types of data for the calibration and test array are listed in Table 2. Apparently, in the ideal case, the slope and the correlation factor must be unity, and the offset, zero.

It follows from the results presented that using the dynamic response makes it possible to improve the accuracy of determination of transition metal cations in their simultaneous presence in solution, compared to the case when only the peak height serves as analytical signal. At the same time, no significant difference was observed between the calibration models obtained for 2D developed and 3D data, which is, on the whole, in agreement with published data [12, 16–18].

As already noted, use of multilinear methods for data processing makes it possible to obtain simpler and more noise- and overtraining-resistant calibration models. Also, the smaller number of parameters is to be evaluated, the smaller number of samples is necessary for obtaining a stable calibration model. The simplicity of a calibration model is determined by the number of parameters evaluated in calibration, i.e., by the number of variables. Let us consider as an example the load plots obtained for different types of data (Figs. 5a–5d). The load plots describe the con-

tributions of the input variables to the calibration model and are, as a rule, used to choose the most informative variables and to optimize the calibration model. When only the peak height is used as analytical signal, seven parameters are evaluated for the sensors used (as there are seven sensors). The resulting model is sufficiently simple, and the load plot is easy to interpret (Fig. 5a). However, as shown above, the prognosticating capacity of such a calibration model is poor. When a 2D reduced array of dynamic responses of an array of sensors is used, the number of variables is 210. The resulting load plot has the form of a cloud of points (Fig. 5b), which is rather difficult to analyze. When 3D dynamic data are used in calculations, two sets of loads are evaluated: those in the directions of sensors and time, a total of 37 parameters. The load plots in the direction of sensors (Fig. 5c) and in that of time (Fig. 5d) are sufficiently simple for interpretation.

CONCLUSIONS

(1) Using the calibration dependence of the dynamic response of a flow-injection multiple-sensor system makes it possible to improve the accuracy of determination of lead and zinc cations simultaneously present in solution, compared with the case when only the maximum response (peak height) is employed.

(2) Using a 3D data array and the trilinear method of projection to latent structures for the processing of this array yields a simpler calibration model, compared to the case of reduced 2D data.

CATALYSIS

Modification of the Alumina-Supported Platinum Catalyst of Reforming

Abstract—The catalytic activity of alumina-supported platinum catalysts modified with rare earth metal (samarium, europium, gadolinium, ytterbium, yttrium) complexes in C_6 hydrocarbon reforming was studied.

Production of aromatic hydrocarbons, in particular, benzene, which is a raw material for chemical industry, is an important direction of the catalytic reforming, since the production of polyamide, polyester, and other fibers and, in addition, some types of plastics and specialty rubbers is based on conversion of benzene and its nearest homologs.

Alumina-supported platinum catalysts, which were for many years the main catalysts of hydrocarbon aromatization, now give place to the catalytic systems with a low platinum content, containing other metals (iridium, rhenium, germanium, tin) as modifiers [1].

Modifying additives introduced into the platinum catalyst can affect the properties of both active metal itself and a support. With regard to bifunctionality of the alumina-supported platinum catalyst, whose platinum catalyzes hydrogenation and dehydrogenation, while alumina catalyzes paraffin isomerization and hydrocracking, we took rare-earth metals (REMs) differing in the dehydrogenation and dehydrocyclization power as modifying additives [2]. It was interesting to find how the initial REM compound affects the catalyst activity.

EXPERIMENTAL

The catalyst properties were studied with a flow-type laboratory device within 440–540°C in a hydrogen atmosphere. *n*-Hexane was used as a feed in reforming.

To study the influence of REMs on the alumina-supported platinum catalyst and to develop a high-performance catalyst with a low platinum content, a series of catalysts containing 0.25 wt % platinum and 0.1–0.4 wt % samarium, europium, gadolinium, ytterbium, or yttrium were considered. The activity of the catalysts was evaluated by the content of benzene (aromatization) and C_1–C_5 hydrocarbons (hydrocracking) in the catalyzate. We found that the catalytic activity of the modified catalysts decreases in the order Gd > Y > Eu > Sm > Yb (Table 1).

The catalysts that were more active in aromatization also showed the elevated selectivity. Taking this into account, we studied the properties of the gadolinium-containing catalyst in the *n*-hexane conversion in more detail and found that, in the presence of the catalyst with gadolinium additives (0.1–0.4 wt %), the yield of benzene is higher than in the case of the REM–free alumina-supported platinum catalyst (Figs. 1, 2). Although the Gd-modified alumina-supported platinum catalyst is characterized by the elevated activity in hydrocracking, the ratio of the benzene concentration to the total concentration of C_1–C_5 hydrocarbons $[C_6H_6]/\Sigma(C_1–C_5)$ on the gadolinium-modified alumina-supported platinum catalyst is also higher than on the unmodified alumina-supported platinum catalyst, which indicates higher selectivity of the former in the aromatization.

Table 1. Influence of REMs on catalytic properties of the alumina-supported platinum catalyst at 500°C

REM	Composition of reaction product, wt %				
	ΣC_1–C_5	*iso*-C_6H_{14}	MCP*	C_6H_6	$C_6H_6/\Sigma C_1$–C_5
Sm	10.1	20.1	17.5	5.5	0.5

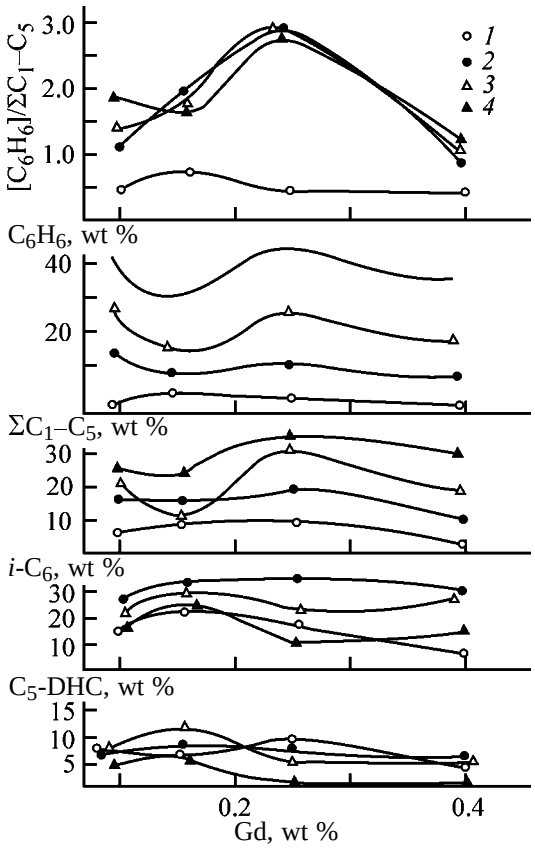

Fig. 1. Influence of the Gd content on the distribution of the products of *n*-hexane conversion on the modified alumina-supported platinum catalyst with the platinum content of 0.25 wt %. Temperature (°C): (*1*) 460, (*2*) 500, (*3*) 520, and (*4*) 540.

It should be noted that an increase in the Gd content to 0.25 wt % increases the aromatization activity of the catalyst. However, at a further increase in the Gd content, the benzene yield decreases (Fig. 1). The effect of the temperature on *n*-hexane conversion on the modified catalysts is shown in Fig. 3. As seen, the Gd content weakly affects the temperature dependence of the product yield. The benzene and $\Sigma(C_1–C_5)$ content increases with temperature; at 520–540°C, the degree of aromatization substantially exceeds the degree of hydrocracking. The temperature dependence of the content of isohexane (i-C_6) and C_5 dehydrocylization (C_5-DHC) products has a maximum at 460–520°C. The catalyst selectivity with respect to aromatization increases with temperature (Fig. 3).

To study the effect of Gd additives on the activity of the alumina-supported platinum catalyst, gadolinium was introduced into the catalyst with a gadolinium metanilate solution. A series of catalysts with the platinum content from 0.1 to 0.4 wt % and Pt : Gd ratio from 1 : 4 to 4 : 1 was prepared. As a whole,

(*1*) $\Sigma(C_1–C_5)$, (*2*) benzene, (*3*) isohexanes, (*4*) products of C_5-DHC, and $[C_6H_6]/\Sigma(C_1–C_5)$; the same for Fig. 3.

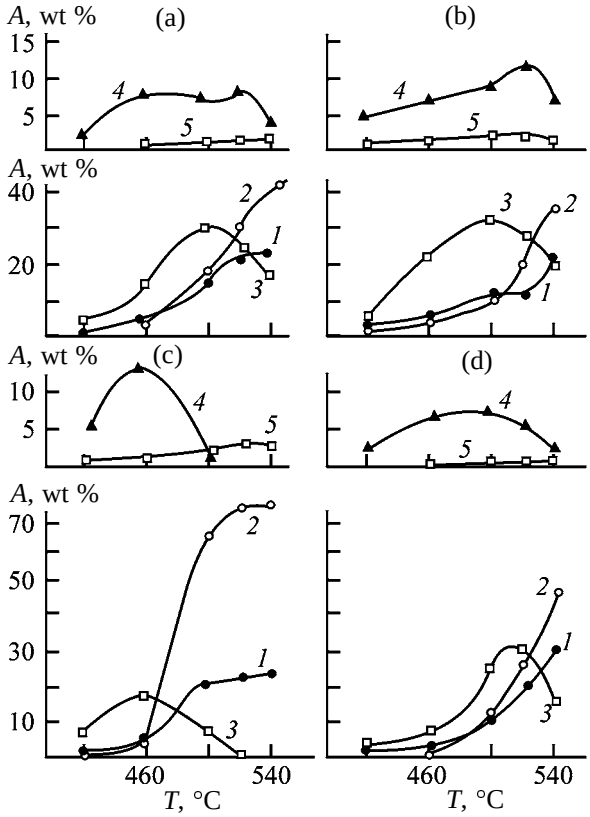

Fig. 3. Temperature dependence of the contents of the products of *n*-hexane conversion, *A*, on the alumina-supported platinum catalysts modified with gadolinium. Gadolinium content (wt %): (a) 0.1, (b) 0.15, (c) 0.25, and (d) 0.4.

Table 2. Conversion of *n*-hexane on the Gd-modified alumina-supported platinum catalysts

Catalyst, wt %	*T*, °C	Product composition, wt %				
		ΣC_1–C_5	*iso*-C_6H_{14}	MCP	benzene	$C_6H_6/\Sigma C_1$–C_5
0.1Pt + 0.1Gd	520	9.1	27.8	11.5	9.5	1.0
0.4Pt + 0.4Gd	520	27.9	25.9	8.8	23.7	0.7
0.25Pt + 0.25Gd	500	20.2	5.0	2.7	61.0	3.0
	520	23.5	–	–	72.5	3.0
	540	21.4	–	–	72.6	3.0
0.25Pt + 0.1Gd	520	32.4	4.3	0.6	62.5	1.9
0.25Pt + 0.5Gd	520	16.3	23.2	10.8	13.7	0.8
0.25Pt + 0.05Gd	520	7.3	15.8	10.5	17.1	2.3
0.4Pt + 0.1Gd	520	45.9	13.8	2.6	33.3	0.7
0.1Pt + 0.4Gd	520	20.7	8.4	8.4	23.2	1.0

the Gd added increases the activity and selectivity of the catalyst in the *n*-hexane aromatization.

The effect of the Pt : Gd ratio (wt %) on the catalyst activity in various directions of *n*-hexane conversion (0.1 Pt : 0.4 Gd, 1 : 4; 0.25 Pt : 0.5 Gd, 1 : 2; 0.25 Pt : 0.25 Gd, 1 : 1; 0.4 Pt : 0.1 Gd, 4 : 1) is shown in Fig. 4. The benzene yield grows with increasing Pt : Gd ratio to 1 : 1 at a slight increase in the yield of C_1–C_5 products (Fig. 4, curves *1*, *2*). The catalyst containing 0.25 wt % Pt and 0.25 wt % Gd showed the highest activity. The yield of the target product on this catalyst at 540°C and contact time of 0.6 s reaches 72.6 wt %. The selectivity in aromatization at 500–540°C is 3. At Pt : Gd > 1, the yield of hydrocracking products exceeds the yield of benzene. The decrease in the selectivity of the aromatization at increasing Pt : Gd ratio and a maximum in the benzene yield at 540°C show that the Pt : Gd ratio of 1 : 1 is optimal for the catalyst modification in the *n*-hexane conversion.

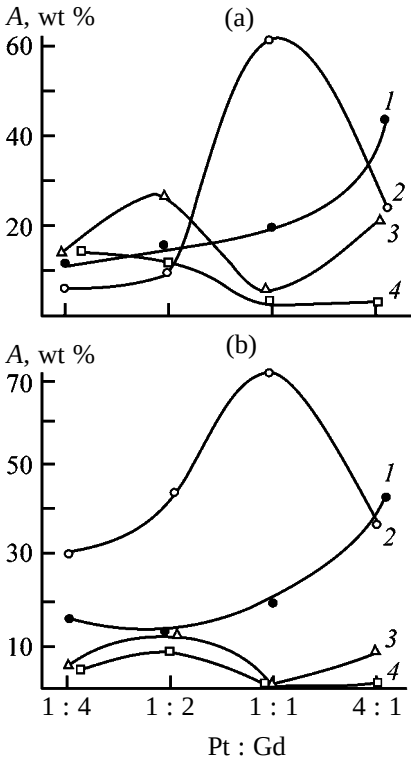

Fig. 4. Influence of the Pt : Gd ratio on the composition of the products of *n*-hexane conversion, *A*, at (a) 540 and (b) 500°C. Contact time 0.24 s. (*1*) $\Sigma(C_1$–C_5, (*2*) benzene, (*3*) isohexanes, and (*4*) products of C_5-DHC.

At the same Pt : Gd ratio, the content of the active components affects the catalyst activity. At the Pt : Gd ratio of 1 : 1, the aromatizing activity increases with increasing platinum and gadolinium content up to 0.25 wt %. Further increase in the Pt and Gd content is accompanied by a decrease in the catalyst activity. Thus, the catalyst sample containing 0.25 wt % Pt and 0.25 wt % Gd is the most active (Table 2).

The experimental data were treated with the Bassett–Habgood equation for first-order heterogeneous catalytic reactions [3]:

$$kK = \frac{F_0}{273Rm} \ln[1/(1-x)],$$

where *k* is the rate constant (s^{-1}); *K*, adsorption equilibrium constant; F_0, carrier gas flow rate recalculated to the normal conditions (ml s^{-1}); *x*, degree of conversion; and *m*, catalyst amount (g).

From the $\log(1/m)\ln[1/(1-x)]$–$1/T$ dependence, we calculated E_{app} of *n*-hexane aromatization. The *n*-hexane aromatization on the industrial alumima-sup-

ported platinum catalyst proceeds mainly through the C_5-DHC with the subsequent methylcyclopentane dehydroisomerization. The apparent activation energy of the *n*-hexane aromatization amounts to 134 kJ mol^{-1}. On the base-modified industrial alumina-supported platinum catalyst, when methylcyclopentane dehydroisomerization is suppressed because of blocking of acid centers, the *n*-hexane aromatization proceeds through the C_6-DHC. In this case, the apparent activation energy of the *n*-hexane aromatization is equal to 164 kJ mol^{-1} [4].

E_{app} on a Gd-modified alumina-supported platinum catalyst is 163 kJ mol^{-1}, i.e., coincides with E_{app} of the *n*-hexane aromatization on base-modified alumina-supported platinum catalyst (Fig. 5). Hence, modifying Al_2O_3 with the Gd compounds blocks active centers responsible for isomerization in the stage of methylcyclopentane isomerizatrion, which causes aromatization through the C_6-DHC [5, 6].

Thus, modifying the alumina-supported platinum catalyst with REM (samarium, europium, gadolinium, ytterbium, yttrium) increases its aromatization activity in the *n*-hexane conversion. Among the REMs studied, gadolinium is the most active.

Modifying alumina-supported platinum catalyst with REM suppresses the acid function of the support, which is accompanied by a decrease in the contribution of the C_5-DHC reaction in favor of benzene formation by successive dehydrogenation. In the REM series, the dimensions of atom and ion decrease with increasing atomic number, which decreases the basicity of REM oxides. Although the chemical properties of all the lanthanides(III) are similar, they regularly change from La to Lu. Yttrium has an ionic radius intermediate between those of Dy and Ho, which causes its similarity with lanthanides. The basicity of gadolinium oxide is higher than that of ytterbium oxide, which is manifested in their different influence on the support acidity.

To confirm this suggestion, we studied the IR spectra of the catalyst modified with Gd and Yb, which occupy the first and the last place, respectively, in the order of the activity of the modified alumina-supported platinum catalysts in the *n*-hexane aromatization. After the interaction with pyridine, the bands at 1630, 1580, 1490, and 1440 cm^{-1} appear in the IR spectrum of Al_2O_3 (Fig. 6). In accordance with the published data [7, 8], the bands at 1630 and 1490 cm^{-1} belong to vibrations of pyridine molecule coordinated to Lewis acid centers of the alumina surface, while the bands at 1580 and 1440 cm^{-1} correspond to physically adsorbed pyridine molecules.

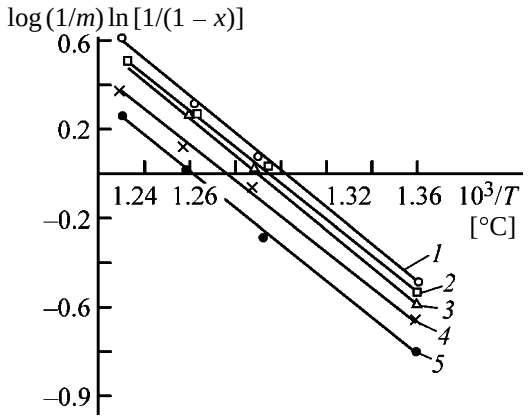

Fig. 5. The $\log(1/m)\ln[1/(1-x)]$–$1/T$ dependence for *n*-hexane aromatization on (*1*–*4*) Gd-modified alumina-supported platinum and (*5*) alumina-supported platinum catalysts. Gadolinium content (wt %): (*1*) 0.1, (*2*) 0.15, (*3*) 0.25, and (*4*) 0.4.

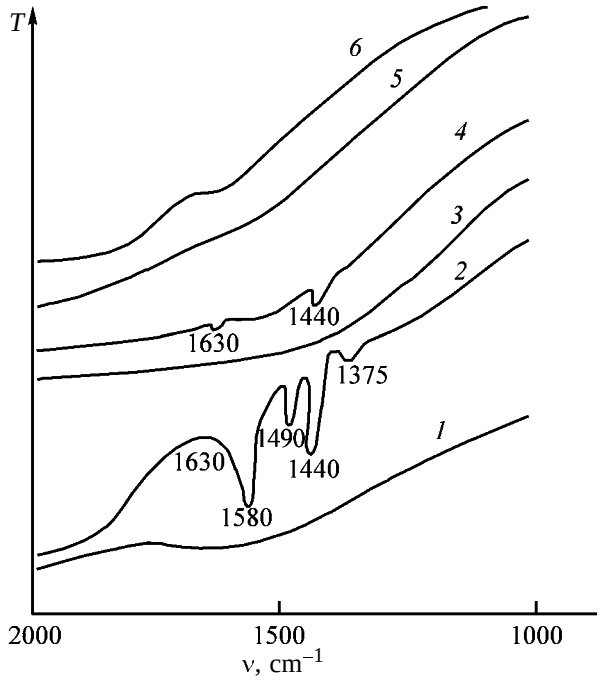

Fig. 6. IR spectra of (*1*, *2*) Al_2O_3, (*3*, *4*) Yb/Al_2O_3, and (*5*, *6*) Gd/Al_2O_3. (*T*) Transmittance and (ν) wave number. (*1*, *3*, *5*) Initial samples and (*2*, *4*, *5*) after pyridine adsorption.

Under the action of ytterbium as a modifying additive, the relative power of the active surface centers substantially changes. Although the bands at 1630 (Lewis acid centers) and 1440 cm^{-1} (physically adsorbed pyridine) are present in the IR spectrum of the catalytic system with sorbed pyridine, their intensities are substantially lower than after pyridine adsorption on the initial aluminum oxide, suggesting a substantial decrease in the surface acidity due to modification with ytterbium. It follows from the

IR spectrum that aluminum oxide modified with gadolinium contains almost no acid centers. Indeed, after slight evacuation, the bands of free and physically adsorbed pyridine completely disappear, bands characteristic for pyridinium ion are not observed, and the band at 1630 cm^{-1} assigned to pyridine molecules coordinated to Lewis acid centers is very weak. Thus, these data show different influence of REMs on the support acid function, which is manifested in the different catalytic activity of the modified alumina-supported platinum catalysts.

The apparent activation energy of the *n*-hexane conversion on the Gd-modified alumina-supported platinum catalyst, coinciding with E_{app} on the base-modified alumina-supported platinum catalyst, which is characterized by consecutive mechanism of the *n*-paraffin aromatization, confirms the REM influence on the acid properties of the support.

CONCLUSIONS

(1) An order of the activity and selectivity of modifying REMs in the *n*-hexane aromatization was determined: in the series Gd > Y > Eu > Sm > Yb; the catalyst modified with gadolinium is the most active.

(2) The optimal composition of the Gd-modified alumina-supported platinum catalytic system was found for the *n*-hexane aromatization.

(3) On the basis of the study of physicochemical and catalytic properties, the mechanism of the influence of the modifying additives on the activity and selectivity of the catalysts studied was suggested. Modification of the alumina-supported catalyst with rare-earth metals suppresses the acid centers of the support responsible for isomerization of hydrocarbons and, as a result, aromatization of *n*-paraffins proceeds through their successive dehydrogenation.

ENVIRONMENTAL PROBLEMS OF CHEMISTRY AND TECHNOLOGY

Chemical Oxygen Demand

A. M. Pisarevsky, I. P. Polozova, and P. M. Hockridge

Research Institute of Chemistry, St. Petersburg State University, St. Petersburg, Russia
Virginia Commonwealth University, Richmond, the United States

Received November 28, 2003

Abstract—New instrumental methods and tendencies of development of direct potentiometric determination of the chemical oxygen demand in the framework of the standard technique are considered.

In view of the increasing contamination of water, both the number of analyses made and that of studies of the analytical capacity of methods for determining the quality of water of various kinds are steadily growing [1–4]. The main parameter in the case in question is the oxygen concentration maintaining the normal ecological situation in water reservoirs. However, it is insufficient to determine only this parameter. The main task consists in monitoring the concentrations of substances (reducing agents of mostly organic nature) that can disturb the oxygen balance of water reservoirs, which leads to environmental disasters [1–4]. This problem has been solved by developing two integrated techniques for determining the parameters "biological oxygen demand" (BOD) and "chemical oxygen demand" (COD): in both cases, the total concentration of substances that can be oxidized, biologically or chemically, to inorganic final products is determined [3–6].

In the COD method, the results obtained are recalculated to the oxygen concentration (oxidizing agent, mg O_2 per liter).

Determination of BOD is a complicated analytical procedure requiring a high skill of analysts.[1] Two main difficulties have been noted [2, 5]: the necessity for introduction of a bacterial microflora and biogenic elements into a sample and the long duration of analysis. In practice, results obtained after incubation for five days (BOD_5) are most frequently used, but complete biochemical oxidation by oxygen may require 20–25 days. Even with substances chosen as reference for determination of BOD, the deviation from the calculated values is ±5 rel. %, and the reproducibility in the case of real wastewater is ±15–20 rel. % [5].

The introduction of such a parameter as COD into the analytical practice made it possible to obviate the above difficulties. The standard procedure involves boiling of a sample (2 h) in an 8 M H_2SO_4 solution, with introduction of $K_2Cr_2O_7$ and Ag_2SO_4 as catalysts and mercury salts for binding of chlorides. The unreacted $Cr_2O_7^{2-}$ is removed by titration with Mohr's salt. The standard procedure for determining COD makes it possible to achieve in many cases the required extent of oxidation, e.g., in analyses of household sewage (90–100% relative to the theoretically calculated values). In some cases, however, it is inefficient, which is primarily determined by the composition of water being studied. The COD method is inapplicable to water containing (upon dilution) more than 2 g l^{-1} chlorides.

Some countries use their own conditions of COD determination. For example, Japanese scientists believe that it sufficient to make analysis only for easily oxidizable components, which represent an immediate danger to the state of water reservoirs [2]. In this approach, $KMnO_4$ is chosen as an oxidizing agent and the conditions of analysis (temperature, acidity, and duration) are considerably milder. It is noteworthy that use of integral parameters is always rather difficult, because not only general principles are to be standardized, but also all details of the analytical procedure.

The method of direct potentiometric determination of COD (without sample titration) and the necessary apparatus were suggested in [7–9].[2]

The aim of this study was to reveal the most important issues associated with application of direct po-

[1] The parameter BOD corresponds to a greater extent to the natural conditions of oxidation of organic substances in water (according to the commonly accepted procedure, its determination resembles the process used in aerotanks in treatment of wastewater with activated sludge).

[2] Carried out at the Research Institute of Chemistry, St. Petersburg State University; the manufacture of the corresponding analyzers has been commenced in Russia.

Table 1. Potentiometric determination of COD in solutions of oxalic, tartaric, and phthalic acids

COD_{preset}, mg O_2/l	ΔE_{calc}, mV	COD_{exp}, mg O_2/l	Δ,* %
60	6.0	68	+13.3
120	11.3	116	–3.3
400	30.9	408	+2.0
600	41.9	584	–2.7
1200	69.4	1188	–1.0

* $\Delta = [(COD_{exp} - COD_{preset})/COD_{preset}] \times 100\%$.

tentiometry to determination of COD and to analyze the tendencies of development of new instrumental techniques for COD monitoring.

The voltaic cell developed in [7–9] can be represented as follows:

Glass pH electrode	Working solution	Glass redox electrode EO-021	(I)
	7.5 M H_2SO_4, $K_2Cr_2O_7$, $Ce(SO_4)_2$, $Ce_2(SO_4)_3$, Ag_2SO_4, $MnSO_4$		

The potentiometric determination of COD was made possible by use of new electrode systems. In voltaic cell I, having no liquid interface, the glass pH electrode is used as a reference [10], because the concentration of H_2SO_4 is high and constant, the electrochemically reversible metallic contact to the inner side of the glass membrane (LiSn alloy) ensures stable operation of the electrode at temperatures higher than 100°C, and the internal resistance of the electrode at 130°C does not exceed 300 kΩ.

The choice of a glass redox electrode (membrane made of electron-conducting titanosilicate glass) as an indicator, instead of the traditional platinum, gold, or iridium electrode, is due to the high selectivity of such electrode to the redox system $Ce^{4+/3+}$ (compared to components of other systems present in the working solution). The electrochemical reversibility of the voltaic cell as a whole made it possible to calculate the concentration dependence of the electromotive force on the solution composition in accordance with the Nernst equation. Severe difficulties in the development of cell I were encountered in choosing the composition of the working solution, because the system $Cr^{6+/3+}$ is not reversible on the known redox electrodes, including glass electrodes of the EO-021 type, owing to low exchange currents. This difficulty could be overcome by introducing the components of the $Ce^{4+/3+}$ redox system and minor amounts of $MnSO_4$ (catalyst of homo- and heterogeneous reactions of electron exchange) into the working solution.

The potentiometric COD analyzer comprises the following three basic units [7–9]: cell made of a heat-resistant glass (equipped with a reflux condenser), in which an indicator electrode, a reference, and a heater in a quartz sheath are placed; measuring unit[3]; and power source.

The range of COD measurements was from 30 to 1300 mg l^{-1}. The following formula was used in calculations (mg l^{-1}):

$$[COD_{pot}] = \frac{(A-1)[Ce^{4+}][Ce^{3+}] \times 8 \times 10^6}{A[Ce^{3+}] + [Ce^{4+}]V_s}, \qquad (1)$$

where $A = 10^{(E_1 - E_2)/\theta}$; $E_1 - E_2$, difference of the successive values of the electromotive force (mV) of cell I before and after introduction of a sample under study into the working solution; $\theta = 2.3RT/F = 79.2$ mV at 128°C; V_s, sample volume commonly equal to 5 or 10 ml.

The concentrations $[Ce^{3+}]$ and $[Ce^{4+}]$ (g-equiv l^{-1}) were found by calibrating the working solution. Oxalic acid or, as recommended in the standard method, potassium biphthalate was used in calibration [6, 7].

The principal results of the study performed are as follows.

(1) The conditions of COD determination close to those in the standard method as regards the concentration of $K_2Cr_2O_7$ and H_2SO_4 (and, consequently, as regards the boiling point of the working solution, too) could be created in the working solution. It proved to be possible to diminish by an order of magnitude the concentration of silver, $[Ag^+]$ [8, 9]. The concentration of cerium(IV, III) sulfates was chosen in such a way that just these system determined the redox buffer capacity of the working solution. The initial [Ce(IV)] : [Ce(III)] ratio in the working solution was $3.5 \times 10^{-3} : 0.5 \times 10^{-3}$. The correctness and accuracy of potentiometric determinations of COD in the range 60–1200 mg O_2/l are shown in Table 1 for model solutions of oxalic, tartaric, and phthalic acids. It is known that these acids are 100% oxidized to CO_2 and H_2O in the standard method.

(2) The formal potential of the $Ce^{4+/3+}$ system is approximately 120 mV higher than that of the $Cr^{6+/3+}$

[3] As measuring devices can be used digital voltmeters, pH-meters–millivoltmeters, or specially developed automated microprocessor devices (manufactured by LEK, Ekoniks, Ekoniks-Ekspert, etc.).

system. Such a difference is sufficient for ensuring virtually complete oxidation of chromium(III) with cerium(IV). From the standpoint of thermodynamics, it is easier to achieve complete oxidation of organic substances with the cerium system, and this system should be preferred in monitoring of COD. However, the specific features of oxidation reactions and of their kinetics were found to be the key factor. It was shown on model solutions that both a faster rate and a higher extent of oxidation can be achieved with $Cr_2O_7^{2-}$ (combined with a catalyst common in these cases, Ag^+). Therefore, the suggested mixture of oxidizing agents played an important part and provided close agreement between the results furnished by chemical and potentiometric methods for determining COD [7, 8] (Table 2).

The mechanism of oxidation of the total organic substance (Org) can be written as

$$Cr_2O_7^{2-} + Org \rightarrow 2Cr^{3+} + CO_2 + H_2O$$

$$Ce^{4+} + Org \rightarrow Ce^{3+} + CO_2 + H_2O \qquad (2)$$

$$Ce^{4+} + 2Cr^{3+} + H_2O \rightarrow Ce^{3+} + Cr_2O_7^{2-} + H^+$$

$$Ce^{4+} + Org \rightarrow Ce^{3+} + CO_2 + H_2O$$

System of equations (2) illustrates the assertion that only Ce(IV) is consumed in the course of the oxidation, irrespective of the actual relative amounts in which Ce(IV) and $Cr_2O_7^{2-}$ are involved in oxidation.

(3) The potentiometric technique obviates the problem of strict regulation of the analysis duration (more than 2 h in the standard method). After a sample is introduced into the working solution and boiling starts (2–3 min), it becomes possible to record the variation of the emf of the voltaic cell and, consequently, to monitor the oxidation rate. Figure 1 shows the dependences E–τ, measured both in the calibration of the working solution (successive introduction of two equal amounts of oxalic acid) and in experiments with model (working) solutions containing phenol, soluble cellulose, or isoamyl alcohol. In the latter case, no 100% oxidation is observed, and making the determination time any longer has no effect on the result obtained. On the whole, the determination time decreases dramatically in potentiometric determination of COD. For example, an analysis for COD of water before and after biological treatment took 50 an 20 min, respectively, at a water treatment plant[4] and 20 and 10 min at sewage treatment works.[5]

Table 2. COD values in wastewater. Standard and potentiometric methods

Wastewater	Sample no.	COD_{stand}	COD_{potent}	Δ,* %
		mg O_2/l		
Industrial before treatment	1	150	140	–7
	2	170	170	0
	3	420	400	–5
	4	600	600	0
Household (St. Petersburg) before treatment	5	325	265	–18
	6	285	295	4
	7	180	155	–14
	8	220	215	–2
after treatment	9	43	36	–16
	10	41	52	27
	11	45	57	27

* $\Delta = [(COD_{potent} - COD_{stand})/COD_{stand}] \times 100\%$.

In both cases, the COD of water delivered to treatment was 180–400 mg l^{-1}. Permanent control measurements by the standard method demonstrated that the difference between the COD values obtained by the two methods (standard and potentiometric) does not exceed, on the average, 8 rel. % in the range in question [11, 12].

(4) The possibility of monitoring of the kinetic parameters of the oxidation in analysis for COD is largely associated with the correct choice of the EO-021 electrode as indicator in cell I. The difference in behavior between these and platinum electrodes was the most clearly manifested in those cases when samples contained chlorides and bromides, but it was also

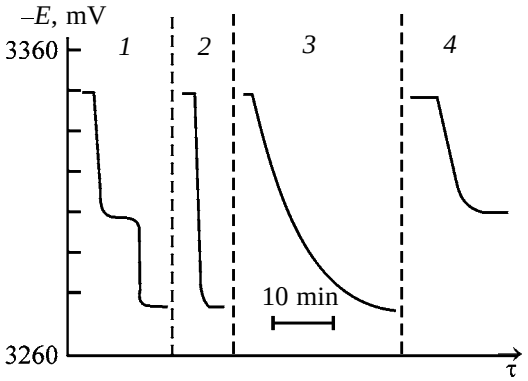

Fig. 1. Kinetic curves of oxidation of various organic substances in the working solution. (E) Potential and (τ) time; the same for Fig. 2. (*1*) Oxalic acid (calibration), (*2*) phenol, (*3*) cellulose (soluble), and (*4*) isoamyl alcohol.

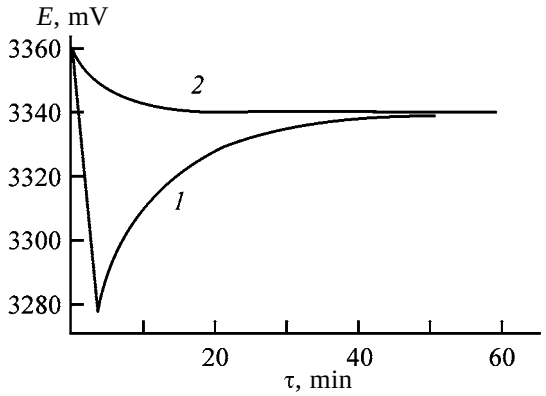

Fig. 2. Comparison of the selectivities of (*1*) Pt and (*2*) glass redoxmetric electrodes in oxidation of a mixture of chlorides and bromides in the working solution.

observed for solutions exhibiting a noticeable electrochemical activity on platinum. Figure 2 illustrates the difference in the properties of the indicator electrodes. Among the large number of determinations performed with cell (I), not a single case of violation of the reversibility of glass redox electrodes was recorded, which confirms their high selectivity toward the $Ce^{4+/3+}$ system [9, 12].

The possibility of differentiation of the contribution from difficultly and readily oxidizable substances to the COD value is an important advantage of the potentiometric method. The interpretation of kinetic dependences is strongly facilitated by the fact that the concentration of $Cr_2O_7^{2-}$ remains constant in the course of analysis (see paragraph 2).

(5) For particular cases,[6] the existence of a stable correlation between BOD_5 and COD_{potent} was established.

In the last 15 years, more than a hundred reports and patents reflecting the tendencies of development of the generalized COD parameter have been published. These publications emphasize the importance of using this parameter for monitoring of the composition of potable, natural, process, and wastewater and for control over industrial processes for which COD is a key parameter. Conventionally, the main areas of research, most important in the authors' opinion, can be formulated as follows: choice of oxidizing agents, new methods and apparatus, and relationship between COD and other parameters that characterize the quality of water.

Choice of an oxidizing agent. In view of the important role of cerium salts in the above-discussed "cocktail" for potentiometric determination of COD, the studies [13–16] in which use of cerium salts was continued should be mentioned first. Ce(IV) was used as an oxidizing agent in analyses of river water and industrial sewage under comparatively mild conditions as regards the concentration of the acid and temperature, i.e., in determination of readily oxidizable components that present an immediate hazard to the state of water reservoirs. According to Japanese regulations [13, 14], the procedures suggested can compete with the permanganate method. The main advantage of the cerimetric technique for determination of COD consists in its insensitivity to presence of very high concentrations of chlorides (up to 30 000 mg l^{-1}) in the samples, which eliminates the necessity of using mercury [13, 14]. The capabilities of the direct potentiometry were not used in these studies, and the loss of cerium(IV) in the course of oxidation was monitored spectrophotometrically.

At the same time, manganese salts started to be used extensively in new techniques as catalysts for homogeneous oxidation with potassium dichromate, instead of silver sulfate in the standard procedure [17]. An even more important step in the improvement of parameters of COD determination was made in [18]: it was suggested to replace $K_2Cr_2O_7$ as oxidizing agent with Mn(III), with no silver salt required in this case as catalyst. Also, the problem of elimination of mercury from the process was solved by preliminary removal of chlorides by treating a sample with sodium bismuthate. It was established for model solutions and wastewater of varied origin that the time of determination of COD at 150°C does not exceed 60 min. The procedure for removal of chlorides by preliminary treatment of a sample with sodium bismuthate (or, more precisely, with an adsorbent based on this compound) was also studied in [19].

Noteworthy among other solutions of interest are use of granulated titanium and Fenton's reagent as oxidation catalyst and coulometric determination of COD in an alkaline medium with a copper anode [20]. Coulometric generation of oxidizing agents [Ce(IV), Cl_2, BrO^-] for COD determination was also studied in [21].

New methods and apparatus. The aim of studies in this field has been to make the analysis time shorter and the determination threshold lower as compared to the standard method. Studies employing the microwave technology for sample heating and new analytical techniques based on flow-through and flow-injection methods (FIM) of analysis have been the focus of attention in recent years.

[6] Household sewage in St. Petersburg and Kharkov, wastewater of a poultry plant and a brewery.

Microwave heaters have been used in experiments devoted to COD determination under nearly standard conditions [22–25]. Water samples were placed both in sealed and in open cells. In all cases, it was possible to substantially diminish the time of analysis both by raising the temperature of the oxidation and by using spectrophotometric techniques to determine the loss of Cr(IV) or gain of Cr(III). For sealed Teflon cells with a sample volume of 0.5–2.0 ml and microwave heating, the analysis time decreased to 7 min at a COD of the samples of less than 1000 mg l^{-1} [25]. It may be assumed that application of the microwave technology in analysis for COD will be developing fast in the future.

The use of modern technology was excellently demonstrated in a study of Beltra *et al*. [26], who employed microwave heating, spectrophotometric determination of the reaction rate from the accumulation of Cr(III) (absorption at λ = 590 nm), and automated computer processing of the results obtained. Such parameters as the concentrations of an acid and silver and determination time were varied by a specially designed program. Analyzers of this kind will extend the field of research and will make it possible to find the optimal modes of analysis for samples of particular compositions.

Versions of flow-through and flow-injection methods (FIM) have been used under mild conditions of COD determination at a relatively low acidity and temperature [with $KMnO_4$ and Ce(IV) as oxidizing agents] [15, 27–31]. Only in [29], COD could be determined by FIM under standard conditions. It was also possible, in all of these studies, to diminish the determination time to 10 min and avoid introduction of Hg(II) to mask chlorides in samples. At present, it is difficult to assess the extent to which FIM-based analyzers can be widely used in determining COD.

The new approach to COD determination was also implemented in [30, 31], where a thin-layer flow-through electrochemical cell was used in combination with coulometric generation of reagents. The adequacy of analyses was achieved [30] owing to formation of highly active ozone or $OH^{\bullet}$ radicals. A lead dioxide electrode served as an anode, and a platinum or titanium plate, as a cathode. Ozone was also used as an oxidizing agent in [32, 33]. The indubitable interest in these studies is due to use of ozone chemiluminescence in monitoring the sample composition.

The enhanced capabilities of the relatively fast and reliable instrumental determinations of COD and the accumulation of data obtained by various methods promoted investigations aimed to gain deeper insight into the contribution of various substances and processes to the COD values of water of various kinds, and primarily wastewater. The interest in distinguishing the contributions of readily and difficultly oxidizable components, obtaining the kinetic data as an advantage of the potentiometric determination of COD, and different approaches to the choice of standard techniques were already mentioned above. The contributions of different kinds of substances and the approach to modeling of water-treatment processes were the subject of [34–37]. The closest attention is focused on gaining insight into the process of biological purification of wastewater [35]. The problem was analyzed from the seemingly opposite standpoint, by calculating the COD values from parameters of UV absorption spectra of organic compounds [38].

Relationship between COD and other parameters. Directly to in-depth studies of the problem are adjacent investigations in which relationships between parameters characterizing the extent of contamination of water are analyzed. In [39, 40], correlations between the total organic carbon (TOC) and COD were discussed; in [40], [TOC]/[COD] ratios of 0.91 were obtained for some kinds of wastewater. Of particular interest for paper-making is the paper by Bristol *et al*. [41]. Although empirical ratios [TOC]/[COD] or [COD]/[BOD] are known for wastewater of this industry, the [TOC]/[COD] ratio was very important both by itself and as regards its fluctuations, which made it possible to use this ratio as a contamination indicator. A classification of wastewater by the [TOC]/[COD] ratio has been suggested.

The existence of a stable correlation between COD and BOD has long been known in food industries, with the preference given to the first of these parameters in analyses of wastewater [42]. Now, the number of studies of this kind is growing because the main substances contained in sewage and process features of various industries became known. Of interest are the data reported in [43]: the [BOD]/[COD] ratio in wastewater formed in manufacture of various compounds is 0.97 for glucose and phthalate, 0.87 for near beer and ice-cream, and 0.93 in processing of fruits and vegetables. It is noteworthy that use of COD as a process parameter requires another approach to the problem of standardization of determinations.

CONCLUSIONS

(1) The standard chemical method for determining the chemical oxygen demand has become poorly applicable to monitoring the contamination of water,

primarily because of the toxicity of the reagents involved and due to the comparatively long time of determination. The steep rise in the number of analyses performed made this problem more acute.

(2) Analysis of tendencies in the development of new techniques and analyzers of the chemical oxygen demand, operating on electrochemical and spectrophotometric principles, including flow-through and flow-injection variants, made it possible to conclude that new devices will provide in the nearest future analysis durations shorter than 15 min and a detection limit of 10 mg l^{-1}.

(3) The results obtained in the last decade when studying the kinetics of oxidation with oxygen of substances dissolved in water revealed the key role of the chemical oxygen demand. This quantity is already being used as a parameter of new technologies in biological treatment of wastewater; in food, pulp-and-paper, and other industries; and in environmental monitoring.

Abstract—A method for determining the kinetic parameters of crystallization in a flow-through mixing cell using a mathematical model that takes into account the nonideality of agitation and the possible dependence of the growth rate of crystals on their size is suggested.

The kinetics of crystallization from solutions is mainly characterized by the nucleation function density and crystal growth rate, which depend on the composition, physicochemical and thermodynamic properties of the medium, and the hydrodynamics and fundamental aspects of mass transfer at the fluid–solid interface. The values of these parameters are commonly determined using indirect methods based on measuring in the course of an experiment some parameters related by known expressions to the crystallization kinetics. In one of methods used for determining kinetic parameters, the nucleation function density and the crystal growth rate are found from the theoretical dependence of the density of the crystal size distribution function (CSDF), which describes the CSDF at the outlet of a flow-through cell of ideal mixing, by minimizing the discrepancy between the results of calculation by the theoretical expression from the experimental CSDF [1]. This method is used in kinetic studies of crystallization on the assumption that the growth rate of crystals is independent of their size (McCabe's rule) and the hydrodynamic mode completely corresponds to that of ideal agitation. However, these assumptions are not always in agreement with the experimental conditions in actual practice. In an experimental study of the kinetics of crystallization in a flow-through mixing cell, it is difficult to choose *a priori* the working parameters of the stirrer and the drive power that would ensure uniform suspension of a polydispersed mass of the forming crystals at the originally unknown size distribution of crystals and their growth rate.

Particles are commonly suspended in a fluid in the turbulent mode in an apparatus equipped with a stirrer, with the parameters of the particle transport depending on the power consumed for agitation, flow structure, and characteristics of the apparatus and stirrer. If the energy supplied is insufficient for complete suspension of particles in the fluid, axial and radial nonuniformity of distribution of solid particles in the fluid is observed. However, even at a sufficient energy, the flow structure may differ from that in the ideal agitation mode [2].

Assuming that the main factor governing the hydrodynamics of motion of the suspension in the mixing cell is energy dissipation in the unit volume of the suspension agitated with a stirrer, let us evaluate the limiting size of growing crystals starting to settle down to the bottom of the flow-through mixing cell. The condition for the ascent of crystals of nominal size r in a turbulent flow from the sediment at the bottom follows from the inequality [3]

$$V'_a \geq [2r(\rho_s - \rho_f)g\varphi_0/\rho_f]^{1/2}, \quad (1)$$

where V'_a is the lifting component of the pulsation velocity at the bottom; ρ_s, ρ_f, densities of a solid particle and the fluid; and φ_0, volume fraction of particles contained in the sediment at the bottom.

The relationship between the thickness of a viscous sublayer, δ_0, and the normal component of the averaged pulsation velocity V'_0 on the scale δ_0 is known [4]:

$$\mathrm{Re}_{\delta_0} \sim \frac{V'_0\delta_0}{\nu_{\delta_0}} = 11.6, \quad (2)$$

where Re_{δ_0}, ν_{δ_0} are the Reynolds number and kinematic viscosity for a thickness δ_0.

1070-4272/05/7801-0108© 2005 Pleiades Publishing, Inc.

The quantity V'_0 on the scale of the thickness of the viscous sublayer (δ_0), regarded as a function of energy dissipation ε_0 (i.e., the power consumed per unit volume of a suspension volume agitated), is given by [4, 5]

$$V'_0 \sim (\varepsilon_0\delta_0)^{1/3}. \quad (3)$$

From Eqs. (1)–(3), we can find the size r_p of a solid particle in relation to the maximum radius r_{max} observed in crystallization. Particles of size $r < r_p$ are partly or completely suspended in the turbulent flow:

$$r_p \sim \frac{11.6k_f \nu_{\delta_0} \varepsilon_0 \rho_f^2}{[2(\rho_s - \rho_f)g\varphi_0]^2} < r_{max}, \quad (4)$$

where k_f is the ratio of the longitudinal component of the pulsation velocity of ascent of particles at the bottom, V'_{la}, to the normal component of the pulsation velocity V'_0 (according to [3], $k_f \approx 0.8$ and $\varphi_0 \approx 0.65$–0.68 for $r \geq r_p$ in the sediment [6]).

Knowing how the thickness of the viscous sublayer depends on the minimum characteristic rate of pulsations, we can use the density of the diffusion flow to find the mass-transfer rate and determine the range of crystal sizes in which the crystal growth rate is independent of the particle size [2, 3].

The crystallization process may be kinetically or diffusion-controlled; in the latter case, the crystal growth rate can also be strongly affected by parameters of the pulsation velocities V_0 on the scale of the thickness of the viscous sublayer, δ_0. In the case of a turbulent flow and large Peclet (Pe) and Reynolds (Re) numbers (Pe $\gg$ 1, Re $\gg$ 1), it follows from the equations for the diffusion flow density that, with account of relations (1) and (3), the mass-transfer rate is independent of the particle size r and the mass-transfer coefficient k_L is applicable to particles of size $r > (\lambda_0 < \delta_0)$, where λ_0 is the internal scale of turbulence [4]. For particles of smaller size in a turbulent flow (Pe $\gg$ 1, Re < 1), i.e., for $r < (\lambda_0 < \delta_0)$, the mass-transfer coefficient is determined by the velocity of the relative motion of a particle in the fluid and is inversely proportional to the particle size r raised to the power m. For the Stokes mode of a fluid flow around a particle and for Re < 1 [4], but with account taken of the natural convection around the particle [7], and for the fluid at rest [8], the mass-transfer coefficient is inversely proportional to the particle size r raised to the power $m = 0.25$ in the case of a natural convection or $m = 1$ for a fluid at rest.

As further development of the method for studying the crystallization kinetics in a flow-through cell with ideal mixing [1], we suggest a procedure for studying the crystallization kinetics in a flow-through cell with nonideal mixing and any crystallization mode, which is described by a mathematical model based on parameters of the structure of the flows of phases, determined preliminarily in experiments with the same mixing cell. Further, crystallization is performed, and kinetic parameters of the process are found from the densities of CSDF by minimizing the disagreement between the results of calculation and the experimental values at the outlet of the mixing cell.

In a flow-through mixing cell with a stirrer (300 rpm) and mass volume $V_c = (0.5–0.8) \times 10^{-3}$ m^3, the structure of the flow of phases was studied by means of pulsed introduction of tracers into the flow. An aqueous solution of sodium chloride was used as a tracer for the fluid phase, and sand composed of four fractions with a prescribed size of particles and the same number of particles in each fraction, as a solid phase in pulsed introduction. The concentration of sodium chloride at the outlet was measured conductometrically, and the composition of the solid phase at the outlet was found by sampling and subsequent determination of the number of particles in each fraction. The initial content of the solid phase in the pulsed introduction mode, recalculated to the volume of the mass in the cell, did not exceed 8 vol %, which is commonly sufficient for kinetic studies in a flow-through cell. The elution curves were processed using the method of moments. The measurement results and values of moments M_i for some experiments are listed in the table.

As seen from the table, the agitation in the fluid phase deviates only slightly from the ideal agitation mode (variance $\sigma^2 > 0.7–0.8$). The energy dissipation ε_0 is 1.8 W. A loose sediment was observed at the bottom of the mixing cell, with the minimum diameter of the sedimented particles $r_p \approx 0.16 \times 10^{-3}$ m. The average residence time of particles, τ^j, where j is the fraction number equal to the dimensional first moment M_1^j, varies approximately in proportion to the ratio of the average concentration of the solid phase in the bulk to its concentration at the outlet of the mixing cell. Turbulent transfer of solid particles is characterized by the second dimensionless moment M_2^j or by variance σ_j^2.The latter is considerably smaller than unity, which points to nonideality of agitation of the solid phase in the flow-through mixing cell.

The structure of flows can be approximated with a

typical cell model. Taking into account the relationship between the variance σ^2 and the number of cells, N, $\sigma^2 = 1/N$, it is allowable to describe the balance of substance in the fluid with a single cell. For describing the balance of the density of CSDF in the case when N is noninteger or more than integer, equations are written for $N - 1$ cells of equal volume, with an additional equation for a cell of smaller volume. For the steady state, the balance equations for the substance and the number of crystals take the form

$$\gamma c_0 - c = \sum_M \int_N \tau_{1,2} \rho_s \eta(r, \Delta c) \times 0.5\pi r^2 \, dr, \qquad (5)$$

$$\left.\begin{aligned}
&\frac{d[f_1^j \eta_1^j(r, \Delta c)]}{dr} = -\frac{1}{\tau_1^j} f_1^j, \\
&\cdots\cdots\cdots\cdots \\
&\frac{d[f_i^j \eta_i^j(r, \Delta c)]}{dr} + \frac{1}{\tau_1^j} f_{i+1}^j = \frac{1}{\tau_1^j} f_i^j, \\
&\frac{d[f_{N-1}^j \eta_{N-1}^j(r, \Delta c)]}{dr} + \frac{1}{\tau_1^j} f_{N-1}^j = \frac{1}{\tau_1^j} f_{N-2}^j, \\
&\frac{d[f_N^j \eta_N^j(r, \Delta c)]}{dr} + \frac{1}{\tau_2^j} f_N^j = \frac{1}{\tau_1^j} f_{N-1}^j,
\end{aligned}\right\} \qquad (6)$$

where τ_1^j, τ_2^j are the average residence times in cells of equal volume and in a cell of smaller volume, respectively; γ, ratio of the solution flow rate at the inlet to that of the suspension at the outlet; η, crystal growth rate; f_i^j, density of CSDF, $i = 1, \ldots, N$ and $j = 1, \ldots, M$, where M is the number of fractions; Δc, supersaturation of the crystallizing solution.

As Δc and temperature are virtually constant in the flow-through mixing cell under study, the crystal growth rate η_i remains unchanged in going from one cell to another for all jth fractions at $r > (\lambda_0 < \delta_0)$ and may depend on the crystal size r for fractions with $r < (\lambda_0 < \delta_0)$. It is assumed that nucleation occurs at the inlet into the flow-through mixing cell at the interface with a fresh supersaturated solution, i.e., only at the inlet of the first cell of the CSDF model. The density of CSDF is found by solving system of equations (6), and then parameters of the crystal growth rate η, $\eta(r)$, and density of the nucleation function, f_0, are determined by comparing the results of calculation and experimental data from the coincidences of the CSDF densities. Equation (5) is used to verify the material balance for the substance that passed from solution into crystals. For the general case of a model comprising $N - 1$ cells of equal volume, supplemented with a cell of smaller volume, for which the growth rate of crystals depends on their size and crystal size varies from that of a nucleus, r_{nuc}, to r_n, where $r_n \approx r_{\lambda_0}$, the solution to model (6) is as follows:

$$f_N(r) = (1/k\tau_1)^{n-1} \frac{f_0}{r_{nuc}^m} \frac{r^m}{(m+1)^{n-1}} \left\{ [(-1)^n r^{(m+1)} r_{nuc}^{n(m+1)} D_1 \right.$$

$$+ (-1)^{(n+1)} n r^{2(m+1)} r_{nuc}^{(n-1)(m+1)} D_2 + (-1)^{(n+2)} n(n-1)(2!)^{-1}$$

$$\times r^{3(m+1)} r_{nuc}^{(n-2)(m+1)} D_3 + \ldots + (-1)^N \frac{n(n-1)\ldots(n-N+3)}{(N-2)!}$$

$$\left. \times r^{(N-2)} r_{nuc}^{(n-N+2)(m+1)} D_{N-1}] - (-1)^{(n+1)} r_{nuc}^{(n+1)} \left[D_{0(N-1)} \right.\right.$$

$$\left.\left. - \sum_{l=1}^{N-1} (-1)^l D_{0l} \right] \right\} \exp\left[-\frac{1}{k\tau_2} \frac{r^{(m+1)}}{(m+1)} + \frac{1}{k\tau_1} \frac{r_{nuc}^{(m+1)}}{(m+1)} \right],$$

$$n = N - 2, \; i = 1, 2, \ldots N - 1; \qquad (7)$$

$$D_i = \left(1 + \frac{A^2 r^{(m+1)}}{1!(i+1)} + \frac{A r^{(m+1)^2}}{2![i + (m+1)]} + \frac{A^3 r^{(m+1)^3}}{3![i + (m+1)^2]} + \ldots \right),$$

$$D_{0i} = D_i \text{ at } r = r_{nuc};$$

$$A = (m+1)^{-1}(-1/k\tau_1 + 1/k\tau_2),$$

where k is a function of the mass-transfer coefficient in the region in which the crystallization rate depends on the crystal size, found from equations for Nusselt numbers [2, 4, 7].

For N cells of equal volume and a growth rate of crystals dependent on their size in the range from r_{nuc} to r_n, solution of model (6) gives for the density of CSDF

$$f_N(r) = \frac{1}{n!}(1/k\tau_1)^n \frac{f_0}{r_{nuc}^m}\frac{r^m}{(1+m)}(r^{m+1} - r_{nuc}^{m+1})^n \times \exp\left[-\frac{1}{k\tau_1(m+1)}(r^{m+1} - r_{nuc}^{m+1})\right], \quad (8)$$

where $n = N - 1$.

At $r > r_n$, the growth rate of crystals is independent of their size, and the solution to model equation (6) for the density of CSDF for $N - 1$ cells of equal volume, supplemented with a smaller cell at $f_i^0 = f_i(r_n)$, where i is the cell number, takes the form

$$f_N = \sum_{i=1}^{N-1}\left\{\frac{1}{(n+1-i)!}(\eta\tau_1)^{i-n-2} f_i^0 \{[(r - r_n)^{n+1-i}B^{-1} - (n+1-i)(r-r_n)^{n-i}B^{-2} - (n+1-i)(n-i)(r-r_n)^{n-1-i} \times B^{-1} \ldots + (-1)^{n-i}(n+1-i)!(r-r_n)B^{i-n-1} - (-1)^{n-i}(n+1-i)!B^{i-n-2}]\exp[-(\eta\tau_1)^{-1}(r-r_n)] - (-1)^{n+1-i}(n+1-i)!B^{i-n-2}\exp[-(\eta\tau_2)^{-1}(r-r_n)]\}\right\} + f_N^0 \exp[-(\eta\tau_2)^{-1}(r-r_n)], \quad (9)$$

where $n = N - 2$, $B = 1/(\eta\tau_1) + 1/(\eta\tau_2)$, and f_i^0 are the CSDF densities found from Eqs. (7) and (8).

For N cells of equal volume, Eq. (9) can be brought to the form

$$f_N = \sum_{i=1}^{N}\left[\frac{1}{(n-i)!}(\eta\tau_1)^{i-n} f_i^0 (r - r_n)^{n-i}\right] \times \exp[-(\eta\tau_1)^{-1}(r-r_n)], \quad (10)$$

where $n = N$.

The size of crystal nuclei, r_{nuc}, can be evaluated by comparing the CSDF density calculated by Eqs. (7)–(10) with the experimental CSDF density at known hydrodynamic conditions of agitation in the flow-through mixing cell and hydrodynamic and mass-transfer parameters at the phase boundary. If the influence of only the nonideality of agitation on the crystal growth rate and density of the nucleation function in the flow-through mixing cell is assumed in the model (6), then Eqs. (7)–(10) are brought, in passing to the limits $r_{nuc} \to 0$, $r_n \to 0$, $f_1 \to f_0$, $f_{i+1}(r_n) \to 0$, to the following form:

$$f_N = \frac{1}{n!}(\eta\tau_1)^{-(n+1)}\{[r^n B^{-1} - nr^{n-1}B^{-2} + \ldots + (-1)^{n-1}n!rB^{-n} + (-1)^n n!B^{-(n+1)}] - (-1)^n n!\exp(Br)\} f_0 \exp(-r/\eta\tau_1), \quad n = N - 2, \quad (11)$$

for $N - 1$ cells of equal volume, supplemented with a smaller cell ($N \geq 2$); and

$$f_N = \frac{1}{(n-1)!}(\eta\tau_1)^{-n} r^n f_0 \exp(-r/\eta\tau_1), \quad n = N - 1, \quad (12)$$

for N cells of equal volume ($N \geq 1$).

The method for studying the kinetics of mass crystallization from solution was tested for the example of a well-studied process, isothermal crystallization of sodium chloride [9]. In accordance with the technique suggested, the structural parameters of the flow of phases were determined, isothermal crystallization of sodium chloride was performed, the CSDF density was found experimentally for sodium chloride, and kinetic parameters of crystallization were determined by comparing the experimental CSDF density with the calculated value. Equations (5)–(12) were solved numerically for prescribed input and output parameters of the process and hydrodynamic characteristics for each jth fraction, and the sought-for parameters were varied, with the hydrodynamic and mass-transfer parameters adjusted, to give their optimal values at the minimum rms deviation of the results of calculation from the experimental data. In calculating the CSDF density by Eqs. (7)–(10), the exponent was taken to be equal to the average value $m = 0.5$ for the region in which the growth rate of crystals depends on their size, and parameter k was taken to be equal to the average value for calculation in the range from between r_{nuc} and r_n.

Figure 1a shows the experimental and calculated CSDF densities for a mode of crystallization of sodium chloride. The disagreement between the calculation and the experiment did not exceed ±9%. The calculated CSDF density was used to find the nucleation function density $f_0 = 1.9 \times 10^{13}$ m^{-1} m^{-3} and the crys-

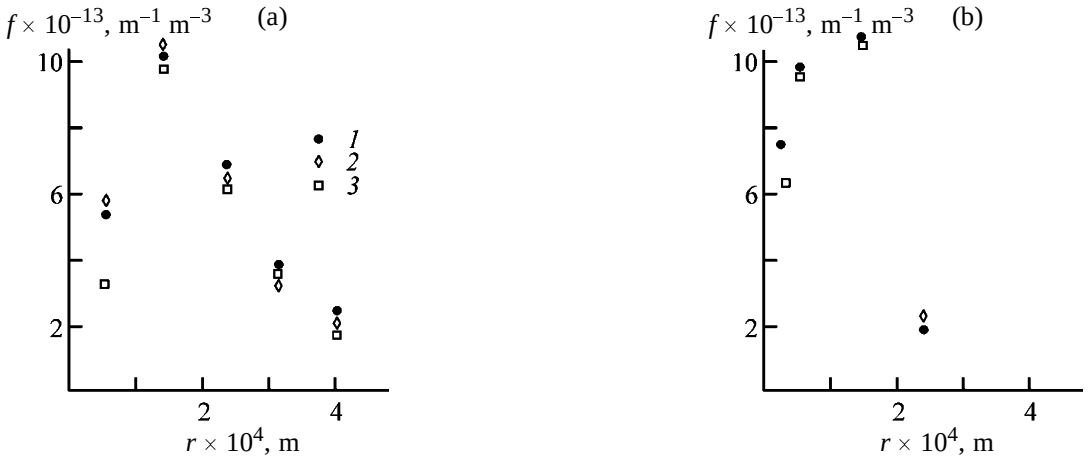

Fig. 1. Density of the distribution function f of crystals over size r in isothermal crystallization of (a) sodium chloride and (b) calcium formate. Crystallization modes for sodium chloride and potassium formate, respectively: suspension flow rate at the outlet, 0.43×10^{-3} and 1.0×10^{-3} m^3 h^{-1}; γ, 1.44 and 1.4; pressure, 0.009 and 0.017 MPa; temperature difference between the heat-exchange wall and the mass in crystallization, 15 and 12°C; and water evaporation rate, 0.19×10^{-3} and 0.25×10^{-3} m^3 h^{-1}. (*1*) Experiment; calculation by Eqs. (*2*) (7)–(10) and (*3*) (11) and (12).

tal growth rate $\eta = 8.1 \times 10^{-8}$ m s^{-1}. These values are close to published data [9], which indicates that the method and model are adequate. If the kinetic parameters are calculated by Eqs. (11) and (12) with the region in which the growth rate of crystals depends on their size disregarded, then, as follows from Fig. 1a, the disagreement between the calculation and the experiment for the fraction $r < \sim 0.1 \times 10^{-3}$ m grows, with the calculated density of the nucleation function increasing by an order of magnitude. However, taking into account the relatively insignificant contribution from the size of these crystals to the overall balance, solutions (11) and (12) to the model of CSDF can be used to make the calculations simpler.

The method was applied to a study of the kinetics of crystallization in manufacture of ultrapure calcium formate, which is used in electronics, radio engineering, and instrument making. Figure 1b shows as an example the experimental and calculated dependences of the CSDF density for a mode of crystallization of calcium formate. The disagreement between the experiment and the calculation did not exceed ±8.9%.

The kinetic parameters for this mode of crystallization of calcium formate are as follows: nucleation function density $f_0 = 2.5 \times 10^{13}$ m^{-1} m^{-3}, crystal growth rate $\eta = 0.12 \times 10^{-7}$ m s^{-1}.

CONCLUSIONS

(1) A cell model of the process of crystallization in a flow-through cell with nonideal mixing was constructed. The equations of the model for the density of the crystal size distribution function were solved for any crystal size, including the region at Re < 1, in which the crystal growth rate may depend on the crystal size.

(2) The method was tested in a study of the kinetics of mass crystallization from solutions of sodium chloride and calcium formate.

Abstract—The possibilities of improving operation of one-zone autoclave and tubular reactors using appropriate initiating systems without changes in the reactor design and process scheme were analyzed and experimentally tested on pilot and industrial installations for high-pressure polymerization of ethylene.

Despite rapid development of processes for catalytic polymerization of ethylene at low pressures in the gas phase and solution, high-pressure polymerization of ethylene is still of industrial importance. At present, nearly 25% (~22 million tons per year) of the total production volume of polyolefins (~84 million tons) is produced using high-pressure autoclave and tubular reactors. Thus, the improvement of operation of reactors for high-pressure polymerization of ethylene, especially without changes in the reactor design and process scheme, is an urgent problem.

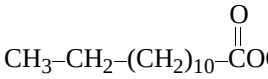
In this paper we analyzed the possibility of improving the operation of high-pressure autoclave and tubular reactors without changes in the reactor design and process scheme, on the basis of the analysis of the operation conditions and mechanism of polymerization as influenced by various initiating systems (peroxides and their mixtures, and mixtures of peroxides and oxygen).

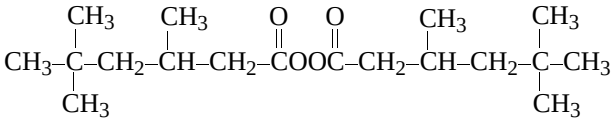
The structure of peroxide initiator determines its important properties and feasibility of its use [1–3]. The later notion involves: (1) kinetic characteristics, operation temperature range, and performance; (2) solubility in oils (hydrocarbons) and thus simplicity of supply into the reactor; (3) absence of corrosion effect on the installation; (4) safe use and storage; and (5) hygienic, sanitary, and toxicological properties.

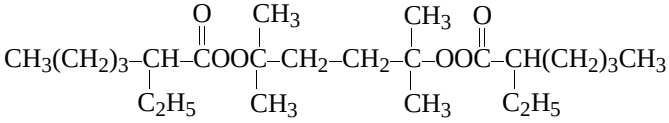
These requirements were used in selection of peroxides recommended for high-pressure polymerization of ethylene by the producer of peroxides, Akzo Nobel Company [3].

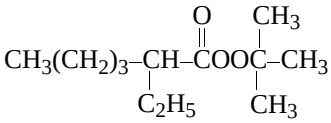
However, even for this group of reagents the operation parameters and conditions providing the most efficient use of peroxide, taking into account the specific consumption and quality (amount of extractable impurities) and assortment of the products, should be tested experimentally. This especially concerns the use of peroxide mixtures in autoclave reactors and mixtures of peroxides and oxygen in tubular reactors.

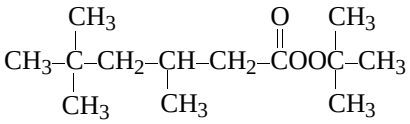
The data on the optimal use of peroxides in one- and two-zone industrial reactors of autoclave type (ideal mixing reactors) with production capacity from 16 to 20 thousand tons per year are given below.

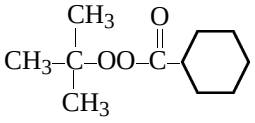


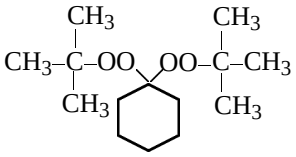


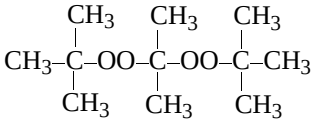


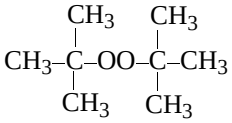












AUTOCLAVE REACTORS

Initiator performance. In our work we tested nine peroxy initiators; data on their initiation power are listed in Table 1.

As seen, the specific consumption of initiators decreases on passing from low-temperature (Tr-36) to high-temperature (Tr-B) peroxides. Only two peroxides do not obey the general trend toward a decrease in the specific consumption with increasing temperature: Tr-D initiator with very high performance in the corresponding temperature range and Tr-C initiator with increased specific consumption, which is due to its use in industrial reactors at temperatures higher then the optimum to provide the process stability. With increasing temperature of the reaction mixture, the generation of heat decreases and the temperature in the reaction zone begins to decrease, i.e., the process passes to the self-control mode. Specifically this operation mode is used with Tr-C initiator (240–255°C).

Table 1. Specific consumption of peroxides per ton of polyethylene (PE) in industrial and pilot installations, as influenced by their structure

Initiator brand	Structure	Specific consumption per ton of polyethylene	
		kg	mol
Laurox		5–6	12.5–15.0
Trigonox-36 (Tr-36)		2.5	8.0
Trigonox-141* (Tr-141)		2.4	5.5
Trigonox-21 (Tr-21)		0.6	2.8
Trigonox-42 (Tr-42)		0.4	1.7
Trigonox-C (Tr-C)		0.35–0.5	1.8–2.5
Trigonox-22* (Tr-22)		0.47	1.8
Trigonox-D* (Tr-D)		0.14–0.24	0.6–1.0
Trigonox-B (Tr-B)		0.10–0.15	0.65–1.03

* Bifunctional peroxide.

Low activity of Laurox is due to its poor solubility. As a result, this initiator is only rarely used in reactors for ethylene polymerization.

We analyzed the operation of various autoclave installations for production of polyethylene with a melt flow index (MFI) of 2 g/10 min with the most widely used and available Tr-C initiator.

Amount of extractable impurities in polyethylene as influenced by Trigonox-C peroxy initiator. The data on the amount of extractable impurities in

* Low-molecular-weight impurities (such as oil or oligomers) remaining in polyethylene.
** Peroxide added into the top/bottom section of the reactor.

polyethylene prepared in a one-zone industrial autoclave reactor at various initiating modes using Tr-C, Tr-B, and Tr-42 are listed in Table 2.

In some experiments, the oil (solvent for initiator) was replaced by isododecane (IDD) to exclude the transfer of oil-solvent into the extractable impurities, because IDD dissolves in ethylene in the low-pressure separator and does not remain in the polymer. In this case, the fraction of oil in the total amount of extractable impurities is about 30% of its specific consumption.

The correlation of the specific consumption of Tr-C initiator X and the residual content of extractable impurities in polyethylene A, which was calculated as the difference between the total content of extractable compounds E and amount of extractable compounds originating from the oil solvent ($0.3G$) is shown in Fig. 1.

As seen from Fig. 1, the residual content of extractable impurities linearly depends on the specific consumption of Tr-C initiator, and with a change in the specific consumption of Tr-C initiator by 0.1 kg per ton polymer the content of extractable impurities changes by 0.1 wt %. When the consumption of Tr-C initiator is close to 0, the content of extractable impurities decreases to 0.25–0.30 wt %, which is probably due to the contamination of the polymer with oil from compressors.

Table 2 shows that the Tr-C + Tr-42/Tr-C + Tr-B and Tr-C + Tr-42/Tr-B (run nos. 3, 8) systems provide the greatest increase in the process efficiency with simultaneous decrease in the content of extractable impurities.

Process improvement and increase in the product assortment using one-zone industrial autoclave reactor. The one-zone autoclave allows synthesis of polyethylene with MFI > 1 g/10 min, whereas preparation of polyethylene with MFI < 1 g/10 min requires a two-zone autoclave reactor with low operation temperature in the upper zone (<200°C) in which low-temperature peroxide initiators of Tr-36 type are used.

To make possible preparation of polyethylene with MFI < 1 g/10 min in a one-zone autoclave, the temperature in the top section of the reactor should be decreased, i.e., a relatively low-temperature peroxide should be used in this section. However, due to the rapid temperature increase along the reactor profile in the top section of the reactor, this peroxide will lose

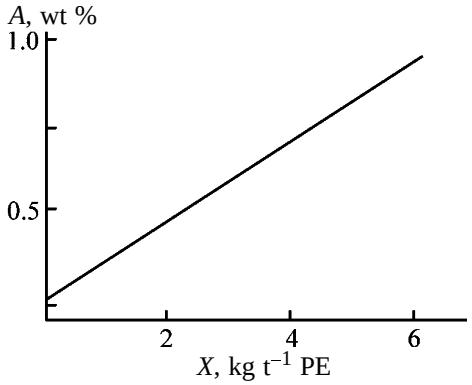

Fig. 1. Content of extractable impurities in polyethylene A as influenced by the specific consumption of Tr-C initiator X.

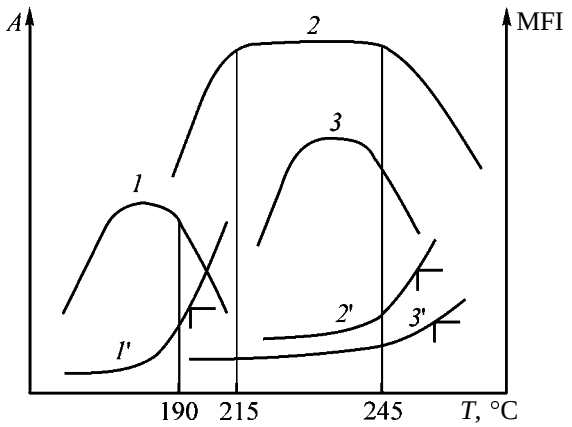

Fig. 2. (*1–3*) Polyethylene yield *A* and (*1'–3'*) MFI as influenced by temperature *T*. (*1, 1'*) Tr-36, (*2, 2'*) Tr-D, and (*3, 3'*) Tr-C.

the performance and decrease the molecular weight of the resulting polyethylene, i.e., will increase its MFI.

This process is schematically shown in Fig. 2 presenting the temperature dependences of MFI and specific consumption, determined for three peroxides.

In general, the use of each peroxide in the temperature range providing the highest yield of polyethylene seems to be optimal. However, monoperoxides are characterized by very narrow temperature range of the maximal polyethylene yield, and industrial operation in such a narrow range is very difficult and fraught with the loss of the temperature stability of the process. The loss of the temperature stability is related to the fact that, with changes in temperature in the reaction zone, the specific yield will always decrease [4, 5].

With decreasing temperature of the reaction medium, the rates of polymerization and heat release both decrease, and the temperature of the reaction zone also decreases. As a result, further decrease in the heat release and temperature are observed, which can cause the process termination (heat "removal" from the reaction zone by flow of cold ethylene supplied into this section of the reactor).

The temperature dependences of the PE yield and MFI (Fig. 2) show that bifunctional peroxide Trigonox-D allows preparation of polyethylene with low MFI and maximal specific yield in a fairly wide temperature range. Thus, Trigonox-D can be used in the top section of the one-zone reactor for process initiation at temperatures from 215–218 to 240–245°C to prepare polyethylene with a low MFI and the highest yield in this reactor section. As a result, the assortment of polyolefins prepared in the one-zone reactor can be expanded up to production of polyethylene with MFI of 0.2–0.3 g/10 min.

The experimental results obtained using industrial one-zone reactors are as follows.

(1) The use of polymerization initiator Tr-D provides easy start of the process, stability of its operation, and production of polyethylene with MFI from 0.3 to 2.0 g/10 min.

(2) When preparing polyethylene with MFI of 2 g/10 min, replacement of Tr-C by Tr-D initiator decreases the consumption of the initiating system (recalculated to 100% initiator) by a factor of 1.6 with preservation of all the operation parameters.

(3) Replacement of Tr-C + Tr-B by Tr-D + Tr-B mixture in the top and bottom sections of the reactor decreases the specific consumption of Tr-D peroxide by a factor of 2.1–2.6 as compared to Tr-C initiator; simultaneously, the specific consumption of Tr-B initiator decreases by a factor of 1.5.

(4) The use of Tr-D initiator in the top section and Tr-D peroxide or Tr-D + Tr-B mixture in the bottom section allows the pressure in the reactor to be decreased from 1440–1470 to 1290 kgf cm^{-2}, i.e., by 150–180 kgf cm^{-2}.

(5) The use of Tr-D + Tr-B and Tr-C + Tr-B mixtures in the top and bottom sections of the reactor increases the conversion, which (due to the temperature decrease in the top section and its increase in the bottom section) increases by 15 rel % the installation capacity in production of 10 803-020 brand polyethylene with MFI of 2.0 g/10 min.

The results obtained in comparative analysis of mono- and bifunctional peroxides showed that Tr-D peroxide is a promising initiator, providing lower specific consumption in wider ranges of initiation temperatures (in comparison with kinetically similar monoperoxides) and allowing preparation of polymers with a higher molecular weight. These data were confirmed experimentally using pilot setup and industrial installations with one-zone autoclave reactors.

TUBULAR REACTORS

The use of oxygen as initiator is well known. The disadvantages of the oxygen initiation are as follows.

(1) The use of oxygen as polymerization initiator almost excludes the possibility of control of the reaction temperature. Only maximal temperatures can be corrected, because of long dead time (7–15 min) for

oxygen transport from the dosing unit to the active zone of the reactor.

(2) Since preheating of the reaction mixture to relatively high temperatures (190–205°C) is necessary for the oxygen initiation of polymerization, fairly long sections are required for heating of the reaction mixture, with partial pressure loss in these sections. In this case, heating of the mixture to 150–180°C proceeds at low initiating activity of oxygen with formation of small amounts of the polymer with very high molecular weight, which condenses on the colder walls of the reactor. This decreases the heating rate of the reaction mixture and, as a rule, decreases the quality of the final product.

(3) Maintenance of the prescribed temperature ranges of the reaction mixture in various sections of the multizone reactor requires a complex system to control the oxygen concentration in the system of interconnected sections of the reactor, when any change in the oxygen concentration in a certain section requires the corresponding correction both in the total amount of oxygen supplied and in its distribution in the reactor zones.

(4) Relatively high temperature for initiation "start" decreases possible conversion and, thus, performance characteristics of the process.

Temperature profile of the reaction medium along a tubular reactor at oxygen initiation. Polymerization in a tubular reactor can proceed at variation of certain process parameters, including the temperature of the heating water.

In Fig. 3 we show the temperature profiles in the first zone of a tubular reactor differing in the temperature of the heating water: (*1*) 217–220°C, mode 1; (*2*) 205°C, mode 2; and (*3*) 195°C, mode 3.

As seen, heating of the reaction mixture to temperatures lower than 190°C proceeds linearly, i.e., the temperature of the reaction mixture is determined by the temperature of the heating water. This fact suggests very low rate of oxygen initiation at temperatures lower than 190–195°C. If in this temperature range the reaction mixture still receives sufficiently much heat from the heating water (mode 1), then the sum of this quantity with the heat of polymerization is sufficient to provide significant increase in the polymerization rate.

However, if the temperature of the heating water is close to the above temperature range (modes 2 and 3), then the amount of heat received from the heating water becomes insignificant, and further heating of the reaction mixture is due only to the heat of polymerization. We can conclude that the temperature at which the polymerization rate starts to increase (start temperature) is inversely proportional to the temperature of the heating water.

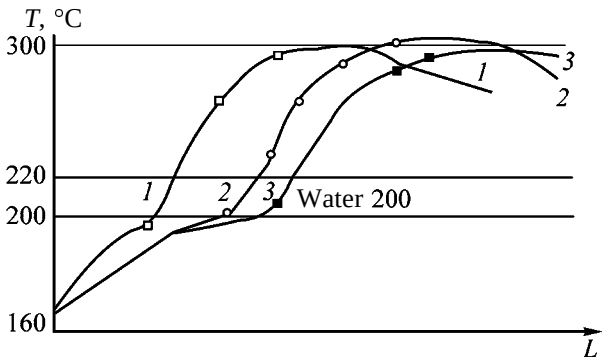

Fig. 3. Temperature profile of the reaction mixture *T* along the tubular reactor length *L* as influenced by the temperature of the heating water; pure oxygen initiation. Heating water temperature, °C: (*1*) 217–220, (*2*) 205–207, and (*3*) 195–197.

Further analysis of the temperature dependences (Fig. 3) shows that, after reaching the start temperatures in all of the above experimental modes, the polymerization rate and temperature of the reaction mixture sharply increase, and the rate of temperature increase is independent of the start temperature.

To decrease the length of the section for preheating of the reaction mixture to the temperatures of the oxygen initiation start and to eliminate the negative effect of hot water in the temperature range from 155–160°C to 225°C, additional heat supply using peroxy initiation systems is required.

In contrast to the oxygen dosing, solutions of peroxy compounds can be supplied in required amounts independently of the ethylene supply directly in any section of the reactor with very short dead time (several seconds). Various low-viscosity hydrocarbons from isododecane to oils of Risella-17 type are used as solvents for peroxides.

A feature of using peroxy initiators in tubular reactors is relatively narrow temperature range of efficient initiation, i.e., the temperature interval where the specific consumption of the given peroxide is minimal.

The specific consumption of peroxides in ethylene polymerization in autoclave and tubular reactors at operation in the temperature ranges of efficient initiation are listed in Table 3.

Table 3. Specific consumption of peroxides at optimal temperatures of initiation of ethylene polymerization

Initiator	*T*, °C	Specific consumption per ton polyethylene					
		autoclave reactor			tubular reactor		
		kg	mole	available O_2	kg	mole	available O_2

Trigonox-42	215	0.44	1.9	15			
Trigonox-C	230	0.39	2.0	15	0.7	3.0	20
Trigonox-B	255	0.15	1.0	10			

Polymerization of ethylene with oxygen and peroxide initiation. The combined oxygen and peroxide initiation allows improvement of polyethylene polymerization in tubular reactors.

The use of low-temperature peroxy initiator at temperatures at which the initiating activity of oxygen is very low does not noticeably affect the efficiency of oxygen initiation, but the temperature profile will shift toward the zone start due to more rapid heating of the reaction mixture to the temperatures of the start of the oxygen initiation. This assumption was confirmed experimentally on an industrial tubular reactor using various systems of initiation of the ethylene polymerization in the first and second zones of the reactor. The temperature profiles of three modes of initiation studied are shown in Fig. 4.

Profile *1* in the first and second zones of the tubular reactor corresponds to the conditions of initiation using only oxygen in each section. The maxima of the temperature profiles are shifted to the end of each zone. Owing to the restrictions on the temperature of the reaction mixture at the outlet from the second zone, the temperature at the inlet of this second zone is increased to 225°C; as a result, the maximum of the temperature profile still more shifts toward the zone end and the temperature at the outlet exceeds the permissible range. Under the process conditions corresponding to profile *1*, conversion reaches only 19%.

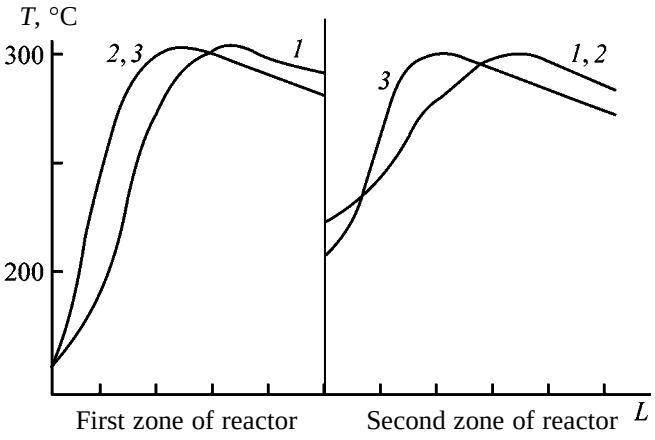

Fig. 4. Temperature of the reaction mixture *T* along the tubular reactor length *L* as influenced by initiation system. (*1*) Pure oxygen initiation in both zones, (*2*) Tr-36 and oxygen in the first zone and only oxygen in the second zone, and (*3*) Tr-C + Tr-36 and oxygen in the first zone and Tr-C and oxygen in the second zone.

Profile *2* was recorded at initiation using oxygen and Trigonox-36 peroxide in the first zone and only oxygen initiation in the second zone. In this case, the amount of oxygen supplied into the first and second zones of the reactor is similar to that used at pure oxygen initiation (profile *1*). In the first zone, the maximum in the temperature profile shifts to the zone start by 80–100 m, and the temperature at the first zone outlet decreases by 10°C. To maintain the required temperature at the inlet into the second zone, 225°C, the temperature of the ethylene flow supplied into the second zone should be increased to 150°C. Under these conditions, maximal temperatures in the first and second zones of the reactor are close to those observed at pure oxygen initiation (profile *1*).

As a result, te conversion increased by 2% and reached 21%. The consumption of Tr-36 per ton PE was about 2.6 kg.

Thus, a combination of low-temperature peroxide and oxygen initiation shifts the temperature profile toward the zone start, increases the polymer yield in the low-temperature initiation region (conversion increases by ~ 1%), and allows the polymerization to be performed locally in the low-temperature section without affecting the temperature of the reaction mixture in the remaining volume.

The use of a single low-temperature peroxide in the

first zone of the tubular reactor is a necessary but insufficient condition at low temperature of heating water (180–185°C). This water temperature allows the temperature difference between the reaction mixture and heat carrier to be increased by 20–30°C, thus enhancing the heat removal and increasing the conversion by ~1.5%. Efficient initiation should also be provided in the temperature range from 180 to 215–240°C, and this problem can be solved with peroxy initiators of Tr-21, Tr-C, and Tr-D types.

Temperature profiles *3* correspond to the combined use of oxygen and peroxide initiation in both reactor zones. In our case, along with oxygen we used Tr-36 + Tr-C mixture and Tr-C peroxide in the first and second zones of the reactor, respectively.

To provide similar temperature range in all the modes studied, in this process mode the oxygen supply in each section was decreased by 20%.

The temperature profile in the first zone remained unchanged in comparison with the process using a combination of Tr-36 and oxygen (profile *2*), i.e., Tr-C initiated polymerization and partially replaced oxygen initiation at relatively low temperatures (up to 25°C).

The use of Tr-C in the second zone allowed a decrease both in the oxygen supply and in the temperature at the inlet in the second zone (from 225 to 213°C), thus shifting the maximum in the temperature profile toward the start of this zone by almost 200 m.

In this case (profile *3*), the conversion was about 23%, i.e., 4% greater than at oxygen initiation (profile *1*).

The consumption of Tr-C per ton of additionally prepared PE was 1.0–1.2 kg.

Thus, the use of mixtures of Trigonox-21 and Trigonox-36 type peroxides in the first zone of a tubular reactor at a relatively low temperature (180–185°C) of heating water provides optimal operation conditions of the tubular reactor with simultaneous increase in the absolute capacity with respect to polyethylene by more than 5 abs. %.

CONCLUSION

Theoretical assumptions and experimental data show that the correct selection of the peroxy initiator significantly improves the efficiency of both autoclave and tubular reactors in production of polyethylene at high pressures.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Preparative Synthesis of Vanillin and Vanillal Alkanoates

Abstract—Procedures for preparing vanillin and vanillal alkanoates were developed.

Vanillin (4-hydroxy-3-methoxybenzaldehyde, **Ia**) and its homolog, vanillal (4-hydroxy-3-ethoxybenzaldehyde, **Ib**) are widely used in food and perfume industries [1–3]. Vanillin can also be used as a synthetic precursor of biologically active substances [4, 5]. However, new processes in food industry demand new aroma chemicals that would have vanilla smell but be more heat-resistant than vanillin and stable in a wide range of pH in the presence of enzymes. These requirements stimulate chemists to prepare new vanillin and vanillal derivatives; many of them appeared to exhibit stronger vanilla smell, compared to the initial compounds, with diverse tints.

Here we report convenient synthetic routes to vanillin (**IIa**–**IIm**) and vanillal (**IIIa**–**IIIg**) esters.

II a–m, III a–g

II, R = Me, R' = H (**a**), Me (**b**), Et (**c**), Pr (**d**), Me_2CH (**e**), Bu (**f**), Me_2CHCH_2 (**g**), C_5H_{11} (**h**), C_6H_{13} (**i**), C_7H_{15} (**j**), $C_{12}H_{25}$ (**k**), CH_2Cl (**l**), 4-$MeC_6H_4O(CH_2)_2$ (**m**); **III**, R = Et, R' = H (**a**), Me (**b**), Et (**c**), Pr (**d**), Me_2CH (**e**), Bu (**f**), Me_2CHCH_2 (**g**).

Some of them were characterized [6–13], but the lack of some esters in the homologous series of the vanillin and vanillal derivatives and incompleteness of the available physicochemical data for the previously described compounds stimulated us to make this study, aimed to develop new flavor additives derived from vanillin and vanillal.

The formates were prepared by the reactions of vanillin **Ia** and vanillal **Ib** with formic acid in the presence of dicyclohexylcarbodiimide [14], which is a simpler procedure compared to the known routes [11]. The other esters **IIb**–**IIm** and **IIIb**–**IIIg** were prepared by reactions of **Ia** and **Ib** with alkanecarboxylic acid chlorides in the presence of pyridine [15, 16]. To simplify the production process and improve the purity of the target products for their use in formulations for perfume and food industry, the esters were also prepared by the Schotten–Baumann reaction [9, 17]. The resulting esters **IIb**–**IIe** and **IIIb**–**IIIe** (Tables 1, 2) do not require additional purification. They are free of benzene and pyridine impurities and can be directly used in the perfume industry.

The organoleptic assessment of the scents of **IIa**–**IIg** and **IIIa**–**IIIg** was made by the Tasting Council at the Accredited Checkout and Analytical Laboratory of the Tereza Inter Limited Liability Company (Moscow, Russia). Esters **IIa**–**IIg** and **IIIa**–**IIIg** have pronounced vanilla smell with various intense tints (Table 3). Esters **IIh**–**IIm** have no odor.

EXPERIMENTAL

The IR spectra of the compounds were recorded on a Protege-460 IR Fourier spectrometer (Nicolet) from the samples prepared as thin films or KBr pellets; the UV spectra, on a Specord UV-Vis spectrophotometer from 1×10^{-4} M solutions in 1-butanol; the ^1H NMR spectra, on a BS-587A spectrometer (100 MHz, Tesla) from 5% solutions in $CDCl_3$, with octamethyltetracyclosiloxane as internal reference; and the mass spectra, on a Chrommas GC/MS Hewlett–Packard 5890/5972 gas chromatograph–mass spectrometer equipped with an HP-5MS column, at an ionizing electron energy of 70 eV.

Alkanecarboxylic acid chlorides were prepared by refluxing the corresponding carboxylic acids with a 1.5-fold excess of $SOCl_2$ in benzene.

Vanillin and vanillal formates IIa and IIIa. A 0.12-mol portion of 99% formic acid was added to a solution of 0.1 mol of **Ia** or **Ib** and 0.1 mol of dicyclohexylcarbodiimide in 500 ml of absolute benzene. The mixture was stirred and kept at 20–23°C for 24–36 h. The dicyclohexylurea precipitate was filtered off and washed with 100 ml of benzene; the filtrate was washed with water and saturated aqueous $NaHCO_3$. The benzene solution was dried over $CaCl_2$, the solvent was distilled off, and the residue was recrystallized from methanol.

Vanillin and vanillal alkanoates IIb–IIm and IIIb–IIIg. A 0.25-mol portion of anhydrous pyridine was added to a solution of 0.2 mol of vanillin **Ia** or vanillal **Ib** in 500 ml of anhydrous CH_2Cl_2, and 0.2 mol of appropriate alkanecarboxylic acid chloride was added in small portions, with stirring by shaking the reaction flask. The mixture was refluxed for 1 h, the solvent was distilled off by heating on a water

Table 3. Results of organoleptic assessment of the smell of esters **IIa–IIg** and **IIIa–IIIg**

Ester	Smell
IIa	Vanilla, wood, with powder tint
IIb	Vanilla-wood, with clove-spicy tint
IIc	Vanilla, honey
IId	Cream-milk, vanilla
IIe	Chocolate-vanilla, cream
IIf	Vanilla-rum, with cream tint
IIg	Vanilla-rum, with fruit tint
IIIa	Wood, vanilla, with spicy tint
IIIb	Vanilla-flower, with honey tint
IIIc	Vanilla-honey, with wood tint
IIId	Cream-vanilla, with baked milk tint
IIIe	Vanilla-cream, with white chocolate tint
IIIf	Vanilla-rum, with cream chocolate tint
IIIg	Vanilla-fruit, with cream-clove tint

bath, and the residue was dissolved in 500 ml of benzene, washed three times with water and three times with 5% aqueous $NaHCO_3$, and dried over $CaCl_2$. The solvent was distilled off, and the residue was distilled in a vacuum (**IId**, **IIf**–**IIj**, **IIId**, **IIIf**, **IIIg**) or recrystallized from benzene–hexane (**IIb**, **IIc**, **IIe**, **IIm**, **IIIb**, **IIIc**, **IIIe**). In the case of **IIk** and **IIl**, the residue was a noncrystallizing greasy substance.

The solvents CH_2Cl_2 and C_6H_6 distilled from the reaction mixture can be reused after distillation from P_2O_5 on a Vigreux column.

Vanillin and vanillal alkanoates IIb–IIg and IIIb–IIIg. A 1-mol portion of appropriate alkanecarboxylic acid anhydride was added in small portions with vigorous stirring to a solution of 1 mol of vanillin **Ia** or vanillal **Ib** in 1.1 l of 1 N aqueous KOH. The mixture was stirred for 3–5 h and allowed to stand for 10–15 h at 20–23°C. Compounds **IIb**–**IIg** and **IIIb**–**IIIg** were isolated by filtration or decanting, washed with water, and dried in air.

CONCLUSION

A procedure was developed for preparing vanillin and vanillal alkanoates in 70–96% yield. These compounds are of interest as components of flavor food additives with popular chocolate, caramel, and milk-cream smells.

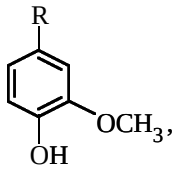
ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Acidity of Guaiacol Derivatives in Water–Acetone Mixtures

N. V. Shorina, D. S. Kosyakov, and K. G. Bogolitsyn

Arkhangelsk State Technical University, Arkhangelsk, Russia



Received April 7, 2004

Abstract—Acid ionization constants of the phenolic hydroxy groups of guaiacol derivatives in water–acetone mixtures were determined. The acidity of these phenols was analyzed in relation to both the acetone content in the mixed solvent and kind of *para*-substituent.

Neat acetone and water–acetone mixtures are promising solvents for cooking of wood and modification of commercial lignin [1–3]. However, the solvent effect on the protolytic properties of phenol-containing structural units of lignin, mainly governing their reactivity, is poorly understood. In order to characterize the lignin reactivity, data on the acidity of its separate structural fragments in aqueous and aqueous–organic media are required [4].

In this work we studied the acidity of phenolic hydroxy groups of a series of guaiacol derivatives in water–acetone mixtures. The most reliable data on protolytic equilibria in solutions can be obtained by potentiometric titration with a glass electrode and by UV spectrophotometry [1, 3, 5–7]. However, the spectrophotometric determination of pK_a of phenols in water–acetone mixtures is impossible since the absorption bands of phenols and acetone (<300 nm) overlap [8]. Therefore, in this work pK_a of phenolic hydroxy groups was determined by potentiometric titration with an aqueous base using a glass electrode [11].

In this work we studied the acidity of nine guaiacol derivatives modeling certain structural fragments of coniferous lignin containing substituent R in α-position to the propane chain in the lignin structure:

where R = H (guaiacol), CH_3 (creosol), COH (vanillin), $COCH_3$ (acetovanillone), CH=CHCH (isoeugenol), $CH_2CH=CH_2$ (eugenol), CH=CHCOOH (ferulic acid), COOH (vanillic acid), and CH_2OH (vanillic alcohol).

All the guaiacol derivatives were of pure grade (Aldrich). Acetone, chemically pure grade (Ekros), was used without additional purification.

In our experiments, the acidity of guaiacol derivatives was studied using their 0.01 M solutions in water–acetone mixtures. 20% aqueous tetraethylammonium hydroxide (Merck) was used as titrant. The potentiometric titration of aqueous-acetone solutions of guaiacol derivatives was carried out under argon with continuous stirring in a temperature-controlled glass cell at 25 ± 0.1 °C. pH was measured on an Ekspert-001 (Ekoniks–Ekspert, Moscow) pH-ionometer equipped with an ESL-63-07 glass electrode and an EVL-1-M3 silver chloride electrode. This device was calibrated relative to aqueous reference solutions immediately before measurements. pK_a was determined in each point of the titration curve by the equation

$$pK_a = pH + \log[(V_e - V)/V],$$

where pH is the measured pH value in each point along the titration curve up to an equivalent point; V_e, equivlent volume of titrant; and V, added titrant volume.

The averaged experimental pH values of aqueous-acetone solutions of guaiacol derivatives were recalculated to the negative logarithm of the proton activity pa_{H^+} relative to the proton activity in the infinitely dilute aqueous-acetone solution as standard state. This recalculation was carried out using the correction factor δ [12] taking into account both the interface electrochemical potential at the boundary between aqueous and nonaqueous solutions and the free energy of proton transfer from aqueous to aqueous-acetone solution:

$$pa_{H^+} = pH - \delta.$$

The curves of potentiometric titration of weakly acidic phenols have a smeared equivalence point due to strong hydrolysis of the phenolate anions. This fact hinders the determination of the acid ionization constants of phenols. Therefore, for eugenol, vanillic

* Numerator refers to experimental pK_a, and denominator, to pK_a calculated by the Henderson equation.

alcohol, isoeugenol, guaiacol, and creosol, the equivalent titrant volume was determined by calculation. The pH values were calculated from the results of no less than 2–3 replicate determinations. The determination error did not exceed 0.05 pK_a unit.

To determine K_a more reliably, this factor was independently calculated by Henderson's method [13] based on comparative determination of the acidity of the substance under consideration and some reference substance:

$$pK_{a(X)} = pK_{a(HBz)} + (E_{1/2(X)} - E_{1/2(HBz)})/0.059 = pK_{a(HBz)} + pH_{1/2(X)} - pH_{1/2(HBz)},$$

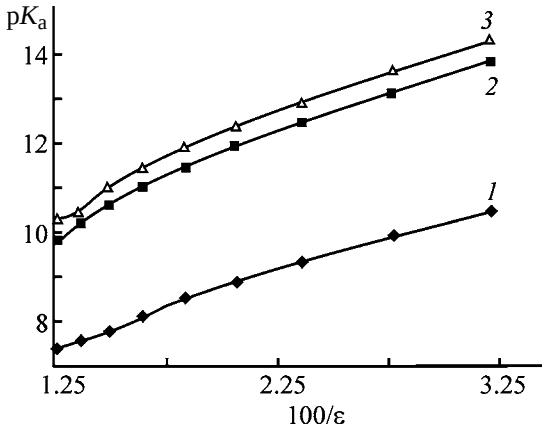

Fig. 1. Plot of pK_a of the phenolic hydroxy groups of guaiacol derivatives vs. the reciprocal permittivity ε of water–acetone mixtures: (*1*) vanillin, (*2*) vanillic alcohol, and (*3*) creosol. The same for Figs. 2 and 3.

where $E_{1/2}$ and $pH_{1/2}$ are the electrode potentials and pH of half-neutralization of the compound X being studied and the reference compound (benzoic acid HBz in our case) in water–acetone mixture.

The pK_a of benzoic acid within the entire range of acetone concentrations was calculated by the Harned–Robinson equation using the coefficients reported in [14].

EXPERIMENTAL

The pK_a values of the guaiacol derivatives in their aqueous-acetone solutions, obtained in our experiments, are listed in Table 1. The maximal difference between the experimental and calculated pK_a was 0.2.

Table 1 shows that, with an increase in the acetone mole fraction in aqueous-acetone solution, the acidity of guaiacol derivatives decreases (acid ionization constants decrease by 3–4 orders of magnitude). This is caused by a change in the free energy of solvation of both the nondissociated guaiacol derivatives and their ionized species in going from aqueous to aqueous-acetone solutions.

In order to elucidate how guaiacol derivatives are solvated in aqueous-acetone solutions, pK_a of phenolic hydroxy groups and carboxy groups was analyzed in relation to physicochemical parameters of water–acetone solvent characterizing its specific and nonspecific interactions with the solute. Figure 1 shows the dependence of pK_a of the phenolic hydroxy groups

of three guaiacol derivatives on reciprocal permittivity of water–acetone solvent. The guaiacol derivatives used in this experiment differ in the kind of substituents located *para* to the phenolic hydroxy group and are typical of the lignin molecular structure [15, 16].

According to the Brønstedt theory [17, 18], the effect of solvent on pK_a of acid is completely determined by electrostatic characteristics of acid molecule irrespective of its chemical composition. Therefore, in the absence of specific interaction between the acid and solvent, pK_a should be a linear function of 1/ε [18]. However, we found that the linear correlation between pK_a of phenolic hydroxy groups of the guaiacol derivatives in their aqueous-acetone solutions and 1/ε is observed only within a limited range of acetone content. This fact shows that the specific interactions of phenols with the solvent contribute to solvation. Therefore, in analysis of the influence of mixed water–acetone solvent on the acidity of phenolic hydroxy groups, the chemical features of the solvent components should be taken into account.

Figure 2 shows the plot of pK_a of the phenolic hydroxy groups of guaiacol derivatives vs. the Dimroth–Reichardt parameter E_T^N reflecting the electron-acceptor power (acidity) of water–acetone mixture. Figure 3 shows the plot of pK_a vs. B_{KT} parameter characterizing the electron-donor power (basicity) of water–acetone solvent [19].

These plots show that, with increasing E_T^N, the acid ionization constants of phenols increase nonlinearly (Fig. 2), and at the acetone content exceeding 60% the correlation between pK_a and B_{KT} is lacking (Fig. 3).

These results suggest that phenolic groups of the guaiacol derivatives are solvated in water–acetone mixtures due to both specific and nonspecific interactions with the solvent molecules. The similar pattern was observed for DMF and DMSO in water–aprotic solvent mixtures [10].

This multimode solvation of the guiacol derivatives in water–acetone mixtures is confirmed by the fact that pK_a of phenolic hydroxy groups of these model compounds is a linear function of the acetone mole fraction in water–acetone mixture (correlation factor 0.97–0.99) (Fig. 4). This correlation shows that the phenols under consideration are similarly solvated with water and acetone molecules in water–acetone mixtures [20].

We found that the effect of nonaqueous solvents on the acidity of guaiacol derivatives depends on the kind of *para*-substituent. The pK_a values of guaiacol derivatives containing nonolar *para*-substituent (eugenol, guaiacol, creosol) are the most sensitive to the composition of water–acetone solvent. The minimal effect of solvent composition on pK_a is observed with electron-acceptor substituents (vanillin, acetovanillone).

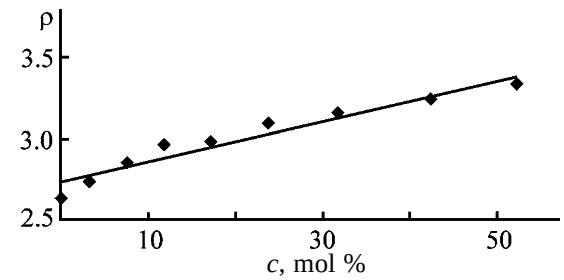

Fig. 6. Plot of the the sensitivity factor ρ vs. acetone content *c* in water–acetone mixtures at 25°C.

It is known that the slope of the plot of pK_a of acid in nonaqueous solvent (S) vs. pK_a of the same acid in aqueous solution characterizes the differentiating effect of the solvent on the acid strength: the larger the slope, the stronger the differentiating effect of the solvent [1].

By analysis of data on acid ionization constants of phenols in water–acetone mixtures and those in aqueous solutions [21], Ermakova *et al*. found that these data can be correlated by an empirical equation pK_a(S) = apK_a(H_2O) + b [22, 23]. This equation allows calculation of pK_a of phenol in nonaqueous solvent if its pK_a in aqueous solution is known. We can also determine pK_a of any water-insoluble phenol through its pK_a in nonaqueous solvent. Furthermore, the coefficients *a* and *b* in this equation allow quantitative characterization of the differentiating effect of aprotic solvents and their aqueous mixtures on acidity in some series of phenols [24] (Table 2).

Figure 5 shows that, within the limits of the determination accuracy, pK_a of all guaiacol derivatives under consideration is a linear function of the Hammett σ constant of their *para*-substituents [10, 25]. This correlation reflects the well-known effect of *para*-substituents on ionization of phenolic hydroxy groups described by the Hammett equation [20]

$$pK_a = pK_a^g - \rho\sigma_p,$$

where σ_p is the Hammett constant of a *para*-substituent; ρ, factor characterizing sensitivity of a given reaction to the substituent properties, and pK_a^g, ionization constant of phenolic hydroxy group of nonsubstituted quaiacol.

The sensitivity factors ρ of the phenolic hydroxy groups of guaiacol derivatives were calculated from the slope of the linear plots of pK_a vs. σ (Fig. 5). As seen from Fig. 6, the reaction factor ρ is a linear function (correlation factor 0.98) of the acetone content in water–acetone mixtures.

We believe that this correlation is caused by the following factors: (1) variation in the permittivity of mixed solvent influencing the contribution of the inductive effect of *para*-substituent to protonation of the phenolic hydroxy group; (2) change in solvation of *para*-substituents in the mixed solvents, affecting their Hammett constants [19].

CONCLUSIONS

(1) Acid ioniztion constants of phenolic hydroxy and carboxy groups of guaiacol derivatives in water–

acetone solvent were determined by potentiometric titration.

(2) pK_a of the phenolic group of guaiacol derivatives is a linear function of the acetone mole fraction in water–acetone mixtures at widely varied acetone content.

(3) pK_a of the phenolic groups of guaiacol derivatives in water–acetone mixtures is a linear function of their pK_a in aqueous solutions.

Abstract—Star-like water-soluble macromolecules with fullerene as the branching site were synthesized by the reaction of fullerene C_{60} with polyvinylpyrrolidone whose molecules contain one terminal primary amino group. The initial and C_{60}-containing polymers were studied by UV spectroscopy, thin-layer chromatography, centrifugal sedimentation, translation diffusion, and viscometry in aqueous buffer solutions. Diffusion–sedimentation and sedimentation two-detector analyses of the initial and fullerene-containing samples were performed. The molecular weights of the polymers were estimated by the Svedberg equation. The proportion of the fullerene-containing segment in the samples synthesized was determined, and the number of the branches in the fullerene-containing macromolecules was estimated.

Fullerenes have recently become a subject of active studies in macromolecular chemistry. The specific features of the chemistry of fullerenes are determined by their aromatic nature and a high symmetry. Both fullerene-containing polymers with covalently bound fullerenes and fullerene-based noncovalent complexes were synthesized [1–3]. Fullerenes and their derivatives exhibit a spectrum of biological properties. They are capable of penetrating lipid membranes and exhibit antioxidative, antimicrobial, and antiviral activities and immunomodulating properties [4–7].

The biological properties of fullerenes should be studied with their water-soluble derivatives. There are published data on water-soluble derivatives of fullerene based on hydrophilic polymers such as poly(ethylene oxide) and polyvinylpyrrolidone (PVP), prepared by radical or anionic polymerization of the corresponding monomers in the presence of fullerene [8–10], as well as on noncovalent complexes of fullerene with PVP [11, 12]. Water-soluble compounds of fullerene based on polyalkylenimines and polyoxyethylene were synthesized by polymer-analogous transformations [13, 14]. Reactions of amine-containing polymers with fullerenes represent a convenient method of synthesis of their polymeric derivatives, since primary aliphatic amino groups under mild conditions easily react with fullerenes. This procedure was used for synthesizing compounds based on polyalkylenimines, polyallylamine, and allylamine copolymers with styrene, methyl methacrylate, and hydroxypropyl methacrylate [15, 16]. The reactions of fullerenes with polymers containing one terminal amino group should yield star-like derivatives, as revealed for polystyrene, polyoxyethylene, and polyoxypropylene [17, 18].

In this work, we studied reactions of fullerene C_{60} with a water-soluble polymer, poly-*N*-vinylpyrrolidone containing a terminal amino group (PVP-NH_2). We studied the fullerene-containing and initial PVP samples by molecular hydrodynamics methods (centrifugal sedimentation, translational diffusion, and viscometry) in aqueous buffer solutions.

EXPERIMENTAL

The initial polymers PVP-NH_2 (PVP-1 and PVP-2) were synthesized as described previously in [19]. We took advantage of the capability for chain propagation in radical processes, characteristic of thiols. We subjected *N*-vinylpyrrolidone to radical polymerization in the presence of an amine-containing thiol, cysteamine hydrochloride.

Reactions of fullerene with PVP-1 and PVP-2 were carried out at room temperature in a mixed solvent (dimethylformamide–toluene) for 24 h at the $[NH_2]:[C_{60}]$ molar ratio of 1 : 1 in the case of PVP-1 and 6 : 1 in the case of PVP-2. Next, the reaction mix-

1070-4272/05/7801-0130 © 2005 Pleiades Publishing, Inc.

ture was filtered, and the solvent was removed in a vacuum. The dry residue was dried to constant weight and dissolved in water, whereupon the resulting aqueous solution was filtered. The reaction products were isolated by freeze drying.

The UV spectra were taken in chloroform on a Specord M-40 spectrophotometer.

The adsorption thin-layer chromatography (TLC) variance was carried out on Alugram Sil G/UV$_{254}$ (Macherey-Nagel, Germany) silica gel plates with toluene, chloroform, or carbon tetrachloride as eluent.

The translation diffusion coefficients were determined by recording the time dependence of the variance of the diffusion boundary of the solution with the concentration $c = 0.07 \times 10^{-2}$ g cm^{-3} on a Tsvetkov diffusometer [20] (Fig. 1). The resulting values were taken as equal to those extrapolated to zero concentration. The refractive index increments $\Delta n/\Delta c$ were determined from the area enclosed by the interference curve.

Centrifugal sedimentation was studied on MOM-3170 and Beckman XLI analytical ultracentrifuges. The sedimentation coefficient was determined in cells in which the boundary was artificially formed by depositing a layer of the solvent onto the solution with the concentration $c = 0.3 \times 10^{-2}$ g cm^{-3} at the rotor rotation rate n = 40 000 rpm (Fig. 2). The resulting values were reduced to those corresponding to zero concentration, using the relationship

$$s^{-1} = s_0^{-1}(1 + k_s c) = s_0^{-1}\{1 + (k_s/[\eta])[\eta]c\}.$$

The dimensionless parameter $k_s/[\eta]$ was taken equal to that known for flexible-chain polymers, namely, ≈1.7 [21]. In all cases, the sedimentation boundaries preserved their unimodal nature throughout the experiment (~90 min). The primary experimental data were processed using well-known procedures [20, 22, 23]. The experiments on the Beckman XLI analytical ultracentrifuge were carried out at the rotor rotation rate n = 55 000 rpm using both interference and absorption optical devices (at the light wavelength λ = 250 nm) at the concentration $c = 0.03 \times 10^{-2}$ g cm^{-3}. The data were processed using the Sedfit routine [24].

In independent experiments we determined the density increments $\Delta\rho/\Delta c$ of the initial and fullerene-containing samples (Fig. 3). The measurements were carried out on a Kratky densitometer [25] (A. Paar, Austria) at 20°C. Since the $\Delta\rho/\Delta c$ parameters for the initial and fullerene-containing PVPs are virtually

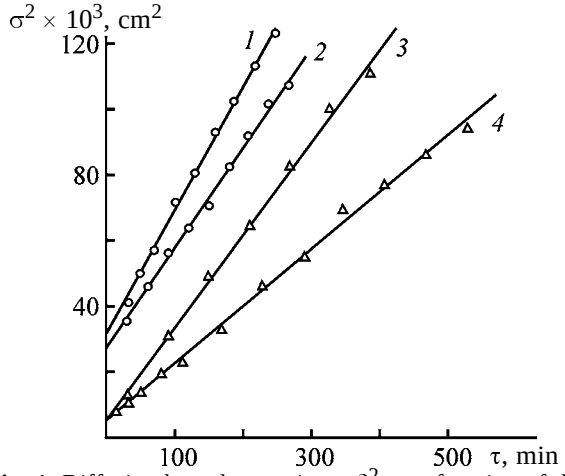

Fig. 1. Diffusion boundary variance δ^2 as a function of the diffusion time τ for the initial and fullerene-containing samples. Digits at curves corresponds to sample nos. in Table 1; the same for Fig. 2.

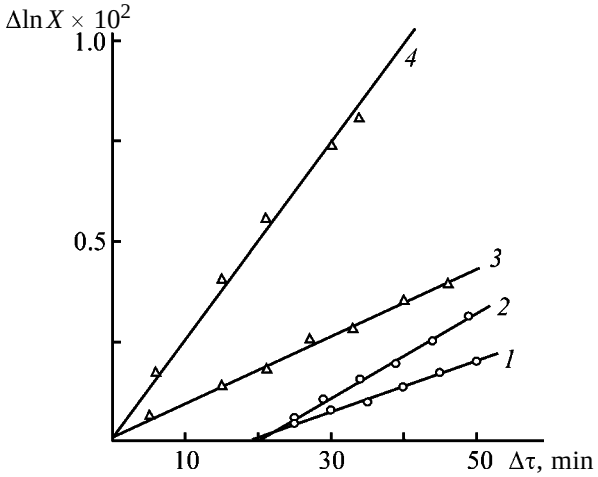

Fig. 2. Shift $\Delta\ln X$ of the sedimentation peaks obtained on a polarization interferometer (MOM 3180) as a function of the time $\Delta\tau$ for the initial and fullerene-containing samples. The sedimentation coefficient was calculated using the slope $s = \Delta\ln X/\omega^2\Delta\tau$, where $\omega = 2\pi n$.

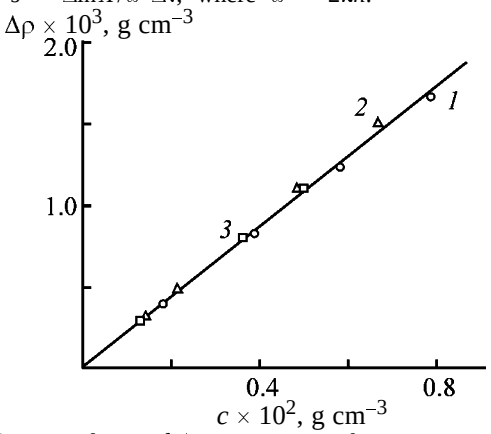

Fig. 3. Dependence of $\Delta\rho = \rho - \rho_0$ on the concentration of solution c for (*1*) the initial PVP and (*2, 3*) fullerene-containing PVPs. ρ and ρ_0 are densities, g cm^{-3}, of the solution and solvent, respectively.

Table 1. Hydrodynamic and molecular characteristics of the initial and fullerene-containing polymers in 0.1 M solution of sodium acetate at 25°C. Solvent viscosity η_0 = 0.92 cP, density ρ_0 = 1.002 g cm^{-3}, and specific partial volume of PVP $v = 0.782 \pm 0.006$ cm^3 g^{-1}

Sample no.	Polymer	$s_0 \times 10^{13}$, s	$D_0 \times 10^7$, cm^2 s^{-1}	$\Delta n/\Delta c$, cm^3 g^{-1}	$[\eta]$, cm^3 g^{-1}	k'	$M_{sD} \times 10^{-3}$	$A_0 \times 10^{10}$	M_2/M_1
1	PVP-1	0.65	15.5	0.19	6.5	0.75	4.6	3.19	–
2	PVP-1–C_{60}	1.1	12.6	0.18	5.6	1.50	9.7	3.17	2.1
3	PVP-2	0.8	11.7	0.17	9.5	0.70	7.7	3.26	–
4	PVP-2–C_{60}	2.3	7.25	0.18	12	0.65	35.7	3.64	4.6

identical, we used an average value $\Delta\rho/\Delta c = 1 - v\rho_0 = 0.22 \pm 0.01$ for further estimations.

The viscometric measurements were carried out on an Ostwald viscometer. The intrinsic viscosities $[\eta]$ and the Huggins parameters k' are listed in Table 1.

Reactions of PVP–NH_2 with fullerene C_{60} yielded water-soluble products PVP-1–C_{60} and PVP-2–C_{60}, which were colored, unlike the initial polymers. These products are characterized by intense absorption at 250–350 nm. However, by contrast to free C_{60} and its complexes with PVP, the UV spectra of PVP-1–C_{60} and PVP-2–C_{60} did not contain bands with λ_{max} = 260 and λ_{max} = 330 nm. The spectra are, essentially, monotonically descending curves with minor inflections near 260 nm, characteristics of covalently bound C_{60} [6, 8, 9].

The covalent nature of the polymer–fullerene bonding in the resulting derivatives is confirmed by the adsorption TLC analysis using toluene, chloroform, or carbon tetrachloride as eluent. When chromatograms are recorded on silica gel, free C_{60} moves together with the solvent front (Fig. 4, spot *1*). Out of the noncovalent complex of C_{60} with PVP, specially prepared for comparison, fullerene is also washed out (Fig. 4, spot *6*), like free C_{60}, moving together with the front, while PVP is adsorbed irreversibly (Fig. 4, spots *2* and *3*). When chromatograms of PVP-1–C_{60} and PVP-2–C_{60} are taken under identical conditions, C_{60} is not washed out (Fig. 4, spots *3* and *5*). After the PVP-1–C_{60} and PVP-2–C_{60} samples are eluted, a light brown spot remains at the start. This spot is also detected from UV absorption at 254 nm and from dark brown fluorescence at 366 nm, which is not typical for the initial PVP–NH_2 samples and can be due to the presence of covalently bound C_{60} only.

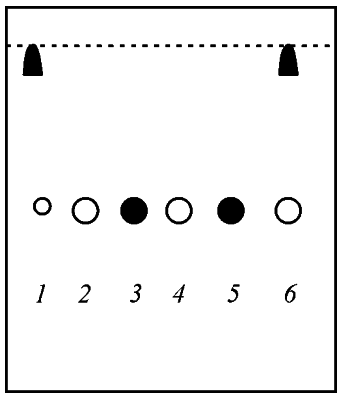

Fig. 4. TLC of (*1*) fullerene C_{60}, (*2*) PVP-1, (*3*) PVP-1–C_{60}, (*4*) PVP-2, and (*5*) PVP-2–C_{60} samples, and (*6*) PVP–C_{60} complex. Adsorbent silica gel, eluent toluene.

The initial and fullerene-modified polymers were studied by molecular hydrodynamic methods. As the main hydrodynamic characteristics served the centrifugal sedimentation coefficients s_0 and translation diffusion coefficients D_0, as well as intrinsic viscosities $[\eta]$.

The measurements of the refractive indices and density increments showed that both the $\Delta n/\Delta c$ and $\Delta\rho/\Delta c = 1 - v\rho_0$ parameters are virtually identical for the initial and fullerene-containing macromolecular systems, which is due to a relatively low content of the fullerene.

The specific partial volumes v were used for calculating by the Svedberg procedure [20]

$$M_{sD} = [RT/(1 - v\rho_0)]s_0/D_0,$$

the net molecular weights (see Table 1). This table also contains the M_2/M_1 ratio, where M_1 is the molecular weight of the initial polymer, and M_2, the corresponding weight of the polymer that reacted with C_{60}. The M_2/M_1 ratio is over unity, which suggests formation of new polymer structures incorporating fullerene molecules.

Also, we calculated the hydrodynamic invariant A_0 by the formula $A_0 = (R[D]^2[s][\eta])^{1/3}$, where $[D] = D\eta_0/T$, $[s] = s\eta_0/(1 - v\rho_0)$. The A_0 values have a

usual order, confirming consistency between the three independent experimental parameters s_0, D_0, and [η].

The sedimentation data obtained on a Beckman XLI analytical ultracentrifuge were processed using the Sedfit routine [24]. This routine allows the solution of the general Lamm equation for centrifugal sedimentation of a dilute solution of an ensemble of specifically noninteracting particles (molecules) that affords the best fit of the experimental and calculated profiles of the sedimentation boundary. The sum of the discrepancies between the experimental and calculated profiles of the sedimentation boundary is minimized using the regularization procedure based on the CONTIN routine [26]. The Sedfit routine allows the use of the mass-spectrometric potential of the centrifugal sedimentation method at a new level and furnishes additional molecular information about the samples under study (Fig. 5).

First, the data obtained with the use of interference optical devices show that the samples of the initial PVP are unimodal and are characterized by one narrow peak near 0.6 and 0.8 Sv for PVP-1 and PVP-2, respectively. These sedimentation coefficients are virtually identical to those yielded by analysis of migration of the sedimentation boundary (Fig. 2, Tables 1 and 2). Such comparison of the sedimentation coefficients yielded by various experimental data processing algorithms also serves as a test of the suitability of the Sedfit routine for estimating the centrifugal sedimentation coefficients of nonglobular macromolecules.

Second, the functions of distribution with respect to the sedimentation coefficients of the fullerene-containing samples contain peaks for which the sedimentation coefficients are virtually identical to those of the initial PVP samples. This means that the fullerene-containing samples comprise a part of the initial polymer that did not react with the fullerene. By comparing the distribution functions, we estimated the proportion of the fullerene-containing PVP macromolecules at ca. 40% for PVP-1–C_{60} and PVP-2–C_{60} (Fig. 5). This allows estimation of the average number of the polymer molecules corresponding to one fullerene molecule.

In view of the additivity of the weights, we can take, to a first approximation, the molecular weight of the fullerene itself negligible compared to that of the initial polymer molecule. Then, taking into account virtual identity of the density increments of the initial and fullerene-containing molecules (Fig. 3), we will change from the molecular weights to the ratio of the sedimentation coefficient to the translation diffusion coefficient:

$$M_{sD} = [RT/(\Delta\rho/\Delta c)]s_0/D_0 \sim s_0/D_0.$$

Hence,

$$s_0/D_0 = (s_0/D_0)_1 w_1 + (s_0/D_0)_2 w_2,$$

where s_0/D_0 is the net ratio yielded by the sedimentation diffusion analysis of the fullerene-containing sample; $(s_0/D_0)_1$, ratio yielded by the sedimentation diffusion analysis of the initial sample (without fullerene); w_1, proportion of unchanged initial sample in the fullerene-containing sample; w_2, proportion of the fullerene-containing segment of the sample (in the fullerene-containing sample); and $(s_0/D_0)_2$, desired average ratio for the fullerene-containing segment of the sample.

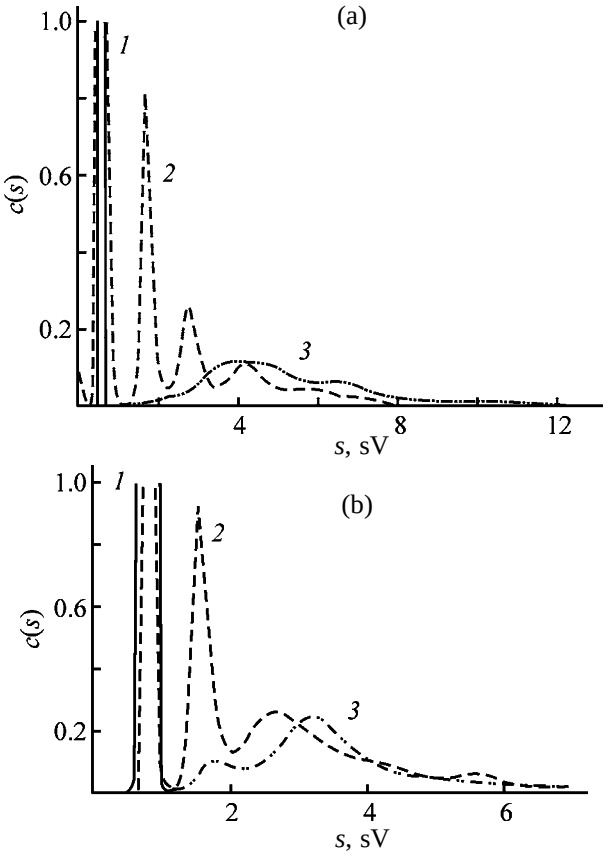

Fig. 5. Distribution $c(s)$ of the (*1*) initial and (*2, 3*) fullerene-containing samples with respect to the sedimentation coefficients s obtained by processing (*1, 2*) interference and (*3*) absorption scans (Beckman XLI analytical ultracentrifuge) by the Sedfit routine [24]. Concentration c of the initial PVP and fullerene-containing PVP–C_{60} polymers 0.10×10^{-2} and 0.02×10^{-2} g cm^{-3}, respectively. (a) PVP-1–C_{60} and (*2*) PVP-2–C_{60}.

Table 2. Sedimentation coefficients s and number of branches f in star-like polymers.* Solvent viscosity η_0 = 1.016 cP, density ρ_0 = 1.0069 g cm^{-3}

Sample/Fraction	Interference		Absorption		f
	$s \times 10^{13}$, s	fraction content, %	$s \times 10^{13}$, s	fraction content, %	
PVP-1	0.56	100	–	–	–
PVP-1-C_{60}/1	0.62	60	–	–	–
PVP-1–C_{60}/2	1.9	18	2.0	5	7
PVP-1–C_{60}/3	2.9	10	–	–	11
PVP-1–C_{60}/4	4.4	10	4.3	57	17
PVP-1–C_{60}/5	7	~2	6.8	24	29
PVP-1–C_{60}fr	4.5	75	4.7	78	19
PVP-2	0.71	100	–	–	–
PVP-2–C_{60}/1	0.79	58	–	–	–
PVP-2–C_{60}/2	1.8	15	1.7	12	4
PVP-2–C_{60}/3	2.9	15	3.3	59	9
PVP-2–C_{60}/4	4.2	11	5.4	10	15
PVP-2–C_{60}/5	–	–	8	10	26

* The measurements were carried out in 0.2 M NaCl solution at 20°C.

Evidently, $w_1 + w_2 = 1$, and the average number of the polymer molecules n, corresponding to one C_{60} molecule, will be equal to

$$n = (s_0/D_0)_2/(s_0/D_0)_1.$$

Then, the average number of the PVP molecules corresponding to one C_{60} molecule is equal to 4 for PVP-1–C_{60} and 10 for PVP-2–C_{60}; the larger the initial $[NH_2] : [C_{60}]$ ratio, the larger the number of the branches in the resulting star-like derivative.

The interference system of sedimentation recording (Beckman XLI) furnishes information about distribution with respect to the sedimentation coefficients for the entire sample, while the absorption system, only about the fullerene-containing segments of the sample, since fullerene is specifically responsible for the UV absorption. Comparison of the sedimentograms obtained with both recording systems suggests that the absorption optical devices record large sedimentation coefficients, which directly confirms formation of bulkier fullerene-based molecules compared to the initial polymers. Also, we revealed a molecular inhomogeneity of the fullerene-containing samples in the region of sedimentation coefficients larger than that of the initial PVP.

Since the initial polymers had one terminal amino group, it is reasonable to assume a star-like structure of the fullerene-containing macromolecules. Star-like polymer molecules are smaller in size than the corresponding linear macromolecules with identical molecular weight. For regular stars built up of chains of random wanderings of sufficient length, the following analytical expression for the ratio of the rms inertia radii g of the star-like and linear molecules was obtained [27]:

$$g = \langle R^2\rangle_{star}/\langle R^2\rangle_{lin} = (3f - 2)/f^2,$$

where f is the number of the branches in a regular star-like macromolecule.

A decrease in the size decreases the intrinsic viscosity, the translation friction coefficient, and, correspondingly, increases the sedimentation and diffusion coefficients of the star-like molecule relative to the linear molecule with identical molecular weight. Taking into account the decrease in size and the Kirkwood–Reisman hydrodynamic interactions of star-like molecules and using the model applied in [27], Stockmayer and Fixman [28] obtained the relationship

$$h = (s_0)_{lin}/(s_0)_{star} = 2.414f^{1/2}/(f + 2^{1/2}). \quad (1)$$

The theoretically calculated parameters h are slightly smaller than the corresponding $g^{1/2}$ parameters. This is due to strengthening of the hydrodynamic interaction in a star-like molecule, since $h = (P_{star}/P_{lin})g^{1/2}$, where P_{star} and P_{lin} are the hydrodynamic Flory parameters for the star-like and linear molecules, respectively. We calculated the molecular

weights of the macromolecules as $M_f = fM_1$ by expressions like the Kuhn–Mark–Houwink relationship, which we previously obtained for the linear homologous series of PVP [29, 30], and then calculated the $(s_0)_{lin}$ parameters corresponding to different M_f parameters. Next, using the h parameters calculated by formula (1), we estimated possible theoretical sedimentation coefficients of star-like PVP molecules at different numbers of branches, i.e., plotted the corresponding $s_{star} = s_{star}(f)$ nomograms for different M_1 parameters. By comparing the theoretical and experimental parameters s, we estimated the number of the branches in various fractions of the fullerene-containing samples. The results are presented in Table 2.

To test the possibility of separating the fullerene-containing segment out of the overall sample, we fractionated PVP-1–C_{60} on a column packed with a Sephadex G-200 gel (45×2 cm, eluent H_2O) and took the PVP-1–C_{60}fr fraction absorbing at 260 nm. Sedimentation analysis of this part of the sample shows that all its characteristics correspond to the PVP-1–C_{60}/4 fraction (Table 2), responsible for the maximal absorption in PVP-1–C_{60}. Thus, we isolated the fraction containing most of the covalently bound fullerene.

The occurrence in the fullerene-containing samples of fractions characterized by large sedimentation coefficients (high molecular weights) can be due to formation of more complex structures such as, e.g., stable clusters based on primary star-like macromolecules, which retain the macromolecular order both in size and weight. The solutions remain transparent and are not colloidal. Notably, cluster formation in fullerene-containing PVPs was also observed in studies of the same samples by small-angle neutron scattering [31].

CONCLUSION

Sedimentation and diffusion analysis allowed direct detection of formation of bulky fullerene-containing polyvinylpyrrolidone-based macromolecules. The primary fullerene-containing macromolecules have presumably a star-like structure with $n \leq 10$ arms. Simultaneously, fullerene-containing samples comprise bulkier water-soluble molecular structures.

Abstract—Poly(methyl methacrylate) samples and their analogs containing covalently bound fullerenes C_{60} and C_{70} were prepared under varied synthesis conditions. The molecular weights and the electrooptical characteristics of the polymers in solutions were determined. The influence of the fullerenes on the molecular properties of poly(methyl methacrylate) was elucidated, and the most efficient method of its modification with fullerenes was proposed.

Fullerenes C_{60} and C_{70}, like other representatives of the family of framework carbon species, including nanotubes, have electronic properties making them promising for diversified applications to microelectronics and photon engineering [1–4]. In particular, the nonlinear optical properties of fullerenes and their derivatives make materials thereof suitable as limiters of laser radiation intensity, optical modulators, and carriers and accumulators of optically recorded information, as well as for other optoelectronic applications [2–4]. One of the problems faced by modern materials science, related to application of fullerenes, is their introduction into polymers. This makes it possible, first, to exploit the properties of fullerenes spread in thin polymer films and, second, to usefully modify the polymer support itself, e.g., to increase its electrical conductivity [5] or to impart to it nonlinear optical properties [6]. Our previous studies of C_{60} derivatives [7, 8] and published data on hybrid polymeric compounds with various types of chemical bonding of fullerenes [1–6, 9] suggest that the outcome of modification of the polymer depends on the method of introducing fullerene into its composition. Even relatively small weight fractions of fullerenes in some cases significantly affect the initial polymer. For example, covalent bonding of the fullerene C_{60} as a site of branching of the macromolecules of polyvinylpyrrolidone (PVP) [7] and polystyrene (PS) [6] of a star-like structure significantly modifies the optical, dielectric, and electrooptical properties of PVP and PS, when the C_{60} fraction is ca. 1 wt %. At the same time, when C_{60} is introduced into PVP by complexing, there are no such changes [8].

Troitskii *et al*. [10] and Lu *et al*. [11] already attempted modification of poly(methyl methacrylate) (PMMA) with fullerenes. In particular, Lu *et al*. [11] showed that PMMA can be endowed with nonlinear optical properties via copolymerizarion of its monomer, methyl methacrylate (MMA), with an amino derivative of C_{60}, benzylaminofullerene. However, these authors failed to enhance the nonlinear optical properties of the amino derivative of C_{60} when bound with PMMA in such a mode.

In this work, we tested various methods of introducing C_{60} and C_{70} into the PMMA structure. We set a task of determining the molecular characteristics of hybrid polymers of PMMA with C_{60} and PMMA with C_{70} and comparing them with the related characteristics of the PMMA samples prepared under identical conditions but in the absence of the fullerenes. To this end, we carried out viscometric studies of the polymer solutions in benzene, determined their molecular weights M, and studied their electrooptical properties by the method of the Kerr effect in a pulsed electric field [12]. We chose the Kerr effect for this study, since it is highly sensitive to any changes due to structural transformations in the polymer chain, as well as

	PMMA-4–C_{60}		0.04	1030	2.02	0.70
	PMMA-4–C_{70}		0.01	1670	2.88	0.45

since it already demonstrated its suitability for detecting the changes in the properties of fullerene-containing compounds relative to the initial analogs [7, 8]. The Kerr effect depends on the optical polarizability, which is also contributed by hyperpolarizability responsible for the occurrence of nonlinear optical properties of the molecules [13], and on the polarity of the covalently bound nanoparticles, fullerene derivatives, in the composition of the polymer. Thus, the change in the equilibrium electrooptical properties of PMMA–C_{60} (C_{70}) relative to the polymer support is suitable as a criterion of the efficiency of various methods of modification of PMMA with fullerenes [7, 8. 14].

EXPERIMENTAL

Samples of PMMA-1–C_{60} and PMMA-1–C_{70} were prepared by radical polymerization using the dicyclohexyl percarbonate–tri-*n*-butylboron (DCHPC–TNBB) initiating system, with the fullerenes introduced into the reaction mixture in varied weight proportions (Table 1). It should be emphasized that the procedure of synthesizing these samples took advantage of a limited solubility of the fullerenes in the monomer. Polymerization was run at 30°C in a sealed glass ampule for 24 h. The fullerene was introduced into MMA until complete dissolution, whereupon DCHPC was introduced, and the solution was degassed. Next, TNBB was introduced from another evacuated ampule, whereupon the ampule that served as reactor was sealed. The ratio (mol %) of DCHPC : TNBB = 0.17 : 0.80 to the total volume of the reaction mixture was identical for all the samples, and varied was only the content of C_{60} (C_{70}) in the reaction mixture. The UV and IR spectra of these samples in chloroform confirmed the absence of chemically unbound fullerenes in PMMA-1–C_{60} and PMMA-1–C_{70}.

The PMMA-2–C_{60} sample was synthesized using another initiator, azobis(isobutyronitrile) (AIBN). Polymerization was run at 60°C for 24 h. Before adding the initiator, the solution of C_{60} in MMA was ultrasonically treated for 1 h to convert the fullerene into a dispersed state, since its concentration much exceeded the limiting concentration (Table 1). We found experimentally that, at 60°C, no more than 0.11×10^{-2} g of fullerene C_{60} can be dissolved in 1 cm^3 of MMA.

The PMMA-3–C_{60} sample was synthesized by adding to the fullerene the PMMA whose macromolecules contained one terminal amino group. The initial PMMA–NH_2 was prepared by radical polymerization of the monomer in the presence of AIBN as the initiator and cysteamine hydrochloride (an amine-containing mercaptan) as the chain-terminating agent. The ethanolic solution of cysteamine hydrochloride was added to a benzene solution of the monomer and initiator. Polymerization was run for 24 h at 60°C in sealed ampules purged with argon. The polymer was isolated by precipitation into diethyl ether and reprecipitated many times. The reaction between fullerene and PMMA–NH_2 was run in a toluene solution by adding dropwise, with stirring, the polymer solution to the C_{60} solution. After 72 h, the mixture was filtered, and the solvent was removed on a rotary

evaporator. The product was dissolved in chloroform, filtered off, and precipitated into diethyl ether. Thin-layer chromatography on SiO_2 plates showed that the product contained the fullerene convalently bound to the polymer, as well as free fullerene from which the product was separated by reprecipitation from chloroform. A similar reaction between fullerene C_{60} and polyvinylpyrrolidone bearing a terminal $–NH_2$ group yielded a product containing 60 wt % homopolymer [15]. This suggests that PMMA-3–C_{60} contains the initial polymer which is difficult to separate from the overall product. The content of the bound fullerene in PMMA-3–C_{60} was estimated as the difference between the amounts of the initial and unchanged C_{60} (Table 1).

The PMMA-4–C_{60} and PMMA-4–C_{70} samples were synthesized similarly to PMMA-1–C_{60} (C_{70}), except that the fullerenes were introduced into the reaction mixture as a solution in *ortho*-dichlorobenzene, in which the fullerenes are strongly solvated at 30°C and form charge-transfer complexes [16]. At the instant when the C_{60}/C_{70} solution was combined with MMA, a finely ground suspension was formed, but after 5-min stirring the reaction mixture turned transparent again.

The fullerene-containing samples of PMMA were readily soluble in benzene, toluene, ethyl acetate, and chloroform, i.e., were identical in solubility to the initial PMMA. Therefore, the procedure for preparation of solutions in benzene, in which all the measurements were carried out, was identical for all the subjects of investigation: The samples were dissolved during 5 days at room temperature. The choice of the solvent in this case was dictated by reliable published data concerning the ratio of the intrinsic viscosity and molecular weight determined by light scattering method for a homologous series of PMMA in benzene [17], as well as by the tasks of electooptical measurements, where a nonpolar solvent (in our case, benzene) is always preferred. Benzene at 25°C had the following characteristics: density $\rho_0 = 0.873$ g cm^{-3}, viscosity $\eta_0 = 0.59$ cP, refractive index $n = 1.4979$, and dielectric permittivity $\varepsilon_0 = 2.252$.

The intrinsic viscosity [η] of the samples was measured at 25°C in an Ostwald capillary viscometer; the time of the solvent outflow was 119.9 ± 0.1 s. Figure 1 presents the concentration dependences of the specific viscosity $\eta_{sp}/c = (\eta - \eta_0)/(\eta_0 c)$, where η and η_0 are the viscosities of the solution and solvent, respectively, and c, solution concentration.

The intrinsic viscosities [η] were determined as the limits of the experimental dependence of $\eta_{sp}/c = f(c)$ at $c \to 0$. Using the resulting [η] values (Table 1), we estimated the molecular weight M of the samples by the Kuhn–Mark–Houwink relationship [17] $[\eta] = 4.68 \times 10^{-5} M^{0.77}$.

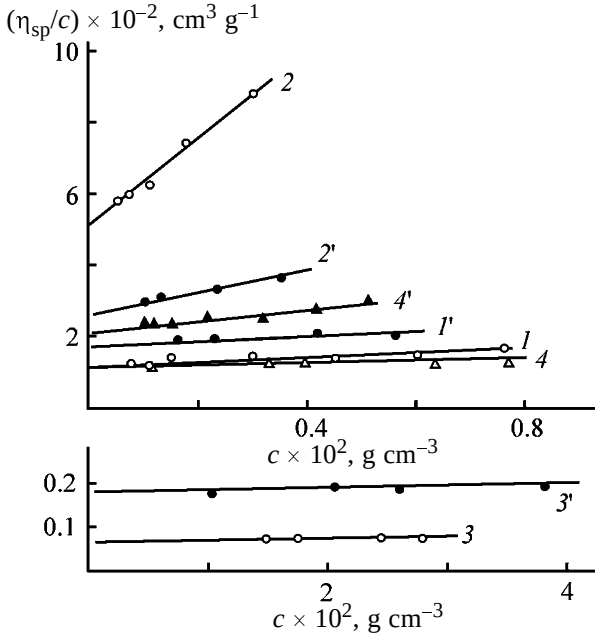

Fig. 1 Specific viscosity η_{sp}/c as a function of the concentration c of benzene solutions of (*1*) PMMA-1, (*1'*) PMMA-1–C_{60} (0.17 wt % C_{60}), (*2*) PMMA-2, (*2'*) PMMA-2–C_{60}, (*3*) PMMA-3, (*3'*) PMMA-3–C_{60}, (*4*) PMMA-4, and (*4'*) PMMA-4–C_{60} samples.

In [18], we substantiated the suitability of the scaling relationships, established for ordinary nonstereoregular PMMA, for estimating the molecular weights M of hybrid fullerene-containing PMMAs. We showed that, when fullerenes C_{60} (C_{70}) are introduced into PMMA during initiation of polymerization, the degree of branching of PMMA–C_{60} (C_{70}) does not markedly increase relative to the PMMA samples synthesized in a similar way by bulk polymerization.

The electrooptical Kerr effect, or birefringence under exposure to an external electric field, depends on the optical and dielectric susceptibilities of the molecular objects studied in solution or, more specifically, on their polar and anisotropic optical properties [12]. In this work, we studied the equilibrium electrooptical effect in the rectangular-pulsed electric field, where birefringence can be measured under conditions when it is independent of the duration and frequency of the pulses fed to the measurement cell. The electrooptical effect was characterized by the specific Kerr constant K defined by the relationship

$$K = \lim_{\substack{E \to 0 \\ c \to 0}} [(\Delta n - \Delta n_0)/E^2 c], \quad (1)$$

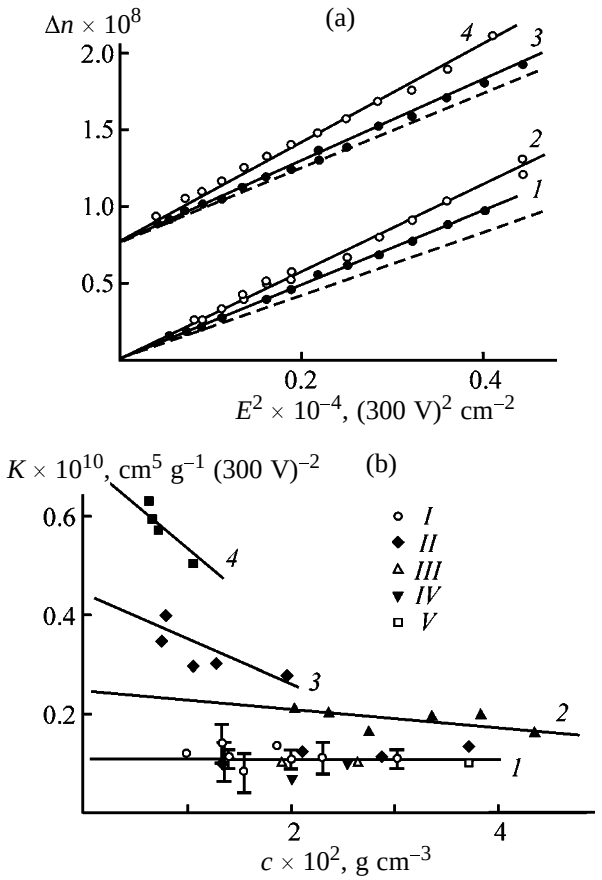

Fig. 2. (a) Birefringence Δn as a function of the squared electrical field intensity E^2 for (*1, 2*) PMMA-1–C_{70} (0.03%) and (*3, 4*) PMMA-3–C_{60} and (b) specific Kerr constant K as a function of the concentration of solutions in benzene c for fullerene-containing samples identical in the properties to (*1*) PMMA-1, (*2*) PMMA-3–C_{60}, (*3*) PMMA-4–C_{70}, and (*4*) PMMA-4–C_{60}. (a) Solution concentration, g cm^{-3}: (*1*) 2.14, (*2*) 3.79×10^{-2}, (*3*) 1.09, and (*4*) 3.83×10^{-2}. (Dashed line) The same dependence for the solvent, benzene. (b) (*I*) PMMA-1, (*II*) PMMA-1–C_{60} (0.09%), (*III*) PMMA-1–C_{60} (0.17%), (*IV*) PMMA-2–C_{60}, and (*V*) PMMA-1–C_{70} (0.11%).

where $\Delta n - \Delta n_0$ is the difference between the birefringences arising under field exposure of a solution of the substance studied at the concentration c and of the solvent, respectively, and E, electric field intensity.

We employed a standard compensation procedure of measuring the Kerr effect in weak electric fields using low-frequency light modulation [12]. The measurements were carried out in a 1.2 cm^3 cylindrical quartz cell. The voltage was supplied to the parallel-plane titanium electrodes soldered into the cell, which were separated by 0.05 cm; the cell length along the light beam path was 2 cm. The light source was a low-power He–Ne laser (1.5 mW cm^{-2}, λ = 632.8 nm). This excluded manifestation of laser-excited nonlinear optical effects in the solutions under study. A thin mica plate with an intrinsic phase shift of $0.01 \times 2\pi$ served as the compensator.

Electrooptical effect in solutions of flexible-chain polymers from the vinyl series, in particular, PMMA, is due to a small-scale, virtually free, orientation of their side groups when exposed to an electric field. The mono unit of PMMA is weakly polar with a dipole moment of 1.2 D [12, 19]. Therefore, PMMA in solutions exhibits a small electrooptical effect (Fig. 2) and has a low specific Kerr constant $K = (+0.11 \pm 0.04) \times 10^{-10}$ cm^5 g^{-1} (300 V)$^{-2}$.

As already mentioned, the synthesis of the PMMA-1–C_{60} (C_{70}), PMMA-2–C_{60}, and PMMA-4–C_{60} (C_{70}) samples was distinguished by the preliminary dissolution of the fullerenes in MMA. As known, radical bulk polymerization of MMA can be carried out with various initiators, which, along with their primary functions, can also affect the properties of the polymerization product [20–22]. For example, Dodonov *et al*. [21] showed that, when the MMA polymerization is initiated by DCHPC in the presence of TNBB and α,β-unsaturated carbonyl compounds, PMMA acquires an enhanced resistance to thermal oxidation, and the films of the PMMA synthesized in the presence of phthalides exhibit fluorescent properties [22]. Dodonov *et al*. [21] and Puzin *et al*. [22] modified the properties of PMMA by introducing special additives into the compound initiating polymerization of MMA and elucidated how these additives affect the polymerization rate and the molecular weight of the final product. Also, these authors found that, when added to the polymerization initiator, fullerenes affect the molecular weight of PMMA.

Studies of the PMMA-1, PMMA-2, and PMMA-4 samples in comparison with similarly prepared fullerene-containing samples of PMMA-1–C_{60}, PMMA-2–C_{60}, and PMMA-4–C_{60} showed that the effect exerted by the fullerenes in the reaction mixture on the properties of the final product of bulk polymerization varies with the type of the initiator. Table 1 lists the molecular weights of the samples studied, which were estimated from the [η] parameters measured in benzene at 25°C. These molecular weights agree well with those of the same samples, determined by the diffusion sedimentation analysis [17]. The intrinsic viscosity [η] and the molecular weight of the PMMA-1–C_{60} (C_{70}) and PMMA4–C_{60} (C_{70}) samples prepared using DCHPC–TNBB exceed those of the initial PMMA-1 and PMMA-4 samples (Table 1), while

* The designations 2-1, 2-2, 3-1, etc. correspond to conformers with identical numbers of the addition sites *m* allowed by the regioselective scheme of addition to C_{60} [25] and close in the heats of formation ΔH.

** The molar Kerr constants were calculated by the formula $K_M = 2\pi N_A(\theta_1 + \theta_2)$, where $\theta_1 = (45kT)^{-1}[(b_1 - b_2)^2 + (b_2 - b_3)^2 + (b_3 - b_1)^2]$, $\theta_2 = (45k^2T^2)^{-1}[(\mu_1^2 - \mu_2^2)(b_1 - b_2) + (\mu_2^2 - \mu_3^2)(b_2 - b_3) + (\mu_3^2 - \mu_1^2)(b_3 - b_1)]$; b_i are the main values of the linear optical polarizability tensor; μ_i, projections of the dipole moment on the main axes of polarizability of the molecule; *k*, Boltzmann constant; N_A, Avogadro number; and *T*, absolute temperature.

with AIBN as initiator the molecular weight *M* of PMMA-2–C_{60} is smaller than that of PMMA-2.

We found no systematic variation of the molecular weight *M* of the PMMA-1–C_{60} (C_{70}) samples with varying concentrations of the fullerenes introduced (Table 1). In view of the above-mentioned dependence of the molecular weight of the fullerene-containing PMMAs on the specific initiator–fullerene system, we can suggest that, most probably, fullerene introduced into MMA during polymerization initiation participates in interaction with the initiator. Hence, the interaction of fullerene with the propagating polymer chains depends on the initiating system, i.e., on the polymerization mechanism. This holds for synthesis procedure nos. 1, 2, and 4.

By contrast to the PMMA-1, PMMA-2–C_{60}, and PMMA-4–C_{60} samples, for which we revealed no enhanced degree of branching of the chains [18], the PMMA-3–C_{60} macromolecules were branched, as predetermined by the synthesis conditions, at which reactions of C_{60} with amino derivatives yield star-like adducts of fullerene with a random number of addition sites [15, 23]. This is confirmed by an increase in the molecular weight of PMMA-3–C_{60} by a factor of 3.5 relative to that of PMMA-3. Thus, the synthesis procedure and the structure of this fullerene-containing sample radically differed from those of other samples.

Electrooptical studies of solutions of fullerene-containing PMMAs were highly representative and demonstrated how the method of introduction of the fullerene affects the polymer properties. First, the electrooptical properties of PMMA-1–C_{60} (C_{70}) and PMMA-2–C_{60} (C_{70}), on the one hand, and of the initial PMMA-1 and PMMA-2 samples, on the other, were identical (Table 1). This suggests a similar (absolutely neutral) state of the fullerenes in these polymers, whatever their content. Fullerenes C_{60} and C_{70} in these polymers behave similarly, namely, do not affect the electrooptical properties of PMMA when their content is varied from 0.03 to 0.48 wt %. Thus, when introduced into MMA directly during polymerization initiation, the fullerenes do not markedly change the electrooptical properties of PMMAs. Hence, this method is unsuitable for stimulating new properties of this polymer by the fullerenes. This is not true, however, of the two other methods of introduction of the fullerenes into PMMA.

Branched PMMA-3–C_{60}, prepared by adding a terminal amino group of the polymer to the fullerene, is characterized by a specific Kerr constant that is more than twice that of the initial PMMA. Such a change in the properties of PMMA-3–C_{60} is related to its specific structure.

Addition of primary amines to C_{60} yields compounds with random distribution with respect to the number of amino groups added [23]. Table 2 presents the polarity characteristics (dipole moment μ) and optical polarizability anisotropy Δ*b* of the model adducts of fullerene C_{60} with 1 to 6 arms. Table 2 shows how the properties of the butylamino adducts

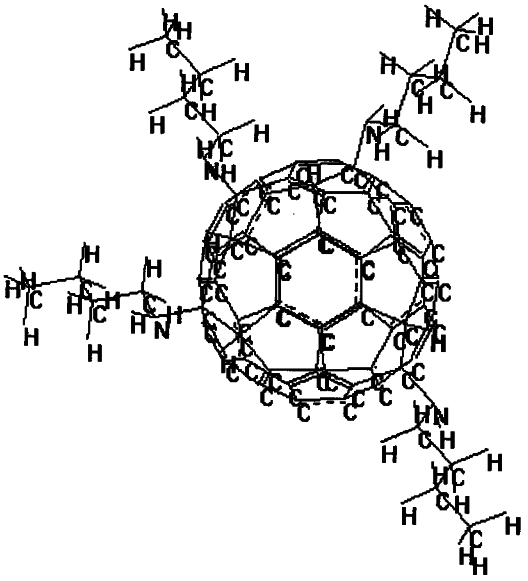

Fig. 3. Structure of butylaminofullerene C_{60} with $m = 4$ addition sites (an analog of the core of the star-like PMMA-3–C_{60} molecules), optimized by the PM3 method.

of C_{60} vary with the number of the addition sites allowed by the regioselective scheme [25]. The fullerene inclusions in branched PMMA-3–C_{60} correspond to the structure of the cores of the model molecules of the amino adducts of C_{60} (Fig. 3). Table 2 suggests that the fullerene-containing branching sites of the PMMA-3–C_{60} macromolecules with 1, 3, or 5 branches will have a dipole moment and exhibit an optical polarizability anisotropy and, thus, will make a noticeable positive contribution to the total electric birefringence observed experimentally in the PMMA-3–C_{60} solutions. The molar Kerr constant, i.e., that corresponding to a mole of the substance (by contrast to the previously introduced specific Kerr constant corresponding to a unit mass) exhibits additivity in solutions [12]. Therefore, assuming that the contributions from PMMA and the amino derivative of the fullerene in PMMA-3–C_{60} are independent, we can use the experimental molar Kerr constant $K_{M(\text{exp})}$ of PMMA-3–C_{60} for estimating the average number of the addition sites of the PMMA branches to C_{60} in the hybrid sample by comparison with the calculated data:

$$K_{M(\text{exp})} = K_{M_1} w_1 + K_{M_2} w_2, \qquad (2)$$

where K_{M_1} and K_{M_2} are the molar Kerr constants for free PMMA and branched PMMA with the C_{60} core, respectively, and w_1 and w_2, their mole fractions in solution.

The molar K_M and specific K Kerr constants are interrelated by the expression

$$K_M = [6n_0 K/(n_0^2 + 2)^2(\varepsilon_0 + 2)^2]M. \qquad (3)$$

For PMMA, $K_{M_1} = 2.3 \times 10^{-10}$, since its monomeric unit with the molecular weight $M_0 = 100$ is a polymer chain fragment, independently orienting in the electric field. According to Table 1, the experimental value for PMMA-3–C_{60} exceeds by a factor of 2.5 that for PMMA-3, $K_{M(\text{exp})} = 5.7 \times 10^{-10}$. By recalculating the weight fraction of the fullerene in PMMA-3–C_{60} (Table 1) into mole fraction, we will obtain $w_1 = 0.89$ and $w_2 = 0.11$, respectively. By substituting K_M, K_{M_1}, w_1, and w_2 into formula (2), we obtain $K_{M_2} = 33.2 \times 10^{10}$, which is close to the average of the nine calculated molar Kerr constants of 34.51×10^{10} (Table 2). This confirms, on the whole, an equally probable (from 1 to 6) number of the possible addition sites of the amino groups to the fullerene. Earlier [26] we studied the properties of the PVP–C_{60} prepared, similarly to PMMA-3–C_{60}, by adding the PVP branches to C_{60} via the terminal amino group of the polymer and showed that, because of a large positive contribution to the electrooptical effect from the PVP–C_{60} core, the negative electrooptical constant of the initial PVP changes to positive [26].

Six-arm adducts C_{60} (Table 2), like the fullerene proper, are characterized by a high symmetry (symmetry group S_6) and, thus, are virtually nonpolar and optically anisotropic compounds. It is known that reactions between C_{60} and free radicals yield predominantly hexa adducts [25]. Thus, it can be assumed that the reaction of C_{60} with an excess of various radicals during synthesis of PMMA-1–C_{60} (C_{70}) and PMMA-2–C_{60} (C_{70}) involves specifically such "neutralization" (saturation) of the fullerene. Thus, the resulting adducts of C_{60} do not contribute to the electroopticl properties of the fullerene-containing PMMA prepared by procedure nos. 1 and 2.

The electrooptical properties of PMMA-4–C_{60} (C_{70}) differ most profoundly from those of the initial polymer (Table 1). It should be reminded that, in this case, by contrast to PMMA-1–C_{60} (C_{70}) and PMMA-2–C_{60} (C_{70}), the fullerene was introduced into MMA in an *ortho*-dichlorobenzene solution, with which it forms crystal solvates and charge-transfer complexes [16]. The role of *ortho*-dichlorobenzene in the synthesis of PMMA-4–C_{60} (C_{70}) can only be hypothesized in the present stage of investigation. For example, we can assume that formation of very stable complexes between C_{60} and *ortho*-dichlorobenzene

prevents synthesis of symmetrical, nonpolar, and optically isotropic star-like PMMA with a C_{60} core. In any case, it is evident that the state of the fullerenes during polymerization and in PMMA-4–C_{60} (C_{70}) differs from that in PMMA-1–C_{60} (C_{70}) and PMMA-2–C_{60} (C_{70}). This is evidenced not only by a manyfold change of the electrooptical specific Kerr constant, but also by a more significant increase in the molecular weight of the PMMA-4–C_{60} (C_{70}) samples compared to the initial PMMA-4 and the PMMA-1–C_{60} (C_{70}) samples prepared using the same initiator (Table 1).

CONCLUSIONS

(1) Electrooptical properties of hybrid poly(methyl methacylates) are governed by the state of the fullerene in these polymers, which, in turn, is determined by the mode of its introduction into the polymer chains.

(2) The electrooptical properties of the product of bulk polymerization of methyl methacrylate changed most profoundly in the case when very small amounts of the fullerene (0.04 wt % C_{60} and 0.0053 wt % C_{70}) were introduced into the reaction mixture in the initiation stage as a complex with *ortho*-dichlorobenzene. This mode seems to be the least labor-consuming and the most suitable for stimulating new electrooptical properties of poly(methyl methacrylate) via introducing fullerenes into its structure.

Abstract—Polycondensation of dihydroxydiphenylpropane diglycidyl ether and allyl halides in the presence of some polyamines was studied. The optimal conditions of formation of ion-exchange polymers with three-dimensional structure, their composition and structure, and also physicochemical characteristics were determined.

The use of dihydroxydiphenylpropane diglycidyl ether (ED-20) as initial monomer for synthesis of ion-exchange resins and membranes provides formation of ordered structures improving the main physicochemical, optical, and strength characteristics of the resulting polymers [1, 2]. Introduction of allyl compounds into the reaction mixture improves the performance of the materials [3]. Therefore, in this work we used allyl halides [allyl bromide (AB) and allyl chloride (AC)] as comonomers. The choice of the above compounds is caused by the fact that these compounds readily react with homolytic rupture of the C–X bond (where X is Br, Cl, I, and F) due to conjugation with the C=C bond [4].

The aim of this work is development of methods for synthesis and study of characteristics of ion exchangers based on industrial epoxy resin, allyl halides (AHs), and some aromatic and aliphatic polyamines.

EXPERIMENTAL

Condensation of allyl halides with dihydroxydiphenylpropane diglycidyl ether and amines was carried out at 18–25°C for 1–2 h with subsequent curing of the prepolymer at 80–100°C. The gel was milled and dispersed and the fraction with a grain size of 0.25 mm was selected [5, 6].

Pretreatment and determination of the main physicochemical characteristics were performed by the procedures described previously [7].

The IR spectra of the initial, intermediate, and final products prepared as thin layers and KBr pellets (1 mg substance + 200 mg KBr) were recorded on a Specord M80/M85 spectrophotometer.

The potentiometric titration was carried out by the method of individual weighed portions. A weighed portion of air-dry anion exchanger (0.20–0.25 g) was brought into contact with various amounts of 0.1 N nitric acid (from 0.5 to 50 ml). The ionic strength of the solution (approximately 1 M) was supported by adding the corresponding amount of potassium nitrate. After the equilibrium was reached (7–10 days), the pH of the solution was measured on a DL-55 titrator.

With the aim to find the optimum conditions of synthesis of ion exchangers based on AHs, ED-20, and amines, we studied how the ratio of the initial components, the kind of AH, prepolymerization temperature, and curing conditions affect some characteristics of the anion exchangers (Tables 1 and 2) [8]. A decrease in the amine concentration results in a decrease in the static exchange capacity (SEC) from 9.5 to 6.3 in the case of polyethylenimine (PEI) and from 3.9 to 2.7 mg-equiv g^{-1} in the case of poly-2-methyl-5-vinylpyridine (PMVP). At the same time, its increase significantly hampers curing of the gel, which results in deterioration of the mechanical strength. The kind of allyl compound does not significantly affect the SEC. The presence of pyridine group assists to an increase in the exchange capacity with respect to highly basic groups.

In condensation of polyfunctional monomers, unchanged functional groups remain in the resulting macromolecules, which is caused by their different reactivity an also by steric and concentration factors. The presence of double bonds in allyl compounds

plays a certain part in formation of cross-linked structures. The probability of their scission under the action of atmospheric oxygen in aftercuring increases. In this connection, we determined the optimum temperature at which all functional groups enter into the reaction and the degree of scission of double bonds is maximal.

The influence exerted by prepolymerization temperature and curing conditions on SEC and swelling of the resulting ion-exchangers is illustrated by Table 2. With increasing prepolymerization temperature from 13 to 25°C, the sorption capacity of the ion exchanger significantly increases, from 5.6 to 9.5 mg-equiv g^{-1} in the case of PEI and from 2.2 to 3.9 mg-equiv g^{-1} in the case of PMVP. The increase in curing temperature from 80 to 120°C results in decreasing SEC of anion exchangers and correspondingly in decreasing swelling, which is caused by significant compaction of the copolymer structure during the reaction.

We found that the yield of the copolymer with the three-dimensional structure depends on the reaction temperature and duration (Fig. 1). With increasing temperature, the yield of the final product increases. The maximum yield of the anion exchanger based on ED-20, AB, and PMVP (80%) is reached in 120 min at 13°C, 90 min at 18°C (88%), and 60 min at 25°C. With PEI, the reaction proceeds at a higher rate and with a higher yield (96% in 40 min at 25°C).

		chemical			thermal			
		5 N H_2SO_4	5 N NaOH	10% H_2O_2	3 h	5 h	7 h	12 h
ED-20 : AB : PEI	9.5	9.1 (4)	9.1 (4)	8.1 (15)	9.3 (2)	9.3 (2)	9.1 (4)	8.9 (6)
ED-20 : AC : PEI	9.2	8.4 (9)	8.7 (5)	7.6 (17)	8.8 (4)	8.7 (5)	8.9 (7)	8.5 (8)
ED-20 : AB : PMVP	3.9	3.8 (2)	3.8 (2)	3.6 (7)	3.8 (2)	3.8 (2)	3.8 (2)	3.8 (3)
ED-20 : AC : PMVP	3.5	3.4 (4)	3.4 (3)	3.2 (8)	3.4 (3)	3.4 (3)	3.4 (4)	3.4 (4)
ED-10P	8.0	7.9 (1.2)	7.9 (1.2)	3.3 (58.7)	7.4 (9.2)	7.1 (9)	6.3 (8)	6.3 (8)

The results of studying chemical resistance and thermal stability (Table 3) show that anion exchangers based on PEI are less resistant to solutions of acids, alkalis, and oxidants, since an increase in the fraction of tertiary amines decreases the thermal stability of the copolymer. In this case, the loss of the capacity does not exceed 17%, while under the same conditions ED-10P commercial ion exchanger loses 58.7% of its capacity [9]. The study of thermal stability of the synthesized ion exchangers in water in the range 80–100°C for 12 h (Table 3) shows that the loss in capacity does not exceed 8%. The most stable are anion exchangers based on PVMP.

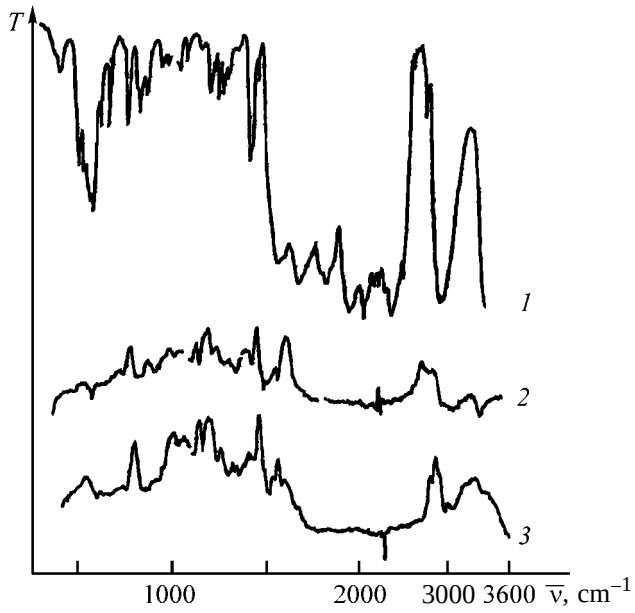

Fig. 2. IR spectra of ED-20 and anion exchangers based on it. (*T*) Absorption and ($\bar{\nu}$) wave number. (*1*) ED-20, (*2*) ED-20 : AB : PEI, and (*3*) ED-20 : AB : PMVP.

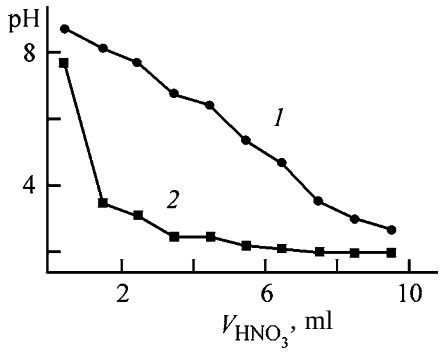

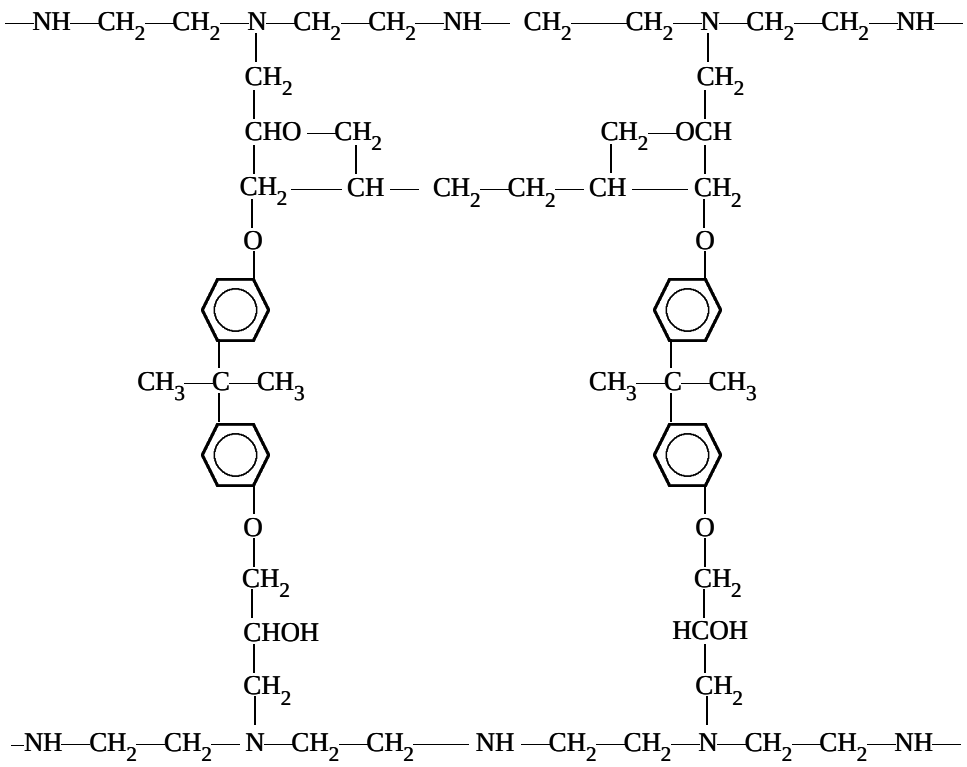

Fig. 3. Potentiometric titration curves of anion exchangers based on ED-20, AB, and polyamines (*1*) PEI and (*2*) PMVP. (V_{HNO_3}) volume of 0.1 N HNO_3.

Thus, the optimal conditions of synthesis of polyfunctional anion exchangers based on the above monomers are 25°C, 1–2 h, and weight ratios ED-20 : AB : PEI = 1.5 : 1.0 : 3.0 and ED-20 : AB : PMVP = 1.5 : 1.0 : 2.0.

The structures of the initial and final products were studied by IR spectroscopy (Fig. 2). The epoxy groups in ED-20 give rise to the absorption bands at 832, 916, 1240, and 3056 cm^{-1}. In the spectra of the synthesized anion exchangers, these bands are absent, which suggests chemical transformation of epoxy groups. The absorption bands corresponding to the stretching modes of amino groups appear in the range 3600–3300 cm^{-1}, and the bands characteristic of bending modes, in the range 1650–1550 cm^{-1}. Stretching modes of the C–N bonds are manifested in the range 1360–1250 cm^{-1}. The presence of absorption bands at 832 cm^{-1} and in the range 1600–1500 cm^{-1} confirms the presence of aromatic fragments. The spectra of the synthesized polyelectrolytes contain bands at 1075–1020 cm^{-1} of the in-plane bending modes of the C–H bonds in the benzene ring. The band at 1470–1460 cm^{-1} corresponds to the CH_2 group, at 1350–1300 cm^{-1}, to the CH_3 group, and at 1200–1180 cm^{-1}, to the quaternary carbon atom. The absorption bands of the stretching modes of the CH bonds (at 3070–3020 cm^{-1}) and the C=C and C=N bonds of pyridine ring (1660, 1560, and 1460 cm^{-1}) undergo certain changes. In the spectrum of the anion exchanger based

on PEI, there is a broad band in the range 1664 cm^{-1} characteristic of the C–N bond.

Thus, the structure of the elementary unit of the three-dimensional polyfunctional anion exchanger prepared using PEI can be schematically presented in the form

In the reaction of ED-20 with allyl halides and amines, nucleophilic attack of the epoxy ring with the nitrogen atom causes the ring opening. As a result, OH groups, which can enter into the reaction with allyl halides, are formed. The resulting allyl ether is apparently oxidized with atmospheric oxygen. In this case, isomerization of allyl radical takes place to form hydroperoxide of substituted vinyl ether, in which the double bond is activated by conjugation with an unshared pair of the ether oxygen atom; this enhances its capability for polymerization.

The functionality and basicity of the synthesized anion exchangers with the three-dimensional structure was studied by potentiometric titration. The negative logarithm of the acid dissociation constant of the ionogenic groups of the polymer pK_a and empirical coefficient m considering interunit interaction were determined by graphic method (Figs. 3, 4) from the Henderson–Hasselbach equation [10]. The pK_a value of the polyelectrolyte based on PEI is 7.0, of that based on PMVP, 3.6, and m is 2.5 and 2.3, respectively.

The shape of the potentiometric titration curve of the polyelectrolyte based on PMVP (Fig. 3) and also lower values of pK_a suggest its increased basicity in comparison with anion exchangers based on PEI.

It is evident that higher values of the empirical co-

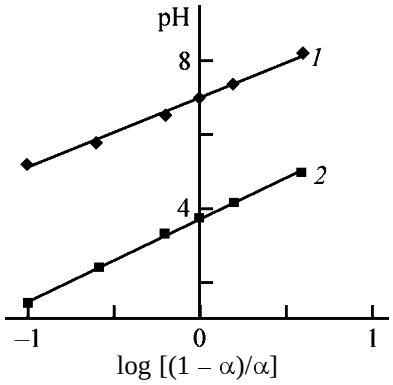

Fig. 4. Dependence of pH of the equilibrium solution on log[(1 – α)/α]. (α) Degree of protonation of functional groups of the ion exchanger. (*1*) ED-20 : AB : PEI and (*2*) ED-20 : AB : PMVP.

efficient *m* characterizing the electrostatic interaction of functional groups in the polymer can be explained by high concentration of ionogenic groups [11].

CONCLUSIONS

(1) Procedures were developed for synthesis of highly permeable polyfunctional anion exchangers based on dihydroxydiphenylpropane diglycidyl ether, allyl halides, and some polyamines. The resins are chemically resistant to solutions of acids, alkalis, and oxidizing agents.

(2) The acid dissociation constants of ionogenic groups of the polymer and the empirical coefficients considering interunit interaction suggest formation of weakly basic anion exchangers in the case of polyethylenimine and of highly basic anion exchangers in the case of poly-2-methyl-5-vinylpyridine.

(3) The synthesized anion exchangers are recommended for development of a sorption procedure for separation of transition and noble metal ions.

Abstract—Radical copolymerization of new redox monomers based on derivatives of monoethanolamine vinyl ether and naphthoquinones with acrylic acid was studied.

With the aim to extend the set of monomers suitable for synthesis of redox polymers, new redox monomers based on monoethanolamine vinyl ether (MEAVE) and quinones [1] were prepared, and radical homo- and copolymerization of some of these monomers was studied [2–7]. It was found that quinoid derivatives of MEAVE fairly readily enter into homo- and copolymerization, contrary to the initial ether, which practically does not form polymers [8], and to quinones being polymerization inhibitors.

In this work we studied the influence of chemical structure of naphthoquinones on the reactivity of redox monomers in radical copolymerization with acrylic acid (AA).

EXPERIMENTAL

Redox monomers based on MEAVE and 1,2-naphthoquinone (MEAVE–1,2-NQ), MEAVE and 1,4-naphthoquinone (MEAVE–1,4-NQ), and dichloro-1,4-naphthoquinone (MEAVE–DC-1,4-NQ) were synthesized by the procedure described in [1]. Azobis(isobutyronitrile) (AIBN) was recrystallized from dry methanol; mp 102–103°C.

Copolymerization of redox monomers with AA was carried out in hermetically sealed tubes in DMF at 68°C in the presence of 6 wt % AIBN for 0.5 h. Conversion of monomers was judged from variation of their concentration, which was determined by the polarographic method (redox monomers) and titration (AA).

The polarographic curves were recorded in a temperature-controlled cell at 25 ± 0.5°C on a PU-1 polarograph (mercury dripping electrode with the capillary characteristic at open circuit $m^{2/3}\tau^{1/6} = 4.38\ mg^{2/3}s^{-1/2}$ [m is the weight of mercury outlowing from the capillary in 1 s and τ is the period of mercury dropping (s)] with phosphate buffer solution (pH 7.4) with DMF content of 25 wt % as supporting electrolyte. The reference electrode was a saturated calomel electrode. Oxygen was removed from the solutions used for polarography by bubbling with argon.

Determination of the constants of relative activity of monomers r_1 and r_2 is an important problem both in direct study of copolymerization and for establishment of the relation between the chemical structure of unsaturated compounds and their reactivity.

Copolymerization of MEAVE derivatives and various naphthoquinones (M_1) with AA (M_2) was studied in DMF solutions in the presence of AIBN. The composition of the copolymers was evaluated from data listed in Table 1. As seen from Table 1 and Fig. 1, none of the systems forms an azeotropic copolymer. In the case of joint polymerization of MEAVE–1,2-NQ and MEAVE–1,4-NQ with AA ($r_1 > 1$, $r_2 < 1$), the composition curves are located above the azeotropic line, i.e., at all the ratios of the initial compounds, the copolymers are significantly enriched with redox monomer units. For the monomer pair MEAVE–DC-1,4-NQ and AA ($r_1 < 1$, $r_2 > 1$), the composition curve is located below the azeotropic line and the copolymer is enriched with AA units.

The copolymerization constants were evaluated by the Mayo–Lewis integral equation of copolymer composition [9]. The parameter p in this equation was

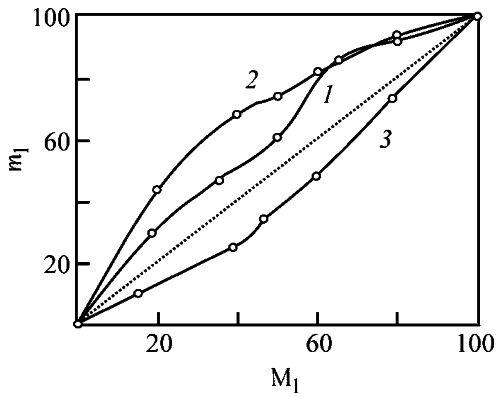

Fig. 1. Diagram of monomer–copolymer composition for the systems (*1*) MEAVE–1,2-NQ : AA, (*2*) MEAVE–1,4-NQ : AA, and (*3*) MEAVE–DC-1,4-NQ : AA. Mole fraction of redox monomers: (M_1) in the mixture of monomers and (m_1) in copolymers.

selected by the Shtraikhman graphic analytical method [10]. The polymerization constants and the Alfrey–Price parameters of resonance stabilization Q_1 and polarity e_1 for new redox monomers are given in Table 2. For AA, Q_2 = 1.15 and e_2 = 0.77 were taken from [11].

Table 2 shows that the monomer MEAVE–1,2-NQ is the most active, and the radical formed from this monomer is less reactive with respect to the monomer MEAVE–1,2-NQ. The radical MEAVE–1,4-NQ exhibits the highest activity in the reaction with the polymer radical AA; this is apparently caused by the influence of the polarity factor *e*, whose value in this case is negative. The greater the difference in the polarity of the two monomers Δe and the smaller the product r_1r_2, the stronger the tendency to alternation of the monomers in the copolymer [9]. For the system

MEAVE–1,4-NQ : AA, the lowest product r_1r_2 and the highest Δe suggest a strongest tendency to cross coupling of the monomers. For the other two monomer systems, the product r_1r_2 is close to 1, i.e., the copolymerization is "ideal": the monomer molecules randomly add to the polymer chain and the tendency to alternation of the monomer units is low. Short blocks of one monomer following blocks of the other monomer are more frequent in the copolymer. For MEAVE–DC-1,4-NQ, the lowest value of Q corresponds to the lowest activity of this monomer. Comparing the parameters Q of redox monomers, one can expect that MEAVE–1,4-NQ should be the most reactive; however, actually, MEAVE–1,2-NQ is the most active.

It is well-known [11] that the activity of radical governs the rate of homopolymerization. However, in other cases the governing factor is the activity of molecules rather than of the polymer radical. In the series of structurally related compounds, the homopolymerization rate varies in parallel with the activity of monomer molecules. The kinetic curves (Fig. 2) and also data listed in Table 2 show that the monomers can be ranked in the following order with respect to their reactivity: MEAVE–1,2-NQ : AA > MEAVE–1,4-NQ : AA > MEAVE–DC-1,4-NQ : AA. Apparently, for the systems studied the factor governing the main kinetic parameters of copolymerization is the activity of the monomer rather than of the polymer radical. The results obtained show that the reactivity of redox monomers depends on the chemical structure of naphthoquinones used for modification of MEAVE. The presence of a substituent (chlorine atom) and the

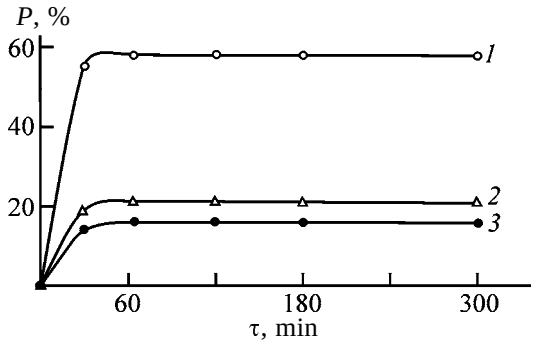

Fig. 2. Kinetic curves of copolymerization of systems redox monomer (M_1) : AA (M_2). (P) Yield of copolymers and (τ) time. M_1: (*1*) MEAVE–1,2-NQ, (*2*) MEAVE–1,4-NQ, and (*3*) MEAVE–DC-1,4-NQ.

ortho and *para* positions of carbonyl groups in the quinoid ring affect the donor–acceptor characteristics, which results in different electron density distribution in the molecules of these monomers and different polarization of the double bond. Since redox monomers (M_1) and AA (M_2) have different activity, in the systems at various monomer ratios different diads are formed: M_1M_1, M_1M_2, and M_2M_2. The probability of formation of these diads in the chain f and average statistical lengths of monomer blocks L_{M_1} and L_{M_2} were evaluated by the equations given in [13, 14] (Table 3).

At different ratios of the initial monomers, copolymers with different compositions are formed. It is seen from Table 3 that, at the composition of monomer mixture from 80 : 20 to 50 : 50, the derivatives MEAVE–1,2-NQ and MEAVE–1,4-NQ are more actively combined with "own" radicals to form mainly M_1M_1 and M_1M_2 diads. The higher the content of these monomers in the initial mixture, the larger the block length L_{M_1}. For the monomer systems studied, copolymers with more regular structure are obtained at the following ratios of the initial monomers: MEAVE–1,2-NQ : AA = 35 : 65, MEAVE–1,4-NQ : AA = 20 : 80–50 : 50, and MEAVE–DC-1,4-NQ : AA = 60 : 40.

CONCLUSIONS

(1) Radical polymerization of derivatives of monoethanolamine vinyl ether and naphthoquinones with acrylic acid was studied. As a result of this radical polymerization, macromolecular compounds having, along with redox characteristics, also adsorption and ion-exchange power are formed.

(2) The constants of the relative activity of monomers and the parameters of resonance stabilization and polarity of the new redox monomers were evaluated. The microstructure of the copolymers was determined.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Properties of Solutions and Films of Fibroin–Poly-3-Hydroxybutyrate Polymer Blends

E. S. Sashina, N. P. Novoselov, and K. Heinemann

St. Petersburg State University of Technology and Design, St. Petersburg, Russia
Thuringian Institute of Textile and Plastics, Germany

Received April 12, 2004

Abstract—Solutions of fibroin–poly-3-hydroxybutyrate polymer blends in hexafluoro-2-propanol and films obtained after removal of the solvent are experimentally studied at various polymer ratios.

Bombyx mori silk fibroin is a biopolymer with unique chemical, physical, and mechanical characteristics [1]. Silk is of a great interest not only as a textile material. It can also be used for biotechnological and biomedical purposes in manufacture of suture materials, contact lenses, biosensors, etc. Silk fibroin is used as fibers, gels, powders, and porous membranes. However, a significant drawback of films and other goods from regenerated fibroin is their brittleness. The mechanical characteristics of fibroin may be improved through blending with other natural or synthetic polymers [2–8]. Blends are prepared by simultaneous dissolution of polymers in an appropriate solvent or by grinding.

Dissolution of a polymer mixture in a single solvent to obtain a compatible blend in the form of a film appeared to be a very difficult problem because of phase segregation. The major factor causing incompatibility of polymers is a small gain in the entropy in mixing [9, 10]. The effect of this factor could be reduced through interpolymer interaction, e.g., hydrogen or ionic bonding [11]. Therefore, solution of the problem is reduced to selection of such compositions of a polymer blend in which interpolymer interaction is realized.

Keeping in mind the fact that fibroin has many hydrophobic sites in its structure, being, therefore, capable of forming hydrophobic bonds, we studied solutions and films of mixtures of fibroin with a hydrophobic polymer, poly-3-hydroxybutyrate (P3HB). This optically active biodegradable thermoplastic product containing (*R*)-3-hydroxybutyric acid units is synthesized by *Alcaligenes eutrophus*, *Pseudomonas oleovorants*, *P. Putida*, and *Phodospillium rubrum*. Poly-3-hydroxybutyrate is manufactured by ring-opening polymerization of β-butyrolactone racemic mixture in the presence of base catalysts containing Al, Zn, and other metals [12]. The (*R*) to (*S*) isomer ratio affects the melting point (it ranges from 58 to 180°C), crystallinity, and rate of enzyme-catalyzed hydrolysis of the product. High hydrophobicity of P3HB in combination with its biodegradability makes this polymer indispensable in biotechnology, food industry, and medicine. Also it can be used as a component of polymer blends [13–18].

The solubility of P3HB in a series of organic solvents, its mechanical characteristics, and biocompatibility and biodegradability are good reasons to consider this polymer as suitable for preparation of blends with fibroin. Fibroin is mostly dissolved in aqueous salt solutions with subsequent dialysis to remove salts, which confines the fibroin concentration in the solution because of gel formation in concentrated solutions after dialysis. Furthermore, P3HB is insoluble in aqueous salt solutions. Therefore, we selected hexafluoro-2-propanol (HFIP) as a solvent for fibroin–P3HB blends.

EXPERIMENTAL

Bombyx mori silk fibroin was pretreated prior to use to remove sericin and fatty, resinous, and mineral compounds, and then it was cut into short (3.6 mm) fibers 34.6 μm in diameter. In the work we used syndiotactic P3HB with MW 145 000 (M_w/M_n = 1.8), representing an 1 : 1 mixture of poly(*R*)- and poly(*S*)-3-hydroxybutyrate (mp 58.3–58.8°C; zero moisture content under normal conditions). As a solvent we used 1,1,1,3,3,3-hexafluoro-2-propanol (Merck) (main product content 99%, bp 58°C, d^{20} 1.615–1.618 g cm^{-3}).

Table 1. Properties of 1% fibroin–poly-3-hydroxybutyrate solutions in HFIP at 25°C

P3HB concentration, wt %	ρ, g cm^{-3}	η_{rel}	η_{ad}
0	1.60	5.0	–
20	1.61	8.6	12.1
40	1.52	13.3	19.3
60	1.59	19.1	26.5
80	1.64	29.0	33.6
100	1.58	40.8	–

Before dissolution in HFIP, fibroin was activated by dissolution in aqueous 6 M LiBr at 60°C, followed by dialysis through a semipermeable membrane [19]. Dialysis was carried out at room temperature with continuous stirring for a day with intermittent refreshment of water. This procedure provided complete removal of LiBr. The fibroin solution after dialysis was air-dried at room temperature to obtain a film, and then vacuum-dried at 40°C for 4–6 h. A weighed portion of thus activated fibroin was dissolved in HFIP at 25°C to obtain the desired concentration.

Poly-3-hyroxybutyrate was dissolved in HFIP at room temperature with stirring to obtain a clear solution of the desired concentration. Then estimated volumes of the equimolar solutions of both polymers were mixed with continuous stirring for an hour. As a result, stable clear solutions were obtained.

After filtration with a Büchner funnel, we measured the pycnometric density of the dilute solutions. The viscosity of the solutions η_{rel} was measured at 25°C with an Ubbelohde viscometer. The additive viscosity was estimated as

$$\eta_{ad} = \eta_1 c_1 + \eta_2 c_2,$$

where c_1 and c_2 are the concentrations of the first and second components in the mixture; and η_1 and η_2, exhaust times of the solutions of individual components.

The films were prepared by pouring the solutions onto foil plates, followed by removal of the solvent. The film thickness was 0.4–0.6 μm. Mechanical characteristics of the films were determined using an Instron tensile-testing machine in accordance with DIN EN ISO 527-3 standard. Swelling of the films in water was studied gravimetrically. The films were kept in distilled water at room temperature for 30 min (this time was demonstrated to be sufficient to reach the maximal swelling). The degree of swelling was estimated as

$$\Delta w = 100(w_1 - w_0)/w_0,$$

where Δw is the degree of swelling (%); w_1, weight of the swollen film (g); and w_0, weight of the dry film (g).

The density of the films was determined on an AccuPyc 1330 V2.01 He pycnometer. The film morphology was studied in a polarized light using an Olympus U-SMAD-2 BX-50 JVC microscope (magnification ×200). The infrared spectra of the films were recorded on an IFS25 spectrometer. Thermal analysis was carried out on a Mettler Toledo Star scanning calorimeter with heating from 25 to 350°C at a rate of 10 deg min^{-1} under nitrogen (N_2 flow rate 50 ml min^{-1}). The estimated enthalpies of melting were then used for determination of the degree of crystallinity (DC) of P3HB in the mixtures:

$$DC = \Delta H_{m.ap}/\Delta H_m^0,$$

where $\Delta H_{m.ap}$ is the apparent enthalpy of melting of P3HB in the mixture, as obtained from the DTA data; and ΔH_m^0, enthalpy of melting of fully crystalline P3HB (145 J g^{-1} [12]).

Based on comparative analysis of the rheological characteristics of dilute solutions of the individual polymers and their mixtures in HFIP, some conclusions could be made on the occurrence or lack of interaction between the fibroin and P3HB macromolecules.

The viscosity η and density ρ of the 1% solutions in HFIP, prepared at various fibroin to P3HB ratios, are given in Table 1. At a P3HB concentration in the mixture below 20 and above 80%, the density of mixed solutions in higher as compared to that of the solutions of the individual components, while at a P3HB concentration of 20–80%, the density decreases, reaching the minimum at a P3HB concentration of 40%.

The relative viscosity of mixed solutions η_{rel} is lower than the additive value η_{ad} estimated neglecting the interpolymer interaction. The negative deviation of the viscosity from the additive law suggests either the lack of interpolymer interaction in the solution or the formation of comb- or star-shaped intermolecular complexes [20]. Here we should keep in mind that the interpolymer interaction proceeds through local contacts caused by the presence of groups capable of a given type of interaction.

Straight fibroin films prepared from 4% solutions in HFIP are optically transparent. Films of polymer

blends are practically transparent too, except for the 40% P3HB blend. In the latter case, noticeable phase segregation was observed: the films appeared to be opalescent, suggesting the formation of agglomerates with a size comparable with the light wavelength.

The microscopic examination revealed that the film of straight fibroin is quite homogeneous with a clearly pronounced orientation of the fibrils (Fig. 1a). The film of straight P3HB consists of fine closely packed spherulites. Hardening of P3HB in the form of spherulites was also observed earlier [12, 14, 16, 18]. In the case of 20% P3HB, we observed microsegregation of the phases (Fig. 1b): irregular-shaped particles 1–4 μm in size, consisting of the finest P3HB spherulites, are surrounded by more hydrophilic fibroin representing a dispersion medium. At a P3HB concentration of 40%, the segregation is the most clearly pronounced: there are domains enriched with fibroin and P3HB-saturated domains (macrosegregation). With increasing P3HB concentration to 60%, the phase segregation decreases, and in the case of 80% P3HB, the most homogeneous structure of closely packed spherulites is realized (Fig. 1c). In this case, the size of spherulites is minimal.

Thus, microsegregation is found for all the samples, and macrosegregation, in the case of 40% P3HB. The microstructure of the polymer blend films can be easily controlled by changing the component ratio. In the case of microsegregation, a microdomain structure is formed, in which more energetically favorable contacts between the units of the same polymer are realized, as well as interactions between active groups of different polymers. At a P3HB concentration above 80%, the most homogeneous supramolecular structure is formed. Most likely, in this case, fibroin plays a role of a plasticizing agent, filling the interspherulite space.

The phase transition temperatures and thermal effects were studied in the range 25–500°C by scanning calorimetry for films of the individual polymers and their blends, prepared from 4% solutions in HFIP (Table 2). The DSC curve of regenerated fibroin shows an endothermic peak near 78°C, which is associated with removal of adsorbed water. The endothermic effect near 152°C is caused by glass transition of amorphous fibroin, which is followed by a weak exothermic effect due to transition of the amorphous phase into β-folded crystalline structure [21]. The exothermic peak at 246°C (not given in Table 2) reflects molecular motion in α-crystals of the polymer, which is observed only in the film of straight fibroin. Finally, the endothermic peak at 276°C is caused by thermal degradation of the disordered β-structure.

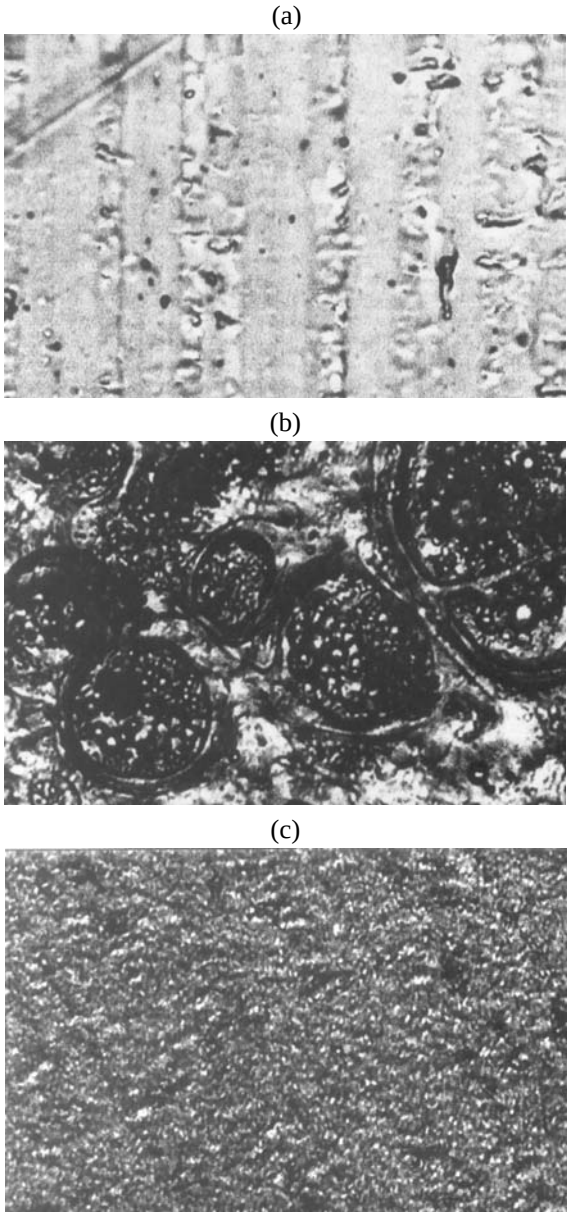

Fig. 1. Photomicrographs of films in a polarized light: (a) fibroin, (b) fibroin : P3HB = 80 : 20, and (c) fibroin : P3HB = 20 : 80.

The film of 100% P3HB demonstrates two endothermic peaks near 58 and 334°C. The former is associated with melting of the sample, and the latter, with onset of thermal degradation of the polymer. We found no glass transition of P3HB over the temperature range studied (it occurs at 3–7°C [12].

The blend films demonstrate the same set of endothermic peaks as for the individual compounds, but their temperatures and thermal effects change. For

* Not determined.

example, the endothermic peak due to removal of adsorbed water is found near 78°C for the film of straight fibroin; it is lacking at all in P3HB because of its hydrophobicity; and, in blend films, it shifts toward higher temperature (92°C for 80% P3HB), which can be attributed to the decreased crystallinity.

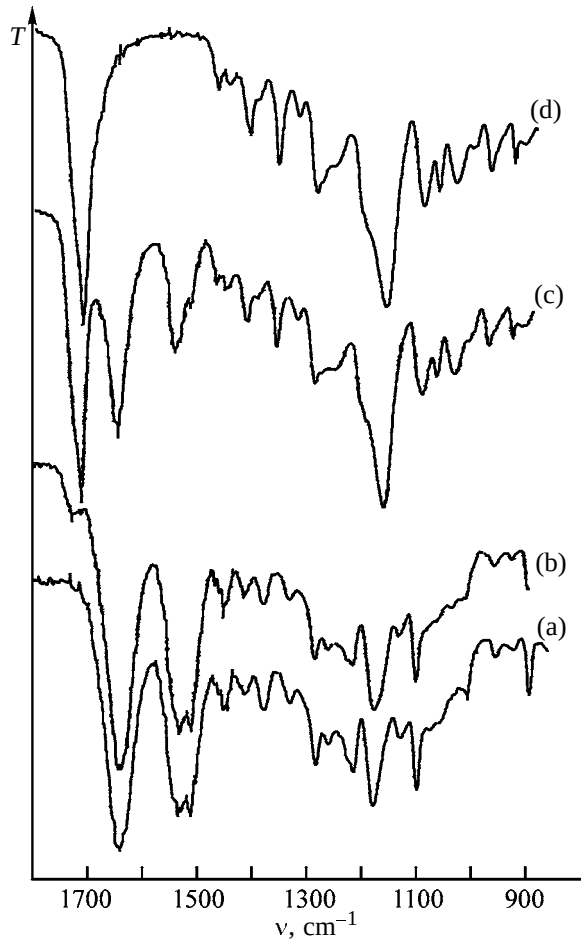

Fig. 2. IR spectra of polymer films: (a) fibroin, (b) fibroin : P3HB = 80 : 20, (c) fibroin : P3HB = 20 : 80, and (d) P3HB. (T) Transmission and (ν) wave number.

With increasing P3HB concentration, the endothermic effect due to glass transition in amorphous fibroin domains drifts towards higher temperature (from 151.8 to 178.4°C). The drift of the peaks in the presence of the second component suggests the possibility of intermolecular interaction with the second component in the amorphous fibroin domains and at the interface, which hinders the devitrification. At P3HB concentrations of 20 and 80%, its melting point in the blend decreases by 2–3°C, and at concentration of 40 and 60%, on the contrary, it increases by 1–2°C, i.e., in the presence of the second component, P3HB tends to melt more readily or vice versa, depending on the component ratio. The crystallinity of P3HB changes in parallel to its concentration in the blend. With decreasing P3HB concentration, the crystalline fraction decreases (from 29.4 for 100% P3HB to 6.3 for 20% P3HB). It may be concluded that the polymers plasticize each other, i.e., one affects crystallization of another, even though no cocrystallization occurs.

The IR spectra of the films of the individual components and their blends are presented in Fig. 2. The film of straight fibroin (Fig. 2a) shows a doublet at 1630 and 1642 cm^{-1} and a shoulder at 1660 cm^{-1}, which are assigned to absorption of the C=O groups [22, 23] in crystalline β-folded and α-spiral, and amorphous randomly globular conformations of the macromolecules, respectively. The absorption bands of the bound N–H and C–N groups at 1513, 1530, and 1540 cm^{-1} are assigned, respectively, to β-, α-, and amorphous conformations. With decreasing fibroin concentration to 80%, the intensity of the absorption band characteristic of α-spiral conformation increases, the band drifting to 1536 cm^{-1} (Fig. 2b). In the case of 20% fibroin, the spectrum shows only two absorption bands at 1650 and 1546 cm^{-1} corresponding

Table 3. Mechanical properties of fibroin–P3HB films

P3HB, wt %	G, N mm^{-2}	L, %	ρ, g cm^{-3}	Swellability, %	
				experiment	additive value
–	37.2	4.2	1.41	36.4	36.4
20	26.9	181.9	1.61	40.0	29.1
40	18.4	71.0	1.58	24.0	21.8
60	39.1	360.9	1.48	10.0	14.6
80	47.5	439.0	1.27	1.1	7.3
100	47.8	592.0	1.28	~0	~0

to the amorphous randomly globular conformation (Fig. 2c). Therefore, as the concentration of the second component increases, the crystallinity of fibroin in the blend decreases, and the β-folded conformation changes for α-spiral and then amorphous randomly globular conformations.

The spectrum of the film of straight P3HB (Fig. 2d) shows a strong peak at 1715 cm^{-1} due to absorption of the C=O groups characteristic of the crystalline domains, and also including absorption of the amorphous domains of the polymer [24]. In the spectrum of the blend with 80% P3HB (Fig. 2c), this strong peak is also found, but in the case of 20% P3HB (Fig. 2b), the corresponding band is shifted toward higher frequencies, suggesting practically total disappearance of crystalline domains of P3HB [24], i.e., in P3HB-rich blends crystalline domains occur along with amorphous ones, while at a P3HB concentration decreased to 20%, amorphous domains dominate.

The IR and DSC data show that, in mixing of fibroin with P3HB, a component dominating by the weight remains more crystalline, forming a polymer matrix, while small amount of the second component forms a dispersed phase. Interaction between different macromolecules can occur in amorphous domains and at the interface.

Films of straight fibroin demonstrate increased brittleness. In this case, the occurrence of a system of strong intermolecular bonds causes formation of a rigid, strained, and brittle structure. Films of straight P3HB are stronger and more elastic. Table 3 shows the mechanical characteristics of the films at various component ratios.

At a 40% concentration of P3HB, the breaking stress and elongation of the films are considerably lower as compared to the other samples, which can be attributed to the heterogeneity of the structure (macrosegregation) observed in this film. The swellability of this film is higher than that of the other samples including the film of straight fibroin. This is also caused by the heterogeneity, and occurrence of cavities at the interface, i.e., by the weakness of intermolecular interactions. For the film with 80% P3HB, the breaking stress is 47.5 N mm^{-2}, exceeding the additive value of 45.6 N mm^{-2} estimated neglecting interpolymer interaction. Evidently, this is a result of homogenization of the supramolecular structure, as was demonstrated by optical microscopy.

Finally, analyzing the results obtained, we may distinguish three ranges of the component compositions.

Range I covers P3HB concentrations below 20 wt %. In this range, fibroin is a more crystalline component forming a continuous polymer matrix with amorphous P3HB dispersed in it. Within this composition range, the swellability of the films exceeds the additive values, since amorphous P3HB domains loosen fairly hydrophilic fibroin. In this case, the fibroin structure remains crystalline, and P3HB plays a role of a plasticizing agent. Such films are characterized by higher elongation at break and increased density, which can be attributed to the interpolymer interaction at the interface. The occurrence of the interpolymer interaction is supported also by the increased density of the corresponding initial solution.

Range II covers compositions with a P3HB concentration from 20 to 80 wt %. In this range, two phases coexist, the interpolymer interaction being minimal. The films are characterized by the minimal breaking stress and by the swellability close to the additive values, i.e., two phases exist independently. The corresponding initial solutions have the lowest density.

Range III corresponds to compositions with a P3HB concentration above 80 wt %. Amorphous fibroin is dispersed in the continuous matrix of more crystalline P3HB. The swellability of the films is lower than the additive values, which is due to the fact

that the crystallites of hydrophobic P3HB hinder penetration of the liquid to the amorphous domains of hydrophilic fibroin. Interpolymer interaction can be realized at the interface. The density of the corresponding initial solutions is higher than that of the solutions of the individual components.

Generally, the fibroin and P3HB macromolecules in the blend solutions may interact through local contacts. On removing the solvent with formation of a film, macromolecules of the same sort tend to form a crystalline structure typical of the corresponding polymer, since the interaction energy in this case is higher than that between different macromolecules because of a smaller number of contacts. The crystallization depends on the component ratio in the blend. At a concentration of the second component below 20%, the macromolecules dominating in the quantity form a partially crystalline structure with inclusions of amorphous domains of the second component. If the components are taken in comparable concentrations, the structure appears to be loosened as a result of phase segregation. Since the polymers composing the blend crystallize separately, it may be suggested that, despite their incompatibility, intermolecular interactions with P3HB do affect the glass transition of fibroin in the blend, and that the presence of fibroin decreases the crystallinity of P3HB. The heterogeneity of the blend depends on the component ratio, controlling the mechanical properties of the resulting films.

CONCLUSIONS

(1) The compatibility of hydrophilic silk fibroin and hydrophobic poly-3-hydroxybutyrate in hexafluoro-2-propanol solutions and films prepared by removing the solvent is studied by IR spectroscopy, scanning calorimetry, viscometry, and optical microscopy.

(2) The indicated polymers are found to be incompatible at the molecular level, and no cocrystallization occurs after removal of the solvent.

(3) The microstructure of the films depends on the component ratio in the blend. When one of the components dominates, it forms a polymeric matrix with another polymer being dispersed in it. At comparable component ratio, macrosegregation occurs, thus deteriorating the mechanical characteristics of the films.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis of Carboxylated Monodisperse Latexes and Their Self-Organization in Thin Films

Abstract—The capability of carboxylated latexes of poly(methyl methacrylate) and copolymers of styrene with glycidyl methacrylate or methacrylic acid for self-organization in thin films was studied in relation to the compositions of the dispersion medium and polymer and to the latex particle size.

Monodisperse polymer particles of submicrometer size can serve as basis for formation of photonic crystals (PCs), a new class of dielectric materials promising both for experimental and theoretical studies of nonlinear optical effects and for development of new devices for quantum electronics and telecommunications industry [1–5]. In the PC lattice, the dielectric permittivity modulates with a period of the order of the light wavelength. This fact accounts for the existence of the photonic band gap (PBG), an energy range in which the light propagation inside the crystal is suppressed [1]. Of particular interest are three-dimensional (3D) photonic crystals in which a high density of structural components can be attained.

Composites based on synthetic opals with a fcc lattice formed by close-packed submicrometer spheres of amorphous silica are considered as promising materials for obtaining the required photonic-crystal properties [6–8]. However, obtaining a perfect 3D lattice with these materials involves serious technological problems. The high density of SiO_2 results in particle sedimentation, giving rise to stresses and defects in the ordered structure. As a result, synthetic opals have a polydomain structure with a domain size of 30–100 μm. Furthermore, the surface nonuniformity of amorphous SiO_2 microspheres formed by aggregation of nanometer-sized particles results in considerably increased diffuse scattering of electromagnetic waves at the phase boundary and in suppressed photonic-crystal effects [8]. Methods of polymer chemistry allow preparation of monodisperse surface-uniform submicrometer-sized particles of a lower density compared to inorganic materials [9–12]. Development of 3D ordered structures based on polymer particles of various diameters and compositions would allow their optical properties (primarily the PBG position and width) to be varied in a wide range.

To reveal factors that act in the step of self-organization of the primary polymer matrix and affect the structure and optical characteristics of the forming PCs, it seems appropriate to study systematically how the structure of the polymer and the size and surface properties of the polymer particles affect their capability for formation of highly ordered 3D structures. For this purpose, we studied various kinds of latexes based on poly(methyl methacrylate) (PMMA) and copolymers of styrene with methacrylic acid (PSt–MAA) or glycidyl methacrylate (PSt–GMA).

To ensure monodisperse composition and stability of latexes, their polymer base was modified in the course of the synthesis with carboxy groups; their ionization imparts a surface charge to the particles. By varying the composition of the dispersion medium, it is possible to control this charge and hence the forces of electrostatic repulsion between the latex particles, and thus to optimize the conditions of formation of the ordered structures.

EXPERIMENTAL

Styrene (St) and dimethylformamide (DMF) were purified by distillation, following standard procedures. Glycidyl methacrylate (GMA), methacrylic acid (MAA, pure grade), and $K_2S_2O_8$, NaOH, HCl, and Na_2HPO_4 (chemically pure and analytically pure grade) were used without additional purification. The purification procedures and characteristics of

4,4'-azobis(4-cyanoisovaleric acid) (ACVA) are given elsewhere [9]. As dispersion medium we used double-distilled water. The latexes were prepared by emulsion polymerization without emulsifier [9–12]. The synthesis conditions and characteristics of the resulting particles are given in Table 1. The diameters of latex particles were measured by transmission electron microscopy (JEM 100 S JEOL microscope). For a set of more than 400 particles, the variance σ and polydispersity coefficient K were determined ($K = D_m/D_n$, where D_m and D_n are the weight-average and number-average diameters, respectively). The surface concentration of carboxy groups was determined by conductometric titration [13] after threefold washing of the latexes to remove water-soluble impurities by successive centrifugation and redispersion in double-distilled water. The intrinsic viscosities determined viscometrically in DMF were used to calculate the viscosity-average molecular weight of the polymers in the particles, M_η, by the Mark–Kuhn–Houwink equation $[\eta] = KM_\eta^{-\alpha}$ with the following parameters: for polystyrene, $K = 4.16 \times 10^{-5}$ and $\alpha = 0.788$; for PMMA, $K = 1.73 \times 10^{-4}$ and $\alpha = 0.645$ [14].

Thin films were prepared by self-organization of latex particles from their dispersions in water and ethanol (Table 2). Dispersion samples (40 μl) were applied to cover glasses which had been treated with CrO_3/H_2SO_4 and washed with double-distilled water. Aqueous dispersions formed a drop owing to surface tension forces; alcoholic dispersions, on the contrary, spilt over the whole support surface. After leaching of the glasses for 30 min in 30% NaOH followed by washing with double-distilled water, aqueous dispersions wetted the whole support surface also. Glasses with the applied dispersion were placed in desiccators in which the dispersion medium slowly evaporated. In the process, the polymeric particles formed a close-

packed fcc lattice. Some samples in the course of film forming were ultrasonically treated in a Unitra-Unima UM-4 ultrasonic bath. The structure of the thin films obtained was examined by optical and scanning electron microscopy (JEM 100 C JEOL micrioscope). For nondestructive monitoring of the structure of the ordered polymer matrices and evaluation of the photonic-crystal properties, we studied the spectra of Bragg light reflection from surface spots of a size corresponding to the characteristic monodomain size, 10–50 μm (in terms of the approach suggested in [15]). By this method we studied the spectra of mirror reflection from [111] growth surfaces of the thin films in the visible and IR ranges. The incidence angle θ was 10°.

To obtain monodisperse polymer particles which could act as structural elements of 3D ordered lattices exhibiting photonic-crystal properties, we performed emulsifier-free emulsion polymerization of MMA and copolymerization of St with GMA (ACVA initiator) or of St with MAA ($K_2S_2O_8$ initiator). Based on the previously revealed relationships between the polymerization parameters and characteristics of polymer particles (diameter, size distribution, surface properties) [10–12], we prepared series of latexes differing in the particle diameter and dispersity.

For preliminary examination of the influence exerted by the characteristics of monodisperse polymer particles on their capability for self-organization into a three-dimensional lattice of a photonic crystal, we chose four latexes with the narrowest particle size distribution (Table 1, Fig. 1). The diameters of particels of these latexes fell within a narrow range, 250–330 nm, which allowed us to study how the polymer base affects the capability of the particles for ordering and to find the optimal method for formation of the ordered structures from each latex.

We found that glass degreased with CrO_3/H_2SO_4 is the best support for obtaining highly ordered lattices from particles of copolymers of St with GMA and MAA. The alcoholic dispersions, whose drops spilt over the whole support surface, formed more uniform thin films with a smaller number of defects than water-based latexes. Thus, passing from an aqueous medium to an alcoholic medium decreases the surface tension forces in a drop of the polymer dispersion and favors its self-organization to a more ordered structure under the conditions close to equilibrium. On the contrary, with PMMA particles, which are less hydrophobic than those of St copolymers, the best thin films were obtained by applying aqueous dispersion on glass hydrophilized by alkali treatment.

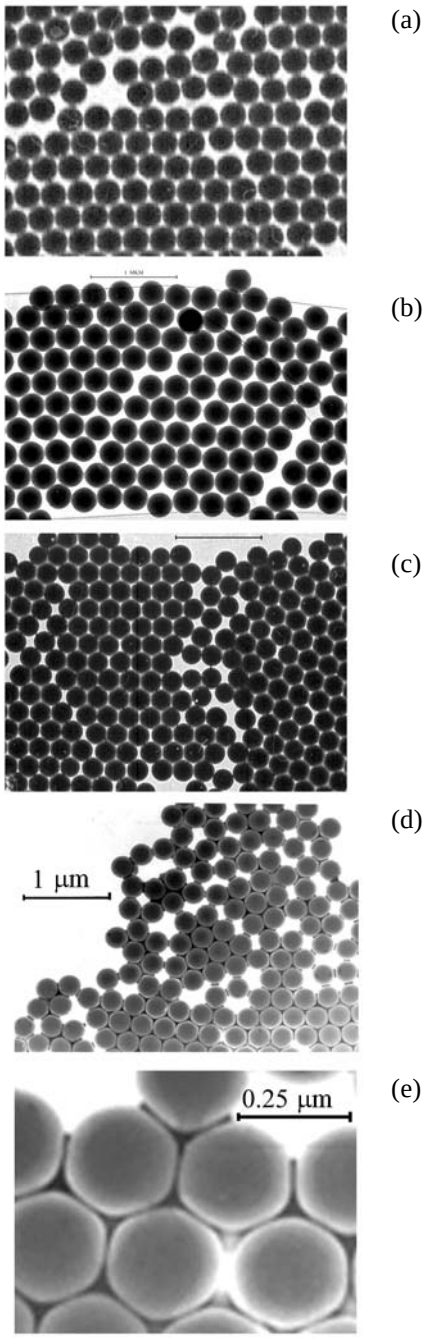

Fig. 1. Electron micrographs of latexes (a) IV, (b) III, (c) II, and (d, e) I.

Ultrasonic treatment of glasses in the course of self-organization of latex particles on them had no appreciable effect on the quality of the resulting thin film. The characteristics of the most ordered samples of the thin films obtained are given in Table 2. Examination by scanning electron microscopy showed that particles of all the latexes studied under the empirically chosen conditions form an fcc lattice with the

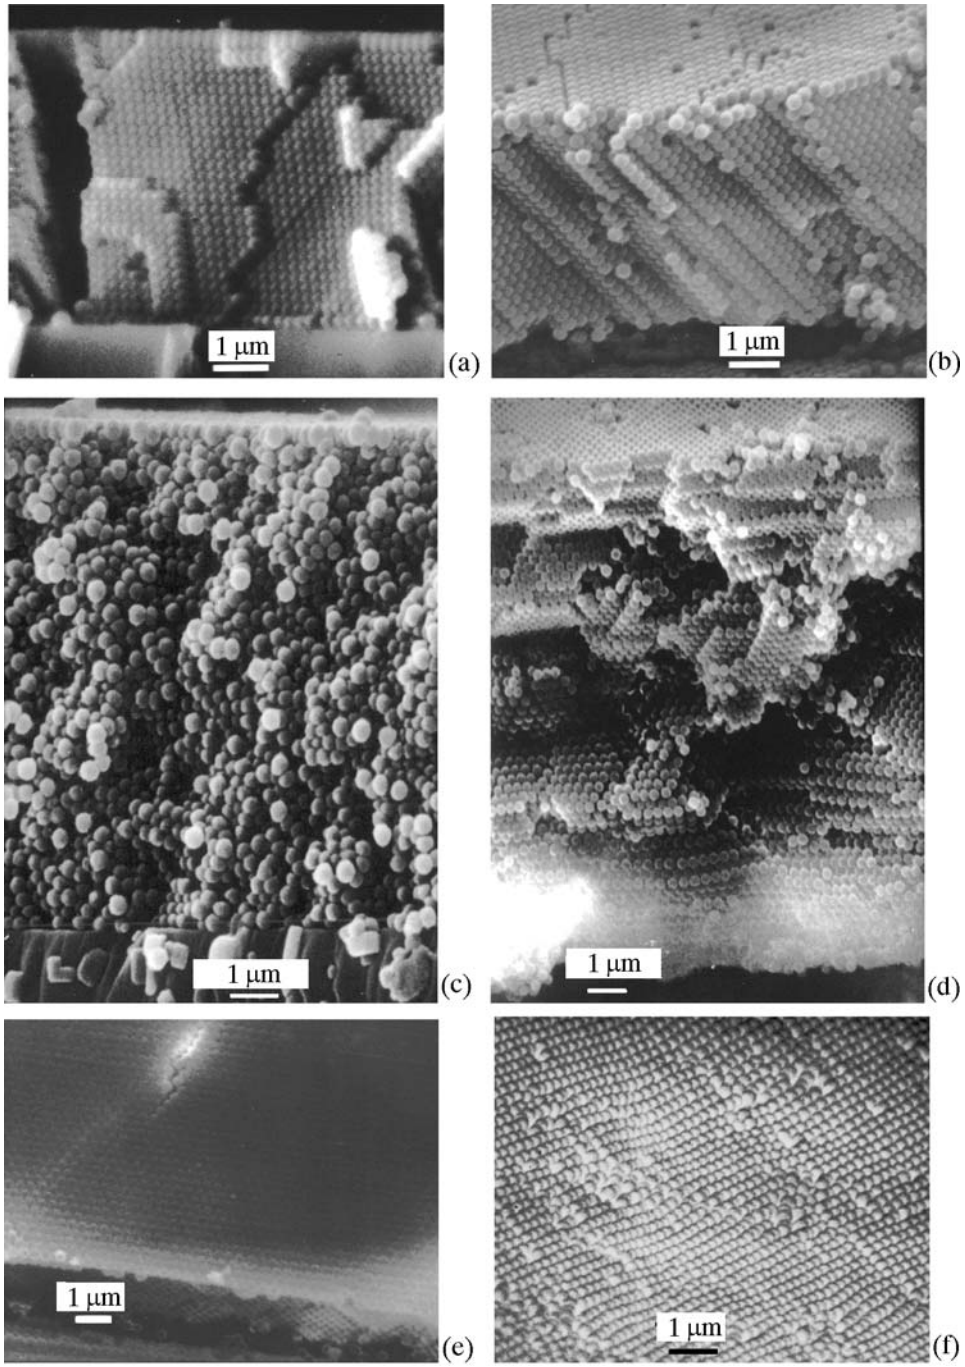

Fig. 2. Electron micrographs of thin films formed from particles of latexes (a, e) I, (b) II, (c) III, and (d, f) IV. (a–d) Side view and (e, f) top view.

structure thickness of up to 50–60 layers (Fig. 2). The quality of the thin films obtained (presence of point defects and breaks) depends on the composition of the dispersion medium (water, alcohol), rate of its evaporation, and also conditions of the preteatment of the glass supports. In particular, rough leached surface of the support in the case of PMMA (Figs. 2d, 2f) results in a shift of the layers relative to each other (corrugation effect), and particles based on copolymers of St with GMA, which is a bifunctional monomer and yields a cross-linked polymer matrix, get nonuniformly "crumpled" when forming a multilayered structure (Fig. 2c).

For the films prepared from PMMA and PSt–GMA particles, direct determination of the number of layers

in the film from electron micrographs and calculation of the number of layers from the film thickness (measured by optical microscopy) and particle diameter taking into account the fcc structure gave different results. The values obtained were close or coinciding only for the films formed from particles that had been obtained by copolymerization of St with MAA; this fact, along with the electron micrographs (Figs. 2a, 2b, 2e), suggests that their structure is the most perfect.

It is well known that emulsion copolymerization with water-soluble carboxyl-containing comonomers yields polymer particles whose surface layer is enriched in polymer chains with increased content of carboxyl-containing hydrophilic units [16]. Such a surface layer can change its volume depending on the salt composition and pH of the dispersion medium. For example, variation of the diameter of particles of latex I depending on pH of the dispersion medium was noticeable at an electrolyte concentration of 10^{-3} M (Fig. 3, curve *1*). The particle diameter appreciably increased in an alkaline medium, in parallel with an increase in the negative charge of the surface, inversely correlating with the electrophoretic mobility (Fig. 3, curve *2*). Swelling of the hydrophilic surface layer due to mutual repulsion of the ionized carboxy groups results not only in an increase in the particle diameter. Another consequence is that this surface layer can uniformly contract, with uniform shrinkage occurring upon particle packing and evaporation of the dispersion medium. In the process, the particles in the monolayer acquire hexagonal shape, similarly to honeycomb (Fig. 1e), and the structure of the multilayer fcc lattice formed from such particles is more perfect.

The structures obtained by self-organization of latex particles were examined by such a nondestructive method as spectral optical microscopy. The reflection spectra of all the synthesized films at inclined light incidence have a pronounced peak originating from the Bragg diffraction of electromagnetic waves on a large-scale periodic lattice. The photonic band gap appearing in the yellow–red range (Fig. 4) shows that the monodisperse latex particles self-organize to form a photonic crystal lattice. The structure of the polymer, along with the diameter of the monodisperse particles, significantly affects the PBG position (Fig. 4a). The long-range order of the periodic lattice based on St–MAA copolymer particles is confirmed most clearly by the reflection spectra of thick films, which, despite large thickness (several millimeters), show photonic-crystal properties (Fig. 4b).

Polymeric photonic crystals of millimeter size with

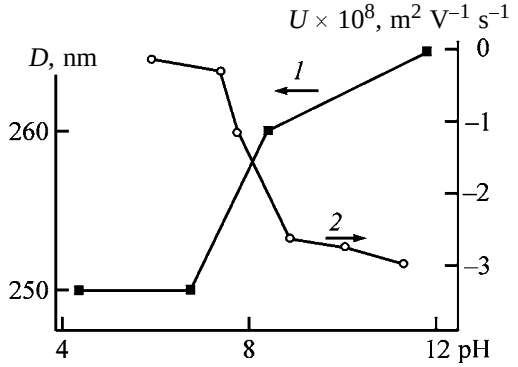

Fig. 3. Influence of the pH of the dispersion medium on the (*1*) diameter *D* and (*2*) electrophoretic mobility *U* of particles of latex I.

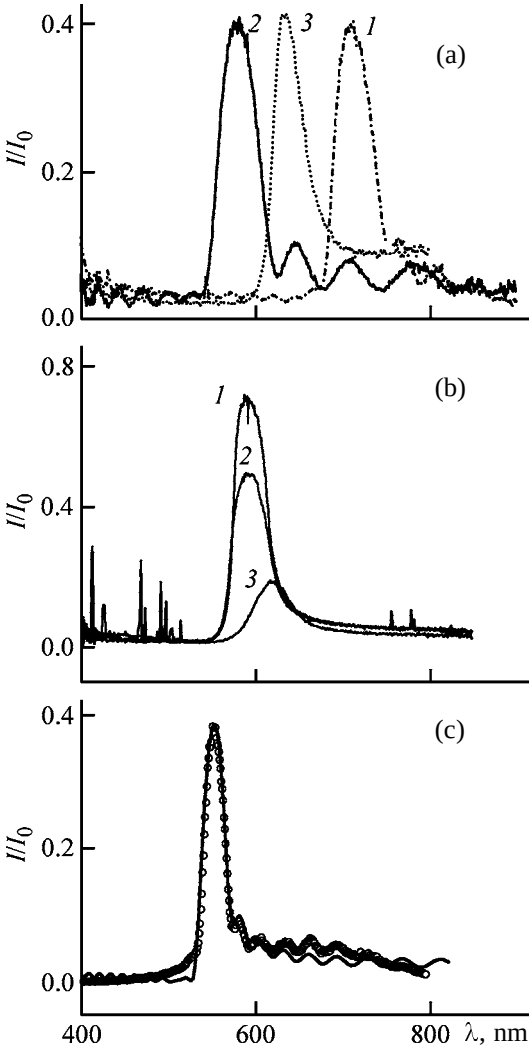

Fig. 4. Reflection spectra (a) of thin film nos. (*1*) 6, (*2*) 2, and (*3*) 5; (b) of bulk sample of latex IV of thickness (*1*) 1, (*2*) 2, and (*3*) 3 mm; and (c) of film no. 1. (c) Points, experimental data; solid line, theoretical calculation.

a high degree of ordering and a period that can be varied in the submicrometer range by varying the particle size can be considered as reference objects for studying the interaction of light with a 3D regular structure of a photonic crystal. Experimental data obtained with the most perfect thin-film structures based on PSt–MAA particles can be used as a basis for constructing a theoretical model describing the specific features of photon propagation in a 3D large-scale (of the order of light wavelength) periodic lattice [17].

In the model developed, a 3D fcc lattice is approximated by a layered periodic system with the dielectric permittivity modulated along the [111] direction. The specific profile of the dielectric function was calculated with its averaging within the unit cell in the plane perpendicular to the [111] direction. The results of numerical calculations by the method of transfer matrices [17] appeared to be well consistent with the experimental reflection spectrum of a thin film obtained from latex I (Fig. 4c).

The theoretical calculations also allowed independent determination of the optical constants of the structures synthesized and of the geometric parameters of polymer particles in a film. The refractive index of the particles is similar to that of bulk polystyrene (1.59 at 20°C). The calculated particle diameter, 252.4 nm, is very close to the value determined by electron microscopy (250 nm). The calculated number of layers in the film (26) coincides with the results of electron-microscopic examination (Table 2). The model developed takes also into account the effects of contraction of latex particles, arising in the course of formation of the bulk material. The calculated shrinkage coefficient of particles in film no. 1 (Table 2) was 3%. As the latex particle diameter is 250 nm, their contraction in the film can amount to approximately 7.5 nm. This value seems quite reasonable, since it is comparable with the change in the particle diamater due to swelling of their hydrophilic surface layer (Fig. 4). Thus, the theoretical model is in good agreement with the experiment, which indicates that, on the one hand, the thin-film polymer periodic structures obtained are perfect and, on the other hand, these structures can be used as model objects in theoretical studies of interaction of light with the 3D lattice of photonic crystals.

CONCLUSIONS

(1) Procedures are optimized for preparing monodisperse latexes of poly(methyl methacrylate) and copolymers of styrene with glycidyl methacrylate and methacrylic acid and for obtaining highly ordered 3D lattices from these latexes. Dispersions of monodisperse polymer microspheres with the preset size and definite surface structure were prepared, and thin-film ordered lattices were obtained from them. The 3D periodicity of these lattices was proved by electron microscopy.

(2) In the examined objects, the electromagnetic waves strongly interact with the periodic lattice, and a photonic band gap arises. The photonic-crystal properties of thin films are significantly influenced by the structure of polymer particles from which they are prepared.

(3) Films based on particles of styrene–methacrylic acid copolymer form a more regular structure and are the most promising as structural elements for preparing 3D photonic crystals fully consisting of monodisperse polymer particles.

(4) The reflection spectra calculated within the framework of the theoretical model of light propagation in the synthesized structures, taking into account deformation of the monodisperse polymer particles, are well consistent with the experiment.

ACKNOWLEDGMENTS

The study was supported by the Scientific Program of the Presidium of the Russian Academy of Sciences "Nanostructures in Polymer Systems, Promising for Optoelectronics," by the Russian Foundation for Basic Research (project no. 04-03-33 080), and by the Scientific Program of the Division of Chemistry and Materials Science of the Russian Academy of Sciences "Development and Study of Macromolecules and Macromolecular Structures of New Generations."

The authors are grateful to A.B. Pevtsov and A.V. Sel'kin (Ioffe Physicotechnical Institute, Russian Academy of Sciences, St. Petersburg) for discussion of the results and assistance in measurements and theoretical treatment of the optical spectra.

HISTORY OF CHEMISTRY AND CHEMICAL TECHNOLOGY

Theodor Grotthuss (to 220th Anniversary of His Birthday)

Theodor Grotthuss, a talented scientist, physicist, and chemist from the Baltic region, went down in history as the author of an original theory of electrolysis of aqueous solutions and of studies in the field of photochemistry and analytical chemistry. The theoretical ideas presented in his works largely foreshadowed the physical theory of solutions, concepts of electrolytic dissociation, and understanding of the phenomenon of luminescence and chemical action of light. Grotthuss made first observations in the field of electrochemistry of organic compounds. A major contribution to the study of the scientific legacy of Grotthuss and his life was made by J.P. Stradins, a known Latvian electrochemist and historian of science [1–5].

Baron Christian Johann Dietrich von Grotthuss, more known as Theodor Grotthuss, was born on January 24, 1785, in Leipzig, during a trip of his parents abroad. His family, belonging to an ancient house, owned a small estate Geduchi (Geduchai) in northern Lithuania, at the very border with Kurlandia. At this estate passed the youth and most part of the scientist's life. His father died soon after his birth, and Grotthuss was brought up by his mother and numerous teachers. Despite the humanitarian orientation of his home education and the obvious talent for music, the youth was strongly interested in natural sciences and self-educated using his father's library. In the spring of 1803, the eighteen-years-old Grotthuss first went to West Europe to be educated in natural sciences, and primarily in chemistry. The first stop was in Leipzig, but, at that time, the city was not yet among prominent centers of chemical science. Therefore, Grotthuss moved in the autumn of the same year to Paris, where he entered as an external student the Ecole Polytechnique, one of the best educational institutions of that time. Among Grotthuss's teachers are primarily named A.-F. de Fourcroy (1755–1809), a scientist, statesman, science popularizer, member of the Paris Academy of Sciences (since 1785), and an honorary foreign member of the St. Petersburg Academy of Sciences (since 1802); and also C.L. Berthollet (1748–1822) and L.N. Vauquelin (1763–1829), members of the Paris Academy of Sciences. Grotthuss

spent in Paris only a year, and the aggravation of relationships between France and Russia forced him, a Russian citizen, to move to Italy in September 1804.

After A. Volta (1745–1827), an Italian physicist, created the first chemical dc power cell (1799), scientists from many countries, and those from France and Italy in the first place, studied, with varied success, the electrolysis process. Grotthuss knew from lectures delivered by Fourcroy, Berthollet, and Vauquelin about difficulties encountered in explanation of electrochemical phenomena. Having acquired a power cell, Grotthuss carried out numerous experiments on electrochemical decomposition of aqueous solutions. He spent the whole year of 1805 in Naples and finished there his best-known study in September 1805. He, a twenty-years-old youth who had not received any systematic education, managed to be the first to give an interpretation of the electrolysis process and current transport in solutions. According to Grotthuss, electric energy is transferred through formation of chains of polar molecules in solutions. The decomposition of water at electrodes occurs via liberation of molecular fragments at places of direct contact between the chains and the electrodes [1, 2, 6–9]. This first study under the title "On Decomposition of Water and Substance Dissolved in It under the Action

1070-4272/05/7801-0166© 2005 Pleiades Publishing, Inc.

of Galvanic Electricity," published in French in Rome in the end of 1805, made him famous. Already in April 1806, Grotthuss's work was published in France in the journal *Annales de Chimie*; in the same year, it was published in British journals and, as a separate edition, in France in scientist's motherland at the town of Mitava (Elgava), the capital of Kurlandia. This work by Grotthuss was included, in Russian translation, into the collection of works [9]. Before that, the study had not been published in Russia, but Grotthuss's hypothesis was discussed in detail in the first Russia's textbook on physical chemistry [10].

From November 1805 till the end of 1806, Grotthuss lived in Rome and other Italian cities, improved his knowledge of Italian and mathematics, and commenced examination of bioluminescence. The young scientist spent nearly the whole year of 1807 in Paris, where he continued his scientific activities and, in particular, tried to reveal the role of galvanic electricity in formation of metallic dendrites. In addition, Grotthuss carried one of the first studies in organic electrochemistry. In 1807, Grotthuss was elected an honorary member of the Paris galvanic society. In the autumn of 1807, he left Paris and went home via Munich and Vienna. Since 1808, he never left Russia. As mentioned in Stradins's monograph [1], Grotthuss neither finished his education nor got scientific training or obtained a scientific degree. However, the talented young man was actively engaged in self-education, made acquaintance with a number of leading scientists of that time, comprehended the most topical problems in the fields of science he was interested in, and carried out investigations that got him a deserved fame. In 1814, Grotthuss was elected a corresponding member of the Munich Academy of Sciences.

Grotthuss lived without break at his mother's estate and encountered severe difficulties in obtaining scientific information, only being in correspondence with several scientists, and possessed only the simplest equipment. The only Grotthuss's far travel, to St. Petersburg for six months in 1812, occurred when he was compelled to go by the approaching French troops. During these months he made friends with A.I. Sherer (1772–1824), a professor of chemistry and later (since 1815) a member of the St. Petersburg Academy of Sciences. Sherer was the author of the first original textbook of chemistry in Russia, in which he, in particular, presented the oxygen theory developed by A.L. Lavoisier (1743–1794). A regular correspondence between Grotthuss and Sherer continued till the end of Grotthuss's life. A number of papers by Grotthuss were published in the journal published for a while by Sherer.

In 1817, Kurländiche Gesellschaft für Literatur und Kunst (Kurlandian Society of Literature and Fine Arts) was organized at Mitava. In conformity with its regulations, the society was to be engaged in historical-literature, scientific, and educational activities. During the first years of existence of the society, the natural-science area of these activities was predominant. Grotthuss became one of the most active members of the society. He repeatedly reported on his research activities at meetings of the society and published some of his works in the *Annual Report of the Society*. In particular, the most important of his investigations, "On the Chemical Action of Light and Electricity," was published in German in the first volume of this edition (1819). In this paper, occupying the central position in his scientific works, his ideas concerning the origin of photochemical and electrochemical phenomena were presented. Grotthuss was the first to establish that only absorbed light causes chemical transformations, he also noticed the proportionality of the photochemical effect to time. Important results of photochemical studies were also published by Grotthuss in one of his earlier papers "On an Absorbent of Light and Some General Considerations Concerning the Phosphorescence and Colors" (1815). Photochemical studies by Grotthuss have been analyzed by B.Ya. Dain [11] and Stradins [1].

The second in importance to Grotthuss's investigations in the field of electrochemistry, theory of light, and photochemistry are his studies of combustion of gas mixtures, carried out in 1809–1812. The widely diverse scientific activities of the Baltic scientist are discussed in ample detail in a monograph devoted to him [1]. Among prominent Grotthuss's publications, mention should be made of the collection of his physicochemical works [12] (only the first volume was published) and a separate volume, including works by Grotthuss, in the series of publications, *Klassiker der exacten Wissenschaften* (1906), founded by W. Ostwald. After this book was published, the attention of physical chemists and historians of science to Grotthuss's works became markedly closer. Grotthuss's activities were highly appreciated by Russian academician P.I. Walden (1863–1957). He believed that works by Grotthuss "...are exactly formulated predecessors of our modern molecular-kinetic and electrolytic theories" [13]. At the same time, Grotthus had to defend repeatedly, frequently without any good reason, his priority in separate issues.

Beginning at the age of 17, the scientist suffered from a severe hereditary abdomen illness, whose true nature remained unclear. On March 14, 1822, Grotthuss shot himself being in the state of a deep depres-

sion. He had virtually no disciples and followers. The interest in most of the problems Grotthuss studied arose only in the late XIX century, when physical chemistry formed as an independent scientific discipline. The list of Grotthuss's scientific works was given in the monograph [1], with some supplements made in [4]. The main publications by Grotthuss were listed in a reference bibliographic publication by Poggendorff [14]. The material concerning the life and scientific activities of Grotthuss is included, together with his scientific biography [1], in quite a number of reference publications [5, 15, 16] and monographs [6, 8, 17].

INFORMATION

Fourth International Workshop "Intrachamber Processes, Combustion, and Gas-Dynamics of Dispersed Systems"

The Fourth International Workshop "Intrachamber Processes, Combustion, and Gas-Dynamics of Dispersed Systems" was held in St. Petersburg from June 28 to July 3, 2004. Similarly to the three preceding workshops devoted to this topic, the workshop in question was held under the auspices of the Ministry of Science and Education of the Russian Federation (Northwestern Division of the Scientific Council for Combustion and Explosion at the Presidium of the Russian Academy of Sciences) and Russian Academy of Rocket and Artillery Sciences (Northwestern Center). Among the main organizers of the workshop were the Voenmekh Baltic State Technical University and the Semenov Institute of Chemical Physics, Russian Academy of Sciences.

The international scientific committee of the workshop included, together with Russian scientists, representatives from the United States, Italy, Israel, France, Germany, India, Finland, and Ukraine. The workshop was one of the youth-oriented undertakings of the Integration Federal Target Program. Its main purpose was to satisfy the demand for scientific communication of scientists belonging to various generations. The youth had an opportunity to make direct scientific contacts with representatives of research centers of Russia and foreign countries. Fifty-three Russian and 8 foreign scientific institutions took part in the activities of the international workshop.

The reports submitted to the workshop were delivered at seven sections:

(1) Combustion of solid fuels and of their components.

(2) Gas dynamics, heat-and-mass exchange, and heat protection.

(3) Intrachamber processes, internal ballistics.

(4) Dynamics of gas–liquid heat-mechanic systems.

(5) Nonstationary combustion, explosion, impact, protection.

(6) Problems of ecology and safety.

(7) New computer technologies and means of computer simulation of intrachamber processes and related problems.

The program of the plenary meeting included the reports "Modern Problems of Internal Ballistics and of the Theory of Combustion" (A.M. Lipanov, Institute of Applied Mathematics, Ural Division, Russian Academy of Sciences, Izhevsk) and "Physics and Chemistry of Combustion of Gas Mixtures" (Yu.V. Polezhaev, Institute of High Temperatures, Russian Academy of Sciences, Moscow).

Staff members of the Voenmekh Baltic State Technical University (St. Petersburg) took the most active part in the workshop: they presented 28 out of 124 sectional and poster reports included in the program of the workshop. Among representatives of other scientific institutions of St. Petersburg, who delivered reports, were staff members of the Academy of Civil Aviation, Prikladnaya Khimiya Russian Scientific Center, Leninets Holding Company, and State University of Aerospace Instrument-Building. Representatives of higher-school institutions, institutions of the Russian Academy of Sciences, and other institutions from Moscow, Volgograd, Izhevsk, Kazan, Kemerovo, Novosibirsk, Perm, Tomsk, Tula, Chelyabinsk, Biisk, and Togliatti participated in the workshop.

The reports delivered were distributed among the sections as follows: 32 reports in Section 1, 29 in Section 2, 25 in Section 3, 21 in Section 4, 8 in Section 5, 6 in Section 6, and 3 in Section 7. The proceedings of the workshop were published as a collection of works in two volumes. The first of these (229 pp.) briefly describes the reports from the first and second sections, and the second (228 p.), the rest.

INFORMATION

Fifth International Congress on Chemical Technologies

The Fifth International Congress on Chemical Technologies was held in St. Petersburg on October 12–14, 2004, in the framework of the traditional Week of Chemical Technologies. It was organized by the Ministry of Education and Science of the Russian Federation, Federal Atomic Energy Agency, St. Petersburg State Technological Institute (Technical University), St. Petersburg Scientific Center of the Russian Academy of Sciences, and Vystavki–Seminary–Biznes (Exhibitions–Seminars–Business) Ltd., with the active support by a number of other scientific institutions and enterprises.

The program of the plenary session devoted to "Chemical Industry in Russia, Prospects for Development" included three reports: "Promising Areas of Nanotechnology" (A.P. Alekhin and A.A. Malygin, St. Petersburg), "Strategy of SIBUR Joint-Stock Company in Solving the Problem of Doubling of the Gross National Product" (B.L. Baiburskii, Moscow), and "New Chemical Technologies for Processing of Liquid Radioactive Waste by Means of Nonstationary Membrane Processes" (M.A. Afonin and A.A. Kopyrin, St. Petersburg).

Three conferences: "Modern Inorganic and Organic Composites and Their Processing. Polymeric Materials: Technologies. Quality. Equipment," "Processing of Wastes. Materials and Technologies for Environment Conservation," and "Functional Coatings," were held in the framework of the Congress. The program of the first, second, and third of these conferences included 20, 33, and 14 reports, respectively. A rather high activity in the work of all the three conferences was exhibited by staff members of St. Petersburg Technological Institute (31 reports). Of other institutions, mention can be made of the Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Resources, Kola Scientific Center, Russian Academy of Sciences (Apatity) and the Khlopin Radium Institute (St. Petersburg). Specialists from Belarus and Estonia took part in the work of the Congress.

The reports were published in a special collection of works (V International Congress on Chemical Technologies, Proceedings, 2004, 96 pp.) The report by M.P. Fedorov and co-authors (St. Petersburg) "Processing of Wastes: the Most Important Environmental Issue of the XXI Century" discussed the necessity for a systematic and directed training at higher-school institutions of specialists in utilization of wastes with account of the recent advances in science and technology and in development and application of environmentally clean and low-waste technologies. To the problem of process waste were devoted the reports by L.A. Vaisberg (St. Petersburg) "Processing of Industrial and Household Wastes as a Basis for Global Resource Saving" and by D.A. Golubev and co-authors (St. Petersburg) "Organization of a Medical-Ecological Monitoring of the Environmental Safety at the Krasnyi Bor Site in Processing of Dangerous Industrial Wastes," and quite a number of other reports. The regulations concerning waste processing in the Russian Federation, new technologies for processing of the municipal waste, use of polymers for solidification of some radioactive wastes, transfer of toxic industrial wastes into a nontoxic product that can be used for a variety of purposes, and quite a number of other important environmental problems were considered.

A large group of reports was devoted to fabrication technology of new structural materials for various purposes and to protective coatings. To these reports belong those by S.S. Ordan'yan (St. Petersburg) "Physicochemical Foundations of Synthesis of Ceramic Composites Based on High-Melting Compounds," I.B. Panteleev and Ordan'yan "New Instrumental Hard Alloys Based on Tungsten Carbide," O.M. Merkushev and co-authors (St. Petersburg) "Sol–Gel Synthesis of Nanosize Electrochromic Films," V.Yu. Dolmatov (St. Petersburg) "Detonation-Synthesized Nanodiamonds as a Basis of a New Generation of Various Composite Coatings," and N.A. Zaitseva and A.V. Vasil'eva (St. Petersburg) "Electrodeposition of Metal Coatings onto Aluminum and Its Alloys."

The program of the Congress on chemical technologies was rather diverse and rich. A number of exhibitions were opened during the Week of chemical technologies. The Congress participants had an opportunity to visit some enterprises and scientific centers of St. Petersburg and Leningrad oblast. On October 14–16, 2004, a group of Congress participants went to southeastern Finland, where an out-of-town seminar "New Technologies for Processing and Storage of Household and Industrial Wastes" was held.

The next, Sixth International Congress on Chemical Technologies is to be held in October 2005.

Abstract—X-ray phase and differential thermal analyses were used to study in detail how the morphology of aluminum hydroxides changes in separate stages of the technological process. The assumption that two pseudoboehmite modifications differing in crystallite dimensions and lattice constants can be formed in the course of precipitation was considered.

The effectiveness of catalytic systems based on γ-Al_2O_3 largely depends on their morphological structure, which affects a number of important characteristics of the support: specific surface area, porometric volume, pore size distribution, etc. [1]. Active alumina is for the most part industrially produced by thermal decomposition of aluminum hydroxide [2], which inherits the texture of the precursor because of the pseudomorphism in calcination. In turn, the texture of the precursor is determined by the conditions of precipitation and further technological procedures [3].

The influence exerted by the technological stages of industrial synthesis of aluminum hydroxide (AH) on the morphology of the active alumina obtained gas been insufficiently covered in the literature.

Previously, the transformation of the porous structure of AH synthesized under industrial conditions by the double-flow sulfate technology based on periodic precipitation upon mixing of low- and high-temperature hydroxides has been studied [4, 5]. It was established that the way in which the texture characteristics of the mixed hydroxide are formed is primarily determined by properties of individual hydroxides, type of interaction between particles, and transformation of the porous structure in all stages of the technological process.

It should also be noted that, in the course of industrial synthesis, AH passes a number of stages, each making its own contribution to the texturing of aluminum hydroxide in precipitation and of the resulting oxide in calcination [6]. At the same time, it was demonstrated in [7] that the texture of the system being synthesized is mainly formed in the precipitation stage. This texture can be controlled by varying the conditions in which the process occurs.

The aim of this study was to analyze in detail the influence exerted by factors associated with separate stages of synthesis on the formation of AH manufactured by continuous precipitation by the nitrate technology used at Novokuibyshev Plant of Catalysts Ltd.

EXPERIMENTAL

The object of study was AH synthesized by continuous reprecipitation of alumina trihydrate by the nitrate method. The samples to be examined were selected after the following stages of synthesis: (1) precipitation at 32°C and pH 8.6; (2) stabilization at 102°C, pH 5.0, τ = 90 min; (3) bringing the pH to 8.9, T = 80°C, τ = 130 min; (4) stabilization at 80°C, pH 8.8, τ = 4 h; (5) agitation; (6) pressing on a filter press; (7) repulpation; and (8) bringing the pH to 9.2.

Differential thermal analysis was performed with a Q-1500D derivatograph in air in the temperature range 20–1000°C at a heating rate of 10 deg min^{-1}; the sample mass was 200 mg. The accuracy of determining the loss of mass was ±0.5%.

X-ray diffraction patterns were measured on a DRON-2 instrument (Fe_{K_α} radiation, beta filter, 2θ = 5°–100°, 30 kV, 15 mA). Annealed copper foil was used as reference for determining the dimensions of

* Content of gibbsite in the starting sample no. 1, 40 wt %.

** No defectiveness of the crystal lattice on the [200] and [002] faces (Pb, pseudoboehmite).

crystallites (coherence domains) and microstrains. The interplanar spacings were found using the ASTM file. The accuracy of determining the lattice constants for samples of hydroxides was ±0.003 Å.

The results obtained in the X-ray phase (XPA) and diffraction analyses are listed in Table 1. The phase composition, lattice constants, and dimensions of the coherence domains were calculated using a special program package, Material Analysis Using Diffraction (MAUD). The content of particular crystalline forms in the samples obtained was evaluated by the ratio of the integral intensities of the lines characteristic of a given hydroxide form found in the mixture.

The X-ray diffraction pattern of a sample that passed the precipitation stage (Table 1, sample no. 1) shows narrow high-intensity characteristic reflections of gibbsite with interplanar spacings *d*/*l* of 4.856 and 4.373 Å at angles $2\theta \approx 17°–20°$, with a crystallite dimension of 300.54 Å. The content of the trihydrate present in a fresh precipitate because of the incomplete neutralization is 40 wt %.

The fact that the diffraction pattern contains low-intensity doublet peaks with asymmetric profiles, to which correspond interplanar spacings d/l_{020} = 6.056 and 6.709 Å at small angles ($2\theta \approx 10°–16°$), d/l_{120} = 2.364 and 2.522 Å at medium angles ($2\theta \approx 30°–60°$), and d/l_{200} = 1.871 and 1.925 Å and d/l_{002} = 1.441 and 1.378 Å at large angles ($2\theta \approx 70°–90°$) indicates that the pseudoboehmite phase is present in the precipitate.

The attempt to describe the X-ray diffraction pattern on the assumption that only gibbsite and one type of pseudoboehmite are present in the precipitate failed to produce any reliable result. The total rms deviation of this calculation, *W*, was 30304. Therefore, an assumption was made that the phase composition of the hydroxide is more complex. It was assumed, with account of the asymmetric profile of the pseudoboehmite peaks, that two pseudoboehmite modifications are present in the precipitate, together with gibbsite, and these modifications differ in the dimensions of crystallites (coherent domains). In this case, the experimental diffraction curve well coincides with that calculated with additive superposition of differential lines for separately taken components. The smallest value of *W* (8142) was obtained with this approach.

Table 2. Classification of AH

Criterion	Amorphous AH	Pseudoboehmite		Boehmite
		poorly crystallized	well-crystallized	
Specific surface area, $m^2 g^{-1}$	Not determined or <1	≥300	100–300	≤10
Number of H_2O moles per mole of Al_2O_3	≥1.7	2.0–1.2	1.2–0.9	<1.0
Interplanar spacing along the *b* axis, Å	–	13.0–12.5	12.5–12.3	<12.3
Defectiveness of the unit cell, %	–	>11	3–11	<3
Crystallite dimensions along the [020] face, Å	<13.0	13–20	>20	>35

Thus, the content of pseudoboehmite Pb_1 in a freshly precipitated hydroxide is 57 wt %, The crystallite dimensions are (Å) 35.89 × 48.95 × 68.60 along the planes [020] × [200] × [002], and the most defective crystallographic face is [020] (defectiveness 7%; Table 1, sample no. 1). In this case, the content of water in the interplanar space of the crystal lattice of the monohydroxide is 1.00 mol per mole of Al_2O_3 [6]. The pseudoboehmite Pb_2, simultaneously present in the precipitate in an amount of 3 wt %, has properties markedly different from those of Pb_1. First, the dimensions of primary particles along the corresponding cleavage planes ([020] × [200] × [002]) are (Å) 48.83 × 998.60 × 978.66, with the defectiveness of the structure on the [020] face being lower (~3%). Second, the significant expansion of the unit cell to 13.42 Å along the *b* axis indicates that an excess structural water is incorporated in an amount of 2.08 mol per mole of Al_2O_3.

The X-ray diffraction pattern of a hydroxide that passed the stabilization stage contains no lines of gibbsite. Calculations show that the fraction of Pb_1 increases by approximately 40 wt % (Table 1, sample no. 2), in agreement with published data [8], according to which large crystallites of trihydrate disintegrate in the course of time at relatively low pH values (4–6) to form pseudoboehmite particles about 30 Å in size. The dimensions of primary particles of the forming pseudoboehmite are virtually unchanged (Table 1) and the lattice constants *a*, *b*, and *c* remain constant. The defectiveness of the crystal lattice along the [020] face decreases by 4% to 3%. It is noteworthy that the amount of structural water between the cleavage planes along the [020] face also decreases only slightly, by 0.02 mol (0.98 mol H_2O/mole of Al_2O_3). The total rms deviation *W* for the given sample is 5809.

Similarly to the case of Pb_1, the dimensions of Pb_2 particles remain unchanged (Å): 932.35 × 979.38 × 1001.94 along the planes [020] × [200] × [002], with the lattice constants *a*, *b*, and *c* decreasing. It is of interest that, in contrast to the case of Pb_1, the lattice constant *b* of Pb_2 markedly decreases (to 12.38 Å) because the dehydroxylated layers become closer. This is due to removal of 0.92 mol of structural water (1.16 mol H_2O/mole of Al_2O_3) and the resulting approach of the dehydroxylated layers in the direction [020].

In the general case, crystallites of each pseudoboehmite modification have individual properties with isotropy along the crystallographic faces [020] × [200] × [002], and, as indicated by Table 1, can retain these properties in all stages of the technological process. The aforesaid is in agreement with the opinion [9] that the dimensions of primary particles formed in precipitation remain constant during the whole time of crystallization, because the structure is formed within the crystallites.

To discriminate more clearly between the pseudoboehmite phases described here by comparing the results obtained with published data [3, 10], the following criteria were suggested (Table 2).

The interpretation of the results of the X-ray phase analysis is in a good agreement with the data obtained by means of derivatography. For example, the thermal decomposition of the AH samples studied occurs in at least four stages with low- and high-temperature endothermic peaks recorded in DTA and DTG curves (Table 3).

In the initial stage of the thermal decomposition of a sample that passed the precipitation stage (Table 3, sample no. 1), unbound water is removed, which is accompanied by the appearance of an endothermic effect at 70–220°C, peaked at 145°C. The second complex endothermic effect is observed at 220–350°C. There is no commonly accepted opinion in the literature, concerning the genesis of the products formed

upon thermal decomposition in the given temperature interval. That is why a detailed phase analysis of the starting AH was performed by successive treatment of the sample in accordance with the thermal effects.

As indicated by X-ray phase analysis of a sample calcined at 270°C, the content of crystalline gibbsite markedly falls by the instant of a decrease in the mass of the sample, indicated by thermogravimetric curves (Table 3). This follows from a substantial decrease in the intensity of lines associated with trihydroxide in the diffraction pattern. A new aluminum oxide phase is formed in this sample in an amount of 39 wt %, as indicated by the appearance of peaks with d/l 2.330, 2.130, and 1.392 Å. This phase is χ-Al_2O_3, with the dimensions of primary particles along the [020] × [200] × [002] faces equal to 280.26 Å. At the same time, there is evidence [6, 11] that a minor amount of pseudoboehmite can be formed as an intermediate in dehydration of gibbsite at 250–360°C because of the creation of hydrothermal conditions in the bulk of particles. However, the dimensions of the coherent domains in the trihydrate must be no less than 680 Å in this case. An X-ray diffraction analysis of the systems under study demonstrated that the average size of gibbsite crystallites does not exceed 300 Å, and, therefore, thermal treatment of $Al(OH)_3$ leads directly to crystallization of the oxide χ-Al_2O_3 without formation of any intermediate phase.

It is noteworthy that the endothermic effect at 290°C in the DTA curves has a pre-effect at 265°C, which is probably associated with thermal decomposition of basic aluminum salts (the content of NO_3^- ions is 0.04–0.06 wt %, according to the results of an elemental analysis by the Kjoldahl method [12]). It was difficult to evaluate the contribution to the loss of mass (effect at 265°C) because of the closeness of

the temperature ranges of thermal decomposition. The presence of aluminum nitrate is confirmed by IR spectra (not given here), which contain an absorption band at 1385 cm^{-1}, associated with NO_3^- ions [13].

In addition, the X-ray diffraction pattern of a sample subjected to thermal treatment at 270°C shows a certain decrease in the intensity of pseudoboehmite peaks and the appearance of weak lines with *d*/*l* 1.827 and 1.409 Å. It is known [6] that pseudoboehmite, which is characterized as a hydroxide with a low crystallinity because of the presence in its structure of an excess amount of water, is converted to γ-Al_2O_3 at 280–330°C. This gives reason to believe that further removal of moisture at 305°C is due to thermal decomposition of Pb_2 containing 2.08 mol H_2O per mole of Al_2O_3. It was shown in [6, 14] that low temperatures of the phase transition pseudoboehmite $\rightarrow$ γ-Al_2O_3 are characteristic of fine and poorly crystallized hydroxides. The result obtained suggests that the phase transition temperature is determined largely by the crystallinity of pseudoboehmite, as well as by the size of crystallites. According to the results of calculations, the content of γ-Al_2O_3 (γ_2) formed in gradual dehydroxylation of Pb_2 in the given stage of thermal treatment is 1 wt %. Because of the pseudomorphism [1, 15], the dimensions of coherent domains in Pb_2 are comparable with those of its precursor (950.0 Å along the crystallographic planes [020] $\times$ [200] $\times$ [002]).

The absence of lines associated with gibbsite in the X-ray diffraction pattern of a sample calcined at 330°C indicates that it completely thermally decomposes into χ-Al_2O_3, whose content in the precipitate is 40 wt %. According to calculations, a certain increase in the intensity of peaks associated with γ_2-Al_2O_3 results from the completion of dehydration of Pb_2. The presence of broad bands associated with pseudoboehmite in the X-ray diffraction patterns indicates that the precipitate contains Pb_1 (~57 wt %).

The stage of dehydration of Pb_1 is observed in the DTA curves at 350–550°C, with a peak at 430°C. It is known [6, 16] that thermal decomposition of a pseudoboehmite with a high crystallinity occurs in this temperature range. According to [17], the temperature of dehydration of pseudoboehmite can be used to evaluate the dispersity of particles of the starting hydroxide. The dimensions of the coherent domains of Pb_1, which undergoes dehydration at around 430°C, do not exceed 100 Å (Table 1), in agreement with published data [15]. The presence of a high-temperature peak at 870°C indicates that there occurs a phase transformation χ-$Al_2O_3 \rightarrow$ *x*-Al_2O_3, with loss of 5% of mass.

The derivatogram of a hydroxide stabilized for 90 min shows the following changes (Table 3, sample no. 2). The endothermic peak associated with the dehydration of gibbsite is entirely absent in the DTA curves because of its phase transformation into pseudoboehmite [8], in agreement with the results of an X-ray phase analysis of the samples (Table 1, sample no. 2). It is of interest that the curves of thermal decomposition show, on the background of the disappearance of a broad peak at 290°C, a low-intensity peak at 275°C, with a loss of mass equal to 3%, which is due to thermal decomposition of basic aluminum salts.

The increase in the fraction of Pb_1 in this sample by approximately 40 wt % leads to a substantial loss of mass by the monohydroxide in the course of thermal decomposition, which is manifested in the DTA curves as an endothermic peak at 460°C (Table 3, sample no. 2). The observed shift of this peak by 30°C to higher temperatures is probably due to an increase in the crystallinity of the structure of Pb_1, which is indicated (according to XPA, by a decrease in the lattice constants (Table 1, sample no. 2). The high-temperature endothermic peak at 870°C, associated with the phase transition χ-$Al_2O_3 \rightarrow$ *x*-Al_2O_3, is not observed in the DTA curves because of the absence of gibbsite in the precipitate.

The derivatogram of a hydroxide that passed the stage in which the pH value is brought to 8.9 by adding a solution of sodium aluminate (Table 3, sample no. 3) shows an endothermic effect in the range 240–300°C, with a peak at 290°C and a pre-effect at 265°C. This is due to dehydroxylation of gibbsite formed in accordance with the scheme

$$NaAlO_2 + 2H_2O = Na^+ + Al(OH)_4^-,$$

$$Al(OH)_4^- \rightleftarrows Al(OH)_3 + OH^-,$$

in the first case, and to thermal decomposition of aluminum nitrate, in the second. The total loss of mass, associated with this effect, is 4 wt %.

The derivatogram of a hydroxide that passed the stage of stabilization for 4 h shows, in the range 240–300°C, only the effect of thermal decomposition of basic aluminum salts with a loss of mass equal to 3% (Table 3, sample no. 4). No changes are observed in other stages of dehydration of the given sample.

On the whole, the phase composition of the hydroxides does not change substantially in the subsequent stages of the technological process (Table 3), and, therefore, the pattern of thermal decomposition of sample nos. 5–8 is the same. It can be stated, on the

basis of the whole set of XPA and DTA data, that the morphology of aluminum hydroxides obtained under the conditions of industrial synthesis is mostly formed in the stages of precipitation and stabilization. In the subsequent stages of the technological process, the phase composition of the samples does not change significantly (Table 4).

CONCLUSIONS

(1) It was suggested, on the basis of the results of X-ray phase and differential thermal analyses, that two pseudoboehmite phases are formed in the course of precipitation, Pb_1 and Pb_2. The dimensions of primary particles and the lattice constants of these two phases are strongly different.

(2) A thermal analysis demonstrated that Pb_2 undergoes thermal decomposition at low temperatures (300–330°C), and Pb_2, at high temperatures (350–580°C). The difference between the temperature ranges in which the phase transformations pseudoboehmite → γ-Al_2O_3 occur can be attributed to different degrees of crystallinity of the structure of Pb_1 and Pb_2.

(3) It was suggested to discriminate between the monohydroxide phases described (Pb_1 and Pb_2) on the basis of the lattice constant b of pseudoboehmite. For example, b does not exceed 12.19 Å for Pb_1, with 1.01–0.95 mol H_2O per mole of Al_2O_3 contained in the interlayer space, and 12.33 Å for Pb_2, with an excess amount of structural water (2.09–1.12 mol H_2O per mole of Al_2O_3).

(4) It was established that the morphology of aluminum hydroxides obtained under the conditions of industrial synthesis is formed in the stages of precipitation and stabilization. The other stages of the technological process have no effect on the composition of the phases and their relative amounts.

(5) An X-ray phase analysis revealed the following: the freshly precipitated hydroxide is a three-component system containing gibbsite and two modifications of pseudoboehmite (Pb_1 and Pb_2); no amorphous phase is formed; and stabilization leads to a complete phase transformation of gibbsite into Pb_1.

(6) Gibbsite contained in the freshly precipitated aluminum hydroxide undergoes a phase transition $Al(OH)_3$ → χ-Al_2O_3 in the course of thermal treatment, with no pseudoboehmite formed.

Received November 2, 2004

Abstract—Specific features of hydrochloric-acid leaching of residues formed in synthesis of carbonyl nickel without removal and with forced removal of the gas phase were studied.

In producing metallic nickel by carbonylation of a nickel-containing raw material, residues substantially enriched with cobalt and platinum metals[1] are formed. However, the content of platinum group metals in these residues is approximately 10 times lower than that in anodic slimes, and, therefore, their joint processing to produce conditioned concentrates of platinum metals (PM) seems to be impossible. At present, residues of carbonyl nickel synthesis (RCS) are recycled, which leads to loss of non-ferrous and platinum metals and to the enrichment of the nickel raw material with copper. Removal of the carbonylation residues from the pyrometallurgical process to be subjected to a hydrometallurgical processing is a possible way to raise the recovery of both nonferrous and noble metals.

It is known [1, 2] that the specificity of synthesis of nickel tetracarbonyl is primarily associated with the reactivity of the material subjected to carbonylation, which is, in turn, proportional to its surface area accessible to the reaction with carbon oxide. The specific surface area of the material is most frequently raised through formation of sulfides at grain boundaries in metal phases, which leads to a spongy structure of the material. After the carbonylation is complete, with the main part of nickel and iron evaporated as the carbonyls $Ni(CO)_4$ and $Fe(CO)_5$, the impurities, namely copper, cobalt, noble metals, and sulfur, are concentrated in a solid residue.

[1] Severonikel' combine of Kola Mining and Smelting Co.

It is known that processing of RCS can be carried out by either a pyro- or a hydrometallurgical method, depending on their phase composition. The hydrometallurgical method for processing of RCS of the above-mentioned composition involves two-stage sulfatization, autoclave sulfuric-acid leaching, and ammonia-carbonate leaching [1, 3–7]. The low extraction of cobalt and platinum group metals is a disadvantage of the ammonia method [8], and leaching with sulfuric acid involves autoclave processes, which requires that expensive and power-consuming equipment should be used. Therefore, we tested several schemes of hydrochloride processing of these products [9–12]. These schemes use hydrochloric-acid solutions of iron(III) and gaseous chlorine and make it possible to process the material at atmospheric pressure, remove sulfur in the elementary form, and concentrate platinum metals in the final product.

As the acidity of the leaching solution strongly affects the phase transformations in the material under study, the initial stage of development of a hydrochloride technology for RCS processing consisted in a study of the behavior of separate phase components of the residues in their leaching with hydrochloric acid. The starting RCS samples, selected as the objects of study were decarbonylated by keeping them in a vacuum at the boiling point of nickel carbonyl (~43°C). They had the following composition (wt %): Ni 5.1–9.1, Co 12.0–18.0, Cu 29.0–43.2, Fe 3.8–7.9, S 18.9–21.4, and ΣPM 0.15–0.22.

1070-4272/05/7802-0178 © 2005 Pleiades Publishing, Inc.

The redox potentials of solutions in use were measured with a V7-34A voltmeter. Silver chloride and platinum electrodes served as a reference and an indicator electrode, respectively.

Two modes of leaching were used. In the first of these, reaction products were not removed from the reaction space before the process was complete, and in the second, they were forced from the gas-vapor phase (GVP). The effect of leaching parameters on the extraction of RCS components into solution was studied by analyzing samples of solid and liquid phases of the sludge. The concentrations of nickel, cobalt, iron, and copper in solutions and precipitates after their decomposition were determined by the atomic-absorption method, and that of platinum metals in solid products was found by X-ray fluorescence analysis. A comparison of the data for various samples of the starting material did not reveal any significant difference between them.

To study the main RCS phases and to determine their composition, we carried out mineralogical and X-ray phase analyses of the starting samples and products of their leaching. For the mineralogical analysis, we used preparations based on an epoxy resin, which were studied in reflected light under an Opton Ultarphot-3 microscope with a resolution of 0.2 μm. The main phases were analyzed by the X-ray fluorescence method on a Cameca MS-46 microprobe analyzer.

The mineralogical and electron-microprobe analyses demonstrated that the structure of characteristic particles of RCS is represented by spongy spherical aggregates with walls formed by a pentlandite-like phase (PP–M_9S_8, where M is Co, Ni, Fe, or Cu) and chalcosine (Cu_2S) in a tight and even accretion in a 50 : 50 (%) proportion. The pentlandite-like phase, in turn, consists of three sulfide components: nickel-rich $Ni_{3.18}Fe_{3.36}Cu_{2.25}Co_{0.21}S_8$ (~20%), copper $Cu_{7.13}Fe_{1.07}Ni_{0.48}Co_{0.35}S_8$ (~40%), and cobalt components $Co_{4.74}Fe_{2.06}Cu_{1.32}Ni_{0.84}S_8$ (~40%). A chalcosine mass is situated between sponge walls. The X-ray phase analysis revealed the presence of the main sulfide phases: $Cu_{1.96}S$, (Co, Ni, Fe)$_9S_8$, and Co_8FeS_8 (Fig. 1a).

The behavior of chalcosine and pentlandite in hydrochloric-acid leaching has been adequately described in the literature. For example, the dissolution of chalcosine in hydrochloric acid in the absence of oxidants proceeds in two stages [13–16]: in the first stage, a part of copper is extracted into solution as Cu^+, and CuS (covellite) is formed; in the second,

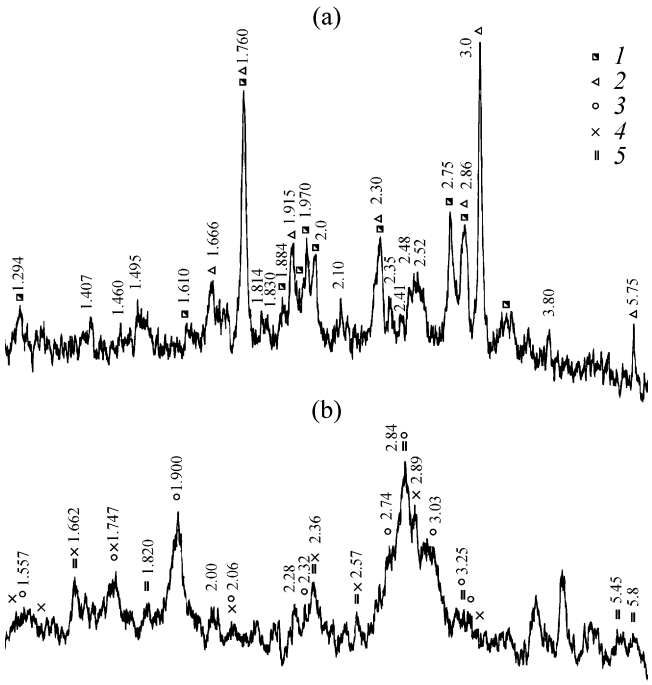

Fig. 1. X-ray diffraction pattern of a residue formed in synthesis of carbonyl nickel: (a) initial and (b) leached with 3.5 M HCl. (*1*) $Cu_{1.961}S$; (*2*) (Co, Ni, Fe)$_9S_8$, Co_8FeS_8; (*3*) CuS; (*4*) CuS_2; (*5*) Ni_2CoS_4, Co_3S_4.

CuS slowly dissolves as an intermediate phase with evolution of hydrogen sulfide. Presence of an oxidant leads to formation of sulfur in the second stage of decomposition.

It was shown in [17, 18] that the reaction of pentlandite (Fe, Ni)$_9S_8$, which contains a constant excess of metals over sulfur, with hydrochloric acid (1 M) proceeds mostly as the overall equation

$$M_9S_8 + 18HCl = 9MCl_2 + 8H_2S + H_2. \quad (1)$$

It involves reduction of hydrogen ions in the acid medium to the elementary state

$$2H^+ + 2e = H_{2(g)}$$

and oxidation of pentlandite

$$(Fe, Ni)_9S_{8(s)} + 16H^+_{(aq)} = 4.5Fe^2_{(aq)} + 4.5Ni^2_{(aq)} + 8H_2S + 2e.$$

If the potential of pentlandite increases under polarization with an external current or upon introduction of oxidants into the solution (e.g., $FeCl_3$), it decomposes to give an intermediate phase of violarite (Fe, Ni)$_3S_4$.

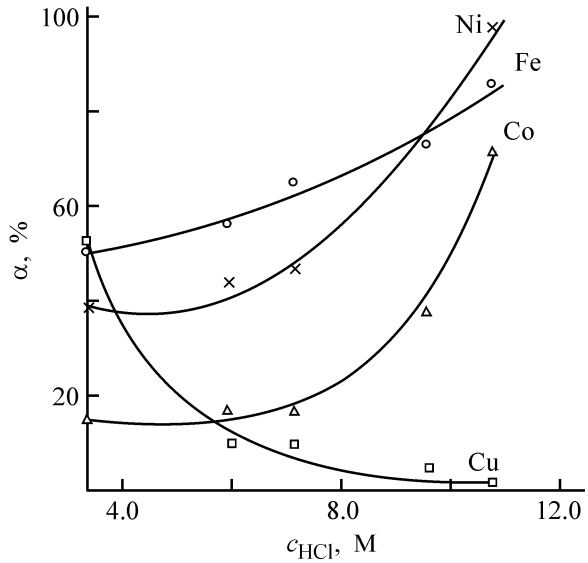

Fig. 2. Degree of extraction, α of nonferrous metals and iron from residues formed in synthesis of carbonyl nickel vs. the concentration of hydrochloric acid c_{HCl}, without removal of GVP. τ 5 h, s : l = 1 : 2, *T* 80°C.

Special experiments demonstrated that the redox potential of the solution, established in leaching of pentlandite (containing the main phase inan amount of about 95%) with hydrochloric acid (1 M) at 80°C is 0.04 V. When chalcosine (Cu content 76.5%) is leached under the same conditions, the potential is 0.20 V. The simultaneous presence of chalcosine and PP in the composition of RCS strongly affects the degree of extraction in the case of their decomposition with hydrochloric acid, with the HCl concentration being the key factor (Fig. 2). An examination of the results of the microscopic, X-ray fluorescence, and X-ray phase analyses revealed that leaching with the acid present in a concentration lower than 6 M in the atmosphere of evolving gases results in the decomposition of the pentlandite-like phase to give intermediate phases by the reactions

$$(Cu, M)_9S_8 + 8HCl = 4MCl_2 + M_3S_4 + Cu_2S + 3H_2S + H_2, \quad (2)$$

where M is Fe, Ni, or Co.

The M_3S_4 phase is represented by the sulfides Ni_2CoS_4, Co_3S_4, and $(Ni, Fe)_3S_4$, which have a trivalent cation in their lattice [17].

Chalcosine present in the starting material and formed via decomposition of PP to give covellite (CuS) dissolves in parallel to this reaction. The X-ray phase analysis also reveals the presence of CuS_2 (Fig. 1b). In this case the redox potential of the solution is 0.20 V, which corresponds to the potential of the equilibrium system Cu^{2+}/Cu^{+}, and tends to increase as the concentration decreases.

The dissolution of RCS PP in the acid with a concentration exceeding 6 M at 80°C mainly occurs by reaction (1). The redox potential of the solution is shifted in the negative direction to become lower than 0.04 V.

The results obtained show that the main part of RCS PP decomposes already within 2 h of leaching with 7.9 M hydrochloric acid, the degree of nickel, iron, and cobalt recovery being 80.5, 80.9, and 60.3 wt %, respectively. Making the process duration longer can raise the extent to which the above-mentioned metals pass into solution; however, a considerable part of cobalt (~30%) remains in the solid residue as linnaeite (Co_3S_4). Our earlier study [10] has shown that the presence of metallic nickel, which remains in RCS in the case of incomplete carbonylation, strongly lowers the redox potentials in the leaching solution, with no linnaeite formed and cobalt virtually completely (~97%) passing into solution. In a reducing atmosphere, copper passes into the solid residue as Cu_2S.

Thus, the data obtained indicate that the presence of chalcosine in RCS results in an increase in the redox potential of a leaching solution, which promotes formation of intermediate phases (and, in the end, linnaeite Co_3S_4) in PP decomposition. If a reducing atmosphere is created by raising the concentration of hydrochloric acid or by adding a reducing agent (e.g., metallic nickel), PP decomposition proceeds most completely, with copper concentrated in a residue ~80% composed of copper sulfide (Cu_2S).

Based on the results obtained, we suggested a scheme for RCS processing, which involves a two-stage leaching of a starting material. The selectivity and depth of nickel, cobalt, and iron recovery in the first stage was ensured by leaching with concentrated hydrochloric acid at an elevated temperature. The use of an iron(III) chloride solution in the second stage of leaching of the resulting copper residual allowed us to transfer 99% of copper into solution and to obtain a primary platinum concentrate containing ~1% platinum metals, which is suitable for processing together with anodic slimes. In this case, the residual concentration of platinum metals in solution was not higher than 0.1 mg l^{-1}. However, despite the possibility of the high level of metal recovery, concentration of platinum metals in the residue, and partial removal of sulfur in the elementary form, the scheme we developed has certain disadvantages. For example, use

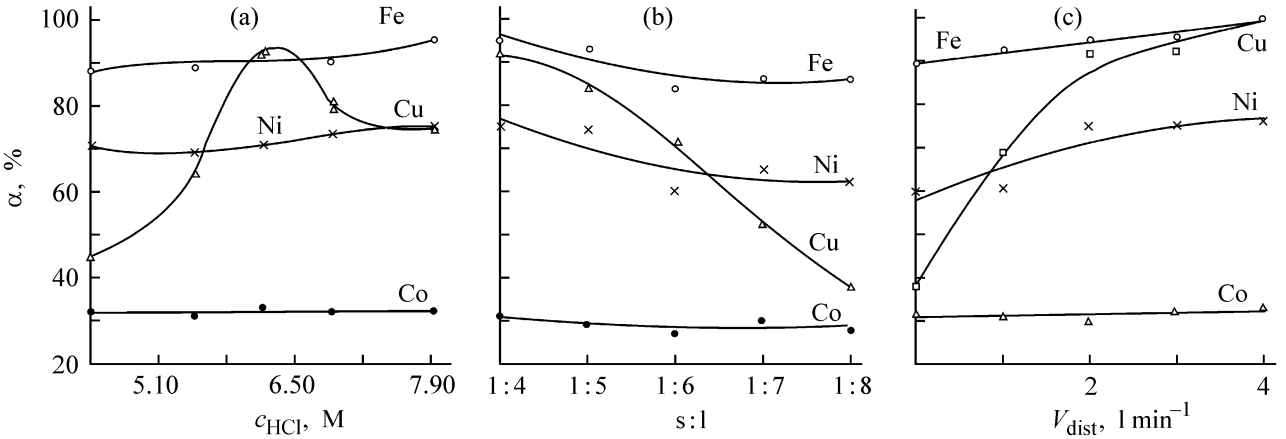

Fig. 3. Degree of extraction, α, of nonferrous metals and iron from residues formed in synthesis of carbonyl nickel with removal of GVP vs. (a) concentration of hydrochloric acid c_{HCl}, (b) solid-to-liquid ratio s : l, and (c) rate of removal of the gas-vapor phase, V_{dist}. τ = 4 h, T = 80°C. (a) s : l = 1 : 4, V_{dist} = 2 l min^{-1}; (b) c_{HCl} = 6 M, V_{dist} = 2 l min^{-1}; (c) c_{HCl} = 6 M, s:l = 1:4.

of concentrated hydrochloric acid imposes stringent requirements on the apparatus employed and on the working conditions.

To study the possibility of utilization of effluent gases and to achieve the most complete decomposition of the sulfides by shifting the equilibria of the occurring reactions on the basis of the Le Chatelier principle, we studied leaching of residues formed in nickel carbonylation in hydrochloric acid with a forced removal of a GVP. According to the Henry law, the concentration of hydrogen sulfide in solution is related to its partial pressure in the GVP by

$$[H_2S]_{aq} = fP_{H_2S}. \quad (3)$$

Here the coefficient f depends on temperature and salt composition of the solution and decreases as either of these factors increases [19].

Thus, we can change the concentration of hydrogen sulfide in solution by varying the composition of a GVP over the solution. Furthermore, it was of certain interest to compare the behavior of separate RCS phase components in acid leaching, with the reaction products removed by evaporation and bound during chlorination or in leaching with an iron(III) chloride solution [11] by the reactions

$$2FeCl_3 + H_2S \rightarrow 2FeCl_2 + S + 2HCl, \quad (4)$$

$$H_2S + Cl_2 \rightarrow S + 2HCl. \quad (5)$$

In these experiments, the GVP was removed from the reaction vessel through a system of absorption flasks, and the rate of the evaporation was measured with a rotameter. After a prescribed time of leaching, the sludge was filtered in a vacuum and the precipitate formed was washed with water and dried at 105°C. The influence exerted by the concentration of hydrochloric acid, solid : liquid ratio, and rate of removal of the gas-vapor mixture on the degree of recovery of the main components were studied. All the experiments were carried out at 80°C.

Preliminary experiments demonstrated (see table) that forced removal of GVP from the reaction space results in a virtually complete dissolution of chalcosine, and the pentlandite-like phases decompose to give intermediate compounds by reaction (2).

The dependence of the degree of copper extraction from RCS into a solution, with GVP removed from the reaction space, on the concentration of hydrochloric acid has a well pronounced maximum (Fig. 3a). In this case, the redox potential of the leaching solution is higher than 0.20 V in the range of acid concentrations used in the study. Raising the HCl concentration from 4.5 to 6 M leads to an increase in the degree of decomposition of copper sulfides, which becomes 92% at the removal rate of 2 l min^{-1}. Then, as the acid concentration is raised further, the degree of

Recovery of metals into solution in the case of a forced removal of the GVP in RCS leaching with hydrochloric acid (T = 80°C, c_{HCl} = 6 M, τ = 4 h, V_{dist} = 2 l min^{-1}, s : l = 1 : 4)

Leaching conditions	Extraction into solution, %			
	Ni	Co	Cu	Fe
Without evaporation	59.8	30.5	38.1	89.0
With evaporation	74.6	30.8	91.7	94.8

copper extraction decreases by 20%, with the transfer of nickel, iron, and cobalt into solution remaining virtually constant. The dependence observed can be explained if the arguments of the authors of [20] in favor of the possible oxidation of Fe^{2+} ions by Cu^{2+} ions are accepted. In this case, copper reduced to a monovalent state is incorporated into the lattice of solid covellite to form chalcosine.

The results of the experimental determination of the degree of copper, cobalt, nickel, and iron recovery in relation to the s : l ratio (Fig. 3b) indicate that the extent to which these components pass into solution falls as this ratio becomes lower, with the extraction of copper decreasing from 91.7 to 37.8% as the s : l ratio decreases from 1 : 4 to 1 : 8. It is most likely that the sharp decrease (by almost a factor of 2.4) in the copper extraction into solution is due to a change in the salt composition of the solution, which results, according to Eq. (3), in an increase in the content of hydrogen sulfide in the liquid phase.

The dependence of the degree of copper extraction into solution on the rate of GVP removal from the reaction vessel (Fig. 3c) conclusively shows that this parameter is one of main factors affecting the process. The recovery of copper is 38.1% without removal of the gas phase, but increases to 91.7% at a removal rate of 2 l min^{-1} and to almost 100% at a rate of 4 l min^{-1}. The extent to which cobalt and iron pass into solution varies within the indicated range of GVP removal rates insignificantly, being 32.0–33.4 and 88.5–99.3 wt %, respectively.

Thus, leaching of RCS with 6 M hydrochloric acid for 4 h, with GVP removed at a rate of 4 l min^{-1} at 80°C and an s : l ratio of 1 : 4, the degree of copper, nickel, and iron extraction into solution is 99.9, 77.0 and 99.3 wt %, respectively. The resulting solutions have the following composition (g l^{-1}): Cu 98.0, Ni 38.0, Co 12.0, and Fe 15.0. Cobalt is concentrated in the solid phase in the form of Co_3S_4. The content of copper in the residues obtained upon leaching is 2–3%.

CONCLUSIONS

(1) A study of the behavior of separate phase components of the residues formed in synthesis of carbonyl nickel by leaching with hydrochloric acid has shown that nickel, iron, and cobalt can be selectively leached, with copper isolated in a solid residue, when the process is carried out under atmospheric pressure without removal of the gas-vapor phase.

(2) It was found, when determining the optimal conditions of leaching, that the completeness of separation depends on the redox potential of the acid solution.

(3) The possibility of selective extraction of nickel, iron, and copper by leaching, with isolation of cobalt in a solid residue, was demonstrated for the case when the process is carried out with the gas-vapor phase removed from the reaction space.

(4) It was shown that the rate of removal of the gas-vapor phase and the solid-to-liquid ratio in leaching exert the decisive influence on the degree of copper recovery.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

A Study of the Kinetics of Synthesis of Potassium Superoxide from an Alkaline Solution of Hydrogen Peroxide

D. V. Zhdanov, M. A. Ul'yanova, and Yu. A. Ferapontov

Tambov Research Institute of Chemistry Federal Unitary Enterprise, Tambov, Russia

Received April 20, 2004

Abstract—Kinetic aspects and the mechanism of shaping of particles of potassium superoxide in its synthesis from drops of an alkaline solution of hydrogen peroxide in a flow of a drying agent were studied.

The method for synthesis of potassium superoxide KO_2 is based on the fact that, being a weak acid, hydrogen peroxide enters, under certain conditions, into an exchange reaction with potassium hydroxide [Eq. (1a)] to give an intermediate adduct $K_2O_2 \cdot 2H_2O_2$ (potassium peroxide diperoxohydrate) [1]. This adduct disproportionates upon heating to above 40°C [Eq. (1b)] to give KO_2. The overall process of formation of potassium superoxide from the starting reagents is described by Eq. (1):

$$2KOH + 3H_2O_2 = K_2O_2 \cdot 2H_2O_2 + 2H_2O \quad (1a)$$

$$K_2O_2 \cdot 2H_2O_2 = 2KO_2 + 2H_2O \quad (1b)$$

$$2KOH + 3H_2O_2 = 2KO_2 \cdot 4H_2O. \quad (1)$$

Previously, this process has been carried out by spraying an alkaline solution of H_2O_2 onto the heated surface of a rotating drum blown over from the outside with an inert gas [2]. When the solution dries up, potassium superoxide is formed on the drum surface, cut-off with a blade, and discharged into the receiving bin.

However, this method has an important disadvantage: it is necessary to supply a saturated steam, which serves as a heat-transfer agent, into a rotating drum under elevated pressure and to remove the forming condensate from the drum. This impairs the reliability of the process and hinders its industrial application.

To eliminate these disadvantages, it is suggested to perform the process in a direct-flow spray reactor, with the synthesis of KO_2 and its drying in a dispersed state combined. The resulting powdered target product is separated from the drying agent in a cyclone and collected in a bin. Heated, dried, and purified (to remove CO_2) air or any inert gas can be used as a drying agent [3].

It is reasonable to assume that, under the experimental conditions, the disproportionation of $K_2O_2 \cdot 2H_2O_2$ may be accompanied by the following chemical side reactions:

$$2KO_2 + 3H_2O = 2(KOH \cdot H_2O) + 1.5O_2, \quad (2)$$

$$2KOH + CO_2 = K_2CO_3 + H_2O. \quad (3)$$

In the case of an intensive dehydration and low concentrations of H_2O and CO_2 vapor in the drying agent, the influence of these reactions can be neglected.

The rate of reaction (1) in a spray reactor depends on a number of factors (temperature, concentrations of the starting reagents, etc.). Therefore, determination and subsequent generalization of the fundamental kinetic aspects of this process and analysis of the shape of the forming grains is an obligatory stage in developing the scientific prerequisites for calculation of its performance and design parameters.

As shown by practical experience [4], the choice and substantiation of the optimal modes of synthesis of particular products should be primarily based on the information about the mechanism of internal processes and thermal characteristics of the substance being dried. It is the kinetics of heat-exchange processes in a separate particle that determines such important characteristics of the target product as dispersity, reactivity, bulk density of the powder, and its tendency toward caking.

1070-4272/05/7802-0184 © 2005 Pleiades Publishing, Inc.

Physicochemically, the process being considered consists in dispersion of an alkaline solution of hydrogen peroxide and its subsequent crystallization to give potassium superoxide under drying, with a simultaneous occurrence of chemical reactions.

In studying under laboratory conditions the kinetics of the internal heat-and-mass-exchange processes and the mechanism of shaping in a separate particle, this particle was regarded as a unit element of the whole dispersed system present in the chamber of the reactor. Therefore, the primary goal in studying the kinetics of the process in question was to examine just those external conditions that are experienced by a unit element of the system in a real apparatus. This refers, in the first place, to the basic characteristics of the drying agent: temperature, pressure, relative velocity, and chemical composition.

The information that can be directly obtained in an experiment with a single drop of the solution with a drying agent is a set of data on how its temperature, mass, size, and shape vary in the course of synthesis. Processing of the resulting experimental data enables a conclusion about the nature of the internal heat-and-mass-transfer processes in a particle under varied external conditions.

EXPERIMENTAL

The kinetics of synthesis of potassium superoxide from an alkaline solution of hydrogen peroxide in a flow of a drying agent was studied on an experimental stand shown schematically in Fig. 1.

The drying agent is delivered by a gas blower *1* through a flow control valve *2* into a psychrometer *3* and rheometer *4*, which measure the humidity and flow rate, respectively. Then the drying agent is delivered for heating into an electric air heater *5* and, further, discharged via pipe *6* into the atmosphere through a nozzle 17 mm in diameter. A thermocouple *7* is fixed on a special bracket *8* connected to a high-precision electronic microbalance *9*. The temperature and mass of a drop suspended on the junction of the thermocouple is recorded by self-recorders *10* and *11*. The temperature of the drying agent is determined from the reading of the recorder *10* in the absence of drop suspended on the thermocouple after the stand attains a steady state. A video camera *12* with a microattachment enables a continuous video recording of the drop in the course of synthesis.

To make lower the radiation heating of the drop, the pipe *6* has a 90° elbow. To diminish the heating

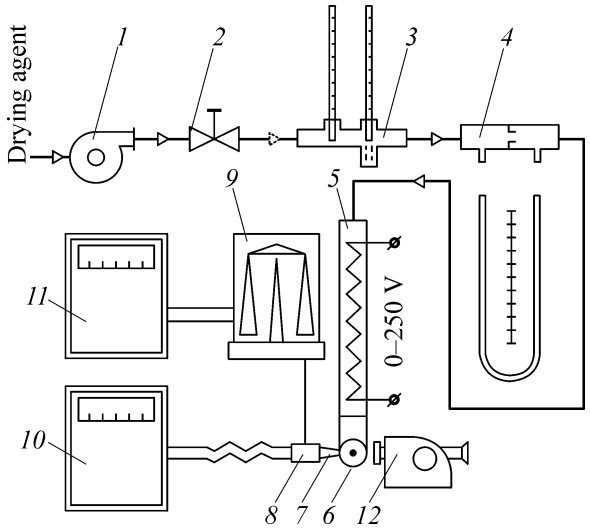

Fig. 1. Experimental stand for a study of the kinetics of synthesis of potassium superoxide from an alkaline solution of hydrogen peroxide in a flow of a drying agent.

of the drop via thermal conduction, the diameter of the wires of the thermocouple is chosen to be the minimum possible. In the case in question, this diameter is 50 μm. All this is done with the only objective, to ensure a mainly convective heat supply and to make the experimental conditions as close as possible to the real process of dehydration of solution drops in an industrial apparatus.

The alkaline solution of hydrogen peroxide to be used in the study was prepared by mixing 50% solutions of KOH and H_2O [5].

A drop of the resulting solution was suspended on the junction of the thermocouple and blown over with the drying agent (for its parameters, see table). The following parameters were recorded in the course of the experiment: temperatures T_{dr} and T_{moist} of dry and moistened thermometer, respectively; flow rate G_A; and temperature T_{DA} of the drying agent. As a result, curves describing how the temperature [$T_d = f(\tau)$], mass [$m_d = f(\tau)$], and diameter [$d_d = f(\tau)$] of a drop under study vary with the time τ of the process were obtained.

Experimental conditions (drying agent, atmospheric air purified to remove CO_2)

	°C			
1	27.6	12.4	50	150
2	21.9	15.5	50	187
3	22.6	21.4	50	225

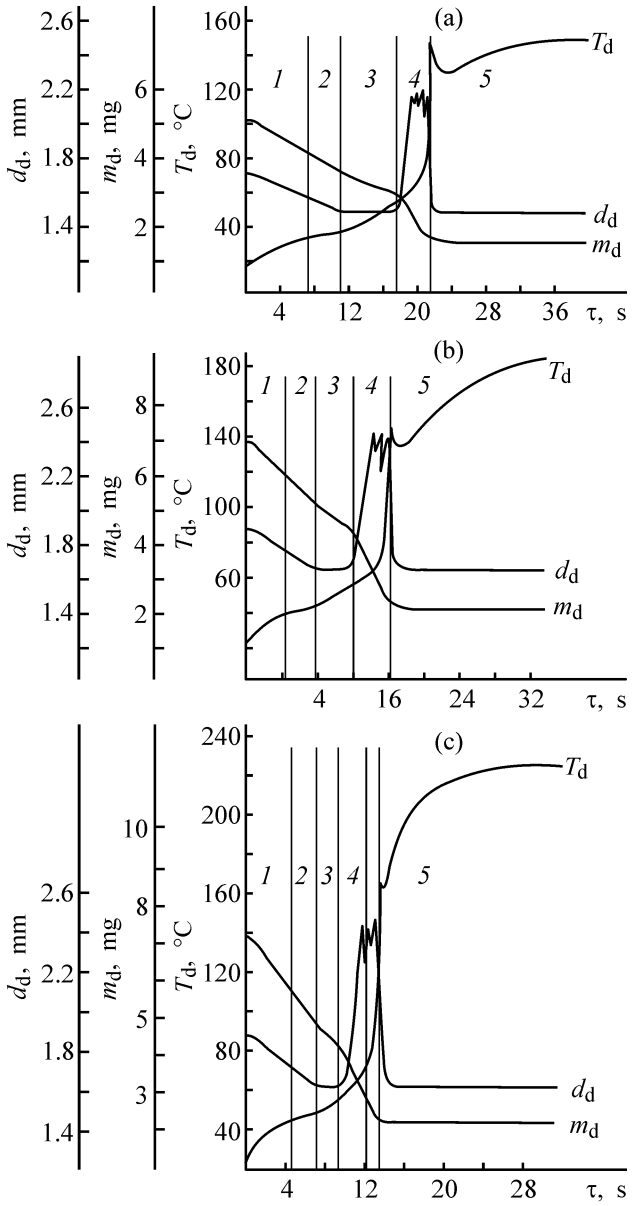

Fig. 2. Kinetic curves of synthesis of potassium superoxide for sample nos. (a) 1, (b) 2, and (c) 3. (d_d) Drop diameter, (m_d) drop mass, (T_d) drop temperature, and (τ) time. (*1*–*5*) Characteristic stages in synthesis of potassium superoxide.

The plots (Figs. 2a–2c) experimentally obtained at different temperatures and humidities of the drying agent make it possible to distinguish five characteristic stages in synthesis of potassium superoxide.

(1) The stage in which the drop is heated from the initial temperature T_0 to a temperature T_{eq}, which corresponds to the temperature of equilibrium evaporation of the solution at a given temperature and humidity of the heat-transfer agent.

(2) The stage of equilibrium evaporation, during which the moisture is intensively removed from the drop surface upon a slight increase in the temperature $T_{eq} = f(T_{DA}, \varphi_{DA}, c_s)$. The increase in the drop temperature at a fixed temperature T_{DA} and humidity φ_{DA} of the drying agent is due to a steady rise in the solution concentration c_s in the surface layer of the drop and to the resulting redistribution of heat flows in the heat exchange between the drop and the gaseous heat-transfer agent. During this period of time, the temperature of the drop at any given instant can be considered identical to the temperature of a moistened thermometer at the appropriate values of T_{DA} and φ_{DA}. The time of completion of this period is an important parameter of the kinetics of the internal processes, because it determines the instant of transition from the low-temperature stage of the process to the high-temperature stage.

(3) The stage of foam formation, which begins when the concentration of the dry substance reaches a value $c_s = 40–43\%$, and continues at a constant drop diameter. The process of moisture removal is accompanied by an inconsiderable release of oxygen in thermal decomposition of the excess amount of hydrogen peroxide. The release of oxygen leads to agitation of the substance in the drop. This gives reason to believe that the temperature and concentration gradients in the material of the drop are negligible, i.e., the assumption that the temperature $T_d(r, \tau) = T_s(\tau) = T_d(\tau)$ and concentration $c_d(r, \tau) = c_s(\tau) = c_d(\tau)$ are constant over the cross-section of the drop is not too exacting. This assumption is confirmed by the experimental curves $m_d = f(\tau)$: the rate of loss of mass by the drop changes by an exceedingly insignificant amount during the entire period. The increase in the temperature of the drop is due to a rise in the concentration of the solution (temperature depression) and to the exothermic nature of its decomposition. A hollow particle starts to be formed during this period.

(4) The stage of synthesis of KO_2 via formation of an intermediate adduct $K_2O_2 \cdot 2H_2O$. According to the dependences presented above, this period of time begins at a drop temperature $T_d = 53–57$°C.

The crystallization of $K_2O_2 \cdot 2H_2O$ from solution is accompanied by decomposition of an excess amount of hydrogen peroxide by the reaction

$$2H_2O_2 = 2H_2O + O_2. \quad (4)$$

This results in an intensive release of oxygen and an abrupt increase in the particle diameter, with an inflation coefficient $k_{in} = d_4/d_3 = 1.43–1.46$. The ab-

sence of a boiling stage characteristic of most of solutions subjected to spray drying suggests that there are no internal limitations to moisture transfer in the crystallization of the solution.

Further, $K_2O_2 \cdot 2H_2O_2$ disproportionates to give KO_2 and free water in accordance with the reaction equation (1b). In this case, a side reaction (2) of decomposition of the target product inevitably occurs and the oxygen released inflates the drop, thereby intensively agitating the reaction mass.

The completion of this period is visually determined from an abrupt contraction of the drop with a contraction coefficient $k_c = d_4/d_5 = 1.43–1.46$, to give a solid hollow particle of yellow-canary color virtually instantaneously. The completion of this period is the most clearly seen from the presence of an exothermic peak in thermograms.

(5) The stage of a decreasing rate of drying, which begins at the instant of time when the rate of moisture removal from the particle starts to be limited only by the rate of transition of water bound to the material into the free state. During this period, the intensity of dehydration noticeably falls, which can be attributed to a decrease in the amount of remaining water and its stronger binding to the material. However, the drop mass remains virtually unchanged during this period, and, therefore, this time can be excluded from consideration in calculating the reactor.

In the course of synthesis, the drop was transformed into a grain with an elastic crust. In all the experiments performed, the dried particles were hollow, with thin, nearly spherical shells.

The data obtained can be used as a basis in calculations of performance and design parameters of the process of synthesis of potassium superoxide from potassium hydroxide and hydrogen peroxide in a spray reactor.

CONCLUSIONS

(1) A study of the basic kinetic aspects of the physicochemical process of synthesis of potassium superoxide from an alkaline solution of hydrogen peroxide in a flow of a drying agent yielded thermograms, gravimetric curves, and video records and made it possible to distinguish five characteristic stages of the process.

(2) It was established that drying is the rate-determining stage in the synthesis of potassium superoxide by the method suggested.

(3) It was established experimentally that particles of the target product, formed by the technique suggested, are hollow spheres.

Received June 29, 2004

Abstract—Energetic metal complexes, pentammine(cyclopentamethylenetetrazole)cobalt(III) perchlorate and tetraammine-bis(cyclopentamethylenetetrazole)cobalt(III) perchlorate, were obtained by reaction of aquapentaamminecobalt(III) and diaquatetraamminecobalt(III) ions with cyclopentamethylenetetrazole. Microwave heating was used, together with the conventional convective heating, for thermal activation of the process. The thermal decomposition of the compounds synthesized was studied. The explosive characteristics and toxicity of the metal complexes were determined.

Worldwide, researchers try to find ecologically safe, low-toxic explosives (problem of development of "green" energetic materials) [1]. For example, perchlorates of Co(III) amminates with 5-substituted and 1,5-disubstituted tetrazoles are explosives, which have a short time of transition from combustion to detonation and are safer and less toxic than the standard priming explosives (mercuric fulminate, lead azide, and lead styphnate) [2, 3]. Lead is exceedingly hazardous for the environment, because it strongly enhances the toxicity of other transition metals when present together with these metals in ecosystems. Mercury is intensively transformed in the environment to give alkyl derivatives, which show a pronounced ability to be accumulated in living organisms [4]. The maximum permissible concentrations of these metals in a working zone (MPC_{wz}) are 0.01, 0.01, and 0.1 mg m^{-3} for Hg, Pb, and Co, respectively. Consequently, energy-saturated salts of cobalt are less toxic than the standard priming explosives [5]. Thus, synthesis of new compounds from the series of complex cobalt(III) perchlorates with tetrazole ligands and study of their properties are a matter of current interest.

Perchlorate penta- and tetraaminate complexes of Co(III) with cyclopentamethylenetetrazole [cyclo-$(CH_2)_5$Tetr] were synthesized:

The presence of four nitrogen atoms in the ring enhances the coordination capacity of this reagent as compared with the more extensively studied ligands, imidazoles and pyrazoles. Cyclopentamethylenetetrazole (corazol) is a medicine that has a stimulating ("wakening") action and is a human anti-anxiety agent. It is widely used as a reference in a search for, and study of, anticonvulsive and other neuro(phsycho)-tropic preparations [6].

In obtaining cobalt(III) tetrazolates, it is convenient to use water-containing cobalt(III) amminates (**I**, **II**). Water as a ligand in the system of ammonia complexes of cobalt(III) is less firmly bound to the central atom than the ammonia molecule and can be substituted with tetrazole derivatives [7].

It may be assumed that cyclopentamethylenetetrazole can substitute water in the inner sphere of complexes **I**, **II** and form compounds with a neutral ligand **III**, **IV** by the scheme below

$$[Co(NH_3)_{6-n}(H_2O)_n]^{3+}(ClO_4^-)_3 + n[\text{cyclo}(CH_2)_5\text{Tetr}]$$
$$\mathbf{I}\,(n = 1),\ \mathbf{II}\,(n = 2)$$

$$\rightarrow \{Co(NH_3)_{6-n}[\text{cyclo}(CH_2)_5\text{Tetr}]_n\}^{3+}(ClO_4^-)_3 + nH_2O.$$
$$\mathbf{III}\,(n = 1),\ \mathbf{IV}\,(n = 2)$$

The substitution reaction is commonly performed in a weakly acidic aqueous solution at 90–100°C in the course of 2–3 h [6]. Accordingly, the reactions of compounds **I** and **II** with cyclopentamethylenetetrazole were first performed at ~100°C (on a boiling water bath) in a 5% aqueous solution of hydrochloric acid in the course of 3 h. Already in 2 h,

1070-4272/05/7802-0188 © 2005 Pleiades Publishing, Inc.

the starting diaqua complexes are completely consumed and the expected products **III**, **IV** are contained in the reaction mass, and in the case of the tetraaminate complex, also compound **V**, which is a product of substitution of a water molecule in the inner sphere of the initial diaqua complex and has a structure $\{Co(NH_3)_4(H_2O)[cyclo(CH_2)_5Tetr]\}(ClO_4)_3$. In this way, pentammine(cyclopentamethylenetetrazole)cobalt(III) perchlorate and tetraammine-bis(cyclopentamethylenetetrazole)cobalt(III) perchlorate were obtained and also tetraammine(aqua)(cyclopentamethylenetetrazole)cobalt(III) perchlorate was isolated. It was established that the process first yields compound **V**, and only after its certain concentration in the reaction mass is reached, compound **VI** starts to be formed, i.e., the complexation is steplike in the given case.

Microwave heating accelerates the anionization reaction in ammine complexes of Co(III) [8]. For example, the same compounds were found in the case of tetraamminates after microwave heating for 1 h. However, their relative amounts substantially changed toward a higher content of compound **IV**. The yield of compound **IV** increased by 15% as compared with the conditions of conventional heating, which can only be in part accounted for by a difference in the temperature modes: in the case of the microwave heating, the reaction occurred with intensive boiling of the reaction mass (~102°C), whereas the conventional heating was on a boiling water bath. Thus, the microwave heating of the reactants raises the yield of compound **IV**, with the time of the complexation reaction considerably decreasing.

IR spectra of the compounds synthesized contain absorption bands of all the fragments: coordinated molecules of water and ammonia, pentamethylene and tetrazole rings, and perchlorate anions.

The electronic spectra of complexes **III** and **IV** in an aqueous solution are typical of the given class of compounds and are associated with the *d–d* transition ($^1T_{1g} \leftarrow {}^1A_{1g}$) at 462 nm with $\varepsilon = 42$ l cm^{-1} mol^{-1} and 456 nm with $\varepsilon = 71$ l cm^{-1} mol^{-1}, respectively. Another strong absorption band ($^1T_{2g} \leftarrow {}^1A_{1g}$) lies at 332 nm with $\varepsilon = 45$ l cm^{-1} mol^{-1} for compound **III** and 331 nm with $\varepsilon = 75$ l cm^{-1} mol^{-1} for compound **IV**. Apparently, the complexes obtained contain an octahedral chromophore CoN_6.

Cyclopentamethylenetetrazole occupies in the spectrochemical series of ligands the place between water and ammonia [10], which is confirmed in the case of the compounds synthesized by a calculation of the constant Δ of splitting of the d orbitals of the central atom under the action of the crystal field of the ligands: 21 930 cm^{-1} for compound **III** and 21 650 cm^{-1} for compound **IV**. These values do not exceed Δ of ammonium (22 886 cm^{-1}) for Co(III) hexaaminates [11].

The ^{1}H NMR spectra of complexes **III**–**V** show peaks at 3.4–4.4 ppm, which correspond to equatorial (in a weak field) and axial (in a strong field) molecules of ammonia. The difference in the positions of the peaks in these spectra is in an agreement with the fact of coordination of the heterocyclic ligands via a nitrogen atom [2], and their splitting in two in the case of compound **IV** points to nonequivalence of the related ammonia protons. This splitting is probably due to coordination of organic ligands to the metal ion by different N atoms of tetrazole rings. Previously, coordination of cyclopentamethylenetetrazole by N^3 or N^4 nitrogen atoms of the heteroring has been observed [13]. In all probability, bonding isomers are formed in this case, in agreement with [14], where the simultaneous N^3/N^4 coordination was confirmed by means of X-ray diffraction analysis for tetrammine-bis(1-methyl5-aminotetrazole)cobalt(III).

A study of the thermal decomposition of the products in nonisothermal conditions at a heating rate of 5 °C min^{-1} demonstrated that the cobalt(III) tetrazolate amminates synthesized are rather thermally stable, because the onset temperature of their intensive decomposition exceeds 230°C (Table 1).

In the first stage of decomposition of compound **III**, a broadened endothermic peak is observed at 95–245°C, with 14.7 wt % of a sample decomposing. Presumably, this stage involves elimination of four ammonia molecules from the inner sphere of the complex. Further, the sample starts to melt and at 245°C to thermally decompose, with a pronounced exothermic effect (250–350°C) and 71 wt % of the sample lost. It may be assumed that these are stages of melting and decomposition of the pentamethylenetetrazole ligand via rearrangement of the inner sphere of the complex and oxidation of the complex by outer-sphere anions. As a result of processes of additional oxidation, formation of cobalt oxide Co_2O_3, which is commonly produced in decomposition of cobalt(III) complexes in air [15], and its decomposition (14.1 wt % of the sample) are probable.

It was established in a study of the thermal decomposition that compound **IV** is less thermally stable than the compound containing a single tetrazole ligand. The onset temperature of its intensive decomposition is 235°C. A study of the decomposition of this complex demonstrated that molecules of coordi-

nated ammonia are removed in the temperature range 95–235°C, with the loss of mass by a sample constituting 9.7 wt %. The strong overall exothermic effect (245–335°C) in the derivatogram of compound **IV** corresponds to decomposition of its organic constituent via oxidation by outer-sphere perchlorate anions, accompanied by a considerable loss of mass (48%).

This decomposition gradually gives way to the last exothermic effect, with the remaining organic part of a sample under study decomposing (30.5 wt %).

A study of the decomposition of complex **V** demonstrated that coordinated molecules of water and ammonia are removed in the first stage (60–195°C), with the loss of mass by a sample equal to 14.8%. To oxidation of the pentamethylenetetrazole ligand by perchlorate anions from the outer sphere, which occurs as a result of destruction of the inner sphere of the complex, and to their joint decomposition corresponds a strong exothermic effect (220–380°C) accompanied by a considerable loss of mass (71%). Presumably, Co_2O_3 is formed and decomposes in the final stage of decomposition of compounds **IV** and **V**.

The results obtained in examining compounds **III**, **IV**, **V** by thermogravimetric (TG) and differential-thermal (DTA) analyses are listed in Table 1.

The T–TG, T–DTG, and T–DTA curves were used to calculate the kinetic parameters of thermal decomposition for the compounds synthesized. Below are given for compounds **III**–**V** the onset temperature of intensive decomposition (°C), logarithm of the preexponential factor in the Arrhenius equation, activation energy of the process (kJ mol^{-1}), and the reaction order, all corresponding to the onset temperature of intensive decomposition: **III** 245, 8.6, 116, 1.0; **IV** 235, 9.3, 123, 1.0: **V** 220, 8.4, 114, 1.0. The reaction order equal to unity indicates that the decomposition does not involve diffusion.

Thus, the analysis of the thermal decomposition demonstrated that the complexes synthesized in this study decompose under nonisothermal conditions in several stages. In the first stage, there occurs deaquation and ammonia molecules are removed from the inner sphere of the complex, which leads to its destruction. Then, the tetrazole ligands undergo a steplike thermal decomposition, with the perchlorate ion involved in their oxidation in later stages of decomposition of the complex.

The aim of further studies was to reveal the explosive properties of the compounds obtained. The density and rate of detonation were calculated using the Kotomin method [16]. The impact sensitivity was determined in accordance with GOST (State Standard) 4545–88 (load mass 2 kg, H = 25 cm). The standard high explosive TEN has an impact sensitivity of 12%. The priming capacity of the metal complexes was

Table 2. Explosive properties of the complexes

Compound	Complex	Density ρ, g cm^{-1}	Oxygen factor α	Impact sensitivity measured on a K 44-II impact-testing machine	Minimum charge in terms of hexogen KD no. 8, g	Velocity of detonation, *D*, at ρ, km s^{-1}
III	$[Co(NH_3)_5(CH_2)_5–CN_4](ClO_4)_3$	1.82	0.55	16	0.4	6.98
IV	$[Co(NH_3)_4((CH_2)_5–CN_4)_2](ClO_4)_3$	1.80	0.34	16	>0.5	6.7

evaluated by their minimum charge in terms of hexogen [17]. The explosive properties of the compounds synthesized are illustrated by Table 2. Complex **III** is a priming explosive with a calculated velocity of detonation comparable with that of TNT and sensitivity to mechanical impact close to that of modern powerful high explosives.

The toxicity of corazol and complex **III** was experimentally determined on laboratory animals.[1] The experiments were performed with outbred males of white mice, with a mass of 26–30 g. It was established that the average lethal dose of corazol is, in the case of enteral introduction, ~70 mg kg^{-1} (0.0006 mol kg^{-1}) body mass. Complex **III** caused 50% loss of animals at a dose of ~300 mg kg^{-1} (0.0006 mol kg^{-1}), which indicates that the toxicities of these compounds are close and complex **III** can be tentatively placed in the third hazard class. Also, a tentative conclusion can be made that the coordination of corazol in an ammonia complex of Co(III) does not increase its toxicity as compared with the free ligand.

The average lethal dose of complex **III** in terms of pure metal is 35 mg kg^{-1}. Soluble salts of cobalt(II) and, in particular, cobalt(II) nitrate have LD_{50} of ~160 mg kg^{-1}, which equals 40 mg kg^{-1} in terms of pure metal [4]. Thus, the toxic effect of Co(III) is not enhanced by the complexation.

Consequently, the ammonia complex **III** is less toxic than the most widely occurring high explosive TNT, which belongs to the second hazard class [18, 19].

EXPERIMENTAL

The IR spectra were recorded on a Specord M-80 spectrophotometer in thin layer. The ^{1}H NMR spectra were obtained on a Bruker AC radiospectrometer with a working frequency of 300 MHz, with HMDS as internal reference. The UV spectra were recorded with a Perkin-Elmer LAMBDA 40 spectrometer in quartz cuvettes (l = 1 cm). The reaction course was monitored by means of thin-film chromatography on Silufol UV-254 plates, with a 3% aqueous solution of $NaClO_4$ as eluent.

As the device for microwave heating served a short-circuited 9 × 4.5-cm waveguide connected to a microwave generator (output power 600 W, working frequency 2450 MHz). The reaction vessel, a glass tube 35 mm in diameter (equipped with a thermometer and a reflux condenser), was introduced into the waveguide via a special opening.

The thermographic studies were carried out on a measuring and recording device (Derivatograph system: F. Paulik, J. Paulik, L. Erdey) at a heating rate of 5 °C min^{-1}.

Aquapentaamminecobalt(III) perchlorate **I** and tetrammine-bis(cyclopentamethylenetetrazole)cobalt(III) perchlorate **II** obtained by means of procedures described in [16] were used in further synthesis without their isolation from solution.

Pentaammine(cyclopentamethylenetetrazole)cobalt(III) perchlorate III and tetrammine-bis(cyclopentamethylenetetrazole)cobalt(III) perchlorate IV were obtained under the conditions described in [7] in 71 and 59% yield, respectively. Compound **III**: IR spectrum, ν, cm^{-1}, 1576 med, 1260 med (NH_3, Tetr), 1080 med (ClO_4), 1928 med, 1472 med (CH_2). ^{1}H NMR spectrum (DMSO–d_6), δ, ppm: 4.70 [CH_2 (N^1)]; 3.21 [CH_2 (C^5)]; 1.95, 1.82, 1.71 (CH_2–CH_2–CH_2); 3.75, 3.60 (15H, NH_3).

CONCLUSIONS

(1) Two energetic coordination compounds, pentammine(cyclopentamethylenetetrazole)cobalt(III) perchlorate and tetraammine-bis(cyclopentamethylenetetrazole)cobalt(III) perchlorate, were synthesized by reaction of aquapentaamminecobalt(III) perchlorate **I** and diaquatetraamminecobalt(III) perchlorate **II** and studied.

(2) It was shown that, as judged from the whole set of its properties, compound **III** is a promising low-toxic priming explosive ("green" energetic material).

ACKNOWLEDGMENTS

The study was financially supported by the Ministry of Education of the Russian Federation, Intercollegiate program "Priority Areas of Development of Science and Technology."

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Some Properties of Chemically Deposited Ni–B Coatings

Yu. V. Prusov and V. F. Makarov

Nizhni Novgorod State Technical University, Nizhni Novgorod, Russia

Received June 3, 2004

Abstract—The influence exerted by impurities present in dimethylaminoborane and in solutions used for deposition of nickel–boron coatings on their properties was studied.

Nickel–boron alloy coatings exhibit increased microhardness and wear resistance, low contact resistance and resistivity, good solderability and microweldability, and satisfactory corrosion resistance. All these factors make these coatings competitors of gold and silver coatings for elements of microelectronic devices. Such deposits can be obtained chemically [1] or electrochemically [2] from aqueous solutions, with boron-containing substances as solutes.

Different fields of technology impose different requirements upon coatings. These requirements can be satisfied by depositing alloys with varied (8 to 0.1 wt %) content of boron. The alloy composition can be varied by changing the solution composition and deposition conditions. This requires that the mechanism of the process, which may depend on the composition of a boron-containing reducing agent [3] and on deposition conditions [4], should be known.

The aim of this study was to examine how the composition and some properties of Ni–B films depend on the composition of a reducing agent and deposition conditions. The Ni–B coatings were chemically deposited at 70°C in the course of 1 h onto pretreated steel, palladium, or nichrome samples from a weakly acidic solution of the following initial composition (g l^{-1}): $(NH_4)_2SO_4$ 60, sodium lauryl sulfate 0.03, $NaNO_2$ 0.003, NH_4OH 6.5, $NiSO_4 \cdot 7H_2O$ 30; pH 7.1. Dimethylaminoborane (DMAB) from different batches of the product was used as a reducing agent.[1] The coating deposition rate was calculated from the mass gain by a sample. The adhesion was measured from the loss of mass by a sample after making on its surface a grid of scratches with a step of 1 mm on an area of 1 cm^2. An exfoliated coating was removed with a brush, with the loss of mass recorded. The microhardness was measured using a PMT-3 device with an indenter load of 50 g. The solderability of the coatings was evaluated by the spreading coefficient of the POS-60 solder (with an FKDT flux) in conformity with GOST (State Standard) 9.302–79. The resistivity and contact resistance were measured using standard techniques described in [5].

Anodic polarization curves were obtained with a P-5848 potentiostat on the edge of a palladium rod embedded in fluorioplastic by compression. The amount of boron on the surface of the palladium sample was found from the quantity of electricity consumed for its oxidation, calculated on the assumption of three electrons per atom.

It is known that boron forms a series of hydrides, the simplest of which, monoborane BH_3, is unstable because of having an unsaturated coordination and actively tends to form coordination compounds with various radicals or species: amines, hydrazine, etc. Depending on the structure and composition, the forming compound will be more or less stable. The "longer" and more branched the chain of the molecule of an amine radical, the stronger the bonding between nitrogen and boron (N–B) and the weaker that between hydrogen and boron. This reflects, in particular, upon the susceptibility of boranes to hydrolysis, e.g.:

$$(CH_3)_2HN(BH_3) + 3H_2O = (CH_3)_2HN + H_3BO_3 + 3H_2. \quad (1)$$

In actual practice, DMAB, having the optimal relative strength of the N–B and B–H bonds, is frequently used as a reducing agent. This makes it sufficiently

[1] Commercially manufactured (in batches of several tons each) by Aviabor Joint-Stock Company (Dzerzhinsk, Nizhni Novgorod oblast).

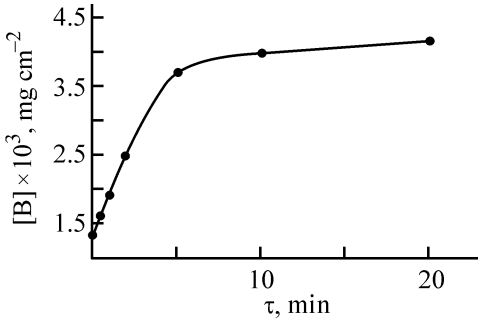

Fig. 1. Amount of boron, [B], formed on palladium vs. time τ of treatment in a solution. Solution composition (g l^{-1}): DMAB 3, $CH_3COONa \cdot 3H_2O$ 10, $Na_3C_6H_5O \cdot 5.5H_2O$ 10; pH 6, T = 70°C.

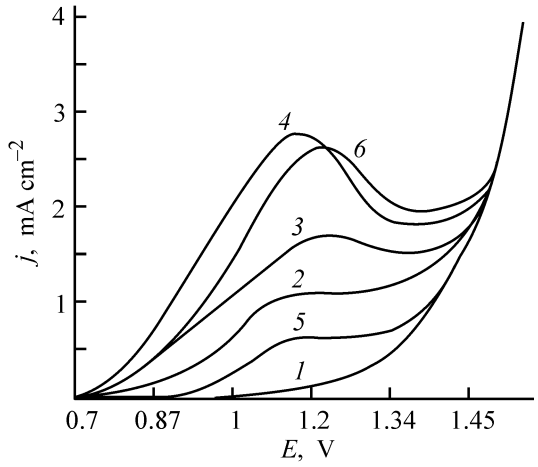

Fig. 2. Anodic polarization curves obtained on palladium treated in a DMAB-containing solution. (*j*) Current density and (*E*) potential. Treatment time (min): (*1*) 0, (*2*) 1, (*3*) 2, (*4–6*) 10. Keeping in air for (*1–4*) 10 min at 20°C, (*5*) 1 h at 150°C, and (*6*) 10 h at 20°C.

stable (in particular, against hydrolysis) and a rather strong reducing agent.

The deposition mechanism of the Ni–B alloy can be represented by the following scheme. The first stage of decomposition of the reducing agent is its dissociative adsorption onto the surface of a metal (Ni or Fe), with rupture of the H–B bond in the reducing agent:

$$(CH_3)_2HN(BH_3) + M = (CH_3)_2HN + M(BH_3)_{ads}. \quad (2)$$

The forming radical of borane BH_3 decomposes to give boron, firmly bound to the metal (by the coordination bond involving vacant *d*-orbitals of the metal) and hydrogen:

$$2M(BH_3)_{ads} = 2MB + 3H_2. \quad (3)$$

Surface layers of the metal are saturated with boron in the course of time, depending on the DMAB concentration in solution (Fig. 1). This process is accompanied by a competing reaction of hydrolysis of monoborane

$$M(BH_3)_{ads} + 3H_2O = M + H_3BO_3 + 3H_2. \quad (4)$$

After the surface layer of the metal is saturated with boron, B(M), other processes become possible, e.g., chemical or electrochemical oxidation of boron (Fig. 2) by the reaction

$$B(M) + 3H_2O = H_2BO_3^-(M) + 4H^+ + 3e, \quad (5)$$

whose equilibrium potential is described by the expression $E = -0.687 - 0.0788pH + 0.0197\log[H_2BO_3^-]$, or diffusion of boron deeper into the metal. The role of acceptors of electrons formed in oxidation of the surface boron by reaction (5) can be played by ions of hydrogen or metal, or other ions present in solution:

$$2H^+ + 2e = H_2, \quad (6)$$

$$M^{2+} + 2e = M. \quad (7)$$

Boron diffusing deeper into the metal enters into the composition of the alloy being deposited. The content of boron in the alloy is determined by the relative rates of reduction of metal ions and of the diffusion of boron into the alloy. In this way, a two-component alloy is formed. The electrons generated in reaction (5) can be consumed for reduction of ions of any metals present in solution, to give multicomponent alloys.

It is shown that elements belonging to Groups I, II, and III of the periodic system are codeposited in rather small amounts because of their strongly negative potential. The same is observed for elements that belong to the succeeding groups because of their increasing nonmetal properties (gallium, indium, thallium, tin, antimony, bismuth, selenium, and tellurium). The content of a third component can be raised by carrying out the process at a higher temperature, lowering the solution pH, and varying the composition of the buffer–complex–forming system. Commonly, the growth rate of a coating markedly decreases in the case of codeposition of these elements. For example, the deposition rate of nickel–iron–boron coatings decreases as the concentration of iron sulfate in solution increases, because Fe^{2+} ions affect the process of alloy formation as inhibitors of the reaction of reduction. This is due to the fact that iron has a much lower capacity for formation of coordination compounds

$M(BH_3)_{ads}$ than nickel. The content of iron in the alloy may be as high as 20 wt % at a deposition rate of up to 6 μm h^{-1}. In other cases, the deposition rate changes more significantly in obtaining alloys. This is due to the fact that poison-metals (bismuth, cadmium, tin, etc.) codeposited onto the surface of active nickel have high exchange currents and, therefore, being preferentially deposited (compared with nickel), enforce their potential to the surface, thereby shifting its potential in the negative or positive direction. The renewed surface is predominantly composed of the impurity metal, which has a low affinity for boron and does not form with it any coordination compound. As a result, the rate of reaction (5) occasionally decreases to zero. Nickel present in solution has a low exchange current and cannot compete with impurity metals in deposition onto the surface. This scheme is indirectly confirmed by a decrease in the boron content of the alloy [6].

Tin, arsenic, thallium, and other elements are frequently not revealed by X-ray diffraction analysis in three-component coatings containing these metals, despite their high content. Consequently, these elements form X-ray-amorphous solid solutions in the alloys.

Nonmetal elements can be incorporated into an alloy by another mechanism. If a catalytically active component (e.g., phosphorus in the form of a hypophosphite) is introduced into the solution, the deposition rate not only does not decrease, but may even increase [8]. These observations served as a basis for the method, developed by the authors, for deposition of a nickel–boron–phosphorus alloy with a high metallization rate. The deposit obtained has a low resistivity, high solderability (preserved in the course of time), and corrosion resistance.

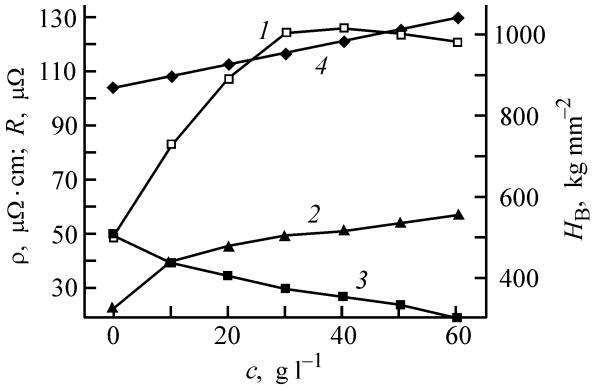

Fig. 3. (*1*) Resistivity ρ, (*2*) contact resistance *R*, and (*3*, *4*) microhardness H_B of coatings vs. caprolactam concentration *c*. (*3*) Without thermal treatment and (*4*) with thermal treatment at 350°C for 1 h.

Introduction of caprolactam into a solution for electroless nickel plating results in that the whole molecules of this compound or their fragments are incorporated into the resulting coatings. Deposits of this kind may contain up to 1.35 wt % carbon and 0.5 wt % hydrogen. The amount of nitrogen in the coating is small, which may indicate that the nitrogen-containing group is eliminated in adsorption and overgrowth of caprolactam with nickel. This leads to a significant decrease in the internal stresses and grain size, which is accompanied by an increase in the contact resistance and chemical activity (Fig. 3). Coatings

** Type of DMAB: (nos. 1–10, recrystallized and purified; nos. 11–14, containing various products used in its manufacture; no. 5, reference manufactured by BAKER (Austria).

of this kind can be deposited onto aluminum without its special pretreatment, with a high adhesion.

It may be assumed that the properties of a nickel–boron coating can also be strongly affected by the composition of DMAB. Synthesis of the dimethylaminoborane complex from diborane and dimethylamine in a diethyl ether or other media yields as the final product a mixture of DMAB with mono- and trimethylaminoborane and other boron-containing compounds, which are rather difficult to separate because they are determined and calculated as DMAB in an analysis for boron. Even the amount of determinable impurities in commercial batches may be as high as 0.65 to 1.8 wt % (see table).

As it can be seen from the table, no influence of the impurities on the characteristics under study is revealed. All these characteristics are in the same ranges for DMAB manufactured by BAKER Co. and domestic samples. Consequently, further deep purification of commercial DMAB is inexpedient.

CONCLUSION

It was shown that nickel–boron coatings deposited from solutions whose composition includes dimethylaminoborane may contain carbon, nitrogen, hydrogen, sulfur, phosphorus, cadmium, and other alloying components, which can modify the functional properties of the coatings. Coatings composed of such alloys have properties valuable for microelectronics.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Synthesis and Structure of Composites of Nanosize Silica Particles Modified with Glass Microspheres

V. M. Ogenko, L. V. Dubrovina, and S. V. Volkov

Vernadskii Institute of General and Inorganic Chemistry, National Academy of Sciences, Ukraine, Kiev

Received May 27, 2004

Abstract—A method for production of porous composites from pyrogenic silicas, whose surface is preliminarily modified with methyl and trimethyl siloxane groups, was developed. In order to diminish shrinkage, glass microspheres and organosilicon compounds were used as modifiers. The total porosity of the composites obtained was 0.28–0.55.

Porous materials are widely used as sorbents, catalyst supports, and membranes. The effectiveness of their various applications is mainly determined by the capacity and rate of sorption, which largely depend on the porous structure of a material. However, materials based on inorganic compounds do not have a rational porous structure, and, consequently, synthesis of complex composite structures with improved functional parameters is a matter of current interest [1–4].

Silica gel is a porous material of particular importance. The scale of its use exceeds that of any other oxide adsorbent and the fundamental aspects of formation of its porous structure have been studied in sufficient detail. Commonly, silica gels are obtained from silicates of alkaline metals by precipitation with an acid. Use of sols of silicic acid makes it possible to control the structure of the resulting silica gel, whose porosity depends on the size distribution of colloid particles [1–4]. Xerogels of varied porosity are also obtained by the sol-gel technique from silicon alcoxides. Monolithic samples of xerogels produced by any synthesis method undergo shrinkage and cracking in drying. This disadvantage can be eliminated by varying the composition of the dispersion medium, making longer the duration of drying, or using special additives [1–9].

The aim of this study was to obtain composites with an openwork structure constituted by silica nanoparticles and glass microspheres and to study the properties of these composites.

As structure-forming elements of the composites served pyrogenic silicon dioxides (aerosils) composed of 5–50-nm spherical particles of nonporous amorphous SiO_2. These primary particles form sufficiently stable 100–500-nm aggregates. These aggregates mostly disintegrate upon a short-time ultrasonic or mechanical treatment of suspensions [10]. When mixed with appropriate liquids, aerosils form gels, which are transformed into xerogels upon drying. This makes it possible to obtain nanostructure composites of varied porosity.

EXPERIMENTAL

As starting silica particles were taken pyrogenic silicon dioxides: hydrophobic aerosils (AD, with a surface modified with methyl groups, S_{sp} = 175 $m^2 g^{-1}$, and AO, with a surface modified with trimethylsiloxane groups, S_{sp} = 195 $m^2 g^{-1}$).

As the dispersion media served water, ethanol, and hexane. The composition of xerogels was modified with tetraethoxysilane (TES), whose hydrolysis gives silicon dioxide:

$$(C_2H_5O)_4Si + 2H_2O \rightarrow 4C_2H_5OH + SiO_2\downarrow.$$

Polydimethylsiloxane (PMS) and SIEL silicon rubber were also used for this purpose. SF glass microspheres, d = 10–40 μm (ρ = 30 kg m^{-3}), washed in hexane served as a filler.

In order to obtain xerogels, to the aerosil were added the dispersion medium (until fluidity appeared), modifying agents, and glass spheres, and the mixture was stirred. The gels formed were placed in Petri dishes and dried in air, first at room temperature (20 ± 2°C) and then at 160°C. Electron micrographs of composites dried on silicon supports were obtained with an REM-101 electron microscope.

1070-4272/05/7802-0197 © 2005 Pleiades Publishing, Inc.

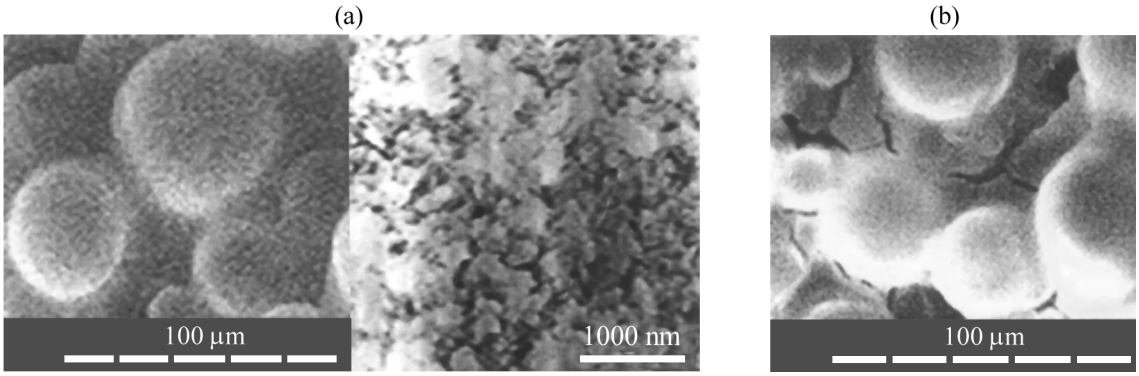

Fig. 1. Electron micrograph of a composite formed from aerosil and glass spheres. [SF] : [AD]: (a) 3.3 and (b) 2.6.

The total porosity *W* of the samples was determined by their impregnation with carbon tetrachloride [11]. The volume of the samples was calculated from their dimensions.

It was shown [12] that replacing quartz with glass makes lower the adhesion between a quartz plate and glass particles or a glass plate and quartz particles. Consequently, introduction of glass microspheres can give a three-dimensional (3*D*) structure of SiO_2 particles and glass spheres with coagulation contacts weakened as compared with a gel formed only from SiO_2 and make looser the aggregates formed.

SiO_2 particles of hydrophobic aerosil AD are wetted in ethanol via adsorption of alcohol molecules on the aerosil surface, with the C_2H_5 groups of these molecules facing the particle surface and the OH groups looking in the opposite direction. Glass spheres are wetted by both water and ethanol, with molecules of the latter adsorbed on their surface with the OH groups facing the surface. The C_2H_5 groups are turned away and can be adsorbed on the surface of aerosil particles. This may lead to binding of glass spheres, SiO_2 particles, and aggregates of these particles. In addition, since the reagent used was not absolute alcohol, its water molecules can bind particles and aggregates of aerosil with glass spheres via formation of hydrogen bonds with the OH groups of ethanol molecules adsorbed on the SiO_2 surface. As a result, a solid 3*D* structure can be formed from aggregated aerosil particles of various sizes, glass spheres, water, and ethanol, bound by a system of nonvalence interactions. Drying of these gels gives monolithic samples in the form of close-packed glass spheres, with the inter-sphere space filled with openwork structures constituted by aerosil particles (Fig. 1a). The composition and selected parameters of the composites obtained are listed in the table.

* AO used instead of AD. ** Hexane as the dispersion medium.

Monolithic samples could not be obtained at [glass spheres] : [aerosil] ratios of up to 3.0. Shrinkage, cracking (Fig. 1b), and lamination of samples (upper layers were enriched in glass spheres) were observed in the course of drying. As can be seen from the table, the apparent sample density decreases as the concentration of glass spheres becomes higher. Composites with [SF] : [AD] = 3.3 have the best physicomechanical properties. Modification of the composite with TES, PMS, or SIEL affects the properties of the composite, although the nature of this influence varies. As already noted, hydrolysis of TES yields an additional amount of SiO_2, which makes the concentration of the dispersed phase higher, and the porosity of the resulting composite, lower. Macromolecules of PMS and SIEL adsorbed on the surface of aerosil particles bind the aggregates together and thereby diminish the looseness of the 3*D* network of the gel. This leads to a decrease in the porosity of the composite and an increase in its apparent density. The SIEL silicon rubber differs from PMS in a greater length of macromolecules, and, therefore, its effect is stronger.

The loss of weight by samples heated to 160°C to remove physically bound water [13] did not exceed 0.6%, i.e., the pores obtained are virtually empty even upon drying at room temperature. Such a heating can be to a certain extent compared with hydrothermal treatment of silica gels, which is confirmed by the data in the table. Samples of the composite samples have a higher density and porosity upon heating.

Replacement of AD with AO, which has a greater number of surface CH_3-groups per silicon atom, raises the porosity of the composite owing to formation of looser aggregates and, possibly, leads to a decrease in the pore size. If hexane is used as the dispersion medium, complete wetting of the surface of AD aerosil particles occurs, but it does not promote their binding into aggregates. At the same time, hexane does not wet glass spheres and favors their aggregation with coagulation contacts weaker than those in aerosil aggregates. Combined, these factors make it possible to produce a composite with a low density and the highest porosity among all the samples. The composite has a virtually zero mechanical strength and disintegrates in CCl_4.

CONCLUSIONS

(1) Monolithic samples of porous composites were obtained in the form of close-packed glass spheres with the inter-sphere space filled with structured nanosize particles of nonporous silica.

(2) The porosity and density of the composites can be controlled by modifying the surface of SiO_2 particles and varying the nature of the dispersion media, concentration of glass spheres and silicon dioxide, and temperature mode of drying.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Study and Thermodynamic Analysis of the ZrO_2–SiO_2 System

D. N. Kamaev, S. A. Archugov, and G. G. Mikhailov

South-Ural State University, Chelyabinsk, Russia

Received November 2, 2004; in final form, September 2004

Abstract—The system ZrO_2–SiO_2 was additionally studied by means of differential thermal analysis. The temperatures of the solid-state decomposition of zircon and the coordinates of the eutectic point were refined. A thermodynamic calculation of the system in terms of the theory of subregular ionic solutions was carried out on the basis of the experimental data obtained.

The positive effect of zirconium on steel properties [1] is caused by its vigorous reaction with oxygen, nitrogen, sulfur, and silicon to give stable chemical compounds [2]. In particular, zirconium additives make smaller the grain size, raise strength, improve weldability, and enhance oxidation and corrosion resistance. A thermodynamic analysis of how zirconium added to a steel interacts with oxygen dissolved in it is necessary for solving problems associated with steel alloying with zirconium in metallurgy. If silicon is present in a steel, information on the interaction of zirconium and silicon with oxygen can be obtained when precise data on the Fe–Zr–Si–O system are available. In an attempt to carry out a thermodynamic analysis, we found that published data on the phase diagram of the ZrO_2–SiO_2 system are ambiguous.

It has been shown [3–5] that heating of zircon ($ZrSiO_4$) to high temperatures leads to its dissociation into oxide components. There is an opinion [3] that zircon melts incongruently at 1775 ± 10°C, whereas its eutectic temperature is appreciably lower: 1675°C (94 mol % SiO_2). According to [4], the melting point of zircon is 1720 ± 20°C. The authors of [5] believe that $ZrSiO_4$ decomposes even in the solid phase at 1540°C.

According to experimental data on the high-temperature behavior of zircon [6], it decomposes into component oxides at 1676°C, and its eutectic point is 1687°C. These data are consistent with the results of [7], but differ from the data of [3]. However, the eutectic point was not determined in [7], and only the decomposition of zircon in the solid phase and the approximate eutectic composition (about 97 mol % SiO_2) were reported.

However, assessment [8] of the results obtained in a study of the zircon synthesis from ZrO_2 and SiO_2 [5] shows that zircon is thermodynamically stable approximately up to 1727°C, and the free energy of its dissociation into component oxides is zero at 1771°C. This value differs by only 4°C from the temperature reported in [3].

To eliminate these contradictions and to obtain a thermodynamic description of the system ZrO_2–SiO_2, we determined the temperature of zircon decomposition, its eutectic point, and eutectic composition.

EXPERIMENTAL

A modified installation for precision high-temperature thermal analysis [9] was used in the experiments. The addition of the third crucible with a reference substance with well-known properties [10] into the cell maked it possible to obtain data accurate to no less than ±10°C in the temperature range 1700–2100°C. Earlier, experimental data of high precision have been obtained on a similar installation [11, 12].

Samples for the experiments were prepared from analytically pure silicon and zirconium oxides. To remove moisture and adsorbed admixtures, the starting oxides were calcined in air at 1200°C for 3 h and immediately after that were placed in weighing bottles stored in a desiccator in dry air. The accuracy rating of the balance used to prepare weighed samples guarantied that the composition deviated from a calculated value by no more than 0.01 wt %.

Samples with the SiO_2 content varied in the range 80–100 mol % with a step of 2% and a sample containing 50 mol % SiO_2 were prepared. After being

1070-4272/05/7802-0200 © 2005 Pleiades Publishing, Inc.

mixed, the samples were compacted in a special hard-alloy press mold. The compacted samples were weighed and placed in a crucible of the thermographic installation. The weight of samples placed in the crucible was varied in the range 0.0500 – 0.0900 g.

Analytically pure aluminum oxide was used as a reference. The experiments were carried out in the atmosphere of argon at a pressure of 1 atm.

The following procedure was suggested for obtaining DTA curves: (1) heating of a sample to 1500°C at a rate of 60 deg min^{-1} with a subsequent cooling at the same rate to 800°C; (2) heating of the sample to 1400°C at a rate of 60 deg min^{-1} and annealing at this temperature for 3 min; (3) heating of the annealed sample to a temperature exceeding by 20–50°C the presumed eutectic point at a rate of 30 deg min^{-1} and its keeping at this temperature for 3 min with a subsequent heating to 2100°C at the same rate; (4) cooling of the sample to a temperature higher by 20–50°C than the presumed eutectic point at a rate of 60 deg min^{-1} and keeping it at this temperature for 3 min; (5) cooling of the sample to room temperature at a rate of 60 deg min^{-1}; and (6) heating of the sample to 2100°C at a rate 30–100 deg min^{-1}.

The first two stages were sufficient for synthesizing zircon from the starting components, which was confirmed by X-ray fluorescence spectroscopy: only zircon and silicon oxide were detected in the samples. The other stages were necessary for obtaining equilibrium compositions. Thermocouples were calibrated in stages 3 and 6 against the peak of Al_2O_3 melting in the reference crucible.

The most reliable DTA data were obtained in stage 6. Up to 12 samples of the same composition were studied to gather statistically significant data on each transformation.

An examination of the DTA curves of the samples under study (Fig. 1), measured with heating at different rates (30–100 deg min^{-1}), revealed the effect of heating rate on DTA curves and allowed us to extrapolate these data to zero heating rate. This made it possible to determine the dissociation temperature of zircon, its eutectic point, and the liquidus temperature for samples containing 80 to 100 mol % SiO_2 (Fig. 2).

Three successive peaks can be seen in the DTA curve. It was found that the first two peaks correspond to dissociation of zircon and its eutectic transformation, and the third peak, to melting of the solid phase formed upon the eutectic transformation (liquidus line). If the first peak corresponded to eutectic transformation, the formation of a liquid would be visually detected after terminating the heating and withdrawing the crucible with a sample.

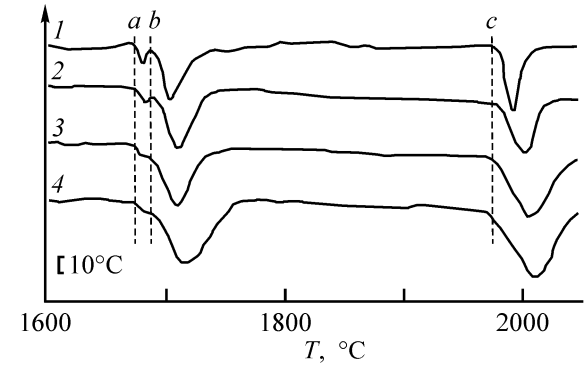

Fig. 1. DTA curves of a sample containing 90 mol % SiO_2. (*T*) Temperature. The temperature of (*a*) zircon decomposition, (*b*) eutectic transformation, and (*c*) liquidus was measured. Heating rate (deg min^{-1}): (*1*) 30, (*2*) 40, (*3*) 50, and (*4*) 60.

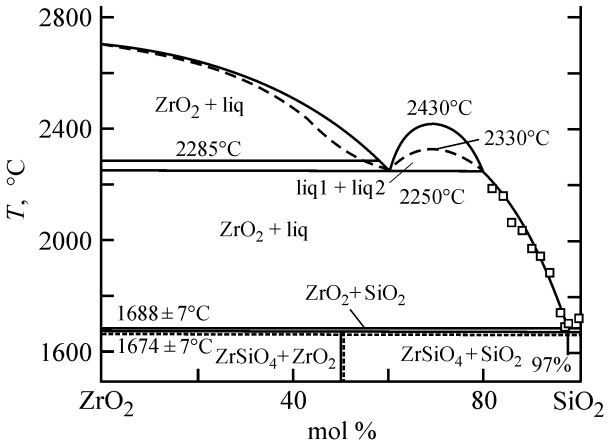

Fig. 2. Phase diagram of the ZrO_2–SiO_2 system, plotted using the data of [6] and the experimental and calculated data of the present study. *Points*, experimental data for the liquidus line; *dashed line*, calculation.

To confirm the decomposition of zircon in the solid phase and to determine the dissociation temperature, we heated the sample containing 50 mol % ZrO_2 and 50 mol % SiO_2 (initial composition for synthesis of zircon in stages 1 and 2). When the peak corresponding to a probable decomposition appeared in the thermogram, the sample was kept for a few minutes at a temperature higher than that at which the first peak appeared, but lower than that of the second peak. Then the sample was cooled to room temperature. After being removed, the sample retained its initial shape and exhibited no traces of melting. It should be also noted that the peaks corresponding to solid phase transformations are commonly lower than melting

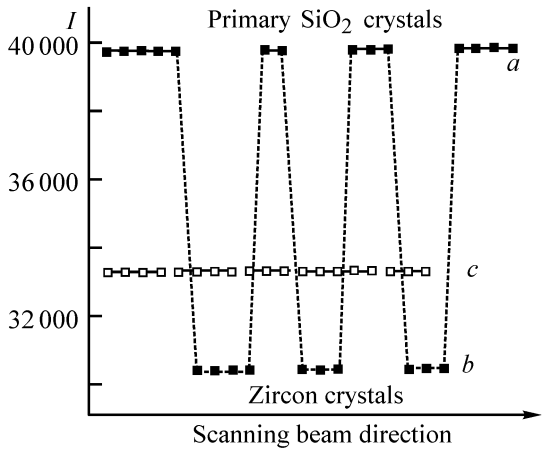

Fig. 3. Silicon distribution. (*I*) Intensity of characteristic pulses of Si. (*a*, *b*) Primary SiO_2 crystals and zircon (sample with 88 mol % SiO_2); (*c*) synthesized zircon (sample with 50 mol % SiO_2).

peaks. For comparison, a sample containing 88 mol % SiO_2 was subjected to the heating–cooling procedure in the same temperature mode, and similar results were obtained.

The distribution of silicon in grains of synthesized zircon with 50 mol % SiO_2 and of a sample with 88 mol % SiO_2 (primary SiO_2 crystals and zircon crystals) are shown in Fig. 3. This distribution was determined from the intensities of characteristic pulses in scanning in an X-ray microanalyzer. If the intensity of the characteristic radiation of silicon in scanning of synthesized zircon is constant, this means that the sample is homogeneous and zircon is stable at temperature below 1674°C.

The liquidus line constructed within the range of compositions under study (Fig. 2) is in a good agreement with other published data [6, 7].

The eutectic temperature was determined from all experimental temperatures corresponding to the liquidus line peaks. In the course of experiments, thermocouple readings were corrected against the peaks corresponding to melting of alumina and then against those associated with copper melting [13–15]. The eutectic composition was determined from the point of intersection between the experimental liquidus line and the conode at 1688°C.

As a result, it was found that the heating first leads to a solid-phase decomposition of zircon at 1674 ± 7°C and then to an eutectic transformation at 1688 ± 7°C. According to our estimates, the eutectic melt contains 97 mol % SiO_2.

Based on the experimental data obtained, we carried out a thermodynamic calculation of the phase diagram in terms of the theory of subregular ionic solutions [16]. According to this theory, the chemical potentials of components in a binary oxide system have the form

$$\mu_1 = \mu_1^0 + \nu_1[RT\ln x_1 + 3x_1^2x_2^2Q_{1112} + x_1x_2^2(2 - 3x_1)Q_{1122} + x_2^3(1 - 3x_1)Q_{1222}],$$

$$\mu_2 = \mu_2^0 + \nu_2[RT\ln x_2 + x_1^3(1 - 3x_2)Q_{1112} + x_1^2x_2(2 - 3x_2)Q_{1122} + 3x_1^2x_2^2Q_{1222}].$$

Then the equilibrium constant of zircon formation by the reaction

$$ZrO_2 + SiO_2 = ZrSiO_4$$

can be expressed as

$$\log K = -\frac{A}{B} + B = \frac{\nu_1[3x_1^2x_2^2Q_{1112} + x_1x_2^2(2 - 3x_1)Q_{1122} + x_2^3(1 - 3x_1)Q_{1222}]}{2.3RT} + \frac{\nu_2[x_1^3(1 - 3x_2)Q_{1112} + x_1^2x_2(2 - 3x_2)Q_{1122} + 3x_1^2x_2^2Q_{1222}]}{2.3RT} + \nu_1\log x_1 + \nu_2\log x_2.$$

Here R is the universal gas constant; T, absolute temperature; ν_i, number of cations in an oxide molecule; μ_i^0, standard chemical potential; Q_{1112}, Q_{1122}, and Q_{1222}, energy parameters of the interaction between components; x_i, molar fraction; K, equilibrium constant of the reaction of zircon formation; and A and B, numerical constants; subscripts 1 and 2 refer to ZrO_2 and SiO_2, respectively.

The following reference points were chosen for the calculations: experimental eutectic point (97 mol % and 1688°C), points corresponding to the composition of monotectic transformation at 2250°C (78 mol % SiO_2 and 60 mol % SiO_2) [6], and point of syntectic transformation (50 mol % SiO_2 at 1674°C). In the calculation, expressions for monotectic, syntectic, and eutectic equilibria were written, and the resulting set

of equations was solved. The thus found energy parameters are as follows: Q_{1112} = –15850, Q_{1122} = 86630, and Q_{1222} = 27600 J mol^{-1}. The constant of zircon formation from the starting oxides is given by

$$\log K = \frac{76\,026}{T} + 25.90.$$

Further, we calculated the whole phase diagram of the ZrO_2–SiO_2 system (Fig. 3), using the values obtained. There is a certain disagreement between the resulting calculated and experimental diagrams at temperatures above 2250°C. The most likely reason is that the effect of temperature on the interaction parameters was disregarded in the calculations and the parameters were averaged over a rather wide temperature range.

CONCLUSIONS

(1) The solid-phase decomposition of zircon was confirmed experimentally and the temperatures of this decomposition (1674 ± 7°C) and of the eutectic transformation (1688 ± 7°C) were refined. The eutectic composition was found to be 97 mol % SiO_2.

(2) The thermodynamic calculation confirmed the stratification of melts in the ZrO_2–SiO_2 system. The information obtained makes possible further thermodynamic analysis of the FeO–ZrO_2–SiO_2, Fe–Zr–Si–O, and other multicomponent systems containing zirconium and silicon, which, in turn, allows evaluation of parameters of the interactions between oxygen and zirconium added to a steel, in the presence of silicon and other elements. These data are of great importance for the theoretical metallurgy.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Temperature Dependences of HCl Activity Coefficients in Aqueous Solutions

G. M. Poltoratskii, I. I. Osovskaya, and S. V. Chumanov

St. Petersburg State Technological University of Phytopolymers, St. Petersburg, Russia

Received January 15, 2004

Abstract—Temperature coefficients of activity of the ionic fraction of HCl in water, calculated from tensimetric and calorimetric data, are compared. A correlation dependence is suggested for recalculating the activity coefficients of hydrochloric acid from 298 K to other temperatures.

It is commonly believed that solutions of HCl in water are sufficiently well studied, and, therefore, they are widely recommended for use as reference in calibration of various devices and, in particular, those intended for measuring electromotive forces and pH values [1]. At the same time, recent studies have revealed an inconsistency in published data, especially as regards the quantitative characteristics of ionic dissociation and the methods of their determination [2, 3].

It is known that the Guggenheim equation [4] makes it possible to correlate the temperature dependences of activity coefficients of an electrolyte in solution with the corresponding values found from experimental data on the heats of dilution.

Relative partial molal (r.p.m.) enthalpies of a solvent and an electrolyte in solution, $\bar{L}_1$ and $\bar{L}_2$ (subscripts 1 and 2 refer to the solvent and the electrolyte, respectively) are commonly calculated from the results of direct calorimetric measurements (integral heat of electrolyte dilution) [5, 6].

These data must coincide with the results of calculation of the same values from the temperature dependences of the activities of the corresponding solution components.

The activity coefficients of water are commonly recalculated into those of an electrolyte and back with the use of the known Bierrum's relation [5], from which follows an expression that makes possible a mutual recalculation of the temperature coefficients of the activities of a solvent and an electrolyte:

$$\left(\frac{\partial \ln \gamma}{\partial T^{-1}}\right)_m = -\frac{55.51}{\nu m}\left(\frac{\partial \ln a_w}{\partial T^{-1}}\right)_m. \quad (1)$$

Here a_w is the activity of a solvent (water, in particular); γ, average ionic activity coefficient of an electrolyte; ν, number of ions formed in dissociation of the electrolyte; and m, molality of the solution.

A comparison of the values of $\bar{L}_1$ and $\bar{L}_2$, calculated from calorimetric data, with the same values calculated using the derivatives $(\partial \ln a_w/\partial T^{-1})_m$ and $(\partial \ln \gamma/\partial T^{-1})_m$ for aqueous solutions of HCl demonstrated that detailed and repeatedly published data on the heats of dissolution and dilution are available only for 298 K [7]. For other temperatures, only results of fragmentary measurements can be found [8–11].

The overwhelming majority of authors and reference books indicate a linear, within the limits of errors declared by the authors, temperature dependence of the logarithms of the activity of water over the whole interval of compositions and temperatures studied. At the same time, both the linearity [12] and minor deviations from this behavior [13–16] have been observed for the logarithms of the average ionic activity coefficients in a limited range of compositions and temperatures. Such discrepancies primarily contradict Eq. (1). Moreover, the values of $R(\partial \ln \gamma/\partial T^{-1})_m$ and the r.p.m. enthalpies $\bar{L}_2$ are constant within the errors of determination of the initial values, i.e., they are independent of temperature.

To analyze this discrepancy, we decided to supplement with our own calorimetric measurements primarily that range of concentrations and temperatures in which deviations from the main body of data were observed.

We measured the heats of HCl dilution in water at 288, 298, and 308 K in a calorimeter with an iso-

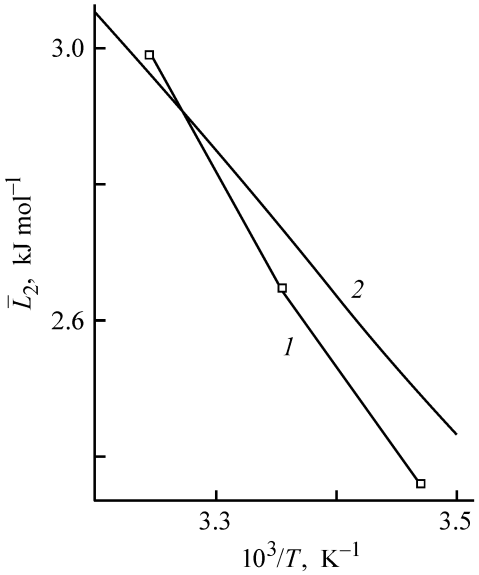
* Calculation from the data of [13].

thermal jacket at an average measurement error of 0.5%. The results for 298 K are in a full agreement with the most reliable published data [7]. We did not find any systematized published data for 288 and 308 K. The design of the devices used and the measurement procedure have been described in detail earlier [17, 18]. The results of direct measurements of the dilution heats at three temperatures and r.p.m. enthalpies calculated on their basis are listed in the table.



It can be seen that the variation of $\bar{L}_2$ with temperature is not so narrow as it would be expected, at least within the range from 288 to 308 K at molalities of 0.1 to 4 mol kg^{-1} of H_2O. Consequently, the temperature coefficients of the average ionic activity coefficients are not constant, but also depend on temperature. This fact contradicts the majority of published tabulated data on the activity coefficients for various temperatures. At the same time, $\bar{L}_1$ also depends on temperature, but deviates from constancy far beyond the errors of the majority of modern methods for measuring a_w (±5–10%) and derivatives $(\partial \ln a_w / \partial T^{-1})_m$. Therefore, in our opinion, Eq. (1) can be used for calculating the temperature dependence of the logarithm of the activity of water, but there is no sense in the reverse calculation.

Within the experimentally accessible ranges of concentrations and temperatures, $\bar{L}_2$ can be expressed as an empirical dependence $\bar{L}_2 = f(m, 1/T)$, which makes it possible to interpolate $\ln \gamma$ to any temperature with a substantially better accuracy, since it allows integration of Guggenheim the equation within the required limits:

$$\ln \gamma(T) = \ln \gamma(298) + \frac{1}{\nu R} \int_{298}^{T} \bar{L}_2 \, \mathrm{d}T^{-1}. \qquad (2)$$

The authors of [13] measured the electromotive force of the systems with a chloride electrode at temperatures of 298 to 353 K and concentrations m of 1 to 11 mol kg^{-1} of H_2O. They approximated the dependences of $\ln \gamma$ on $1/T$ with parabolas and calculated $\bar{L}_2$ from these parabolas to obtain a perfect agreement with published data [7] for 298 K.

As can be seen from the figure, the dependence of $\bar{L}_2$ on inverse temperature, obtained in direct calorimetric measurements at a molality m = 1 (curve *1*), is not linear. The linearity (curve *2*) results from differentiation of the parabolic approximation to the de-

Comparison of r.p.m. enthalpies $\bar{L}_2$ of HCl in an aqueous solution with a molality m = 1 mol kg^{-1} of H_2O, calculated from calorimetric and electrochemical data. (T) Temperature. (*1*) This study and (*2*) calculation from the data of [13].

pendence of $\ln\gamma$ on $1/T$ ($\ln\gamma = a + b/T + c/T^2$), obtained using the data of [13] with a standard deviation of 0.11% (average measurement error is 0.15% [13]).

The approximation of the same data with a straight line $\ln\gamma = a + b/T$ gives a standard deviation of 0.22%, a value that is not considerably higher than that in the case of a parabolic approximation. Differentiating the linear regression equation, we come to a constant value of $\bar{L}_2$ over the whole temperature range under study for each of the concentrations used. Consequently, the data obtained by most of authors can be reproduced with an error somewhat exceeding that in the majority of reports, using an equation based on the assumption that $\bar{L}_2$ is independent of temperature:

$$\ln\gamma(T) = \ln\gamma(298) + \frac{\bar{L}_{2(298)}}{\nu R}(T^{-1} - 298^{-1}). \quad (3)$$

CONCLUSIONS

(1) The temperature dependences of the logarithms of the activity coefficients of HCl in aqueous solutions, obtained from calorimetric experiments, were compared with published data. It was shown that calorimetry can give more accurate results.

(2) Equations (2) and (3) were suggested for recalculating the activity coefficients of HCl in aqueous solutions from 298 K to any other temperature within the existence limits of a solution, with varied error not exceeding the accuracy of the majority of published data.

(3) The possibility, in principle, of more accurate calculations by equation (2) requires additional labor-consuming calorimetric measurements.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Limiting Activity Coefficients of Phenol in Hydrocarbons

I. E. Dobryakova and Yu. G. Dobryakov

Research Institute of Chemistry, St. Petersburg State University, St. Petersburg, Russia

Received November 29, 2004

Abstract—The activity coefficients of phenol in a number of hydrocarbons were determined from experimental data on phenol distribution between aqueous and hydrocarbon liquid phases, using data on the limiting activity coefficients of phenol in water. Ten systems containing saturated and aromatic hydrocarbons were examined in the temperature range 283–328 K.

The limiting activity coefficient γ^∞ is an important thermodynamic parameter, which characterizes the properties of a dissolved substance and is necessary for calculation of processes of impurity removal and substance separation. A knowledge of γ^∞ makes it possible to describe a liquid–vapor equilibrium at a small content of a dissolved component and to estimate the degree of nonideality of the system. The distribution coefficients between liquid and vapor phases can be readily determined from experimental values of γ^∞, which is especially important both for chromatography and for solution of various problems of analytical ecology, e.g., for determining trace amounts of toxic substances (including phenol) in the environment. The fact that the limiting activity coefficient is an important parameter for calculation of phase equilibria has been reported elsewhere [1–3]. It has been shown [4–6] that, with only binary data on the limiting activity coefficients used for estimating the energy characteristics of model systems, one can calculate characteristics of liquid–vapor and liquid–liquid–vapor equilibria in binary and multicomponent systems. For this reason, experimental γ^∞ values are thoroughly studied, systematized, and introduced into experimental databases and reference books [7, 8].

The goal of this study was to determine the limiting activity coefficients of a low-volatile component, phenol, in volatile hydrocarbons by an indirect method based on the previously obtained experimental data on the phenol distribution between liquid phases in the water–hydrocarbon system [9].

The distribution coefficient of a dissolved component between the organic and aqueous phases is related to the activity coefficients by

$$K_x = \frac{x_{org}}{x_{aq}} = \frac{\gamma_{org}}{\gamma_{aq}},$$

where x is the mole fraction, and γ, the activity coefficient of the solute in terms of a pure component.

At $x \to 0$, K_x takes a constant value (Berthelot–Nernst law):

$$K_x^\infty = \lim_{x \to 0} K_x = \frac{\gamma_{org}^\infty}{\gamma_{aq}^\infty},$$

where the superscript ∞ stands for an infinitely diluted solution.

Thus, if the distribution coefficient of a dissolved component between the aqueous–organic phases and the limiting activity coefficient of this component in either of the solvents are known, then the limiting activity coefficient of this component in another solvent can be readily estimated. This "indirect measurement method" [10] was applied, in particular, for determining γ^∞ for a number of organic substances in water. As reference was used the activity coefficient γ^∞ of a component under study in a heavy hydrocarbon (hexadecane), measured by dynamic gas–liquid chromatography [11].

The limiting activity coefficients of phenol in the organic solvent were calculated by the formula

$$\gamma_{org}^\infty = \frac{\gamma_{aq}^\infty}{K_x^\infty}. \quad (1)$$

The limiting activity coefficient of phenol in water at a given temperature, γ_{aq}^∞, was determined from the temperature dependence of the data obtained by ebullioscopy [12–15]. The dependence of the nat-

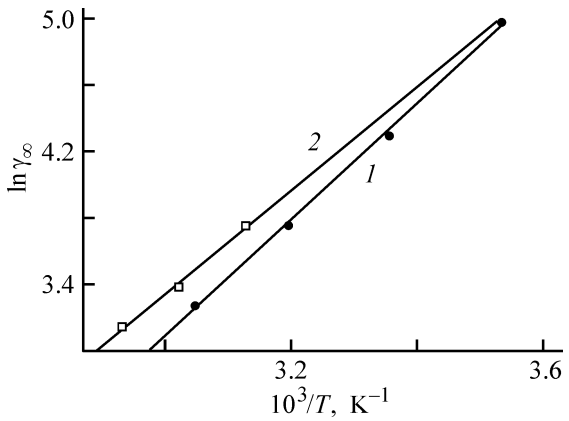

Fig. 1. Comparison of the limiting activity coefficients of phenol, γ^∞, in cyclohexane determined in (*1*) this study and (*2*) in [14]. (*T*) Temperature; the same for Fig. 2.

ural logarithm of γ_{aq}^∞ on the reciprocal temperature was linearly approximated with a straight line for all the available published data falling within a 5% range of deviations from the approximating line. The molar distribution coefficient (according to [9]) was recalculated to K_x by the formula:

$$K_x^\infty = K_c \frac{\rho_{org}}{\rho_{aq}} \frac{M_{org}}{M_{aq}}, \quad (2)$$

where K_c is the distribution coefficient of phenol between the aqueous and organic phases in terms of molar concentration; ρ_{aq} and ρ_{org}, densities of aqueous and organic phases, respectively; and M_{aq} and M_{org}, molecular weights of water and organic solvent, respectively.

As the organic substances used here are to a certain extent mutually soluble and the density of a liquid layer somewhat differs from that of a pure solvent, the layer densities were determined experimentally for each temperature studied. Since the ratio of densities of the liquid phases, rather than their absolute values, are necessary for calculation by formula (2), the Archimedean method of hydrostatic weighing is the optimal procedure for measurements.

We used an Ohaus Explorer electronic balance with an accuracy of 0.1 mg, a 50-ml glass cell thermostated with a Julabo F-32 thermostat (Germany), and a probing glass ball suspended by a thin metallic wire from an arm attached to the balance pan. The ratio of changes in the probe mass with respect to its initial value G_0 in two different liquids is proportional to the ratio of densities of these liquids.

$$\frac{\rho_{org}}{\rho_{aq}} = \frac{G_0 - G_{aq}}{G_0 - G_{org}}.$$

This method can be employed to determine the density of an organic phase that is in equilibrium with an aqueous phase at a given temperature, using pure water, whose density is known in a wide temperature interval, to calibrate the probe. In our study, the densities of organic phases were determined by this method with an accuracy of ± 0.0004 g cm^{-3}. The data obtained were compared with the densities of pure solvents [16] and with those calculated for the temperatures studied by Francis and Cibulka equation [17, 18]. We used in measurements a specially prepared double-distilled water. The density of water was taken for calibration from a reference book [19].

It was found that the densities of the organic phases under study differ only slightly from those of the corresponding pure solvents. The deviations are ± 0.0007 g cm^{-3}, on the average, which is close to the experimental error of the method used. As the experimental error in determining K_c is considerably larger than that in measuring the solvent density, the densities of pure solvents can be also used in calculations for hydrocarbon–water systems by formula (2). In our study, the experimentally determined density ratios of two phases were used in calculations.

Thus, we studied the temperature dependences of the limiting activity coefficients of phenol in hydrocarbons in 10 binary systems at four temperatures. For seven of these, data were obtained for the first time. The limiting activity coefficients are listed in the table.

The error of the indirect method used is largely determined by the reliability of data obtained for the standard system. If it is assumed that the accuracy of determining the limiting activity coefficients for the standard system is about 5% and that for the distribution coefficient in the liquid–liquid system, 3–5%, we have a value of 8–12% for the accuracy of γ_{org}^∞ determination by the distribution method. Presumably, the application field of this method is limited to systems in which the limiting activity coefficients are on the same order of magnitude and the distribution coefficients fall within the range $0.01 < K_c < 100$.

The only data available for the limiting activity coefficients of phenol in organic solutions have been obtained by differential ebullioscopy for systems containing *n*-hexane, benzene, cyclohexane, and tetrachloromethane [14]. However, the measurement error was large because of the low relative volatility of components, as also noted by the authors themselves. The limiting activity coefficients of phenol in cyclohexane are shown in Fig. 1 in comparison with those

determined by ebullioscopy in [14]. The discrepancy is 10–15% for this system and somewhat larger for other systems studied.

The dependence of the logarithm of the limiting activity coefficient of phenol in alkanes on the reciprocal temperature is shown in Fig. 2a, and that in aromatic hydrocarbons, in Figs. 2b and 2c.

It can be seen that the values for alkanes differ only slightly and become somewhat closer at higher temperatures. These systems exhibit a strong positive deviation from Raoult's law, especially pronounced at about 10°C (where the activity coefficient exceeds 100), which is responsible for the stratification of these solutions at medium concentrations. By contrast, deviations from ideality for phenol in arenes are smaller and the limiting activity coefficients do not exceed 20. Therefore, phenols exhibit, as a rule, a better solubility in aromatic hydrocarbons and are easily extracted with these compounds from aqueous solutions. Data for *m*- and *p*-xylenes virtually coincide within the experimental error.

The method for determining the limiting activity coefficients, considered in this study, can be used when direct methods are technologically difficult or fail to give satisfactory results. For systems with a low relative volatility of the constituent components, the present method is the optimal.

Using the limiting activity coefficients of phenol, we calculated by Eq. (3) the limiting coefficients of phenol distribution K_2^∞ for the liquid–vapor equilibrium at four temperatures (here and hereinafter, subscripts 1 and 2 refer to the solvent and solute, respectively).

$$K_2^\infty = \lim_{c_2 \to 0} \frac{c_2^{\text{liq}}}{c_2^{\text{vap}}} = \frac{RT\rho_1^{\text{org}}}{\gamma_2^\infty p_2^0 M_1^{\text{org}}}, \qquad (3)$$

where R is the universal gas constant, equal to 8.315 J K mol^{-1}; ρ_1^{org} and M_1^{org}, density (g cm^{-3}) and molecular weight (g mol^{-1}) of organic solvent, respectively; p_2^0, vapor pressure of pure phenol (MPa) at T (K); p_2^0 was calculated by Antoine's equation [20].

The values of K_2^∞, calculated by Eq. (3), are listed in the table. The solvation functions can be calculated from the temperature dependence of the distribution coefficient of a dissolved component between the liquid and vapor phases.

Solvation involves the whole set of energetic and structural changes in that occur in the system in the course of the vapor–liquid phase transformation to give a homogeneous solution of certain chemical composition and structure.

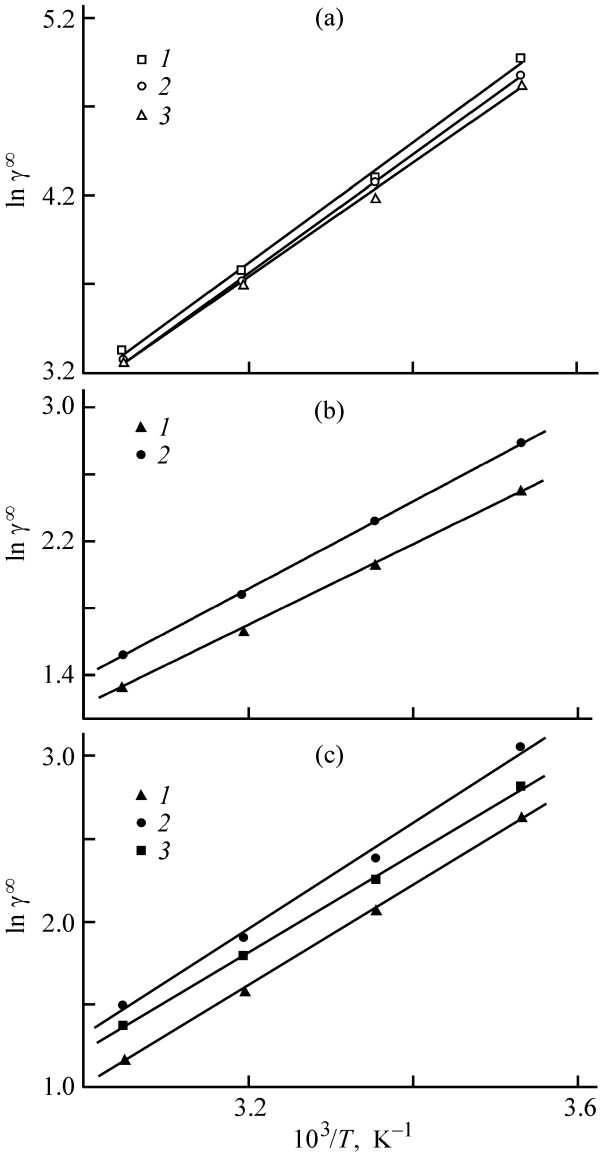

Fig. 2. Limiting activity coefficients of phenol, γ^∞, in (a) alkanes and (b, c) aromatic hydrocarbons. (a) (*1*) hexane, (*2*) heptane, and (*3*) octane; (b) (*1*) benzene and (*2*) toluene; (c) (*1*) benzene, (*2*) ethyl benzene, and (*3*) *para*- and *meta*-xylene.

The energetic changes that occur in solvation are largely determined by the enthalpy characteristics of solvation, and the structural changes, by its entropy characteristics. Both kinds of changes reflect the total changes in the Gibbs energy in the course of solvation and are determined by the chemical structure of a solution.

The quantity $\Delta G_{\text{sol}} = -RT\ln K_2^\infty$ is equal to the difference of the chemical potentials of phenol in solu-

tion and in the form of an ideal gas at equal bulk concentrations. This quantity is the contribution of intermolecular interactions to the chemical potential of phenol in a given solvent and a quantitative characteristic of the Gibbs energy of a dissolved substance in a given solvent.

As known from the literature, the free energy of solvation is frequently defined as $-RT\ln K_H$, where K_H is Henry's constant:

$$K_H = \lim \frac{p_2}{x_2^{liq}} = p_2^0\gamma_2^\infty = \frac{K_2^\infty M_1^{org}}{RT\rho_1^{org}}.$$

The enthalpy of solvation can be found from the temperature dependence of the distribution coefficient

$$\Delta H_{\text{solv}} = R\frac{\partial \ln K_2}{\partial(1/T)}.$$

The entropy of solvation was calculated by the relation:

$$\Delta S_{\text{solv}} = \frac{\Delta H_{\text{solv}} - \Delta G_{\text{solv}}}{T}.$$

The calculated thermodynamic characteristics of the solvation are listed in the table.

CONCLUSION

The limiting activity coefficients of phenol in cyclohexane, *n*-hexane, *n*-heptane, *n*-octane, benzene, toluene, ethyl benzene, and *ortho*-, *meta*- and *para*-xylene at 10, 25, 40, and 55°C were determined with an accuracy acceptable for an indirect method. The results obtained are in a satisfactory agreement with the scarce published data. The distribution coefficients of phenol between the liquid and vapor phases were calculated, and the solvation functions at infinite dilution were evaluated.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Rheological Equations for Concentrated Suspensions

E. E. Bibik

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received February 13, 2004

Abstract—The dependence of viscosity on stress in stable concentrated suspension is studied, the physical meaning of rheological constants in the rheological equation for these suspensions is revealed, and a method for experimental determination of these constants is described.

Concentrated suspensions (CS) are the most important element of the technology of manufacture of ceramic articles for various purposes, from large electric insulators and abrasive wheels to minute components of electronic devices. The quality and manufacturability of articles are largely determined by properties of suspensions from which these articles are formed. These are primarily the rheological properties, which characterize the ability of a suspension to be deformed, i.e., to acquire and retain the required shape of the article to be obtained. The rheological properties of a suspension, as also those of any other material, are described by rheological laws: dependence of the rate of deformation of a material, $\dot{\gamma}$, on the amount of stresses τ existing in the material. As a rule, these laws are not universal, being only applicable to materials (suspensions) with a certain prescribed structure.

It is known that the maximum concentration of a dispersed material can be only reached in well-stabilized suspensions [1]. In suspensions of this kind, the interaction between particles of the dispersed material is characterized by predominance of repulsion forces. Therefore, neighboring particles of the suspension lie at the maximum possible distance from one another. At identical sizes and regular shapes of particles, this leads to their fixation at sites of a regular crystal-like lattice. Such a structure has been named "periodic colloid structure" (PCS [2]) or quasi-crystalline structure. In the extent of spatial filling by the particles, such suspensions are similar to liquids and solids, and, therefore, the concepts of the activation mechanism of molecular motion [3] and deformation in these bodies were extended to these objects. The activation mechanism of flow was quantitatively expressed as Eyring's rheological law [4]

$$\dot{\gamma} = f_0 \sinh z, \quad (1)$$

where $\dot{\gamma}$ is the rate of shear deformation, and f_0 is a characteristic parameter having the meaning of the frequency of thermal oscillations of a particle at a lattice site.

Under the action of shear stresses τ, the amplitude of a certain part, $\sinh z$, of these oscillations reaches a value equal to the distance between neighboring stable positions of a particle, and, therefore, the particle jumps at a frequency $f = f_0 \sinh z$ in the direction of the force it experiences. The parameter $z = \tau/nkT$ is a dimensionless acting stress (stress related to the volume density nkT of the kinetic energy of particles); n, the concentration of particles; k, the Boltzmann constant; and T, temperature. At $z << 1$, $\sinh z = z$. Then, $\dot{\gamma} = f_0 \tau/nkT$ and, according to Newton's law of internal friction,

$$\tau = \eta\dot{\gamma}. \quad (2)$$

The viscosity of the suspension, $\eta = \tau/\dot{\gamma}$, is given by

$$\eta_0 = nkT/f_0. \quad (3)$$

The subscript "0" on the viscosity indicates that it characterizes the behavior of the liquid only at low stresses. For ordinary liquids, any stress of interest is low because of the high value of nkT. Therefore, the viscosity remains constant and equal to η_0 as the stress increases (i.e., the liquid is Newtonian).

1070-4272/05/7802-0212 © 2005 Pleiades Publishing, Inc.

The situation in suspensions is the opposite (even in those highly dispersed and concentrated, in which the number of particles in unit volume may be as large as 10^{18} m^{-3}). This means that, according to expression (1), the deformation rate will progressively grow with increasing stress, and the viscosity will accordingly decrease. Such a dependence of the deformation rate and viscosity on stress is qualitatively characterized as thixotropic.

The practical experience shows that a dilatant dependence of the shear rate on stress is more characteristic of stable concentrated suspensions. In this case, the increment in the shear rate lags behind that in the stress, and the more so, the higher the stress. At high stresses, the shear rate asymptotically approaches a constant value (limiting shear rate), and the viscosity, accordingly, tends to infinity.

The impossibility of shear deformation of a system of densely packed particles without an increase in the volume occupied by them has been regarded as the reason for the dilatant behavior. Such an explanation has become commonly accepted [5] and was fixed in the name of the phenomenon of "dilatancy," which consists in a disproportionately strong rise in resistance upon a minor increase in the deformation rate. It can be readily seen that the activation and dilatation models of deformation lead to fundamentally different laws of rheological behavior, even though these models refer to one and the same structural model of a material being deformed.

It was shown in [1] that the controversy between these two concepts is eliminated if the flow of these systems is adequately described quantitatively in terms of the Frenkel–Eyring activation mechanism. The changes that should be made in the classical theory are as follows.

(1) The shear rate is to be calculated by the formula

$$\dot{\gamma} = (c/n) fs/d \qquad (4)$$

instead of its classical variant $\dot{\gamma} = fs/d$. Here, c is the concentration of vacant sites in the CS lattice; s, the length of a single jump of a particle, equal to the distance s between CS lattice sites; d, the distance between a jumping particle and the nearest layer of immobile particles. It can be taken that d is also equal to the lattice constant s. Then the classical theory gives $\dot{\gamma} = f$, and its modernized variant,

$$\dot{\gamma} = (c/n) f, \qquad (5)$$

where $f = f_0 \sinh z$.

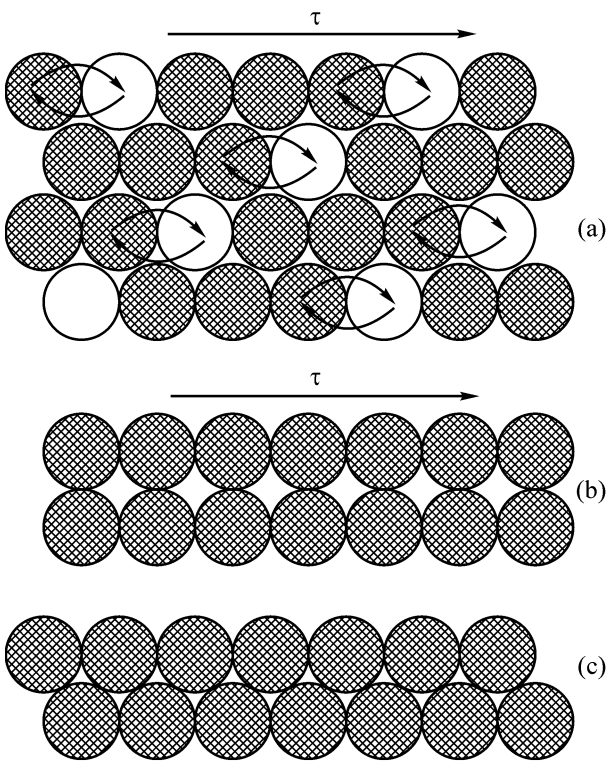

Fig. 1. Schematic of particle motion under the action of shear stress. (a) In the case of the activation mechanism, a group of three particles moves to a distance equal to a single lattice constant after all of them, by turns, move to this distance. In the case of a dilatation mechanism, stress cause a shift of all particles of a layer with respect to the neighboring one and leads to a change of particle packing from (c) denser to (b) looser one.

The physical substantiation of this modernization consists in that, to find the shear rate, i.e., the ratio between the motion velocity of a layer of particles and the distance from the mobile to immobile layer (or, more precisely, to the layer taken to be immobile), it is necessary, at least, to calculate this velocity. At the same time, the classical variant of the theory actually uses, instead of the layer motion velocity, the velocity of a local motion of a particle to a neighboring site. Apparently, for the whole layer of particles to be displaced to a distance s, equal to the lattice constant, all particles of this layer are to jump to the same distance in the necessary direction. This will require a time longer by a factor equal to the number of particles in a layer. In a defect-free lattice, the number of particles in a layer (or, more precisely, in a group of particles extended along the direction of motion) can be considered infinite, or, even if finite, then dependent on the geometry of the deforming device.

The situation changes if account is taken of the known fact, the imperfectness of real lattices, and its quantitative characteristic, concentration c of vacant lattice sites, is introduced. In this case, the length of the group of particles, which can move under the action of the deforming force, is determined by the number of particles along the line of their motion from one vacancy to another (Fig. 1a). The number of particles in such a group is n/c, and just this number appears in the correct formula for calculating the shear rate. In a defect-free lattice ($c = 0$), flow by the activation mechanism becomes impossible, but the deformation can be formed by the dilatation mechanism (Figs. 1b, 1c). The difference between these two cases is fundamental. In the first case, application of a stress results in that particles move by turns and, accordingly, the activation energy of flow is equal to the energy of displacement of a single particle, with the increase in the volume of the system being virtually zero. In the second case, only a simultaneous displacement of all the particles of a layer is possible, associated with a shear deformation of the lattice (change in the particle arrangement from the scheme in Fig. 1c to that in Fig. 1b), i.e., with a change of its crystallographic type and increase in its volume and energy. In this case, the activation energy of flow is orders of magnitude higher than that for the activation mechanism, and the resistance to deformation strongly depends on the opportunity to increase in volume, furnished by the experimental conditions. This means that, in the case of a purely dilatation mechanism of deformation, the rheological constants of suspensions depend on the geometrical conditions of the experiment, rather than being an invariant characteristic of a suspension.

(2) A defective structure can be regarded as a kind of an inhomogeneous mixture of two components: particles of the dispersed phase and voids. Deformation affects this mixture in the same way is it does for any inhomogeneous system: makes it more homogeneous. It is for this purpose that various kinds of suspensions are agitated. The higher the deformation rate, the more uniform the distribution of the components of the system (in the given case, spatial regions unoccupied by particles) over its volume. This circumstance is quantitatively manifested in a decrease in the concentration of vacancies and, in accordance with formula (4), in a decrease in the deformation rate. It is noteworthy that, at a concentration of vacancies comparable with that of particles, transition to their uniform distribution would actually lead to disintegration of the coagulation structure and to a decrease in the activation energy of flow to zero. In what follows, it is assumed that the concentration of vacancies is sufficiently low and their spreading over the interstitial spaces in the lattice has no effect on the activation energy of flow.

The dependence of the concentration of vacancies on the deformation rate can be obtained by introducing a formal parameter ϑ, relaxation time of vacancies, so that the rate of their generation will be $(c_0 - c)/\vartheta$, where c_0 is the initial concentration of vacancies. The parameter c_0 can be evaluated by the difference between the limiting theoretical concentration of particles, corresponding to a certain structural model, and the actual (prescribed) concentration of particles in the system. At the same time, vacancies disappear upon deformation. Each jump of a vacancy into a new position means that it disappears for a certain time, and, therefore, the disappearance rate of vacancies coincides with the number of their jumps, cf, in a unit volume of the dispersed system in unit time. In the steady state, the rates of generation and disappearance are equal, which gives

$$c = c_0/(1 + f\vartheta). \quad (6)$$

Combined with Eq. (5), this expression gives a new rheological law of shear deformation:

$$\dot{\gamma} = \left(\frac{c_0}{n}\right)\frac{f_0 \sinh z}{1 + \vartheta f_0 \sinh z}. \quad (7)$$

This expression contains two undetermined constants, f_0 and ϑ. They can be found using some model of particle motion over lattice sites [1]. However, more reliable in practical calculations are constants that can be determined experimentally. Therefore, it is desirable to transform the dependence (7) so that it would contain experimentally determinable rheological constants. One of these latter is the product ϑf_0, which is conveniently dimensionless and has a simple physical meaning: this is the ratio of the relaxation time of a vacancy to the period of particle oscillations in the lattice. In what follows, it is named the relaxation parameter and denoted by a symbol θ. For introducing the other rheological constant, it is convenient to represent expression (7) as a dependence of the viscosity on stress:

$$\eta = \left(\frac{n}{c_0 f_0}\right)\left[\frac{1}{\sinh z} + \theta\right]\tau. \quad (8)$$

If this expression is simplified for the case of low stresses, the combination $n^2kT/c_0 f_0$ of a number of quantities, to which the whole right-hand part of (8) is reduced, has the meaning of viscosity of a dispersed system at the minimum stress (initial viscosity η_0).

Hence follows the method of experimental determination of this constant. Further, it is denoted by the same symbol η_0 as the initial viscosity in the classical theory. However, it should be remembered that the latter is understated by a factor of n/c_0. With the new rheological constants introduced, dependence (8) takes the form

$$\eta = \eta_0\left[\frac{1}{\sinh z} + \theta\right]z. \qquad (8a)$$

Thus, to find out how the viscosity changes as the stress becomes higher, it suffices to analyze the expression

$$F = \left[\frac{1}{\sinh z} + \theta\right]z. \qquad (9)$$

which contains only a single unknown rheological constant θ. This expression gives the relative viscosity $F = \eta/\eta_0$ as a function of the dimensionless stress. The dependence is shown in Fig. 2 at different values of the relaxation parameter θ.

At $\theta = 0$, the dependence shows a steady decrease in viscosity as the stress increases, in conformity with the classical theory. At $\theta \geq 0.32$, the system exhibits a dilatant type of the dependence of viscosity on stress over the entire range of stresses and a more or less pronounced inflection at dimensionless stresses $z \leq 2$. At $0 < \theta < 0.32$, the dependence is of a mixed dilatant-thixotropic type. In a narrow range of low stresses ($z < 1$), the viscosity grows as the stress becomes higher. Then follows the range of medium stresses, in which the viscosity decreases. Finally, at sufficiently high stresses, it again starts to increase. Accordingly, the rheological viscosity–stress curves show a minimum and a maximum. The difference between their coordinates along both axes grows as the relaxation parameter θ decreases. Its value of 0.32 is critical: the maximum and minimum merge to give an inflection point, with the curve running horizontally in its vicinity. At $\theta > 0.32$, the inflection is preserved, but becomes less pronounced and the viscosity grows with increasing stress in the vicinity of the inflection.

The asymptotic dependence of F on z is described at large z by the equation

$$F = \theta z. \qquad (10)$$

Hence follows that the relaxation parameter θ is found experimentally as the slope of the asymptotic straight line, the ray running from the origin of coordinates and passing very close to the right-hand branch of the plot, but not intersecting it, even with account of its extrapolation to infinity.

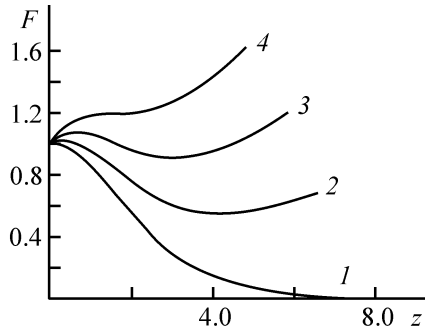

Fig. 2. Relative viscosity F vs. dimensionless stress z at different values of the relaxation parameter θ. θ: (*1*) 0, (*2*) 0.1, (*3*) 0.2, and (*4*) 0.32.

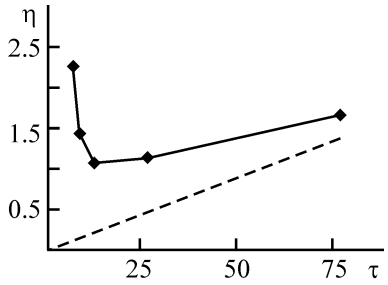

Fig. 3. Viscosity η of alundum suspended in a 0.5 wt % solution of starch vs. stress τ. Composition of suspension (wt %): Al_2O_3 60, liquid phase 30, components of binder the rest. *Dashed line*: asymptotic dependence at $\eta/\tau = 0.018$.

Because of the limited capabilities of instruments, experiments commonly cover only a certain relatively narrow range of stresses, so that it is only possible to observe a part of the full rheological curves in Fig. 2. Figure 3 shows as an example the results of measurements carried out with a suspension of alundum (Al_2O_3) on an RPM 1 rotation viscometer.

Noteworthy in the first place is the absence of the initial portion in the plot, which means that it is impossible to find the initial viscosity η_0 and then pass to its dimensionless value F. However, the asymptotics of the dependence of viscosity on stress remains the same:

$$\eta = (n/c_0)\vartheta\tau. \qquad (11)$$

This expression follows directly from Eq. (8) at $z >> 1$. The slope of the asymptotic straight line is 0.018 in the given case. The meaning of this value is clear from Eq. (11). The formulation of the suspension gives, to a certain extent conventionally, the ratio n/c_0. In the given case, this ratio was, probably, equal

to several dimensionless units, which gives a relaxation time of vacancies, ϑ, (time in which their number is restored by approximately 30% after total disappearance) of about 0.01 s.

Similar rheological properties were observed for other suspensions (based on silicon carbide and silicon carbide mixed with alundum) used to fabricate abrasive tools by slip casting.[1] The dispersed phase of these suspensions contained, in addition to Al_2O_3 and SiC, up to 10 wt % highly dispersed components intended for formation of a ceramic binder in calcination of half-finished articles.

A large body of dependences of this kind has been obtained by Pivinskii [6] on suspensions intended for fabrication of ceramic, refractory, and building articles. It is this abundance of experimental data that stimulated a study of the rheology of concentrated suspensions. It should be noted that the rheological law (7) itself was derived theoretically more than 20 years ago [1]. However, there was no representative experimental database at that time, which made impossible any conclusion about the typical nature of the thixotropic-dilatant flow or about the range and field of applicability of this law. It is clear now that curves with a minimum viscosity are typical of concentrated, aggregatively stable suspensions, which are widely used in technology. Moreover, the practical experience and prerequisites for derivation of this law suggest that the presence of a minimum is a criterion for a high quality of a suspension.

[1] Formulations developed with participation of E.A. Popova.

CONCLUSION

Experimental data for thixotropic-dilatant suspensions conform to the rheological pattern that is based on the activation mechanism of flow of a suspension with a crystal-like structure and takes into account the role of vacant sites in the lattice. The dependence of the viscosity of such suspensions on the shear stress is determined by two rheological constants: their initial viscosity and relaxation parameter. It is shown how these constants and the basic structural characteristic of the suspension, fraction of vacant sites in the lattice, can be found from experimental data.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Electrokinetic Potential of Particles in Suspensions and Donnan Equilibrium in a Thin Gel Film

E. E. Bibik

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received February 13, 2004

Abstract—The influence exerted by the thickness of a gel layer on the difference of the electric potentials of phases and on the distribution of the potential near the phase boundary are considered in terms of the classical theory of the Donnan equilibrium in a two-phase system constituted by a gel and an electrolyte solution. The results obtained make it possible to explain a number of experimental facts.

The electrokinetic potential of the surface is the only electrical characteristic of a dispersed system that can be directly determined experimentally, irrespective of the aggregative state, chemical nature of particles, and topological features (structure) of dispersed systems. This predetermines the exceedingly important role of this potential as a guiding line in choosing and adjusting the ionic composition of the dispersion medium for industrially used dispersed systems: slurries for fabrication of ceramic articles, clayey solutions for well drilling, suspensions for hydroclassification and flotation dressing of minerals, etc. Some methods for medical diagnostics are also based on phenomena directly related to the electrokinetic potential of cell membranes in a living organism. The information obtained by measuring the electrokinetic potential can be used correctly only if the mechanism of the influence exerted by various factors on the potential is known. Below, some aspects of this mechanism are considered.

The surface of real solids differs from its representation as a smooth surface, which is frequently used in describing theoretically properties of solids and phenomena occurring on the surface of solids. This also refers to electrochemical properties of the surface, among which of fundamental importance are the equilibrium surface potential, thickness of the electric double layer (EDL), its capacitance (or surface charge), and electrokinetic potential. A number of experimental results cannot be explained in terms of the double-layer theory for smooth surfaces. To these results belong the following: an increase in the electrokinetic potential, observed in some electrochemical systems when the concentration of an indifferent electrolyte is raised at low concentrations [1]; an exceedingly high adsorption capacity of the EDL [2]; manifestations of liophility in typical liophobic colloids [3]; etc. Various reasons for such anomalies have been named, including the presence of a thin gel film or a porous layer of the substance itself on the surface of a solid.

Theories of the electric double layer on an uneven surface (rough, porous, covered with a gel layer) have been developed [4, 5]. However, these theories have not been brought to a level that enables a comparison of theoretical and experimental results related to the anomalies mentioned above. Most frequently, this is due to the fact that the formulation of the problem is a complicated task. Meanwhile, many features of uneven surfaces can be revealed without using the EDL theory. This can be done in terms of the Donnan equilibrium, which determines the difference between the electric potentials and ionic compositions of two phases, one of which is inaccessible to charge carriers of a certain type. This may be a gel whose structural units (colloid particles, polyelectrolyte molecules) can only be present in the gel phase.

The Donnan theory is based, as it is commonly emphasized in its presentation [1], on the concept of ideal electrolyte solutions. Therefore, we further represent phases 1 and 2 in a two-phase system as follows: phase 1, as a gel, a swollen, weakly dissociated, ionogenic polymer of the CP type; and phase 2, as a dilute solution of an ordinary CA electrolyte. Here, C stands for the cation common to the electrolyte and the gel; A is anion, and P, polyanion (or a negatively

1070-4272/05/7802-0217 © 2005 Pleiades Publishing, Inc.

charged colloid particle). The dilution is meant to be a way to make the solution ideal.

As the basic parameters describing the state of the two-phase system, we chose the concentration P of ionogenic groups in the gel (in equivalents) and the concentration A_1 of co-ion A in the gel. In the initial state, immediately after the two phases are brought in contact, the concentration A_1 is zero, and the concentration A_2 in phase 2 is equal to the initial concentration c_0 of the CA electrolyte in this phase. The concentration of the polyion remains unchanged and not equal to zero only in phase 1.

After the two phase are brought in contact, co-ion A starts to diffuse from phase 2 (solution) into phase 1 (gel), where it was absent originally. This gives rise to a potential difference Ψ_f associated with the fact that ions of only one sign pass from one phase into the other. Naturally, this also leads to transfer of counterions C in the same direction and in the same amount, so that both phases remain electrically neutral

$$C_2 = A_2, \quad C_1 = P + A_1, \tag{1}$$

where C_1 and C_2 are the concentrations of the common ion C in the first and second phases, respectively.

To these equations should be added the material balance equation for the co-ion. At equal volumes of the phases

$$c_0 = A_1 + A_2. \tag{2}$$

In the state of equilibrium, the difference between the ion concentrations in the two phases is maintained by the difference Ψ_f between the electric potentials of the phases and by the corresponding term $z_i F \Psi_f$ for the chemical potential of the ions, where z_i is the valence of ions of ith type. It is convenient to reckon the electric potentials from the potential of phase 2, which is, consequently, taken to be zero. From the equality of the chemical potentials in the phases brought in contact (at $z_1 = 1$) follows that [1]:

$$\begin{aligned} \Psi_f F + RT\ln(C_1/C_2) &= 0 \text{ for cations,} \\ -\Psi_f F + RT\ln(A_1/A_2) &= 0 \text{ for anions.} \end{aligned} \tag{3}$$

Summing up these expressions, we obtain that $\ln(C_1A_1/C_2A_2) = 0$ or

$$C_1A_1 = C_2A_2. \tag{4}$$

which gives, after substituting (1) and (2) and making some rearrangements

$$A_1 = c_0^2/(2c_0 + P). \tag{5}$$

Then, the concentrations of other ions in both phases can be readily calculated. It should be noted that A_1 is far from being small. Roughly speaking, near half of the electrolyte passes from phase 2 into phase 1 (exactly the half at equal volumes of the phases and $P = 0$, which goes without saying). The same refers to the counterion.

The Donnan potential Ψ_f is related in the standard way to the concentrations of the common ions in phases 1 and 2 by expressions (3). Replacing in these expressions the concentrations of ions (at $z = 1$) with the concentration of the electrolyte in the solution phase and that of ionogenic units in the gel phase with the use of formulas (2) and (5), we obtain

$$\Psi_f = -(RT/F)\ln(1 + P/c_0),$$

where c_0 is the initial concentration of the electrolyte in the solution phase. In equilibrium and equal volumes of the phases, $c_0 = A_1 + A_2$, and then

$$\Psi_f = -(RT/F)\ln[1 + P/(A_1 + A_2)]. \tag{6}$$

At small P/c_0, the concentrations of anions, A_1 and A_2, in both phases are approximately the same. In turn, A_2 is equal to the equilibrium concentration c of the electrolyte in the solution phase, and, therefore, we have, approximately, $A_1 + A_2 = 2c$. Under the same conditions, $\ln[1 + P/2c] \approx P/2c$ and then

$$\Psi_f \sim -PRT/2cF. \tag{7}$$

If the ratio between the volumes V_1 and V_2 of the solution and gel phases, respectively, is arbitrary, the only changes in the system of equations (1)–(4) are those in the material balance equation (2):

$$c_0V_2 = A_1V_1 + A_2V_2 \tag{8}$$

and in the expressions for the concentrations of ions in the solution phase, $A_2 = c_0 - rA_1$ and $C_2 = c_0 - rA_1$, where $r = V_1/V_2$. Their substitution in the equilibrium equation (4) yields the following algebraic equation

$$A_1^2(1 - r^2) + (2rc_0 + P)A_1 - c_0^2 = 0. \tag{9}$$

At $r \neq 1$, this equation gives

$$\begin{aligned} A_1 = &-(2rc_0 + P)/2(1 - r^2) \\ &+ \{[(2rc_0 + P)/2(1 - r^2)]^2 + c_0^2/(1 - r^2)\}^{1/2}. \end{aligned} \tag{10}$$

If there is a gel-like phase in the form of thin films on the surface of particles of the dispersed phase present in the electrolyte solution, then, apparently, $r \to 0$. In this case, only a negligible fraction of the electrolyte passes into the film, so that its equilibrium concentration c in solution is virtually equal to the initial concentration c_0. Therefore,

$$A_1 = -P/2 + \{P^2/4 + c^2\}^{1/2}. \quad (11)$$

In this case, however, the relationship between the film thickness g and the thickness δ of the electric double layer in the film becomes rather important. Relation (11) makes sense only for thick films ($g >> \delta$). Anyway, it is expedient to determine the law by which the potential varies near the phase boundary between the gel and electrolyte solution. Finding this law requires that the Poisson–Boltzmann equation should be solved for the gel phase. In the gel, the positions of the ionogenic groups P are fixed at units of the chain of the cross-linked polymer and, therefore, remain unchanged when the potential varies:

$$(d^2\Psi/dx^2) = [PF + 2cF\sinh(F\Psi/RT)]/\varepsilon\varepsilon_0, \quad (12)$$

where c is the equilibrium concentration of the 1–1 electrolyte in solution.

The coordinate x is directed from the gel phase into the solution phase perpendicularly to the phase boundary; the zero x is at this boundary, i.e., $x < 0$ in the gel phase.

The expression in the square brackets is, apparently, the volume density of charge in the gel, taken with the opposite sign. It is zero in a thick gel layer, far away from the phase boundary, and the potential difference Ψ between two regions of the two phases, which are remote from the phase boundary, must be equal to the Donnan potential Ψ_f, which gives an alternative method for calculation of this potential:

$$\Psi_f = -(RT/F)\,\mathrm{Arcsinh}(P/2c), \quad (13)$$

which, naturally, coincides with the previously obtained result (7) at $P/2c < 1$.

A thin film of the gel ($g < \delta$), bounded by the solid phase, substrate (Fig. 1, shaded band), on one side and by the electrolyte solution on the other, is not electrically neutral. Under the conditions specified above, it has a distributed negative charge and acts as the inner part of the electric double layer with respect to the adjacent electrolyte solution. The charge of the film is neutralized by the opposite charge of the outer part of the EDL, the diffuse layer in the solution phase occupying in Fig. 1 the whole space at $x > 0$. From the equality to zero of the total charge of the film and the diffusion layer in solution follows, in accordance with Gauss law, that the field strength at the inner side of the film (on its boundary with the substrate) is zero, i.e., $d\Psi/dx = 0$ at $x = -g$. In this case, the potential has a certain, highest in magnitude, value Ψ_g (Fig. 1) and is equivalent to the interphase potential difference of the classical EDL. This potential is the main electrochemical characteristic of a two-phase system in the case when a gel film is present at the phase boundary. The potential at the outer side of the film (at $x = 0$) has a value Ψ_0. In accordance with the existing concepts of the nature of electrokinetic phenomena, Ψ_0 can be taken equal to the electrokinetic potential of the surface.

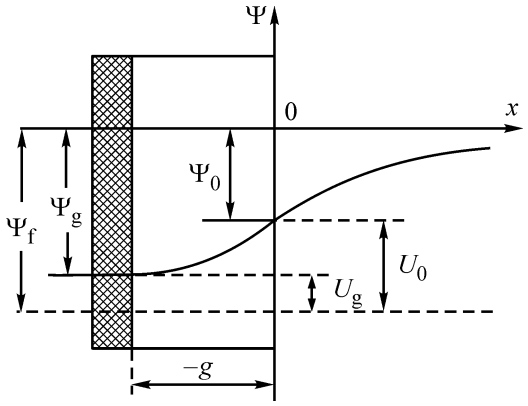

Fig. 1. Distribution of the potential Ψ at the interface between a gel film of thickness g with an electrolyte solution and characteristic potentials of this distribution.

At a low potential, $\sinh(F\Psi/RT) = F\Psi/RT$, which simplifies Eq. (12) and brings it to the form

$$(d^2\Psi/dx^2) = k^2(\Psi - \Psi_f). \quad (14)$$

Here, we take into account that $2cF^2/\varepsilon\varepsilon_0 RT = k^2$ and, according to expression (7), $PRT/2cF = -\Psi_f$. Integrating this equation, we obtain $(d\Psi/dx)^2 = k^2(\Psi - \Psi_f)^2 + C_1$. Using the above-mentioned conditions at the interface with the substrate ($d\Psi/dx = 0$ and $\Psi = \Psi_g$), we find the integration constant $C_1 = -k^2(\Psi_g - \Psi_f)^2$ and obtain a differential equation in the finished form:

$$(d\Psi/dx) = \pm k[(\Psi - \Psi_f)^2 - (\Psi_g - \Psi_f)^2]^{1/2}. \quad (15)$$

The outer boundary of the gel film is permeable, so that ions cannot be fixed there to create a surface charge, i.e., the dense part of the double layer, or cause other effects associated with the finite size of

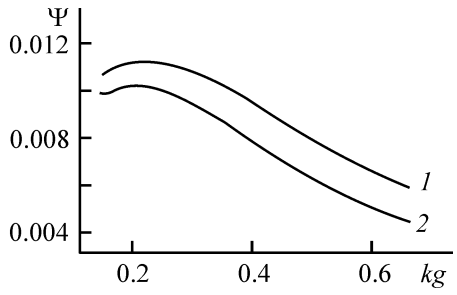

Fig. 2 Potentials Ψ_g and Ψ_0 of (*1*) inner and (*2*) outer sides of a gel layer of thickness $g = 2 \times 10^{-9}$ m at a concentration of ionogenic groups in the layer $P = 0.01$ kmol m^{-3} vs. the dimensionless layer thickness kg (at the electrolyte concentration increasing from 0.0005 to 0.01 kmol m^{-3}.

ions [6]. Therefore, the potential distribution in the solution phase is fully described by the classical Gouy–Chapman theory: $\Psi = \Psi_0 \exp(-kx)$. The potential distribution in the gel phase can be obtained by integrating Eq. (15) and making some rearrangements:

$$U + (U^2 - U_g^2)^{1/2} = H\exp(kx), \qquad (16)$$

where $U = \Psi - \Psi_f$, $U_g = \Psi_g - \Psi_f$, $U_0 = \Psi_0 - \Psi_f$ are potentials reckoned from the potential Ψ_f of the gel phase (Fig. 1); $H = U + (U_0^2 - U_g^2)^{1/2}$.

Equation (16) adequately describes how the potential Ψ depends on the distance x in the gel layer of arbitrary thickness g at any characteristic potential, which, however, should satisfy the condition $|\Psi_f| > |\Psi_g| > |\Psi_0|$, but do not give a unique solution to the problem. To obtain a unique solution, we have to find an additional equation that would relate these parameters. We can use as an equation of this kind the matching conditions for equations describing the potential distribution in both phases at the gel–solution interface. One of these conditions consists in that the potential Ψ_0 is a common value of the following functions at $x = 0$: dependence (16) of the potential on the distance x in the gel film and the dependence of the potential on distance in the solution phase. Another condition refers to the field strengths $-(d\Psi/dx)_0$ at the phase boundary on the gel and solution sides. As already noted, no concentrated charge can appear at the interface. In addition, the difference between the dielectric constants of the gel and solution phases can be neglected at a low concentration of the polymer. In this case, the derivative $(d\Psi/dx)_0$ will have the same value on the gel and solution sides. At a low potential Ψ_0 on the solution side, $(d\Psi/dx)_0 = -k\Psi_0$; on the gel side, $(d\Psi/dx)_0 = \pm k[(\Psi_0 - \Psi_f)^2] - [(\Psi_g - \Psi_f)^2]^{1/2}$ in accordance with Eq. (15). Hence, we find

$$\Psi_0 = \Psi_g[1 - (\Psi_g/\Psi_f)/2]. \qquad (17)$$

We can derive one more equation relating these same potentials from Eq. (16), provided that $U = U_g$ at $x = -g$ (g is the gel layer thickness):

$$U_0 = U_g\cosh(kg). \qquad (18)$$

Having solved the system of equations (17) and (18), we obtain

$$\Psi_g = \Psi_f\{[\cosh^2(kg) - 1]^{1/2} - \cosh(kg) + 1\}. \qquad (19)$$

According to Eq. (19), the potential difference Ψ_g between two extended phases, substrate and solution, separated by a thin gel layer, increases as the relative thickness kg of this layer grows, and approaches asymptotically the potential difference Ψ_g between the bulk phases of the gel and solution. The interphase potential difference Ψ_g can also increase with the electrolyte concentration in the solution phase (Fig. 2, upper plot). At a constant potential Ψ_g of the substrate surface, the potential Ψ_0 at the gel–solution interface will exponentially decrease with increasing concentration of the electrolyte, in accordance with Eq. (18). However, owing to a simultaneous increase in the potential Ψ_g of the substrate surface, the potential Ψ_0 of the outer side of the gel layer may vary nonmonotonically, first increasing and then decreasing as the concentration of the indifferent electrolyte increases (Fig. 2, lower plot), which is indeed occasionally observed experimentally.

It should be kept in mind that the presence of a gel layer at the interface between two phases may be not the only reason for the appearance of a potential difference between these phases. In this case, the dependence of the electrokinetic potential, whose role is played in such a situation by Ψ_0, on the electrolyte concentration will be a combination of the dependence presented above and the classical monotonic dependence. The occurrence of a maximum will then become even less clearly pronounced [1].

The energy of electrostatic repulsion between charged surfaces or colloid particles is determined by the distance between the localization planes of the surface charge [1]. Apparently, if this charge is actually spread within the gel layer, its effective plane of localization will lie in the gel layer at a distance comparable with the thickness of this layer from the surface of the solid phase. If the density of the gel is considerably lower than that of the solid phase on whose surface it is situated, then the energy of molecular

attraction between particles of the solid phase will be determined by the distance h between the solid–gel interfaces, which exceeds by $2g$ the distance between the charge localization planes. This circumstance may fundamentally change the relationship between the repulsion and attraction forces acting between dispersed particles in such a way that irreversible coagulation of dispersed systems at higher electrolyte concentrations will become impossible [7]. Such a behavior is characteristic of liophilic systems [8]. Thus, the liophilicity can be explained in terms of the same concepts as those underlying the theory of stability of liophobic colloids, if these concepts are supplemented with a point that is apparent by itself and is not necessarily associated with the presence of a gel layer. It consists in that the localization plane of the surface charge responsible for repulsion between particles does not necessarily coincide with the phase boundary determining the attraction forces between particles. The presence of a gel layer is a possible reason for noncoincidence of the charge localization planes and the phase boundary and, consequently, for the appearance of liophilic properties.

Apparently, the presence of a gel layer on the surface of the adsorbent or a microporosity of this surface, disregarded in determining the specific surface area of the adsorbent, make the actual exchange capacity of the adsorbent higher than its calculated value, and this may be the reason for the apparent superequivalent exchange of ions [2].

CONCLUSION

The electric potential of the outer boundary of a thin gel layer grows as the concentration of an indifferent electrolyte in solution becomes higher. This leads to an increase in the electrokinetic potential of the surface covered with a thin gel layer at low electrolyte concentrations and to appearance of liophilic properties in typical liophobic colloids at higher electrolyte concentrations. The latter can be predicted on the basis of the classical theory of stability of these colloids.

SORPTION AND ION-EXCHANGE PROCESSES

Sol–Gel Technique for Production of Spherically Granulated Zirconium(IV) Phosphate

L. M. Sharygin, M. L. Kalyagina, and S. I. Borovkov

Termoksid Research-and-Production Company, Zarechnyi, Sverdlovsk oblast, Russia

Received May 12, 2004

Abstract—A sol–gel technique for production of spherically granulated zirconium(IV) phosphate of Termoksid-3A brand is described. The method includes the following main stages: electrolysis of a zirconium(IV) chloride solution to give a sol of zirconium(IV) hydroxide, drop dispersion of the sol into an ammonia solution, conversion of gel-spheres of zirconium(IV) hydroxide into zirconium(IV) phosphate, and washing and drying of gel-spheres. The physicochemical and ion-exchange properties of the product obtained were studied.

The physicochemical properties of zirconium(IV) phosphate, a promising inorganic adsorbent, cation-exchanger, and catalyst, obtained by the conventional precipitation method have been studied in sufficient detail [1–7]. The properties of the product strongly depend on the composition characterized by the atomic ratio $\overline{P}/\overline{Zr}$, conditions of gel preparation and dehydration, and degree of crystallinity. For the stoichiometric zirconium(IV) phosphate, $\overline{P}/\overline{Zr} = 2$ and the formula $Zr(HPO_4)_2 \cdot xH_2O$ is ascribed to this compound. Crystalline α-phosphate of zirconium α-$Zr(HPO_4)_2$[1] has exactly the above stoichiometric composition and a layered structure [2, 8]. The layers in α-$Zr(HPO_4)_2$ are composed of zirconium(IV) ions lying nearly in the same plane and bound via phosphate groups situated above and below the plane of zirconium atoms. The layers are packed into blocks in such a way that they constitute a structure in the form of a monoclinic lattice with lattice constants $a = 0.9097$, $b = 0.5307$, and $c = 1.6284$ nm; $\beta = 111.38°$. Most of zirconium phosphate gels have an amorphous or semicrystalline structure composed of fragments of crystalline α-$Zr(HPO_4)_2$.

A sol–gel method has been suggested for obtaining zirconium(IV) phosphate in the form of spherical grains with high mechanical strength [9–13]. This method consists of the following main stages: synthesis of a sol of zirconium(IV) hydroxide by electrolysis of a $ZrCl_4$ solution, drop dispersion of the sol into an ammonia solution to give gel-spheres of $Zr(OH)_4$, conversion of gel-spheres of $Zr(OH)_4$ into zirconium(IV) phosphate, and washing and drying of gel-spheres of zirconium(IV) phosphate.

This communication describes the sol–gel technique for production of zirconium(IV) phosphate and reports on a study of its physicochemical properties.

The basic stage of the method under consideration and of the sol–gel processes suggested by other authors [14, 15] is that of conversion or the stage of treatment of $Zr(OH)_4$ gel-spheres with a H_3PO_4 solution, which leads to transformation of gel-spheres of zirconium(IV) hydroxide into gel-spheres of zirconium(IV) phosphate. Carrying out the sol–gel process became at all possible because gel-spheres do not disintegrate in the conversion stage. This is due to the layered structure of zirconium(IV) phosphate and hydroxide. In accordance with the model of [2], zirconium(IV) hydroxide layers are formed by tetrameric ions bound together by hydroxide groups lying above and below the layer plane. As a result, each zirconium(IV) ion is surrounded by eight hydroxy groups forming a distorted cube. The hydroxy groups lying above and below the layer of zirconium(IV) ions are replaced with hydrophosphate ions without any significant change in the positions of zirconium(IV) ions in the layer, with the result that the integrity of the gel-spheres is retained. The conversion process can be regarded as an acid–base reaction described by the equation

$$Zr(OH)_4 + 2H_3PO_4 = Zr(HPO_4)_2 + 4H_2O.$$

[1] $Zr(HPO_4)_2$ is zirconium(IV) hydroorthophosphate, α-$Zr(HPO_4)_2$ is named here and hereinafter α-phosphate of zirconium.

1070-4272/05/7802-0222 © 2005 Pleiades Publishing, Inc.

The chemical composition of the product is commonly characterized, with the crystallization water disregarded, by the $\bar{r} = \bar{P}/\bar{Zr}$ ratio, where $\bar{P}$ and $\bar{Zr}$ are the numbers of moles of phosphate ions and zirconium(IV) ions in the product. The value of $\bar{r}$ for the reaction product primarily depends on the ratio of the reactants, i.e., on the atomic ratio r = P/Zr in the starting mixture, where P and Zr are the numbers of moles of phosphoric acid in solution and zirconium(IV) hydroxide in gel-spheres, respectively. Figure 1 shows the chemical composition of zirconium(IV) phosphate as a function of the P/Zr ratio in the starting mixture. The study was carried out with gel-spheres of zirconium(IV) hydroxide, obtained using the procedure described in [16] and having the following characteristics: zirconium(IV) hydroxide concentration 1.2 M, pH value of the mother liquor 5.5, grain diameter 0.6–1.5 mm, moisture content of grains 62 wt %. To a certain volume of gel-spheres was added the same volume (s : l = 1 : 1) of a H_3PO_4 solution in the presence of 0.4 M of HCl, with r varied from 1.0 to 2.0. The mixture was kept at 80–85°C for 4 h with agitation. It can be seen from Fig. 1 that H_3PO_4 virtually completely enters into the reaction and the composition of the final product is determined by that of the starting mixture. Even at r = 2, more than 99% of phosphoric acid enters into the reaction. As phosphate ions are present in zirconium(IV) phosphate as hydrophosphate HPO_4^{2-} [2] at any $\bar{r}$, the conversion process for $r < 2$ can be described by the expression

$$Zr(OH)_4 + xH_3PO_4 = Zr(OH)_{4-2x}(HPO_4)_x + 2xH_2O.$$

Varying the HCl concentration within the range 0.1–0.5 M has no effect on the chemical composition of the final product.

Figure 2 shows kinetic curves for conversion of $Zr(OH)_4$ gel-spheres at s : l = 1 : 1, r = 1.8, and HCl concentration of 0.4 M, under agitation to lift outer-sphere restrictions. The degree of conversion is plotted along the ordinate axis. This parameter is defined by $F = (c_t/c_0) \times 100$, where c_t and c_0 are the H_3PO_4 concentrations in solution at an instant of time t and in the initial solution. The reaction of $Zr(OH)_4$ with H_3PO_4 is fast. The time of half-conversion at 25°C is less than 3 min. The high rate of the reaction would be expected because gel-spheres are highly dispersed macroporous bodies with a moisture content of 60–70 wt %. However, the extent of the process strongly depends on temperature. The degree of conversion in 2.5 h is 99.97% at 85°C and only 93% at 25°C. At 25°C, the value of F was 96% even after keeping for 24 h.

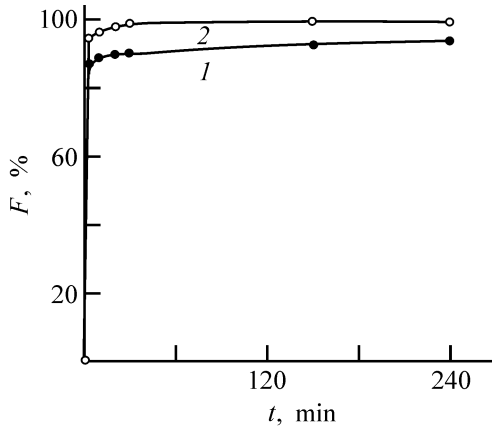

Fig. 2. Kinetic curves for conversion of gel-spheres of zirconium(IV) hydroxide at (*1*) 25 and (*2*) 85°C. (F) Degree of conversion and (t) time.

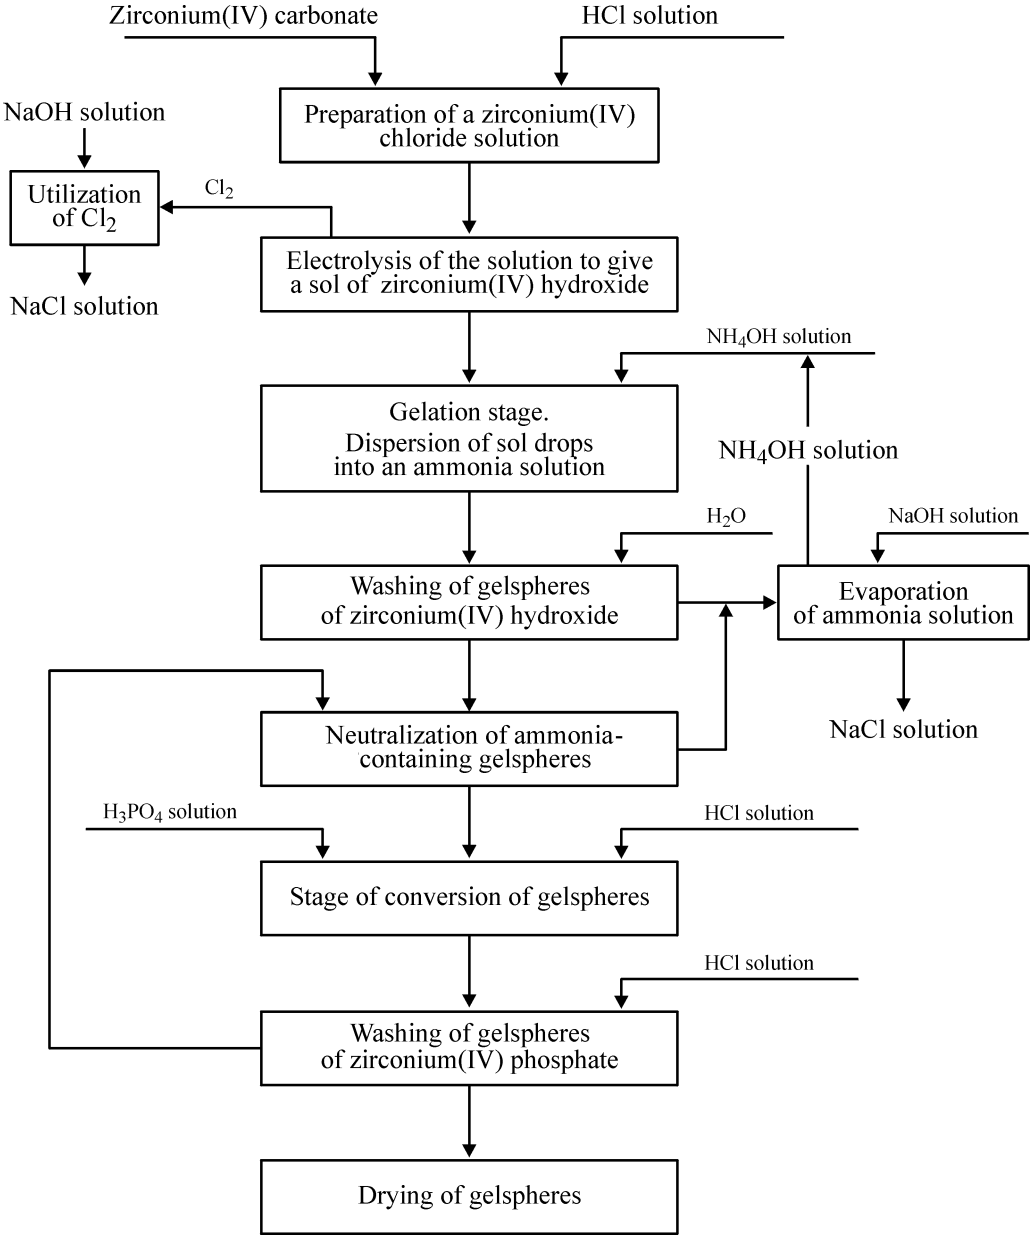
In [11], the influence exerted by the duration and temperature (25–90°C) of pretreatment of $Zr(OH)_4$ gel-spheres on their interaction with H_3PO_4. In aging, grains shrink and the reactivity of gel-spheres becomes lower, which is manifested in a decrease in the degree of hydroxide conversion into the phosphate, especially at low equilibrium concentrations of H_3PO_4. In aging of $Zr(OH)_4$, there occur ocolation chemical processes [2, 17] leading to conversion of diol bonds into oxo bonds with elimination of a water molecule by the reaction

$$\rangle Zr\langle^{OH}_{OH}Zr \langle \rightarrow \rangle Zr{-}O{-}Zr\langle + H_2O.$$

Being more stable, the oxo bond is less active in the interaction with H_3PO_4, and it is this fact that accounts for the lower reactivity of the aging product. Therefore, conversion of zirconium oxo hydroxide into zirconium phosphate can be represented as the reaction



$$ZrO_x(OH)_{4-2x} + (2 - x)H_3PO_4 = ZrO_x(HPO_4)_{2-x} + (4 - 2x)H_2O.$$

However, as the equilibrium concentration of H_3PO_4 becomes higher, the reaction products have $r \le 2$, irrespective of the aging conditions of gel-spheres [11]. In this case, the oxo bonds formed as a result of aging are involved in the interaction with H_3PO_4 and the overall reaction can be represented as

$$ZrO_x(OH)_{4-2x} + 2H_3PO_4 = Zr(HPO_4)_2 + 4H_2O.$$

A similar effect is caused by raising the treatment temperature (Fig. 2). As this temperature increases, oxo bonds enter into the reaction with H_3PO_4.

The gel-spheres of zirconium(IV) phosphate, obtained after the conversion stage, have a moisture content of 60–70 wt %, which is found by drying a sample to constant weight at 100°C, and a pore volume of 1.5–2.3 $cm^3\ g^{-1}$ per 1 g of solid mass. This means that these gel-spheres are liquefied highly dispersed porous bodies. To improve their mechanical strength and optimize other characteristics, gel-spheres are subjected to drying. In the process, the grains shrink considerably, their mechanical strength in-

Technological flow diagram for manufacture of spherically granulated zirconium(IV) phosphate.

creases, porosity decreases, bulk mass becomes higher, and other physicochemical properties of the sorbent change [9, 12]. A xerogel of zirconium(IV) phosphate, obtained by drying of gel-spheres at 100°C, is a nonporous product that is impermeable to molecules of nitrogen, benzene, and helium, which restricts its use as an adsorbent in this form. However, the material slowly swells in the presence of water or in an aqueous solution, its moisture content increases to 25 wt %, and its pores become accessible to ion sorption.

In [18], the evolution of the structure of gel-spheres of zirconium(IV) phosphate with the changing content of water in the course of drying was studied by means of structural neutron diffraction analysis and small-angle neutron scattering. The starting gel-spheres and products formed in initial stages of drying are constituted by fragments of two-dimensional (2*D*) layers of α-zirconium phosphate. As the content of water decreases in the course of drying, blocks are formed from α-$Zr(HPO_4)_2$ layers without changes in the positions of zirconium(IV) ions in the layers. The blocks are 1.6–2.1-nm-thick, i.e., contain 2 to 3 layers, and have a lateral size of 5.0 ± 0.1 nm and no clearly delimited boundaries. Thus, gel-spheres with varied moisture content are constituted by branched fragments (layers, blocks) of α-zirconium(IV) phosphate.

According to the flow diagram for production of spherically granulated zirconium(IV) phosphate, presented below, the starting raw material for manufacture of the product is $Zr(CO_3)_2$, which is decomposed in a HCL solution to give a zirconium(IV) chloride solution with a concentration of 1.3–1.5 M in terms of zirconium(IV) and a Cl/Zr ratio of 1.4–2.0. It is possible to use zirconium(IV) oxochloride as a starting raw material. A solution of zirconium(IV) chloride is subjected to electrolysis to obtain a sol of zirconium(IV) hydroxide [16]. In the course of electrolysis, the HCl concentration in solution decreases because of the decomposition of the acid at electrodes into gaseous Cl_2 and H_2, the extent of hydrolysis and polymerization of zirconium(IV) ions increases, and a sol of zirconium(IV) hydroxide is formed with the following parameters: concentration in terms of zirconium(IV) 1.3–1.5 M, Cl/Zr = 0.15–0.3, pH 1.8–2.2, and viscosity 8–30 cSt. Gaseous Cl_2 evolved in electrolysis is caught with a NaOH solution to give sodium hypochlorite, which gradually decomposes into NaCl. The resulting sol of zirconium(IV) hydroxide is delivered to the gelation stage.

The gelation is performed by drop dispersion of the sol into aqueous ammonia. Diffusion of $NH_3 \cdot H_2O$ into a sol drop leads to neutralization of free HCl and chloride ions bound to colloid particles and to gelation of sol drops to give gel-spheres of $Zr(OH)_4$ with a mechanical strength sufficient for further operations.

Gel-spheres are washed to remove the excess amount of ammonia. The washing solutions are fed into evaporators to remove ammonium, which is recycled into the gelation stage as a solution of $NH_3 \cdot H_2O$.

Ammonia-containing gel-spheres show an alkaline reaction. They are neutralized with a hydrochloric solution formed in the conversion stage. The solutions formed in the stage of neutralization of gel-spheres are delivered to evaporation of the ammonia solution.

The conversion stage is carried out by treating gel-spheres of zirconium(IV) hydroxide with a H_3PO_4 solution at a P/Zr ratio of 1.8–2.0, HCl concentration in solution in the range 0.3–0.5 M, and temperature of 80–90°C in the course of 2–4 h. Gel-spheres of zirconium(IV) phosphate are washed to remove the excess amount of the acid and the washing solutions are delivered into the stage of neutralization of ammonia-containing gel-spheres.

To improve the mechanical strength and form the necessary porosity, gel-spheres of zirconium(IV) phosphate are dried in air to residual moisture content of 20–36 wt % and used as spherically granulated zirconium(IV) phosphate in the H^+ form. The sorbent can be transferred into the salt form, e.g., of sodium type, by treating the product with a Na_2CO_3 solution.

A pilot production of the product was set-up by the Termoksid research-and-production company. The spherically granulated zirconium(IV) phosphate manufactured by the so-gel method has a brand name Termoksid-3A. The main physicochemical parameters of the sorbent are listed below:

Chemical composition	
$Zr(OH)_{4-2x}(HPO_4)_x$	$x = 1.8$
	$x = 2.0$
Moisture content determined	30–36 wt %
by drying at 100°C	18–20 wt %
Grain shape	Spherical
Grain size	0.4–1.0 mm
Bulk mass	1.04–1.1 kg l^{-1}
Mechanical strength	150–300 kg cm^{-2}

The products are chemically, morphologically, and crystal-chemically homogeneous. The chemical homogeneity with respect to zirconium and phosphorus, evaluated as a scatter of the content of a macrocomponent relative to the average value, which is determined with an electron probe 2–3 μm in diameter,

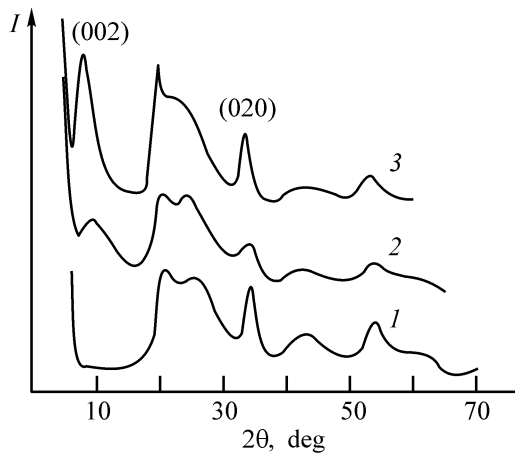


Fig. 3. X-ray diffraction patterns of Termoksid-3A samples. (*I*) Intensity and (2θ) Bragg angle. $\bar{r}$: (*1*, *2*) 1.8 and (*3*) 2.0. Moisture content (wt %): (*1*, *3*) 36 and (*2*) 20.

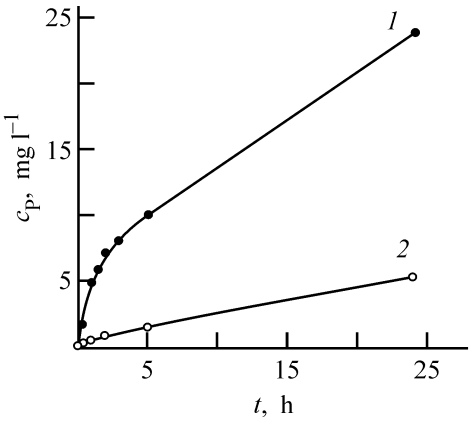

Fig. 4. Kinetic curves for hydrolysis of Termoksid-3A samples in the Na^+ form. (c_P) Concentration of phosphate ions in solution in terms of P and (*t*) time. Moisture content (wt %): (*1*) 36 and (*2*) 20.

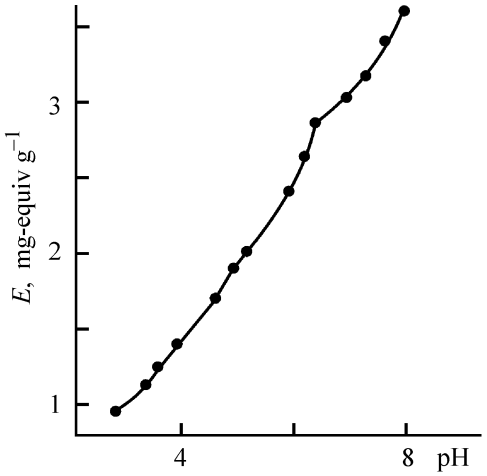

Fig. 5. Titration curve for a Termoksid-3A sample. Moisture content 36 wt %, $\bar{r}$ = 1.8. (*E*) Capacity.

does not exceed ±1.5 rel. % for a two-sided confidence probability of 0.99 [19]. Also, products with a varied degree of crystallinity are manufactured.

Figure 3 shows X-ray diffraction patterns of products in the H^+ form. Reflections genetically related to the corresponding Bragg reflections of crystalline α-$Zr(HPO_4)_2$ are indicated in the figure. In the X-ray diffraction pattern of Termoksid-3A sample no. 1, there is no reflection from the (002) plane. As the (002) reflection is related in crystalline α-zirconium phosphate to spacings between layers of zirconium(IV), the solid-phase skeleton of the ion-exchanger under consideration is constituted by fragments of 2*D* α-$Zr(HPO_4)_2$ layers about 6 nm in size. Therefore, this product has the lowest steric hindrance to cation exchange. The X-ray diffraction pattern of Termoksid-3A sample no. 2 contains a broad reflection from the (002) plane, which indicates that blocks composed of layers with an interplanar spacing of 1.05 nm are present in the system. Termoksid-3A sample no. 3 has a higher degree of crystallinity, its solid-phase structure is constituted by α-$Zr(HPO_4)_2$ blocks with an interplanar spacing of 1.05 nm. The blocks have dimensions in the (002) plane of about 4.5 nm, i.e., they are constituted by four layers, on the average. The dimensions in the (020) plane are, as for the first two samples, about 6.0 nm.

In aqueous solutions, zirconium(IV) phosphate is subject to hydrolysis [2, 7, 20], accompanied by replacement of hydrophosphate groups by hydroxy groups, which can be represented, e.g., for the H^+ form, as

$$Zr(HPO_4)_2 + xH_2O = Zr(OH)_x(HPO_4)_{2-x/2} + (x/2)H_3PO_4.$$

The resistance to hydrolysis increases when the degree of crystallinity becomes higher, and the $\overline{P}/\overline{Zr}$ ratio in the ion exchanger, decreases. In an alkaline medium, hydrolysis is enhanced, which hinders use of the material at pH > 8. Figure 4 shows kinetic curves for hydrolysis of Termoksid-3A samples ($\overline{P}/\overline{Zr}$ = 1.8, Na^+ form, content of Na^+ 2.4 mg-equiv g^{-1}), measured under static conditions at s : l = 5 g : 100 cm^3 and pH 7.4–7.5, with solution agitation. In the course of time, the hydrolysis rate decreases. Therefore, it is better to compare the hydrolytic stabilities of the samples with the use of the average hydrolysis rate, determined during the first 24 h of keeping, by the expression

$$\vartheta = \frac{c_P V}{m\tau},$$

where c_P is the concentration of phosphate ions in solution in terms of phosphorus; V, solution volume; m, sorbent mass; and τ, time of keeping, equal to 24 h.

The average hydrolysis rate for Termoksid-3A sample no. 1 during the first 24 h of keeping was 2×10^{-2} mg g^{-1} h^{-1}. For the Na^+ form of Termoksid-3A sample no. 3 ($\overline{P}/\overline{Zr}$ = 2.0), the hydrolysis rate has a close value. A higher hydrolytic stability is observed for Termoksid-3A sample no. 2, for which the hydrolysis rate is 5.8×10^{-3} mg g^{-1} h^{-1}. Thus, the hydrolysis rate depends on how a sorbent is prepared and treated.

Figure 5 shows as an example a typical titration curve for a Termoksid-3A sample ($\overline{P}/\overline{Zr}$ = 1.8, moisture content 36 wt %), measured with respect to the Na^+ cation under static conditions at an ionic strength of the solution of 0.1 M. The sorbent is a weakly acidic ion exchanger whose capacity strongly depends on the pH value of the solution. The titration curve has a shape typical of zirconium(IV) phosphate having and amorphous or semicrystalline structure [1–3, 6]. Some ion-exchange properties of Termoksid-3A were studied in [21–23]. The ion exchanger has perfect kinetic characteristics [24] and an increased selectivity toward cesium radionuclides, which made it possible to use this sorbent industrially to purify water from spent fuel storage reservoirs of the first and second reactor units of Beloyarskaya nuclear power station [25]. The use of the sorbent enabled elimination of a potentially dangerous radiochemical contamination. The ion-exchange properties of zirconium(IV) phosphate synthesized by the precipitation technique have been studied extensively and the main results obtained are summarized in reviews [1–3, 7]. The fundamental aspects of the ions exchange, revealed in these studies, can be extended to Termoksid-3A with account of its structure and the preparation method.

CONCLUSIONS

(1) The statics and kinetics of the interaction between gel-spheres of zirconium hydroxide and phosphoric acid were studied.

(2) A sol–gel method for synthesis of spherical zirconium phosphate was described.

(3) Physicochemical characteristics, phase composition, titration curve, and hydrolytic stability of zirconium(IV) phosphate of Termoksid-3A brand were presented.

SORPTION AND ION-EXCHANGE PROCESSES

A Study of the Competitive Equilibrium in Ion Exchange of Calcium(II) on Zirconium Phosphate in Multicomponent Salt Solutions

S. I. Borovkov and L. M. Sharygin

Termoksid Research-and Production Company, Zarechnyi, Sverdlovsk oblast, Russia

Received July 14, 2004

Abstract—A sorption technology for stabilization of multicomponent salt solutions (wines) subject to calcium clouding is being developed on the basis of an inorganic cation-exchanger of Termoksid-3A brand. In this connection the ion-exchange equilibrium on a zirconium(IV) phosphate of Termoksid-3A brand in multicomponent solutions at pH 2.5–3.0 was studied. The selectivity series of the sorbent were determined in relation to the solution composition.

A topical goal of wine industry is to ensure a reliable stability of finished wines, which become cloudy in the course of time [1]. Wine is a complex solution of salts of potassium, calcium, magnesium, sodium, and other cations [2, 3]. The high mass concentration of calcium(II) in wine, exceeding the solubility of calcium salts (calcium tartrate, mucate, oxalate) leads to formation of calcium-containing dregs. Wine can be stabilized by removing the excess amount of calcium(II). Development of a technique for wine stabilization is an exceedingly complicated task because of the influence exerted by a wide variety of factors both on the wine formation and on processes associated with removal of excess calcium(II) from wine materials [1].

It was shown in [4] that the sorption method can be, in principle, used for removing excess amounts of calcium(II) from wines with an inorganic spherically granulated zirconium phosphate cation-exchanger of the Termoksid-3A brand, $Zr(HPO_4)_2 \cdot nH_2O$. It has been noted [5] that the process of ion removal from solutions with ion-exchangers is strongly affected by the pH value of the medium and by the nature and concentration of competing ions. Mg^{2+}, K^+, and Na^+ cations present in wines in macroscopic amounts can exert a competing influence on the sorption of Ca^{2+} cations by the Termoksid-3A cation exchanger. However, the fundamental aspects of the competing influence of the above-mentioned cations on the sorption of Ca^{2+} by inorganic cations of this kind have not been studied in sufficient detail.

The aim of this study was to examine the ion exchange of Ca^{2+} on the inorganic sorbent Termoksid-3A in multicomponent salt systems at pH 2.0–3.5.

Termoksid-3A is the trademark of the known inorganic zirconium phosphate cation exchanger synthesized by the sol-gel method [6] in the form of spherical grains with a good mechanical strength. The main physicochemical characteristics of Termoksid-3A are as follows:

Granulometric composition	0.4–1.0 mm
Bulk mass	1.1 ± 0.1 kg cm^{-3}
Moisture content	32 ± 2 wt %
Crushing strength	15 ± 10 MPa

Termoksid-3A has, in outward appearance, the form of glass-like spherical grains with a semicrystalline structure. The product is chemically, morphologically, and crystal-chemically homogeneous. Termoksid-3A has good kinetic characteristics, which compare well with those of medium-linked organic sulfocation exchangers [7]. The sorbent is chemically stable in wine materials and does not exert any adverse influence on the organoleptic characteristics of processed wines.

Sorption experiments were carried out under dynamic conditions by passing metal chloride solutions with a certain pH value through a sorption column with an inner diameter of 6 mm and sorbent bed height of 70 mm until the pH values and metal concentrations at the inlet and outlet of the column became equal. The necessary pH value of the solution was

maintained by introducing hydrochloric acid. The rate of solution filtration was 30 column volumes per hour. The total concentration of metal cations in solution was 0.1 g-equiv l^{-1}. The column with the sorbent was washed with desalted water and cations sorbed were eluted with a 3M HCl solution. The content of calcium and magnesium ions in the initial solutions and eluates was determined by complexonometry with NaEDTA, and that of sodium and potassium, by flame photometry.

First, the ion-exchange equilibrium in binary systems Ca^{2+}–Mg^{2+}, Ca^{2+}–Na^{+}, and Ca^{2+}–K^{+} in the pH range 2.0–3.5.

The selectivity of the Termoksid-3A sorbent toward the Ca^{2+} ion can be formally characterized by the concentration constant of ion exchange, which is described, in accordance with the mass action law for a binary system, by the expression [8]:

$$\tilde{\tilde{K}}_{M}^{Ca} = \frac{\bar{x}_{Ca}^{1/2} x_{M}^{1/z}}{x_{Ca}^{1/2} \bar{x}_{M}^{1/z}}, \quad (1)$$

where $\bar{x}_{Ca}$ and $\bar{x}_{M}$ are the equivalent fractions of Ca^{2+} and the competing ion in the sorbent; x_{Ca} and x_{M}, equivalent fractions of Ca^{2+} and the competing ion in solution; and z, charge of the competing ion.

The equivalent fraction of calcium in the sorbent was determined using the formula

$$\bar{x}_{Ca} = \frac{\bar{c}_{Ca}}{\bar{c}_{Ca} + \bar{c}_{M}}, \quad (2)$$

where $\bar{c}_{Ca}$ and $\bar{c}_{M}$ are the concentrations of Ca^{2+} and the competing ion in the sorbent.

As Termoksid-3A is virtually not subject to swelling in aqueous solutions, it is more convenient to express the concentration in the solid phase in equivalents per unit volume or mass. For convenience of practical use, the results obtained in determining the capacity in this study are reduced to unit bulk volume of the sorbent. For practical purposes, it is more convenient to use as a quantitative characteristic of selectivity in describing the interphase distribution of ions the separation factor calculated by the formula [8]:

$$\alpha_{M}^{Ca} = \frac{\bar{x}_{Ca} x_{M}}{\bar{x}_{M} x_{Ca}}. \quad (3)$$

Figures 1–3 show ion-exchange isotherms for the systems under study at different pH values of solutions in the coordinates of the equivalent fraction of

Ca^{2+} in the sorbent against the equivalent fraction of the same ion in solution. As can be seen from Figs. 1 and 2, the ion-exchange isotherms for the systems Ca^{2+}–Na^{+} and Ca^{2+}–Mg^{2+} lie above the diagonal, which indicates that the Termoksid-3A sorbent is selective toward the Ca^{2+} ion in the entire range of pH values and compositions of the solution. For the Ca^{2+}–Na^{2+} system, the selectivity of the sorbent toward the Ca^{2+} ion increases in the entire range of solution compositions (Fig. 1). For example, the separation factor α_{Na}^{Ca} grows at x_{Ca} = 0.5 from 5.3 at pH 2.5 to 9.0 at pH 3.5. For the system Ca^{2+}–Mg^{2+} (Fig. 2), changing the solution pH from 2.0 to 3.5 does not affect the selectivity of the sorbent toward Ca^{2+} ions.

For the system Ca^{2+}–K^{+} (Fig. 3), the ion-exchange isotherms strongly vary with the solution pH. For example, the ion-exchange isotherm at pH 2.0 lies below the diagonal (curve *1*), which indicates that the selectivity of the sorbent toward K^{+} exceeds that for Ca^{2+} at this acidity in the entire range of solution compositions. As the pH value of the solution increases, the selectivity of the sorbent toward the Ca^{2+} ion grows, so that, already at pH 2.5 (curve *2*), the sorbent preferably absorbs Ca^{2+}, except at solution compositions with $x_{Ca} > 0.85$.

In the general case, the selectivity of cation exchangers depends on the charge, size, hydration, and hydrolysis of cations, as well as on polarization, specific interaction, sieve effect, and some other factors [5, 8, 9]. If the selectivity is regarded as a competition of the co-ions of a solution, fixed groups of the ion-exchanger, and water molecules for solvation of an ion being exchanged [9], then the inversion of selectivity on changing the pH value can be attributed to an enhancement of the solvating ability of phosphate groups of the sorbent toward the Ca^{2+} ion as a result of an increase in the degree of their dissociation upon a decrease in the concentration of H^{+} ions. The ion-exchange isotherms at pH 2.5, 3.0, and 3.5 (Fig. 3, curves *2*–*4*) are S-shaped.

At $x_{Ca} > 0.85$, i.e., at high degrees of filling of the sorbent capacity with Ca^{2+} ions, a selectivity inversion is observed. Ion-exchange isotherms of this kind are characteristic of inorganic ion exchangers with a rigid skeleton (zeolites, clayey materials, zirconium phosphate) in exchange of ions strongly differing in size, e.g., in ion exchange in the systems Cs^{+}–H^{+} and Rb^{+}–H^{+} on zirconium phosphate [10, 11]. On the whole, the selectivity of the sorbent toward the Ca^{2+} for the system Ca^{2+}–K becomes higher as the pH value increases, with the exception of solution compositions with $x_{Ca} > 0.85$. The separation factor α_{K}^{Ca} at x_{Ca} = 0.5 grows from 0.7 at pH 2.0 to 2.0 at pH 3.5.

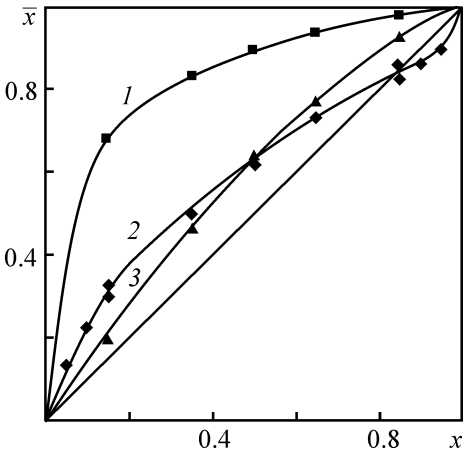

Fig. 4. Ion-exchange isotherms for the systems (*1*) Ca^{2+}–Na^{+}, (*2*) Ca^{2+}–K^{+}, and (*3*) Ca^{2+}–Mg^{2+} at pH 3.0.

Figure 4 shows ion-exchange isotherms for the systems Ca^{2+}–Na^{+}, Ca^{2+}–Mg^{2+}, and Ca^{2+}–K^{+} at constant pH value of the solution, equal to 3.0. Commonly, the equivalent fraction of Ca^{2+} relative to other cations in the solutions studied does not exceed 0.2. The separation factors calculated using the data of Fig. 4 for x_{Ca} = 0.2 have the following values: α_{Na}^{Ca} = 8.6, α_{Mg}^{Ca} = 1.4, and α_{K}^{Ca} = 2.4.

The results obtained indicate that Termoksid-3A has a higher selectivity toward Ca^{2+} ions, compared with other ions (Mg^{2+}, Na^{+}, and K^{+}). The order in which the selectivity of the sorbent toward the cations under consideration increases, which is determined by the order in which the separation factor grows, depends on the solution composition. For solutions with x_{Ca} in the range from 0 to 0.50, the selectivity series has the form $Ca^{2+} > Mg^{2+} > K^{+} > Na^{+}$.

Such an order of selectivity variation does not contradict the concept of electroselectivity [5] and corresponds to the selectivity series for amorphous zirconium phosphate toward ions of alkali and alkaline-earth elements [12].

At x_{Ca} of 0.50 to 0.85, the selectivity series changes to $Ca^{2+} > K^{+} > Mg^{2+} > Na^{+}$. Finally, the selectivity series for x_{Ca} ranging from 0.85 to 1.0 is as follows: $K^{+} > Ca^{2+} > Mg^{2+} > Na^{+}$.

The fact that the selectivity series varies with the solution composition is due to an increase in the selectivity of the sorbent toward K^{+} ions. As already noted, the ion-exchange isotherm for the system

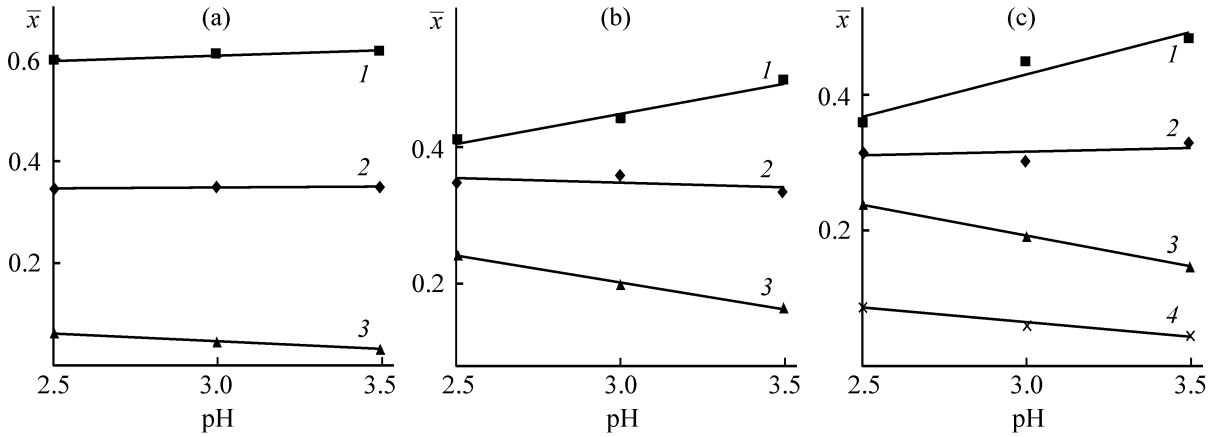

Fig. 5. Equivalent fraction of the metal ion in the sorbent, $\bar{x}$, vs. the solution pH for the systems (a) Ca^{2+}–Mg^{2+}–Na^+, (b) Ca^{2+}–Mg^{2+}–K^+, and (c) Ca^{2+}–Mg^{2+}–K^+–Na^+. (a) (*1*) Ca^{2+}, (*2*) Mg^{2+}, and (*3*) Na^+; (b) (*1*) Ca^{2+}, (*2*) Mg^{2+}, and (*3*) K^+; (c) (*1*) Ca^{2+}, (*2*) Mg^{2+}, (*3*) K^+, and (*4*) Na^+.

Ca^{2+}–K^+ is S-shaped, which results in a selectivity inversion at $x_{Ca} > 0.85$.

As the solutions studied contain simultaneously all the cation metals under consideration, the ion-exchange equilibrium was examined in the systems Ca^{2+}–Mg^{2+}–Na^+, Ca^{2+}–Mg^{2+}–K^+, and Ca^{2+}–Mg^{2+}–Na^+–K^+, which contain equal equivalent fractions of ions in equilibrium solutions. The total concentration of metal ions was 0.1 g-equiv l^{-1}, the acidity of the solutions was adjusted by introducing hydrochloric acid. The results obtained are shown in Figs. 5a–5c and listed in Tables 1 and 2. It can be seen that, if the cations are simultaneously present in solution in equal equivalent concentrations, the sorbent capacity for each cation corresponds to the above selectivity series $Ca^{2+} > Mg^{2+} > K^+ > Na^+$.

For the system Ca^{2+}–Mg^{2+}–Na^+ (Fig. 5a), the equivalent fraction of Ca^{2+} in the sorbent increases, the equivalent fraction of Na^+ decreases, and that of Mg^{2+} remains unchanged as the solution pH grows in the range 2.5–3.5. A similar behavior is observed for the system Ca^{2+}–Mg^{2+}–K^+ (Fig. 5b): an increase

Table 1. Ion-exchange equilibrium on a Termoksid-3A sorbent in three-component systems

pH	Exchange capacity of the sorbent, mequiv cm^{-3}, for indicated system							
	Ca^{2+}–Mg^{2+}–Na^+				Ca^{2+}–Mg^{2+}–K^+			
	Ca^{2+}	Mg^{2+}	Na^+	total	Ca^{2+}	Mg^{2+}	K^+	total
2.5	0.487	0.276	0.049	0.812	0.338	0.287	0.199	0.824
3.0	0.688	0.397	0.050	1.135	0.505	0.408	0.224	1.137
3.5	0.950	0.540	0.054	1.544	0.800	0.540	0.263	1.603

Table 2. Ion-exchange equilibrium on a Termoksid-3A sorbent in the system Ca^{2+}–Mg^{2+}–K^+–Na^+

pH	Exchange capacity of the sorbent, mequiv cm^{-3}				
	Ca^{2+}	Mg^{2+}	Na^+	K^+	total
2.5	0.288	0.255	0.192	0.070	0.805
3.0	0.508	0.342	0.218	0.070	1.138
3.5	0.750	0.510	0.231	0.070	1.561

in the equivalent fraction of Ca^{2+} and a decrease in that of K^+ in the sorbent are more clearly pronounced.

For the four-component system Ca^{2+}–Mg^{2+}–K^+–Na^+ (Fig. 5c), the equivalent fraction of Ca^{2+} in the sorbent increases, the equivalent fractions of K^+ and Na^+ decrease, and that of Mg^{2+} remains virtually unchanged as the solution pH grows.

The pattern revealed is associated with a rise in the sorbent selectivity toward Ca^{2+} as the solution pH increases. Comparison of Figs. 5a and 5b shows that replacing the Na^+ ion in a three-component solution with an equivalent amount of the K^+ ion, which has a higher selectivity toward the sorbent, leads to a noticeable decrease in the equivalent fraction of Ca^{2+} in the sorbent. It follows from Tables 1 and 2 that the total capacity of the sorbent for all the cations is virtually independent of the solution composition at a constant pH value of the solution. As the pH value increases, the total capacity of the sorbent grows, which is characteristic of zirconium phosphate, a bifunctional cation exchanger of medium strength [13, 14].

Thus, zirconium phosphate of the Termoksid-3A brand shows in ion exchange in the system Ca^{2+}–Mg^{2+}–K^+–Na^+ at pH 2.5–3.5 and low and medium filling of the sorption capacity with calcium the following selectivity series: $Ca^{2+} > Mg^{2+} > K^+ > Na^+$.

CONCLUSION

Termoksid-3A sorbent enables an effective decalcination in the column mode of solutions imitating the average macroscopic composition of wines in the content of mineral impurities at pH 3.0–3.2. The total capacity of the sorbent for all the cations at a constant pH value of a solution is virtually independent of its composition, being equal to 1.45 mequiv cm^{-3} at pH 3.2. The capacity of the sorbent for the Ca^+ ion strongly depends on the concentration of K^+ and Mg^{2+} ions, whereas that of Na^+ exerts a weak competitive influence.

SORPTION AND ION-EXCHANGE PROCESSES

Influence of Surfactants on Structuring of Molding Blends Based on ZnO

V. Yu. Prokof'ev, A. P. Il'in, and T. V. Basova

Ivanovo State Chemical-Engineering University, Ivanovo, Russia

Received October 22, 2004

Abstract—The correlation between the surfactant sorption and structural mechanical properties of molding blends and granulated sorbents was studied.

ZnO is widely used a a chemisorbent foo removing impurities and, in particular, sulfur compounds [1], from process gases. Zinc oxide almost irreversibly sorbs hydrogen sulfide to form solid zinc sulfide, which allows almost complete removal of H_2S from the gas being treated. At the same time [1, 2], granulated sorbent should have not only a strongly developed microporous structure but also large pores for penetration of reagents deep into a granule.

Uzugi and Tamia found [3] that the sorption of hydrogen sulfide on zinc oxide depends not only on its specific surface area but also, to a great extent, on the pore size distribution. Zinc oxide having, along with micropores, coarse pores with radius larger than 100 nm exhibits the highest sorption activity. As follows from the stoichiometry of the reaction of ZnO with H_2S, the highest sorption capacity of zinc oxide for hydrogen sulfide is 39 wt%. The actual sorption capacity is lower than 20 wt%. Hence, the H_2S sorption strongly depends on its diffusion into the sorbent matrix. Under the industrial conditions, only the external surface of zinc oxide granules is converted into the sulfide, and the internal surface does not work.

It is known that pelletized granules have a nanoporous structure, whereas extruded granules contain broad transport pores, along with narrow pores. Preparation of extruded sorbents based on ZnO was examined in our previous study [4].

Surfactants are widely used to improve the moldability of blends (including those based on ZnO) to be extruded.

EXPERIMENTAL

We used ZnO powder with an almost 100% content of the main compound. The molding blends were prepared by addition of polyvinyl alcohol (PVA) or carboxymethyl cellulose (CMC) solutions of different concentrations to a ZnO powder. The mixture was stirred to obtain a homogeneous suspension.

The optimal water content in the blend, φ_{opt}, was determined on a conical Rebinder plastometer by the procedure described in [5]. The structural-mechanical constants (ultimate shear stress P_{k1} and maximum plastic viscosity η_1) and parameters (plasticity Ps and relaxation time Θ) were calculated using the Maxwell–Shvedov and Kelvin model. For this purpose, we used the time–strain curves measured on a D.M. Tolstoi's plastometer [6]. The complete rheological curves were measured on a Rheotest-2 rotary viscometer in the range of shear rates 2–4960 s^{-1}. The data obtained were processed by the procedure described in [6, 7]. We calculated the following rheological parameters: full power consumed for flow N, power for degradation of the coagulation structure ΔN, consistency constant η_0, and flow index n.

The butt crushing strength of the granules was measured on a hydraulic press [8]. The BET specific surface area was determined from low-temperature sorption of argon [9].

We studied the sorption of CMC and PVA on ZnO particles under different conditions. A maximum at a 1–2 wt % PVA concentration in the solution is observed in all the sorption curves (Fig. 1). The maxima in the sorption curves are due to structuring of more concentrated CMC and PVA solutions with the formation of aggregates. The sorption capacity of the solid phase in dispersed solutions is higher by a factor of 2 than that in the stirred solutions.

The sorption capacity depends on the hydrophilic shell on the surface and the size of oxide particles.

1070-4272/05/7802-0234 © 2005 Pleiades Publishing, Inc.

The ion-exchange sorption from 0.l N HCl shows that the ZnO surface is almost completely coated with OH groups. In addition, the particle size of zinc oxide decreases from 250 to 20 μm after dispersion in a high-speed homogenizer. It should also be noted that diffusion of a large polymeric molecule into a porous particle is virtually impossible. Thus, the polymer sorption depends mainly on the size and hydroxyl shell of zinc oxide particles, rather than on their specific surface area.

The influence of the surfactant concentration on the optimal water content in the blend, φ_{opt}, was studied for the example of the ZnO–CMC–water system. The φ_{opt} decreases from 31.6 to 29.9 wt % with the CMC concentration increasing to 2 mg g^{-1} ZnO (Fig. 2). As the CMC concentration increases further, the optimal water content in the blend monotonically increases to 30.9 wt %. The dependence of the plastic strength at φ_{opt} is similar. At a CMC concentration of 2 mg g^{-1}, $P_m|_{\varphi=\varphi_{opt}}$ decreases by a factor of 2 and then monotonically increases, virtually reaching the initial value.

Comparison of the dependences shown in Figs. 1 and 2 shows that a decrease in φ_{opt} and $P_m|_{\varphi=\varphi_{opt}}$ corresponds to an increase in the surfactant sorption, i.e., the maximum in the $A = f(c_{surfactant})$ curve corresponds to the minium in the $\varphi_{opt} = f(c_{surfactant})$ and $P_m|_{\varphi=\varphi_{opt}} = f(c_{surfactant})$ curves. Hence, the intermolecular bonds of sorbed CMC macromolecules that substitute water molecules in the solvation shells make an increasing contribution to the coagulation interactions with increasing sorption. This accounts for the fact that the optimal water content in the blend decreases at a surfactant concentration of up to 2 mg g^{-1}. At the same time, the strength of coagulation bonds between polymer macromolecules is lower than that of the bonds formed by the hydration shell of zinc oxide particles. As a result, the plastic strength of the molding blends decreases at the best water content in the blend. As noted above, the surfactant sorption decreases with a further increase in the CMC concentration in the system (Fig. 1). This results in the formation of additional hydration bonds between ZnO particles, and hence φ_{opt} and $P_m|_{\varphi=\varphi_{opt}}$ increase (Fig. 2). Thus, structuring in molding blends depends not only on the total surfactant content in the system, but also, and to a greater extent, on the surfactant sorption on the surface of dispersed particles.

Let us consider the influence of the surfactant concentration (for the example of PVA) on the properties of molding blends based on ZnO at the optimal water content in the blend. Our experimental results (Fig. 3a) show that the dependence of ultimate shear

Rheological properties of molding blends based on zinc oxide

PVA content, wt %	N, MW m^{-3}	ΔN, MW m^{-3}	η_0, Pa s	n
0	22.7	3.1	228	0.501
3	23.6	4.7	194	0.476
5	25.6	5.2	178	0.471
7	25.8	6.2	133	0.459
10	26.1	6.3	128	0.414

stress on the PVA content is S-shaped, with the steepest portion of the curve corresponding to a PVA content of 5–7 wt %. The dependence of the maximum plastic viscosity on the surfactant concentration is initially exponential and then, at a PVA concentration higher than 7 wt %, flattens out. The dependence of the plasticity on the surfactant concentration is also S-shaped, and the dependence of the relaxation time is exponential (Fig. 3b).

These phenomena can be explained as follows. At a PVA content of up to 5–7 wt %, the polymolecular sorption layer is formed incompletely. Hence, a change in the surfactant concentration strongly affects the structuring processes in the system, namely, formation of coagulation bonds between solid particles. Structuring of the polymer solution starts to affect the structural-mechanical properties of the molding blends at PVA concentrations higher than 7 wt %, i.e., when the surfactant molecules cease to be sorbed on zinc oxide particles. Clearly, the influence of these structures on P_{k1} and η_1 and hence on Pl and Θ is lower than that of coagulation bonds between ZnO particles.

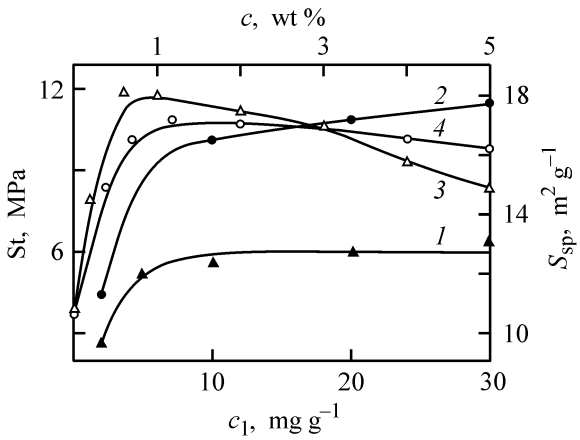

Fig. 4. (*1*, *2*) Mechanical strength St and (*3*, *4*) specific surface area S_{sp} of granulated sulfur adsorbent based on ZnO vs. the polymer content c and c_1. Surfactant: (*1*, *3*) CMC and (*2*, *4*) PVA.

It should be noted that the total power N consumed for flow of the blends remains unchanged, and the power for degradation of the coagulation structure ΔN increases by a factor of 2 (see table) with increasing PVA content. At the same time, the constant η_0 decreases by a factor of 2, and the flow index n only slightly varies in the range 0.4–0.5. It should be noted that the rheological parameters also noticeably change at the PVA concentrations lower than 7 wt %. This is also due to the processes occurring in sorption of PVA molecules on ZnO particles. These processes have the strongest effect on the structure of the system, i.e., on ΔN and η_0.

The mechanical strength and specific surface area of extruded articles strongly depend on the concentration and type of a surfactant. In our case, the strength of ZnO granules grows as the polymer concentration increases to 15–20 mg g^{-1} (Fig. 4). The strength is the highest at the surfactant concentration of about 5 wt %. Our calculations show that the sorbent prepared under these conditions contains about 1.5–2.0 wt % surfactant. As can be seen from Fig. 1, this surfactant content is close to the maximum sorption. Hence, the mechanical strength of the extrudate will be the highest when the surface of solid particles is completely covered with a polymer layer. It should be noted that the mechanical strength of the granules increases at high concentration of the polymeric adsorbate (PVA) in the extrudate.

The specific surface area of molded zinc oxide prepared from 0.5–0.2 wt % solutions of CMC or PVA increases from 12 to 18 m^2 g^{-1} (Fig. 4). At surfactant concentrations higher than 2 wt %, the specific surface area does not exceed 13–14 m^2 g^{-1} due to three-dimensional structuring of the polymer in the solution, which prevents dispersion and stirring of the system.

It is known that the properties of a ready extrudate depend not only on the physicochemical properties of the initial composition, but also on the extrusion conditions. We have shown previously [10] that the mechanical strength of extruded granules depends on the molding rate. These dependences may pass both through maxima and through minima. One of parameters depending both on the properties of the molding blend and on the extrusion conditions is the Weissenberg criterion [11].

The dependences of the mechanical strength and pore volume of ZnO sorbent on the Weissenberg criterion We are shown in Fig. 5. The dependence of the mechanical strength passes through a maximum, and the dependence of the pore volume, through a minimum. All the extrema appear at Weissenberg criteria of 200–300. The opposite course of these dependences is due to the fact that the strength of granules decreases with an increase in their porosity, all other conditions being the same.

Let us consider the factors responsible for appearance of the extrema. The relaxation time Θ entering into the equation for calculation of We characterizes the development of the plastic strain [6, 11]. When the extrusion is slow and, hence, We is low (up to 200), the plastic strain develops to a high extent and the sample is not ruptured. To increase the extrusion rate, the molding stress should be increased, which results in densification of the sample and, hence, in shortening of the interparticle distance. As result, the mechanical strength of the granules increases and their pore volume decreases.

At a higher extrusion rate, the strain of the molding charge at the extruder outlet is incomplete and fluctuations appear. The sorbent prepared under these conditions has a defective structure; its mechanical strength decreases and pore volume increases.

One more feature of the dependence of the pore volume on We is a strong influence of the extrusion rate on the volume of open pores (Fig. 5).

The total porosity strongly depends on the volume of open pores. This is probably due to the fact that, in accordance with Poiseuille's law, the flow rate of the molding charge at the center of a channel is substantially higher than that in the near-wall layer [7]. Hence, the defectiveness of the structure at the center of granules, where the flow rate is the highest, will be more pronounces than that at the periphery. The porosity of peripheral layers largely determines the volume of open pores.

Thus, PVA is a more effective surfactant, since it strengthens the interparticle interactions, whereas CMC promotes structuring of the dispersion medium. This is confirmed by the change in all the rheological properties of the suspensions. The influence of PVA on the rheological behavior of the ZnO suspension is stronger than that exerted by CMC.

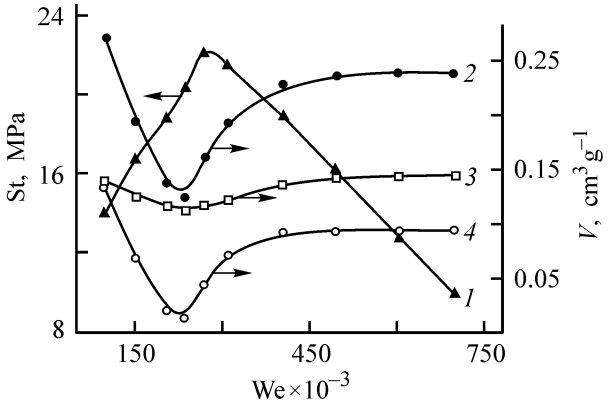

Fig. 5. (*1*) Mechanical strength St and (*2*) total pore volume, (*3*) volume of closed pores, and (*4*) volume of open pores, *V*, of ZnO sorbent vs. the Weissenberg criterion We.

CONCLUSIONS

(1) The curves of sorption of the surfactants from aqueous solutions on zinc oxide have maxima at a surfactant concentration of 1–2 wt %. This is due to structuring of the surfactants in the solution.

(2) The correlations between the surfactant sorption on ZnO particles and the structural-mechanical and rheological parameters of the molding formulation were revealed, as well as the correlation between the mechanical strength and the specific surface area of granules. All these phenomena are caused, on the one hand, by formation of sorption layer on the particle surface and, on the other, by structuring of the polymer solutions.

(3) The mechanical strength and pore structure of the granules are determined both by the properties of the molding blends and by the extrusion conditions. These parameters are related by the Weissenberg criterion. Hence, if the properties of a molding blend are known, the granules with required strength and porosity can be prepared by varying the extrusion rate and the die size.

Abstract—The kinetics of adsorption of model hydrocarbons (benzene, toluene, ethyl benzene, isopropyl benzene, cyclohexane) from the gas phase on the surface of ozonized and maleized petroleum-polymeric resins was studied. The dependences of the dynamic equilibrium capacity of the petroleum-polymeric resins and of the adsorption kinetic parameters on the composition of the adsorbent–adsorbate system were elucidated.

Physical adsorption is low-selective process governed by the ratio of the translation kinetic energy of sorbate molecules to the surface energy of the adsorbent. This predetermines the ways of improving the adsorption-structural parameters of the adsorbent. Along with the sorption power of porous materials, the selectivity of the adsorbent is also of importance. In this study, we examined modified (ozonized and maleized) petroleum-polymeric resins (PPR) as new adsorbents for adsorption of hydrocarbons from the gas phase.

EXPERIMENTAL

To prepare adsorbents based on modified PPR, the piperylene-amylene (C5), styrene-indene (SIF), and dicyclopentadiene (DCPDF) fractions of the liquid products of pyrolysis of straight-run naphtha were subjected to catalytic polymerization at 80°C for 3 h in the presence of the Ziegler–Natta catalytic system based on $TiCl_4$–$(C_2H_5)_3Al$ system at a 1 : 0.33 component molar ratio and $TiCl_4$ concentration of 2 wt % [1]. Crystalline, insoluble in hydrocarbons, PPRs ($OPPR_{C5}$, $OPPR_{SIF}$, $OPPR_{DCPDF}$) were prepared by ozonation of a 10% PPR solution in xylene with an air–ozone mixture (O_2–O_3 flow rate 38.5 l h^{-1}, O_3 concentration 2 vol %) in a bubbler at 5°C for 3 h [2]. The maleization was performed by the PPR reaction with 10 and 20 wt % maleic anhydride in the melt at 180°C for 4 h. The subsequent ozonation of maleized PPR gave modified PPRs ($OPPR_{SIFM10}$ and $OPPR_{SIFM20}$).

The samples of modified PPRs were ground into powders, and the 200–250-μm fraction was separated. Before experiment, the adsorbent samples were vacuum-treated for 5–8 h at 50–60°C and 0.133 Pa. The true and bulk densities of the adsorbent were found densimetrically [3].

Chemically and analytically pure benzene, toluene, ethyl benzene, isopropyl benzene, and cyclohexane were additionally distilled and stored in hermetically sealed vessels over freshly calcined NaA zeolite.

Adsorption of the model hydrocarbons from an air–gas mixture was performed at 20°C on a device equipped with a compressor, Drechsel bottle charged with the adsorbate, and a filter with the adsorbent. The adsorbent (2–5 g) was loaded into the filter as a continuous bed. An air–gas flow generated by the compressor was filtered through the adsorbent layer at the initial pressure of $(2–3) \times 10^4$ Pa. The rate of hydrocarbon feeding with the air–gas flow was 5–6 $cm^3 h^{-1}$. The weight of the adsorbed hydrocarbon was determined gravimetrically at 15–20 min intervals until the equilibrium was attained.

The process duration for each adsorbent–adsorbate system studied and the total weight of the adsorbed hydrocarbons at equilibrium were determined from the kinetic dependences of the hydrocarbon adsorption (Figs. 1a, 1b). From the total increase in the weight,

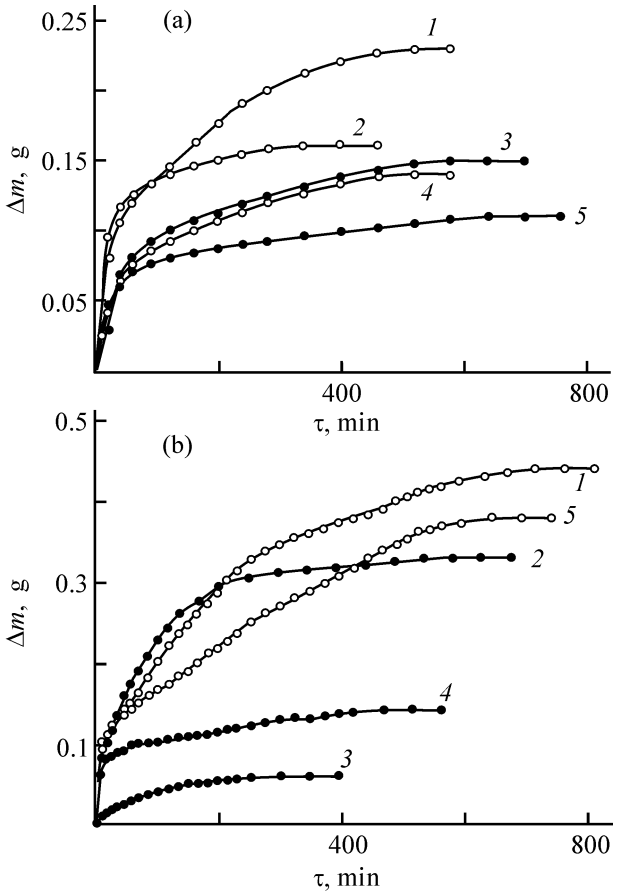

Fig. 1. Kinetics of (a) cyclohexane and (b) toluene adsorption. (Δm) Total weight of hydrocarbons adsorbed and (τ) process duration. Adsorbents: (*1*) $OPPR_{SIFM10}$, (*2*) $OPPR_{SIFM20}$, (*3*) $OPPR_{C5}$, (*4*) $OPPR_{DCPDF}$, and (*5*) $OPPR_{SIF}$.

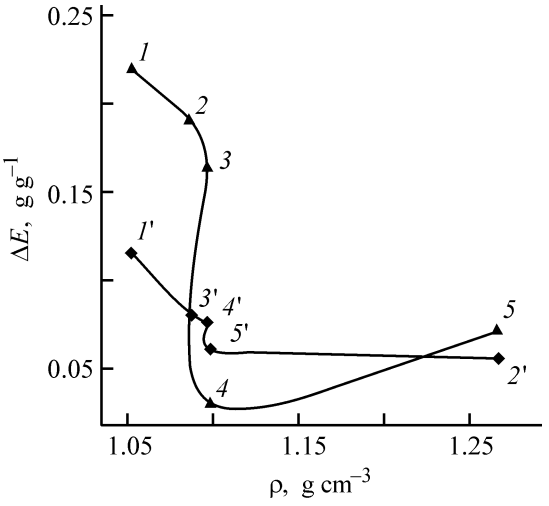

Fig. 2. OPPR capacity ΔE, in adsorption of (*1*–*5*) toluene and (*1*'–*5*') cyclohexane vs. adsorbent density ρ. (*1*, *1*') $OPPR_{SIFM10}$, (*2*, *2*') $OPPR_{SIF}$, (*3*, *3*') $OPPR_{SIFM20}$, (*4*, *4*') $OPPR_{C5}$, and (*5*, *5*') $OPPR_{DCPDF}$.

the equilibrium adsorbent capacity was calculated with respect to each adsorbate by the formula

$$\Delta E = (\Sigma \Delta m)/m,$$

where $\Sigma \Delta m$ is the weight gain due to the adsorbed hydrocarbon at equilibrium (g), and m, adsorbent weight in the filtering bed (g).

The adsorption of hydrocarbons from the gas phase on the resin surface is an equilibrium nonlinear process described by the equation

$$\Delta m_\tau = \Delta m_1(1 - e^{-k_1\tau}) + \Delta m_2(1 - e^{-k_2\tau}), \quad (1)$$

where Δm_τ is the total weight of the hydrocarbons adsorbed (g); Δm_1, weight of hydrocarbons adsorbed on the external surface (first-kind centers) (g); Δm_2, weight of hydrocarbons adsorbed on the internal surface (second-kind centers) (g); k_1, rate constant of hydrocarbon adsorption on the external surface (s^{-1}); k_2, rate constant of hydrocarbon adsorption on the internal surface (s^{-1}); and τ, duration of adsorption (s) (independent variable).

Equation (1) containing five parameters was solved by the unconstrained optimization method with the OPTIM software, including zeroth, first, and second optimization orders [4–6]. The zeroth order is a direct method for search and calculation of the function being optimized, the first order is the calculation of its first derivative, and the second order is the calculation of its first and second derivatives.

The rate constants k_a and k_d (s^{-1}), equilibrium constants K_{eq}, and Gibbs energies ΔG (kJ g^{-1} sorbate) of adsorption–desorption of hydrocarbons on the external and internal adsorbent surfaces were determined by Eq. (1) and equations $K_{eq} = k_a/k_d$ and $\Delta G = -RT \ln K_{eq}$, respectively, with an error of 0.1–0.3% (Table 1).

The OPPR surface was regenerated by forced displacement of adsorbed hydrocarbons with an air flow. The kinetic parameters of this procedure are listed in Table 2.

The time of equilibrium attainment (TEA) depends on the surface area of the adsorbent and kind of an adsorbate (Figs. 1a, 1b). On the surface of maleized $OPPR_{SIF}$ and $OPPR_{DCPDF}$, the equilibrium in the adsorbent–cyclohexane system is attained faster than on $OPPR_{C5}$ (Fig. 1a), and in adsorbent-toluene system, by contrast, TEA is shorter on $OPPR_{C5}$ (Fig. 1b). In contrast to TEA, the adsorption capacity of $OPPR_{SIF}$, $OPPR_{SIFM10}$ and $OPPR_{SIFM20}$ with respect to toluene increases by a factor of 2–3 as compared to cyclohexane (Fig. 2). On the surface of $OPPR_{DCPDF}$, and

especially, $OPPR_{C5}$, the capacity with respect to cyclohexane is higher than with respect to toluene. The surfaces of $OPPR_{SIF}$ and its maleized modifications demonstrate selectivity with respect to aromatic hydrocarbons, and especially to benzene and toluene. The correlation between the adsorbent capacity and its density is noteworthy. The lower the OPPR density, the higher its adsorption capacity (Fig. 2). The decrease in the material density must lead to an increase in its porosity. As seen (Fig. 2), maleization

of $OPPR_{SIF}$ increases the adsorbent capacity due to an increase in its porosity (surface area). $OPPR_{SIFM10}$ has the highest capacity.

The kinetic parameters, similarly to the capacity and TEA, depend on the nature of a particular OPPR–hydrocarbon system. In adsorption of hydrocarbons on OPPR, the equilibrium of adsorption on the external surface is shifted toward desorption (K_{eq} is less than unity, ΔG is positive), and on the internal surface, toward adsorption (Table 1). The maleization of $OPPR_{SIF}$ causes a noticeable redistribution of the values of the kinetic parameters. In particular, k_d exceeds k_a by 1–2 orders of magnitude on the external surface of $OPPR_{SIFM10}$. At the same time, k_a increases and k_d decreases on the internal surface. In accordance with such a redistribution of the rate constants, the weight of hydrocarbons adsorbed on the OPPR internal surface increases, which agrees with the change in the adsorbent density and capacity, caused by $OPPR_{SIF}$ maleization (Fig. 2). The adsorbent capacity decreases and density increases with increasing degree of maleization. Hence, the surface porosity of petroleum-polymeric resins can be controlled by their modification and, in particular, by maleization. Along with structural changes, maleization increases the OPPR selectivity with respect to aromatic hydrocarbons.

In contrast to equilibrium adsorption-desorption of hydrocarbons on OPPR, the nonequilibrium process of OPPR regeneration is characterized by very high rate constants and short time of displacement of the adsorbed hydrocarbon from the polymer surface (Table 2). The rate constants of regeneration of the external surface increase and those of the internal surface area decrease with increasing degree of $OPPR_{SIF}$ maleization. This agrees with kinetic parameters of the equilibrium adsorption-desorption of hydrocarbons on the same surface of the maleized $OPPR_{SIF}$ (Table 1) and with the capacities and densities of the adsorbents.

CONCLUSIONS

(1) Ozonized and maleized petroleum-polymeric resins were tested as adsorbents of aliphatic and aromatic hydrocarbons from the gas phase. The equilibrium adsorption capacity and selectivity of the adsorbents depend on the degree of resin maleization and the composition of the adsorbent–adsorbate system.

(2) Maleization leads to an increase in the internal surface area of the ozonized petroleum-polymeric resins. This is manifested in a decreased resin density and an increased adsorption capacity.

(3) Maleization provides a thermodynamic stability of adsorbed hydrocarbons on the internal surface of the ozonized petroleum-polymeric resins. The adsorption of hydrocarbons on the internal surface of the resin is spontaneous: $K_{eq} > 1$ and $\Delta G < 0$.

Received July 26, 2004

Abstract—The electrochemical synthesis of a mixture of dispersed oxides (CuO and ZnO) from secondary lump braze was studied. The influence exerted by electrolysis parameters on the intensity of synthesis of the oxide mixture was investigated. The design of the electrolyzer and the flow diagram for synthesis of a mixture of oxides (CuO and ZnO) from lump braze was suggested.

The electrochemical synthesis of inorganic compounds of nonferrous metals: oxides [1, 2], hydroxides [3, 4], and salts [5, 6], is one of the areas of preparative chemistry that have been rapidly developing in the last decade. Use of electrolysis makes it possible to obtain not only pure target products, but also substances with certain physicochemical characteristics. For example, electrochemically obtained vanadium(V) oxide is distinguished by good performance as a cathode material for lithium batteries [7], and copper(II) oxide, by high dispersity and purity [8].

In this study, we continued a comprehensive study of the electrochemical synthesis of hydroxides, oxides [2], and salts [6] of nonferrous metals from secondary raw materials.

EXPERIMENTAL

Anodic polarization curves were measured in a standard thermostated electrochemical cell at a potential sweep rate of 5.0 mV s^{-1} with a PI-50-1.1 potentiostat. Platinum was used as the auxiliary electrode, and silver chloride, as reference. Zinc, copper, and braze (L63 brand, 63 wt % copper and 37 wt % zinc) in the form of rods 2-mm in diameter pressed into a fluoroplastic cartridge served as working electrodes. The samples were trimmed with a fine emery paper and washed with ethanol prior to each experiment. A 0.5 M solution of Na_2SO_4 was used as a working electrolyte.

The mixture of oxides CuO and ZnO was synthesized from lump braze in an electrolyzer schematically shown in Fig. 1.

The steel vessel of the electrolyzer is coated with nickel by means of electroless plating. The inner walls are lined with a dielectric film. Current is conveyed to the bulk anode through the bottom. The cross-sectional diameter of the bulk anode is 100 mm. As the cathode serves a copper disc 60 mm in diameter, closed from above and on sides with a polypropylene cap, so that only its lower part is working. The spacing between the cathode and bulk anode can be adjusted by moving the cathode. In the experiments, braze cuttings with a conventional diameter of 2–3 mm, length of 3–30 mm, and a bulk weight of 1.0–1.1 g cm^{-3}

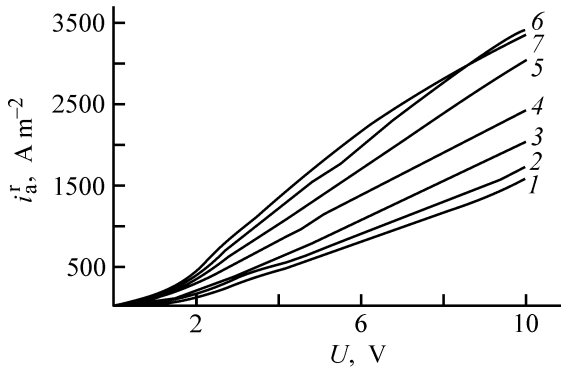

Fig. 2. Current–voltage curves measured in anodic dissolution of L63 braze in a 0.5 M Na_2SO_4 solution. (i_a^r) Current density and (U) voltage. Temperature (°C): (*1*) 20, (*2*) 30, (*3*) 40, (*4*) 50, (*5*) 60, (*6*) 70, and (*7*) 80.

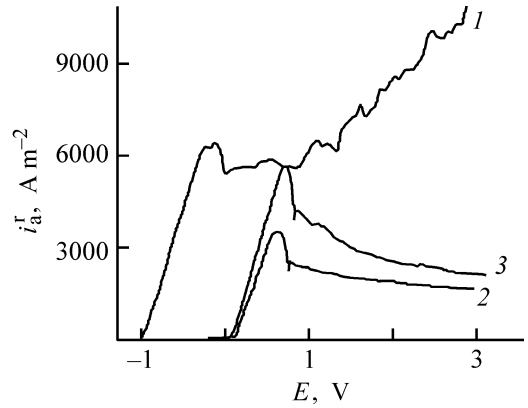

Fig. 3. Anodic polarization curves obtained under hydrostatic conditions for (*1*) zinc, (*2*) copper and (*3*) braze in a 0.5 M Na_2SO_4 solution at 60°C. (i_a^r) Current density and (E) voltage.

(copper 1.3–1.4 g cm^{-3}) were charged, after being degreased, into the electrolyzer to a height of 150 mm. The electrolysis was performed in the flow-through mode using a preheated 0.5 M solution of Na_2SO_4. The working temperature of the electrolyte was maintained by thermostating the electrolyzer. Current–voltage characteristics were recorded in the range 20–80°C, with voltage sweeping from 0 to 10 V in steps of 0.5 V and the system kept for 30 s at each point. The electrochemical synthesis was performed at U = const. The suspension passed through the electrolyzer was filtered immediately after that or upon being heated to the boiling point. Then it was allowed to settle, washed with water, and dried at 50°C in air. The pH value of the filtrate was adjusted when necessary and again fed into the electrolyzer. The CuO + ZnO content was determined by calcination of predried powders at 600°C.

The powders obtained were subjected to an X-ray phase analysis on a DRON-3M diffractometer (Cu_{K_α} radiation, θ–2θ scan angle, Bragg–Brentano technique), with a stepwise recording of diffraction patterns.

In a flow-through electrolyzer (Fig. 1), Zn^{2+} and Cu^{2+} ions formed in the near-anode space through anodic dissolution of braze are carried by the electrolyte into the interelectrode space and the near-cathode layer, where pH > 7 is established because of the occurrence of a cathodic reaction

$$2H_2O + 2e \rightarrow H_2 + 2OH^-. \quad (1)$$

Therefore, insoluble complexes $Zn(OH)_2$ and $Cu(OH)_2$ are formed in the interelectrode space and, in part, in the near-cathode space, which predetermines electrodeposition of copper and zinc onto the cathode.

As temperature increases (≥50°C), $Cu(OH)_2$ starts to decompose by the reaction

$$Cu(OH)_2 \rightarrow CuO + H_2O, \quad (2)$$

which is indicated by the fact that the deposit turns dark, to become virtually black at above 90°C, and by the results of the X-ray phase analysis.

The results of the study show that the reduced anodic current density i_a^r ($i_a^r = I/S$, where I is current strength, and S, surface area of the bulk anode) is proportional to the voltage across the electrolyzer and grows with increasing temperature (Fig. 2). Above 70°C, a decrease in the rate at which the i_a^r increases is observed.

The anodic currents of dissolution of lump braze are considerably higher than those of lump copper under the analogous conditions of electrolysis.

For example, at voltages of 5, 7, and 9 V and a temperature of 70°C, i_a^r is 1605, 2445, and 3159 A m^{-2}, respectively, for lump braze and 1120, 1745, and 2370 A m^{-2} for lump copper. This is due to the fact that the anodic dissolution currents of the main component of braze, zinc, are higher than those of copper (Fig. 3). In addition, the dissolution of braze is a selective process: first dissolves zinc, as a more electronegative metal, and only after that, copper [9]. The surface of braze becomes porous after the removal of zinc, which also facilitates the anodic dissolution.

The intensity of electrochemical synthesis of the oxide mixture may be governed by (1) electrolysis voltage, (2) concentration of a supporting electrolyte (Na_2SO_4), and (3) temperature.

As the voltage increases, the current density at the electrodes grows; however, the limiting anodic current density [10, 11], which increases for a bulk anode owing to the electrochemical inhomogeneity of the surface, is not reached even at 10 V.

The concentration of the supporting electrolyte is not the limiting factor, because, as shown in our study, the dissolution currents of braze in a 0.2–0.5 M Na_2SO_4 solution are virtually equal even at a voltage of 15 V.

With temperature raised by 10°C, the rate of electrochemical synthesis increases by 15–25% (table, Fig. 2). Apparently, this result can be accounted for by a decrease in the electrical resistance of the electrolyte and by the diffusion factor.

In addition, raising the temperature accelerates the coagulation of the deposit and leads to changes in its composition. For example, according to the results of an X-ray phase analysis, the deposit obtained below 50°C contains only the hydroxide $Cu(OH)_2$, and that formed at 60°C, also the oxide phase CuO. The content of the oxide phase grows with increasing temperature and, after the boiling temperature is reached, the suspension is virtually composed of a single phase, CuO. An X-ray phase analysis of powders obtained from the suspensions below 100°C revealed intermediate compounds of basic salts. For example, the powders synthesized below 50°C contain $6Zn(OH)_2 \cdot ZnSO_4 \cdot 4H_2O$.

The rate of removal of the products formed in the dissolution of the anode (braze) is determined by the flow rate of the electrolyte. Calculations show that, at a flow rate of the electrolyte in the electrolyzer equal to 1 $dm^3\ min^{-1}$, its flow velocity near the anode surface is about 1 $cm\ s^{-1}$. It was experimentally established that higher flow rates of the electrolyte (≥2–3 $dm^3\ min^{-1}$) lead to removal of fine metallic particles from the surface layer and to contamination of the oxides synthesized with these particles. In addition, these values are lower by one or two orders of magnitude than those in fast anodic dissolution of metals in electrochemical anodic sizing (EAS) [12]. Consequently, the electrolyte flow velocity is not an essential parameter in control over the rate of electrochemical synthesis of the oxides CuO and ZnO.

Thus, the main factors responsible for the intensification of the electrochemical synthesis of a mixture of oxides CuO and ZnO from lump braze in a vertical flow-through electrolyzer are the electrolyzer voltage and temperature. However, as the electrolyzer voltage increases, the specific electric power consumption W_{sp} ($W_{sp} = U/1.5CE_a$, where CE_a is anodic current efficiency) becomes higher. By assuming that CE_a is approximately 100% (electrochemical equivalent of the CuO and ZnO mixture is 1.5 $g\ A^{-1}\ h^{-1}$), a value of 3.33 $kW\ h\ kg^{-1}$ is obtained for the specific power consumption W_{sp} (CuO, ZnO) at 5 V, which increases by 0.67 $kW\ h\ kg^{-1}$ as the voltage is raised by 1 V.

* In terms of anhydrous metal oxides CuO and ZnO.

Our study demonstrated that the interelectrode spacing is predetermined by the electrolysis rate. The higher i_a^r, the more vigorous is the gas evolution at the cathode. When interelectrode spacing is small, the resulting gaseous foam can reach the bulk anode, which results in the formation of hydroxides (oxides) and their adherence in the zone of the lump metal. It was found that, at an electrolyte flow velocity of 1 $cm\ s^{-1}$ and more and a reduced anodic current density of 2000, 3000, and 4000 $A\ m^{-2}$, the optimal interelectrode spacing is 15, 20, and 25 mm, respectively.

It was found that raising the electrolyte temperature to above 70°C is ineffective as regards the electrolysis intensification. However, with account of the necessity for boiling of the sludge of copper and zinc hydroxides in order to enhance the coagulation and, accordingly, the filterability of the deposit obtained, to prevent formation of basic salts, and to ensure complete transformation of oxides into hydroxides, the optimal temperature of the electrolysis should be 70–80°C.

Based on the results obtained, we suggested the following flow diagram of the electrochemical synthesis of a mixture of oxides CuO and ZnO from lump braze.

Flow diagram of synthesis of dispersed oxides.

In the stage of classification of the scrap, the impurities are removed from braze cuttings by a method dependent on the type and content of impurities. After that, the cuttings are degreased, if necessary.

The thus prepared cuttings are charged into the electrolyzer as a bulk anode. The electrolyte (Na_2SO_4 solution) is fed into the electrolyzer continuously, thus ensuring removal of the electrolysis products in the form of a sludge. The sludge is boiled to improve its filterability, separated from the electrolyte by filtration, and washed. The mother liquor is recycled into the stage of electrolyte preparation. The deposit obtained is dried at 150–200°C.

CONCLUSIONS

(1) It is suggested to perform the electrochemical synthesis of a mixture of oxides CuO and ZnO by anodic dissolution of lump braze in a flow-through vertical electrolyzer in a Na_2SO_4 solution.

(2) It is shown that the main factors important for raising the electrolysis rate are the temperature of the electrolyte and the electrolysis voltage. The intensity of electrochemical synthesis of oxides CuO and ZnO may be as high as 4.8 kg m^{-2} h^{-1} and more when the temperature and voltage have the optimal values.

(3) The flow diagram of electrochemical synthesis of a mixture of oxides CuO and ZnO from lump braze is suggested and tested in laboratory conditions.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Effect of ac Polarization on Characteristics of Coatings formed from Polyphosphate Electrolytes of Ni(II) and Zn(II)

Abstract—Characteristics of microplasma-produced coatings formed on an aluminum alloy under anodic and combined anodic–cathodic polarizations in electrolytes with polyphosphate complexes of Ni(II) and Zn(II) are compared.

Two areas can be conventionally distinguished in research and development concerned with formation of anodic electrolytic coatings on aluminum and its alloys under the action of electric discharges giving rise to a large group of microplasma-assisted electrochemical processes [1].

The first of these is associated with the development of methods for implementation and monitoring of advantageous current (current–voltage) modes and analysis of how they affect the composition, structure, and properties of protective layers. Mostly simple aqueous electrolytes, acids, alkalis, silicate-alkaline solutions have been used in these studies [2–13]. It is within this area of research that a group of scientists from Novosibirsk was the first to establish that combining the anodic and cathodic polarizations may dramatically improve the quality of the coatings obtained (with diminished and even completely eliminated through porosity and increased adhesion, microhardness, wear resistance, corrosion resistance, etc.) [4, 14, 15]. This is mostly due to inclusion of high-temperature aluminum oxide phases (γ- and(or) α-Al_2O_3) in the microstructure of the composite layer adjacent to the substrate. It is quite natural that the development of these studies is aimed at a search for optimal current modes. It was possible to raise the growth rate of microplasma-produced layers, improve their operation parameters and diminish the energy intensity of the process as a whole by controlling the repetition frequency of cathodic and anodic current pulses and varying their widths and relative amplitudes [16–18]. It was shown in a generalizing analytical review that analysis of particular results and general patterns should take into account not only a specific current–voltage mode, but also the type (composition and state) of an electrolyte.

The second area of research is aimed to find electrolyte compositions that would make it possible to use microplasma-assisted processes to form on the surface of rectifying metals, including aluminum and its alloys, complex oxide structures in order to provide a wide variety of their properties. However, only anodic polarizations have been commonly employed. A considerable progress has also been made in this area, e.g., conditions have been developed in which layers containing oxides of transition metals [19, 20], spinels [21], phosphates [22–24], and perovskite structures [25, 26] can be obtained on aluminum alloys. These layers have found use or show promise in medicine and catalysis, as active elements of gas analyzers, layers resistant to hard ultraviolet and protecting from the action of corrosive media, and structures exhibiting bioinert or biocide properties.

It has been shown [22–24] that it is possible to form, in electrolytes with water-soluble polyphosphates and salts of M(II) and M(III), oxide structures containing, together with oxides of a metal being treated, also compounds of M(II) and M(III), including, under certain conditions, high-temperature phosphates of M(II) and M(III). The potential fields of application of coatings containing high-temperature metal phosphates are rather wide: catalysts and catalyst supports, sublayers under paint-and-varnish materials, anticorrosive colored decorative layers, and structures with bactericide or biocompatible properties.

Formation mode: anodic (*full symbols*) and AC + C (*open symbols*); formation time 10 min, oxygen concentration in the coatings undetermined. (*1*) Al, (*2*) P, (*3*) Zn, and (*4*) Ni.

It was of interest to find out whether the previously established patterns of influence exerted by the composition and state of electrolytes with polyphoshate complexes on certain characteristics of coatings formed on an aluminum alloy in the anodic mode are valid, if this mode is changed for the anodic–cathodic mode.

EXPERIMENTAL

The coatings were formed under anodic (mode A) and combined anodic–cathodic (mode AC) polarizations. In the first case, a TEP4-100/460 thyristor source of unipolar current was used, with an effective current density of galvanostatic formation j = 0.05 A cm^{-2}. In the second case, a capacitive power source providing alternating trains of anodic–cathodic and cathodic current pulses (mode AC + C) with a repetition frequency of 50 Hz was employed.[1] The effective current density in an anodic–cathodic train was j_{ac} = 0.05 A cm^{-2}, with equal cathodic and anodic components, and that in a cathodic train, j_c = 0.005 A cm^{-2}. The duration of the anodic–cathodic and cathodic pulse trains was 2 and 0.66 s, respectively.

The surface of a 10-l cylindrical stainless-steel bath was used as a counter electrode. The electrolyte was agitated by air bubbling. To cool the system, cold water was pumped through hollow walls of the bath. The solution temperature in the course of treatment did not exceed 45°C.

The electrolytes were prepared from sodium hexametaphosphate (HMP) of pure grade and $Ni(CH_3COO)_2 \cdot 4H_2O$ and $Zn(CH_3COO)_2 \cdot 4H_2O$ salts of chemically pure grade. First, 30 g l^{-1} of HMP was dissolved in distilled water and then a weighed portion of a salt was introduced into the solution to obtain the required molar ratio $n = [P_6O_{18}]/[M]$ in the bulk of the electrolyte.

The coatings were formed on preliminarily degreased $40 \times 10 \times 1$ and $40 \times 20 \times 1$ mm samples of an AMtsN alloy. Six samples with a total area of 62 cm^2 were placed in the bath simultaneously. The treatment duration was 10 or 60 min. Samples with a deposited coating were washed with distilled water and dried in air at 60–70°C.

The elemental composition of the coating surface was studied with a JXA-5A *n* electron-probe X-ray fluorescence microanalyzer, and the phase composition was judged from X-ray diffraction patterns obtained with a DRON-2.0 X-ray diffractometer (Cu_{K_α} radiation) for coatings on substrates. The coating thickness was determined with a VT-10NTs vortex thickness meter. The average thickness was calculated from the results of 20 measurements. The coating roughness was determined with a Kalibr profile meter with an accuracy of ±10%. The volume porosity of the coatings was calculated from data on oil absorption measured in conformity with GOST (State Standard) 9.302–88 with the use of a VM-1 vacuum oil.

Dependences of the thicknesses and elemental compositions of Ni- and Zn-containing coatings formed in the anodic and combined AC + C modes on the molar ratio n of components in the electrolyte are shown in Figs. 1 and 2. Similar dependences have been ob-

[1] Experiments with a unipolar pulsed thyristor unit were carried out at the Institute of Chemistry, Far-Eastern Division, Russian Academy of Sciences, and those with a combined anodic–cathodic power source, at the Institute of Inorganic Chemistry, Siberian Division, Russian Academy of Sciences.

	Pulsed	18.6 (±7)	0.49 ± 0.08

tained previously in electrolytes containing acetates of various metals (e.g., Mg^{2+}, Mn^{2+}, Pb^{2+}) and polyphosphates, using a thyristor power source with unipolar pulsed current [22–24, 27] or ac and half-wave sinusoidal current [28].

In all the current modes considered, two characteristic regions can be distinguished in the experimental curves (Figs. 1–4). In the first of these ($n > 3$), the coating thickness becomes virtually independent of n (Fig. 1), the content of electrolyte components in the coating is virtually zero (Fig. 2), the roughness remains virtually uchanged (Fig. 3), and the porosity varies without any clearly pronounced specific features (Fig. 4). It is also noteworthy that the initial electrolyte is a true solution at these values of n.

In the second region ($n < 3$), the thickness (Fig. 1) and composition of the coatings (Fig. 2) vary monotonically, and variation of other characteristics shows clearly pronounced specific features (Figs. 3, 4). As regards the state of the electrolyte, this region can be subdivided in two: metastable subregion with a colloid component ($1.5 \le n \le 3$) and a subregion ($0.25 \le n \le 1.5$) in which the "bulk" of the initial solution contains a suspension of dispersed phases or even a precipitate. Presumably, just the last factor tells on the way in which n affects the roughness (Fig. 3). Possibly, the position of the local porosity maximum at $n \approx 1.5$ (Fig. 4a) is also associated with differences in the above-described states of the initial electrolytes.

Making longer the time during which coatings are formed in an electrolyte with Zn polyphosphate in the AC + C mode (from 10 to 60 min) leads to a substantial increase in the coating thickness (Fig. 1b), which is especially noticeable for small n and low roughness (Fig. 3b). In this case, the generality of the type of the dependences observed is retained.

It has been shown previously [28, 29] that the effect of the molar ratio n on the thickness of coatings formed in electrolytes with polyphosphate complexes of metals on aluminum and titanium at different kinds of anodic polarization is well approximated with a power function $h(n) = h_0 n^{-b}$, where h_0 and b are fixed parameters of a model adequate for a certain range of n in the vicinity of $n = 1$. The dependences of the thickness of coatings formed in the AC + C mode at $0.25 \le n \le 3$ are also satisfactorily approximated with a similar function. The points for $n > 3$ were disregarded because the coating thickness is virtually constant at these values. It is noteworthy, in addition, that, in the range $n < 0.25$ not examined in this study, this approximation will undoubtedly be equally inadequate.

Table 1 lists estimates of the parameters h_0 and b, calculated by the least-squares method, and their standard

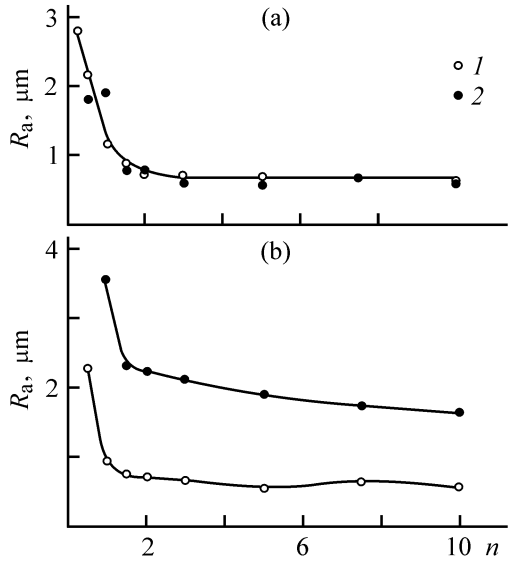

Fig. 3. Roughness R_a of the coatings vs. the molar ratio n of the electrolyte components.

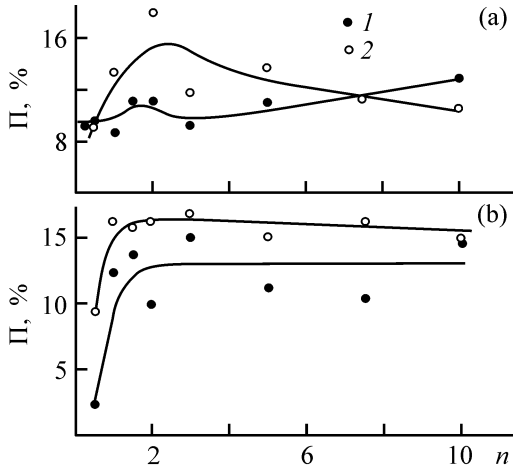

Fig. 4. Volume porosity П of the coatings vs. the molar ratio *n* of the electrolyte components.

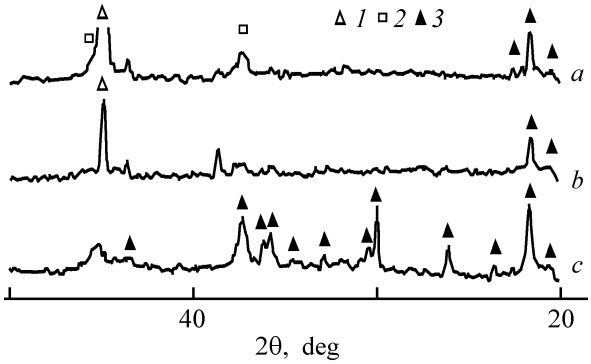

Fig. 5. X-ray diffraction patterns of nickel-containing coatings formed on substrates in an electrolyte with $[P_6O_{18}]/[Ni] = 1$ in different modes. (*a*) Anodic mode, formation time 10 min; (*b*) AC + C mode, formation time 10 min; and (*c*) AC + C mode, formation time 60 min. (*1*) Al, (*2*) γ-Al_2O_3, and (*3*) $AlPO_4$.

deviations for data obtained for $0.25 \le n \le 3$ in this study in the AC + C mode and, previously, in other (anodic) modes at equal quantities of electricity consumed in the process. It should be, first of all, noted that the standard relative deviations were 5–7% for the curves included in the processing, which exceeds by a factor of 2–3 the values expected on the basis of starting error model. It can be seen that, irrespective of the current mode, the approximation parameters have sufficiently close values and agree well with previously obtained data, including those for coatings formed in electrolytes with polyphosphate complexes of Mg(II), Mn(II), Pb(II), and Eu(II) and electrolytes with $Na_6P_6O_{18}$ replaced with $Na_5P_3O_{10}$ [29].

Introduction of a cathodic component in the forming current affects the phase composition of the oxide layers obtained (Fig. 5, Table 2). All other conditions being the same, coatings formed in the AC + C mode are better crystallized. In addition, introduction of a cathodic component of the current at $n > 1.5$ results in that high-temperature Al_2O_3 phases, including α-Al_2O_3, appear in the coatings. Making longer the time of AC + C formation leads to an increase in the crystallinity of the coatings and to appearance of $NiAl_2O_4$ spinel at $n = 1.5$ and α-$Zn_3(PO_4)_3$ at $n = 0.5$ in Ni- and Zn-containing electrolytes, respectively.

For coatings with nickel, it is necessary to note once more the presence of a clearly pronounced maximum in the dependences of the coating porosity on *n* in the region of transition from a metastable solution (colloid state) to a solution with a precipitate ($n \approx 1.5$) (Fig. 4a). The maximum is also observed in the anodic mode, but is less pronounced.

For electrolytes with $n > 1$, the porosity of AC + C coatings with zinc is comparable with that calculated for coatings with nickel (Fig. 4). At the same time, the porosity of coatings with zinc becomes substantially lower as *n* decreases to 0.5, for formation times of both 10 and 60 min. The coatings obtained in this case have the form of a partly fused glassy mass. On the whole, the volume porosity of the coatings formed

Table 2. Phase composition of coatings formed on AMts alloy in different modes

Electrolyte	Mode	Phase composition at *n*		
		10	1.5	0.5
$Na_6P_6O_{18} + Ni(CH_3COO)_2 \cdot 4H_2O$	A, 10 min	æ-Al_2O_3	γ-Al_2O_3, $AlPO_4$	γ-Al_2O_3, $AlPO_4$
	AC + C:			
	10 min	α,γ,η-Al_2O_3	γ-Al_2O_3, $AlPO_4$	$AlPO_4$
	60 min	α,γ,η-Al_2O_3	Al_2O_3, $AlPO_4$, $NiAl_2O_4$	$AlPO_4$

	AC + C:			
	10 min	α,γ-Al_2O_3	α-Al_2O_3	Al_2O_3, $AlPO_4$
	60 min	α,γ,η-Al_2O_3	α,γ,η-Al_2O_3	Al_2O_3, $AlPO_4$, α-$Zn_3(PO_4)_2$

in the AC + C mode somewhat exceeds that obtained in the anodic mode (Fig. 4).

The specific features of growth and the composition of microplasma-produced coatings formed on rectifying metals in the anodic mode in polyphosphate electrolytes were reported in [22–24, 28–30]. It was established that the composition and parameters of coatings of this kind depend in a certain way on the molar ratio of the electrolyte components (n = [polyphosphate]/[M]), which also determines the state of the electrolyte (true, metastable, or colloid solution, solution with an admixture of suspended dispersed phases or even with a precipitate). It was reasonable to relate these facts to a difference between "mechanisms of coating formation" in true ($n > 3$) and other ($n \le 3$) solutions. The whole set of data obtained [22–24, 28–30] indicates that a decrease in n (approach of the electrolyte to the state of precipitation leads to predominance of the "thermolytic formation mechanism," in which the mass of a coating increases mainly through thermally induced transformations of the colloid and dispersed fractions of polyphosphates in the vicinity of electric discharges. In the region of true polyphosphate electrolyte solutions, the "coating growth mechanism" predominates because of the formation of oxides from the components of the substrate.

The anodic–cathodic microplasma-assisted processes have been studied extensively [4, 13–18, 31–34]. During the cathodic half-period, defects that facilitate the process under the anodic polarization can be formed [31]. In the opinion of the authors of [32], stronger discharges that fuse the oxide layer occur during the periods of cathodic polarization. According to [33], the cathodic polarization leads to a decrease in the space charge in the oxide, which facilitates coating formation under the succeeding anodic polarization. Use of ac current not only limits the time of action of discharges during the anodic period, but is also accompanied by flow of currents associated with recharging of the metal–oxide–electrolyte system [13]. In addition, the hydrogen evolution during the cathodic period creates conditions under which gas bubbles are formed near the surface, and their breakdown affects the growth of oxide films. In any case, introduction of a cathodic component of the current leads to heating of the inner part of the oxide layer, which favors formation of high-temperature phases in this region [4, 13–18].

However, the data obtained in this study demonstrate that, all other conditions being the same, introduction of an additional cathodic component into the current at the accepted initial and boundary conditions does not exert any significant influence on the elemental composition, thickness, and roughness of coatings formed in electrolytes with polyphosphate complexes at $n \le 3$. This confirms the previously made conclusion about the thermolytic mechanism of formation of coatings in electrolytes of this kind. The assumption that the α-Al_2O_3 phase crystallizes in the coatings seems to be reasonable with account of the heating of their inner part. However, the absence of crystalline phases with phosphorus and nickel or zinc, despite the high content of these elements in the coatings, was rather unexpected in this case. The heating by the cathodic component of the current of the inner part of a growing coating favors formation of high-temperature phases of aluminum oxide, but does not lead to crystallization of nickel or zinc phosphates. The possible reason is that phases based on the electrolyte components are concentrated in the outer layer of a coating.

It is noteworthy that surface layers containing crystalline phosphates $Ni_2P_2O_7$ and $NaNiPO_4$ are obtained on aluminum in an electrolyte with polyphosphate complexes only if dc current is used (full-wave rectifier with a capacitance filter [28]). In other current modes, mainly X-ray-amorphous layers are formed, which crystallize upon a high-temperature heating (>500°C) in air [22–24]. Presumably, this is due to the following. In the course of a microplasma treatment with a dc current, a separate discharge passing all stages of its development exists for a comparatively long time and heats the adjacent layers of the oxide. In various pulsed modes, including that with an additional cathodic component of the current, higher working voltages can be achieved, but the discharge duration is limited to that of a single current pulse. The melt locally formed in the discharge zone is in contact with the electrolyte and, therefore, it cools fast, which favors formation of amorphous phases. It is noteworthy that synthesis of crystalline anhydrous phosphates, e.g., nickel pyrophosphate $Ni_2P_2O_7$, by thermal decomposition of nickel phosphates requires their prolonged (not pulsed) heating at a temperature exceeding 600°C [35, 36].

The volume porosity of the coatings strongly depends on the current mode. In the case of nickel-containing layers (Fig. 4a), the data obtained, combined with the results of [28], indicate the following. In the region of true solutions ($n > 3$), the porosities of the coatings formed in various pulsed modes are rather close (10–15%). At the same time, if the process is performed with a dc current, coatings with

an increased porosity (>20%) are obtained. This fact can also be attributed to different times of action of discharges in the dc case and in pulsed mode. For metastable solutions or those already containing a dispersed phase (at $n \leq 3$) the situation is different. The current modes can be arranged, with account of the data of [28], in order of increasing porosity of the resulting nickel-containing coatings as follows: half-wave current mode, pulsed mode (thyristor power source), ac current mode ($j_a = j_c$, 50 Hz), and ac current mode with an additional cathodic component.

Thus, the cathodic component of the current does not diminish the volume porosity of coatings deposited from dispersed polyphosphate electrolytes with nickel. The porosity of zinc-containing coatings formed from dispersed solutions (with *n* decreasing from 1–1.5 to 0.5, Fig. 5) is considerably lower, in contrast to that of nickel-containing coatings. This may be due to a poorer thermal stability of zinc polyphosphates, compared with nickel polyphosphates. The melting points of zinc polyphosphates are 830–1106°C, and those of nickel phosphates, 1200–1400°C [35]. In all probability, the discharge energy is sufficient for a Zn-containing coating to be fused and an amorphous layer with low porosity to be formed. Unfortunately, such characteristics as through porosity, adhesion, microhardness, corrosion resistance, and layer-by-layer wear resistance could not be subjected to an experimental analysis as yet. According to the available data, it is these characteristics, or part of them, that may prove significantly different for the anodic and AC + C modes.

CONCLUSIONS

(1) The main patterns concerning the variation of the thickness, elemental composition, and surface roughness, established for the case when microplasma-produced coatings are formed on aluminum alloys in electrolytes with polyphosphate metal complexes under anodic polarization are also valid in the case of anodic–cathodic formation conditions.

(2) The incorporation of components of polyphosphate electrolytes into the coatings is associated, for both the anodic and the ac anodic–cathodic polarizations, with thermolysis of the colloid and(or) dispersed components of the electrolyte in the vicinity of the zones affected by electric discharges.

(3) Compared with the anodic modes, the combined anodic–cathodic + cathodic mode leads to changes in the phase composition of the coatings and to a higher crystallinity of some of the phases.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Dependence of the Current Efficiency by Target Product of Electrosynthesis on Polarization

Yu. V. Saltykov and V. L. Kornienko

Institute of Chemistry and Chemical Technology, Siberian Division, Russian Academy of Sciences, Krasnoyarsk, Russia

Received October 6, 2004

Abstract—The known dependences of the current efficiency by target products of electrosynthesis on polarization are analyzed for the cases when the principle of independent occurrence of concurrent reactions is observed or not.

It is known that electrochemical methods for synthesis of chemical products are ecologically safer than the conventional chemical techniques. This is primarily due to the fact that electrochemical methods use electric current, which is ecologically clean, as an oxidizing or reducing agent. However, the rate of electrode transformations is rather low under ordinary conditions and limited by the interface between the electrolyte and an electrode. The electrode transformations in electrosynthesis are commonly intensified by using electrodes with a developed surface, e.g., porous hydrophobized [1–4], or by making stronger the polarization [5–8].

It is known that the current efficiency (CE) by the target product is frequently lower than 100%. This is due to the fact that, virtually in all cases, the target reaction is accompanied by competing concurrent or consecutive electrochemical reactions. The behavior of CE with polarization is largely determined by the extent to which the competing reactions affect one another. It is known that, in the case when the mutual influence of competing electrochemical reactions is insignificant, the principle of independence of concurrent reactions (PICR) can be used [9, 10]. According to this principle, each of the concurrent electrode reactions proceeds independently of the others, as if it were the only reaction occurring at the given electrode. It has been shown previously [11] that, when the PICR is applicable, the CE of the target products increases as the polarization becomes stronger if the ratio of the Tafel slopes of the target (b_1) and side (b_2) reactions is less than unity and, conversely, decreases at $b_1/b_2 > 1$. It may occur in electrosynthesis that the PICR is not observed. This is the case when the course of the electrode process is strongly affected by the starting reagents, intermediates, and final product. Naturally, the influence exerted by the target electrochemical reaction may vary: the side reaction may be virtually completely suppressed, as in dechlorination of 1,1,2-trichlorotrifluoroethane on zinc and cadmium hydrophobized electrodes (HPE) [2, 12]. Also possible is a comparatively weak influence, as, e.g., in electrochemical chlorination of alkanes [2, 13, 14].

In the simplest case, the influence exerted by the target reaction on the side process may consist in that the surface concentration of electrically active species involved in the rate-determining stage of the side reaction is diminished. It would be expected that this should lead to a decrease in the overall rate of the side process at an unchanged Tafel slope. Then, the behavior of CE with polarization should be the same as that in the case when the PICR is observed.

If the products of the target reaction strongly affect the side reaction, the mechanism of the latter may change. In this case, the pattern based on applicability of the PICR may be invalid when the CE by the target product changes as the polarization becomes stronger.

In this communication, the known experimental data on the polarization dependence of CE, obtained in electrosynthesis of various chemical substances in HPE in aqueous electrolytes are analyzed and compared with the theoretical dependence to be observed in the case when the PICR is valid.

EXPERIMENTAL

At present, the following electrosynthesis processes performed in HPE are known, for which the depen-

1070-4272/05/7802-0254 © 2005 Pleiades Publishing, Inc.

dence of the CE by the target product on potential has been determined [2].

(1) Reduction of carbon monoxide on Ni and other metals in a 3M solution of H_2SO_4 [2, 3, 15]. It was found that, as the polarization becomes stronger, the CE by the target products (ethane and other hydrocarbons) increases. The reaction proceeds on the background of a vigorous evolution of hydrogen, and the CE by the target products is several percent. In this case, it may be assumed that the PICR is observed.

The data of [16] show that the Tafel slope for the reaction of hydrogen evolution is close to 0.12 V in this case.

The authors of [2, 15] assume that the rate-determining stage of electroreduction of CO under the conditions studied is addition of a first electron to an adsorbed molecule of carbon monoxide. Then, the apparent transfer coefficient of the electrochemical reaction with a successive transfer of several electrons is equal to the true coefficient [10]. One of definitions of the transfer coefficient means that this coefficient accounts for the asymmetry of the forward and reverse processes [17], i.e., the reverse reaction is strongly hindered. It may be assumed, on the basis of this definition, that the transfer coefficient exceeds 0.5 in the case in question. Then the Tafel slope for the electrochemical reaction of CO reduction must be less than 0.12 V, and the ratio of the Tafel slopes of the forward and side reactions, less than unity. Then, the CE by the target product must grow with increasing polarization, and this is the case in actual practice.

(2) Reduction of carbon dioxide on Zn and Sn in $NaHCO_3$ solutions [2]. The current efficiency by the electrosynthesis product, formic acid, is virtually independent of the electrode potential. Hydrogen evolution is the competing reaction.

As in the case of CO, it may be assumed that the rate-determining stage is addition of a first electron to an adsorbed CO_2 molecule. In this case, the apparent transfer coefficient must be equal to the true one. A reverse reaction, oxidation of formic acid to CO_2, is known, and, therefore, it would be expected that the transfer coefficient is close to 0.5. Then the Tafel slope for the electrochemical reaction of CO_2 reduction to formic acid must be close to 0.12 V. It would be expected that the ratio of the Tafel slopes of the forward and side reactions should be close to unity and no significant change in CE must occur as the polarization becomes stronger.

(3) Electrochemical chlorination of *N*-alkanes on graphite in a 6 M solution of HCl [2, 13, 14]. The current efficiency by the products of electrosynthesis, monochloralkanes, markedly increases as polarization becomes stronger. The competing reaction is evolution of chlorine gas. The Tafel slope for chlorine evolution on graphite at comparatively strong polarizations is 0.12 V [18].

In evaluating the Tafel slope for the reaction of electrochemical chlorination of alkanes, the process of chlorination itself can be understood as the succeeding chemical rate-determining stage in which no electron is transferred. Naturally, the assumption that the chlorination process occurs in a single stage is rather incorrect, but has no effect on the substance of the matter. In this case, the apparent transfer coefficient is equal to the ratio between the number of preceding stages, *m*, and the stoichiometric number, which is unity for hydrogen evolution [10]. Consequently, the Tafel slope can be taken to be approximately 0.03 V for the process of electrochemical chlorination. Then the ratio of the Tafel slopes for the forward and reverse reactions is less than unity and the CE by monochloralkanes must increase as polarization becomes stronger, and this is the case in actual practice.

(4) Electroreduction of nitromethane to methylhydroxylamine in a 3 M solution of HCl [2, 19]. The competing reaction is electroreduction of nitromethane to methylamine. The current efficiency by methylhydroxylamine decreases as polarization becomes stronger.

According to the scheme of electrochemical reduction of nitroalkanes, presented in [20], methylhydroxylamine formed in four-electron reduction of nitromethane can undergo further two-electron reduction to methylamine.

It is known that, for electrochemical reactions with successive transfer of several electrons, there exists the relation [2]:

$$\alpha_{eff} = m/\nu + n\alpha, \quad (1)$$

where α_{eff} is the apparent transfer coefficient; *m*, number of stages preceding the rate-determining stage; ν, stoichiometric coefficient; α, true transfer coefficient; and *n*, number of electrons transferred in the rate-determining stage.

When successive reactions occur, different numbers of stages that precede the rate-determining stage correspond to formation of the first and second prod-

uct. This means that that the quantity m in Eq. (1) for the second stage increases by a certain amount p, which shows how far apart are the rate-determining stages of formation of the first and second product. In the simplest case, it can be taken that, in considering the succeeding reaction, ν, n, and α remain the same as those for the first reaction. Then, it can be written that

$$\alpha_{\text{eff}_2} = (m + p)/\nu + n\alpha. \quad (2)$$

Comparison of expressions (1) and (2) shows that the ratio of Tafel slopes for the first and second stages is less than unity, and, therefore, the rate of the second stage must grow as potential increases, and this is the case in the actual practice.

(5) Electroreduction of *ortho*-nitrophenol to *ortho*-aminophenol [2, 21] **on copper electrodes.** The competing reaction is formation of azoxyphenol and azophenol in an alkaline medium and evolution of hydrogen in an acid medium.

The formation of noticeable amounts of side products in reduction of *ortho*-nitrophenol in an alkaline medium can be accounted for by the fact that the rate-determining stage is the same for the target and side processes [8]. If a medium of another type is taken, the ratio of the rates of the target and side reactions substantially changes, with the result that *ortho*-aminophenol is mostly formed in an acid medium in the given case.

In an acid medium, the share of the side process, i.e., hydrogen evolution, is insignificant and it increases as polarization becomes stronger. Nevertheless, the potentials at which the process is performed are sufficiently high for hydrogen evolution to occur. Hence follows that, in the case in question, PICR is not observed and it is difficult to explain the polarization dependence of the CE.

(6) Electrooxidation of aliphatic alcohols in HPE under the conditions of formation of higher nickel oxides [2, 22]. The competing reactions are formation of higher nickel oxides and oxygen evolution.

As the electrode potential becomes higher, the current efficiency by carboxylic acids first increases and then falls. At low polarizations, the CE by carboxylic acids grows with increasing potential. This behavior can be readily understood if the reaction of higher nickel oxides with adsorbed alcohol molecules is taken to be the rate-determining stage. Then, according to EQ. (1), the Tafel slope for the reaction of electrooxidation of alcohols will be smaller than that for the reaction of formation of higher nickel oxides, and, consequently, a rise in the CE by carboxylic acids must be observed as the potential becomes higher. With the potential increasing further, O_2 evolution commences, i.e., there appears an extra competing reaction and, as a result, the CE by carboxylic acids starts to decrease.

(7) Dechlorination of 1,1,2-trichlorotrifluoroethane [2, 23–25]. The target electrochemical reaction occurs at potentials of hydrogen evolution, but the CE by the target product is close to 100%. This means that the electrochemical reaction of H_2 evolution is very strongly suppressed in dechlorination of 1,1,2-trichlotrifluroethane, and, consequently, application of PICR is not justified.

(8) Electrochemical reduction of oxygen to hydrogen peroxide [3, 26]. The target electrochemical reaction occurs with a sufficiently high current efficiency. The CE by hydrogen peroxide decreases as polarization becomes stronger.

In electrosynthesis of H_2O_2 from oxygen in hydrophobized carbon black electrodes, hydrogen evolution is not a competing reaction. The fact that the current efficiency is less than 100% in this case can be attributed to occurrence of processes involving H_2O_2, of both electrochemical and purely chemical nature. Therefore, it can be assumed that the sum of processes of H_2O_2 decomposition can be represented in a certain overall form and the Tafel slope of such an electrochemical dependence will be smaller than that of the reaction of H_2O_2 formation. Then, it would be expected that the CE should decrease with increasing polarization, and this is the case in actual practice.

It should be noted that the considerations concerning the possible Tafel slopes of the target and side reactions are rather simplified. Nevertheless, a slope ratio larger or smaller than unity can be used, with certain reservations, to make the necessary conclusions. For clarity, the results of discussions of the known polarization dependences of CE are summarized in the table.

In those cases when PICR is observed, the CE by the target product increases or decreases as polarization becomes stronger, depending on the ratio of the Tafel slopes of the target and side reactions. If this ratio is less than unity, the CE by the target product increases with polarization. Then, it is advisable to perform the process of electrosynthesis at strong polarizations. If, by contrast, this ratio exceeds unity, the CE by the target product decreases as polarization

Character of variation of the CE of the target reactions with increasing polarization and deviation of the ratio of the Tafel slopes of the target (b_1) and side (b_2) reactions from unity for some processes of electrosynthesis in HPE

Electrosynthesis process	Applicability of PICR	Presumed b_1/b_2 ratio	Behavior of CE with increasing polarization
$CO \rightarrow C_2H_6$	+	<1	Grows
$CO_2 \rightarrow HCO_2H$	+	≈1	No noticeable change
$HR \rightarrow ClR$	+	<1	Grows
$CH_3NO_2 \rightarrow CH_3NHOH$	+	>1	Decreases
ortho-Nitrophenol → *ortho*-aminiphenol:			
in alkaline medium	–	?	No noticeable change
in acid medium	–	?	≈100%, decreases
$RCH_2OH \rightarrow RCOOH$	+	<1	Grows
1,1,2-trichlorotrifluoroethane → chlorotrifluoroethylene	–	?	≈100%, decreases
$O_2 \rightarrow H_2O_2$	+	>1	Decreases

becomes stronger. Then, a high CE by the target product can be achieved if electrosynthesis is carried out at low polarizations.

A clearly pronounced noncompliance with the PICR in electrosynthesis is observed when the competing process is strongly suppressed by the products formed in the target reaction. In this case, the CE by the target process is, as a rule, high. The CE becomes considerably less than 100% when the rate-determining stages for the target and side processes coincide. In this case, the CE can be raised by creating conditions under which the rate of the side process becomes considerably lower than that of the target process.

CONCLUSIONS

(1) If the principle of independence of concurrent reactions is observed, the current efficiency of the target reaction depends on the ratio of the Tafel slopes of the target and side reactions. If this ratio is less than unity, the current efficiency by the target product increases with polarization. At a slope ratio exceeding unity, the current efficiency decreases.

(2) If the principle of independence of concurrent reactions is not observed, the competing process is strongly suppressed and a rather high current efficiency by the target product is observed.

(3) If the principle of independence of concurrent reactions is not observed and the limiting stages of the target and side processes coincide, the current efficiency may be considerably less than 100%.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Cyclic Voltammetry of a Fluoride-Selective Electrode in Contact with Metals

Abstract—Electrochemical behavior of the interface between a $LaF_3 : Eu^{2+}$ single-crystal fluoride-selective membrane and Bi, Sn, Pb, Sb, and Cd metallic microelectrodes is considered with the aim to apply a fluoride-selective electrode in solid-state voltammetry. The ionization–discharge processes on the metals in air, involving mobile fluoride ions from the LaF_3 membrane, were studied by cyclic voltammetry.

Eu^{2+}- or Sr^{2+}-doped LaF_3 single crystals exhibit unique properties, of which the most important are the homopolar fluoride ionic conductivity and high chemical resistance in aqueous and nonaqueous solutions and in air. These features enabled application of fluoride-conducting solid electrolytes (FSELs) in various devices, such as fluoride-selective electrode (FSE) [1, 2], sensors for F and HF [3–5], oxygen and oxygen-containing gases [6–8], and chemical power sources [9, 10].

The aim of our studies is to apply FSELs to full-solid-state voltammetry with FSE. Previously, we have shown that anodic polarization of the interface between the LaF_3 (0.8 mol % Eu^{2+}) membrane of an FSE with metals produces an intermediate phase and modifies the interface to give $LaF_3 \mid MF_n \mid M$ electrodes. A stripping voltammetric (SVA) study of electrochemical processes involving mobile fluoride ions from FSEL revealed such trends as the dependence of the peak potential of cathodic curves on the nature of the metallic electrode and the dependence of the peak current of the cathodic curves on the potential sweep rate V and on the charge Q consumed for formation of MF_n [12–14]. These trends have been found for the interface between a metallic electrode and a membrane of FSE with an aqueous [12–14] or solid-state reference system [15]. We have also reported relationships between the peak current and the contact area of Bi [16] and Ag [17] with the membrane.

Here we report the results of further studies of the electrochemical behavior of the interface between $LaF_3 : Eu^{2+}$ single-crystal membrane of FSE and metallic electrodes in air in systems simulating trace contamination of a metallic surface (Ag foil) with such metals as Bi, Sn, Sb, Pb, and Cd. The possibility of simultaneous solid-phase determination of several metals on the surface of conducting solids was studied using cyclic voltammetry.

EXPERIMENTAL

In this study we used fluoride-selective electrodes with polished membranes (1–1.5 mm thick, 5 mm in diameter) prepared from single-crystal LaF_3 activated with Eu^{2+} (0.8 mol %). The internal reference system was built up using a large-area Ag/AgCl electrode and an aqueous solution with high fluoride and chloride concentrations. The use of the aqueous electrolyte allowed elimination of uncontrollable polarization effects at the junctions between the FSE membrane and the reference system in studying the processes at the FSEL | M interface.

The measurements were carried our in FSE | M two-electrode pressed-contact cells using a PU-1 polarograph, an LKD 4-003 *x–y* recorder, and an I-120 ion meter. The solid electrolyte and metal surfaces were pretreated as in [13, 14]. Experimental data were processed using the Microcal Origin v.7.0 software package.

To improve the data reproducibility, we tested fluoride-selective electrodes prior to use. The procedure involved (1) measurement of electromotive force of FSE as a function of the F^- activity in aqueous KF solutions (acetate buffer, pH 5) over

We experimentally demonstrated the necessity for a preliminary control of the voltammetric and potentiometric responses of FSE. It was confirmed the quality of the surface of the FSE membrane to affects the electrode sensitivity and the response time in dilute fluoride solutions (pF ~ 5). Contamination of the membrane surface makes shorter the linear portion in the concentration dependence of the electromotive force and impairs the lower detection limit of the fluoride ion in aqueous solutions.

In the potentiometric mode, we found no effect of cleaning; however, voltammograms of cell (1) appeared to be more sensitive to this factor. The potentiodynamic curve allows detection of a contamination that remained unnoticed under the equilibrium conditions. The criteria of thorough cleaning of the membrane surface and readiness of FSE to be used in an experiment was the linearity of the *I–E* curve of cell (1) within ±3 V and also the independence from the sweep rate over the range 0.002–0.05 V s^{-1} (Fig. 1a, curves *1*, *1*'). The deviation of the *I–E* curve from linearity in the experimental potential range, hysteresis of the curve, which becomes more pronounced as the sweep rate V increases, and also the rise in the cell resistance, determined as the slope of the linear portion of the *I–E* curve of cell (1), as compared to the active component of the impedance at a frequency of 1 kHz, all these facts indicated that an additional cleaning of the membrane was necessary. The current–voltage characteristic of symmetric cell (1) was also used in choosing the potential sweep rate, estimating of the ohmic drop of the potential across the solid electrolyte, and selecting electrodes with a membrane resistance of no more than 50 kΩ.

A steady-state or dynamic current–voltage curve of asymmetric cell (2) (Fig. 1a, curves *2*, *2*', *3*) allowed estimation of the working potential range within which one could observe formation of fluorides of the metals in contact with the FSE membrane and also their reduction. In the cathodic range (Fig. 1a, curve *2*), at a potential more negative than E^0 = –2.94 V, the current is mostly caused by the reduction of the fixed cation of the membrane, whose anodic oxidation is reflected by curve *2*' in Fig. 1a [11]. An anodic polarization of the LaF_3 | Y interface from –1.5 V to E > +4.0 V produced a weak current, which decreased or even disappeared upon repeated polarization (Fig. 1a, curve *3*). Therefore, the reaction of the fluoride ion with yttrium as a working electrode was not detected, which can be attributed to the fact that fluorination of yttrium is hindered, and the electrochemical treatment of the interface results in inhibition of the reaction. Furthermore, the standard potential $E^0(Y, YF_3)$ = –2.81 V, estimated from $\Delta G^0_{298}(YF_3)$ = –1655.2 kJ mol^{-1}, is more negative than $E^0(La, LaF_3)$ = –2.76 V, estimated from $\Delta G^0_{298}(LaF_3)$ = –1643 kJ mol^{-1}, or that determined experimentally (–2.765 ± 0.005 V) [11]. Thus, the charge transfer at the ionic semiconductor–electronic conductor (LaF_3 | Y) heterojunction in cell (2) is blocked up to the potential corresponding to decomposition of the membrane by the reaction $La^{3+}_M + 3e \rightarrow La_M$, and the fluorine evolution $2F^- - 2e \rightarrow F_2\uparrow$ (E^0 = +2.87 V)

has a high overvoltage. Therefore, the current–voltage characteristic of the cell has a wide ideal polarizability range, and it could be regarded as a background curve in studying reactions between the fluoride ions from the FSE membrane and metals. Such an electrochemical stability of the membrane allows extension of the working potential range in solid-state voltammetry with FSE to 7 V.

An inadequate treatment of the $LaF_3 \mid Y$ interface is reflected in the voltammogram of cell (2) as overvoltage of La reduction with the current of the reaction appearing at a more negative potential than –3.0 V. In some cases, we observed in a cathodic potential sweep polarization at a more positive potential than –3.0 V. Presumably, this is caused by adsorption relaxation of the electrical double layer with participation of the cations of the membrane, as a result of hindered injection of electrons. We could eliminate the indicated undesirable effects, which make both the experiment and interpretation of the results more difficult, by mechanical or chemical treatment or by using electrochemical regeneration of the surface of the solid electrolyte in strongly acidic fluoride solutions [13, 14].

We studied the voltammetric response of the FSE membrane/metal interface in the cycling mode using cells (3)–(5), which gradually become more complex:

$$Ag, AgCl \mid KCl\ 1\,M,\ KF\ 1\,M \mid LaF_3 : Eu^{2+} \mid M_s, \quad (3)$$

$$Ag, AgCl \mid KCl\ 1\,M,\ KF\ 1\,M \mid LaF_3 : Eu^{2+} \mid M_1\ (M_s), \quad (4)$$

$$Ag, AgCl \mid KCl\ 1\,M,\ KF\ 1\,M \mid LaF_3 : Eu^{2+} \mid (M_1 + M_2)\ (M_s). \quad (5)$$

In cell (3), the metallic support M_s was used as a working electrode, while in cells (4) and (5), the working electrodes were microsamples of metals M_1 and M_2, with M_s serving as a support and a current lead. The fluoride-selective electrode operated as a counter electrode and a reference. As a support and current lead we used a 0.1 mm-thick high-purity silver foil pretreated by annealing at 300 – 400°C to refresh the surface. Silver was chosen because it has the highest positive potential of formation of the fluoride, $E^0(Ag \mid AgF) = 0.95$ V (Fig. 1b), which restricts the anodic potential range of cycling in cells (4) and (5). Another reason was the reversibility of this reaction. The working electrodes investigated were Sn, Bi, Pb, Cd, and Sb metals. The standard potentials of formation of the corresponding fluorides $E^0(M \mid MF_n)$ (SnF_2 –0.23, BiF_3 –0.01, SbF_3 –0.05, PbF_2 –0.34, and GdF_3 –0.45 V, respectively), determined from experimental data [12, 16] using stripping voltammetry, are shown in Fig. 1b. The area of metallic microsamples on the support ranged from 0.01 to 0.08 mm^2. The area was determined before the experiment, using an ocular micrometer of an MBS-1 microscope (magnification ×64). After the experiment, the contact spot area was determined similarly.

The experimental system was designed as a voltammetric sensor [16], providing mechanical contact of the metal with the FSE membrane and the support.

Microamounts of Bi, Sn + Bi, Pb + Sb, and Cd + Bi were arranged on Ag foil. Such a selection of the pairs is caused by the fact that the potentials at which the electrode reactions involving a metal and the fluoride ion from the solid electrolyte take place differ by more than 120/*n* mV, suggesting the possibility of simultaneous detection of the metals. Our previous studies of the $LaF_3 \mid M$ interface by stripping voltammetry [12, 13] revealed that the formation of Bi and Sn fluorides at the optimal generation potentials can be quasi-reversible, while Pb and Sb irreversibly react with the fluoride ion. Therefore, it was of interest to study the interface between the FSE membrane and Cd + Bi electrodes on the Ag support, i.e., the effect of electropositive elements on the cathodic signals of cadmium, in view of the fact that stripping voltammograms showed one reduction peak upon anodic polarization of the interface, and after repeated polarization, the cathodic current abruptly dropped and then disappeared at all [16].

$LaF_3 : Eu^{2+} \mid Ag$ interface. In order to specify the anodic limit of cycling in simulating contamination on a conducting substrate, we recorded the cyclic voltammogram of the cell

$$Ag,\ AgCl \mid KCl\ 1\ M,\ KF\ 1\ M \mid LaF_3 : Eu^{2+} \mid Ag \quad (6)$$
$$\text{or } FSE \mid Ag,$$

where the working electrode was an Ag foil. The current–voltage characteristic of the FSE membrane/Ag foil interface, recorded at $V = 0.05$ V s^{-1} in the ranges from 0 to +1.2 V and from +1.2 to –3.0 V, is shown in Fig. 1a (curves *2*, *2*', *4*, *4*'). As mentioned above, curves *2* and *2*' refer to the oxidation–reduction of lanthanum, and curves *4* and *4*', to oxidation–reduction of silver, which was observed at a potential of about 0.7 V. The anodic–cathodic curve of the FSE | Ag interface shows a hysteresis loop (Fig. 1a, curves *4*, *4*'), which suggests, in solutions, hindered crystallization [18, 19]. However, this does not contradict our previous potentiostatic data on the formation of metal fluorides at the unconditioned FSE | metal interface in air [14]. From curves *2*, *2*', *4*, and *4*' (Fig. 1a) we determined the anodic limit of the potential range in which

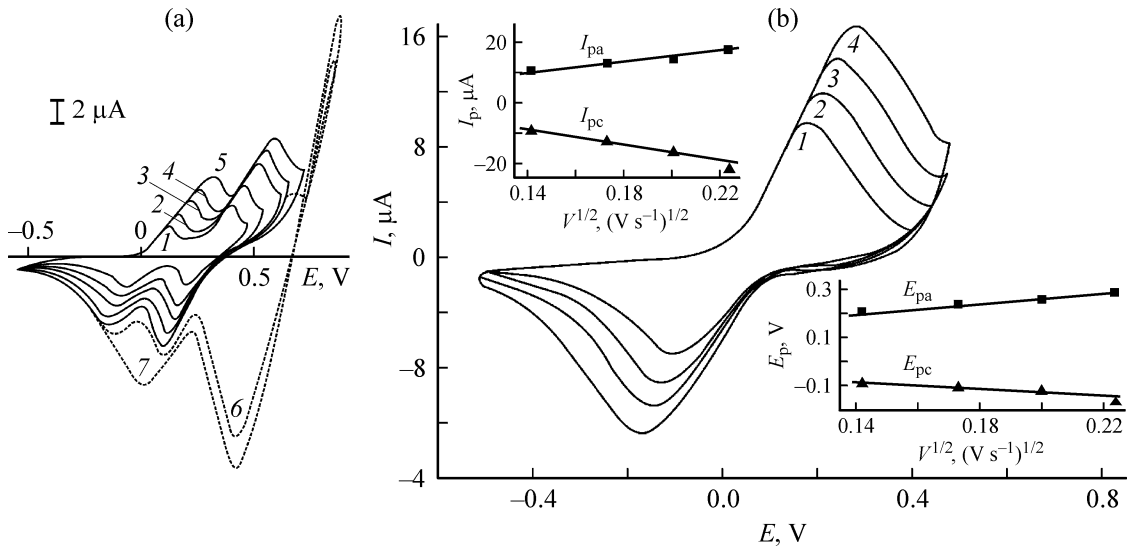

Fig. 2. Cyclic voltammograms *I*–*E* of the cell FSE | Bi | Ag, recorded at V = 0.01–0.05 V s^{-1} and the anodic polarization limit extended to (a) (*1*–*5*) 0.7 and (*6*, *7*) 0.9 V, and (b) at a potential of –0.5 to +0.5 V (first peak) and a sweep rate of (*1*) 0.02, (*2*) 0.03, (*3*) 0.04, and (*4*) 0.05 V. (b) Upper inset: the anodic peak current I_{pa} and cathodic peak current I_{pc} vs. $V^{1/2}$; lower inset: anodic peak potential E_{pa} and cathodic peak potential E_{pc} vs. $V^{1/2}$; for explanations, see text.

a voltammetric response from the microsamples on the Ag support (conducting matrix) could be detected.

LaF_3 : Eu^{2+} | Bi | Ag interface. In the cell

$$\text{FSE} \mid \text{Bi} \mid \text{Ag}, \qquad (7)$$

the FSE membrane was in contact with a microsample of Bi (S = 0.008 mm^2) and the Ag support. The potentiodynamic *I*, *E* response of the solid-phase interface, obtained in the potential range from –0.5 to +0.75 V at a sweep rate varied from 0.01 to 0.05 V s^{-1}, showed two anodic and one cathodic peaks corresponding to oxidation–reduction of Bi (Fig. 2a, curves *1*–*5*). Data presented in Fig. 2a were obtained after the 12th anodic–cathodic cycle. The extension of the anodic limit to +0.9 V and a reverse potential sweep resulted in occurrence of the third cathodic peak corresponding to the reduction of oxidized silver (Fig. 2a, curves *6*, *7*).

A more detailed examination of the first peak corresponding to oxidation of Bi is presented in Fig. 2b as an anodic–cathodic cyclic voltammogram (CVA) of the FSE|Bi interface on the Ag foil, obtained with a Bi microsample (S = 0.02 mm^2) in the potential range from –0.50 to +0.48 V at the sweep rate varied from 0.02 to 0.05 V s^{-1}. When recording the curve from –0.1 to +0.2 V and altering the sweep direction, we observed a typical hysteresis loop similar to that considered above for the FSE | Ag interface, suggesting hindered growth of a new phase with Bi. In the initial portion, the anodic curve is independent of *V*, which is indicative of hindered charge transfer.

The following trends were observed for the anodic and cathodic peaks. The dependences of log I_{pa1} and log I_{pc1} on log V are linear with a slope of 0.52 and 0.58, respectively. Therefore, I_{pa1} and I_{pc1} are linear functions of $V^{1/2}$ (Fig. 2b), confirming that the process is diffusion-controlled. The I_{pa1}/I_{pc1} ratio is close to unity (1.1–1.2) at a sweep rate from 0.02 to 0.04 V s^{-1}, which is one of the criteria of process reversibility. With increasing sweep rate (V > 0.06 V s^{-1}), the I_{pa1}/I_{pc1} ratio increases. The peak potentials E_{pa1} and E_{pc1} are linear functions of $V^{1/2}$ (Fig. 2b, lower inset). The dependence of the anodic peak potential T_{pa1} on the peak current I_{pa1} is linear over the entire experimental sweep rate range. The linear dependences of I_{pa} and E_{pa} on $V^{1/2}$ and also of E_{pa} on I_{pa} are typical of the growth of passivation films in electrolyte solutions, which is controlled by the electrolyte resistance in pores of the passivation layers [18, 20]. This suggests that the growth rate of the intermediate phase is controlled by the interfacial resistance R_c between the membrane and working electrode, allowing estimation of R_c from the slope of the E_{pa}–I_{pa} curve at $V \neq$ const. In the potentiodynamic experiments,

$$E(t) = E_s + Vt + R_c I(t), \qquad (8)$$

where E_s is the initial potential; V, sweep rate; and $I(t)$, current across the working electrode.

The peak potential E_{pa} is written as

$$E_{pa} = E_o + R_c I_{pa} + \eta_r, \qquad (9)$$

where E_o is the potential at which the reaction current appears; I_{pa}, anodic peak current; and η_r, overvoltage limiting the growth rate of the phase.

The parameter $A = E_o + \eta_r$ in the equation $E_{pa} = A + R_c I_{pa}$ is independent of the sweep rate up to 0.05 V s^{-1}. The potential difference of the first peak, corrected for the ohmic polarization of the contact, $E_{pc1} - E_{pa1} = 2.2RT/nF = 0.06$, corresponds to single-electron charge transfer.

The potential difference of the second peak is $E_{pc2} - E_{pa2} = 0.12$ V (Fig. 2a). The linear dependence of the current of the second cathodic peak on $V^{1/2}$ was observed until the 11th cycle over the sweep rate range 0.01–0.05 V s^{-1}. However, in the 12th anodic–cathodic cycle at $V = 0.05$ V s^{-1} the function deviated from linearity (Fig. 2a). The limitation of the process rate is probably due to a conjugated chemical reaction. The potentials E_{pa2} and E_{pc2} are linear functions of $V^{1/2}$ up to $V = 0.05$ V s^{-1}. The dependence of E_{pa2} on the peak current I_{pa2} is also linear, but its slope is lower than that for the E_{pa1}-vs.-I_{pa1} plot. The extension of the polarization range toward the more positive values and the delay at $E = 0.9$ V gave rise to the third cathodic peak associated with the reduction of AgF formed as a result of anodic polarization of the FSE | Ag interface, and also to an increase in the currents of the two peaks of step-by-step decomposition of BiF_3. An increase in the delay time at $E = 0.9$ V resulted in that the cathodic peaks corresponding to electrochemical transformations of the products of anodic oxidation of Bi merged.

After multiple cycling, we observed a finely dispersed black deposit at the FSE | Bi interface. At the same time, the shape of the curves, as well as the formal potential, remained unchanged.

The formation of BiF_3 involves several stages.

$$nF^-_{FSEL} \rightleftarrows nF^-_{sur}, \quad (10a)$$

$$Bi \rightleftarrows Bi_{ad}. \quad (10b)$$

Presumably, the fluoride ions play a role of an initiator for ionization of Bi. In this case, Bi adatoms can react with the fluoride ions of the solid electrolyte:

$$Bi_{ad} + nF^-_{sur} \rightleftarrows [BiF_n]^{n-}_{ad}, \quad (10c)$$

$$BiF^{n-}_{nad} \rightleftarrows BiF^{n-}_n. \quad (10d)$$

Since the adsorption of the reactants does not limit the reaction rate, and the potential difference of the first peak, corrected for the ohmic polarization of the contact, $E_{pc1} - E_{pa1} = 0.06$, the first peak can be assigned to the reaction

$$BiF^{n-}_n \rightleftarrows BiF^{(n-1)-}_n + e. \quad (10e)$$

The second peak corresponds to a reaction whose rate is lower as compared to the sweep rate of the polarization potential, e.g.,

$$BiF^{(n-1)-}_n \rightarrow BiF^{n-3}_n + 2e. \quad (10f)$$

If $n = 3$, the overall reaction can be written as

$$Bi + 3F^- \rightarrow BiF_3 + 3e.$$

The major distinctive features of the processes observed are the shift of the steady-state potential of the reaction $Bi \rightleftarrows Bi^{n+} + ne$ toward positive values and the two-peak nature of oxidation–reduction of Bi.

Previously, we observed in stripping voltammograms after anodic deposition at the FSE | Bi interface (without support or on a support made of an appropriate material) at optimal generation potential ($E_r = 0.4$ V), single-peak cathodic reduction curves of Bi [12]. The steady-state potential E_{st} of the product anodically generated under potentiostatic conditions, i.e., of the $LaF_3:Eu^{2+} | BiF_3 |$ Bi electrode formed at the $LaF_3 |$ Bi interface, was more negative [$E_{st}(Bi/BiF_3) = -0.23$ V] as compared to the product of anodic oxidation of Bi in the cycling mode ($E_{st} = 0.05$ V).

The shift of the deposition potential of metal atoms on a foreign metallic electrode toward a more positive value as compared to the reversible (Nernst) potential is known for electrocrystallization from aqueous and nonaqueous solutions and is actively discussed in the literature. This effect, known as underpotential deposition (ΔU_p), was studied using electrochemical, optical, and radiation-chemical methods. The effect is influenced by the surface conditions of the support (point and linear defects), surface energy, lattice constants of the substrate and deposited material, and also by the electrolyte composition, i.e., by the bulk and surface properties of the solids and components of the solution [21–24]. Lorenz *et al*. [25] interpreted the underpotential deposition of the product on single-crystal substrates as the formation of well-ordered two-dimensional metallic layers (superlattice structures). To explain the energy gain, ΔU_p was studied in relation to some physical characteristics of the system, such as the differences in electronegativities and in work functions of electron, W^e, between the substrate and active material [26]. With Bi as an active material and Ag as a substrate, the electronic work functions

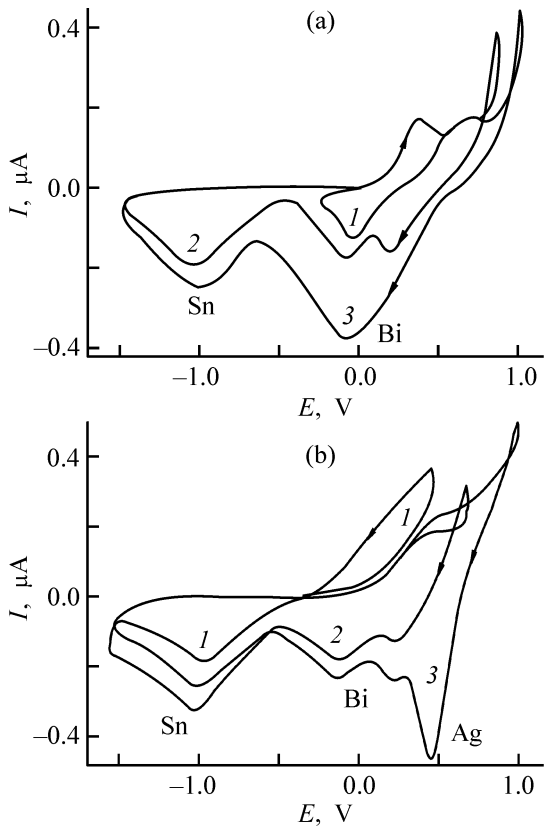

Fig. 3. Voltammogram *I*–*E* of the cell FSE | Bi + Sn | Ag (V = 0.05 V s^{-1}) with extension of the cycling limit and variation of the spot area ratio of the microsamples. (a) $S_{Sn} < S_{Bi}$ and (b) $S_{Sn} >> S_{Bi}$; for explanation, see text.

are quite similar (W^e_{Ag} = 4.3 and W^e_{Bi} = 4.4 eV [27]). A important parameter controlling the mechanism of formation of a new phase at a foreign solid-phase boundary is the binding energy of adatoms (or adions) of the active (deposited or ionized) metal to the substrate [28]. The formation of bismuth fluoride in air and the effect of the Ag support on this process can be accounted for by the fact that the binding between the Bi atoms is weaker than that between Bi and the Ag support. The more positive stationary potential can be attributed to a decreased thermodynamic activity and interaction of Bi with inert Ag support.

The effect of the support was confirmed in the experiments with a copper foil instead of a silver one. The standard potential $E^0(Cu|CuF_2)$ = 0.38 V is more positive than $E^0(Bi|BiF_3)$, but less positive than $E^0(Ag|AgF)$ = 0.95 V. However, after anodic polarization of the $LaF_3:Eu^{2+}|Bi$ (or Cu) interface, the estimated standard electrode potential $E^0(Bi|BiF_3)$ = –0.01 V well corresponded to that determined by SVA, and the reduction of anodically generated Bi was characterized by one broad peak. Evidently, in the case of the $LaF_3:Eu^{2+}|$ Bi (or Cu) interface, the Bi–Bi bonds are stronger than Bi–Cu bonds (W^e_{Cu} = 4.4 eV).

Effects similar to those found with the Ag support (splitting of Bi peaks and two-peak oxidation of Bi at a potential more positive than the equilibrium value) were observed in studying the deposition–ionization of Bi in aqueous solutions [29]. Also, a shift of the peak potential in the anodic curves in the presence of more electropositive components of the solution was reported [30].

$LaF_3:Eu^{2+}|(M_1 + M_2)|$Ag interface. Let us consider how introduction of one more impurity metal affects the voltammogram. After arrangement of Bi and Sn microsamples on the Ag support at a distance of 0.5–0.8 mm, the shape of the cyclic voltammograms of the cell

$$FSE|Sn + Bi|Ag \qquad (11)$$

depended on the spot area ratio of Sn and Bi microsamples. In the case when the Sn spot area was smaller than that of Sn ($S_{Sn} < S_{Bi}$), we observed after anode–cathode polarization from –1.0 to 0.5 V at V = 0.05 V s^{-1} a single-peak curve corresponding to oxidation–reduction of Bi (Fig. 3a, curve *1*), but we detected no reduction of Sn in the cathodic sweep. After an extension of the anodic sweep limit to E = 0.7 V, a delay at this potential, and a subsequent cathodic sweep, we obtained a two-peak Bi reduction curve and a single-peak curve (E_{pc} = 1.05 V) corresponding to reduction of Sn (Fig. 3a, curve *2*). The peak of Sn remained clearly pronounced after a delay at E = 0.9 V in the third cycle, although the overvoltage of Sn ionization increased again (Fig. 3a, curve *3*). To avoid a direct contact of the Ag support with the FSE membrane, the Ag foil was insulated with a Teflon film in this experiment.

In the case when $S_{Sn} >> S_{Bi}$, the shape of CVA somewhat changed (Fig. 3b). An anodic–cathodic sweep from –1.0 to –0.1 V showed oxidation (fluorination) of Sn and a cathodic peak of Sn (Fig. 3b, curve *1*). A repeated sweep with a delay at E = 0.7 V showed cathodic peaks of Bi and Sn (Fig. 3b, curve *2*). Raising the anodic polarization to +0.8 V (reverse sweep) allowed detection of an additional cathodic peak at 0.38 V reflecting the involvement of the Ag support in the reaction with the fluoride ions (Fig 3b, curve *3*) (in this case it was not insulated).

The specific features of the voltammetric response of the solid-phase interface in air are similar to those of anodic dissolution of alloys, when the potential of metal dissolution shifts toward the anodic range,

and, at certain component ratio, more electropositive components prevent or hinder selective dissolution of more electronegative components.

Figure 4 shows CVA of the cell

$$\text{FSE}\,|\,\text{Pb + Sb}\,|\,\text{Ag} \qquad (12)$$

recorded at $V = 0.05$ V s^{-1} with an extension of the anodic limit of cycling first to 0.7 V (Fig. 4, curve *1*) and then to 1.2 V (Fig. 4, curve *2*). The microsamples of Pb and Sb differed in their spot area ($S_{Pb} >> S_{Sb}$). Despite the fact that we used as model impurities metals tending to irreversibly form fluorides, the response of the LaF_3 : $Eu^{2+}\,|\,$Pb + Sb$\,|\,$Ag interface is similar to that observed for LaF_3:$Eu^{2+}\,|\,$Sn + Bi$\,|\,$Ag interface at the same component ratio. The cyclic voltammogram shows clearly pronounced peaks of Pb, Sb, and Ag. The occurrence of the second peak of Sb can be attributed to the fact that, as in the case of Bi, fluorination of Sb proceeds in two stages with step-by-step electron transfer. A repeated cycling of the FSE interface was accompanied by an increase in the overvoltage of the anodic reactions and, accordingly, by a decrease in the peak current of the cathodic curves, with the peak potentials shifted toward more negative values, which is associated with the limitation of the reaction rates by conjugated chemical reactions.

It is known that introduction of a third component frequently improves the sensitivity of voltammetry in aqueous solutions [31]. We observed a similar effect in recording a CVA of the cell with Cd and Bi microimpurities on an Ag support. Figure 5 shows the voltammogram of the FSE$\,|\,$Cd + Bi$\,|\,$Ag interface. After anodic polarization to 0.5 V, we observed in the cathodic sweep a reduction peak of fluorinated cadmium (Fig. 5, curve *1*). In the second cycle, with extension of the anodic polarization limit to 0.9 V, the cathodic curve shows three peaks corresponding to Cd, Bi, and Ag (Fig. 5, curve *2*). The cathodic peak current of reduction of anodically generated cadmium is slightly lower, being shifted toward the negative range. However, this peak is more clearly pronounced than that in the stripping voltammogram without an Ag support [16].

CONCLUSIONS

(1) Cyclic voltammetry of fluoride-selective electrode in contact with metallic microelectrodes allows simultaneous detection of electrochemical responses from several metals. Such a technique can be used for local determination of trace amounts of Bi, Sn, Pb, Sb, and Cd on a silver support in air.

(2) This is a reagent-free method of qualitative analysis, which is nondestructive with respect to both the LaF_3 membrane and a solid phase to be analyzed.

(3) In this method, the medium to be analyzed is a solid, rather than a liquid, and the working potential range (about 7 V) is significantly wider than that in aqueous and nonaqueous solutions with liquid and solid-state electrodes.

(4) The dependence of the voltammetric response of the fluoride-selective electrode on the relative amounts of impurity metals on the conducting support is established.

(5) Electropositive components (silver support) affect the formation of the output signal at the interface between a fluoride-conducting solid electrolyte and metallic electrodes.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Metal Ion Buffer Systems for Ionometry in Water–Ethanol Mixtures and Micellar Medium of Sodium Dodecyl Sulfate

O. S. Chernysheva, L. P. Loginova, and V. D. Bazilyanskaya

Karazin National University, Kharkov, Ukraine

Received January 22, 2003; in final form, April 2004

Abstract—The concentration dissociation constants of nitrilotriacetic acid and the concentration stability constants of Cd(II) complexes with the nitrilotriacetic acid anion in water–ethanol mixtures and of Cu(II) and Cd(II) complexes with *o*-phenanthroline and 2,2'-bipyridine in micellar solutions of sodium dodecyl sulfate were determined potentiometrically. Based on the concentration constants determined, Cd^{2+} and Cu^{2+} buffer solutions were developed for calibration of a Cd^{2+}-selective electrode in water–ethanol mixtures and Cd^{2+} and Cu^{2+}-selective electrodes in micellar solutions of sodium dodecyl sulfate within the ranges pCu 9.7–13.5 and pCd 7.5–11.8.

Mixed, organic, or micellar solutions of surfactants can be an alternative to aqueous solutions for study of protolytic and complexing properties of bioactive substances that are poorly soluble in water by potentiometry with solid membrane electrodes [1].

Change of a medium is accompanied by the shift of the calibration characteristics of ion-selective electrodes (ISE), which should be considered when calibration solutions are prepared.

Electrolyte solutions prepared by successive dilution are suitable for ISE calibration at concentrations of the ion to be analyzed higher than 10^{-4}–10^{-5} M. In more dilute solutions, the actual concentration of the potential-determining ion differs from the calculated concentration because of the solution contamination or losses caused by adsorption, oxidation, etc. [2]. The ISE calibration dependences for dilute solutions deviate from linearity, with their slope decreasing [3], which corresponds to additional supply of the potential-determining ion into the solution, primarily from the membrane material. Iodide and sulfide-selective electrodes with more complex response in dilute solutions are an exception [4].

The stable low (less than 10^{-4}–10^{-5} M) concentrations of the potential-determining ion are provided by metal ion buffer systems based on chemical reactions, involving reactants in relatively high total concentrations. This idea, which is the basis of the calibration in the pH-metry, is used in making metal and anion-buffer systems. Already in early studies concerned with ISE, heterogeneous ion buffer systems containing silver halide and sulfide mixtures were used [5]. Still earlier, metal buffer systems as media for biological investigations were suggested [6, 7]. Metal buffer systems are also used in other analyses [8, 9]. Recently, they have been used in studying the effect of oxygen dissolved on Cu^{2+} ISE [10].

The known ion-buffer systems are mainly used for calibration of ISE with solid-phase membranes, for which transfer of the potential-determining ion from the membrane to the solution substantially exceeds the equilibrium solubility and is caused by the elution processes [4].

In this study, we applied the principle of Cd^{2+} and Cu^{2+}-selective electrode calibration with metal ion buffer solutions to new media: water–ethanol mixtures and media with a higher level of structuring, i.e., surfactant micellar solutions (sodium dodecyl sulfate, SDS).

The commonly used components of metal ion-buffer systems are the carboxyl-containing complexing agents: imidoacetic (H_2Ida), nitrilotriacetic (H_3Nta), and ethylenediaminetetraacetic (H_4Edta) acids, although metal ion-selective electrodes show in their presence an anomalous behaviorwhich becomes more pronounced $Ida^{2-} < Nta^{3-} < Edta^{4-}$ [11]. It has been shown earlier that Cu^{2+} buffer systems based on

* In $\log K_2$ calculation, $\log K_1 = 11.07$ was used.

Cu(II)–Ida^{2-} complexes are suitable for calibration of a Cu^{2+}-selective electrode in aqueous ethanol [12]. In this study, we took nitrilotriacetic acid anion as a ligand for cadmium-buffer systems. The Cd(II) complexes with Nta^{3-} are very stable, and the specific influence of Nta^{3-} on the membrane of the Cd^{2+}-selective electrode is weaker than that in the case of $Edta^{4-}$, at least in aqueous solutions.

The equilibrium constants of complexation and concomitant reactions are required to calculate the main characteristics of the metal-buffer systems. The experimentally found complexation constants are concentration constants. This allows the negative logarithm of the equilibrium concentration of free metal ions $pM = -\log[M^{2+}]$ to be regarded as the main characteristic of metal ion buffer solution [13].

The acid–base equilibria of the components of the cadmium buffer system were studied by pH-metric titration. The logarithms of the acid–base equilibrium constants in the water–ethanol mixture are presented below:

$H_2O \rightleftarrows H^+ + OH^-$, $\log K_w = -14.76 \pm 0.1$;

$H_3NTA \rightleftarrows H^+ + H_2NTA^-$, $\log K_{a1} = -3.24 \pm 0.08$;

$H_2NTA^- \rightleftarrows H^+ + HNTA^{2-}$, $\log K_{a2} = -3.82 \pm 0.08$;

$HNTA^{2-} \rightleftarrows H^+ + NTA^{3-}$, $\log K_{a3} = -8.13 \pm 0.03$;

$Cd^{2+} + 2OH^- \rightleftarrows Cd(OH)_2$, $\log \beta_{OH2} = 14.75$.

The pK_{a3} of nitrilotriacetic acid was calculated with high errors, probably, due to specific interaction of Nta^{3-} with a glass membrane [14]. The pK_{a3} was determined spectrophotometrically in a water–ethanol mixture with Bromocresol Red as an indicator with $pK_a = 7.53 \pm 0.04$ (λ_{max} of the base form 595 nm, and that of the acid form 425 nm).

Complexation of Cd^{2+} with Nta^{3-} should be studied by the method independent of Cd^{2+}-selective electrode. However, the usual method of the competitive pH-metry is inapplicable for determination of the $CdNta^-$ stability constant exceeding the Nta^{3-} protonation constant. At the same time, the result obtained with the Cd^{2+}-selective electrode may be distorted by specific influence of Nta^{3-} on ISE membrane. We applied three different approaches to make the experimental stability constants of the Cd^{2+} complexation with the Nta^{3-} ions more reliable. In each case, the titration conditions were chosen so that the ion determined potentiometrically had the lowest equilibrium concentration [15]. In the first case, it was the cadmium(II) ion and, in the second and third cases, the hydrogen ion. The use of additionally controllable property in the calculations allowed us to obtain a more precise information on the complex composition and constants. The well consistent results (Table 1) show that Nta^{3-} does not exert any specific influence on the Cd^{2+}-selective electrode membrane in aqueous ethanol and that the constants obtained are reliable.

The simple cadmium-buffer systems contain the highest complex $Cd(Nta)_2^{4-}$ and excess unbound ligand; the reaction

$$Cd(Nta)_2^{4-} \rightleftarrows Cd^{2+} + 2Nta^{3-} \quad (1)$$

provides buffer action with respect to Cd^{2+}.

In this case, the unbound Nta^{3-} anion can be involved in the competitive protolytic equilibria. Therefore, simple cadmium-buffer systems are pH-dependent [7]. Their equilibrium composition was calculated with regard to pH measured (Table 2, buffer solutions 1–3).

If there are no competitive protolytic reactions in metal buffer systems, the concentration of the un-

Table 2. Composition and characteristics of aqueous–ethanolic cadmium-buffer solutions, I = 0.01 M ($LiNO_3$)

Version no.	Total concentration, M	Reaction	pH	pCd_{calc}	pCd_{exp}	Buffer capacity, M
1	$Cd(NO_3)_2$, 2.3×10^{-4} H_3Nta, 1.15×10^{-3} NaOH, 3.45×10^{-3} $LiNO_3$, 4.19×10^{-3}	(1)	8.96	12.32	12.32	2.6×10^{-4}

3	$Cd(NO_3)_2$, 5.0×10^{-4} H_3Nta, 7.5×10^{-4} NaOH, 2.25×10^{-3} $LiNO_3$, 5.51×10^{-3}	(1)	7.88	10.19	10.13	2.4×10^{-4}
4	$Cd(NO_3)_2$, 6.9×10^{-4} H_3Nta, 8.4×10^{-4} NaOH, 2.52×10^{-3} $LiNO_3$, 4.71×10^{-3}	(3) pH-independent	–	9.70	9.68 ± 0.09	1.9×10^{-4}

bound ligand and the system as a whole are pH-independent. To make pH-independent buffer systems, we used the fact that, in the region of coexistence of two complexes, the buffer capacity with respect to Nta^{3-} is determined by the equilibrium

$$Cd(Nta)_2^{4-} \rightleftarrows Nta^{3-} + CdNta^{-}. \quad (2)$$

Then, the buffer effect with respect to Cd^{2+} is described by the reaction

$$2Cd(Nta)^{-} \rightleftarrows Cd^{2+} + CdNta_2^{4-}. \quad (3)$$

An optimization of the cadmium-buffer system composition by methods described in [16] showed that, at a fixed ionic strength μ = 0.01 M, the solution containing 2.08×10^{-3} M $CdSO_4$, 2.54×10^{-3} M H_3Nta, and 7.62×10^{-3} M NaOH has the maximum buffer capacity. However, a precipitate was formed when the solution with such a composition was prepared directly. Therefore, the concentrations of the components of the buffer solution were decreased with their optimal ratio preserved (Table 2, buffer solution no. 4). In contrast to the first three buffer solutions, the pCd of solution no. 4 can be calculated without additional pH determination by the equation

$$pCd = 7.14 + \log(c_L - c_{Cd}) - 2\log(2c_{Cd} - c_L), \quad (4)$$

where c_L and c_{Cd} are the total molar concentrations of H_3Nta and $Cd(NO_3)_2$, respectively.

The good agreement of the calculated and experimental pCd values in the buffer solutions confirms linearity of the response of the Cd^{2+}-selective electrode in aqueous–ethanol up to pCd ~12.3.

o-Phenanthroline (phen) and 2,2'-bipyridine (bipy) are appropriate components of metal-buffer systems. They form stable complexes with Ag^{+}, Cu^{2+}, and Cd^{2+}, for which ISE have been developed, and with other ions. They can be auxiliary for the "second-kind buffers" [17]. As these ligands are relatively weak bases (Table 3), competitive protonation reactions affect the complexation insignificantly within a very wide pH range, and the pM of metal-buffer systems is independent of pH.

The published data on ligand protonation constants and stability constants of the complexes in aqueous solutions [17] refer to different experimental conditions. To reveal the effect of the micellar medium, we studied aqueous and micellar solutions under the same conditions. Complexation of Cd^{2+} and Cu^{2+} with phen and bipy in the micellar SDS solution was studied potentiometrically [18]. However, at the total reactant concentrations of approximately 10^{-4} M, we cannot determine the stability constants of the higher complexes CuL_3^{2+}, which should be taken into account when buffer properties of Cu-phen or Cu-bipy systems are estimated. The results of an additional study at the reactant concentrations of approximately 10^{-3} M are listed in Table 3.

Table 3. Logarithms of the concentration constants of ligand protonation and stepwise complexation of Cu^{2+} and Cd^{2+} with *o*-phenanthroline and 2,2'-bipyridine in aqueous and micellar solutions

Ligand	Parameter measured		Complex composition	log *K*, aqueous solutions		log *K* in 0.05 M SDS

			CdL_2^{2+}	10.48 ± 0.02	4.83 (I = 0.1, KCl)	6.31 ± 0.02
			CdL_3^{2+}	–	4.26	3.65 ± 0.03

Table 4. Composition and characteristics of micellar cadmium-buffer (0.05 M SDS) solutions, I = 0.1 M ($NaNO_3$)

Solution no.	Total concentration, M	pCd_{calc}	pCd_{exp}	Buffer capacity, M
1	$Cd(NO_3)_2$, 1.01×10^{-3}; bipy, 3.7×10^{-3}	7.58	7.51	6.8×10^{-4}
2	$Cd(NO_3)_2$, 1.01×10^{-3}; phen, 6.20×10^{-3}	11.95	11.76	6.4×10^{-4}
3	$Cd(NO_3)_2$, 1.01×10^{-3}; phen, 6.35×10^{-3}	12.01	11.87	6.6×10^{-4}
4	$Cd(NO_3)_2$, 1.01×10^{-3}; phen, 4.72×10^{-3}	11.21	11.20	4.3×10^{-4}
5	$Cd(NO_3)_2$, 1.01×10^{-3}; phen, 3.46×10^{-3}	10.02	10.00	2.4×10^{-4}
6	$Cd(NO_3)_2$, 1.01×10^{-3}; phen, 4.06×10^{-3}	10.70	10.58	3.3×10^{-4}

Within the concentration range studied, formation of $Hphen^+$ species in aqueous solution at pH 5.4 [19] and self-association of phen and bipy molecules [20] are not confirmed.

Simple Cd^{2+} and Cu^{2+}-buffer systems contain higher complexes $Cd(bipy)_2^{2+}$, $Cd(phen)_3^{2+}$, $Cu(bipy)_2^{2+}$, or $Cu(phen)_3^{2+}$ and excess unbound ligand (Table 4, buffer solution nos. 1–6; Table 5, buffer solutions nos. 1, 3, 4). As compared to aqueous solutions, the range in which the $Cu(bipy)_2^{2+}$ complex prevails in the micellar media is wider (Table 3). This makes it possible to prepare a Cu^{2+} buffer system with a lower pCu by on the reaction

$$3Cu(dipy)_2^{2+} \rightleftarrows Cu^{2+} + 2Cu(dipy)_3^{2+}. \quad (5)$$

The involvement of the complexing agent in the exchange of counterions on the micelle surface, which can affect the properties of the reaction mixture, additionally restricts the choice of the initial composition of metal-buffer systems in a micellar medium of anionic surfactants. This effect is poorly understood; however, it is known that, when sodium counterions are replaced with double-charged cations, micelles acquire cylindrical shape [21]. In order to provide the constant micelle composition, we used the same total concentration of the complexing agent in the metal-buffer solutions as in determination of the stability

Table 5. Composition and characteristics of copper-buffer micellar (0.05 M SDS) solutions, I = 0.1 M ($NaNO_3$)

Solution no.	Total concentration, M	pCu_{calc}	pCu_{exp}	Buffer capacity, M
1	$Cu(NO_3)_2$, 9.99×10^{-4}; phen, 3.78×10^{-3}	13.26	13.57	2.3×10^{-4}
2	$Cu(NO_3)_2$, 1.01×10^{-3}; phen, 2.94×10^{-3}	11.43	11.59	1.2×10^{-4}
3	$Cu(NO_3)_2$, 1.0×10^{-3}; bipy, 4.66×10^{-3}	12.98	12.96	3.8×10^{-4}
4	$Cu(NO_3)_2$, 1.0×10^{-3}; bipy, 3.51×10^{-3}	11.71	11.19	1.9×10^{-4}
5	$Cu(NO_3)_2$, 1.0×10^{-3}; bipy, 2.48×10^{-3}	8.97	9.77	1.2×10^{-4}

constants (1×10^{-3} M). To stabilize the ionic strength of the metal-buffer solutions, we used $NaNO_3$; its total concentration was 4.70×10^{-3} M.

The pCd values measured with ISE in Cd^{2+}-buffer systems agree with the calculated values within the error of determination of the mass action law (MAL) constants. Buffer solution no. 1 is the best for practical purposes (Table 4). In the solutions containing excess ligand, the $Cd(bipy)_2^{2+}$ complex prevails, whereas the concentration of the 1 : 1 complex is negligible. This simplifies calculation of pCd at varied concentration of the buffer solution:

$$pCd = \log \beta_2 + 2\log(c_L - 2c_{Cd}) - \log c_{Cd}, \quad (6)$$

where c_L and c_{Cd} are the total molar concentrations of bipy and Cd(II), respectively.

After storage of the cadmium buffer solutions for 7 days, pCd changed by less than ± 0.03.

The pCu values measured with ISE (Table 5) are worse consistent with the calculated values than in the case of Cd^{2+}-buffer systems. During storage, the pCu values for Cu^{2+}-buffer solutions substantially changed: pCu increased by 0.6 in two weeks. The error of determination of the stability constants of the Cu^{2+} complexes with phen and bipy is higher compared to the corresponding Cd^{2+} complexes. This fact suggests that some unaccounted processes occur in the solution or at the interface between the solution and the Cu^{2+}-selective membrane. Therefore, we cannot recommend for use the Cu^{2+}-buffer systems listed in Table 5 without understanding of the nature of these processes.

The metal ion buffer systems suggested (except those listed in Table 5) can be useful for calibration ISEs used for studying complexation in the corresponding media. These metal-buffer solutions allow calibration at pM close to the values being determined, as in pH-metry, which improves the accuracy of determination of the MAL constants [15].

EXPERIMENTAL

A Cu^{2+}-selective solid-phase electrode based on chalcogenide glasses $Cu_xAg_{25-x}As_{37.5}Se_{37.5}$ [22], Orion 94-48 Cd^{2+}-selective electrode, ESL-63-07 glass electrode, and EVL-1M3 reference electrode were used for a potentiometric study of the equilibria. A potentiometric cell included a liquid junction of capillary type filled with 2 M KNO_3 aqueous solution. The electromotive force was measured with a compensating scheme (R 307 potentiometer and a pH-121 pH-meter as a null-indicating instrument); all measurements were performed at a constant temperature of 298.0 ± 0.1 K. Chemically pure grade reagents, SDS (Sigma) with the main substance content of no less than 99 wt %, and double-distilled water were used to prepare the solutions. The Cu(II) and Cd(II) content in the initial solutions was determined complexometrically [23]. The ionic strength of the aqueous–ethanol solutions (I = 0.01 M) was supported with $LiNO_3$, and that of micellar solutions (I = 0.1 M), with $NaNO_3$; the contribution of micelles to the ionic strength was disregarded. The Cd^{2+} buffer solutions in aqueous–ethanol were prepared from the component stock solutions and metal-buffer solutions in the SDS medium, using precisely weighed portions of phen or bipy and stock solutions of Cu(II) and Cd(II) salts and $NaNO_3$.

The potentiometric titration data were processed using the CLINP software, which enables calculation of the equilibrium constants and refinement of the complexation model [24]. The equilibrium compositions and buffer capacities of solutions with regard to all the competing reactions were calculated with the projecting method using an appropriate software.

CONCLUSIONS

The compositions of cadmium-buffer solution based on Cd(II) complexes with nitrilotriacetic acid in aqueous–ethanol solutions were developed for calibration of a Cd^{2+}-selective electrode within the pCd

range 9.7–12.3. To calibrate the Cd^{2+}-selective electrode in micellar solutions of sodium dodecyl sulfate, cadmium-buffer systems based on Cd(II) complexes with *o*-phenanthroline and 2,2'-bipyridine were suggested. Similar copper-buffer solutions are characterized by relatively poor repeatability and reproducibility of measured pCu.

CATALYSIS

Pillared Tagan Montmorrilonite in Cracking of Isopropylbenzene

Received September 10, 2004

Abstract—Tagan montmorillonite clay fixed with aluminum and zirconium oxides was prepared, and its catalytic (in cracking of isopropylbenzene), adsorption, and structural characteristics were studied.

It is known that the heat resistance of catalysts derived from clays is poor [1–4] because of the possible closure of the silicate layers at high temperatures. Intercalation of metal oxide clusters (pillars) into the interlayer space of montmorrilonite-type layered clays by cation exchange with inorganic polyoxo cations allows preparation of a new class of materials exhibiting the prescribed porosity, acidity, and heat resistance. Pillared clays attract researchers' attention as adsorbents and catalysts for cracking, isomerization, etc.

Preparation and use of intercalated clays have been discussed in numerous reviews [1–3]. The features of intercalation are specific to montmorillonites from different deposits.

In this study, we examined intercalation of natural Kazakhstan montmorrilonite from the Tagan deposit and tested pillared materials derived from it in cracking of hydrocarbons.

EXPERIMENTAL

Montmorrilonite clay from the Tagan deposit was used without isolation of the monomineral montmorillonite fraction. The initial clay was converted to the Na form by treatment with 1 M NaCl to raise its dispersity. The H form of Tagan montmorillonite was prepared by the standard procedure [4].

As fixing agents we tested oligomeric aluminum hydroxo cations of the presumed composition $[Al_{13}O_4(OH)_{24}(H_2O)_{12}]^{7+}$ (Al_{13}^{7+}) with a four-coordinate Al atom, which were prepared according to [5] at various synthesis temperatures, and aqueous solutions of $ZrOCl_2$, which were introduced into clay according to [6]. As reported in [7, 8], 70–80% of aluminum hydroxo cations have a Keggin structure. Oligomeric Al_{13}^{7+} is commonly prepared by hydrolysis of a 0.2 M $AlCl_3$ solution in 0.5 M NaOH at OH^-/Al^{3+} = 2.5 and final pH 4.1 with vigorous stirring. After aging for 24 h, the fixing agent (oligomeric Al_{13}^{7+}) was added dropwise into a 5% aqueous suspension of the clay. The oligomeric complex was prepared at room temperature [7] and at 353 K [8].

In the synthesized samples, the Al^{3+}/clay ratio was 2.5, 5.0, and 7.5 mmol g^{-1} clay. The resulting product, aluminum–fixed montmorillonite (Al–FM), was separated by centrifugation, washed to negative reaction for Cl^- ions, dried in a thin layer at 293 and 423 K, and calcined at 823 K.

Zirconium–fixed montmorrilonite (Zr–FM) was prepared by slow addition of a $ZrOCl_2$ solution of a given concentration to a 5% clay suspension. The activity of the resulting samples was studied in a micropulse installation in cracking of a model hydrocarbon, isopropylbenzene (IPB), in the temperature range 623–773 K (T_{cr}). The catalysts were preliminarily calcined at 823 and 1023 K (T_{tr}). An X-ray diffraction analysis was performed with a DRON-4.7 diffractometer (Co_{K_α} radiation). An electron-microscopic examination was performed with an EM-125K electron microscope using microdiffraction. The specific surface area, total pore volume, and pore size distribution were determined with an ACCUSORB device from the isotherms of low-temperature nitrogen adsorption.

The structural (first basal reflection in the diffraction patterns, d_{001}, and interlayer spacing Δd) and adsorption (pore volume V and specific surface area S_{sp}, determined from by BET low-temperature N_2 adsorption) characteristics of the samples are listed in Table 1, and the pore size distribution is shown in Fig. 1.

Table 1. Texture characteristics of the initial montmorillonite and pillared samples on its basis, calcined at 823 K

Sample	d_{001}, nm	Δd, nm	S_{sp}, $m^2\ g^{-1}$	V_{max}, $cm^3\ g^{-1}$	R_{eff}, nm
Na form	1.26	–	69	0.275	<5.0
Al–FM	1.76	0.5	232	0.335	5.0–8.0
Zr–FM	Not detected	–	176	0.325	5.0–8.0

Comparative analysis of data in Table 1 and Fig. 1 for the Na form of montmorrilonite, Al–FM, and Zr–FM shows that the material obtained differs from the initial form. Dealumination of the aluminosilicate layers of pillared clays results in that the mesopore range becomes wider (Fig. 1) and the specific surface area (Table 1) increases from 69 $m^2\ g^{-1}$ for the Na form to 232 for Al–FM and 176 $m^2\ g^{-1}$ for Zr–FM.

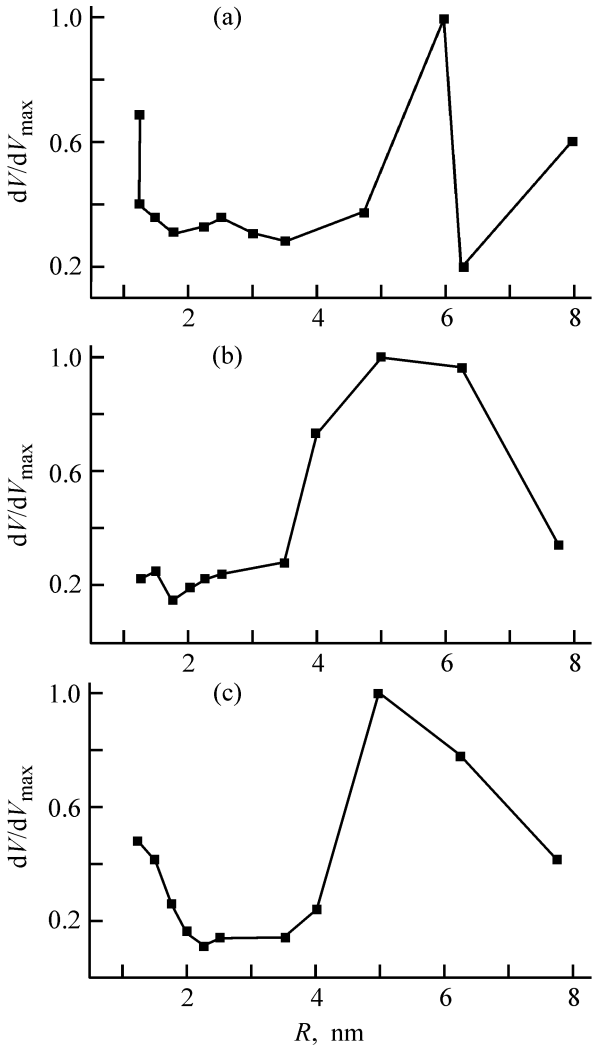

Fig. 1. Distribution of pores (dV/dV_{max}) with respect to effective radius R for samples heat-treated at 823 K. Sample: (a) Na-M, (b) Zr–FM (2.5), and (c) Al–FM (2.5).

The distance between the aluminosilicate layers in Al–FM reaches 0.5 nm.

The electron micrographs of a suspension sample of the initial clay, obtained in the transmission mode, exhibit basal reflections at the bends of montmorillonite lamellas with a set of interplanar spacings (19.10, 17.30, 10.53, 9.21, 8.64, 8.42 Å) corresponding to smectites. Examination of the profile of the aluminum-fixed clay reveals a fine-grained phase of aluminum oxide (particle size 500–1000 Å) on smooth montmorillonite lamellas.

X-ray phase analysis of Zr–FM reveals formation of an amorphous phase. This may be due to dealumination of the crystal lattice of montmorillonite [5].

According to the shape of the desorption branch of the isotherm of low-temperature nitrogen adsorption (76 K), the samples based on fixed montmorillonite belong to type B of IUPAC classification [9], i.e., to materials with slitlike pores [10, 11].

It is of interest to compare the activities of pillared clay samples in IPB cracking. The activities (evaluated as degrees of IPB conversion), apparent rate constants, and activation energies for Na-M and fixed pillared Al- and Zr-montmorillonite samples with various concentrations of fixing agents (mmol g^{-1} clay) in the range of cracking temperatures 623–773 K are given in Table 2 and Fig. 2.

As can be seen from these data, the conversion of IPB on Na-M is low at all the cracking temperatures, and it considerably decreases (by almost a factor of 4) as the pretreatment temperature is raised to 1023 K. Intercalation enhances the activity and heat resistance of the catalysts. With Al–FM (2.5) heat-treated at 823 and 1023 K, the conversion of IPB at T_{cr} = 723 K is 26.0 and 21.4%, respectively. It should be noted that the activity of the Al–FM sample prepared at 353 K is approximately a factor of 3 lower than that of the samples prepared at room temperature; this is apparently due to the formation at elevated temperatures of the cationic species $Al(H_2O)_6^{3+}$ differing from the hydroxylated product Al_{13}^{7+} [12]. The Al_{13}^{7+} species present in the catalyst apparently enhances its heat re-

Table 2. Effect of the nature of a fixing cation on the activity α, apparent rate constant of cracking K_{app}, and activation energy of cracking E for intercalated samples of Tagan montmorillonite in the Na^+ and H^+ forms

* Intercalation at 353 K.

** Samples based on the H form of Tagan montmorillonite.

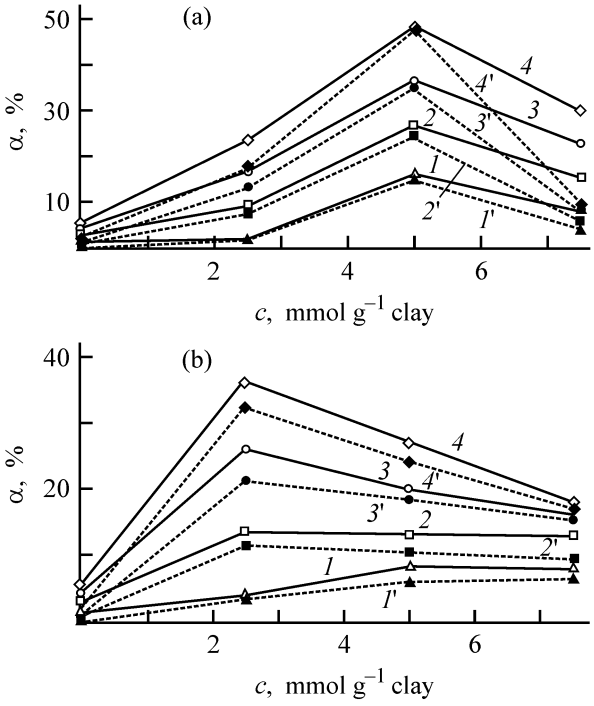

Fig. 2. Catalyst activity α vs. concentration *c* of the fixing agent. Catalyst: (a) Zr–FM and (b) Al–FM. Cracking temperature, K: (*1*) 623, (*2*) 673, (*3*) 723, and (*4*) 773. Pretreatment temperature, K: (*1*–*4*) 823 and (*1*'–*4*') 1023.

sistance. In particular, the activity of Al*–FM (2.5) heat-treated at 1023 K in cracking of IPB at 723 K amounts to 65% of the activity of the same catalyst heat-treated at 823 K, whereas with Al–FM (2.5) the related ratio is 88.5%. The activity of Al–FM (5.0) is somewhat lower than that of Al–FM (2.5) heat-treated at the same temperature (823 K), but its heat resistance is higher (the activity at T_{tr} = 1023 K is 92% of that at T_{tr} = 823 K at the same cracking temperature). As the concentration of the fixing agent is raised to 7.5 mmol g^{-1} clay, α at T_{tr} 823 and 1023 K further decreases to 16.0 and 15.5%, respectively, whereas the heat resistance of the catalyst grows.

With Zr–FM, the intercalation also exerts a positive effect, especially noticeable at the fixing agent content of 5.0 mmol g^{-1} clay. The conversion of IPB is 36.3 and 35.0% at heat treatment temperatures of 823 and 1023 K, respectively. These values of α are the best for the fixed clays examined, which are derived from the Na form of montmorillonite. At the optimal Zr content (5.0 mmol g^{-1} clay), the activity of the catalyst heat-treated at 1023 K is 92.0–98.1% of that of the catalyst heat-treated at 823 K at any cracking temperature in the range from 623 to 773 K. With an increase in the Zr concentration to 7.5 mmol g^{-1} clay, the activity and heat resistance decrease (Fig. 2, Table 2).

Figure 2 shows that the optimal concentration of Al in Al–FM is 2.5, and that of Zr in Zr–FM, 5.0 mmol g^{-1} clay. It is of interest that raising the pretreatment temperature to 1023 K does not appreciably alter the activity of Zr- and Al-fixed clays of the optimal composition, which is one of the most important requirements to hydrocarbon cracking catalysts.

To examine the effect of Al and Zr fixing agents on the activity of the montmorillonite clay in the H form, we prepared samples with the optimal concentrations of the Al^{3+} and Zr^{4+} ions (2.5 and 5.0 mmol g^{-1} clay, respectively). The dependences of the IPB conversion on the cracking temperature for the H form of the clay and samples fixed with Al and Zr and heat-treated at 823 and 1023 K are illustrated in Table 2. As the temperature of the pretreatment of the H form is raised to 1023 K, the activity in IPB cracking at temperatures within 623–773 K decreases by 9–12.7%. With Zr–FM, α decreases by 5.2–7.2, and with Al–FM, by 1.6–5.2%. Thus, the heat resistance of the intercalated samples prepared from the H form of the clay remains fairly high at all the cracking temperatures, being, however, somewhat lower than that of the samples prepared from the Na form (Table 2). The samples differ not only in the apparent rate constants but also in the activation energies. The activation energies are the highest with the Na and H forms of montmorillonite (58.2 and 45.5 kJ mol^{-1}, respectively) and decrease in going to the intercalated samples.

Comparison of the activities of samples of similar composition, prepared from the Na and H forms of montmorillonite, shows that the more active catalyst is obtained by pillaring the H form of natural montmorillonite. This catalyst approaches in the activity and heat resistance the NaHY zeolitic catalyst on clay [13] previously tested in IPB cracking.

CONCLUSIONS

(1) Substitution of the interlayer Na^+ cations with oligomeric aluminum and zirconium hydroxo cations allows control of the pore structure, activity, and acidity of the resulting catalysts.

(2) Intercalation of the H form of montmorillonite with zirconium and aluminum allows preparation of active and heat-resistant catalysts whose activity in isopropylbenzene cracking approaches that of NaHY-zeolitic catalyst on clay.

(3) Pillared Al- and Zr-montmorillonites can be used as hydrocarbon cracking catalysts.

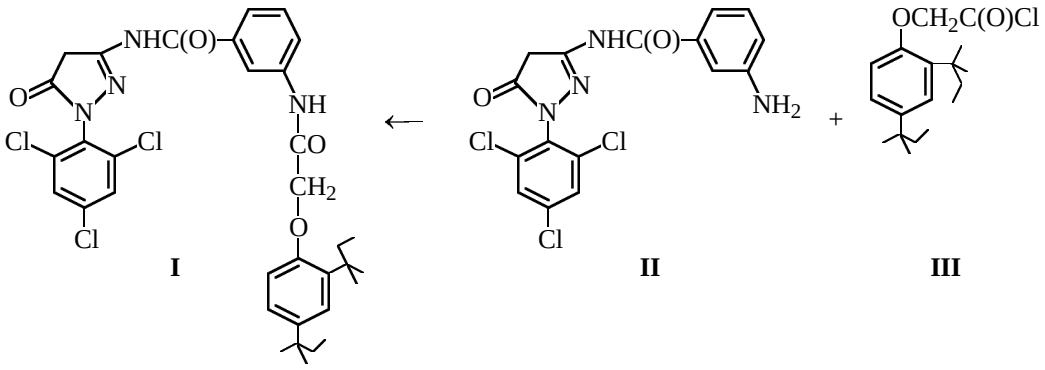
ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis of 3-(3"-Aminobenzoylamido)-1-(2',4',6'-trichlorophenyl)pyrazol-5-one, an Intermediate in the Synthesis of the Purple Component of Color Photographic Materials

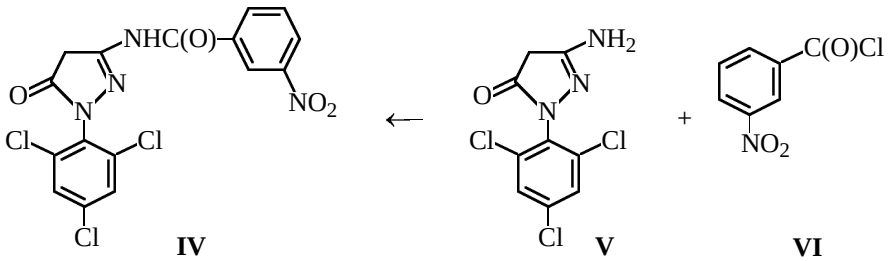
Yu. M. Yutilov, N. N. Smolyar, and L. V. Minkina



Litvinenko Institute of Physical Organic and Coal Chemistry, National Academy of Sciences of Ukraine, Donetsk, Ukraine

Received August 4, 2004

Abstract—Catalytic reduction of 3-(3"-nitrobenzoylamido)-1-(2',4',6'-trichlorophenyl)pyrazol-5-one with hydrogen and hydrazine hydrate to 3-(3"-aminobenzoylamido)-1-(2',4',6'-trichlorophenyl)pyrazol-5-one, the key intermediate in the synthesis of the purple component of color photographic and motion-picture materials, was studied.



It is known that the protectable purple component, 3-[3-(2",4"-di-*tert*-pentyl)phenoxyacetamido]benzoylamido-1-(2',4',6'-trichlorophenyl)pyrazol-5-one **I**, shows high photographic properties [1, 2]. One of procedures for its synthesis is labor-consuming and involves use of difficultly available chemicals [3].

The most facile route to **I** is based on the reaction of 3-(3"-aminobenzoylamido)-1-(2',4',6'-trichlorophenyl)pyrazol-5-one **II** with 2,4-di(*tert*-pentyl)phenoxyacetyl chlolride **III**, with a 75% yield of the target product [4]:

I **II** **III**

Intermediate **II** is formed by reduction of 3-(3"-nitrobenzoylamido)-1-(2',4',6'-trichlorophenyl)pyrazol-5-one **IV**, which is, in turn, prepared by acylation of 3-amino-1-(2',4',6'trichlorophenyl)pyrazol-5-one **V** with *m*-nitrobenzoyl chloride **VI** in 80% yield [4]:

IV **V** **VI**

* According to [6], the melting point of **II** is 297–300°C.

To diminish the corrosive effect of HCl released in the acylation of **II**, it is bound by adding triethylamine [5]; this also favors preparation of pure **I**.

Among the known procedures for reduction of **IV** to **II**, of particular interest is the hydrogenation on Raney nickel [6]. Some alternative reduction procedures are also feasible [6], e.g., those with iron in hydrochloric or acetic acid, with sodium or ammonium sulfide and with hydrogen in acetic acid in the presence of Pd/C. The last procedure allows preparation of amine **II** in a high yield without degradation processes such as, e.g., hydrolytic cleavage of the amide group occurring in other procedures. Other possible side processes are acetylation of the NH_2 group with acetic acid (when reduction of **IV** is performed in this medium) and formation of sulfur (in reduction of **IV** with sodium sulfide) negatively affecting the photographic properties of **II**. Being environmentally clean, reduction with hydrogen on Raney nickel has a drawback: The conditions of reduction of **IV** in alkaline alcoholic solution (1–20 wt % Raney nickel, 20–110°C, 1–20 atm of H_2) give rise to an explosion hazard.

To eliminate these drawbacks, we attempted to improve the procedure for reduction of **IV** with hydrogen. For this purpose, we performed the reduction under the normal conditions (H_2 pressure 1 atm, room temperature) in aqueous-alcoholic NaOH solutions. As catalysts, along with Raney nickel, we also tested 5% Pd/C, 5% Pt/C, 5% $Pd/BaSO_4$, and 5% $Pt/BaSO_4$.

In reduction of **IV** with hydrogen under normal conditions in homogeneous 0.5% and 2% aqueous NaOH solutions, the yield of **II** was 94.5 and 95.7%, respectively. In reduction of **IV** with hydrogen in 2% aqueous NaOH in the presence of 5% Pd/C and 5% $Pd/BaSO_4$, the yield of **II** was 95.1 and 94.9%.

The reduction of **IV** with hydrogen in 1% aqueous NaOH in the presence of 5% Pt/C and 5% $Pt/BaSO_4$ under the similar conditions affords **II** in 96.4 and 94.8% yield, respectively. At a higher (3%) NaOH concentration, the yield of **II** in reduction of **IV** in the presence of 5% Pt/C increased to 96.8%. The conditions of reduction of **IV** and the yield and melting point of **II** are listed in the table.

In view of the problems associated with the use of hydrogen, we attempted to replace it with hydrazine hydrate. In our experiments, we used the same catalysts as in the reduction with H_2. Along with the catalyst, we varied the reaction temperature and NaOH concentration.

Reduction of nitro compound **IV** with hydrazine hydrate in 2% aqueous NaOH at 30 and 40°C in the presence of Raney Ni affords **II** in 95 and 95.7% yield. When the reduction of **IV** with hydrazine hydrate is performed at 40°C in the presence of the same catalyst but in 6% aqueous NaOH, the yield of **II** decreases.

The yield of **II** increases, respectively, to 96.2 and 96.3% when compound **IV** is reduced with hydrazine hydrate at 40°C in the presence of Pd/C (in 2% aqueous NaOH) or $Pd/BaSO_4$ (in 4% aqueous NaOH).

Raney nickel appeared to be the most effective in aqueous NaOH at a 25-fold excess of hydrazine hydrate. In this case, the yield of **II** is the highest, and its melting point and chromatographic characteristics are identical to those of an authentic sample [7].

At a smaller (15-fold) excess of hydrazine hydrate, or with an alkaline alcoholic solution used, the reduction of **IV** to **II** is incomplete.

EXPERIMENTAL

The purity of **II** was checked by high-velocity microcolumn liquid chromatography on a Milikhrom device equipped with a UV detector. A 64 × 2-mm stainless steel column (≥3000 TP) was packed with Separon (particle diameter 4 μm). The best system for elution of **II** was acetone–water–hexane, 86 : 12 : 2 (by volume). The chromatographing conditions were as follows: sensitivity range 1.6, measurement time 0.15 s, wavelength λ in the STOP mode 280 nm, eluent feed rate 200 μl min^{-1}, and paper feed rate 1800 mm h^{-1}. The retention time of **II** under these conditions was 48 s.

Reduction of IV with hydrogen in 0.5–3.0% aqueous NaOH solutions at 20°C. A 10.0-g (23.4-mmol) portion of **IV** was dissolved in 200 ml of water containing 1–6 g (25–150 mmol) of NaOH and subjected to catalytic hydrogenation in the presence of a catalyst (Raney nickel, 5% Pd/C, 5% Pt/C, 5% $Pd/BaSO_4$, or 5% $Pt/BaSO_4$). To do this, the reaction vessel was first purged with nitrogen to remove air, and then nitrogen was replaced with hydrogen. The reduction was performed at 25°C and an H_2 pressure of 1 atm with continuous stirring until the hydrogen uptake ceased (200 ml). The catalyst was filtered off, and the filtrate was acidified with a solution of hydrochloric or acetic acid to pH 6. The precipitate was filtered off, washed with a small amount of water, and dried.

Reduction of IV with hydrazine hydrate in 0.5–6.0% aqueous NaOH solutions at 30–50°C. A 10.0-g (23.4-mmol) portion of **IV** was mixed with a solution of 0.5–6 g of NaOH in 100 ml of water, and 2.0 g of a catalyst (Raney nickel, 5% Pd/C. 5% Pt/C, 5% $Pd/BaSO_4$, or 5% $Pt/BaSO_4$) was added. Then 40 ml (0.8 mol) of 98–100% hydrazine hydrate was added in portions with vigorous stirring and heating to 30–50°C. After heating for 3–4 h under these conditions, the catalyst was filtered off, and the filtrate was acidified with 2% H_2SO_4 to pH 6. The precipitate was filtered off, washed with a small amount of water, and dried.

CONCLUSIONS

(1) Preparative procedures were suggested for the reduction of 3-(3''-nitrobenzoylamido)-1-(2', 4', 6'-trichlorophenyl)pyrazol-5-one with hydrogen or hydrazine hydrate in aqueous NaOH in the presence of Raney nickel, 5% Pd/C, 5% Pt/C, 5% $Pd/BaSO_4$, or 5% $Pt/BaSO_4$ to obtain 3-(3''-aminobenzoylamido)-1-(2', 4', 6'-trichlorophenyl)pyrazol-5-one.

(2) A procedure was developed for prompt analysis of the quality of the amine with a Milikhrom liquid chromatograph.

Received November 15, 2004

Abstract—Decomposition of $KF \cdot H_2O_2$ stabilized with carboxylic acids (maleic, fumaric, succinic, adipic) in storage for more than three years at 20°C was studied. Rate constants of decomposition of stabilized $KF \cdot H_2O_2$ were determined in different time intervals. The chemical reactions in the system $KF–H_2O_2$–carboxylic acid in the stage of preparation of solid $KF \cdot H_2O_2$ stabilized with carboxylic acid and those during prolonged storage of the final product are discussed.

Hydrogen peroxide, is irrespective of its state (pure anhydrous substance, aqueous solutions, salt solvates with hydrogen peroxide), a chemically unstable compound prone to catalytic decomposition. The stability of hydrogen peroxide is raised by adding various stabilizers. As a rule, chemical interactions responsible for the stabilization of hydrogen peroxide are poorly understood [1, 2]. Various approaches to hydrogen peroxide stabilization have been developed. For example, a widely used commercial bleach based on sodium caronate solvate with hydrogen peroxide $Na_2CO_3 \cdot 1.5H_2O_2$ is stabilized by binding catalytic impurities into poorly soluble or inert species (salts, complexes) and by protecting this compound from moisture. It has also been repeatedly shown that hydrogen peroxide can be efficiently stabilized with additives incapable of binding catalytic impurities and protecting the compound from moisture [2].

It has been reported [3] that potassium fluoride solvates with H_2O_2 ($KF \cdot nH_2O_2$) can be stabilized using, along with other compounds, with acidic compounds, such as potassium hydrogen bifluoride and oxalic, citric, and boric acids. It was found that KHF_2 is the most efficient among these stabilizers. However, even minor additions of this compound to $KF \cdot nH_2O_2$ make it corrosion-active.

Modern disinfectants with a broad spectrum of antimicrobial effect are based on potassium fluoride solvate with H_2O_2 ($KF \cdot H_2O_2$) [4]. The stabilization of this compound to ensure its long-term storage at ambient temperature is a topical problem.

In this study, we examined $KF \cdot H_2O_2$ stabilization with carboxylic acids, which are less corrosive than KHF_2. The kinetics of decomposition of $KF \cdot H_2O_2$ stabilized with carboxylic acids in its storage for more than three years was studied at 20°C. We also attempted to elucidate the mechanisms of interaction of $KF \cdot H_2O_2$ with carboxylic acids in liquid systems $KF–H_2O_2$–carboxylic acid and in the solid stabilized solvate.

EXPERIMENTAL

All the compounds studied were prepared under conditions typical of their semicommercial production [4]. Maleic, fumaric, succinic, and adipic acids (pure grade) were added to $KF \cdot 2H_2O$ (analytically pure grade) in aqueous peroxide (30%) in an amount of 0.5–1.0 wt % relative to the mass of the final solid product at an H_2O_2 : KF molar ratio of 1 : 2. To isolate solid $KF \cdot H_2O_2$, the reaction mixture was placed in a metallic device equipped with a film rotary evaporator, and water and excess H_2O_2 were removed at 40–50°C.

The final product was stored in closed polymeric beakers at 20 ± 2°C. The content of hydrogen peroxide in the final product was determined permanganatometrically (at intervals of 10–15 days in the early

stage, and 2–3 months in the periods of later storage). The rate constants k of $KF \cdot H_2O_2$ decomposition were calculated by the equation

$$\ln c_0/c = k(\tau - \tau_0).$$

The IR spectra of the compounds prepared (mulls in Vaseline oil between KBr plates) were recorded in the range 400–4000 cm^{-1} on a UR-20 IR spectrometer.

We found that IR spectra of all the compounds do not change after prolonged storage. These spectra contain the following absorption bands of coordinated hydrogen peroxide (cm^{-1}): ν_3, O–O stretching (855 s, 885 s); ν_4, torsion (960 s); ν_6, OOH bending (1485 m); ν_2, OOH bending (1670 m); ν_5, OH stretching (2600–2800 s. br); and ν_1, OH stretching (3200 s. br) [3].

Analysis of the rate of $KF \cdot H_2O_2$ decomposition over the entire storage period shows that the total decomposition curve consists of separate portions with individual rate constants. The time intervals and average rate constants corresponding to different portions of the total decomposition curve are listed in Table 1.

These data show that, in the early storage period (τ from 0 to 30–60 days), the rate of decomposition of $KF \cdot H_2O_2$ stabilized with maleic, fumaric, and, to a lesser extent, adipic acid is relatively high ($k \times 10^4$ = 2.0–9.1 day^{-1}). The rate constant passes through a maximum in the storage time intervals from 30–60 to 200–500 days and then decreases to $k \times 10^4$ = 0.1–2.6. In the later storage stages (from 200–500 to 900–1257 days), the rate constant decreases to $k \times 10^4$ = 0–0.9.

$KF \cdot H_2O_2$ stabilized with succinic acid shows a different decomposition pattern. This compound does not lose oxygen in the early storage period (from 0 to 43–55 days) and then starts to slowly decompose. The maximal decomposition rate ($k \times 10^4$ = 0.7–1.2 day^{-1}) is reached after a long time (from 45–55 to 333–502 days) and then, during a long

time (1257 days), this compound decomposes either at low rate ($k \times 10^4 = 0.1$ day^{-1}) or is stored without decomposition.

Figure 1 shows the plot for k of $KF \cdot H_2O_2$ stabilized with maleic acid vs. storage time, which is typical of all the stabilizers under consideration except for succinic acid. This figure also shows the time dependence of k for $KF \cdot H_2O_2$ stabilized with succinic acid. These plots were built using the times and rate constants averaged over different portions of the total kinetic curve of $KF \cdot H_2O_2$ decomposition. Table 1 and Fig. 1 show that succinic acid is a more efficient stabilizer of $KF \cdot H_2O_2$ than the other carboxylic acids tested and that the time dependence of k for $KF \cdot H_2O_2$ stabilized with succinic acid considerably differs from that for $KF \cdot H_2O_2$ stabilized with the other carboxylic acids.

It is not improbable that the more efficient stabilization of $KF \cdot H_2O_2$ with succinic acid and the kinetic features of decomposition of $KF \cdot H_2O_2$ stabilized with this acid are caused by reactions of succinic acid with hydrogen peroxide, in particular, with excess hydrogen peroxide present in the initial reaction mixture. These reactions can produce of peroxy derivatives succinic acid, which may be more efficient stabilizers than succinic acid itself.

It was reported in [5] that, depending on conditions, succinic acid can react with hydrogen peroxide to form persuccinic, hydroxysuccinic, malonic, and maleic acids, and also succinic anhydride. No data have been reported on reactions of hydrogen peroxide with the other carboxylic acids that we tested.

We found that the IR spectra of individual carboxylic acids used in our experiments as stabilizers do not change after their treatment with hydrogen peroxide under the same conditions as in preparing KF solvate with hydrogen peroxide. For example, the IR spectra of adipic and succinic acids before and after treatment with aqueous hydrogen peroxide contain the following absorption bands (cm^{-1}). The initial adipic acid: 520 s, 690 s, 740 s, 960 s.br, 1200 s, 1280 s, 1380 s, 1425 s, 1460 vs, 1700 vs, 2800–3000 vs; adipic acid after treatment with aqueous hydrogen peroxide: 520 s, 690 s, 740 s, 930 s.br, 1200 s, 1280 s, 1380 s, 1420 s, 1460 vs, 1700 s, 2800–3000 s.br. The initial succinic acid: 550 s, 585 s, 640 s, 740 w, 810 narrow, 930 s.br, 1205 s, 1300 s, 1380 s, 1440 s, 1470 s, 1700 s.br, 2800–3000 s.br; succinic acid after treatment with aqueous hydrogen peroxide: 545 s, 585 s, 640 s, 745 m, 810 s.

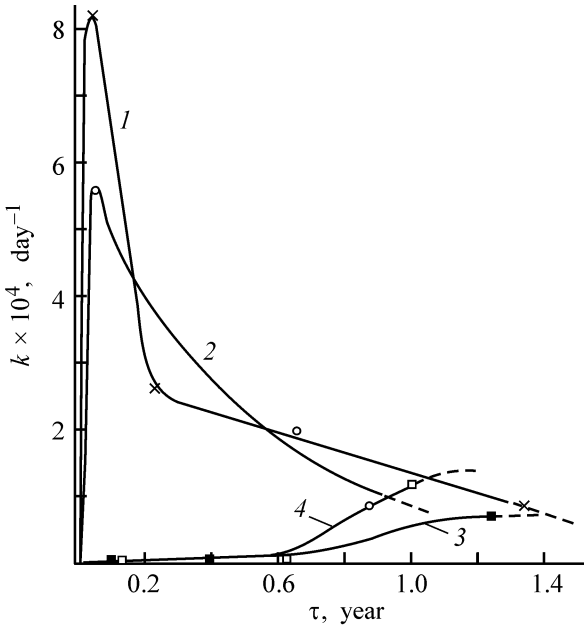

Fig. 1. Rate constants k of decomposition of $KF \cdot H_2O_2$ stabilized with carboxylic acids vs. storage time τ. (τ) average storage time in interval Δτ. Carboxylic acids: (*1*, *2*) maleic and (*3*, *4*) succinic. Acid concentration, wt%: (*1*, *3*) 0.5; (*2*) 2.0, and (*4*) 1.0

narrow, 930 s.br, 1205 s, 1310 s, 1385 s. narrow, 1460–1480 s.br, 1700 s.br, 2800–3000 s.br.

The IR spectra of maleic and fumaric acids also showed no significant changes after treatment with aqueous hydrogen peroxide.

Therefore, we believe that, in the systems under consideration, the exchange reaction between KF and carboxylic acid, yielding potassium carboxylate, is more probable:

$$2KF + (HOOC)_2R = (KOOC)_2R + 2HF. \quad (1)$$

This reaction is accompanied by several additional processes: formation of hydrogen bifluoride anions through association of hydrogen fluoride with fluoride anion

$$KF + HF = KHF_2, \quad (2)$$

solvation of potassium hydrogen bifluoride with hydrogen peroxide [6]

$$KHF_2 + H_2O_2 = KHF_2 \cdot H_2O_2, \quad (3)$$

breakdown of unstable potassium hydrogen bifluoride solvate with hydrogen peroxide

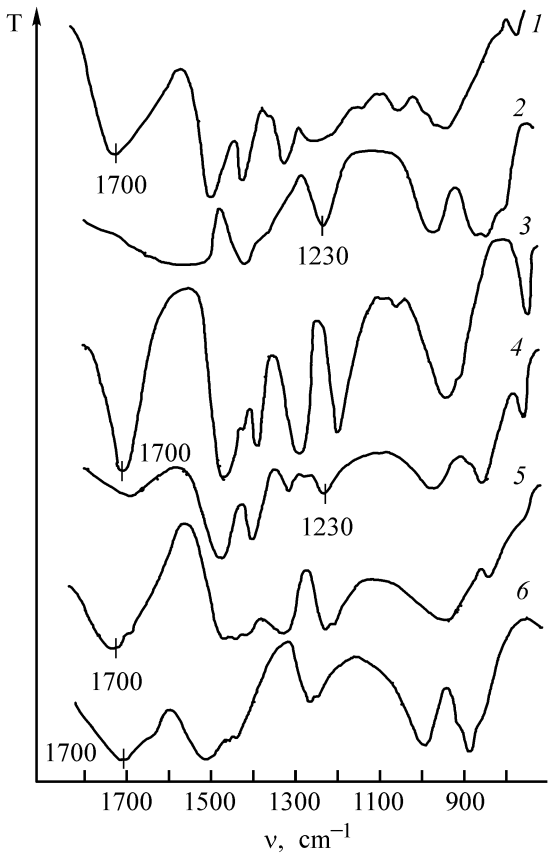

Fig. 2. IR spectra of carboxylic acids before and after their reaction with $KF \cdot H_2O_2$. (T) Transmission and (ν) wave number. Acids: (*1*, *2*) adipic, (*3*, *4*) fumaric, and (*5*, *6*) succinic.

$$KHF_2 \cdot H_2O_2 = KHF_2 + H_2O + 0.5O_2. \quad (4)$$

The formation of potassium carboxylate on treatment of $KF \cdot H_2O_2$ with carboxylic acid is manifested in the IR spectra as disappearance of the broad absorption band of protonated carboxy groups (1700 cm^{-1}) [7]. Potassium carboxylate should exhibit absorption bands of carboxylate anions (1550 and 1400 cm^{-1}). However, these bands are obscured by absorption by coordinated hydrogen peroxide and Vaseline oil.

The formation of potassium hydrogen bifluoride by reaction (2) is manifested in the IR spectrum as a sharp absorption band of bending vibrations of hydrogen bifluoride anions HF_2^- (1230 cm^{-1}) [6]. Thus, the IR spectra clearly show that, in the systems under consideration, potassium carboxylates and HF_2^- anions are formed.

We found that the above-noted spectral effects caused by addition of carboxylic acids (20 wt % of $KF \cdot H_2O_2$ amount) to $KF \cdot H_2O_2$ are clearly manifested with fumaric, and less clearly with adipic acid. At the same time, under these conditions, succinic acid is either completely inert to potassium fluoride or only slightly reacts with it. In this case, the IR spectrum contains an unchanged broad absorption band at 1700 cm^{-1}, and the absorption band at 1200 cm^{-1} only slightly broadens and shifts toward higher wave numbers. We do not rule out that admixture of HF_2^- may contribute to this spectroscopic effect (Fig. 2). Our spectroscopic data show that succinic acid, in contrast to other carboxylic acids tested, is not noticeably converted to the potassium salt by the exchange reaction with $KF \cdot H_2O_2$. We believe that this chemical inertness of succinic acid is responsible for the specific features of the time dependence of *k* for $KF \cdot H_2O_2$ stabilized with succinic acid.

We believe that the sharp increase in the rate of decomposition of $KF \cdot H_2O_2$ stabilized with maleic, fumaric, and, to a lesser extent, adipic acids in the early storage period is caused by successive reactions (1)–(3), followed by decomposition of low-stable potassium hydrogen bifluoride solvate with hydrogen peroxide by reaction (4). The content of KHF_2 solvate with hydrogen peroxide varies in proportion to the content of carboxylic acid in the reaction mixture and does not exceed 1–2 wt %. After decomposition of this unstable compound, the rate of $KF \cdot H_2O_2$ decomposition decreases first sharply and then gradually till the end of storage. We believe that, in the late storage periods, the stabilizing effect is caused not by carboxylic acid but by a mixture of potassium carboxylate with potassium hydrogen bifluoride.

Figure 1 shows that the initial sharp increase in *k* for stabilized $KF \cdot H_2O_2$, typical of carboxylic acids, is not observed for $KF \cdot H_2O_2$ stabilized with succinic acid. We believe that this feature of succinic acid is caused by the fact that, in preparing $KF \cdot H_2O_2$ stabilized with succinic acid, this acid does not react with potassium fluoride (or reacts to a small extent) and, therefore, is not involved in further reactions, including reaction (4) responsible for a sharp increase in rate constant of $KF \cdot H_2O_2$ decomposition.

However, the small positive slope in the plot of *k* for $KF \cdot H_2O_2$ stabilized with succinic acid vs. storage time (Fig. 1) shows that reactions (1)–(4) proceed slowly in prolonged storage of the final product. We found that the IR spectra of the sample prepared by thorough grinding of solid succinic acid and $KF \cdot H_2O_2$ contains a distinct absorption band of HF_2^- anions (1230 cm^{-1}) and no absorption band of

protonated carboxy groups at 1700 cm^{-1}. We believe that these spectroscopic effects are caused by the fact that succinic and, to a smaller extent, adipic acids are weaker ($k_1 = 6.89 \times 10^{-5}$ and $k_1 = 3.7 \times 10^{-5}$, respectively) than maleic and fumaric acids ($k_1 = 1.42 \times 10^{-2}$ and $k_1 = 9.30 \times 10^{-4}$, respectively) [8] and, therefore, they are less reactive (or even inert) with respect to potassium fluoride in preparing stabilized $KF \cdot H_2O_2$. However, in prolonged storage, succinic acid begins to react slightly with $KF \cdot H_2O_2$. In the early period of storage, this reaction is very slow and, after a certain period of time, it stops at all because of rupture of molecular contacts between the components of the system under consideration. Thus, succinic acid efficiently stabilizes $KF \cdot H_2O_2$, preventing its decomposition during prolonged storage.

The ratios of the rate constants of decomposition of the initial and stabilized $KF \cdot H_2O_2$ are listed in Table 2. These data show that the stabilizing power of succinic acid exceeds that of the other carboxylic acids by a factor of 2–5, and the stabilizing power of potassium hydrogen bifluoride, by a factor of 1.5. Thus, among the carboxylic acids tested, succinic acid is the most promising non-corrosive additive ensuring efficient stabilization of modern PFK disinfectants based on potassium fluoride solvate with H_2O_2.

CONCLUSIONS

(1) $KF \cdot H_2O_2$ stabilized with carboxylic acids, prepared under conditions typical of its semicommercial production shows stability in storage for more than 3 years. The H_2O_2 loss during this storage time varies from 1 to 5%.

(2) The rate constant of decomposition of $KF \cdot H_2O_2$ stabilized with carboxylic acids depends on a particular carboxylic acid and storage time.

(3) In the early period of storage of $KF \cdot H_2O_2$ stabilized with carboxylic acids, potassium carboxylate and KHF_2 are formed. In further storage, KHF_2 forms an unstable solvate responsible for H_2O_2 decomposition. Succinic acid is inert toward KF; therefore, its stabilizing efficiency exceeds that of the other carboxylic acids and also of potassium hydrogen bifluoride.

(4) Succinic acid can be used as a non-corrosive stabilizer of modern PFK disinfectants based on potassium fluoride solvate with H_2O_2.

Table 2. Relative performance of stabilizing agents* (storage time 3.4 years)

Stabilizing agent	Content, wt %	H_2O_2 loss, % from the initial amount	β, % day^{-1}	β^{unstab}/β

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Thermally Curable Emulsion Binders for Mold Cores and Molds Based on Tall Pitch

Received July 28, 2004

Abstract—Preparation of thermally curable emulsion binders for mold cores and molds using tall pitch was studied. Preparation conditions, composition, and colloid-chemical properties of the resulting emulsions were investigated.

Thermally curable binders (TCBs) for preparing mold cores and molds should meet rather strict requirements. The compression and tensile strength of mold cores should be no less than 0.12–0.20 (wet state) and 12–20 kgf cm^{-2} (after drying), respectively. At the same time, the mixture should not adhere to casting patterns when preparing mold cores (and molds), especially with the so-called core-blowing procedure [1].

In [2, 3], we studied TCBs for sand and core stocks with a tall pitch (TP) binder, which is a by-product from production of cellulose by the sulfate procedure. One of these TCBs (TOP brand) is a solution of TP (50–90 wt %) in an organic solvent (10–50 wt %), namely, in a hydrocarbon, alcohol, ketone, acetic acid ester, or their mixture. However, aqueous solutions of lignosulfonates (LSs) should be added to the sand stock to provide the required strength and to improve the geometry of mold cores and molds, which somewhat complicates the process.

In [3], we studied a TCB based on equal amounts of a 60–65% TP solution in kerosene and a 50% aqueous solution of LS. However, this TCB fails the provide a stable quality of the resulting molds and cores because of the composition heterogeneity, mainly caused by the low aggregation stability of the emulsion based on the TCB component; it is unstable and separates into aqueous and organic layers during storage and use. Thus, development of stable emulsions containing TP and LS is of particular importance for both foundry and timber enterprises.

In this study, we analyzed formation of stable emulsions based on TP and various LSs and examined their colloid-chemical properties.

It is known that, depending on the composition (TP and LS ratio) and preparation conditions, we can obtain either oil-in-water (direct) or water-in-oil (reverse) emulsions. Due to the intense coloring and high viscosity of the resulting mixtures, their type was determined from the data on the electrical conductivity of the system and its components and from the wetting angles of the glass (θ_g, deg) and waxed (θ_w, deg) supports. In the case of the water-in-oil emulsions, the electrical capacitance reflecting the dielectric properties of the system was also recorded.

Oil-in-water emulsions (Table 1, nos. 1–5) were prepared using nonionic surfactants based on OP-10 polyoxyethylene alkylphenols and Reapon Pluronic with the index of the hydrophilic-lipophilic balance (HLB) equal to ~10. The electrical conductivity χ^{25} of emulsion nos. 1–5 is 1.26 ± 0.06 S m^{-1}, which is close to the conductivity of the aqueous solution (χ^{25} = 0.15 S m^{-1}) and differs from that of the tall pitch by more than three orders of magnitude ($\chi^{25} = 4.8 \times 10^{-4}$ S m^{-1}). These data show that emulsion nos. 1–5 belong to the oil-in-water type. This is also confirmed by the linear dependence of the electrical conductivity on the content of surfactant in the emulsion upon its dilution with water (dispersion medium), which is illustrated by the example for emulsion no. 4 (Fig. 1).

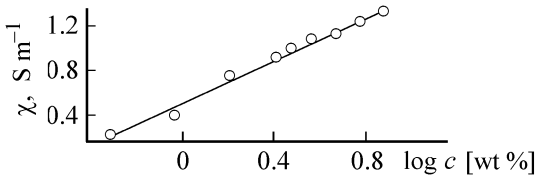

Fig. 1. Electrical conductivity χ of emulsion no. 4 vs. Reapon surfactant concentration c (at dilution of the emulsion with water).

5	43.5	Reapon, 8.7	Urea, 6.1	13.0	28.7	″	50	330

Table 2. Composition and properties of the water-in-oil emulsions based on TP

Emulsion no.	Emulsion composition, wt %						Emulsion properties		
	oil				water		A	θ_g, deg	η, s
	TP	kerosene	surfactant	cosolvent	50 wt % LS in water	water			
6	24.7	16.3	OP-4, 8.2	– –	42.7	8.1	Strong phase separation	24	
7	22.5	14.9	OP-4, 7.4	1-Heptanol, 9.0	38.8	7.4	Slight phase separation	20	
8	24.7	16.3	Ethox CO-5, 8.2	– –	42.7	8.1	Stable	15	250
9	22.5	14.9	Ethox CO-5, 7.4	1-Heptanol, 9.0	38.8	7.4	″	10	180
10	22.5	14.9	Ethox CO-5, 7.4	Glycerol, 9.0	38.8	7.4	″	10	200

As can be seen from Table 1, the aggregation stability A of oil-in water emulsions based on TP can be efficiently controlled by adding hydrotropes and cosolvents (e.g., 2-propanol, urea, and glycerol), which solubilize compounds sparingly or poorly soluble in water. In this case, no phase separation is observed and the limiting wetting angle on the glass support strongly decreases. Emulsion nos. 4 and 5 containing Reapon surfactant and urea and glycerol hydrotropes are the most stable (Table 1); simultaneously, the viscosity η of emulsions, evaluated from the outflow time, decreases to 300–330 s.

The water-in-oil emulsions (Table 2, nos. 6–10) were prepared using nonionic surfactants based on OP-4 polyoxyethylene alkylphenols and Ethox CO-5 polyoxyethylene ester of castor oil, with HLB ~4. Tall pitch was dissolved in a nonpolar solvent (kerosene); 1-heptanol and glycerol were used as cosolvents.

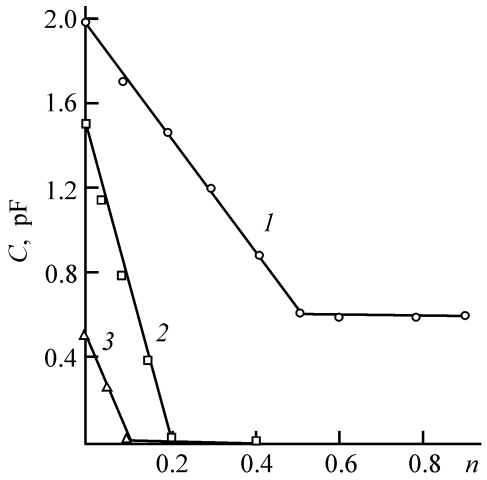

Fig. 2. Electrical capacitance of the emulsions as influenced by dilution with kerosene. Emulsion no.: (*1*) 8–10, (*2*) 7, and (*3*) 6. (*C*) Electrical capacitance and (*n*) dilution ratio [weight ratio of kerosene (dispersion medium) and emulsion].

The electrical capacitance of emulsion nos. 6–10 as influenced by dilution with kerosene is shown in Fig. 2. As seen, the electrical capacitance of emulsion no. 8 containing Ethox CO-5 is 2 pF before dilution. With dilution, the electrical capacitance first decreases linearly to 0.6 pF (0.5 dilution ratio) and then remains constant. It should be noted that addition of 1-hepanol and glycerol affects neither the initial electrical capacitance of the emulsions nor its changes upon dilution with kerosene.

Addition of kerosene does not affect the dependences of the electrical capacitance of emulsion nos. 6 and 7, prepared using OP-4 surfactant (Fig. 2, curves *2*, *3*), but addition of 1-heptanol strongly changes the dielectric properties of the emulsions. The initial electrical capacitance of emulsion no. 6 is 0.5 pF, whereas for emulsion no. 7 containing 1-heptanol it is higher by a factor of 3 (1.5 pF). The inflection points in the dependences of the electrical capacitance on the kerosene content are observed at dilution ratios of 0.1 and 0.2, respectively. In this case, in contrast to the emulsions prepared with Ethox CO-5, the electrical capacitance at the inflection point is 0.

These data, characterizing changes in the dielectric properties of emulsion nos. 6–10, indicate that they belong to the water-in-oil type. However, on adding kerosene to the emulsion up to the dilution ratio corresponding to the inflection point (Fig. 2), the emulsions break down. Thus, water-in-oil emulsions based on TP and LS belong to the limitedly dilutable dispersion systems, and the dilution ratio can be used as a criterion of the aggregation stability of the emulsion, *A*. Apparently, emulsion nos. 8–10 based on Ethox CO-5 (dilution ratio at the inflection point 0.5) are more stable than emulsion nos. 6 and 7 prepared using OP-4 (dilution ratio 0.1 and 0.2, respectively).

As can be seen from Table 2, Ethox CO-5 is preferable as compared to OP-4 surfactant, because in this case, the phase separation is fully absent and the limiting wetting angle on the waxed support decreases to 15°.

On adding 1-heptanol or glycerol, the aggregation stability of the emulsion with Ethox CO-5 increases, which is confirmed by a decrease in the limiting wetting angle to 10°; simultaneously their viscosity (outflow time) decreases to 180–200 s.

It should be noted that glycerol is a versatile component stabilizing both oil-in-water and water-in-oil emulsions based on TP and LS. It has been suggested [4] that the effect of hydrotropes may include three factors: breakdown of the native structure of water and weakening of hydrophobic interactions; complexation with molecules of poorly soluble compounds; and breakdown of the liquid-crystal order and formation

Table 3. Quality parameters of the mold cores and molds prepared using emulsion TCBs based on TP

TCB (emulsion no.)	TCB / sand, wt %	Strength, kgf cm^{-2}		Adhesion to casting patterns
		compression strength in the wet state	tensile strength after drying

10	7.5	0.15	20	"

of mixed aggregates. In our case, the increase in the aggregation stability is probably due to an increase in the thermodynamic compatibility between water and molecules of nonionic surfactants and LSs.

Stable emulsions based on TP and LS, prepared in this study, were tested as TCBs for preparing mold cores and molds; their main performance parameters are listed in Table 3. As seen, our emulsion TCBs provide the required strength of the sand stocks in both wet and dry states, and no additional components are required. Moreover, stable water-in-oil emulsion nos. 8–10 completely suppress adhesion of the sand stock to the casting patterns, which makes them preferable over the existing TCBs.

Since preparation of emulsion TCBs does not require development of special installations, they were industrially produced at the Ural Wood-Chemical Plant, Joint-Stock Company (Neivo-Rudyanka urban village, Sverdlovsk oblast).

The use of emulsion binders for preparing mold cores and molds also does not require development of any special equipment, the process can be performed using available foundry facilities, which was confirmed by the results of their tests at the Nizhni Tagil Plant of Boilers and Radiators, Joint-Stock Company (Sverdlovsk oblast).

EXPERIMENTAL

In our study, we used tall pitch [TU (Technical Specifications) 13-0281078–84 with alternation no. 1 (Tall Pitch for Road Building)] with a softening point of 24°C and acid number of 55 mg KOH per gram of the product; A brand liquid lignosulfonates (TU 13-0281036-029–94) with the weight fraction of the dried compounds of 50%. Since the quality of the other components (surfactants, kerosene, and other chemicals) met the norms and regulations, they were used without additional purification.

The oil-in-water emulsions were prepared as follows. The required amounts of a 50% LS aqueous solution, surfactant, distilled water, and auxiliary component [hydrotrope or cosolvent] were stirred for 20 min at 20°C to complete homogenization, avoiding strong foaming; then the required amount of TP preheated to 100–110°C was slowly added to the reaction mixture with increasing stirring rate, and the mixture was stirred for 30–40 min at 50–60°C to obtain a stable emulsion.

The water-in-oil emulsions were prepared as follows. The required amounts of TP heated to 70–80°C, kerosene, surfactant, and auxiliary component were stirred at 20°C for 20 min to complete homogenization; then the required amount of a mixture of a 50% LS aqueous solution and distilled water, prepared in advance, was slowly added to the reaction mixture with increasing stirring rate, and the mixture was stirred for 30–40 min at 20°C to obtain a stable emulsion.

The aggregation stability of emulsions *A* was characterized by a change in the volume of the separated phases after heating of the emulsions at 70–80°C for 3 h and subsequent settling for 1 month.

The wetting angle on the waxed and glass supports, specific electrical conductivity, and electrical capacitance of the emulsions were measured by procedures given in [5].

The viscosity of the emulsions was evaluated with a VZ-4 viscometer (4 mm orifice diameter) according to the GOST (State Standard) 11503.

The performance of the emulsion systems was tested in accordance with [1]: 1KO-A quartz sand was mixed in a runner with the required amount of TCB, then the core was prepared and its compression strength in the wet state and adhesion to the casting pattern were determined. Then, the mold was dried for 1 h at 230–250°C and its tensile strengths in the dried state was determined.

CONCLUSIONS

(1) Stable oil-in-water (direct) and water-in-oil (reverse) emulsions based on tall pitch and lignosulfonates were prepared.

(2) Addition of hydrotropes (2-propanol, 1-heptanol, urea, and glycerol) increases the aggregation stability of the emulsions probably due to an increase in the thermodynamic compatibility between water and molecules of surfactants (in our case, nonionic surfactants and lignosulfonates). Glycerol stabilizes both oil-in-water and water-in-oil emulsions.

(3) The resulting emulsions are effective thermally curable binders for preparing mold cores and molds providing high compression and tensile strength of the cores: 0.12–0.18 and 14–22 kgf cm^{-2} in the wet and dried states, respectively. The mixture does not adhere to the casting patterns when preparing mold cores.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Radical Copolymerization of Methyl Methacrylate and Styrene in the Presence of Metallocenes

R. Kh. Yumagulova, S. V. Kolesov, and Yu. B. Monakov

Institute of Organic Chemistry, Ufa Scientific Center, Russian Academy of Sciences, Ufa, Bashkortostan, Russia

Received October 5, 2004

Abstract—The effect of ferrocene and zirconocene dichloride on the rate and constants of copolymerization of methyl methacrylate with styrene was studied. The results obtained suggest that the metallocenes in the elementary steps of the reaction.

The main way to control the product composition in radical copolymerization is introduction of special additives (as a rule, protic and aprotic acids). These acids coordinate with the monomers and thus enhance their electron-acceptor properties, which allows preparation of alternating copolymers [1–3]. The major drawback of this approach is that the controlling additive is introduced in an amount comparable with that of the monomer, which results in contamination of the polymer product and impairs its properties. Purification of the products is very expensive; therefore, this method for controlling the composition and structure of macromolecular compounds is of limited use.

Organometallic compounds (OMCs) are free of this drawback, since their controlling effect on the chain propagation is manifested when the amounts of these compounds are comparable with that of the initiator. This fact indicates that, in contrast to Lewis acids, complexation of OMCs occurs with the macroradicals rather than monomers. For example, Grishin and Moikin [4] found, when studying the monomer system methyl methacrylate (MMA)–methacrylic acid (MAA), that addition of triethylantimony results in rigorous alternation of units in the copolymer, instead of enrichment of the copolymer with methacrylic acid as the more active monomer (r_{MAA} = 1.40, r_{MMA} = 0.08). They noted that the alternation of the units is associated with the increased rate of cross coupling as a result of formation of a cyclic reaction complex consisting of the coordination-unsaturated organometallic additive, macroradical, and monomer. However, addition of triethylantimony in copolymerization of MAA with an electron-donor monomer, styrene, considerably accelerates the reaction, but has virtually no effect on the composition of the copolymers and relative activities of the monomers [5].

There are indications in the literature that, in homopolymerization of styrene in the presence of various organometallic compounds of Groups II and III, the chain propagation occurs by the common radical mechanism without participation of the OMCs, since the OMCs do not interact with the propagating polystyrene radicals because of the effect of electronic and steric factors. Furthermore, some Group-III OMCs even inhibit the styrene polymerization [6]. Puzin *et al.* [7] reported that the carbonyl group of the monomer is involved coordination interaction with the organometallic compound in homopolymerization of MMA in the presence of metallocenes. It has also been found [8] that, in contrast to Group II–III OMCs, styrene is also involved in the coordination-radical polymerization in the presence of metallocenes.

In this study, we examined the effect of ferrocene and zirconocene dichloride on the radical copolymerization of methyl methacrylate with styrene.

EXPERIMENTAL

The monomers were purified by standard procedures [9]. Benzoyl peroxide was repeatedly recrystallized from methanol and dried at room temperature in a vacuum to constant weight; mp 108°C (dec.). Ferrocene and zirconocene dichloride (both of analytically pure grade) were used without additional purification.

The copolymerization was performed at 60°C in the metallocene concentration range 0.2×10^{-3}–

* The rate of homopolymerization of MMA and styrene in the absence of metallocenes is 5.89×10^{-3} and 0.95×10^{-3} mol l^{-1} min^{-1}, respectively.

1.0×10^{-3} M at a constant concentration of the initiator (benzoyl peroxide), 1×10^{-3} M.

The radical copolymerization in the bulk was performed in 5–7-ml molybdenum glass dilatometers. The reaction mixture consisting of the monomers, initiator, and metallocene was charged into the dilatometer in air. Then the contents were deoxygenated by three freeze–pump–thaw cycles (residual pressure 0.01 mm Hg), after which the dilatometer was sealed with a gas burner. Polymer samples were obtained at low conversions (≤5%), reprecipitated three times by adding benzene solutions into hexane, and dried in a vacuum to constant weight at 35°C.

The contraction factor required for calculating the degree of conversion of the monomers to the polymer was determined experimentally for each monomer ratio. The copolymerization constants were calculated by the Fineman–Ross method [10].

Addition of ferrocene increases the initial copolymerization rate by an order of magnitude at various monomer ratios. With zirconocene dichloride, the acceleration is insignificant, and at low concentrations of zirconocene dichloride and excess of styrene the copolymerization rate is even lower than that in the absence of the additive (see table).

In copolymerization of MMA and styrene in the absence of ferrocene and zirconocene dichloride, the copolymerization rate is lower than the rates of homopolymerization of these monomers (see table). The copolymerization rate has a minimum at the equimolar ratio of the monomers. These data correlate with the rate constants of addition of a monomer to a radical. It is known that, in the system styrene–MMA, each free radical reacts preferentially with the monomer of the other kind; therefore, the copolymerization rate is higher when one of the monomers is in excess [11].

The experimental data on copolymerization of methyl methacrylate with styrene at a fixed concentration of ferrocene show that the dependence of the copolymerization rate on the composition of the monomer mixture also passes through a minimum at the equimolar ratio of the monomers (Fig. 1a); also, the reaction decelerates with conversion. With zircono-

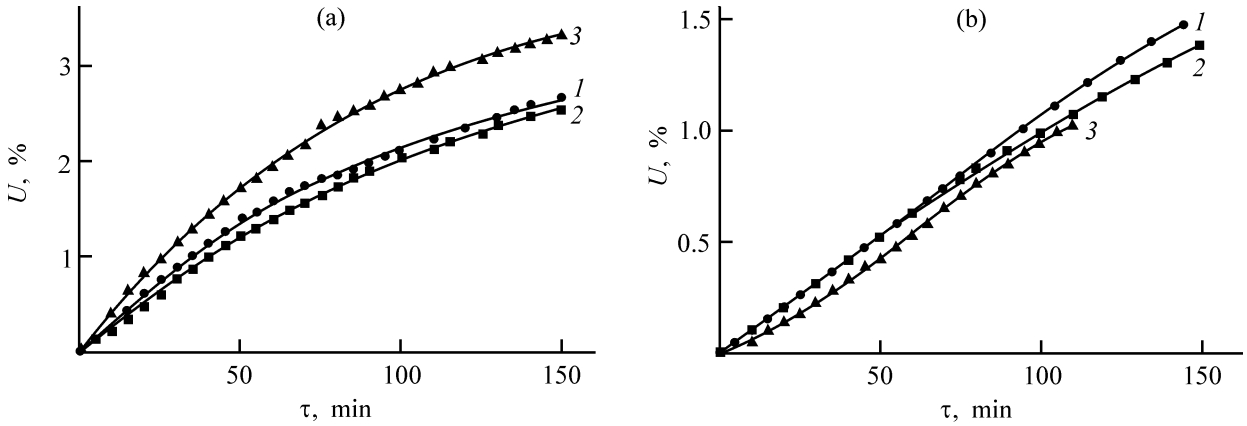

Fig. 1. Copolymerization of methyl methacrylate with styrene in the presence of 0.5×10^{-3} M (a) ferrocene and (b) zirconocene dichloride at 60°C. (U) Conversion and (τ) time; the same for Fig. 2. MMA : styrene ratio: (*1*) 2 : 1, (*2*) 1 : 1, and (*3*) 1 : 2.

cene dichloride, the copolymerization rate decreases with an increase in the styrene content (Fig. 1b).

As the ferrocene concentration increases at a fixed ratio of the monomers, the copolymerization rate grows, reaches a maximum at a ferrocene concentration of 0.5×10^{-3} M, and then decreases (Fig. 2a). With zirconocene dichloride, the reaction rate is the highest at a metallocene concentration of 1.0×10^{-3} M and a twofold excess of styrene (Fig. 2b).

In polymerization of monomers containing a polar substituent, the chain propagation occurs by two mechanisms: on free radicals and on a monomer radical coordination-bound to the metallocene [7]. Radicals of the second type significantly contribute to the polymerization. This fact apparently accounts for a decrease in the copolymerization rate with an increase in the degree of conversion, since the chain propagation mainly occurs on more stable reaction centers. In our case, these are complexes of metallocenes with methyl methacrylate, which are accumulated in the course of the process. Since PMMA radicals are coordinated with metallocene, an increase in the content of ferrocene and styrene is accompanied by an increase in the rate of addition of coordination-bound PMMA radicals to styrene, so that the copolymerization rate becomes higher. The dependences of the reaction rate on the ferrocene concentration and on the MMA : styrene ratio pass through a maximum and a minimum, respectively (in the latter case, at the equimolar ratio of the monomers).

The experimental copolymerization constants are listed in the table. It is seen that, with ferrocene, they tend to decrease with increasing concentration of metallocene. The relative activity of MMA varies to the greatest extent. With zirconocene dichloride, the copolymerization constants only slightly differ from those characteristic of free-radical copolymerization of MMA with styrene.

Our constants are, apparently, effective quantities averaged over two copolymerization pathways: free-radical and coordination-radical. A decrease in the relative activity of MMA in the presence of a metallocene may be due both to a decrease in K_{11} and to an increase in K_{12}, or to simultaneous variation of both constants. These trends may be caused by increased electron-withdrawing power of the poly(methyl methcarylate) radical coordinated with the metallocene. Apparently, with an increase in the electrophilicity of the macroradical, its reactivity toward the π bond of monomeric MMA with an electron-withdrawing substituent decreases, and that toward styrene (electron-donor monomer) increases.

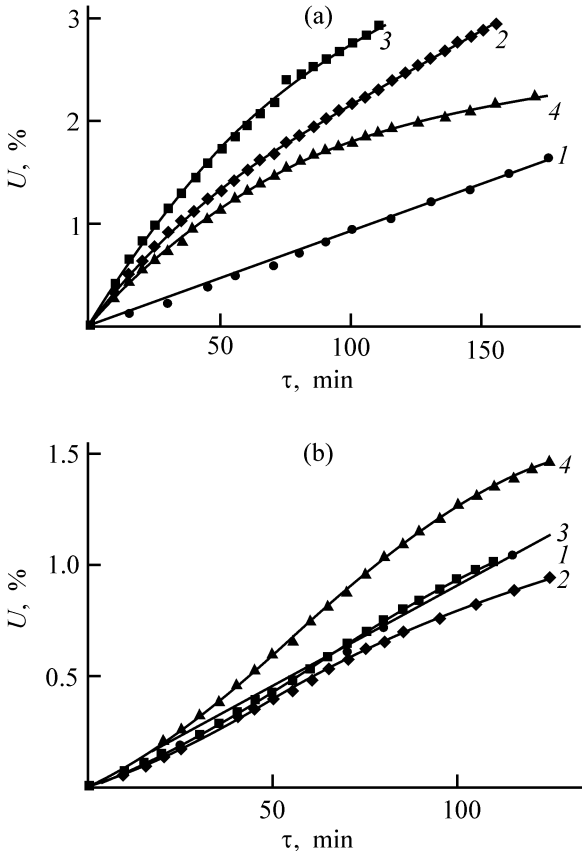

Fig. 2. Copolymerization of methyl methacrylate with styrene at the monomer ratio MMA : styrene = 1 : 2 at 60°C in the presence of (a) ferrocene and (b) zirconocene dichloride. Metallocene concentration $c \times 10^3$, M: (*1*) 0, (*2*) 0.2, (*3*) 0.5, and (*4*) 1.0.

With zirconocene dichloride, this trend is weakly pronounced. The reason is, apparently, the same as that for the weak effect on the copolymerization rate: low rate of formation and hence low concentration of the coordination complexes.

CONCLUSION

Our experimental data show that metallocenes are involved in the elementary events of copolymerization of methyl methacrylate with styrene.

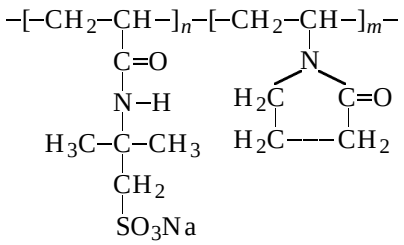
Received September 21, 2004



Abstract—The kinetics of copolymerization of sodium 2-acrylamido-2-methylpropanesulfonate with *N*-vinylpyrrolidone in aqueous solutions in the presence of potassium persulfate at 40–70°C and the molecular characteristics of the resulting complexes were studied, as influenced by the total concentration of the initial monomer mixture, comonomer ratio, temperature, and conversion. The kinetic data were explained taking into account the state of the ionic groups, electrostatic interactions between the reacting particles, and complexation of comonomers in the course of copolymerization.

Radical copolymerization in aqueous solutions is one of the main, but still insufficiently studied procedures for preparing water-soluble copolymers of sodium 2-acrylamido-2-methylpropanesulfonate (Na-AMS) with *N*-vinylpyrrolidone (VP), which exhibit high flocculation [1], adhesive and antistatic properties [2], and thickening and complexing power and show promise for various branches of industry and medicine. In this study, copolymerization of Na-AMS and VP was examined as influenced by concentration. Being unusual from the standpoint of the classical theory, this effect is due to specific features of copolymerization of ionic monomers [3] with, in particular, salts of unsaturated sulfonic acids [4, 5] and can be described as a dependence of the polymer composition on the total concentration of the comonomers in the course of copolymerization at fixed composition of the initial monomer mixture and conversion. The concentration effect in copolymerization of Na-AMS and VP has not been studied previously.

EXPERIMENTAL

The properties of the starting compounds and the experimental procedures used (copolymerization, dilatometric analysis of the reaction kinetics, etc.) were similar to those described in [6]. The initial rates of copolymerization, v_0, at low conversion (<4%) were determined from the kinetic curves obtained dilatometrically.

After copolymerization, the resulting polymers were precipitated from aqueous solutions with acetone, filtered off, washed with acetone, and dried to constant weight in a vacuum at 50°C. The yield of the copolymers was determined gravimetrically. The content of ionic units in the copolymer of Na-AMS and VP

was determined from the content of sulfur [7]. The molecular weight of copolymers (M) was calculated with the Mark–Houwink equation from the intrinsic viscosity [η] of their solutions, which was measured in a 0.5 M NaCl solution at 30°C on a VPZh-3 viscometer (d_c = 0.43 mm). The experimental dependence of the reduced viscosity η_{sp}/c_p on the copolymer concentration c_p was plotted. Then, using the linear dependence $\eta_{sp}/c_p = f(c_p)$, we determined

$$[\eta] = \lim(\eta_{sp}/c_p) \text{ at } c_p \to 0.$$

The IR spectra were recorded on an Avatar 360 Fourier spectrometer (ThermoNicolet, the United States) in the 4000–400 cm^{-1} range using VP and a solution of Na-AMS in VP (1 : 9 molar ratio) prepared by mixing of alcoholic monomer solutions

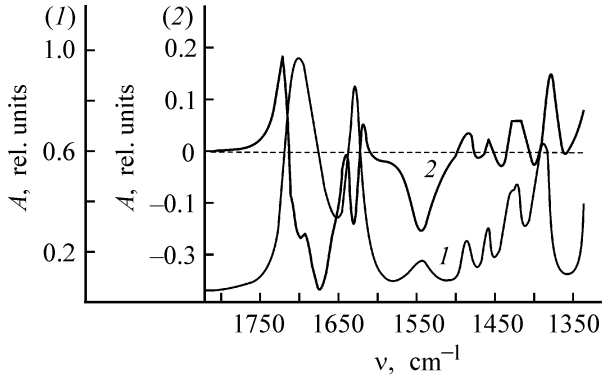

Fig. 2. IR spectrum of (*1*) Na-AMS solution in VP ($[M_1]_0/[M_2]_0$ = 9 : 1) and (*2*) differential spectrum obtained by subtraction of the VP spectrum from the spectrum of Na-AMS solution in VP (for additional explanations, see text). (*A*) Absorption and (ν) wave number.

with subsequent removal of the solvent. The spectra were processed using a KnowItAll software (v.3.0 Academic Edition Bio-Rad Laboratories, the United States).

Copolymerization of Na-AMS with VP was carried out in 10–30% aqueous solutions at 50°C and pH 9. The reaction was initiated by thermal decomposition of potassium persulfate ([PP] = 7.4 × 10^{-4} M). Maintaining pH 9 during copolymerization with PP [8] is necessary to provide fairly high and constant rates of initiation when the ionic strength μ [9] varies due to changes in the Na-AMS concentration in the initial solution and in the course of copolymerization, and also to prevent hydrolysis of Na-AMS [10] and VP [11]. In our experiments, copolymerization proceeded under homogeneous conditions, and no spontaneous formation of the copolymer was observed.

First, we studied the effect of the monomer ratio $[M_1]_0/[M_2]_0$ in the initial solution on the copolymerization, where $[M_1]_0$ and $[M_2]_0$ are the initial concentrations of Na-AMS and VP, respectively. The experiments were performed at the total concentration of comonomers of 10, 25, and 30%, the other experimental conditions being equal. The dependences of v_0 on the concentration of Na-AMS $[M_1]$ in the initial monomer mixture are shown in Fig. 1. As seen, the dependence $v_0 = f(M_1)$ passes through a maximum in the case of copolymerization in 10 and 30% solutions. These results agree with published data [6, 12] and suggest a donor–acceptor interaction between Na-AMS and VP, with Na-AMS being a moderate electron acceptor, and VP, a moderate electron donor.

As seen, the [η] values of the resulting copolymers of Na-AMS and VP vary in parallel with the dependence $v_0 = f(M_1)$, and v_0 and [η] are the highest at $[M_1]_0/[M_2]_0$ = 5 : 5, when the degree of complexation of Na-AMS and VP is the highest. The complexation of Na-AMS with VP is also confirmed by viscometry (Fig. 1, curve *3*). Thus, the dependence $\eta_{sp}/c_m = f(M_1)$ (c_m is the concentration of the monomer mixture) passes through a maximum at the equimolar component ratio corresponding to the highest concentration of Na-AMS–VP complexes.

The complexation in the system was also studied by IR spectroscopy. Due to the low solubility of Na-AMS in VP, we recorded only the IR spectrum of a 1 : 9 (mol/mol) Na-AMS solution in VP. At a large excess of VP, the resulting IR spectrum exhibited only a weak band of Na-AMS near 1545 cm^{-1}, which gave no way of monitoring the monomer interaction. This problem was solved by computer subtraction; the spectrum of pure VP was subtracted from the spectrum of Na-AMS solution (Fig. 2). In curve *2* (Fig. 2) the bands belonging to pure VP and Na-AMS solution in VP lie above and below the zero (dashed) line. Apparently, in the absence of interaction between the monomers, such a subtraction should give only the absorption bands belonging to Na-AMS and occurring below the zero line. As seen, the differential spectrum (Fig. 2, curve *2*) contains a single band at 1545 cm^{-1}, which belongs to Na-AMS and does not overlap with VP bands, and the amide I band near 1675 cm^{-1}, overlapping with the strong band at 1705 cm^{-1}. The occurrence of complexation in the system is confirmed by a shift of the absorption bands at 1705 and 1630 cm^{-1} belonging to vibrations of the pyrrolidone ring. The first of these, originating

from stretching vibrations of the C=O group in the pyrrolidone ring, shifts toward lower frequencies, whereas the band at 1630 cm^{-1} becomes narrower and shifts toward higher frequencies, which is clearly seen when comparing the peak and a higher-intensity low-frequency shoulder of this band, directed below and above the zero line, respectively.

With the total concentration of the comonomers increasing in the course of copolymerization at $[M_1]_0/[M_2]_0$ = const, i.e., on passing from curve *1* to curve *2* (Fig. 1), v_0 and [η] increase. This is probably due to the increasing molecular weight of the resulting copolymers, and the polymer with the highest molecular weight is formed in the course of copolymerization in 30% aqueous solutions.

The yield of Na-AMS–VP complexes increases as the Na-AMS content in the initial monomer mixture is raised from 23 to 58%.

The dependences of the current concentration of the Na-AMS–VP copolymer at low conversions (x < 3%) on the composition of the initial monomer mixture are shown in Fig. 3. In all the cases, the curves are S-shaped with the corresponding azeotropic points. From these data (Fig. 3), we calculated the effective copolymerization constants of the monomers $r_1 = k_{11}/k_{12}$ and $r_2 = k_{22}/k_{21}$ for Na-AMS and VP (see table). The values of r_1 and r_2 confirm that, in the system studied, both macroradicals react with a "foreign" monomer more readily than with their "own" monomer owing to the stabilization of the transition state by the donor–acceptor interaction between the macroradical and the monomer. This provides alternation of the monomer units in the chain ($r_1 r_2 < 1$). As can be seen from the table, $r_2 > r_1$ in all the cases, which confirms the higher copolymerization reactivity of VP as compared to Na-AMS.

As can be seen from Fig. 3, the content of Na-AMS units in the copolymer increases with increasing total concentration of comonomers (from curve *1* to curve *3*) in a wide range of compositions of the initial monomer mixture, which is due to the increase in r_1 and decrease in r_2, respectively (see table).

The above kinetic data on the copolymerization of Na-AMS and VP in aqueous solutions at various concentrations of the initial monomer mixture can be explained taking into account the equilibrium of the ionic groups in Na-AMS and its units in the macroradicals in aqueous salt solutions:

$$\underset{\mathbf{I}}{A^-X^+} \rightleftarrows \underset{\mathbf{II}}{A^- \| X^+} \rightleftarrows \underset{\mathbf{III}}{A^- + X^+},$$

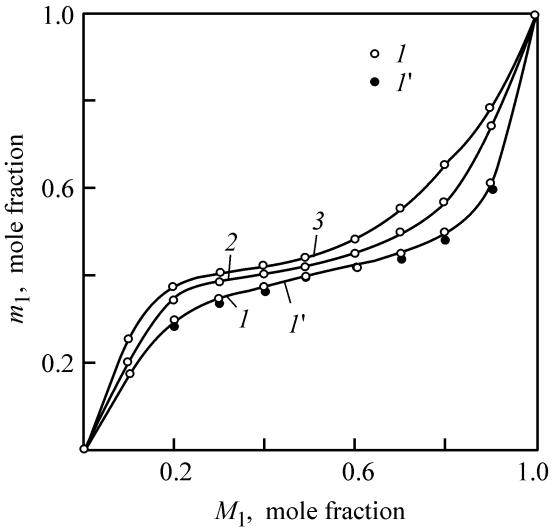

Fig. 3. Mole fraction of Na-AMS units in copolymer, m_1, at conversion x < 3% vs. the Na-AMS mole fraction in the initial monomer mixture, M_1. $[M_1]_0 + [M_2]_0$, %: (*1*, *1*') 10, (*2*) 25, and (*3*) 30. Temperature, °C: (*1*–*3*) 50 and (*1*') 70.

where A^- is the anion of the monomer or macroradical; X^+ is the cation; and **I**, **II**, and **III** are the contact ion pairs, ion pairs separated by a solvent, and free ions, respectively.

Changes in μ with the concentration of Na-AMS in the initial monomer mixture and in the course of copolymerization shift the ionization equilibrium of the ionic groups, thus changing the relative content in the reaction mixture of various ionic species differing in the reactivity. This changes the intra- and intermolecular electrostatic interactions and affects the conformation state of the growing macroradicals and, thus, affects the reactivity of ionic monomers in copolymerization (r_1, r_2). Due to the nonisoionic synthesis conditions, copolymerization of the ionic monomers in the ionizing media cannot be described using fixed copolymerization constants r_1 and r_2. It should be noted that, in copolymerization of Na-AMS and VP, changes in μ did not affect the reactivity of

VP and its macroradical, because the rate of VP polymerization did not change on adding low-molecular-weight salts [13].

In aqueous solutions, the ionic groups in Na-AMS and its units in copolymer are completely ionized, and the ionization equilibrium shifts to the left with increasing μ; this fact is confirmed by viscometry. At c_p = const, η_{sp}/c_p of Na-AMS–VP copolymer decreases with μ increasing upon addition of Na-AMS and NaCl. This is due to a decrease in the electrostatic repulsion between the sulfonate anions along the chain with an increase in their shielding by sodium counterions, which makes shorter the linear size of macromolecular polymer aggregates. In copolymerization of Na-AMS with VP, an increase in μ decreases the electrostatic repulsion between similarly charged particles in the events of chain propagation (in reaction of Na-AMS with a macroradical containing the terminal Na-AMS unit) or termination (in reaction between macroradicals with terminal Na-AMS units), and thus increases the constants of chain propagation k_p and termination k_t. As the concentration of the initial monomer mixture becomes higher, k_p (i.e., k_{11}) increases to a greater extent than k_t, which is confirmed by a rise in the molecular weight of the resulting copolymers and causes the increase in v_0. Moreover, a certain decrease in the charge of the growing chains with increasing μ makes higher the local concentrations of Na-AMS in the environment of the "own" active centers and thus also increases v_0.

To examine the effect of conversion on the molecular properties of the resulting copolymers of Na-AMS and VP, we performed copolymerization in 25% aqueous solutions at $[M_1]_0/[M_2]_0$ molar ratios of 5 : 5 and 7 : 3, the other experimental conditions being equal (Fig. 4). As seen, the copolymer composition does not change with increasing copolymerization time (Fig. 4, curves *1* and *2*). Apparently, in copolymerization in concentrated comonomer solutions, the main contribution to μ is made by changes in the concentration of Na-AMS in the initial monomer mixture, prevailing over the effect of binding of a certain fraction of Na^+ counterions with polyanions. The fact that the composition of the copolymer does not change with conversion agrees with the data on copolymerization of acrylamide with dimethylaminoethyl methacrylate sulfate in aqueous solution [14], which is due to the difference in the local concentration of the monomers near macroradicals as compared to the average concentration of the monomers in the reaction mixture, caused by hydrophobic interactions in the system.

The [η] values increase in the course of the reaction (Fig. 4, curves *3* and *4*), which agrees with the data on copolymerization of complex-bound monomers in other systems [15]. Apparently, the increase in the viscosity of the reaction mixture with conversion decreases the rate of mutual diffusion of the macroradicals and k_t, which promotes the increase in the molecular weight of the copolymer.

The effect of temperature on the copolymerization of Na-AMS and VP was studied at 40–70°C using 25% aqueous solutions ($[M_1]_0/[M_2]_0$ = 5 : 5), the other conditions being equal. As can be seen from Fig. 5a, v_0 increases with temperature. The experimental data give a linear plot in the Arrhenius coordinates (Fig. 5a) and correspond to the effective overall activation energy of copolymerization, E_{tot}, of 44.0 kJ mol^{-1}. The lower E_{tot} in the system studied (compared to common radical polymerization) is frequent in alternating copolymerization [15].

It should be noted that changes in the conformational state of the macroradicals of Na-AMS-VP copolymer with temperature can also affect v_0, which is confirmed by viscometry (Fig. 5b). As seen, η_{sp}/c_p in the solution of Na-AMS–VP copolymer at c_p = const decreases with increasing temperature.

This is caused by a decrease in the effective size of macromolecular aggregates with increasing temperature, which is due to weakening of the electrostatic

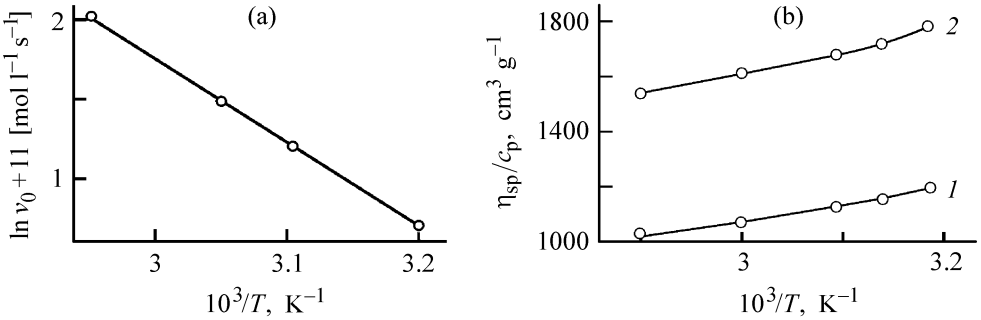

Fig. 5. (a) Initial rate of copolymerization, v_0, of VP with Na-AMS and (b) reduced viscosity η_{sp}/c_p of the aqueous solution of copolymer ([η] = 265 cm^3 g^{-1}, 48 mol % Na-AMS units) vs. temperature T. (a) $[M_1]_0/M_2]_0$ = 5 : 5; $[M_1 + M_2]_0$ = 25%. η_{sp}/c_p (b) $c_p \times 10^2$, g cm^{-3}: (*1*) 0.2 and (*2*) 0.5.

repulsion of the fixed charges along the chain with decreasing ionization of the ionic groups. This, in turn, results in that the local concentration of Na-AMS near the active centers (macroradicals with terminal Na-AMS groups) and, hence, v_0 increase with temperature.

Figure 3 shows the dependence of the copolymer composition on the initial composition of the monomer mixture at 50 (Fig. 3, curve *1*) and 70°C (Fig. 3, curve *1*'), and the temperature dependence of the polymer composition at $[M_1]_0/[M_2]_0$ = 5 : 5 is plotted in Fig. 4 (curve *1*'). These data show that the composition of the Na-AMS–VP copolymer is independent of the copolymerization temperature, which agrees with published data on copolymerization of acrylic and methacrylic acids in solvents capable of hydrogen bonding with the monomers [15]. Obviously, a decrease in the molecular weight of the copolymers due to an increase with temperature in the concentration of radicals generated by the initiator degradation agrees with common trends observed in radical copolymerization.

CONCLUSIONS

(1) The copolymerization rate v_0, molecular weight, and content of the sodium 2-acrylamido-2-methylpropanesulfonate units in the copolymer increase with the concentration of the initial monomer mixture due to the increasing effective relative activity r_1 (for sodium 2-acrylamido-2-methylpropanesulfonate) and decreasing r_2 (for *N*-vinylpyrrolidone).

(2) With increasing $[M_1]_0/[M_2]_0$ in the initial monomer mixture, the dependences of v_0 and molecular weight pass through a maximum at $[M_1]_0/[M_2]_0$ = 1 : 1 due to the formation of donor-acceptor complexes of the comonomers.

(3) With increasing conversion, the molecular weight of the copolymer grows and its composition remains unchanged, whereas with increasing temperature, v_0 becomes higher, molecular weight decreases, and the copolymer composition also remains unchanged.

Received December 5, 2003; in final form, October, 2004

Abstract—The influence of plasticizers, dibutyl phthalate and triphenyl phosphate, on the structure of the surface of cellulose triacetate films was studied. The parameters of an infinite cluster of the cellulose triacetate molecules on the film surface, the correlation radius ξ of the spatial distribution of density, the degree ρ_s of surface filling of the cluster, and the fractal dimensionality D, were calculated from the electron-microscopic data, using the cluster model.

Film bases for film-photographic materials are presently manufactured from partially hydrolyzed cellulose triacetate (CTA) with a degree of substitution equal to 2.75–2.95 [1]. Partially hydrolyzed CTA belongs to semirigid-chain polymers [2] whose macromolecules can form domain-type anisotropic aggregates in solution. The nature of aggregation of the CTA macromolecules in solution [3], at the solution–solid interface [4], and in transition of the polymer to the condensed state [5] is governed by the concentration and thermokinetic modes, as well as by the hydrodynamic volume of the macromolecules. The hydrodynamic volume strongly depends on the molecular weight, degree of substitution, distribution of the primary and secondary hydroxy groups in the macrochain, and solvent quality [3].

Krasovskii *et al.* [3] and Kharlampiev [5] used the cluster lattice model [6] in studies of the hydrodynamic behavior and the structure of the CTA samples in a series of proton-donating solvents; the samples differed in the distribution of the primary and secondary hydroxy groups in the macrochain. The formation of aggregates or clusters of macromolecules was revealed in going from dilute to semidilute CTA solutions. It was found that, with growing polymer concentration c in solution, the finite clusters tend to transform into an infinite (percolation) cluster, which is formed at c = 9–11 wt % and T = 293 K [5].

Our previous studies [7] suggest that the sites of the physical network of macromolecules in the CTA films obtained from polymer solution are represented by aggregates or clusters of the macromolecules, formed in solution. Such clusters have a fractal nature and exhibit an enhanced density of packing of the macromolecules, compared to the average density of the polymer. The topology of the spatial distribution of the cluster density determines the most important parameters of the physicomechanical and performance characteristics of films [8].

In Russia, the natural rigidity of CTA is commonly decreased by plasticization of polymer films with a mixture of triphenyl phosphate (TPP) and dibutyl phthalate (DBP) [1]. However, the influence of the plasticizer additions on the CTA cluster structure topology still remains to be elucidated. As known [9], the plasticizers introduced into the polymer film can modify the cluster topology by various mechanisms. In the case of true, or molecular, plasticization, the plasticizer molecules are incorporated into supramolecular CTA formations and loosen their structure. In the case of the structural plasticization, the plasticizer is localized along the cluster boundaries and in the intercluster space.

In this study, we examined the topology of the cluster structure of the CTA films containing commercial plasticizers, TPP and DBP, with the aim to elucidate the plasticization mechanisms and the influence of the plasticizers on the density of distribution of the supramolecular formations or clusters of the CTA macromolecules.

EXPERIMENTAL

We used a commercial sample of partially hydrolyzed CTA (Svema, Shostka, Ukraine) prepared

by a heterogeneous procedure and having a degree of polymerization of 300, degree of substitution of 2.85, and random distribution of the hydroxy groups. Film samples with a thickness of ca. 100 μm were prepared by casting a 10 wt % polymer solution in a 9 : 1 methylene chloride–ethanol mixture onto a leveled mirror glass at 293 K. The amount of the plasticizers, TPP and DBP, was 10 wt % relative to CTA.

We studied the film surface formed at the film–air interface. The topology of the cluster structure of the polymer on the film surface was studied by electron microscopy with gold decoration and preactivation with bromine. This procedure was suggested for the first time in [10, 11] for studying the structure of the macromolecular aggregates on the surface of amorphous and partially crystalline polymers. Surface activation yields molecular complexes of bromine with electron-donating functional groups of the CTA macromolecules, the so-called "chemical labels," acting as $AuBr_3$ formation sites in decoration, which are potential nuclei for the decorating gold particles. The chemical activation of the surface was carried out in a 0.5 wt % aqueous solution of bromine for 30 s, which was followed by vacuum sputtering of gold to an effective layer thickness of 0.4 nm [7].

Figure 1 presents the electronic absorption spectra of the CTA film before and after activation with bromine. The bromine-activated CTA film was preliminarily kept in a vacuum for 30 min. The absorption band at $\nu = 25\,000$ cm^{-1} was assigned to chemisorbed bromine, since prolonged keeping of the film in a vacuum substantially decreases the band intensity.

Figure 2 presents the electron micrographs of carbon replicas with gold particles, taken from the bromine-activated CTA film surface. The spatial distribution of the decorating particles is nonuniform; the film surface contains areas with enhanced local density of particles. These areas correspond to the macromolecular clusters [7] between which larger gold particles are formed by the "point" particle coalescence mechanism. The surface of the CTA film containing TPP exhibits nonuniformly distributed extended areas, in which large decorating particles are localized (Fig. 2c). These areas can be assigned to discrete TPP inclusions constituting an individual phase.

The pattern of distribution of the decorating gold particles on the surface of the bromine-activated CTA film can be accounted for as follows. The degree of chemisorption of bromine on the polymer film surface depends on the local density of the polymer. Looser areas between the clusters of macromolecules bind a larger amount of bromine, which is responsible for the formation of larger gold particles.

In the presence of DBP, the relative proportion of the large fraction of the decorating particles and,

hence, the proportion of the intercluster space, tend to increase (Fig. 2b). This can be due to possible microphase segregation of the CTA–DBP system.

The topography of the gold particles on the surface of the film samples was studied on an EMV 100L electron microscope at the $\times 40\,000$ magnification and analyzed by the procedure described in [7, 10, 11]. The area of scanning of the micrographs with $\times 150\,000$ magnification, when processed on a PC, was 2–2.5 μm^2.

The agglomerations of the decorating gold particles on the film surface were represented as lattice clusters [6] on a two-dimensional lattice with the interpoint distance equal to the most probable distance r (see table) separating the particles and with the coordination number m corresponding to the average number of the nearest neighbors around an arbitrarily chosen particle [7]. The micrographs show that there is a single cluster of decorating particles on the film surface, and the topology of this duster corresponds to that of the infinite cluster of the CTA macromolecules. Using the procedure from [7], we calculated the correlation radius of the cluster, ξ, and the average lattice density ρ_s of the cluster (equal to the degree of the surface filling by the cluster at $R > \xi$), as well as the fractal dimensionality D of the cluster at $R < \xi$.

Figure 3 presents ρ_s-vs.-R plots (R is the radius of the circle centered at the lattice site occupied by a particle), constructed in the log–log coordinates for the initial and plasticized CTA films. The average lattice density ρ_s of the cluster decreases with increasing scale radius R as $\rho_s(R) \sim R^{D-2}$, and the corresponding log–log plots are straight lines (Fig. 3). The inflection point corresponds to the correlation radius ξ of the cluster or to the alternation period of the density fluctuation L (for the quadratic lattice with $m = 4$). For $R > \xi$, the fractal dimensionality of the infinite cluster is close to 2 (Fig. 3). At $R \le \xi$, D, in turn, determines the pattern of distribution of the density inside the cluster.

When DBP is introduced into the CTA film, the cluster density, and also D at $R \le \xi$, tend to decrease (see table and Fig. 3). This suggests that DBP loosens the structure of the supramolecular formations of CTA, which is typical of true plasticization at the molecular level [9]. The increase in the proportion of the intercluster space and in the correlation radius ξ may be due to possible microphase segregation of the CTA–DBP system.

On the whole, TPP additions do not modify the morphology of the infinite cluster of the CTA macromolecules at $R < \xi$, as suggested by the invariance of the fractal dimensionality D in going from the initial to the TPP-containing CTA film (see table and Fig. 3). This means that, in the presence of TPP, plasticization follows the structural mechanism implying a predominant distribution of the plasticizer between the supramolecular formations of the polymer. This decreases the proportion ρ_s of the surface occupied by the cluster and increases the correlation radius ξ of the density fluctuations. Partial egress of TPP into the microphase, revealed by electron microscopy, is due to a purely surface effect. Indeed, commercial manufacture of plasticized CTA films involves local egress of a port of TPP onto the film surface.

Parameters of distribution of the decorating gold particles and of the cluster structure of the polymer on the surface of the CTA film samples

Sample	r, nm	m	$\rho_s \pm 0.02$	ξ, nm	$D(R \le \xi) \pm 0.03$
CTA	15.5	3.8	0.59	42	1.85
CTA–DBP	12.4	3.7	0.43	51	1.74
CTA–TPP	13.4	4.2	0.54	53	1.83

The correlation radius ξ of the cluster structure of the CTA film surface is virtually independent of the nature of the plasticizer (see table and Fig. 3); it was estimated at ca. 53 nm for plasticized CTA films. Varlamov *et al.* [12] studied the dependence of the small-angle X-ray scattering intensity I for a commercial sample of a plasticized CTA film. The discrete maximum of I corresponds, according to the Bragg formula, to an alternation period of the electron density equal to 53 nm, which agrees well with the electron-microscopic data.

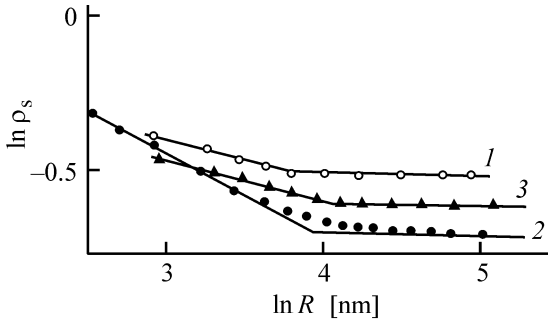

Fig. 3. log–log plot of the dependence of the lattice density ρ_s of distribution of the clusters of decorating gold particles on the radius scale R for (*1*) CTA, (*2*) CTA–DBP, and (*3*) CTA–TPP samples.

CONCLUSIONS

(1) A cluster structure was revealed for the surface of the cellulose triacetate film prepared from a 10 wt % polymer solution in a 9 : 1 methylene chloride–ethanol mixture. Supramolecular formations or aggregates of the cellulose triacetate macromolecules constitute an infinite cluster network.

(2) Introduction of plasticizers into the cellulose triacetate film decreases the proportion of the surface covered with a cluster of macromolecules and increases the alternation period of the cluster density. Dibutyl phthalate additions loosen the structure of the cluster and, hence, decrease its fractal dimensionality. By contrast, triphenyl phosphate additions do not affect the fractal dimensionality D and the cluster morphology. These results suggest the predominantly molecular mechanism of plasticization of cellulose triacetate with dibutyl phosphate and the structural mechanism of plasticization with triphenyl phosphate.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Free-Radical Grafting of Methylenebutanedioic Acid to Polypropylene–Polyethylene Blends and Rheological Properties of Melts

Yu. M. Krivoguz and S. S. Pesetskii

Belyi Institute of Mechanics of Metal-Polymer Systems, National Academy of Sciences of Belarus, Gomel, Belarus

Received June 3, 2004

Abstract—Specific features of grafting of methylenebutanedioic acid to polypropylene–polyethylene blends during reactive extrusion were studied. The ratio of the polymeric components exerts a certain influence on the yield of the grafted product and on the side processes accompanying the grafting reaction. The factors underlying this influence were analyzed.

Functionalization of polyolefins (POs), based on free-radical grafting of polar monomers to PO macromolecules, has been fairly comprehensively studied [1–3] but still remains topical. Of special importance are studies concerned with the reaction extrusion (RE) technology [1]. This method allows preparation of a number of technically valuable products suitable for divers applications, such as adhesives, compatibilizers of blends of incompatible polymers, and additives facilitating the processing of polymer waste and improving its quality [2, 3].

A large number of studies [2–8] have been devoted to elucidating the relationships in free-radical grafting of unsaturated polar monomers to macromolecules of some POs, including polyethylene (PE), polypropylene (PP), and ethylene–propylene copolymer (EPC). It has been found that the grafting reactions may be accompanied by a number of side processes, whose character is determined by the nature of the PO. For example, PE tends to undergo cross-linking [4, 5], and PP, degradation of the macromolecules during functionalization [6–8], whereas EPC exhibits both degradation and cross-linking of the macrochains [2, 9]. Published data suggest that free-radical grafting of polar monomers to PO blends will be accompanied by even more complex macromolecular transformations than those occurring in the course of grafting to homopolyolefins.

Though clearly topical, studies concerned with monomer grafting to PO blends in the course of RE are scarce [10]. Chaoqin *et al.* [10] considered specific features of grafting of maleic anhydride to a PE/PP blend at concentrations of the polymeric components varied within a comparatively narrow range of the component ratios (the PP content in the blend was 5–20 wt %). These authors confirmed that the degree of grafting and the rheological properties of the polymer melt depend on the PP and PE concentrations. However, these data do not disclose the mutual influence of the polymeric components on the main and side processes under varied component ratio throughout the concentration range studied [10].

In this study, we examined the specific features of grafting in the course of RE of unsaturated monomers in PO blends. To this end, we used methylenebutanedioic acid (MA) and a mixed PP/PE system, in which the ratio of the polymeric components was varied over a wide concentration range.

EXPERIMENTAL

In our study we used the following POs: Kaplen isotactic PP [01030 grade, TU (Technical Specifications) 2211-015-00203521–95, density 0.905 g cm^{-1}, mp 169°C (according to DSC data, at β = 16 deg min^{-1}), melt flow index 4.9 g/10 min at 190°C and a load of 5 kg] and low-density polyethylene (LDPE) [15803-020 grade, GOST (State Standard) 16337–77, density 0.92 g cm^{-3}, mp 106°C (according to DSC data, at β = 16 deg min^{-1}), melt

1070-4272/05/7802-0305 © 2005 Pleiades Publishing, Inc.

flow index 7.4 g/10 min at 190°C and a load of 5 kg]. Methylenebutanedioic acid available from Chemical Division Pfizer (US) (molecular weight 130.1 g mol^{-1}, mp 172°C) served as the monomer to be grafted. The grafting reaction was initiated by 2,5-dimethyl-2,5-di(*tert*-butylperoxy)hexane from Atofina Co. (France) under the L-101 trademark ($\tau_{0.5}$ = 0.6 min at 180°C; available active oxygen concentration 11.03%). Acetone (99.5% pure) and absolute ethanol (99.9% pure) served as solvents.

Methylenebutanedioic acid was grafted to PP/LDPE blends in an extrusion reactor based on a Brabender plastograph and equipped with a dynamic mixer [4], in the following modes: worm rotation rate 50 rpm at a shear rate of ca. 100 s^{-1}; temperature 160, 180, and 185°C in zones I, II–III, and IV, respectively. The reaction mixture remained in the reactor for ca. 4 min, on the average.

Prior to grafting, we prepared PP/LDPE blends with the PP : LDPE component ratios (wt %) of 100 : 0, 99 : 1, 95 : 5, 75 : 25, 50 : 50, 25 : 75. 5 : 95, 1 : 99, and 0 : 100, by coextrusion in melt at 200°C in a one-worm extruder (worm diameter 25 mm, $L : D$ = 25), followed by water cooling and granulation of the resulting formulations. Next, granulate of the PP/LDPE formulations was treated with L-101, dissolved in acetone, and with powdered MA. The concentrations of the MA and L-101 introduced into the PP/LDPE blends in all the experiments were constant, namely, 1.0 and 0.3 wt %, respectively. The resulting reaction mixture was passed through the extrusion reactor.

The end products of the grafting reaction were functionalized PP/LDPE ([PP/LDPE]-*graft*-MA) blends containing grafted and nongrafted MA. The nongrafted portion of MA could be removed from the samples by extraction in ethanol. This procedure served as a basis for evaluation of the grafting efficiency α, i.e., the ratio of the amount of the grafted monomer to its total amount introduced into PP/LDPE [4].

To determine the grafting efficiency, 40–50-μm film samples of the [PP/LDPE]-*graft*-MA blends, pressed on a laboratory press, were placed into a temperature-controlled vessel containing ethanol at 70°C, in which the nongrafted portion of MA was extracted. After being kept in ethanol for 18–20 h, the films were removed and analyzed by IR spectroscopy on a UR-20 spectrophotometer (Carl Zeiss, Jena, Germany).

As analytical band we used the absorption band near 1720 cm^{-1}, corresponding to absorption of carbonyl groups. To eliminate the influence of the film thickness fluctuations on the optical density of the absorption band, reduced this optical density to that of the internal reference. To this end, we used the absorption band at 1325 cm^{-1}, corresponding to the stretching vibrations of the C–C bonds [4]. The parameter α, %, was calculated by the formula

$$\alpha = \frac{D_\tau}{D_0} \times 100. \quad (1)$$

Here, D_τ and D_0 are the relative optical densities of the absorption band of carbonyls (ratio of the optical densities of the band analyzed and of the internal reference, ν_{C-C} = 1325 cm^{-1}) before and after extraction of the films in ethanol, respectively.

Taking into account the data from [11], we assumed that the extinction coefficient of the >C=O bonds in the carboxy groups remains unchanged upon grafting. The arithmetic mean grafting efficiency was calculated using the data for nine samples. The relative error of a single measurement was within 8%.

The viscosity of the molten materials was estimated from the melt flow index (MFI). The measurements were carried out on an IIRT-AM device at a load of 5 kg, capillary diameter of 2.095 ± 0.005 mm, and temperatures of 190 and 230°C. A granulated material was charged into the heated cylinder of the device and kept for 4 min. Five replicate measurements were made for each material. The relative error of the measurements was within 1% at a confidence level of 0.95.

Using the MFI values determined at two temperatures and identical loads, we calculated the activation energy E_a of viscous flow by the equation [12]

$$E_a = -R \ln k \frac{T_1 T_2}{T_2 - T_1}. \quad (2)$$

Here, R is the universal gas constant; T_1 and T_2, test temperatures ($T_1 < T_2$); and k, coefficient defined as

$$k = \mathrm{MFI}_{T_1}/\mathrm{MFI}_{T_2}. \quad (3)$$

Using the MFI values at the set temperature, we also determined the melt viscosity η, which is close to the Newtonian viscosity [12]

$$\eta = \frac{P r_c^4 \rho t_c}{2 D_p^2 (L_c + \nu r_c) \mathrm{MFI}}. \quad (4)$$

Here, P is load; t_c, time constant; r_c, capillary radius; L_c, capillary length; D_p, plunger diameter; ρ, melt density; and ν, input correction (eliminated from the calculations).

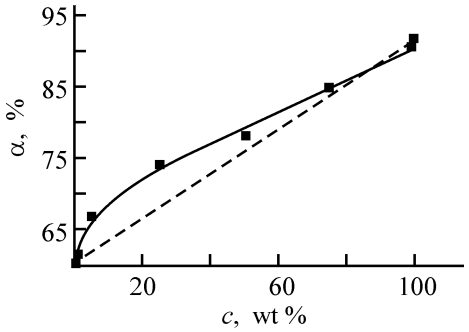

Fig. 1. MA grafting efficiency α vs. the LDPE concentration *c* in the PP/LDPE blend. (*Dashed line*) Additive values; the same for Figs. 2–3.

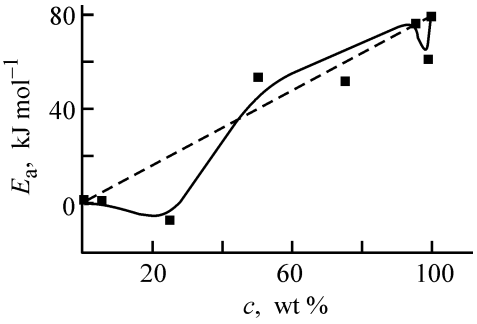

Fig. 2. Activation energy E_a of viscous flow of the [PP/LDPE]-*graft*-MA blends vs. the LDPE concentration *c*.

Figure 1 and the table illustrate the course of the reactions of MA grafting to PP, LDPE, and PP/LDPE blends. Among the materials studied, the lowest grafting efficiencies α were exhibited by the functionalized homopolymer PP (PP-*graft*-MA), and the highest, by LDPE-*graft*-MA. Machado *et al.* [7, 8] also reported a higher, compared to PP, yield of the grafted products in the case when polar monomers were grafted to LDPE. The PP-to-LDPE ratio in the initial reaction mixture strongly affects the parameter α. The grafting efficiency tends to grow with increasing LDPE concentration in the PP/LDPE blend. At relatively small LDPE additions (up to 25 wt %), α tends to grow more rapidly and nonlinearly with increasing LDPE content in the blend. In the 25–95% range, the concentration dependence of α is close to linear. In the 1–90% concentration range, the actual grafting efficiencies exceed the additive values.

On the whole, minor (up to 25 wt %) LDPE additions affect (raise) α more strongly than minor additions of PP affect (decrease) this parameter when MA is grafted to the PP/LDPE blend.

The melt flow index determined at 190°C and a load of 5 kg varies with the PP/LDPE blend composition in a more complex manner than the grafting efficiency (see table). Based on the tabulated data, three groups of blends can be distinguished, depending on their rheological behavior under varied PP-to-LDPE ratio.

For example, at 190°C, the [PP/LDPE]-*graft*-MA blends with the PP content within 99–75 wt % exhibit enhanced MFIs, close to that of PP-*graft*-MA; they are more than three times that of the initial PP. The maximum MFIs are exhibited by the [95PP/5LDPE]-*graft*-MA blend. Blends containing 99–75 wt % PP also exhibit a sharp decrease in the activation energy of viscous flow of their melts, down to negative values for the [75PP/25LDPE]-*graft*-MA blend (Fig. 2).

The 50 : 50 and 25 : 75 PP/LDPE blends exhibit a sharp increase in viscosity (a decrease in MFI). The MFI values for these blends are close to additive.

Further increase in the LDPE concentration (5 : 95 and 1 : 99 compositions) even more strongly decreases the MFI. This is accompanied by an increase in E_a. Notably, the [PP/LDPE]-*graft*-MA blends containing 1 and 5 wt % PP exhibit smaller MFIs than LDPE-*graft*-MA.

The pattern of variation of the MFI at 230°C and a load of 5 kg with the [PP/LDPE]-*graft*-MA blend composition differs from that at 190°C (see table). The primary distinguishing features are that enhanced MFIs, exceeding that of PP-*graft*-MA, are exhibited by a larger number of the formulations and that a sharp increase in viscosity is manifested only when the PP

Efficiency of MA grafting to PP–LDPE blends and rheological properties of the melts, depending on the ratio of the polymeric components

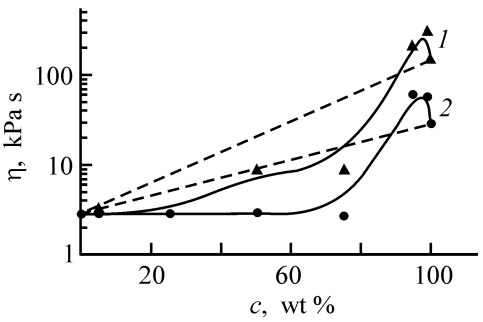
LDPE	–	7.4	18.0



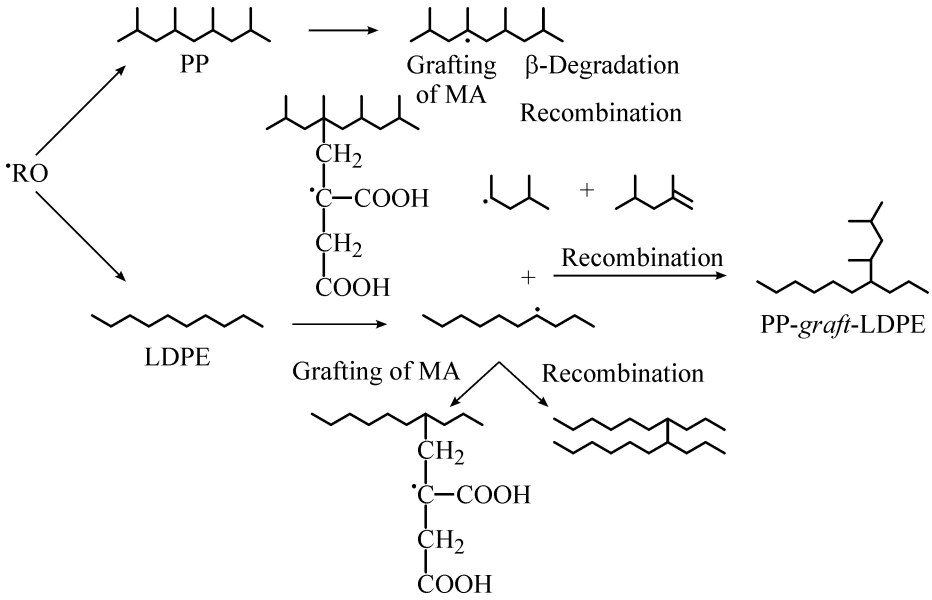


Fig. 3. Newtonian viscosity η of the [PP/LDPE]-*graft*-MA blends vs. the content of LDPE *c* at (*1*) 190 and (*2*) 230°C.

concentration is within 5 wt %. This may be due to major differences in the activation energies of viscous flow of the PP/LDPE blends under study (Fig. 2) because of the processes occurring in the course of free-radical grafting of MA [13]. The Newtonian viscosity of the melts studied and MFI vary in the opposite directions (Fig. 3).

The changes accompanying the MA grafting to the PP/LDPE blends can be explained in the context of the present-day views on the mechanism of the free-radical processes occurring in PP and LDPE melts, initiated by organic peroxides (see scheme). Studies performed in [1–8] suggest that a peroxy initiator forms macroradicals by abstraction of a hydrogen atom from the polymer substrate when reacting with the free radicals yielded by peroxide thermolysis. The resulting macroradicals can be involved in a number of subsequent chemical reactions, such as chemical grafting of the monomer, cross-linking of the macromolecules, their degradation, etc. The tendency of a macroradical toward participation in a reaction is determined by its chemical structure, as well as by the composition of the reaction medium and process factors.

The PP$^{\cdot}$ macroradicals are generated by reactions in which a hydrogen atom is abstracted mostly from the tertiary carbon atoms in the polymer chain [7–9]. Further, the macroradicals can be involved either in β-degradation, with breakdown of the macrochains, or in the monomer addition reactions (see scheme).

Scheme of possible chemical reactions at free-radical grafting of MA to PP/LDPE blends.

The relatively low grafting efficiencies typical of both the initial PP and PP/LDPE blends with a high PP content (from 99 to 75 wt %) may be due to the fact that β-degradation of the PP macromolecules is faster than the MA grafting [7, 8]. Intensive β-degradation is suggested by a major increase in MFI of PP-*graft*-MA and [PP/LDPE]-*graft*-MA relative to the initial PP, with the PP content increasing to 75%.

The methyl group CH_3, close to the reaction center, creates an additional steric hindrance to reactions between the monomer being grafted and the PP macroradicals [14]. This hinders grafting and facilitates β-degradation.

In the case of LDPE, there is no such hindrance for macroradicals formed with secondary carbon atoms involved. As a result, the efficiencies of the MA grafting to the LDPE macromolecules exceed those for PP and grow with increasing LDPE content in the blend. In addition to reactions with the monomer, the LDPE macroradicals are also involved in recombination reactions resulting in cross-linking, branching, or propagation of the macromolecules [2, 4–8]. This is suggested by an increase in the melt viscosity (decrease in MFI) for LDPE-*graft*-MA and a number of blends with increased LDPE concentrations.

The scheme suggests that β-degradation of the PP macromolecules yields new macroradicals at the secondary carbon atom. However, Machado *et al.* [7, 8] reported that these macroradicals rapidly decay and hence do not markedly affect grafting.

The β-degradation and recombination reactions of the macroradicals accompanying monomer grafting to PP and LDPE are side, frequently undesired, processes since they decrease the yield of the grafted product and can deteriorate the rheological and other properties of functionalized POs (FPOs). In view of the fact that PP and LDPE enter into oppositely directed side reactions in grafting (degradation and cross-linking), it can be assumed that the extent of macromolecular transformations and the rheological properties of polymer melts can be controlled by introducing minor additives of a component into the PP/LDPE blend. However, the table suggests that minor PP additives not only do not increase but even decrease the MFI of [PP/LDPE]-*graft*-MA relative to LDPE-*graft*-MA. Minor LDPE additives, in turn, increase the MFI of the FPO blends relative to PP-*graft*-MA, contrary to expectations. In our opinion, these facts are very important for comprehending the general pattern of the transformations of interest. Clearly, in blends with the LDPE concentrations of up to 25 wt %, degradation of the PP macrochains dominates over recombination of the macroradicals and is faster, compared to PP-*graft*-MA. This may be due to two factors. First, the rate of the reaction between the PP macromolecules and free radicals generated by degradation of the peroxy initiator may exceed that for LDPE. Since, in the case of PP, the hydrogen atom is abstracted from the tertiary, rather than secondary, carbon atom, as in the case of LDPE, the resulting radical will be more prone to β-degradation than to recombination. This can hinder formation of grafted copolymers like LDPE-*graft*-PP, which could affect the rheological parameters of the materials. Second, formation of the LDPE-*graft*-PP copolymers can be hindered, as indicated by Braun *et al*. [15], by the two-phase nature of the PP/LDPE blends, also characteristic of their melts. This means that each polymer should participate in free-radical processes independently. However, this would imply additive changes in the MFI.

Clearly, in the region of medium concentrations of the components (~1 : l ratio), their influence on the MFI is determined by the ratio of the degrees of conversion of the blend components.

In the case of minor PP additives, the MFI of [PP/LDPE]-*graft*-MA may decrease relative to that of LDPE-*graft*-MA because of an increase in the concentration of the LDPE macroradicals, whose formation can be promoted by the radical degradation products of the PP macromolecules. Also, in the presence of PP, formation of the LDPE macroradicals may become more probable due to mechanochemical reactions, also typical of reactive extrusion [1, 2].

Along with the above-mentioned factors, the rheological properties of the materials may additionally change during the MFI measurements.

The changes in the E_a are also due to the chemical processes occurring in the course of MA grafting to the PP/LDPE blends and are governed by their composition. Very small activation energies observed for high-index blends, containing 99–75 wt % PP, are, evidently, due to several factors. In particular, β-degradation makes the PP macromolecules less branched because of a decrease in the number of the side substituents (methyl groups), and a major amount of low-molecular-weight oligomers is accumulated in the polymer structure; owing to the plastisizing effect of LDPE, the macromolecules acquire an enhanced flexibility [16, 17]. The negative activation energies for the [75PP/25LDPE]-*graft*-MA blend are, evidently, due to an additional cross-linking of the material in the measuring cylinder of the IIRT-AM device, when the MFI is determined at an elevated temperature. As a result, in particular, the MFI at 230°C proved to be smaller than at 190°C. For compositions containing ≥50 wt % LDPE, E_a grows because of the predominance in these systems of macroradical recombination reactions. These are responsible for an increased number of side branches of the macrochains, which decrease their flexibility and hinder their conformational rearrangements in a flow [16, 17].

Thus, analysis of the rheological behavior of the [PP/LDPE]-*graft*-MA materials shows that the polymeric components affect in a complex manner

the course of the free-radical transformations of the macromolecules during reactive extrusion. Combined analysis of the concentration dependences of the grafting efficiency and MFI gives a better insight into the pathways of the proceeding reactions.

CONCLUSIONS

(1) The polymeric component ratio in polypropylene–low-density polyethylene blends strongly affects the course of the reaction of grafting of methylenebutanedioic acid and its accompanying macromolecular transformations (side reactions). The influence of the polypropylene additions on the monomer grafting is primarily manifested as a decrease in the yield of the grafted product with increasing concentration of this component in the blend.

(2) At relatively small additions of low-density polyethylene (up to 25 wt %), the efficiency of grafting of methylenebutanedione acid to the polypropylene–low-density polyethylene blend grows nonlinearly (exceeding the additive values). At polyethylene concentrations of 25–95 wt %, the dependence of the grafting efficiency on the composition is close to linear: The grafting efficiency α tends to monotonically increase with increasing polyethylene concentration.

(3) When minor additions of a polymeric component are introduced, the rheological properties of the molten blends change in a complex, somewhat unexpected manner. Addition of low-density polyethylene, prone to cross-linking under functionalization, in amounts of up to 25 wt % tends to increase the MFI (to decrease the viscosity) of the [PP/LDPE]-*graft*-MA melt relative to PP-*graft*-MA; additions of polypropylene, prone to degradation under functionalization, in amounts of up to 5 wt % tend to decrease the MFI (to increase the viscosity) of the [PP/LDPE]-*graft*-MA melt relative to PP/LDPE-*graft*-MA. Blends with polyethylene concentrations of up to 25% are characterized by an extremely low viscous flow activation energy, down to negative values for the [75PP/25LDPE]-*graft*-MA blend.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Copolymerization of 2-Chloro-Substituted *p*-Cyclopropylstyrenes with Styrene and Properties of the Resulting Copolymers

K. G. Guliev, G. Z. Ponomareva, and A. M. Guliev

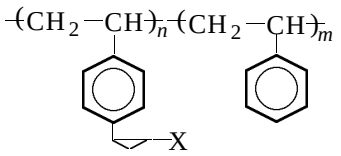
Institute of Polymeric Materials, National Academy of Sciences of Azerbaijan, Sumgait, Azerbaijan

Received July 14, 2004

Abstract—2,2-Dichloro- and 2-chloro-1-(*p*-vinylphenyl)cyclopropanes were prepared and brought into copolymerization with styrene. The effect of substituents on the reactivity of the monomers was examined. The physicomechanical properties of the copolymers were studied.

One of the ways to improve the physicomechanical, thermal, and optical properties and enhance the flame resistance of polystyrene plastics is copolymerization of styrene with other monomers. In so doing, it is possible to vary the properties of the copolymers in a wide range.

The copolymerization of styrene with substituted styrenes has been studied extensively [1–7].



In this study, we prepared 2,2-dichloro- and 2-chloro-1-(*p*-vinylphenyl)cyclopropanes (**I**, **II**, respectively) and performed their copolymerization with styrene in the bulk and in solution; we also examined the effect of the chlorinated substituents on the reactivity of the monomers and on the properties of the resulting copolymers. We found that styrene smoothly copolymerizes with the monomers synthesized, without opening of the cyclopropane ring; the resulting copolymers are soluble.

The copolymerization under the conditions of our experiments occurred through opening of the double bond, yielding macromolecules with pendant phenyl groups (unsubstituted and those bearing chlorinated cyclopropane fragments). This is suggested by the spectra of the copolymers. The ratio of the monomeric units (**I** or **II** to styrene) in the copolymer was estimated from the chlorine content determined by elemental analysis.

The IR spectra of both the starting monomers and copolymers thereof contain characteristic bands belonging to vibrations of the C–Cl bond (675 cm^{-1}) and cyclopropane ring (1030–1040 cm^{-1}). The spectra of the copolymers also contain well-defined bands at 1450, 1500, 1585, and 1605 cm^{-1} belonging to vibrations of the benzene ring. Strong bands at 1213 and 1170 cm^{-1} and bands at 1110 and 1013 cm^{-1} are characteristic of 1,4-disubstituted benzenes and belong to the in-plane bending modes of the four hydrogen atoms of the benzene ring.

Changes in the intensities of the bands belonging to the main functional groups of **I** and **II** suggest changes in the composition of the monomeric units.

The IR data allow us to ascribe the following structure to the copolymers:

where X = 2Cl (**I**), Cl (**II**).

For this pair of monomers, we calculated the copolymerization constants and the Alfrey–Price parameeters *Q* and *e* [8]. To evaluate the distribution of units in the macromolecular chain, we calculated the microstructural parameters L_{M_1}, L_{M_2}, and *R* [9]. The results are listed in Table 1.

Table 1 shows that, at any ratio of the starting monomers, the copolymer is always enriched in units of mono- or gem-dichloro-substituted cyclopropylstyrenes, which is due to the higher reactivity of these monomers, caused by the presence of the substituted cyclopropane ring.

The chlorine atoms, which are present in **I** and **II** as substituents in the cyclopropane ring and are separated from the reaction center by the phenyl ring and a cy-

clopropane fragment in the *p*-position relative to the styrene double bond, decrease the copolymerization constants relative to unsubstituted styrene. This is due to increased conjugation in the monomer molecule as a result of the effect of the substituents additionally stabilizing the forming radical. The copolymerization constants of **I** and **II** differ insignificantly.

The influence exerted by the chlorine atoms on the vinyl group through the three-membered carbon ring and phenyl ring leads to an increase in the extent of conjugation in the monomer molecule, but only slightly depends on the number of chlorine atoms. This is confirmed by the UV spectra of **I** and **II**, in which the absorption maxima are located at 295 and 292 nm, respectively.

Variation with time τ of the (*1*–*5*) yield *A* and (*6*, *7*) intrinsic viscosity [η] of 2,2-dichloro-1-(*p*-vinylphenyl)cyclopropane (**I**)–styrene copolymer. 70°C. Content of **I** in the starting mixture, %: (*1*, *7*) 100, (*2*) 90, (*3*) 80, (*4*, *6*) 70, and (*5*) 0.

To reveal regular trends in the polymerization and study the properties of the copolymers, we performed copolymerization of **I** and **II** with styrene in a wide range of ratios of the starting monomers.

The kinetic curves of initiated copolymerization of **I** with styrene at 70°C (see figure) show that, after 37–46% conversion of the monomers is reached, the copolymerization occurs with autoacceleration. The effect becomes more pronounced as the content of **I** in the mixture is increased. The molecular weight of the forming polymers appreciably increases at high conversions.

Experiments on thermal copolymerization at high temperatures (110–150°C) revealed no appreciable self-acceleration, and the intrinsic viscosity of the copolymers remained virtually constant at all the conversions. Some properties of the copolymers are given in Table 2.

Table 2 shows that introduction of chloro-substituted cyclopropylstyrene units into the polystyrene chain increases the Vicat softening point and enhances the optical and physicomechanical properties, compared to styrene homopolymer. Some of the copolymers obtained show self-extinguishing behavior. This property becomes more pronounced with an increase in the content of **I** in the copolymer.

Table 2. Physicomechanical characteristics of the copolymers prepared

Parameter	Polystyrene	Copolymers with indicated content of **I** or **II**, %			
		40		60	
		I	**II**	**I**	**II**
Intrinsic viscosity [η], dl g^{-1}	1.15	1.17	–	–	
Refractive index	1.5895	1.6010	1.5905	1.6040	1.6010
Vicat softening point, °C	103	119	116	128	126

Ultimate tensile strength, MPa	39.0	34.8	35.0	35.0	
Relative elongation at break, %	1.7	1.5	–	1.5	–

Parameter	Polystyrene	Copolymers with indicated content of **I** or **II**, %					
		70		80		90	
		I	**II**	**I**	**II**	**I**	**II**
Intrinsic viscosity [η], dl g^{-1}	1.15	1.13	–	1.15	–	–	–
Refractive index	1.5895	1.6053	1.6038	1.610	1.6080	1.6115	1.6105
Vicat softening point, °C	103	132	130	139	–	148	136
Brinell hardness, kgf cm^{-2}	14	24	16	–	–	27	19
Ultimate tensile strength, MPa	39.0	–	–	45.0	47.0	46.8	48.7
Relative elongation at break, %	1.7	–	–	1.9	–	1.9	–

Thus, the properties of the copolymers derived from chloro-substituted cyclopropylstyrenes are governed by the substituent in the monomers, and the activity of the monomers in the copolymerization depends on the extent of conjugation of the vinyl π electrons with the substituent *p* electrons.

EXPERIMENTAL

The starting monomer, 2,2-dichloro-1-(*p*-vinylphenyl)cyclopropane **I**, was prepared as described in [6]. 2-Chloro-1-(*p*-vinylphenyl)cyclopropane **II** was prepared as follows. Sodium metal (0.1 mol, 2.3 g) was added in small pieces to a solution of **I** (0.2 mol, 42.6 g) in benzene, after which methanol was added dropwise with stirring and cooling on an ice bath. After the reaction was complete, distilled water was added, the organic layer was separated, and the aqueous layer was extracted with ether. The combined organic phases were evaporated, and the product was vacuum-distilled; bp 78–80°C/1 mm Hg. Yield 36% (12.85 g); n_D^{20} = 1.5630, d_4^{20} = 1.12, $MR_{D\text{calc}}/MR_{D\text{exp}}$ = 52.388/51.76. Analytical data:

Found, %: C 73.95, H 6.16, Cl 19.88.
Calculated, %: C 73.58, H 6.05, Cl 19.75.

The purity of the monomers was checked chromatographically; it was 99.9% in all the cases. The kinetics of the copolymerization of **I** and **II** with styrene was studied in ampules in a nitrogen atmosphere at various ratios of the starting monomers. To determine the copolymerization parameters, the reaction was stopped at ≤10% conversion. The compositions of the copolymers were determined by elemental analysis for chlorine, and their molecular weights were estimated from the intrinsic viscosity, determined with an Ubbelohde viscometer at 25°C in benzene. All the copolymers were reprecipitated from a benzene solution with methanol. The softening points of the copolymers were determined by the Vicat method. The physicomechanical parameters of the copolymers were determined with film samples prepared by casting from a benzene solution. The IR spectra were measured with a Specord M-80 spectrophotometer.

After appropriate purification and drying, all the copolymers were white powders soluble in aromatic and chlorinated hydrocarbons.

CONCLUSIONS

(1) New monomers, 2,2-dichloro- and 2-chloro-1-(*p*-vinylphenyl)cyclopropanes, were prepared, and

their copolymerization with styrene was performed. These monomers are more reactive than styrene in polymerization, owing to the presence of a substituted cyclopropane ring.

(2) The copolymerization constants and Alfrey–Price parameters of the cyclopropylstyrenes were calculated. The chlorine substituents in the cyclopropane ring make higher the relative reactivity constants and the specific activity of the monomers.

(3) The physicomechanical properties of the copolymers were determined. Introduction of chloro-substituted cyclopropylstyrene units into the polystyrene chain increases the softening point, refractive index, and hardness of the copolymers.

Received June 1, 2004

Abstract—The mechanism of depolymerization of polymeric *p*-dinitrosobenzene in vulcanization of unsaturated rubbers is analyzed. The results obtained explain why the vulcanizing activity of *p*-dinitrosobenzene decreases in the course of its prolonged storage.

p-Dinitrosobenzene (DNB) is a component of rubber–substrate adhesion systems [1] and a low-temperature vulcanizing agent for stocks based on unsaturated rubbers [2]. DNB is a polymeric compound virtually insoluble under common conditions in any solvent [3].

The vulcanizing activity of DNB is known to change in the course of its storage [4, 5]; this fact calls for theoretical substantiation. Furthermore, data on the structure of polymeric *p*-dinitrosobenzene (poly-DNB) are contradictory, and nothing is known about the mechanism of its depolymerization in the course of addition to unsaturated compounds (in particular, in vulcanization of unsaturated rubbers).

In the papers concerning the kinetics and mechanism of addition of poly-DNB to unsaturated compounds [6, 7], the authors, as a rule, presented the monomeric DNB structure; some authors assumed the structure has a dimeric sandwich form (Fig. 1) [7–9], but this structure does not stand up to criticism.

It is known that IR spectra of poly-DNB contain a strong band at 1264 cm^{-1} [10, 11], characteristic of nitrosoarene trans dimers [10, 12], with a C–N–N angle in the sandwich structure close to 120°. At the same time, the C–N–N angle in the sandwich structure is close to 90°, and, therefore, this structure should be strained and thermodynamically unstable.

Experimental determination of the poly-DNB structure is complicated by its high dispersity and insolubility in all the solvents under common conditions. Therefore, to study the geometry of poly-DNB and energy effects of its reactions, we used quantum-chemical calculations. We chose the relatively reliable DFT B3LYP method with the 6-31G(d) basis set. The calculations were performed with a computer cluster of the Kazan State Technological University, using the GAUSSIAN 98 program package [13], with full geometry optimization. For the model structures, we calculated the force constants, vibration frequencies, thermodynamic quantities, and variation of the relative energy in extension of the (O)N–N'(O') bond of model structures. To reduce the number of basis functions, we used 2-butene and 2-pentene as structures modeling a fragment of an unsaturated rubber.

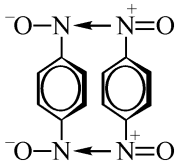

Fig. 1. Presumed dimeric sandwich structure of DNB.

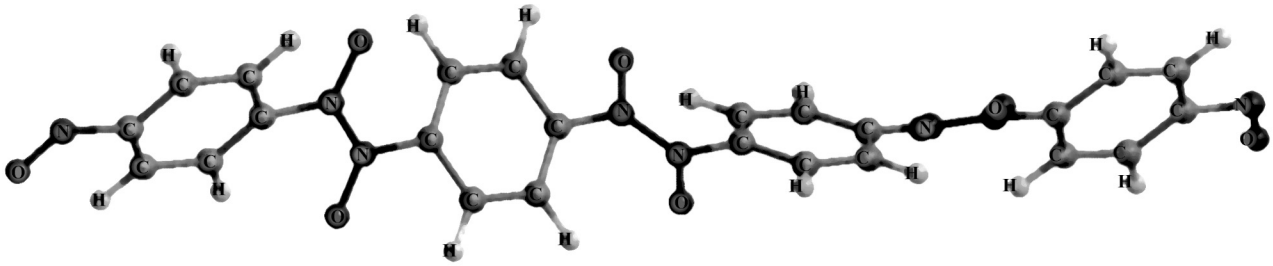

Fig. 2. Geometry of DNB tetramer.

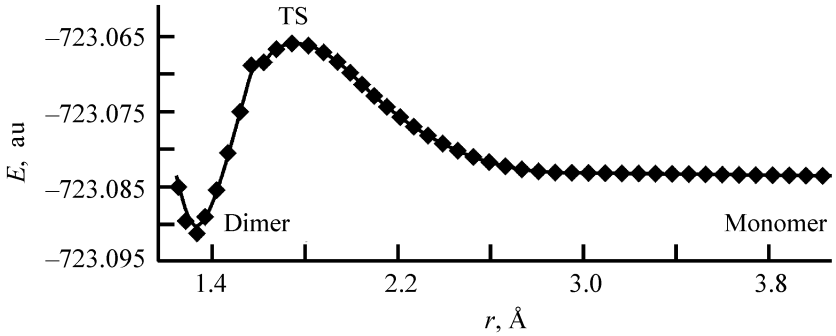

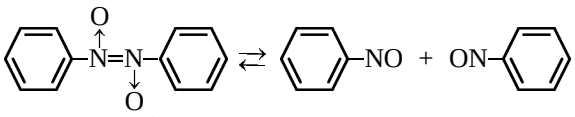

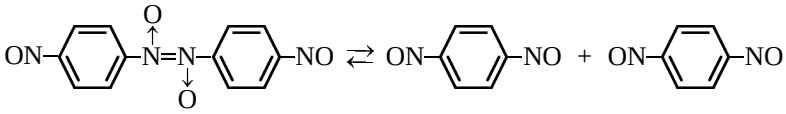

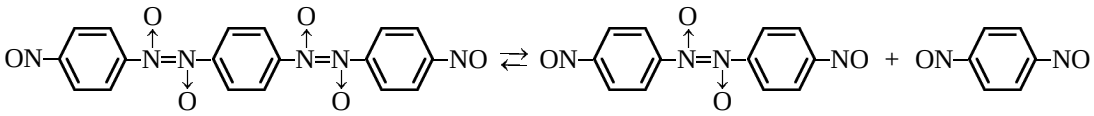

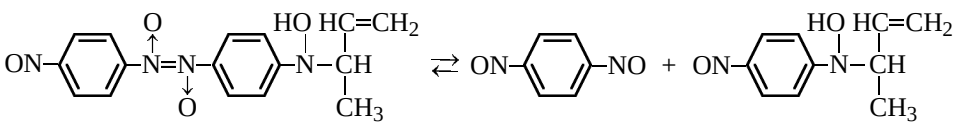

Fig. 3. Variation of the energy E (1 au = 2625 kJ) in extension of the N=N bond in nitrosobenzene dimer. (r) N=N distance; (TS) transition state.

Figure 2 shows the optimized geometry of DNB tetramer as a model of poly-DNB. The tetramer has a linear *trans*-azo-N,N'-dioxy-1,4-phenylene structure twisted in a spiral; the phenylene fragments are turned relative to each other by 45°. Attempts to optimize the geometry of the DNB dimer in the form of a sandwich failed, apparently because of the strain of the C–N–N–C bond system.

Calculations of the relative energy of the nitrosobenzene dimer at extension of the (O)N–N'(O') bond to 5 Å and at its contraction from 5 Å at a 0.05 Å step revealed maxima on the potential energy surface, corresponding to the transition states (TS) with the same geometries and activation enthalpies $\Delta H^{\neq}$ = 66.1 kJ mol^{-1} (Fig. 3). These calculations also showed that the nitrosobenzene dimer has a lower energy than the monomer.

The calculated activation enthalpy of dissociation of the nitrosobenzene dimer is reasonably consistent with the experimental activation energy of

Activation enthalpy of dissociation of the azo-*N*,*N*'-dioxy group to monomeric nitroso groups

Model reaction	$\Delta H^{\neq}$, kJ mol^{-1}
	66.1
	67.4
	66.9
	64.3

the process, determined in dichloromethane: $E^{\neq}$ = 86 kJ mol^{-1} [14].

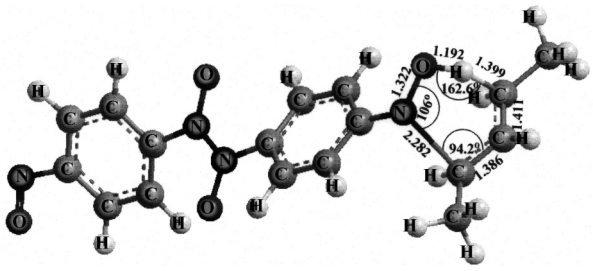
Calculations of the potential energy surfaces in extension of the (O)N–N'(O') bond to separate nitroso groups in the DNB dimer, trimer, and product of addition of DNB dimer to 2-butene gave similar results (see table). These dissociation reactions are also endothermic.

The calculated activation enthalpy of dissociation of the DNB trimer is slightly lower than that of the DNB dimer. Addition of the DNB dimer to the alkene decreases the activation barrier of its subsequent dissociation across the (O)N–N'(O') bond by 3.1 kJ mol^{-1}.

The decrease in the activation parameters of dissociation of the (O)N–N'(O') bond in going from the DNB dimer to trimer can be accounted for by a weaker electron-withdrawing power of the azo-*N*,*N*'-dioxy group, compared to the nitroso group. In addition of DNB dimer to 2-butene, the hydroxylamine derivative can be regarded as a *p*-substituent of the first kind, which makes lower the activation energy of dissociation of the (O)N–N'(O') bond. It is known that, as the electron-donor power of *p*-substituents increases, the energy of dissociation of nitrosoarene dimers to monomers decreases, so that nitrosoanilines exist as stable monomers [12].

A study of the addition of the DNB dimer to 2-pentene showed that the reaction product is a secondary hydroxylamine. In this case, as also in that of the model reaction of addition of the DNB monomer to 2-pentene [15], a six-membered transition state is formed. This was confirmed by calculations involving forward and reverse descent from the transition state along the reaction coordinate to the reaction products and starting compounds.

The calculated thermal effects of the reactons of the DNB dimer with 2-pentene were as follows: activation



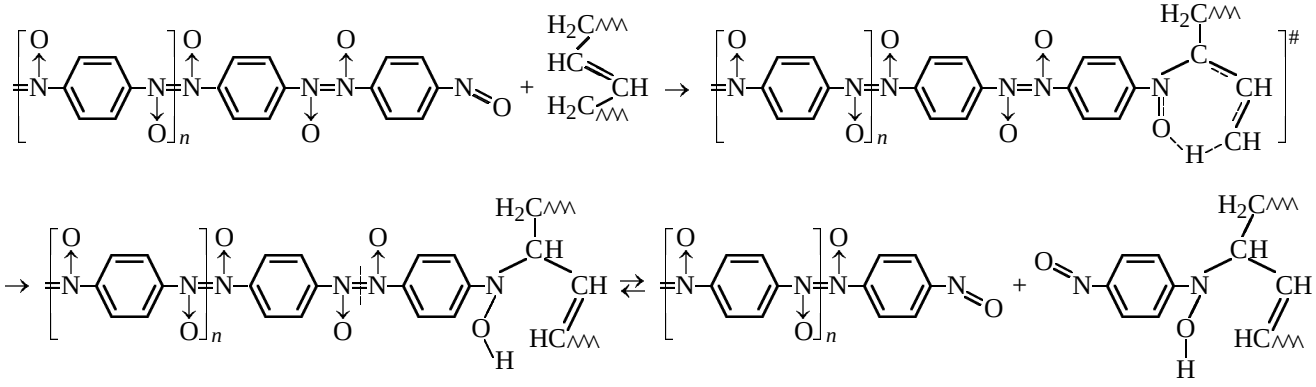


Fig. 4. Structure of the transition state of addition of the DNB dimer to 2-pentene.

enthalpy $\Delta H^{\neq}$ = 97 kJ mol^{-1}, enthalpy of the reaction ΔH = –48 kJ mol^{-1}, and Gibbs energy of the reaction ΔG = –24.7 kJ mol^{-1}. Thus, the reaction is exothermic and can occur spontaneously, which is confirmed by the occurrence of cold curing of unsaturated rubbers with poly-DNB.

The imaginary vibration frequency of the transition state, ν = 1201 cm^{-1}, in combination with the high imaginary vibration intensity, corresponds to the transfer of the methylene proton of 2-pentene to the oxygen atom of the nitroso group.

Figure 4 shows the structure of the transition state and its main geometric characteristics.

Our results suggest the following mechanism of depolymerization of poly-DNB in the course of vulcanization of stocks based on unsaturated rubbers. In the first step, a linear helical molecule of poly-DNB reacts with an alkene fragment of an unsaturated rubber to form a secondary hydroxylamine. The subsequent energetically most favorable step is reversible dissociation of the closest (and weakest) O(N)–N'(O') bond in the *p*-position relative to the hydroxylamine fragment formed by addition of the poly-DNB macromolecule to the unsaturated rubber:

The free nitroso groups subsequently add to other rubber macromolecules to form cross-links, with further fragmentary depolymerization of poly-DNB. Thus, the higher the degree of poly-DNB polymerization, the greater the number of elementary events of dissociation of the (O)N–N'(O') bonds and that of steps in the vulcanization as a whole.

Our results are consistent with the experimental evidence [4, 5] of a decrease in the vulcanizing activity of poly-DNB, caused by an increase in the degree of its polymerization and a decrease in the concentration of terminal nitroso groups during prolonged storage.

CONCLUSIONS

(1) According to the calculation results, polymeric *p*-dinitrosobenzene has a linear *trans*-azo-*N*,*N*'-dioxy-1,4-phenylene structure twisted in a spiral, with the phenyl rings turned relative to each other by 45°.

(2) The activation enthalpy of dissociation of the azo-*N*,*N*'-dioxy groups to monomeric nitroso groups in polymeric *p*-dinitrosobenzene is 64–68 kJ mol^{-1}.

(3) The depolymerization of polymeric *p*-dinitrosobenzene is endothermic.

(4) Changes in the vulcanizing activity of polymeric *p*-dinitrosobenzene in the course of storage are caused by polymerization processes.

ACKNOWLEDGMENTS

The calculations were supported by the Russian Foundation for Basic Research (project no. 03-07-90 092).

Abstract—The conditions of recovery of amorphous and crystalline silicon dioxide from husk and straw of rice cultivated in various regions were studied. The dependence of the impurity composition and characteristics of amorphous silica on the plant strain, waste type, and procedures of waste processing was established. The optimum conditions of production of high-purity silicon dioxide were determined, and its characteristics were compared with those of commercial products.

Amorphous silicon dioxide (silica) has a wide field of application, depending on its structure, purity, and physicochemical characteristics. It is used in food, pharmaceutical, fragrance, paint-and-varnish, chemical, metallurgical, construction, oil-refining, rubber-processing, porcelain, glass, textile, plastic, paper, and other branches of industry. Such forms of amorphous silicon dioxide as diatomite or diatomaceous earth, kieselguhr, tripoli powder, carbon white, Aerosil, and microsilica are used for production of modified silica, sorbents for various purposes, including those for filtration of water, beer, wine, oils, sugar, and other food substances and solvents [1–4].

Traditionally, the main sources of silica are mineral forms, whose resources in our country and in the world are rich. A great number of crystalline modifications of SiO_2 is known: they differ in the content of impurities. Impurity metals are incorporated into the crystal lattice of silica, forming strong bonds. Production of amorphous silica from crystalline SiO_2 involves a large expenditure for pretreatment of the initial raw materials and subsequent removal of concomitant impurities [5, 6]. Amorphous SiO_2 is more chemically active and, if required, it can be easily transformed into the crystalline form.

A promising raw material for production of amorphous SiO_2 is the hydrothermal heat carrier used in regions with operating geothermal power plants [7] and large-tonnage wastes from rice production: straw and fruit shells of corn (husk), in regions of rice cultivation [8–12].

The use of rice husk as a renewable raw material for production of high-quality amorphous SiO_2 is extremely promising, since the husk is concentrated in grain-cleaning plants and is a source for additional production of a number of organic compounds, e.g., furfural, xylose, and polysaccharides [8, 9, 12, 13]. However, until now, the main amounts of husk and straw have not been in industrial use because of the absence of integrated technologies taking into account the regional conditions. To develop an integrated scheme for processing of the waste from rice production, it is necessary to know the chemical composition of raw materials as influenced by the strain and area of plant vegetation, which have not been studied adequately.

This study continues the examination of the integrated processing of waste from rice production [12–14] and the conditions of production, impurity composition, and characteristics of amorphous SiO_2 prepared from rice husk and straw.

EXPERIMENTAL

The objects of study were samples of rice husk (RH) and rice straw (RS) taken in various regions.[1]

The samples of rice husk contained an admixture of corn and meal (product of corn grinding), which were fractionated with respect to the particle size (Table 1). The proportion of the 0.25–0.05-mm fraction varied between different batches of raw materials. Preliminary experiments showed that silica with the highest purity, containing more than 99% SiO_2, is recovered from the husk with a particle size of no less than 0.5 mm (Table 1). In this study, we examined husk samples with a particle size of 0.5 mm and samples of straw cut to 10-mm fragments. The samples were washed with water and dried in air to constant weight. Weighed portions of raw materials were 60–100 g in laboratory experiments and 5–9 kg in a pilot installation.

To recover SiO_2, the RH and RS samples were processed according to various schemes listed in Table 2 and used in [12, 15–18]. Water-soluble substances of RH and RS were extracted with hot water or HCl (analytically pure grade) solution. Thermolysis of the raw materials was carried out at 750°C with deficiency of air or in a helium flow. Oxidative burning was carried out in two stages. First, a weighed portion of a raw material was ashed in a quartz cup on a hot plate to remove volatiles at $T < 500$°C, then the residue was additionally burnt in a laboratory muffle in air at 750 ± 50°C to constant weight and analyzed by chemical, spectral (PGS-2 spectrometer), flame atomic absorption (AA-780 device, Nippon Jharrell Ash, Japan), IR spectroscopic (Specord spectrophotometer, 400–4000 cm^{-1}), X-ray diffraction

[1] The samples of rice husk and straw, locality and year of sampling, and rice strain were as follows: RH-1, Chernigovka, Primorskii Krai, 1995, Dal'nevostochnyi strain; RH-2, Krasnodar, 1999; RH-3–RH-6, Krasnodar, 2002, Kuban'-3, Izumrud, Rapan, and Regul strains, respectively; RH-7, Kiri-Kili, Astrakhan oblast, 1995; RH-8, Kiliya, Odessa oblast, Ukraine, 1993; RH-9, Harbin, China, 2000; RH-10, Shengyang, China, 2000; RH-11 Dunin, China, 2001; RH-12, South Vietnam, 2001; RH-13–RH-15, Novorossiisk, 2002, Slavyanskii, Poltavskii, and Angelinskii KKhP strains, respectively; RH-16, Novoshakhtinsk, Rostov oblast, 2002; RH-17, Timiryazevskii, Primorskii krai, 2000; Khankaiskii 429 strain; RH-18, Seoul, South Korea, 2001; RH-19, Taiwan, China, 2003; RS-1–RS-4, Timiryazevskii, Primorskii Krai, 2001, Darii-8, Dal'nevostochnyi, Khankaiskii 429, and Khankaiskii 52 strains, respectively; RS-5, the same locality, 2002, Darii-122 strain (numbering of the samples of raw materials from rice production wastes is given according to the collection of the Institute of Chemistry, Far-Eastern Division, Russian Academy of Sciences).

(DRON-2.0 diffractometer, Cu_{K_α} radiation), and thermal gravimetric (Q-1000 derivatograph, MOM, Hungary) methods by the standard procedures. The silicon content was found gravimetrically [19]. The content of free carbon was determined by the procedure described in [20], and that of phosphorus, photocolorimetrically [21]. The specific surface area of amorphous SiO_2 was measured by the procedure described in [22], with methylene blue. The substance density in toluene at 25°C, bulk weight, solubility in water, and solution pH were determined by the common procedures. The results of chemical analysis of ash and specific surface area of its particles are listed in Tables 3–5.

Table 5. Solubility of silica *s* (SiO_2 content >95%) and solution pH

Solution temperature, °C	Heating time, min	Solution pH	*s*, %
25	60	8.34	3.2
70	60	8.45	4.6
90	5	7.92	2.4

Table 6. Specific surface area of ash from rice husk and straw in relation to the preparation procedure

Processing scheme	S_{sp}, $m^2 g^{-1}$	
	RH	RS
I	142–459	
II	80–309	230–302
III	159–310	
IV	173–297	
V	270–300	291–309
VI	243–301	
VII	270–303	

All ash samples obtained from RH and RS by the procedures listed in Table 2 have the same powder X-ray patterns, typical of amorphous substances [12]; they contain a single diffuse peak in the range $2\theta = 18°–26°$. In pyrolysis of RH and RS samples in a helium flow or at air deficiency (Table 2, scheme I), a black amorphous product (black ash) is formed. The yield of this product is 14–28% from straw and 36–44% from husk. According to Table 3, the SiO_2 content in this product varies in the range 77–80% in helium flow and 39–88% at air deficiency. The carbon concentration in the black ash is 4–60°C, depending on the conditions of thermolysis and pretreatment of raw materials.

Oxidative burning of RH and RS in an air flow (Table 2, scheme II) is accompanied by formation of a dark grey ash; its yield is 7–14% from RS and 11–21% from RH. The content of amorphous SiO_2 in the ash varies in the range 86–88% for RS and 87–93% for RH.

Leaching of this ash with an acid (Table 2, scheme IV) gives a light finely dispersed amorphous substance with a SiO_2 content of 91–95% for RS and 94–98% for RH (Table 3).

Schemes III, V–VII (Table 2) involve extraction of water-soluble organic and inorganic substances from the raw material with hot water or an acid. The composition and content of the extractive substances depends on the type of a raw material and extraction conditions. Extracts with various compositions can be obtained depending on the goals of their subsequent treatment to recover biologically active polysaccharides [13], xylose [12], and other substances [9].

Oxidative burning of the residue of the raw material after extraction gives light (Table 2, scheme III) or white (schemes V–VII) ash consisting of pure amorphous SiO_2 (Table 3). The SiO_2 content in the product obtained after extraction of the raw material with water is 89–92% for RS and 91–97% for RH. The purest silica samples in which the SiO_2 content reaches 99.99% are obtained from the raw material pretreated with an acid. An increase in the acid concentration from 0.1 to 1 N does not appreciably affect the product quality.

Oxides of the following elements were found in the samples of amorphous silica: Na, K, Rb, Cu, Ag, Mg, Ca, Zn, Al, Mn, Fe, and P. The content of oxides depends on the SiO_2 purity and varies in the following ranges (wt %): Fe(III) 0.5–0.02, Al 0.4–0.02, Ca 0.3–0.005, Mg 0.8–0.03, Zn 0.02–0.003, Mn(II) 0.1–0.01, Cu 0.002–0.0007, and Ag less than 0.0005. Data on the content of the main concomitant oxides in some ash samples are listed in Table 4.

The calcination loss of silica obtained by schemes III and V–VII at 1000°C is 0.1–5%. According to an X-ray phase analysis, after heating all the substances studied transform from amorphous to crystalline state corresponding to α-cristobalite and tridymite.

The density of silica obtained from RH and RS containing no less than 95% SiO_2 was determined in toluene at 25°C to be 2.01 ± 0.05 g cm^{-3}. The bulk weight of the substance obtained from RH compacted under a pressure of 150 kgf cm^{-2} is 867, and that in the case of RS, approximately 600 g l^{-1}. The solubility and pH of the solution of amorphous silica vary with the solution temperature and heating duration (Table 5).

The specific surface area S_{sp} of ash depends on the type of a raw material and procedure of its processing (Table 6). The samples of black ash obtained by scheme I (Table 2) have the highest S_{sp}. This product containing silica and carbon is of independent interest for industries using carbon-silicon materials as fillers for industrial rubber items, in metallurgy, and as a sorbent. The other substances (products obtained by schemes II–VII) also have a large surface area; S_{sp} varies in the range 80–310 $m^2 g^{-1}$, depending on

the type of the raw material and preparation procedure. In crystallization of the substance, the S_{sp} decreases, on the average, to 8–10 $m^2 g^{-1}$.

Comparison of the characteristics of amorphous SiO_2 obtained from rice husk and straw with the main characteristics of some references for silicon dioxide recovered from mineral raw materials shows that the product meets the requirements of GOST (State Standard) 14922–77 and 9428–73. The concentration of concomitant impurities in the samples of silica obtained from rice husk and straw is lower.

Thus, the data obtained suggest that the wastes from rice production, RH and RS, are good raw materials for production of amorphous SiO_2 of varied quality. This product can be used first and foremost in branches using such forms of silica as diatomaceous earth, kieselguhr, tripoli powder, carbon white, Aerosil, microsilica, and carbonized silica.

CONCLUSIONS

(1) Sodium, potassium, rubidium, copper, silver, magnesium, calcium, zinc, manganese(II), aluminum, iron(III), and phosphorus oxides were found among concomitant impurities in samples of amorphous silica obtained from rice husk and straw.

(2) All silicon-containing products obtained in processing of rice husk and straw can be used in various branches of industry as carbon-silicon materials and as pure amorphous or crystalline silica.

ACKNOWLEDGMENTS

The study was financially supported by the Ministry of Industry and Science of the Russian Federation (project no. 02.42.9).

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Composition of Inorganic Components of Buckwheat Husk and Straw

L. A. Zemnukhova, E. D. Shkorina, and G. A. Fedorishcheva

Institute of Chemistry, Far Eastern Division, Russian Academy of Sciences, Vladivostok, Russia

Received June 3, 2004

Abstract—The composition of inorganic components and content of soluble substances in wastes from processing of seed (ordinary) buckwheat were studied in relation to the plant strain, type of a raw material (straw or husk), and processing conditions.

The interest in renewable agricultural wastes as promising raw materials for production of a variety of chemicals has increased recently. Here we studied some characteristics of large-tonnage wastes from processing of buckwheat: straw and husk (fruit shells, shucks). Much less data on these wastes are available as compared to the related products of rice processing [1–4]. In comparison with rice wastes, buckwheat wastes contain more organic matter and significantly less inorganic matter. Among organic substances are compounds of the flavoid group, including rutin and quercetin [5], lipids, and biologically active polysaccharides [5–8]. There are data on recovery of polysaccharides [9–11], cellulose [12], dyes and food additives [13, 14], furfural [8], medicinals [15], antioxidants [16], and sorbents [17] from buckwheat wastes. However, until now, the main part of buckwheat wastes has not been used in chemical industry and is burnt in fields or used as a fuel for boilers, fillers for pillows, packing of fruits and fragile goods, and feed.

In this study, we examined inorganic components in ash and extracts of wastes from production of seed buckwheat in relation to the plant strain, type of raw materials (straw or husk), and processing conditions.

EXPERIMENTAL

We studied samples of buckwheat husk (BH) and straw (BS) taken in 1994–2002 in the Primorskii (BH-2, 3, 6–9, and BS-1–7) and Krasnodar (BH-10) krais, Amurskaya (BH-1) and Nobosibirsk (BH-9) oblasts, and China (BH-4).[1]

[1] The numbering of raw material samples is given according to the collection of the Institute of Chemistry, Far Eastern Division, Russian Academy of Sciences.

Husk was sifted through a sieve, and a fraction with a particle size of no less than 2 mm was selected for experiments. Straw was cut into fragments approximately 10 mm long. The initial raw material was washed with water and dried in air.

All the samples of raw materials were analyzed for the content of ash residue and soluble (extractable) substances. For this purpose, a weighed portion of a raw material (60 g) was carbonized in a quartz cup in air at approximately 300°C to remove volatiles and then burnt in a muffle at 650°C to constant weight to obtain an ash residue. Another weighed portion of the raw material was extracted at 80–90°C for 1 h with water or acid (HCl, H_2SO_4, HNO_3) or NaOH solutions (concentration of acids and alkali 0.1 and 1 N), or a mixture (1 : 3) of chloroform with ethanol. In all runs, the solid : liquid ratio was 1 : 10.

The resulting products (ash, extracts, and insoluble residue of raw materials) were subjected to chemical, spectral (a PGS-2 spectrometer), flame atomic absorption (an AA-780 Nippon Jharrell Ash device, Japan), IR spectroscopic (a Perkin–Elmer spectrophotometer, 400–4000 cm^{-1}), and X-ray phase (a DRON-2.0 diffractometer, Cu_{K_α} radiation) analyses by the standard procedures. The content of silicon was determined gravimetrically [18, 19], and that of phosphorus in the extracts, photocolometrically [20].

The results obtained in studying the ash obtained from buckwheat husk and straw are listed in Tables 1 and 2.

According to the X-ray diffraction analysis, the ash obtained from buckwheat husk and straw is, in contrast to that from rice husk and straw [21], in the crystalline state (Fig. 1). The yield of ash from buckwheat

* Not detected by the atomic adsorption method.

husk is 1.5–2.3% and that from straw, 2.8–11.1%, depending on the plant strain.

In the ash residue of buckwheat husk and straw, we found the same set of elements (they are given in the order of decreasing content): potassium, magnesium, phosphorus, silicon, calcium, iron, sodium, manganese, aluminum, zinc, copper, nickel, chromium, and silver ions. Their concentration in ash depends on the plant strain and raw material type (husk and straw). The intervals of concentrations of the elements are given in Table 1.

Contrary to ash obtained from rice husk and straw, which contains mainly amorphous silica [21], the ash residues of BH and BS contain predominantly K ions, similarly to sunflower ash (ash yield 5–6%), in which the K^+ concentration is approximately 15% [22]. The ash obtained from buckwheat wastes (Table 1) contains a significant amount of Mg ions (especially that from husk, up to 10%) and also Cr and Ni ions, absent in the ash from rice wastes. The compositions of ashes obtained from buckwheat husk and straw and from rice husk and straw are compared in Table 2.

The silica content in BH ash is approximately 4%, and that in BS, up to 2%; this differentiates buckwheat wastes from the similar rice wastes, in whose ash the SiO_2 content is more than 90% (Table 2). An X-ray diffraction analysis of SiO_2 recovered from the BH and BS ashes showed that in contrast to the ash from rice wastes [21], this substance is not amorphous, but crystalline: in the form of α-quartz and cacholong, in the ash from BH; and in the form of α-quartz, cacholong, and tridymite, in the ash from BS. It should also be noted that, among the crystalline phases of SiO_2 from rice husk and straw, formed in heating of the amorphous substance to 1000°C, no cacholong phase was found. The calcination loss of ash samples from BH and BS at 1000°C is 10–22% (Table 1). After calcination, the blue-green

ash becomes grey-beige. Among crystalline compounds contained in the ash obtained at 650°C, K_2CO_3 and $MgCO_3$ were identified by X-ray phase analysis (Fig. 1a). After heating to 1000°C, metal oxides may be present in the ash along with carbonates (Fig. 1b).

The presence of carbonates is also confirmed by gas evolution in the reaction of the ash with an acid solution and by comparison of the IR spectra of the ash residue of the raw materials with the spectra of carbonates [23]. It is well known that the isolated CO_3^{2-} ion (point group D_{3h}) shows a set of IR-active frequencies of 1087 (ν_1), 874 (ν_2), 1432 (ν_3), and 706 cm^{-1} (ν_4). In the formation of coordination compounds or carbonates with a mixed composition, the characteristic absorption bands are split or shifted, which is observed in the IR spectra of the samples of BS and BH ash examined in this study.

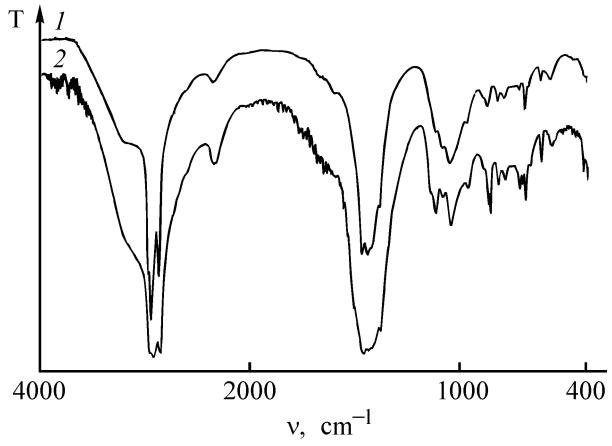

Fig. 2. IR spectra of samples of (*1*) BH-4 ash obtained at 690°C and (*2*) BS-3 obtained at 1000°C. (T) Transmission and (ν) wave number.

Our results show that the IR spectra of ash obtained from buckwheat husk and straw are independent of the plant strain and temperature of oxidative burning of raw materials (650 or 1000°C). However, the splitting pattern of the absorption bands (Fig. 2) is governed by the type of wastes (husk or straw). The absorption peaks (cm^{-1}) in the spectra of the ashes obtained from buckwheat husk and straw are as follows: ash from BH, 470–500 m.br, 620 w, 640 w, 670 w, 690 w, 830 w, 860 w, 1050 m.br, 1260 m, 1630 m, and 3100 w.br; ash from BS, 510 br.m, 560 w, 620 m, 680 w, 880 m, 1040 m.br, 1130 m, 1630 w.br, 1730 w, and 3100 w.br.

The strongest absorption band is in the range 900–1180 cm^{-1}; it is split to two components in the spectrum of BH ash.

The influence of the extractant on the yield of soluble substances from buckwheat husk and straw is demonstrated in Table 3. The yield of extractable substances from buckwheat wastes essentially depends on the extractant, its concentration, and type of a raw material (husk or straw). The content of soluble substances in buckwheat straw is independent of the plant strain and their recovery into the solution is governed by the extractant characteristics only. The recovery of substances from straw (57%) is the highest with 1 N

Table 4. Content of metal ions in extracts of buckwheat husk and straw and sunflower pedicles (SP)

Ion	Content in solution, mg l^{-1}		
	BH-1–10	BS-1–7	SP
K	$(0.4–2.4)\times10^{-1}$	$(2–9)\times10^{-1}$	$(1.45–2.7)\times10^{-1}$
Ca, Mg	$(0.3–7.8)\times10^{-2}$	$(0.3–9.9)\times10^{-2}$	$(0.1–7.5)\times10^{-2}$
Na	$(1.8–4.3)\times10^{-3}$	$(1.5–6.0)\times10^{-3}$	$(4.4–5.0)\times10^{-2}$
Fe	$(1.0–4.0)\times10^{-3}$	$(0.8–1.8)\times10^{-3}$	$(0.3–1.3)\times10^{-3}$
Mn	$(0.9–1.7)\times10^{-3}$	$(1.0–5.0)\times10^{-3}$	$(0.7–2.5)\times10^{-3}$
Zn, Al*	$(0.4–6.0)\times10^{-3}$	$(0.4–8.0)\times10^{-4}$	$(0.6–2.6)\times10^{-3}$
Cu	$(0.4–2.6)\times10^{-4}$	$(0.4–6.0)\times10^{-4}$	$(1.8–2.0)\times10^{-4}$
Ni	1.6×10^{-4}–9.9×10^{-3}	1.4×10^{-4}–4.6×10^{-3}	N/d*
Cr	3.5×10^{-4}–9.3×10^{-3}	2.5×10^{-4}–8×10^{-3}	N/d
Ag	2×10^{-5}–5.5×10^{-4}	1.5×10^{-4}	N/d

* Al, Ni, Cr, and Ag ions in extracts of sunflower pedicels were not detected by the atomic absorption method.

nitric acid and the lower (1%) with 1 N sodium hydroxide.

In contrast to straw, the composition of soluble substances in buckwheat husk depends on the plant strain and their recovery, on the solvent. For example, in treatment of BH with hot water, depending on the buckwheat strain, 13–27% of substances is extracted. The recovery of extractable substances from buckwheat husk with HNO_3 is the highest (Table 3).

The presence of pigments in soluble substances of buckwheat husk and straw results in different color of extractants. Although some flavonoid compounds from buckwheat flowers are used in medicine [5, 13], the chemical composition and content of pigments in processing wastes (husk and straw) are known insufficiently.

In extraction of buckwheat husk and straw, metal ions are recovered into solution along with organic substances. The concentration ranges of metal ions found in the extracts are listed in Table 4. The composition and content of metal ions in hydrolytic solutions from sunflower pedicles, obtained under the similar conditions, are given for comparison.

The residue of buckwheat husk and straw after extraction with water or acid, forms less than 0.8% ash. A fragment of the X-ray diffraction pattern of ash from a BS-1 sample extracted with an HCl solution is shown in Fig. 1c. Identification of the strongest lines in the X-ray pattern suggests the presence of KCl and MgO in this ash. The IR spectrum of this ash contains a strong band at 718 cm^{-1} characteristic of KCl [23].

CONCLUSIONS

(1) The yield of ash from buckwheat husk and straw only slightly depends on the plant strain and is 1.5–2.0%. This value differs from the yield of ash from buckwheat straw, which varies in the range 2.8–11.13%. The ash is crystalline and contains metal carbonates; among these, potassium (9–18%) and magnesium (3–10%) carbonates predominate. As shown by the X-ray phase analysis, silica, whose content in the ash from buckwheat husk does not exceed 4.5%, has three modifications: cacholong, tridymite, and α-quartz.

(2) Extraction of soluble substances from wastes formed in processing of buckwheat depends on the type of a raw material (husk or straw) and on the extractant. The content of soluble substances from husk depends on the plant strain and virtually does not affect the yield from straw.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Cleaning of Microfiltration Membranes for Filtration of Aqueous Extract of Marsh Mallow

B. T. Sagdullaev

Yunusov Institute of Chemistry of Vegetable Compounds, Academy of Sciences of the Republic of Uzbekistan, Tashkent, Uzbekistan

Received January 20, 2004

Abstract—Cleaning of a microfiltration membrane was studied using various chemicals. The activation energy and cleaning constant were estimated for alkaline cleaning.

Baromembrane filtration methods (microfiltration, ultrafiltration, nanofiltration, and reverse osmosis) are widely used in processing of synthetic and natural high-molecular-weight compounds for their concentration, desalination (removal of low-molecular-weight compounds from solutions of macromolecules), and fractionation [1].

Among the most important problems arising in using membrane filtration in biotechnology and food and pharmaceutical industries is that the membrane throughput decreases in the course of filtration [2–4], which is caused by such factors as increase in the concentration of components retained at the membrane surface [5, 6] and adsorption of colloids, microorganisms, and organic compounds on the surface and in the pores of the membrane [6, 7]. Both these factors reduce the effective pore size, thus increasing the resistance of the membrane to the flux [8].

The problems arising from membrane fouling started to be manifested in full measure upon accumulation of data on operation of industrial units [9]. Fouling with organic contaminants plays an especially significant role in filtration of macromolecular compounds, which can form a gel layer on the membrane surface [10]. Studies concerned with the problem of fouling are being conducted in various areas including development of cleaning methods [9]. Chemical cleaning involves treatment of filters with various agents, allowing regeneration of a membrane without disassembling of a membrane unit (cleaning-in-place) [11]. To optimize chemical cleaning, specific features of a given process and the type of the membrane used should be taken into account.

The goal of this study was to optimize the chemical cleaning of a membrane contaminated during microfiltration of the extract of marsh mallow.

EXPERIMENTAL

In the study we used an Alpma microfiltration system (Germany) (Fig. 1) equipped with two membrane units (Kerasep, France). Each unit consisted of nine cylindrical membranes fabricated from TiO_2 with the Al_2O_3/TiO_2 active layer (nominal pore size 0.2 μm). Membranes of this type are thermally and chemically resistant over the pH range 1–14 at 293–358 K.

The water flux across an unused membrane at a transmembrane pressure P_{TM} = 85 kPa was 1650 l m^{-2} h^{-1}, and the resistance, $R_m = 1.96 \times 10^{11}$ m^{-1}.

	0.3	0.49	80
	0.5	0.50	80
	1.0	0.52	80
Ultrasil-11	0.3	0.54	60

We used in experiments an aqueous extract of marsh mallow prepared from roots of *Althaea armeniaca* by turbulent extraction. The total content of extractive substances in the solution was 1.65 wt % and the concentration of water-soluble polysaccharides in the extract, 0.8 wt %. The extract also contained sucrose, pigments, betaine, and mineral substances.

We used as cleaners three different chemicals (Table 1). Ultrasil-11 from Henkel Chemicals is sodium hydroxide with surfactant additives.

All the cleaning experiments were carried at a cross flow velocity of 1 m s^{-1}, low transmembrane pressure (85 kPa), and various temperatures. After filtration, the extract was removed, and the membrane was rinsed with distilled water at 295 K, which removed the residual concentrate from the membrane surface.

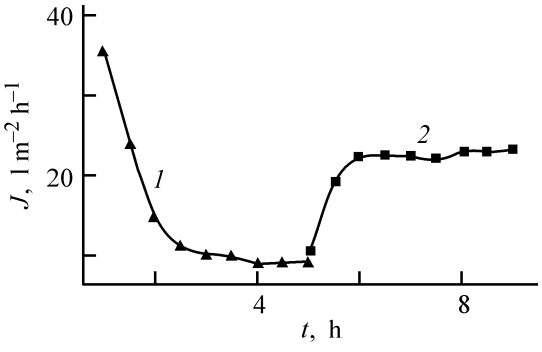

Fig. 2. Flux *J* vs. the time *t*: (*1*) extract of marsh mallow and (*2*) distilled water.

Cleaners were dissolved in distilled water at room temperature and heated to a desired temperature prior to use. After chemical treatment, the membrane was additionally cleaned with distilled water, to determine its permeability to water. To minimize pore plugging, the cleaning was carried out at low transmembrane pressure. To provide cleaning inside the pores of the membrane, the permeate line was switched on throughout the cleaning.

In all the experiments in which the solvent flux was measured, distilled water was used ($[Ca^{2+}] < 10$ mg l^{-1}).

To evaluate the cleaning efficiency, we used two major parameters, namely, (1) the flux recovery FR defined as the ratio of the water flux across the worked membrane after cleaning to that across the unused membrane, and (2) cleaning time t_c [12].

According to Darcy's law, the permeate flux *J* (l m^{-2} h^{-1}) is proportional to the transmembrane pressure P_{TM} (Pa):

$$J = \frac{P_{TM}}{\mu_p(R_m + R_f)}, \quad (1)$$

where μ_p is the permeate viscosity (g cm^{-1} s^{-1}); R_m, initial membrane resistance (m^{-1}); and R_f, resistance after fouling (m^{-1}).

The resistance that appears after fouling (R_f) can be estimated by rearranging (1) to the form of Eq. (2).

$$R_f = \frac{P_{TM}}{\mu_p J} - R_m. \quad (2)$$

R_f includes the resistance R_{ir} of a residual contamination after cleaning, which is due to irreversible adsorption of the molecules in the pores and on the surface of the membrane, and also the resistance R_r of reversible contamination caused by reversible deposition of the molecules on the membrane surface and also by concentration polarization [1], which can be removed by cleaning.

Upon a 5-h filtration of the extract of marsh mallow, the flux decreased to 9.3 l m^{-2} h^{-1} (Fig. 2). To evaluate the nature and amount of contamination, the membrane was first washed with distilled water. The procedure was carried out at P_{TM} = 85 kPa and T = 295 K. Washing with water could only remove the concentrate residue from the surface. As a result, the flux recovery was insignificant (water flux was 22.4 l m^{-2} h^{-1}.

The cleaning efficiencies of three different chemicals at 295 K are listed in Table 2, as influenced by their concentration. As seen, the flux recovery FR and the cleaning time t_c depend on the nature of chemicals

and their concentration. Sodium hydroxide showed the highest cleaning efficiency (0.65) among the chemicals studied. With HNO_3 and Ultrasil-11, the cleaning efficiency was found to be 0.52 and 0.54. Because of the high cost of the latter chemical, its use appears to be inadvisable in this case.

A study of the effect of the cleaner concentration (Table 2) showed that cleaning with NaOH provides the best result (FR = 0.63) at a concentration (0.3%) lower than that of NaOH (0.5%) used for cleaning of a ceramic membrane [12]. Raising the cleaner concentration to above 0.3% provided only an insignificant gain in the flux recovery.

The experiments with 0.3% NaOH showed that the temperature has a considerable effect on both the cleaning time and flux recovery (Fig. 3), the effect being more clearly pronounced at lower temperatures (<313 K). The flux recovery at 353 K was 17.1% higher than that at 295 K. Raising the temperature to above 313 K only insignificantly increases FR, allowing, however, a considerable reduction of the cleaning time (from 27 min at 313 K to 12 min at 353 K).

Bird *et al*. demonstrated [11] that the kinetic equation describing the cleaning can be written as

$$\frac{dR_f}{dt} = k_c R_f. \quad (3)$$

Integrating over the limits from $t = 0$ to t at k_c = const and assuming that R_f varies from R_{max} to R_{ir}, we obtain Eq. (4).

$$\ln(R_{max}/R_{ir}) = -k_c t, \quad (4)$$

where R_{max} is the maximum resistance of the contaminant layer and R_{ir}, residual resistance after cleaning for a time t_c.

In our experiments, the membrane was cleaned until a steady-state water flux was obtained.

The R_{max} depends only on the contamination of the membrane. After a 5-h operation of the microfiltration system, R_f was 3.48×10^{13} m^{-1}. For a given cleaner, R_{ir} varies with temperature (Table 3).

The temperature dependence of the cleaning rate constant can be derived from the Arrhenius equation:

$$k_c = k_{c0} e^{-E_c/RT}. \quad (5)$$

Substituting it into Eq. (4), we obtain

$$\ln(R_{max}/R_{ir})\frac{1}{t} = -k_{c0} e^{-E_c/RT}, \quad (6)$$

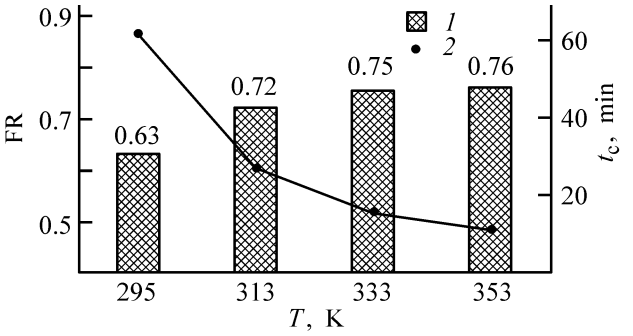

Fig. 3. (*1*) Flux recovery FR and (*2*) cleaning time t_c vs. the temperature T, with 0.3% NaOH as a cleaner.

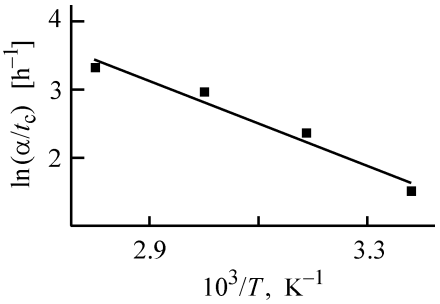

Fig. 4. $\ln(\alpha/t_c)$ vs. reciprocal temperature T.

where E_c is the activation energy of cleaning; k_{c0}, preexponential factor reflecting the cleaning capacity of a chosen cleaning method and membrane cleaning conditions.

Assuming $\alpha = \ln(R_{max}/R_{ir})$, $a = E_c/R$, and $b = \ln k_{c0}$ and rearranging Eq. (6), we obtain

$$\ln(\alpha/t_c) = b - a(1/T). \quad (7)$$

The temperature dependence of $\ln(\alpha/t_c)$ is shown in Fig. 4. A small change in R_{ir} with increasing temperature has no considerable effect on *a* and *b*, suggesting that R_{ir} is a temperature-independent parameter, i.e., the temperature influences the kinetics of cleaning, but not the maximum cleaning capacity of a given chemical.

Table 3. Residual resistance R_{ir} at various temperatures of cleaning with 0.3% NaOH

T, K	$R_{ir} \times 10^{11}$, m^{-1}	$\ln(R_{max}/R_{ir})$
295	3.11	4.72
313	2.72	4.85
333	2.61	4.89
353	2.57	4.91

The activation energy of cleaning, E_c, is the energy required for breaking the bonds between contaminant particles and the membrane. In the case of NaOH, the activation energy was estimated to be 25.4 kJ mol^{-1}. The other kinetic parameters are as follows: k_{c0} = 49.9 s^{-1}, $a = E_c/R$ = 3053, and $b = \ln k_{c0}$ = 12.1.

CONCLUSIONS

(1) It was foun that cleaning of a fouled membrane only with distilled water does not restore its performance.

(2) The effects of the temperature and cleaner concentration on the cleaning efficiency were studied. It was established that cleaning of the microfiltration membrane with 0.3% NaOH proceeds quite rapidly and efficiently: the flux is recovered to 76% of the initial value in 12 min at 353 K.

(3) The activation energy of alkaline cleaning E_c was estimated at 25.4 kJ mol^{-1}, and the preexponential factor of the Arrhenius equation k_{c0}, at 49.9 s^{-1}.

Polythermic Section B_4C–LaB_6 in the Ternary System La–B–C

S. S. Ordan'yan, O. V. Yurchenko, and S. V. Vikhman

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received July 13, 2004

Abstract—The interaction was studied and the polythermic section B_4C–LaB_6 was constructed for the ternary system La–B–C described by a eutectic phase diagram.

Covalent carbides, SiC and B_4C, find increasingly wide application in modern technology, from abrasives to materials for space and nuclear power engineering. Borides of *d*- and *f*-elements, e.g., M^dB_2 and M^fB_6 as substances possessing a complex of properties reflecting the strength of their chemical bonding (hardness, refractoriness, electrical conductivity, and effective thermionic emission), are also rather promising for technical applications. In the LnB_6 series, lanthanum hexaboride has the minimum work function [1]. In a number of cases, it is of interest to use, instead of single-phase LnB_6, composite materials containing this compound. Therefore, a problem arises of the chemical compatibility of the components intended to be used in a material being developed. It has been shown previously that LaB_6 coexists with M^dB_2 and their interaction is described by eutectic phase diagrams [2]. Analysis of the phase composition in the ternary systems M^d–B–C [3] and M^f–B–C [4] shows that the borides M^dB_2 and M^fB_6 coexist with B_4C. The fundamental aspects of their interaction in a quasibinary system B_4C–M^dB_2 were summarized in [3]. Data on the structure of polythermic sections in the systems M^f–B–C are virtually lacking. If obtained, these data will make it possible to differentiate the ternary systems B_4C–M^dB_2–M^fB_6 and to begin a systematic study of these systems as a basis for a large number of composites produced by the ceramic technology or by directed crystallization [5].

We used in this study B_4C and LaB_6 powders (both of pure grade) manufactured by Donetsk Plant of Chemical Reagents. The powders were ground in a vibration mill (TiB_2 milling bodies) to 5–10-μm particles, with the introduction of a milled substance of the milling bodies virtually eliminated, and then the compositions in the B_4C–LaB_6 system under study were prepared. The powders were used to produce mixtures in the entire concentration range by stirring in ethanol (see table). The dried powders were compacted to obtain $3 \times 3 \times 40$ mm prismatic samples and sintered at 1900°C in a high-purity argon. Holes

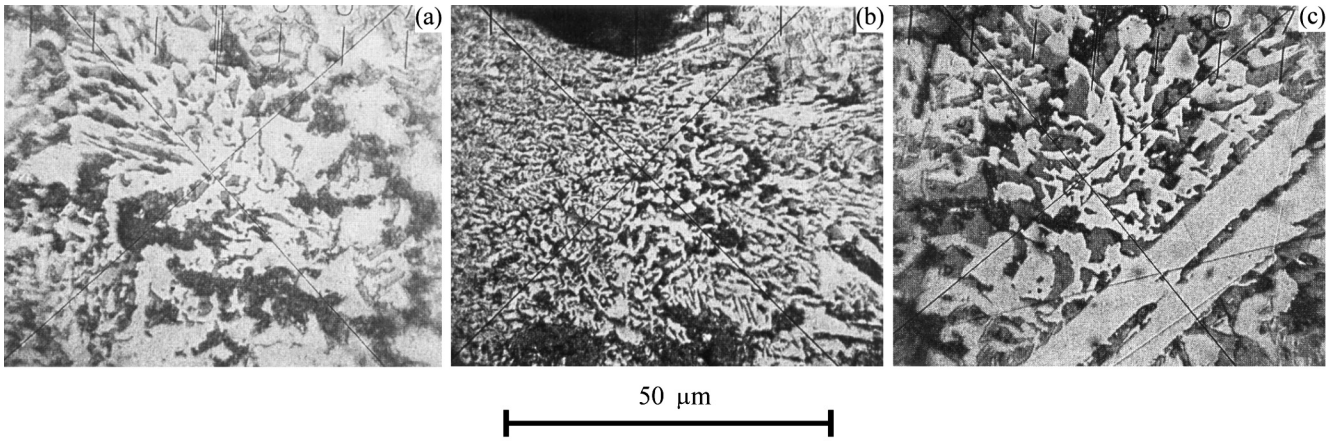

Fig. 1. Microstructure of fused samples in the B_4C–LaB_6 system. LaB_6 concentration (mol %): (a) 25, (b) 30, and (c) 55.

0.5 mm in diameter and 1.5 mm long were made at mid-length of the samples for optical measurements of their temperature with a micropyrometer (blackbody configuration). The melting point was determined with an indirect heating of samples placed within a tubular heater so as to preclude any contact of the samples with the material of the heater. Taking into account the optical absorption in a viewing window [6], we obtained close results, which were then averaged. Sintered, annealed, and fused samples were subjected to X-ray diffraction analysis, to determine the phase composition and the lattice constants and to metallographic analysis. Also the microhardness of the phase components was determined (see table).

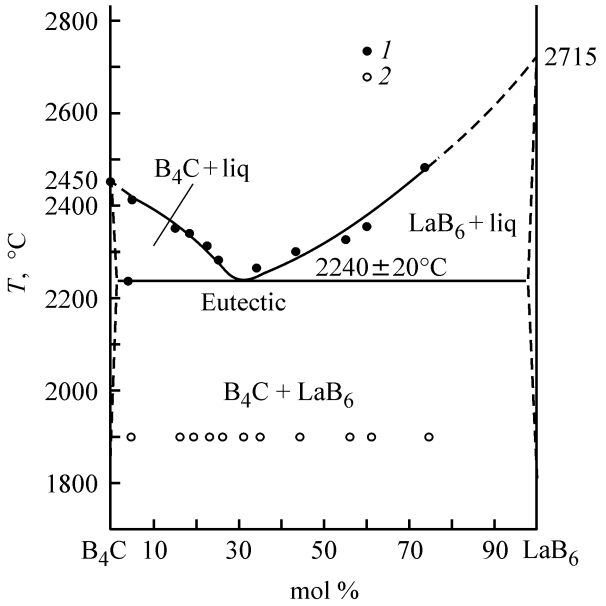

Fig. 2. Polythermic section of the system B_4C–LaB_6. (*T*) Temperature. (*1*) Fusion in indirect heating and (*2*) two-phase material.

As shown in [6], a sample is "ruptured" in direct heating by electric current upon the appearance of a certain amount of melt; therefore, $T_{rup} < T_{liq}$. In eutectic mixtures, $T_{eut} < T_{rup} < T_{liq}$ and direct heating by electric current makes it possible to determine the melting point of congruently melting components and eutectic. T_{liq} can be estimated by the temperature at which a drop appears on the sample in indirect heating.

The data obtained show that, in the B_4C–LaB_6 system, the concentration dependence of the melting point passes through a minimum. The structure typical of eutectic, hypoeutectic, and hypereutectic regions is recorded for samples that have been fused and then crystallized at T_{min} (Fig. 1). The microhardness of the constituent phases corresponds to that of pure components ($H_\mu = 49 \pm 1$ GPa for B_4C and $H_\mu = 26.8 \pm 1.1$ GPa for LaB_6 [7]); and in this system too, the microhardness of the eutectic is markedly lower than the additive value (see table).

The data obtained, as well as the fact that all the heat-treated samples have a two-phase composition, suggest that the polythermic section B_4C–LaB_6 in the ternary system La–B–C is described by an eutectic phase diagram (Fig. 2), with the eutectic composition containing 70 mol % B_4C and 30 mol % LaB_6 and having a melting point $T_{eut} = 2240 \pm 20$°C. This temperature is higher than T_{eut} in the SiC–LaB_6 system [8], although T_{mel} of B_4C < T_{mel} of SiC (2450 and 2760°C, respectively). The last result shows that B_4C has a higher resistance to contact interaction, as already noted in [9] when comparing T_{eut} in the B_4C–M^dB_2 and SiC–M^dB_2 systems, for which an analogous dependence also exists.

Effect of Unpaired Electron in Thermochemical Description of the Dissociation Energy of Heteronuclear Diatomic Molecules

V. M. Yakovlev, D. V. Ovchinnikov, and I. G. Fokeeva

Samara State Railway Academy, Samara, Russia

Gipronikel Institute, Joint Stock Company, St. Petersburg, Russia

Received January 11, 2005

Abstract—The dissociation energy of heteronuclear diatomic molecules with polar covalent bonds was calculated by the modified Pauling procedure taking into account the presence of an unpaired electron on one of the atoms.

Spin polarization caused by the presence of an unpaired outer electron in a diatomic heteronuclear radical AB is believed [1, 2] to destabilize the chemical bond (CB). At first glance, this assumption is obvious because of a certain analogy with the homoatomic anion H_2^-, commonly regarded as a classical example of a system with an antibonding effect. A typical example of the antibonding effect in AB systems is beryllium monofluoride. In this compound and in its analogues, the unpaired *s* electron of Be repulsively interacts with the bonding electron pair [2]. This assumption is confirmed by the fact that the dissociation energies [D(AB)] of gaseous molecules of BeF (5.96 [1], 5.98 [3] eV) and LiF (5.94 [1], 5.98 [3] eV) are virtually equal [2]. In this comparison, noticeable shortening of the CB in going from LiF to BeF [2] was primarily taken into account, whereas the decrease in the ionic character of the bond was ignored. However, the tabulated dissociation energy taken from another source D(BeF) = 6.62 eV [4, 5] suggests strengthening of a BeF molecule, which casts doubt on the above reasoning.

In this paper, we show in what case and how the influence of an unpaired electron on D(AB) should be taken into account. The influence of unpaired electron localized on a metal atom differs from that of the electron localized on a nonmetal atom. Our analysis shows that formation of an antibonding electron pair is energetically favorable only when the electron is localized on the nonmetal atom.

In our calculations, we used the modified Pauling equation [6, 7] suitable for calculating D(AB) of majority of heteroatomic CB with any polarity, provided that at least one *p*-AO is involved in MO, which makes the bond directional and more localized

$$D(\mathrm{AB}) = [D(\mathrm{AB})] + (2c)^{1/2}\Delta\chi^2 \ (\mathrm{eV}), \qquad (1)$$

where $[D(\mathrm{AB})]$ is the geometric mean of D(A–A) and D(B–B) energies of homoatomic covalent bonds; $\Delta\chi$, difference in the Pauling electronegativities (EN) χ(A) and χ(B); and c, degree of covalence of CB, which is unambiguously related to the relative difference in EN (i.e., polarity) $p = \Delta\chi/\chi(\mathrm{B})$ [$\chi(\mathrm{A}) < \chi(\mathrm{B})$] by the equation $c = \exp(-3p^2)$.[1] In particular cases, when atoms of hydrogen and elements of the second row are present in the compound, corrections for donor–acceptor interactions (DAI) and antibonding contribution to CB, i.e., promotion of bonding electron density (ED) from the internuclear region to the metal atom [9], should be taken into account. The latter effect is caused by the difference in the valence ED of atoms in the molecule. The DAI is manifested in interactions of acceptor atoms (H, Li, Be, B, C) with donor atoms (N, O, F). This effect can be taken into account by introducting the electron affinity (EA, Eα) of the acceptor in Eq. (1). The weakening of CB is taken into account by subtracting EA of the metal atom exerting an antibonding effect on the CB from the right-hand part of Eq. (1). This correction is

[1] The effect of saturation of a heteropolar bond [7], mentioned in many reports (e.g. [8]), can be taken into account by introducing parameter c in to the equation of the ionic increment.

Table 1. Calculated dissociation energies of alkali and alkaline-earth metal monoxides*

A	χ(A), $eV^{1/2}$ [2, 5]	$E\alpha$(A), eV [2]	D(A–A), eV [2]	D(AB), eV	
				calculated	experimental
Li	0.98	0.618	1.14	3.62	3.64 [8]
Na	0.93	0.548	0.745	2.83	2.83 [4]
K	0.80	0.501	0.53	2.77	2.77 [4]
Rb	0.75	0.486	0.51	2.78	2.82 [8]
Be	1.45	1.02 [11]	(1.45)	4.66	4.64 [12]
Ca	1.10 [13]	0.63 [14]	0.90	4.18	4.38 [12]; 3.97 [3]
Sr	1.05	0.59 [14]	0.83	4.22	4.30 [3]

* We used χ(O) = 3.30 $eV^{1/2}$ [7] and D(O–O) = 1.86 eV [10] in the calculation. Average value of D(Be–Be) taken from [2, 15] is in parentheses. The electron affinities of Be, Ca, and Sr refer to valence states typical for monochalcogenides.

introduced when this metal atom interacts with a small nonmetal atom of the second row. Analysis of molecular systems [e.g., alkali metal (AM) halides or alkaline-earth metal (AEM) chalcogenide] confirms the validity of Eq. (1) supplemented with the above rules and shows why these corrections should be ignored in the case of monosulfides and monochlorides, but should be taken into account in the case of monoxides and monofluorides.

To analyze the reason for the different strengths of CBs in AB radicals, we assume that the unpaired electron on the metal atom virtually eliminates the antibonding effect. However, when this electron is localized on the nonmetal atom, it weakens the chemical bonds in proportion to EA of the nonmetal atom. Indeed, as can be seen from Table 1, to calculate D(AB) of AM monoxides, not only EA of the metal atom but also $E\alpha$(O) = 1.461 eV [2] should be subtracted from the results of the calculation by Eq. (1). In AEM oxides, in which all the valence electrons are paired, only the antibonding caused by transfer of the ED to the metal atom is observed. It should be noted that the antibonding effect is compensated by DAI in LiO and LiF (Table 2).

Thus, to calculate the dissociation energies of AM monofluorides and AEM monofluorides, the corrections can be introduced in Eq (1). However, the strengthening of CB due to DAI should be taken into account only in calculation of D(AB) of BeF. Since the unpaired electron in CaF, SrF, and BeF is localized on the metal atom, the antibonding effect in their molecules is compensated and D(AB) can be calculated by Eq. (1) without correction (Table 2). As can be seen from Tables 1 and 2, the drastic destabilization of alkali metal monoxides as compared to alkali metal monofluorides and other alkali metal halides can explained in the framework of our approach.

We did not consider Cs and Ba compounds since the relativistic effect observed in these compounds strongly weakens the antibonding influence of the metal atom. We also omitted data on Mg compounds since the strength of CB in these compounds decreases by $E\alpha$ of the Mg atom (in the valence state) owing to its abnormal electronic structure [8]. Presumably, this effect should be observed in all diatomic Mg compounds with any nonmetal atom, irrespective of the presence of an unpaired electron in the AB radical.

Thus, in most cases our approach allows the presence of unpaired electron to be taken into account in thermochemical calculations of the dissociation energies of diatomic heretonuclear molecules.

Table 2. Calculated dissociation energies of alkali and alkaline earth metal monofluorides*

A	D(AB), eV	
	calculation	experimental
Li	5.97	5.98
Na	5.19	(5.17)
K	5.12	5.13
Rb	5.12	5.09
Be	6.62	6.62
Ca	5.72	5.81
Sr	5.72	5.64

* We used $\chi(F)$ = 3.68 $eV^{1/2}$ [16] and D = 1.65 eV [2] and $E\alpha$ of AM and Be given in Table 1 in the calculation. The average of substantially different values tabulated in [3, 4] is in parentheses.

Mechanochemical Changes in the Structure of Layered Silicates according to ^{27}Al and ^{29}Si NMR Data

E. A. Pashchenko

Kiev National University of Technology and Design, Kiev, Ukraine

Received July 20, 2004

Abstract—Mechanochemical structural changes in layered silicates were studied by ^{27}Al and ^{29}Si NMR spectroscopy.

Layered silicates and, in particular, pyrophyllite and montmorillonite, are widely used in manufacture of radio- and electroceramics [1] and as sorbents and various fillers [2]. Their use in some fields involves preliminary dispersion [3].

In this study, ^{27}Al and ^{29}Si NMR spectroscopy was used to examine changes in the coordination state of aluminum and silicon ions in pyrophyllite and montmorillonite upon a mechanical activation.

As objects of study served natural zeolites: mordenite and clinoptilolite. Air-dry samples were activated by dispersion in a mechanical agate mortar for 20–120 min. The ^{27}Al and ^{29}Si NMR spectra were obtained on a Bruker CXP-200 spectrometer with sample rotation at a magic angle to the external field at a frequency of ~3 kHz. The chemical shifts were measured relative to the $Al(H_2O)_6^{3+}$ ion and tetramethylsilane as external standards.

It was found that the mechanochemical activation of pyrophyllite causes a strong distortion of aluminum- and silicon-oxygen polyhedra, which leads to broadening of signals at δ 1 ppm (octahedral oxygen configuration) and 94 ppm (tetrahedral oxygen configuration), respectively, in ^{27}Al and ^{29}Si NMR spectra. However, the positions of the peaks in the spectra do not change noticeably even upon a mechanochemical treatment of a sample for 1 h. This means that the existing Si–O–Al bonds are for the most part preserved in the deformed structure of pyrophyllite.

The study demonstrated that the structure of montmorillonite more readily undergoes profound changes in the course of mechanical treatment, compared with that of pyrophyllite. For example, it was found that changes in the ^{29}Si NMR spectra are similar to those for pyrophyllite, but occur upon a more prolonged treatment. However, changes in the ^{27}Al NMR spectra have a different nature. For example, similarly to the spectra of the initial sample, spectra of activated montmorillonite show two signals with δ close to the initial values. The intensity of the signal at δ = 50 ppm in these spectra markedly increases upon activation, which points to a considerable transformation of the octahedral layer, accompanied by a decrease in the coordination of Al^{3+} ions to a tetrahedral coordination.

Received September 9, 2004

Abstract—Sorption of fullerenes C_{60} and C_{70} from *o*-xylene, toluene, and *o*-dichlorobenzene solutions under static conditions on a sorbent prepared by sublimation of graphite rods was studied. The sorption isotherms of both fullerenes at 25°C were measured.

In this study, we examined sorption of fullerenes from *o*-xylene, toluene, and *o*-dichlorobenzene solutions on a sorbent prepared by sublimation of graphite rods. The research in this field is aimed at determining the conditions of chromatographic separation of fullerene mixtures [1–3]. This study continues our previous investigations concerned with sorption of light fullerenes on unmodified carbon materials [3]. It should be noted that the first works in this field in Russia were those by Samonin *et al.* [4, 5], which, however, disregarded the possibility of chromatographic separation and purification of light fullerenes.

We used fullerene C_{60} containing 99.9 wt % main compound (0.1 wt % C_{70}) and C_{70} containing 99 wt % main compound (1 wt % C_{60}) (ILIP Joint-Stock Company, St. Petersburg, Russia). *o*-Xylene, *o*-dichlorobenzene, and toluene were of analytically pure grade. The sorbent was prepared by sublimation of graphite rods [reactor graphite of ultrapure grade (>99.995 wt %)] at 2500 ± 50°C and a residual pressure of 2×10^{-3} mm Hg. The carbon vapor was condensed on a steel support water-cooled to temperatures below 70°C. The resulting carbon crust was ball-milled using steel balls. The powder was mechanically sieved into fractions. We used a fraction with the following particle size distribution: $d > 70$ μm less than 10 wt %, $d = 40$–70 μm 80–85 wt %, and $d < 40$ μm 5–10 wt %. Just before the experiment, the sorbent was heated in air at 200 ± 20°C for 1.5–2.0 h.

To study the sorption properties of the carbon, concentrated stock solutions of the fullerenes in the above solvents were prepared (taking into account their solubilities) by isothermal saturation at 25°C for 24 h. The concentration of C_{60} and C_{70} in *o*-xylene, toluene, and *o*-dichlorobenzene was 4.1 and 2,3, 1.3 and 0.46, and 26 and 3.3 g l^{-1}, respectively. Less concentrated solutions in all of these solvents were prepared by sequential dilutions.

To weighed portions of the carbon (1 g), 10-ml aliquots of the fullerene solutions of different concentrations were added. The mixture was stirred on a magnetic stirrer for 24 h at 25 ± 0.05°C. This time is required to attain an equilibrium in the carbon-solution system. The mixture was filtered through a Schott filter (porosity 16) to remove the sorbent, and the fullerene content in the resulting solution was determined.

The content of C_{60} and C_{70} in the solutions before and after the sorption was determined spectrophotometrically on an SF-46 spectrophotometer from the optical density at λ = 335.5 and 472.0 nm [6].

The concentrations were calculated by the following empirical equations:

$$c(C_{60}) = 13.10(D_{335} - 1.8080D_{472}), \quad (1)$$

$$c(C_{70}) = 42.51(D_{472} - 1.0081D_{335}), \quad (2)$$

where D_{335} and D_{472} are the optical densities of a 1-cm layer of the solution at the indicated wavelength; $c(C_{60})$ and $c(C_{70})$ are the fullerene concentrations (g l^{-1}).

1070-4272/05/7802-0340 © 2005 Pleiades Publishing, Inc.

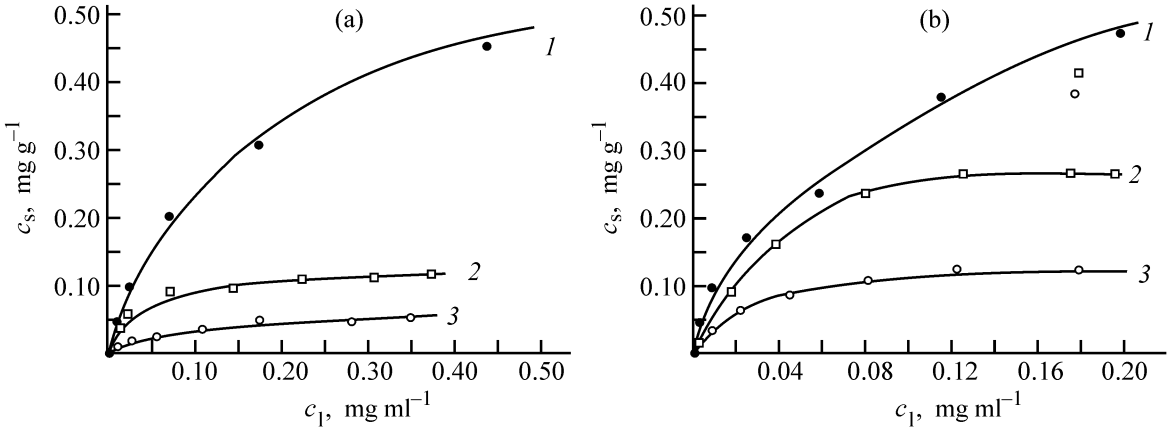

Fig. 1. Isotherms of adsorption of (a) C_{60} and (b) C_{70} from (*1*) *o*-dichlorobenzene, (*2*) *o*-xylene, and (*3*) toluene at 25°C on the unmodified carbon sorbent prepared by vacuum sublimation of graphite rods. Sorbent weight $m \sim 1$ g, solution volume $V \sim 10$ ml. (c_s, c_l) Fullerene concentrations in the solid and solution, respectively.

The sorption isotherms of fullerene are shown in Figs. 1a and 1b.

All the sorption isotherms measured in toluene and *o*-xylene are of Langmuir type. This is not the case for *o*-dichlorobenzene solutions. In this solvent, no saturation is reached in the concentration range examined.

The static sorption capacity of the sorbent in *o*-xylene, toluene, and *o*-dichlorobenzene for C_{60} and C_{70}, determined from the height of the plateau in the isotherms (Figs. 1a, 1b) is 0.10 and 0.24, 0.04 and 0.09, and 0.45 and more than 0.50 mg g^{-1} (the saturation is not reached), respectively.

As can be seen from Figs. 1a and 1b, the distribution coefficients of the fullerenes between the solid and liquid phases strongly depend on the solvent (isotherms measured in these solvents differ) and monotonically decrease for both fullerenes as their concentrations in both phases increase. Finally, the distribution coefficient of C_{70} is higher by a factor of 2–2.5 than that of C_{60}, which is favorable for chromatographic separation of the fullerenes. The only exception are *o*-dichlorobenzene solutions. In this solvent, the distribution coefficients of C_{60} and C_{70} are close, which makes their sorption separation ineffective.

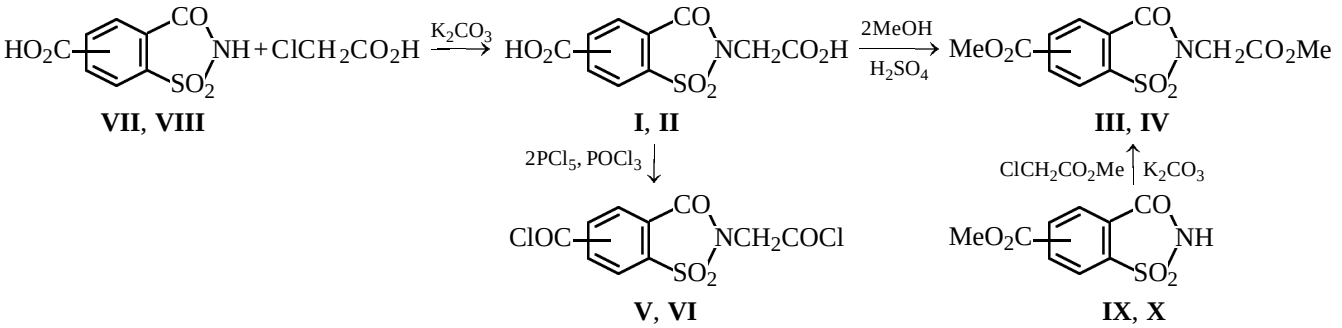
BRIEF COMMUNICATIONS

Synthesis of Saccharindicarboxylic Acids and Their Derivatives

T. A. Aslanov, U. M. Mamedli, and A. M. Guliev

Institute of Polymeric Materials, National Academy of Sciences of Azerbaijan, Sumgait, Azerbaijan



Received June 22, 2004

Abstract—Procedures were developed for preparing saccharindicarboxylic acids and their derivatives.

Imido dicarboxylic acids and their derivatives are used as monomers in synthesis of polyamido imides and polyester imides [1, 2]. Structurally related monomers with aliphatic and aromatic fragments were prepared in [3, 4].

In this study we prepared previously unknown saccharindicarboxylic acids **I** and **II**, their methyl esters **III** and **IV**, and chlorides **V** and **VI**, starting from saccharin-5-carboxylic acid **VII** and saccharin-6-carboxylic acid **VIII**, prepared as described in [4].

The reactions of acids **VII** and **VIII** with monochloroacetic acid were performed in dimethylacetamide (DMAA) in the presence of K_2CO_3:

where compounds **I**, **III**, and **V** are substituted in 5-position, and compounds **II**, **IV**, and **VI**, in 6-position.

The resulting saccharin-5- (**I**) and saccharin-6-carboxy-*N*-acetic (**II**) acids were recrystallized from hot distilled water. The isolated products are crystalline substances, mp 300 and 278°C, respectively.

The composition and structure of **I** and **II** were confirmed by elemental analysis and IR spectroscopy. The IR spectra contain bands at 1690–1700 (C=O of saccharin ring), 1180, and 1365 cm^{-1} (asymmetric SO_2 stretching vibrations in the saccharin ring). Also, the IR spectra of **I** and **II** contain a band at 3480–3600 cm^{-1}, characteristic of stretching vibrations of the O–H group in carboxylic acids [5].

Esters **III** and **IV** were prepared either by esterification of acids **I** and **II** with methanol or by condensation of methyl esters **IX** and **X** with methyl chloroacetate. Compounds **III** and **IV** are crystalline substances, mp 184 and 163°C, respectively, readily soluble in aprotic solvents.

The IR spectra of diesters **III** and **IV** contain absorption bands at 1730–1740 (C=O in ester group), 1370–1380, and 1460 cm^{-1} (CH_3); the band at 720–740 cm^{-1} belongs to the CH_2 group. The bands at 1320–1350 and 1140–1180 cm^{-1} belong to stretching vibrations of the SO_2N group.

Dichlorides **V** and **VI** were prepared by the reactions of acids **I** and **II** with PCl_5 in the presence of a minor amount of $POCl_3$ [6]. Compounds **V** and **VI**

are gray powders soluble in aprotic solvents; mp 166 and 145°C, respectively.

The IR spectrum of dichloride **V** contains, along with other bands, characteristic bands of the imide ring at 1136–1210, 1380, 1720, 1780, and 3220 cm^{-1}.

The characteristics of **I**–**VI** are given in the table.

EXPERIMENTAL

5-Carboxysaccharin-*N*-acetic acid I. To a solution of 11.36 g of **VII** in 130 ml of DMAA, we added 7 g of powdered potassium carbonate, 4.75 g of chloroacetic acid, and 50 g of KI; the mixture was refluxed for 6 h. After the reaction was complete, the mixture was cooled to room temperature, and the precipitate was filtered off and washed with two portions of DMF. The filtrate was evaporated to dryness and vacuum-dried to constant weight.

Acid **II** was prepared similarly.

***N*-Carboxymethylsaccharin-5-carboxylic acid dimethyl ester III.** (a) To a solution of 10 ml of concentrated H_2SO_4 in 250 ml of methanol, we added 14.25 g of acid **I** and refluxed the resulting mixture to obtain a homogeneous solution. Then this solution was mixed with 500 ml of cold distilled water, and the yellowish precipitate was filtered off, washed with distilled water to neutral reaction, and dried first in air and then in a vacuum.

Ester **IV** was prepared similarly.

(b) To a solution of 12.1 g of ester **IX** in 50 ml of DMF, we added 3.5 g of K_2CO_3 at 70°C and then 5.45 g of methyl chloroacetate and 0.5 g of KI; the mixture was heated at 125–130°C for 2 h. Then the mixture was poured into 200 ml of distilled water, and the precipitate was filtered off, recrystallized, and dried first in air and then in a vacuum at 60–70°C.

Diester **IV** was prepared from ester **II** similarly.

***N*-Carboxymethylsaccharin-5-carboxylic acid dichloride V.** Phosphorus pentachloride (2.1 g) and acid **I** (2.85 g) were mixed at room temperature. In so doing, the mixture spontaneously warmed up to 40–45°C. After the exothermic reaction was complete, the mixture was heated to 95–100°C and stirred at this temperature for 2 h. After the reaction was complete, the phosphorus oxychloride formed was distilled off in a water-jet-pump vacuum. The remaining oily product was successively washed with anhydrous chloroform and benzene and then recrystallized from anhydrous toluene.

Dichloride **VI** was prepared similarly.

CONCLUSION

Previously unknown *N*-carboxymethylsaccharin-5- and -saccharin-6-carboxylic acids, their methyl esters, and dichlorides, which are promising monomers for heat-resistant polyimides, were prepared in high yields (70–85%).

========== **INFORMATION** ==========

The XI International Conference on Polymeric Materials: Properties, Processing, Modification, and Applications

The XI conference on polymeric materials was held on September 29 to October 1, 2004, at the Martin Luther University in Halle/Saale, Germany. The Conference Chair was H. Michler. The Conference Committee included such well-known German scientists as Jörg Kressler, Hans-Joachim Radusch, Rainer Schnabel, and others.

Amohg the conference participants were more than 450 scientists from 80 research centers of 33 countries including Algeria, Australia, Austria, Belgium, Brazil, Bulgaria, Canada, China, Croatia, Czech Republic, France, Germany, Greece, Hungary, India, Israel, Italy, Japan, the Netherlands, Poland, Portugal, Romania, Russia, Slovakia, Slovenia, Spain, Sri Lanka, Sweden, Switzerland, the United Kingdom, the United States, and Uzbekistan.

Primary attention was given at the conference to the following problems: structure and morphology; characterization and testing of polymers; modification of polymers; polymer processing; properties of polymers and applications; deformation and fracture processes; new polymeric materials, blends, and nanocomposites; biomedical materials; "green" (ecologically clean) polymers; and sustainable development of polymers and recycling.

The Conference Program included four plenary lectures. Then the Conference was held in the form of a series of minisymposia on five dedicated topics and two poster sessions.

The first plenary lecture [E.J. Balta-Calleja (Spain)] was devoted to micromechanical properties of polymers and polymer blends (nanostructure and morphology). P. Eyrer, R. Emmerich, and M. Kaiser (Germany) reviewed in their lecture processes used for manufacturing polymers with improved characteristics. V. Altstadt and J. Sandler (Germany) considered problems of synthesis and processing of nanocomposites. The main concern of the fourth lecture [K. Friedrich, F. Haupert, and Z. Zhang (Germany)] was the structure and properties of polymers reinforced with spherical nanoparticles.

Section A (Structure and Morphology. Polymer Characterization and Testing) included 30 presentations.

Section B (Modification of Polymers. Polymer Processing) included six presentations covering such topics as organic and inorganic fireproof polymeric materials; cryogenic mechanical milling of thermoplastic polymers and their blends; processing of PVA blends; properties of rubbers, fibers, and films; and use of plasma for modification of the surface of polymeric articles.

Section C (Properties of Polymers and Application. Deformation and Fracture Processes) included 34 presentations.

Section D [New Polymeric Materials, Blends and Nanocomposites, Biomedical Materials] also included 34 presentations.

Section E (Green Polymers. Sustainable Development of Polymers and Recycling) included 14 contributions devoted to synthesis and characterization of new green polymers based on natural products and, in particular, chitin and chitosan, cellulose, sugars, polysaccharides, lignin, starch, and also to the possibility of development of polymer hybrids.

The first poster session included about 80 presentations devoted to the structure, morphology, and properties of polymers.

The second poster session also included about 80 presentations on modification of polymers; polymer processing; new polymeric materials, blends, composites and nanocomposites; biomedical materials; and green polymers.

The conference was accompanied by an exhibition of new scientific instruments for study of properties and structure of polymers.

The conference revealed the steadily growing interest in polymers and polymeric materials. Presently, the world output of polymers (by volume, not by weight) is equal to that of steel, cast iron, rolled metal, and nonferrous metals combined.

Rapid growth of the polymer industry settles many problems, posing, in turn, new problems, which are being gradually solved.

The next XII conference is planned to be held at the Martin Luther University in 2006.

INFORMATION

Symposium "Topical Problems of Chemistry and Physics of Functionalized and Mesophase Polymers"

Symposium "Topical Problems of Chemistry and Physics of Functionalized and Mesophase Polymers" was held on November 3, 2004. The symposium was organized by the Topchiev Institute of Petrochemical Synthesis (TIPS), Russian Academy of Sciences, and the Scientific Council for Macromolecular Compounds, Chemistry Division, Russian Academy of Sciences. The sponsors were the Corium International Co. (the United States) and TNO (Institute for Innovations in Power Engineering) (the Netherlands).

Amond the Symposium participants were about 150 scientists from 38 research centers of France, Germany, Italy, Kazakhstan, the Netherlands, Russia, Tajikistan, the United States, and Uzbekistan. In fact, the Symposium was dedicated to fifty-year research activities and seventieth birthday of Academician N.A. Plate, Vice President of the Russian Academy of Sciences, Director of the Topchiev Institute of Petrochemical Synthesis. The symposium included 17 presentations.

Known Russian scientists: N.A. Plate, V.A. Kabanov, I.A. Oreshkin, V.G. Kulichikhin, A.D. Litmanovich, L.I. Valuev, V.V. Volkov, G.F. Tereshchenko, and S.N. Khadzhiev, took part in the Opening Ceremony. A total of four sessions were held.

In the first session, four reports were presented. H. Finkelman (Germany) reviewed the history of research from mesophase polymers to mesophase elastomers. A group of authors [R.V. Tal'roze, V.N. Vasilets, and G.A. Shandryuk (Russia)] reported on development of novel mesophase polymeric brushes. The lecture given by E.M. Antipov (Russia) was devoted to preparation and characterization of superelastic fibers and nanocomposites based on biodegradable and biocompatible polyhydroxyalkanoates. V.P Shibaev (Russia) considered in his lecture new prospects for development, testing, and application of mesophase polymers.

The second session included five presentations. K. Matyjaszewski (the United States) reported on "well-organized" hybrid polymers as promising materials for the future. The lecture given by A. Jansen (the Netherlands) was devoted to use of membrane processes in oil and gas industry. The molecular design of functionalized polymeric membranes was discussed in the lecture presented by E. Drioli (Italy). A group of Russian researchers (V.V. Volkov, A.G. Fadeev, and G.N. Bondarenko) described the structure, molecular flexibility, and membrane properties of comb-shaped polymers containing perfluoro groups. D. Khalikov (Tajikistan) considered the physicochemical aspects of catalyzed degradation of a natural network polymer, plant-cell protopectin.

Four lectures were delivered in the third session. G. Cleary (the United States) described properties of ternary mixtures of hydrophilic polymers demonstrating adhesion to biological surfaces. The lecture given by L.I. Valuev (Russia) was devoted to synthesis and characterization of polymers having a lower critical temperature of mixing, which can be used as carriers for bioactive agents. D. Duchene (France) presented the results obtained with polymers adapted to targeted drug transportation. Z. Nurkeeva (Kazakhstan) considered new stimulus-sensitive vinyl ether polymers and their complexes.

The last fourth session included four presentations. The lecture given by Ya.V. Kudryavtsev and A.D. Litmanovich (Russia) was devoted to the theory of interchain exchange in polymer blends. V.G. Kulichikhin (Russia) described nanocomposite-based hydrocolloid systems for medical purposes. J. Kirsch (Germany) reported on recent RAS/Bayer collaboration programs. He outlined that the collaboration was enabled by N.A. Plate's activities. In the concluding remarks, N.A. Plate told about his research activities, particularly, in the field of polymer chemistry and physics.

Finally, the symposium revealed that problems of chemistry and physics of functionalized and mesophase polymers are being successfully solved. Russian scientists, primarily Academician Plate's scientific school, contribute significantly to their solution.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Behavior of the Al_2O_3–ZrO_2 System at High Temperatures

D. N. Kamaev, S. A. Archugov, and G. G. Mikhailov

South-Ural State University, Chelyabinsk, Russia

Received September 17, 2004

Abstract—The system Al_2O_3–ZrO_2 at temperatures of up to 2100°C was studied by differential thermal analysis.

The oxide system Al_2O_3–ZrO_2 is of great practical interest. Data on its phase diagram are significant for the production of abrasive and structural materials operating at high temperatures. These materials are produced either by fusion of the components with their subsequent crystallization or by sintering of finely dispersed powders. The phase diagram furnishes information on the material crystallization, and the use of appropriate cooling mode makes it possible to control the product quality. However, the high liquidus temperature in the Al_2O_3–ZrO_2 system significantly complicates studying this system and obtaining reliable results. Therefore, data on this system are far from being exhaustive.

Most authors [1–7] believe that the system components form a simple eutectic and state that any intermediates are absent from the system. However, there is no agreement in the literature regarding the eutectic composition, its temperature, and shape of liquidus lines. In particular, according to the above-mentioned data, the temperature of the eutectic transition varies from 1710 to 1920°C, and the eutectic composition, from 30 to 55 wt % ZrO_2.

According to [5], the eutectic transition takes place at 1890°C, and the eutectic contains about 40 wt % ZrO_2. The eutectic composition was confirmed in [8] by the method of three-crucible thermal analysis, which makes it possible to obtain high-precision data [8–10]; however, the eutectic temperature was found to be 1866 ± 7°C. In addition, according to [8], the liquidus line has a complicated shape, suggesting the tendency of the system to phase separation at temperatures slightly exceeding those of the liquidus line.

Taking into account the importance of the phase diagram of the Al_2O_3–ZrO_2 system for the production of refractories and abrasives and also the ambiguous character of the previously obtained data, we have reexamined the phase diagram of this system.

EXPERIMENTAL

The experiment was carried out on a computer-controlled upgraded installation for high-temperature three-crucible differential thermal analysis, with data processing on a PC [12].

Analytically pure grade aluminum oxide (Al_2O_3) and zirconium nitrate $Zr(NO_3)_4 \cdot 5H_2O$ were used as starting reagents. According to thermographic analysis, zirconium nitrate loses water of crystallization at low temperatures and decomposes to the oxide at high temperatures. Therefore, it was annealed in air for 3 h at 1200°C. Before weighing, the starting oxides were additionally annealed for several hours to remove moisture and adsorbed impurities. Then they were immediately placed in weighing bottles, which were subsequently stored in a desiccator under dry air, which excluded the saturation of the oxides with water vapor and the corresponding weighing errors. The grade of accuracy of the balance in use warranted that the deviation of the obtained composition from the calculated composition did not exceed 0.01 wt %. Samples containing from 0 to 90 wt % ZrO_2 in 10 wt % steps were prepared. In the range from 40 to 60 wt % ZrO_2, the step was 2 wt %. After mixing, the samples were pressed in a special hard-alloy mold.

Despite the fact that ZrO_2 and Al_2O_3 practically do not react with atmospheric moisture and CO_2, the pressed samples were annealed once more at 1200°C under 1 atm of argon. To obtain data required for the subsequent calculations, the sample pellets were weighed before placing in a crucible of the thermographic installation.

The samples under study were homogenized by step-by-step annealing. In the first step, the sample was heated at a rate of 60 deg min^{-1} to 2100°C. In the second step, it was sharply cooled to 800–1000°C. In the third step, the sample was heated at a rate of

1070-4272/05/7803-0347 © 2005 Pleiades Publishing, Inc.

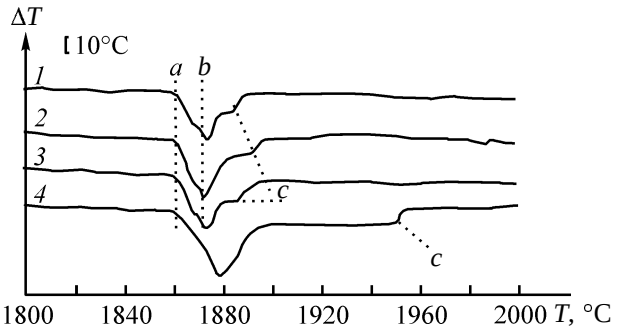

Fig. 1. Typical DTA curves recorded at a heating rate of 60 deg min^{-1}. (*T*) Temperature; the same for Fig. 2. Temperature measured: (*a*) solidus, (*b*) onset of phase separation, and (*c*) liquidus. ZrO_2 content in the sample (wt %): (*1*) 46, (*2*) 50, (*3*) 60, and (*4*) 30.

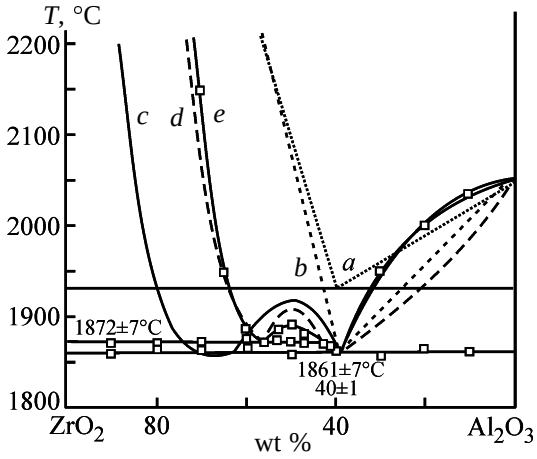

Fig. 2. Phase diagram of the Al_2O_3–ZrO_2 system. Experimental and calculated data: (*a*) model of perfect solutions, (*b*) model of regular solutions, (*c*, *d*) model of subregular ionic solutions, and (*e*) experimental points.

60 deg min^{-1} to a temperature higher by 100–200°C than the expected liquidus point. Finally, after keeping for 3–5 min at the maximal temperature, which provided complete homogenization of the sample, it was cooled at the same rate to the temperature 30–100°C lower than the eutectic point and kept at this temperature for 3–5 min. X-ray spectral microanalysis of the quenched alloys indicates that such a treatment is sufficient for the homogenization.

The resulting sample was subjected to thermal analysis. The sample was heated at a rate of 30 deg min^{-1} to 2100°C and then was cooled at the same rate to a temperature 30–100°C lower than the eutectic transition point. At this temperature, it was kept for 3–5 min. In the next step, the annealed sample was sharply cooled to room temperature. In the final step, the sample was heated at a rate of 20–60 deg min^{-1} to 2100°C and then cooled to room temperature.

Multistep heating and cooling allowed us to obtain highly reproducible results. To collect a statistically significant representative dataset, each sample after homogenization was subjected 7–13 times to the subsequent treatment steps. Thermocouple readings were corrected during an experiment by the Al_2O_3 melting point and further by the copper melting point [13].

The DTA curves of the samples heated at various rates (20–60 deg min^{-1}) demonstrate the effect of the heating rate and allow us to extrapolate the data obtained to the zero heating rate and finally to determine the equilibrium liquidus and eutectic lines in the phase diagram (Figs. 1, 2).

The shape of the experimental liquidus line suggests that either a chemical compound is formed in this system or it separates into layers.

To answer this question, we specially studied several samples containing 50 wt % ZrO_2. Each sample was heated to approximately 1900°C and kept at this temperature for 3 min. Then the temperature was decreased to 1890°C (according to the data obtained, this temperature corresponded to a point in the liquidus line) and the sample was kept at this temperature for 3 min. Then the temperature was further decreased by 10°C, and the sample was kept for about 10 min. If the sample actually separates into layers, such keeping at 1880°C must ensure efficient formation of separable liquids. Then the sample was sharply cooled by purging the furnace with cold argon. The further study has shown that such a sharp cooling conserved to room temperature the phase composition of the samples characteristic of 1880°C.

The quenched samples were studied by the X-ray diffraction analysis, which showed no formation of any chemical compounds in the sample containing 50 wt % ZrO_2.

The distribution of elements in the quenched sample with a total ZrO_2 content of 50 wt % was analyzed with a scanning electron microscope. Phase conglomerates with high and low Zr(IV) content and, correspondingly, with low and high Al(III) content were observed (Fig. 3). No primary crystals of either ZrO_2 or Al_2O_3 were found in this sample. Samples with a ZrO_2 concentration of 60 and 30 wt % kept at the same temperature (1880°C) were quenched for comparison.

Primary crystals of pure ZrO_2 and a phase with the composition corresponding to the melt in equilibrium with ZrO_2 were found in the quenched sample containing 60 wt % ZrO_2 (Fig. 4a). The distribution of elements in these phases was analyzed. In one phase

(quenched melt), the ratio of intensities of Al(III) and Zr(IV) characteristic radiation was invariable. In the other phase (primary ZrO_2 crystals), aluminum was not found at all, but the intensity of Zr(IV) radiation was much higher than in the phase of the quenched melt. The quenched sample containing 30 wt % ZrO_2 was also analyzed. In the quenched melt, the ratio of the intensities of Al(III) and Zr(IV) characteristic radiation was invariable. The other phase appeared to be primary corundum crystals without Zr(IV) (Figs. 4b).

The eutectic temperature was determined by well reproducible bases of the DTA peaks for all the experiments. It was estimated at 1861 ± 6°C. The eutectic composition was estimated at 40 wt % ZrO_2 by the interception point of the liquidus and solidus lines.

The detected invariant monotectic transition has the following parameters: temperature 1861 ± 6°C and melt compositions from 45 to 58 wt % ZrO_2.

Reliable experimental data obtained make it possible to calculate the phase diagram using various mathematical theories of oxide melts, such as theories of perfect, regular, and subregular ionic solutions.

The models of perfect and regular solutions [14, 15] failed to describe satisfactorily the liquidus line of the system (Fig. 2, *a*); therefore, we have attempted to calculate coordinates of the liquidus line within the framework of the theory of subregular ionic solutions [16]. According to this model, the chemical potential of a liquid solution in a binary system is

$$\mu_1 = \mu_1^0 + \nu_1[RT\ln x_1 + 3x_1^2x_2^2Q_{1112} + (2 - 3x_1)x_1x_2Q_{1122} + (1 - 3x_1)x_2^3Q_{1222}],$$

$$\mu_2 = \mu_2^0 + \nu_1[RT\ln x_2 + (1 - 3x_2)x_1^3Q_{1112} + (2 - 3x_2)x_1^2x_2Q_{1122} + 3x_1^2x_2^2Q_{1222}],$$

where R is the universal gas constant; ν_i, number of cations in an oxide molecule; μ_i^0, standard chemical potential; Q_{1112}, Q_{1122}, and Q_{1222}, energy parameters; and x_i, mole fraction, with index 1 referring to ZrO_2 and index 2, to Al_2O_3.

To construct liquidus lines, we choose the experimental reference points without taking into account separation into layers: 20, 40, and 60 wt % ZrO_2; then we wrote down the expressions for the equilibria in these points and solved the resulting system of equations. Using the parameters obtained, we calculated the liquidus line coordinates. The resulting liquidus line points to the separation of the system into layers

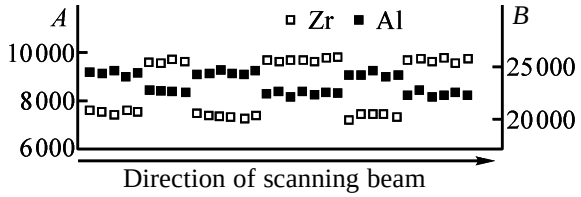

Fig. 3. Distribution of Zr(IV) and Al(III) in quenched samples containing 50 wt % ZrO_2. (*A*, *B*) Intensities of characteristic Zr(IV) and Al(III) radiation, respectively; the same for Fig. 4.

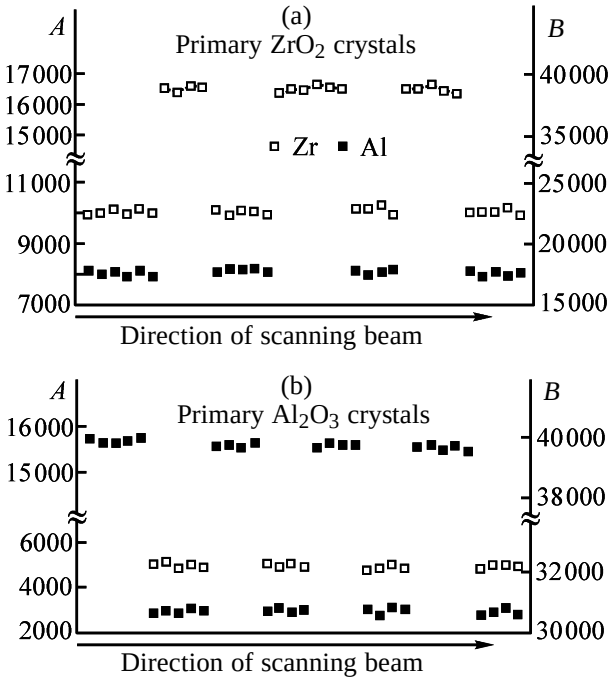

Fig. 4. Distribution of Zr(IV) and Al(III) in quenched samples containing (a) 60 wt % ZrO_2 and (b) 30 wt % ZrO_2: equilibrium of primary ZrO_2 crystals with a melt.

(Fig. 2, *c*), but it agrees with the experimental data insufficiently. Then we carried out calculations taking into account the separation into layers found experimentally. The following points were chosen: 40 wt % ZrO_2, 1861°C; 43 wt % ZrO_2, 1872°C; 56 wt % ZrO_2, 1872°C; and 60 wt % ZrO_2. For these points, we composed equilibrium expressions and solved the system of the resulting equations. The following energy parameters were found: Q_{1112} = 9897, Q_{1122} = 71 280, and Q_{1222} = 20 490 J mol^{-1}.

The liquidus line calculated with the parameters found is shown in Fig. 2, *d*. It differs to some extent from the experimental liquidus line, which may be due to the averaging of the calculated interaction parameters for a relatively wide temperature range.

Thus, the experimental study of the system Al_2O_3–

ZrO_2 and the application of the theory of subregular ionic solutions to this system suggest that the possibility of phase separation in the melt.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Formation of Ferrite–Chromites $BaFe_{10}Cr_2O_{19}$ and $SrFe_{10}Cr_2O_{19}$ in the Solid-Phase Reaction of Fe_2O_3 and Cr_2O_3 with Barium or Strontium Carbonate

Received April 9, 2004; in final form, October 2004

Abstract—X-ray phase analysis and the thermomagnetic method were applied to study solid-phase reactions in mixtures of powders $5Fe_2O_3 + Cr_2O_3 + BaCO_3$ and $5Fe_2O_3 + Cr_2O_3 + SrCO_3$, yielding, respectively, barium and strontium ferrite–chromite solid solutions $BaFe_{10}Cr_2O_{19}$ and $SrFe_{10}Cr_2O_{19}$.

Substitution of Fe^{3+} ions in the crystal lattice of high-coercivity barium and strontium ferrites $BaFe_{12}O_{19}$ and $SrFe_{12}O_{19}$ with a structure of magnetoplumbite by Al^{3+}, Cr^{3+}, Ga^{3+}, Sc^{3+}, and In^{3+} ions significantly alters their magnetic properties, which is used in developing a magnetic material with a prescribed set of magnetic parameters [1].

Bertaut *et al.* [2, 3] found that substitution of Fe^{3+} ions in the ferrites $BaFe_{12}O_{19}$ and $SrFe_{12}O_{19}$ by Cr^{3+} ions yields a continuous series of $BaFe_{12-x}Cr_xO_{19}$ and $SrFe_{12-x}Cr_xO_{19}$ solid solutions. With an increase in the chromium(III) content in these solid solutions, their lattice constants become smaller, and the saturation magnetization and Curie point, lower.

The solid solutions $Ba(Sr)Fe_{12-x}M_xO_{19}$ (M^{3+} = Al^{3+}, Cr^{3+}, Ga^{3+}, In^{3+}, or Sc^{3+}) are commonly obtained using the ceramic method, i.e., they are synthesized by sintering at 1173–1573 K a mixture of powdered oxides Fe_2O_3, M_2O_3 and carbonates $BaCO_3$, $SrCO_3$. The kinetics and mechanism of formation of the ferrites $BaFe_{12}O_{19}$, $SrFe_{12}O_{19}$ have been studied in sufficient detail [4, 5]. They are synthesized by the reaction of iron oxide Fe_2O_3 with a carbonate, $BaCO_3$ or $SrCO_3$, via a step of formation of an intermediate compound, $BaFe_2O_4$ or $SrFeO_{3-x}$, respectively. The kinetics and mechanism of formation of solid solutions based on the ferrites $BaFe_{12}O_{19}$ and $SrFe_{12}O_{19}$ are virtually unknown. It was only found in [6] that ferrite–aluminate solid solutions $BaFe_{1.5}Al_{2.5}O_{19}$ and $SrFe_{1.5}Al_{2.5}O_{19}$ are synthesized via a number of steps and the intermediate phases, $BaFe_{12-x}Al_xO_{19}$ and $SrFe_{12-x}Al_xO_{19}$, formed in the process contain less aluminum(III) than the final product.

This study is concerned with solid-phase reactions of the oxides Fe_2O_3, Cr_2O_3 with the carbonates $BaCO_3$, $SrCO_3$ to give the ferrite–chromites $BaFe_{10} \cdot Cr_2O_{19}$, $SrFe_{10}Cr_2O_{19}$, which have been suggested, together with the ferrite–aluminates $BaFe_{9.5}Al_{2.5}O_{19}$, $SrFe_{9.5}Al_{2.5}O_{19}$, for use as additives to raise the energy product $(BH)_{max}$ of ceramic permanent magnets made of these ferrites.

EXPERIMENTAL

The formation of $BaFe_{10}Cr_2O_{19}$ and $SrFe_{10}Cr_2O_{19}$ was studied in isothermal heating for varied time of pellets compacted from mixtures of powdered iron oxide Fe_2O_3 of MM-2 brand, analytically pure grade chromium oxide Cr_2O_3, and pure grade carbonates of barium, $BaCO_3$, or strontium, $SrCO_3$, taken in a 5 : 1 : 1 molar ratio and thoroughly mixed in a vibration mill. The pellets prepared from the mixture $5Fe_2O_3 + Cr_2O_3 + BaCO_3$ were isothermally calcined in air at 1243, 1263, or 1293 K for a certain time and then rapidly cooled in air. The $5Fe_2O_3 + Cr_2O_3 + SrCO_3$ pellets were isothermally calcined at 1203, 1223, or 1253 K. The X-ray phase analysis of the initial mixtures and samples calcined at a certain temperature for a prescribed time was made on a DRON-3 diffractometer (CuK_α radiation) at the same operation modes of the apparatus. This allowed the changes in the quantitative content of phases in the course of the solid-phase reaction to be monitored by the height (intensity) of X-ray reflections.

The Curie point T_C of the ferromagnetic phase formed in the solid-phase reaction was found from the temperature dependence of the specific saturation

magnetization σ measured by the Faraday method in a magnetic field of 5 kOe. The run of the $\sigma = f(T)$ dependence and the Curie points, combined with published data on the dependence of T_C on the content of chromium(III) in ferrite–chromites, were used to assess the compositional homogeneity of the ferromagnetic phases formed. X-ray diffraction patterns of a mixture of powders $5Fe_2O_3$ + Cr_2O_3 + $BaCO_3$, calcined at 1293 K for varied time, are shown in Fig. 1. Comparison of the X-ray diffraction patterns of the initial mixture (pattern no. 2) and the mixture calcined for 3 min (pattern no. 3) shows that thermal treatment of this kind leads to formation of the magnetoplumbite phase and intermediates $BaFe_2O_4$, $BaCr_2O_4$. It should be noted here that the reflections associated with $BaCO_3$ are virtually absent in the X-ray diffraction pattern of a mixture calcined for 5 min, and the intensities of Cr_2O_3 lines are substantially lower. Longer calcination leads to an increase in the intensity of peaks of the magnetoplumbite phase $BaFe_{12-x}\cdot Cr_xO_{19}$ and to a decrease in the intensities of the peaks associated with Fe_2O_3 and Cr_2O_3.

The temperature dependence of the specific saturation magnetization shows that the intermediate product formed in calcination of the $5Fe_2O_3$ + Cr_2O_3 + $BaCO_3$ mixture is not magnetically homogeneous and contains phases with different Curie points. For example, a ferromagnetic phase with a lower temperature $T_C \approx 600$ K (Fig. 2, curve *1*) is present, in addition to an almost pure ferrite $BaFe_{12}O_{19}$ ($T_C = 750$ K), after the reaction for 5 min. This indicates that the minor amount of the hexagonal ferromagnetic phase formed contains Cr^{3+} ions, and it is their presence that depresses the Curie point of barium ferrite.

The Curie point of the solid solution $BaFe_{10}Cr_2\cdot O_{19}$, obtained at a calcination temperature of 1573 K, is 660 K (Fig. 2, curve *3*). The temperature dependence of the specific saturation magnetization of a mixture calcined at 1293 K for 240 min (Fig. 2, curve *2*) reveals formation of phases with Curie points of 750, ~680, and ~600 K, i.e., nearly pure barium ferrite and $BaFe_{12-x}Cr_xO_{19}$ solid solutions close in composition to $BaFe_{10}Cr_2O_{19}$ ($x \approx 2$, $T_C \approx 680$ K) and of those with an increased content of chromium(III) ($x > 2$, $T_C \approx 600$ K). The phase with a Curie point $T_C \approx 600$ K, which is 60 K lower than the Curie point of the final product $BaFe_{10}Cr_2O_{19}$, is probably formed through diffusion of iron(III) ions into barium chromite $BaCr_{12}O_{19}$ already formed in a minor amount. Diffusion of Cr^{3+} ions from the oxide Cr_2O_3 into $BaFe_{12}O_{19}$ leads to formation of a $BaFe_{12-x}\cdot Cr_xO_{19}$ solid solution ($x \approx 2$, $T_C \approx 680$ K), which is also formed by the reaction

$$BaCr_2O_4 + 5Fe_2O_3 = BaFe_{10}Cr_2O_{19}.$$

The kinetics of formation of the $BaFe_{10}Cr_2O_{19}$

solid solution in the reaction of $BaCr_2O_4$ and Fe_2O_3 powders taken in a 1 : 5 molar ratio was studied in [7]. It is not improbable that mutual dissolution of $BaFe_2O_4$ and $BaCr_2O_4$ to give the $BaFe_{2-x}Cr_xO_4$ solid solution occurs in addition to the above-mentioned solid-phase reactions. We confirmed this possibility in a study of the kinetics of mutual dissolution of $BaFe_2O_4$ and $BaCr_2O_4$ upon heating of a mixture of powders taken in a 1 : 1 molar ratio.

The lattice constants *a* and *c* of the crystalline hexagonal phase were calculated from the reflections (220) and (205). According to published data [8], the lattice constants *a* and *c* of barium ferrite $BaFe_{12}O_{19}$ are 5.887 and 23.192 Å, respectively. Close to these values are the lattice constants *a* and *c* of the hexagonal phase formed at 1293 K during the first 5 min of calcination, 5.891 and 23.222 Å, suggesting predominant formation of a phase of an almost pure barium ferrite $BaFe_{12}O_{19}$ [9]. This is in agreement with the temperature dependence of the specific saturation magnetization.

As the reaction time becomes longer, the lattice constants *a* and *c* of the hexagonal phase decrease to 5.882 and 23.066 Å, respectively. Raising the content of chromium(III) in the $BaFe_{12-x}Cr_xO_{19}$ solid solution leads to a linear decrease in the lattice constant [2]. Consequently, the decrease in the lattice constants *a* and *c*, observed with increasing calcination time, points to a gradual increase in the content of chromium(III) ions in the phase of the $BaFe_{12-x}Cr_xO_{19}$ solid solution through their diffusion from the crystal lattice of Cr_2O_3 or barium chromites $BaCr_2O_4$ and $BaCr_{12}O_{19}$ formed into the crystal lattice of $BaFe_{12}O_{19}$.

Substitution of Fe^{3+} ions in the crystal lattice of barium ferrite $BaFe_{12}O_{19}$ with Cr^{3+} ions leads to significant changes in the exchange interactions responsible for the ordering of the spin magnetic moments of Fe^{3+} ions. This allows the compositional inhomogeneity of $BaFe_{12-x}Cr_xO_{19}$ solid solutions to be revealed from the temperature dependence of the specific saturation magnetization.

Figure 3 shows X-ray diffraction patterns of a $5Fe_2O_3 + Cr_2O_3 + SrCO_3$ mixture calcined at 1253 K for varied time and of the same mixture in the initial state. Calcination at 1253 K for 5 min results in that the intensities of lines associated with α-Cr_2O_3 strongly decrease and lines of strontium chromate $SrCrO_4$ appear. The reflections at 2θ 30.10°, 30.90°, and 34.65°, present in the X-ray diffraction patterns of the mixtures calcined at 1253 K for 5 to 90 min, and

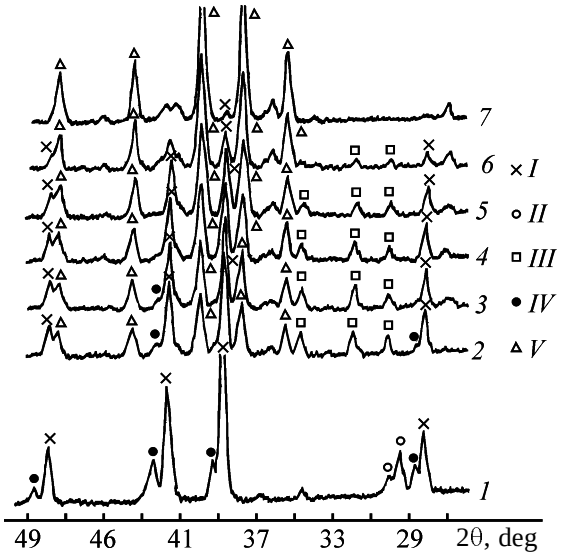

Fig. 3. X-ray diffraction patterns of the $5Fe_2O_3 + Cr_2O_3 + SrCO_3$ mixture calcined at 1253 K for (*1*) 0, (*2*) 5, (*3*) 10, (*4*) 15, (*5*) 60, (*6*) 90, and (*7*) 480 min. X-ray diffraction peak: (*I*) α-Fe_2O_3, (*II*) $SrCO_3$, (*III*) $SrCrO_4$, (*IV*) Cr_2O_3, and (*V*) $SrCr_xFe_{12-x}O_{19}$.

the interplanar spacings calculated from these reflections are in good agreement with published data for $SrCrO_4$ [10], rather than for $SrCrO_{3-x}$ [11]. The X-ray diffraction pattern of a $SrCO_3 + 0.5Cr_2O_3$ mixture calcined in air at 1423 K for 2 h is also in good agreement with published data for $SrCrO_4$, but not for $SrCrO_{3-x}$. The strongest X-ray diffraction line of the intermediate phase $SrFeO_{3-x}$ (2θ = 38.10°, *d* = 2.74 Å) was present only in the diffraction pattern of the $5Fe_2O_3 + Cr_2O_3 + SrCO_3$ mixture calcined at 1173 K for 30 min. In other X-ray diffraction patterns of the same mixture calcined at higher temperatures, this line of the $SrFeO_{3-x}$ phase was absent, suggesting a high reactivity of this intermediate phase.

It should be noted that the strongest lines of $SrCO_3$, present in the X-ray diffraction pattern of the initial mixture, are not observed in the pattern of the mixture calcined at 1253 K for 5 min. Longer heating of the mixture leads to a decrease in the intensity (height) of the X-ray diffraction lines of α-Fe_2O_3 and of the intermediate compound $SrCrO_4$, and to an increase in the intensity of the lines of the hexagonal phase $SrFe_{12-x}Cr_xO_{19}$ (Fig. 4). No shift of the diffraction peaks of α-Fe_2O_3 is observed in this case, which indicates that $Fe_{2-x}Cr_xO_3$ solid solutions are not formed.

The initial $5Fe_2O_3 + Cr_2O_3 + SrCO_3$ mixture is not ferromagnetic, but its calcination at 1253 K for 5 min leads to formation of a ferromagnetic phase and

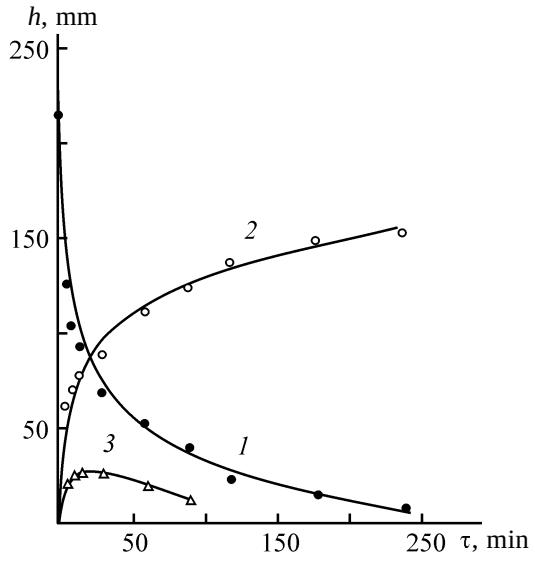

Fig. 4. Height h of X-ray diffraction peaks of (*1*) α-Fe_2O_3, (*2*) $SrFe_{12-x}Cr_xO_{19}$, and (*3*) $SrCrO_4$ vs. the calcination time τ of a $5Fe_2O_3 + Cr_2O_3 + SrCO_3$ mixture at 1253 K.

the specific saturation magnetization of the mixture becomes equal to 17.8 G cm^3 g^{-1}. The calcination for 60 min leads to only a minor increase in the saturation magnetization to 19.2 G cm^3 g^{-1} (Fig. 5, curve *1*). Longer calcination of this mixture at 1223 and 1203 K results in that the specific saturation magnetization first increases, then somewhat decreases, and after that starts to increase again. Such a complicated behavior of the magnetization indicates that the ferromagnetic phase formed in different stages of the process is inhomogeneous as regards the content of chromium(III).

Calculation of the lattice constants a and c of the hexagonal phase $SrFe_{12-x}Cr_xO_{19}$ formed in calcination of the $5Fe_2O_3 + Cr_2O_3 + SrCO_3$ mixture at 1253 K for varied time demonstrated that raising the calcination time to 480 min has virtually no effect on the lattice constant a (5.868–5.872 Å) and leads to a gradual decrease in the lattice constant c from 23.081 to 22.922 Å. The latter trend indicates that, in the course of synthesis, the forming solid solution $SrFe_{12-x}Cr_xO_{19}$ is gradually enriched with chromium(III) to its content in the final product $SrFe_{10}Cr_2O_{19}$.

The magnetic phase formed in $5Fe_2O_3 + Cr_2O_3 + SrCO_3$ mixtures in the initial stage of the reaction has a Curie point of 765 K (Fig. 6, curve *1*), which is close to the Curie point of strontium ferrite $SrFe_{12}O_{19}$ (T_C = 750 K) [4]. Mixtures calcined for a long time contain, in addition to this magnetic phase, a phase with a Curie point of about 680 K (Fig. 6, curve *2*), which is a $SrFe_{12-x}Cr_xO_{19}$ solid solution with a composition close to $SrFe_{11}CrO_{19}$. The Curie point of the final product $Fe_{10}Cr_2O_{19}$ is 600 K (Fig. 6, curve *3*). The results obtained demonstrate that, at the beginning of the solid-phase reaction, $SrCO_3$ is completely consumed for formation of the chromate $SrCrO_4$ and ferrite $SrFeO_{3-x}$, whose reaction with Fe_2O_3 gives the ferrite $SrFe_{12}O_{19}$. Strontium chromate $SrCrO_4$ reacts with Fe_2O_3 to give the solid solution $SrFe_{11}CrO_{19}$ by the reaction

$$SrCrO_4 + 5.5Fe_2O_3 \rightarrow SrFe_{11}CrO_{19} + 0.75O_2.$$

The final product $SrFe_{10}Cr_2O_{19}$ is mainly formed through diffusion of Cr^{3+} ions from Cr_2O_3 or $SrCrO_4$ into $SrFe_{12}O_{19}$ formed in the reaction of $SrCO_3$ and

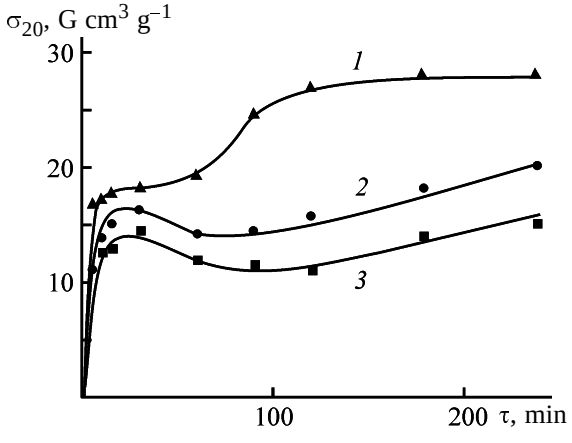

Fig. 5. Room-temperature specific saturation magnetization σ_{20} vs. calcination time τ of a $5Fe_2O_3 + Cr_2O_3 + SrCO_3$ mixture. Calcination time (K): (*1*) 1253, (*2*) 1223, and (*3*) 1203.

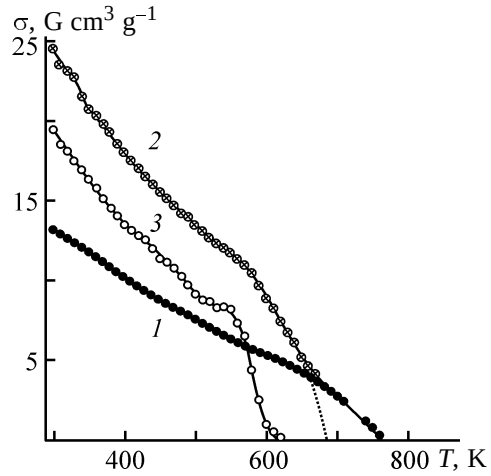

Fig. 6. Specific saturation magnetization σ of a $5Fe_2O_3 + Cr_2O_3 + SrCO_3$ mixture calcined at 1253 K for (*1*) 10 and (*2*) 480 min and (*3*) at 1523 K for 120 min vs. temperature T.

Fe_2O_3. This is the reason why the solid solution $SrFe_{12-x}Cr_xO_{19}$ formed in the course of the reaction is not compositionally homogeneous and has different magnetic characteristics.

CONCLUSIONS

(1) In the initial stage of heating of the mixture of powders $5Fe_2O_3 + Cr_2O_3 + BaCO_3$ at 1243–1293 K, intermediate nonmagnetic phases $BaFe_2O_4$ and $BaCr_2O_4$ and their solid solutions are formed together with a compositionally inhomogeneous ferromagnetic phase with a structure of magnetoplumbite, $BaFe_{12-x}Cr_xO_{19}$. Together with regions having a Curie point of 750 K, i.e., almost pure barium ferrite, there are minor regions with Curie points of 600 and 680 K, which contain, respectively, somewhat higher and somewhat lower amounts of chromium(III), compared to $BaFe_{10}Cr_2O_{19}$. In the concluding stage, there occurs diffusion equalization of the contents of chromium(III) in regions of $BaFe_{12-x}Cr_xO_{19}$ solid solutions with different values of the parameter x to the homogeneous composition of the final product $BaFe_{10}Cr_2O_{19}$, whose Curie point is 660 K.

(2) A study of solid-phase reactions occurring upon heating of the mixture of powders $5Fe_2O_3 + Cr_2O_3 + SrCO_3$ demonstrated that the solid solution $SrFe_{10}Cr_2O_{19}$ is synthesized with formation of intermediate compounds $SrCrO_4$ and $SrFeO_{3-x}$, which further react with Fe_2O_3 and Cr_2O_3 to give, first, almost pure strontium ferrite $SrFe_{12}O_{19}$ and then $SrFe_{12-x}Cr_xO_{19}$ solid solutions with $x \leq 2$.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Obtaining Nickel Hydroxide from Half-Products of Hydrometallurgical Processing of Nickel–Iron Batteries

A. I. Demidov, O. A. Krasovitskaya, V. D. Andreeva, and E. S. Tolypin

St. Petersburg State Polytechnic University, St. Petersburg, Russia

Received January 19, 2005

Abstract—The possibility of obtaining nickel hydroxide from solutions produced in ammonia leaching of the active paste of positive electrodes of a nickel–iron battery was studied.

One of widely occurring kinds of secondary nickel-containing raw materials in Russia is constituted by spent positive electrodes of nickel–iron batteries, which are processed by pyrometallurgical or hydrometallurgical methods [1–3]. A possible scheme for processing of spent nickel–iron batteries includes treatment of the positive electrodes, based on the previously suggested [2] ammonia leaching to recover nickel without preliminary disassembly of lamellas. With the properly chosen processing conditions, the recovery of nickel into solution in this stage may be as high as 96–99%.

Nickel-containing process solutions can be used for further recovery of nickel and its compounds by various methods, e.g., by extraction with organic reagents, electrodeposition, hydrogen reduction, and crystallization in the form of neutral and double salts or nickel hydroxide [1].

In this study we examined the possibility of using ammonia leaching solutions to obtain pure nickel hydroxide, which is a valuable raw material for battery industry. Nickel(II) hydroxide was precipitated from ammonia leaching solutions containing sulfate ions [2] with a 4.85 M NaOH solution (density 1.18 g cm^{-1}). Preliminarily, a 100-ml portion of the solution was evaporated to a volume of approximately 25 ml, with a precipitate of a double complex salt of nickel formed at the end of evaporation. Then the volume was brought to 100 ml with water and the mixture was heated ($T \approx 70$°C), with the precipitate dissolving and the pH of the solution becoming 7. The resulting solution was placed in a buret, and the NaOH solution, in a microburet. The precipitation was performed under continuous agitation in a temperature-controlled ($T = 50$°C) 150-ml vessel. The alkali and ammonia solution were simultaneously introduced into the reaction volume (dropwise and as a flow, respectively), with their volume ratio maintained at 1 : (1–10) and the interval between addition of reagent portions (total volume of a portion 5–10 ml) equal to 10 min. After the last addition of alkali (pH 12), the reaction solution with a precipitate was kept with agitation for 90 min. The precipitate was allowed to settle for 120 min and filtered on a vacuum filter. Then the precipitate was washed with cold distilled water (~800 ml) and dried at 80°C for 120 min.

The precipitates obtained had light emerald to light green color, depending on the volume ratio of the reagent solutions added and on the uniformity of their introduction into the reaction volume. It was established that the optimal, as regards the filterability and homogeneity of the precipitates, ratio of the alkali and the ammonia solution is 1 : 5, with the best results obtained when this ratio is strictly maintained throughout the precipitation time. At the very beginning of the process, immediately after the addition of the first portions of the reagents, a finely dispersed well-agitated precipitate is formed in the reaction vessel. This precipitate can later be well filtered off; it has a light green color upon drying. If the volume ratio was shifted toward an excess (with respect to the optimal value) of an alkali, the precipitate became too dense and gave coarse clotted aggregates. At an excess of the ammonia solution, the precipitate dissolved and the solution acquired an emerald color and was poorly filterable; a dried precipitate had the form of shining crystalline scales of light emerald color. These specific features were the most pronounced in the initially made attempts to perform precipitation, when the ammonia solution was poured to an alkali solution or, in the opposite way, an alkali solution was poured to the ammonia solution. As already noted,

1070-4272/05/7803-0356 © 2005 Pleiades Publishing, Inc.

the optimal method is that of simultaneous mixing of the reagents in a prescribed volume ratio.

The X-ray diffraction pattern of the precipitate obtained from an ammonia–sulfate solution under the optimal conditions is shown in Fig. 1a. The peak positions are characteristic of nickel(II) hydroxide, which has a layered hexagonal crystal lattice of the CdI_2 type. It should be noted that the positions of the diffraction peaks and their relative intensities are in precise agreement with the tabulated data for pure nickel hydroxide, in contrast to those of the starting active paste (Figs. 1b, 1c), which also contain peaks corresponding to impurity phases. This fact confirms the efficiency of iron separation in the stage of nickel recovery by leaching from the spent active paste containing, on the average, 0.3–0.7 wt % Fe at 40–44 wt % Ni [2].

To assess the prospects for their possible utilization, the precipitates obtained from sulfate–ammonia leaching solutions were subjected to a comprehensive study.[1] The chemical analysis of the precipitates demonstrated that they contain (% relative to the initial mass): Ni 59–62, SO_4^{2-} 0.1–0.3, N <0.01, and Na <0.01. These data indicate that the precipitates contain only small amounts of water of crystallization and of main impurities. Figure 2 shows the results of an X-ray fluorescence microanalysis of the nickel hyroxide obtained. It can be seen that both the base elements (Ni and O) and trace impurities (Al, Si, S) are uniformly distributed over the precipitate particles. This indicates that the coagulation of particles in their nucleation and subsequent growth is uniform if the conditions specified above are satisfied. As the concentration of main impurities in the resulting nickel(II) hydroxide is low, it can be further used to obtain nickel salts.

An analysis of the size distribution of $Ni(OH)_2$ particles (Fig. 3a) demonstrated that particles of size 5–20 μm predominate in precipitates obtained under the optimal conditions. Precipitates of this kind have a specific surface area of about 1.6×10^3 $cm^2\ cm^{-3}$ and average pycnometric density of about 3.94 $g\ cm^{-3}$ (measured in a KOH solution of density 1.26 $g\ cm^{-3}$). Figure 3b shows an SEM pattern of nickel hydroxide particles. It follows from this figure that the precipitate is a dispersed system, with its separate particles having no pronounced crystal faceting and their shape being nearly spherical. These properties of the precipitates are of interest as regards their possible application as an electrode material for nickel–metal–hydride batteries in which spherical nickel hydroxide is widely used.

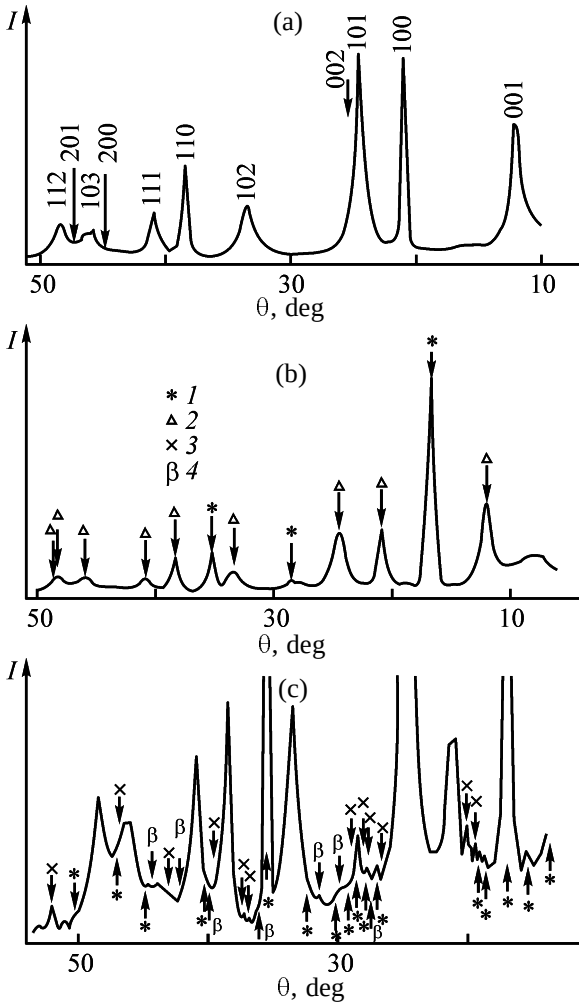

Fig. 1. X-ray diffraction patterns of (a) $Ni(OH)_2$ precipitate obtained upon addition of NaOH to sulfate–ammonia leaching solutions and (b, c) starting active paste of positive electrodes of nickel–iron batteries. FeK_α radiation. (θ) Bragg angle. Phase: (*1*) graphite, (*2*) $Ni(OH)_2$, (*3*) FeOOH, and (*4*) β-FeOOH.

The electrochemical properties of the material obtained were studied on electrodes fabricated by applying the paste on the current-carrying foamed-nickel support, with the subsequent drying and additional compaction. The substrate thickness before the additional compaction was 2.0 mm. The table lists the results obtained in measuring the discharge capacity of electrodes of this kind after the third charging–discharge cycle in comparison with the similar parameters of the electrodes fabricated from $Ni(OH)_2$ manufactured by OMG (Finland).

The data presented demonstrate that the nickel hydroxide precipitates obtained in this study compare

well in their specific characteristics with the commercial material, being, however, looser, i.e., having a lower density, which leads to significant differences of the shape of the electrodes fabricated from these precipitates, compared to the presently existing samples. These facts suggest that, with the technology of $Ni(OH)_2$ precipitation from ammonia leaching solutions further optimized, it will be possible to improve the parameters of the precipitates obtained to values allowing their practical use.

CONCLUSIONS

(1) Pure nickel(II) hydroxide can be recovered from ammonia leaching solutions, which are half-products formed in hydrometallurgical processing of spent positive electrodes of nickel–iron batteries.

Electrochemical properties of electrodes based on OMG and $Ni(OH)_2$

Electrode material	Discharge capacity		Electrode thickness after additional compaction, mm	ρ_r,* g cm^{-1}
	A h g^{-1}	A h cm^{-3}		
OMG	0.22	0.55	~1.3	1.8
	0.24	0.57	~1.3	1.9
$Ni(OH)_2$	0.25	0.42	~0.47	0.7

* Density of rammed powder.

(2) Nickel(II) hydroxide obtained from ammonia leaching solutions containing sulfate ions can be used for subsequent production of pure nickel salts owing to the low content of the main impurities.

(3) Provided that the technology of its precipitation is further optimized, nickel(II) hydroxide obtained from ammonia–sulfate leaching solutions is of interest as a material for the active paste of electrodes of alkaline batteries.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Thermal Dissociation of Sodium Hydroxide upon Evacuation

V. P. Yurkinskii, E. G. Firsova, and S. A. Proskura

St. Petersburg State Polytechnic University, St. Petersburg, Russia

Received December 27, 2004

Abstract—Kinetics of dehydration of sodium hydroxide melt upon evacuation was studied in relation to the temperature. The kinetic parameters of thermal decomposition of NaOH were evaluated. Methods for dehydration of the hydroxide melt were suggested.

Sodium hydroxide melt and fusible mixtures based on it are widely used in production engineering. In particular, they are used as electrolytes in electrochemical purification of steel casts, electrolytic production of sodium, refining of lead and other heavy metals, and also in production of secondary lead [1–4].

As known [2–7], moisture significantly affects the physicochemical properties, electrochemical behavior, and corrosion activity of NaOH melt. However, there is no common opinion about the conditions of dehydration of sodium hydroxide and salt mixtures based on it [6, 7]. The main procedure for dehydration of NaOH melt is prolonged evacuation at 770–820 K for 2–8 h [6, 7].

In this study we examined the kinetics of dehydration of NaOH melt and thermal dissociation of sodium hydroxide upon evacuation at varied temperatures.

EXPERIMENTAL

Experiments were carried out in the temperature range 750–1023 K. Granular NaOH (chemically pure grade) was used. The experimental procedure was as follows. A 100-g sodium hydroxide sample was placed in a corundum beaker with a diameter of 40 and height of 100 mm. The beaker was placed in a quartz tube with a diameter of 50–60 and length of about 400 mm, which had been kept in a furnace at the required temperature. The quartz tube was hermetically sealed and connected to a vacuum system. The residual pressure in the system was 13.3 Pa. The moisture released from the NaOH melt was trapped in a U-shaped vessel which was packed with silica gel and cooled to 263±2 K. Silica gel of KSS no. 4 grade was dried before use at 373–393 K for 3 h. The rate of dehydration of the melt was evaluated by weighing the U-shaped vessel with the collected water at regular intervals of 0.5–2.0 h in the course of the experiment. To check the completeness of moisture recovery, the total mass of the water removed was determined by weighing the corundum beaker with sodium hydroxide before and after the experiment. The weights of water removed from the beaker and collected in the trap coincided within 5–7%.

The data on vacuum dehydration of NaOH melt at various temperatures are shown in Table 1 and Fig. 1.

As seen from Fig. 1, the mean rate v of vacuum dehydration of NaOH melt as a function of time τ at various temperatures is satisfactorily fitted by the empirical equation

$$v = A + B\exp(-\tau/C), \quad (1)$$

where A, B, and C are the temperature-dependent coefficients.

The coefficients A, B, and C were determined using Statgraphics package (Table 2). The correlation coefficient was 0.999.

Table 1. Mean rate v of dehydration of NaOH melt as a function of evacuation time τ and temperature

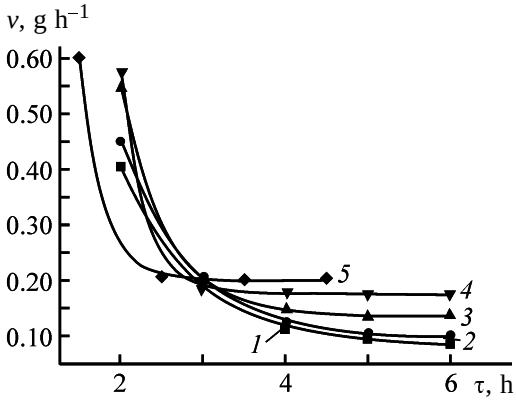

Fig. 1. Mean rate v of vacuum dehydration of NaOH melt as a function of time τ at (*1*) 750, (*2*) 773, (*3*) 823, (*4*) 873, and (*5*) 906 K.

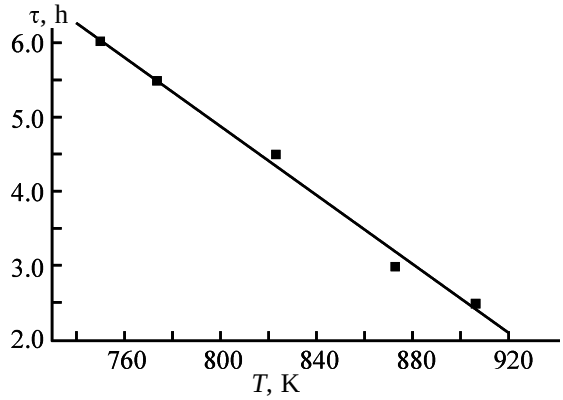

Fig. 2. Optimal time τ of vacuum dehydration of NaOH melt as a function of temperature T.

The v–τ dependences suggest that the vacuum dehydration of the hydroxide melt involves two conjugated processes: removal of crystallization or adsorbed water (2) and decomposition of hydroxide melt (3):

$$NaOH \cdot H_2O \rightarrow NaOH + H_2O, \quad (2)$$

$$2NaOH = Na_2O + H_2O. \quad (3)$$

As seen from Fig. 1, in the initial step of dehydration of NaOH melt processes (2) and (3) occur simultaneously. We believe that removal of crystallization and adsorbed water (2) is completed when the rate of water evaporation becomes constant. Further dehydration is associated solely with decomposition of the melt by reaction (3). From our results (Fig. 1), we determined the optimal time of vacuum dehydration of NaOH melt at various temperatures (Fig. 2).

Figure 2 shows that the dependence of time of NaOH melt dehydration τ (h) on temperature T (K) is linear:

$$\tau = (23.416 \pm 0.937) - (0.0232 \pm 0.0011)T, \quad (4)$$

with the correlation coefficient of 0.996 and variance of 0.149.

The degree of NaOH melt dehydration can be evaluated from its melting point [1–4]. According to published data [1, 2, 8], it is 593–596 K. The melting point of NaOH melt after the dehydration under the conditions found in this work was 594 ± 1 K, suggesting virtually complete dehydration of the melt.

The rate of NaOH decomposition v_{NaOH} within the temperature range studied was determined in accordance with the stoichiometry of reaction (3) from the rate of water removal (Table 1) in the time interval in which it was constant. The results are presented in Table 3.

It should be noted that, in our experiments, the thermal decomposition of NaOH (Table 3) at a given temperature was performed to low conversions (the weight loss of sodium hydroxide in the course of the experiment did not exceed 3.0%). Thus, the change in the composition of the NaOH melt could not affect

Table 2. Coefficients of Eq. (1)

T, K	A	B	C
750	0.083 ± 0.006	2.892 ± 0.477	0.9106 ± 0.0714
773	0.096 ± 0.004	3.793 ± 0.456	0.8448 ± 0.0044
823	0.137 ± 0.001	15.86 ± 0.47	0.5472 ± 0.0045
873	0.176 ± 0.004	308.0 ± 30.9	0.3007 ± 0.0046
906	0.201 ± 0.005	89.8 ± 11.2	0.2772 ± 0.064

Table 3. Mean rates of moisture removal v_{H_2O} and NaOH decomposition v_{NaOH} under evacuation at various temperatures

T, K	v_{H_2O}	v_{NaOH}
	g h−1	
750	0.091	0.404
773	0.104	0.462
823	0.138	0.613
873	0.178	0.791
893	0.200	0.889
906	0.205	0.911
926	0.225	1.00
971	0.260	1.155
1023	0.329	1.462

the rate of process (3) significantly.

In this case, the temperature dependence of the NaOH decomposition rate v_{NaOH} can be treated with the Arrhenius equation

$$\ln v_{NaOH} = A - B/T, \quad (5)$$

where A is a constant, $B = E/R$, E is the activation energy of reaction (3), and R is the universal gas constant (8.314 J mol^{-1} K).

From the mean rates of sodium hydroxide decomposition at various temperatures (Table 3), we determined the coefficients of Eq. (5): $A = 3.9211 \pm 0.0749$, $B = -3636.1 \pm 65.2$. The correlation coefficient was 0.998, and variance, 0.021. The calculated activation energy of thermal decomposition of molten sodium hydroxide, 30.23 kJ mol^{-1}, is indicative of the diffusion control of the process. Presumably, the limiting stage of NaOH thermal dissociation is diffusion of water molecules in a hydroxide melt or water evaporation from the melt surface.

CONCLUSIONS

(1) Dehydration of NaOH melt under evacuation involves simultaneous removal of adsorbed and crystallization water from NaOH and decomposition of NaOH.

(2) The optimal times for NaOH vacuum dehydration at various temperatures were suggested.

(3) The kinetic parameters of thermal decomposition of sodium hydroxide melt were determined. The process is diffusion-controlled. Its activation energy is 30.23 kJ mol^{-1}.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Double Hydrated Cobalt(II) Copper(II) and Nickel(II) Copper(II) Ammine Diphosphates

L. V. Voitenko, I. D. Zhilyak, and V. A. Kopilevich

National Agricultural University, Kiev, Ukraine

Received December 22, 2004

Abstract—Synthesis of amorphous and crystalline double hydrated cobalt copper and nickel copper ammine diphosphates with a coordination structure is described.

Information about synthesis of double hydrated ammine diphosphates of bivalent transition metals is lacking [1–4]. In this context, the aim of our study was to isolate phosphates of this kind, which presumably exhibit a biological or catalytic activity [5–8] or can be used as luminophores or components of these [3], from their ammonia solutions.

EXPERIMENTAL

Double hydrated nickel(II) copper(II) ammine diphosphates were obtained by salting-out from an ammonia solution with an organic solvent [9]. As starting reagents were used a mechanical mixture, in a prescribed molar ratio, of nickel and copper diphosphates synthesized by the procedures described in [10, 11], concentrated aqueous ammonia (23–25 wt %), and acetone. The mechanical mixture of nickel and copper diphosphates with a prescribed Ni : Cu molar ratio was dissolved in concentrated aqueous ammonia. The solution obtained was poured into acetone. As a result, a bottom phase, intensely blue oily liquid, was separated. The mother liquor was separated and the bottom phase was kept in air at 15–25°C to complete hardening and to constant weight. The synthesis conditions and the compositions of the compounds obtained are listed in Table 1.

Double hydrated cobalt(II) copper(II) ammine diphosphates were obtained using a method similar to that for the synthesis of cobalt ammine monophosphate [12]. As starting reagents were used cobalt diphosphate $Co_2P_2O_7 \cdot 6H_2O$ and copper diphosphate $Cu_2P_2O_7 \cdot 5H_2O$, synthesized by the procedure described in [11, 13]. For this purpose, a mechanical mixture of powdered $Co_2P_2O_7 \cdot 6H_2O$ and $Cu_2P_2O_7 \cdot 5H_2O$, taken in prescribed molar ratios, was saturated with gaseous ammonia under static conditions at 15–25°C for 24–36 h, to complete dissolution of the substances. After being extracted from the ammonia atmosphere, the products were kept at 15–25°C in air to constant weight. The synthesis conditions and the compositions of the compounds obtained are listed in Table 2.

The content of Ni^{2+} and Co^{2+} was determined by EDTA titration [14] (with copper masked with thiosulfate); that of copper, iodometrically; P_2O_5, gravimetrically [15]; ammonia, by evaporation in a Seren'ev apparatus [16]; and the total content of water and ammonia, from the weight loss upon heating at 750°C for 2 h. The anionic composition of the synthesis products was analyzed by quantitative paper chromatography [1].

An X-ray diffraction analysis was performed on a DRON-UM1 diffractometer (CuK_α radiation). As a monochromator served a single crystal of graphite, inserted in the path of the diffracted beam. X-ray diffraction patterns were obtained by step scanning in the range 2θ 4°–80°. The scanning step was 0.05°, and the time of exposure at a point, 3–9 s. The experimental diffraction peaks were approximated with a pseudo-Voigt function, with the K_{α_1} component isolated. The IR spectra were recorded with a Specord 75-IR spectrophotometer. Samples for IR spectral measurements were prepared as KBr pellets with the substance content of 0.2–0.3 wt %.

An X-ray phase analysis demonstrated that, at a molar ratio of copper to nickel in the starting mixture exceeding 1.5 : 0.5, crystalline $Ni_{0.10}Cu_{1.90}P_2O_7 \cdot 3.0NH_3 \cdot 2.5H_2O$ and $Ni_{0.20}Cu_{1.80}P_2O_7 \cdot 3.0NH_3 \cdot 2.5H_2O$ are formed. These compounds are isostructural, but differ in the structure from hydrated copper ammine diphosphate, which is confirmed by their

X-ray diffraction patterns (Fig. 1). The reflections of these compounds are satisfactorily indexed in the rhombic crystal system with the unit cell parameters a = 8.455, b = 15.624, c = 18.327 Å, V = 2421.1 Å^3 for $Ni_{0.2}0Cu_{1.80}P_2O_7 \cdot 3.0NH_3 \cdot 2.5H_2O$ and a = 8.531, b = 15.720, c = 18.780 Å, V = 2518.3 Å^3 for $Ni_{0.10} \cdot Cu_{1.90}P_2O_7 \cdot 3.0NH_3 \cdot 2.5H_2O$.

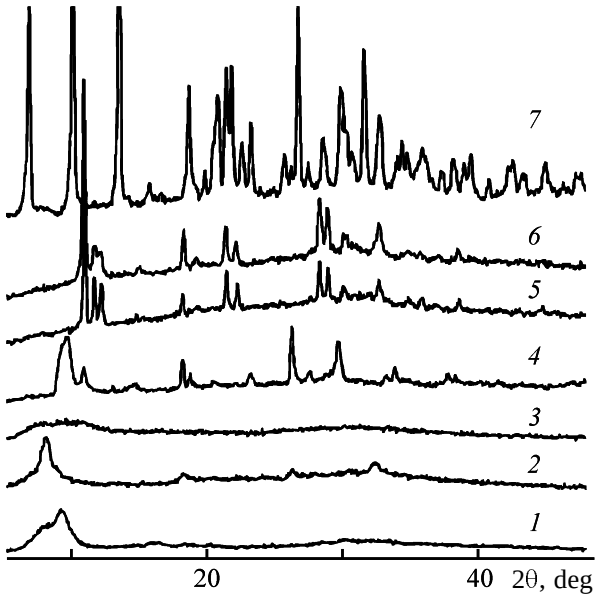

Fig. 1. X-ray diffraction patterns of (*1*) $Ni_2P_2O_7 \cdot 3.0NH_3 \cdot 6.0H_2O$, (*2*) $Ni_{1.40}Cu_{6.60}P_2O_7 \cdot 2.0NH_3 \cdot 5.0H_2O$, (*3*) $Ni_{1.0} \cdot Cu_{1.0}P_2O_7 \cdot 3.0NH_3 \cdot 4.0H_2O$, (*4*) $Ni_{0.45}Cu_{1.55}P_2O_7 \cdot 3.0NH_3 \cdot 5.0H_2O$, (*5*) $Ni_{0.20}Cu_{1.80}P_2O_7 \cdot 2.5H_2O$, (*6*) $Ni_{0.10} \cdot Cu_{1.90}P_2O_7 \cdot 2.5H_2O$, and (*7*) $Cu_2P_2O_7 \cdot 3.0NH_3 \cdot H_2O$. (2θ) Bragg angle; the same for Fig. 2.

According to the results of the X-ray phase analysis of cobalt- and copper-containing samples (Fig. 2), an individual compound is obtained at Co : Cu = 1 : 1. The reflections of the compound synthesized, $Co_{1.00} \cdot Cu_{1.00}P_2O_7 \cdot 3.0NH_3 \cdot 4.0H_2O$, are satisfactorily indexed in the monoclinic crystal system with the unit cell parameters a = 11.064, b = 12.675, c = 10.409 Å, γ = 103.73°, and V = 1417.9 Å^3. The starting $Ni_2P_2O_7 \cdot 6.0H_2O$ and $Cu_2P_2O_7 \cdot 5.0H_2O$ are crystalline, whereas the starting $Co_2P_2O_7 \cdot 6.0H_2O$ is, on the whole, X-ray amorphous, with a single clearly pronounced reflection at 2θ = 6.5° and a broad band peaked at 2θ = 19°–20°. Their X-ray diffraction patterns are in agreement with those reported in [10, 11, 17].

Table 3 lists the IR data for double cobalt copper and nickel copper ammine diphosphates. The spectra of all the compounds contain a strong absorption band associated with stretching vibrations of the NH and OH groups at 3500–2900 cm^{-1} and absorption bands associated with bending vibrations of water and asymmetric bending vibrations of ammonia in ammine complexes at 1650–1500 cm^{-1}. Thus, it is impossible to resolve vibrations of coordinated ammonia and water in these spectral ranges. At 1465–1410 cm^{-1}, the spectra of ammine diphosphates show the presence

of ammonia, which forms a strong hydrogen bond with proton transfer between ammonia coordinated to metal ions and $P_2O_7^{4-}$. This is accompanied by averaging of the electron density over the whole chain of atoms forming the hydrogen bond [5, 6, 18]. The IR spectra of the same compounds contain at around 1325 cm^{-1} an absorption band associated with only bending vibrations of coordinated ammonia molecules [19]. Asymmetric and symmetric vibrations of the $P_2O_7^{4-}$ anion appear at 1135–800 cm^{-1} as strong absorption bands. Weak absorption bands at 700–540 cm^{-1} can be assigned to vibrations of P–O–P and O–P–O groups. Stretching vibrations of the Me–N and Me–O bonds appear in the spectra of the ammine diphosphates at 510–465 cm^{-1} [20, 21].

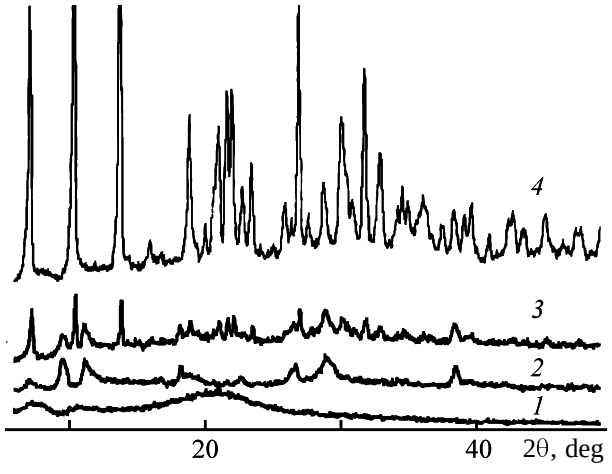

Fig. 2. X-ray diffraction patterns of (*1*) $Co_2P_2O_7 \cdot 3.0NH_3 \cdot 4.0H_2O$, (*2*) $Co_{1.00}Cu_{1.00}P_2O_7 \cdot 3.0NH_3 \cdot 4.0H_2O$, (*3*) $Co_{0.50} \cdot Cu_{1.50}P_2O_7 \cdot 3.0NH_3 \cdot NH_3 \cdot 4.0H_2O$, and (*4*) $Cu_2P_2O_7 \cdot 3.0NH_3 \cdot 2.5H_2O$.

Thus, the IR spectra suggest that double nickel copper and cobalt copper ammine diphosphates contain two different kinds of ammonia molecules: those interacting with metal atoms solely by the donor–acceptor mechanism and those additionally involved in a hydrogen bond with charge transfer.

CONCLUSION

Previously unknown individual solid double hydrated nickel copper and cobalt copper ammine diphosphates were prepared. The composition of the compounds synthesized was studied by IR spectroscopy, and their coordination structure was confirmed.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Calculation of the Stoichiometric Composition of Nanostructures Synthesized by Molecular Layer Deposition on the Surface of Solid Matrices

E. A. Sosnov, A. A. Malkov, and A. A. Malygin

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received December 28, 2004

Abstract—Calculational formulas for determining from the results of chemical and thermogravimetric analyses the true relative contents of components in products formed in molecular layer deposition of nanostructures on the surface of solid matrices are suggested. The approaches considered are illustrated by the example of evaluation of the chemical composition of titanium oxide (nitrogen) and silicon–nitrogen nanolayers synthesized by molecular layer deposition on the silica surface.

Chemical modification of the surface of solid matrices is widely used in modern processes for production of materials and articles. Recent publications have shown convincingly that modern tendencies in the development of many areas of solid-phase materials science (micro- and nanoelectronics; development of luminophores, sorbents, and catalysts) are well matched by the method of molecular layer deposition (MLD), which yields nanostructures of a prescribed chemical composition on the surface of various solid matrices [1–5]. The method consists in that chemical reactions between low-molecular-weight reagents (LMWR) and functional groups (FG) of the starting matrix are performed under nonequilibrium conditions (to achieve the maximum filling of the surface).

In contrast to the conventional techniques for chemical modification of solid substances, the MLD method is a multistage cyclic process in which no more than a single monolayer of new structural units, functional groups, is formed on the surface in each cycle. In the process, the mass ratio of the starting solid matrix and the layer being grown changes after each synthesis stepe. The method used in preparative chemistry to determine the empirical chemical composition of the products obtained not only gives no way of finding the true relative contents of their components, but also hinders a correct comparative analysis of the stoichiometry of the surface nanostructures in various steps of the synthesis. To tackle with these problems, it has been suggested to relate data on the chemical composition of surface structures to unit mass of the starting solid matrix [2, 3]. Thus, the main step in a calculation of the stoichiometric composition of the products is reduced to a choice of a procedure for determining the share of the starting matrix in a unit mass of the sample synthesized.

The approaches suggested have been implemented for a number of particular systems, e.g., various element oxide layers grown on the surface of dispersed silicon dioxide. Previously, Kol'tsov has suggested a procedure [6] for calculating the content p_i of the silica matrix in titanium-containing silica obtained by the schemes

$$k(|\text{–Si–OH}) + \text{TiCl}_4 \rightarrow (|\text{–Si–O})_k\text{TiCl}_{4-k} + k\text{HCl}, \quad (1)$$

where k = 1–3;

$$(|\text{–Si–O})_k\text{TiCl}_{4-k} + \text{H}_2\text{O} \rightarrow (|\text{–Si–O})_k\text{Ti(OH)}_{4-k} + (4 - k)\text{HCl}, \text{ etc.} \quad (2)$$

where the symbol $|$ denotes the skeleton of the solid matrix on whose surface the FGs are situated.

$$p_i = \frac{4a_i + b_i - c_i}{4A_{i-1} + B'_{i-1} - C'_{i-1}}, \quad (3)$$

where a, b, c, and p are the contents of Ti^{4+} (mmol), OH^- (mmol), Cl^- (mmol), and SiO_2 (g) per gram of the product; A, amount of titanium(IV) per gram of SiO_2; B', C', amounts of OH^- and Cl^- per gram of SiO_2 in hydrolysis products; and i, number of an MLD cycle.

1070-4272/05/7803-0367 © 2005 Pleiades Publishing, Inc.

To calculate the stoichiometric composition, it was necessary to determine, on the basis of chemical analytical data, not only the content of the modifying element [Ti(IV) according to scheme (1)] in the product obtained and the amount of a halogen hydride released in vapor-phase hydrolysis of the chemisorbed structures. Also, the amount of newly formed FGs [OH groups, according to scheme (2)] was to be found. This involves certain experimental difficulties in chemical analysis of the silica surface for the content of OH groups by the known reaction with CH_3MgI [6]. Use of formula (3) requires a full elemental analysis of the samples obtained after each cycle of molecular layer deposiiton.

In [7], a simplified procedure for calculating the content of the starting matrix in the products synthesized was suggested for the example of a chromium-containing silica gel. The approach is based on recalculation of the experimental concentrations of elements or groups per gram of the product to the empirical composition in the form of oxides by the formula

$$\{SiO_2\} = 1000 - ([Cr^{6+}](M_{Cr} + 3M_O) + [Cr^{3+}](M_{Cr} + 3/2M_O) + 1/2M_{H_2O}[OH], \quad (4)$$

where $\{SiO_2\}$ is the mass (mg) of the starting matrix in 1 g of a sample synthesized in any stage of MLD; $[Cr^{6+}]$, content of chromium(VI) in terms of CrO_3 per gram of the product; $[Cr^{3+}]$, content of chromium(III) in terms of Cr_2O_3 per gram of the product; [OH], content of hydroxy groups (mmol) in terms of H_2O per gram of the product; and M_{Cr}, M_O, M_{H_2O}, atomic and molecular masses of Cr, O, and H_2O, respectively.

In the case of analysis of chlorine-containing products, the content of chlorine is recalculated to the corresponding oxychloride with account of the oxidation state of the elements involved. Taking into account the methodological difficulties encountered in evaluation of the concentration of OH groups in various stages of MLD, they can be disregarded in the calculation or a constant correction can be used as their concentration. Experiments demonstrated that, in this case, the deviations in calculation do not exceed the error of chemical analysis. Thus, the suggested simplified calculational procedure has a number of limitations associated with the fact that the possibility of an incomplete extent of processes involving, e.g., OH groups is neglected. Considerably more complicated is the calculation of the true composition and structure of surface formations of another chemical nature, when several types of FGs may appear in the course of synthesis on the surface (e.g., ≡N:, =NH, and $–NH_2$ groups can be formed in synthesis of nitrogen-containing structures [8]), when a compound of complex composition (e.g., SiN_xH_y) is formed on the surface, or on nonoxide matrices.

Taking into account the practical importance of obtaining true relative contents of the components on the surface of various solid matrices, we suggest a generalized procedure for calculating the chemical composition of products formed in chemical assembly of element-containing layers. This procedure is based on the results of a chemical analysis of a material in the stage of LMWR chemisorption. The results obtained are compared with the data furnished by calculations by formulas (3) and (4).

In developing the calculation procedure, we specified the following conditions for its applicability.

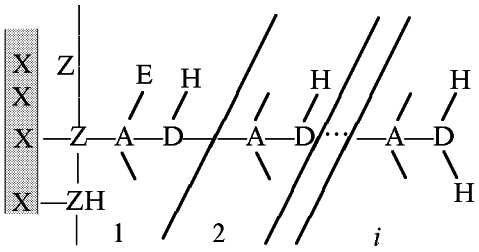
(1) There is no chemical reaction between LMWR and products of their interaction with the matrix and other, non-FG, active centers of the substrate (e.g., direct chlorination of the surface).

(2) The functional groups of the matrix enter into chemical reactions only with LMWR molecules, i.e., there are no interfunctional interactions of the initial FGs (e.g., de- or rehydroxylation of the matrix in the course of synthesis).

(3) The synthesis is performed under the conditions in hich the products of interaction of the LMWRs with the matrix form no sorption complexes at active centers of the substrate (e.g., by adsorption of HCl or NH_4Cl on the surface).

(4) Surface structures are formed in accordance with the law of multiple proportions (it is possible that redox reactions occur in the course of synthesis, without changes in the amount of the modifying element).

Let us consider the course of a chemical assembly of a single-component layer of prescribed thickness on the surface of a chalcogenide matrix having only a single type of reactive FGs (|–X–ZH, where H is hydrogen; X = C, Me, Si; Z = O, S) (e.g., SiO_2, Al_2O_3, ZnO, MgO, ZnS, CdS, etc.). As LMWRs can be used the following reagents: AE_n ($n \geq 3$), where A = M, MO, Si, B, P, PO; E = Hal, OR, and DH_m ($m \geq 2$), where D = O, S, N, P.



In alternating treatments of the starting matrix with the reagents by the MLD method, an element-containing layer can be formed on its surface by the schemes

$$k(|–X–ZH) + AE_n \rightarrow (|–X–Z)_kAE_{n-k} + kHE, \quad (5)$$

where $n \geq k + 1$;

$$(\mid\!\text{–X–Z})_k\text{AE}_{n-k} + \text{DH}_m \rightarrow (\mid\!\text{–X–Z})_k\text{AD}_{m-n-k}) + (n - k)\text{HE}, \text{ etc.} \quad (6)$$

Taking into account the probability of an incomplete substitution of functional groups in each stage of synthesis and assuming, for simplicity of calculations, that all the products of incomplete substitution of E atoms in $–\text{AE}_{n-k}$ groups are associated with the first monolayer, we can represent the structure of the layer synthesized as the following scheme:

(7)

In this case, the content of the starting matrix, {XZ}, in the product obtained after synthesis of *i*th layer can be expressed, with account of the fact that half of the atom Z in ZH groups belongs to the matrix, as

$$\{\text{XZ}\}_i = \{1000 - Z\text{H}_{\text{rem}}(M_\text{Z}/2 + 3M_\text{H}) - Z\text{H}_{\text{sp}}M_\text{Z}/2 - Y_{\text{rem}\,i}M_\text{E} - A_iM_\text{A} - D_iM_\text{D} - H_iM_\text{H} - \sum_{j-1}^{i-1} H_{\text{rem}\,i}M_\text{H}\}/1000, \quad (8)$$

where $\{XZ\}_i$ is the content of the starting matrix (g) in 1 g of the synthesis product; ZH_{sp}, ZH_{rem}, amounts of FGs of the matrix spent in the course of chemisorption of AE_n and remaining on the surface of the support (mmol g^{-1}); A_i, D_i, H_i, $E_{\text{rem}i}$, $H_{\text{rem}i}$, amounts of elements A, D, and hydrogen, and also of element E and hydrogen remaining deep within the *i*th layer (mmol g^{-1}); and M_Z, M_A, M_D, M_E, M_H, atomic masses of elements Z, A, D, E, and hydrogen, respectively.

Henceforth, the quantities expressed in mmol per gram of the matrix without FG (mmol g_0^{-1}) are given in square brackets, and those expressed in mmol per gram of the chemisorption product (mmol g^{-1}), without brackets. It should be noted that A_i, D_i, and $E_{\text{rem}i}$ are commonly determined in chemical analysis of products synthesized by the MLD method. {*XZ*} can be expressed in terms of the experimentally found quantities.

Let us calculate the amounts ZH_{sp} of FGs consumed in the chemical reaction with AE_n and ZH_{rem} of FGs that did not enter into the reaction, using the formulas

$$ZH_{\text{sp}} = [\Delta A]_1(n - ([E_{\text{el}}]_1 + [E_{\text{rem}}]_1)/[\Delta A]_1)\{XZ\}_i, \quad (9)$$

$$ZH_{\text{rem}} = ZH_{\text{st}} - ZH_{\text{sp}} = [ZH_{\text{st}}]\{XZ\}_i - [\Delta A]_1(n - ([E_{\text{el}}]_2 + [E_{\text{rem}}]_1)/[\Delta A]_1)\{XZ\}_i, \quad (10)$$

where $[E_{\text{el}}]_1$ is the amount of element *E* from the first monolayer, eliminated in the course of reaction (6) (mmol g_0^{-1}); and $[ZH_{\text{st}}]$, the amount of FGs on the surface of the starting matrix (mmol g_0^{-1}).

The quantity $[ZH_{\text{st}}]$, which reflects the actual composition of the FGs on the surface of the starting matrix under the synthesis conditions, can be determined by chemical analysis. Let us express the content of hydrogen in the $–\text{DH}_{m-(n-k)}$ structures formed on the surface of the matrix as follows:

$$H_j = [\Delta D]_j(m - [E_{\text{el}}]_i/[\Delta D]_j)\{XZ\}_i. \quad (11)$$

Taking into account that the amount of protons substituted in synthesis of the succeeding layer by the reaction with AE_n is given by

$$H_{\text{sp}_j} = [\Delta A]_{j+1}(n - [\Delta E_{\text{el}}]_{j+1}/[\Delta A]_{j+1})\{XZ\}_i, \quad (12)$$

we can express the number of the remaining protons as

$$H_{\text{rem}_j} = H_j - H_{\text{sp}_j}. \quad (13)$$

Substituting the resulting expressions (9)–(13) into the starting equation (8) and grouping like terms, we obtain

$$1000\{XZ\}_i = 1000 - [ZH_{\text{st}}]\{XZ\}_i(M_\text{Z}/2 + M_\text{H}) - A_i(M_\text{A} - nM_\text{H}) - D_i(M_\text{D} + mM_\text{H}) - [E_{\text{rem}}]_1\{XZ\}_iM_\text{H} - E_{\text{rem}\,i}M_\text{E}. \quad (14)$$

From expression (14), we derive formulas for calculating the content of the starting matrix in the product obtained for $i = 1$ (15) and $i > 1$ (16):

$$\{XZ\}_i = [1000 - A_i(M_\text{A} - nM_\text{H}) - D_i(M_\text{D} + mM_\text{H}) - E_{\text{rem}\,i}(M_\text{E} + M_\text{H})]\{1000 + [ZH_{\text{st}}](M_\text{Z}/2 + M_\text{H})\}^{-1}, \quad (15)$$

$$\{XZ\}_i = [1000 - A_i(M_A - nM_H) - D_i(M_D + mM_H) - E_{rem\,i}M_E]\{1000 + [ZH_{st}](M_Z/2 + M_H) + E_{rem\,i}M_H\}^{-1}, \quad (16)$$

In a chemical assembly of surface structures by the MLD method, two particular cases are possible, which can hinder the calculation of the stoichiometric composition of a layer synthesized: (1) modification of the matrix with a compound of the same class (Z = D) and (2) modification of the matrix with a compound of the same element (X = A). In the first case, we can, taking into account that element D is bivalent, determine its amount in each layer in the reaction of substitution of element E:

$$(|\text{–X–Z})_k\text{AE}_{n-k} + \text{DH}_2 \rightarrow (|\text{–X–Z})_k\text{A(DH)}_{n-k} + (n - k)\text{HE}. \quad (17)$$

It follows from scheme (17) that

$$\Delta D_i = H_i = E_{eli}, \quad (18)$$

$$D = \sum_{j=1}^{i} [E_{el}]_j\{XZ\}_i. \quad (19)$$

Substituting expressions (9), (10), (12), (13), (18), and (19) into the starting equation (8) and collecting like terms, we obtain

$$1000\{XZ\}_i = 1000 - [ZH_{st}]\{XZ\}_i(M_Z/2 + M_H) - A_i(M_A - nM_H) - [E_{rem}]_1\{XZ\}_iM_H - E_{rem_i}M_E - \sum_{j=1}^{i} [E_{el}]_j\{XZ\}_i(M_D + 2M_H). \quad (20)$$

Then we have at $i = 1$

$$\{XZ\}_i = [1000 - A_i(M_A - nM_H) - E_{el}(M_D + 2M_H) - E_{rem\,i}(M_E + M_H)]\{1000 + [ZH_{st}](M_Z/2 + M_H)\}^{-1}. \quad (21)$$

At $i > 1$, the calculation is to be performed using the recurrence formula

$$\{XZ\}_i = [1000 - A_i(M_A - nM_H) - E_{el\,i}(M_D + 2M_H) - E_{rem\,i}M_E]\{1000 + [ZX_{st}](M_Z/2 + M_H) + [E_{rem}]_1M_H + \sum_{j=1}^{i-1} [E_{el}]_j(M_D + 2M_H)\}^{-1}. \quad (22)$$

As a particular example, we present calculational formulas for titanium oxide structures on the surface of silica after single ($i = 1$) and multiple ($i > 1$) treatment of the starting matrix with vapors of $TiCl_4$ and H_2O:

$$\{SiO_2\}_1 = [1000 - Ti_1(M_{Ti} - 4M_H) - Cl_{el1}(M_O + 2M_H) - Cl_{rem\,i}(M_{Cl} + M_H)]\{1000 + [OH_{st}](M_O/2 + M_H)\}^{-1}, \quad (23)$$

$$\{SiO_2\}_i = [1000 - Ti_i(M_{Ti} - 4M_H) - Cl_{eli}(M_O + 2M_H) - Cl_{rem\,i}M_{Cl}]\{1000 + [OH_{st}](M_O/2 + M_H) + [Cl_{rem}]_iM_H + \sum_{j=1}^{i-1} [Cl_{el}]_j(M_O + 2M_H)\}^{-1}. \quad (24)$$

The results of calculations by formulas (23), (24) and Eqs. (3) and (4) earlier suggested in [6, 7] are listed in Table 1. As follows from these data, the discrepancy between the amounts of the starting matrix in 1 g of the product, determined using different methods, and those of the modifying element per gram of SiO_2 do not exceed 3%, which is close to the error in determining the content of the modifying element by chemical methods [10]. However, the fact that it is difficult to determine experimentally the content of OH groups on the sample surface, which is necessary in the procedure described in [6], hinders application of Eq. (3). At the same time, the recurrence formula for calculating the amount of the matrix material in a sample, which makes it possible to determine the chemical composition and structure of nanostructures obtained in any stage of synthesis, requires sampling in each cycle, which is possible in research or testing of the synthesis modes. It is the most appropriate to use the simplified procedure [Eq. (4)] suggested in [7] for evaluation monitoring of the stoichiometry of products in the course of an industrial synthesis. At the same time, this techniques gives no way of determining the structure of the layer synthesized, because it is impossible to find from the empirical formula the multiplicity of bonds of the modifying element and, in the case of multicomponent structures, the order of alternation of the monolayers formed and the chemical composition of a separate layer. Thus, the applicability of a method is determined by the task to be accomplished and by the set of the available experimental data.

In the case of modification of the matrix with a compound of the same element (X = A), the stoichiometric composition of the structures formed can be determined by performing the chemical assembly by the MLD method on a thermogravimetric setup with a spring McBain balance [11]. Experiments on

synthesis of a titanium oxide monolayer on dispersed silica [11] showed good agreement between the changes in mass, experimentally determined in the stages of chemisorption and vapor-phase hydrolysis, and the data calculated from the results of a chemical analysis. This fact makes it possible to find from thermogravimetric data the chemical composition of the surface products synthesized. A typical curve describing the variation of the sample mass, Δm, in different stages of synthesis is shown in the figure. The sample mass gain $\Delta m_{ch.s}$, used in the calculations [formulas (25)–(29)], is determined after the stages of chemisorption of AE_n (figure, step *I*) and removal of physically sorbed gaseous products (step *II*). After the stages of treatment with a DH_m vapor (step *III*) and sample drying (step *IV*), the mass of the product decreases as a result of substitution of atoms of element E with lighter-weight FG, DH_{m-1}, by an amount Δm_G, which is used in further calculations [formulas (29) and (30)].

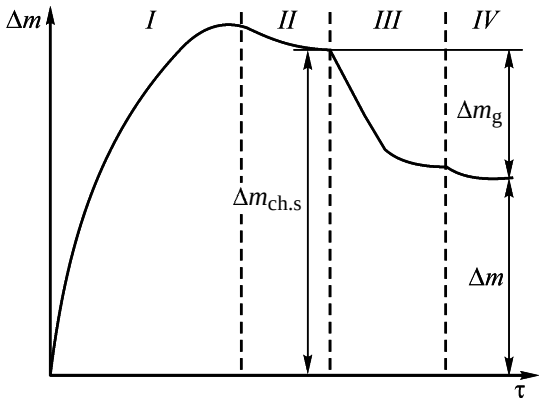
When the first monolayer ($i = 1$) is formed, the gain in mass, $\Delta m_{ch.s}$, in the course of chemisorption of AE_n can be expressed as

$$\Delta m_{ch.s1} = [A]_1 M_A + [E_{el}]_1 M_E + [E_{rem}]_1 M_E] - [ZH_{sp}]M_H, \quad (25)$$

where ΔA is the change in the amount of the modifying element in the stage of chemisorption of AE_n.

At $i > 1$,

$$\Delta m_{ch.s\,i} = [A]_i M_A + [E_{el}]_i M_E - [H_{sp}]_{i-1} M_H. \quad (26)$$



Then, with account of expressions (9) and (12), we obtain for $i = 1$ and $i > 1$, respectively,

$$[A]_1 = \frac{\Delta m_{ch.s1} - ([E_{el}]_1 + E_{rem\,i})(M_E + M_H)}{M_A - nM_H}, \quad (27)$$

$$[A]_i = \frac{\Delta m_{ch.s\,i} - [E_{el}]_i (M_E + M_H)}{M_A - nM_H}, \quad (28)$$

Similarly, the change in sample mass in the course of reaction (6), Δm_g, can be used to calculate the content of element D in each layer:

$$\Delta m_{g\,i} = [\Delta D]_i M_D + [H]_i M_H - [E_{el}]M_E, \quad (29)$$

Changes in sample mass, Δm, in synthesis by MLD, measured on a thermogravimetric setup with a spring McBain balance. (τ) Process duration. (*I*) Chemisorption of AE_n, (*II*) removal of excess reagent, (*III*) treatment with DH_m vapor, and (*IV*) removal of excess reagent.

whence follows

$$[\Delta D]_i = \frac{\Delta m_{g\,i} - [E_{el}]_i(M_E + M_H)}{M_D - mM_H}. \quad (30)$$

The resulting expressions (15), (16), (27), (28), and (30) were used to determine the true stoichiometric composition of the products formed in chemical assembly of titanium–nitrogen (by treatment with $TiCl_4$ vapor and NH_3) of silicon–nitrogen (by treatment with $SiCl_4$ vapor and NH_3) layers on the surface of silica. The synthesis was performed on a thermogravimetric setup with a McBain balance [11]. The concentration of elements in the samples was determined by chemical analysis and from the results of an *in situ* monitoring of the change in the mass of the products on a McBain balance.

Let us consider the applicability of previously developed procedures to analysis of titanium–nitrogen nanostructures on the surface of SiO_2 (Table 2). As the quantitative analysis of the whole spectrum of FG (–NH, ≡NH, and ≡N groups) was not performed after each MLD cycle, it is impossible to use the approach suggested in [6] for calculating the stoichiometric composition of the samples. At the same time, a certain modification of the procedure [7] for recalculation to an empirical composition in the form of titanium-containing compounds (Ti_3N_2, Ti_3N_4, TiO_2, $TiCl_4$) yields adequate results.

Let us present an example of calculation of the content of SiO_2, $\{SiO_2\}$, in 1 g of the product formed at T_s = 400°C. As the N/Ti ratio in the samples is close to 0.67, we can express the layer composition as Ti_3N_2. Then, in accordance with the procedure described in [7],

$$\{SiO_2\}_i = 1000 - (Ti'_i M_{Ti_3N_2}/3 + Ti''_i M''_{TiO_2} + Ti'''_i M'''_{TiCl_4} + [OH_{st}]M_{H_2O}/2), \quad (31)$$

where, judging from the formula composition of the presumed components,

$$Ti'_i = 3/2N_i, \quad (32)$$

$$Ti''_i = 1/4Cl_{rem}, \quad (33)$$

$$Ti'''_i = Ti'_i - Ti''_i = Ti_i - 3/2N_i - 1/4Cl_{rem\,i} = (4Ti_i - 6N_i - Cl_{rem\,i})/4. \quad (34)$$

From here we obtain, substituting expressions (32)–(34) into (31):

$$\{SiO_2\}_i = 1000 - [N_i M_{Ti_3N_2}/2 + (2Ti_i - 6N_i - Cl_{rem\,i})M_{TiO_2}/4 + Cl_{rem\,i}M_{TiCl_4}/4 + [OH_{st}]M_{H_2O}/2). \quad (35)$$

It should be noted that, if $Ti''_i \le 0$ as a result of the error in the chemical analysis, we take $Ti''_i = 0$.

Similar transformations performed for samples synthesized at 600°C yield the following formula:

$$\{SiO_2\}_i = 1000 - [N_i M_{Ti_3N_4}/4 + (4Ti_i - 3N_i - Cl_{rem\,i})M_{TiO_2}/4 + Cl_{rem\,i}M_{TiCl_4}/4 + [OH_{st}]M_{H_2O}/2). \quad (36)$$

The results of a calculation of $\{SiO_2\}$ in the samples synthesized are listed in Table 2. The discrepancy between the amounts of the starting oxide matrix, obtained with formulas (15), (16) and (35), (36), does

not exceed 1%, which indicates that the approach suggested in [7] is applicable to calculation of the stoichiometric composition of nonoxide nanostructures.

Table 3 shows that the procedure we suggested not only makes it possible to calculate the stoichiometric composition of the products synthesized, even in the case when it is impossible to perform a chemical analysis for the content of one or both components of a layer being synthesized, but also enables a study of the formation pattern of nanostructures in the course of MLD on the surface of a matrix (changes in $[\Delta A]_i$, $[\Delta D]_i$, $[E_{rem}]_i/[\Delta A]_i$, $[D]_i/[A]_i$ with increasing number of monolayers). It should be noted that the procedure described in [7] can also be used to determine the stoichiometric composition of the product in the case of titanium oxide structures on SiO_2 (Table 2). At the same time, the procedure we suggest in this communication is the only one applicable to calculation of the stoichiometric composition of surface structures in the case when it is impossible to determine the content of the layer components by chemical analysis (Table 3).

CONCLUSIONS

(1) Generalized formulas were suggested for calculating the change in the content of the starting matrix in products formed in synthesis of nanostructures on its surface by molecular layer deposition in relation to the number of cycles of treatment with low-molecular-weight reagents. The calculation is based on the results of a chemical analysis of the synthesis products for the content of the main grafted components, functional groups on the starting matrix, and takes into account the possibility of incomplete consumption of functional groups in different steps of molecular layer deposition.

(2) The approaches suggested are in good agreement with the previously developed procedures for performing similar calculations.

(3) A combination of the gravimetric methods for monitoring of synthesis by the MLD method and of the formulas suggested made it possible to determine the stoichiometry of surface nanostructures produced by MLD and having the same composition as the matrix, which cannot be done using the previously suggested techniques.

Received July 20, 2004

Abstract—The effect exerted by the anion of Pb and Zn salts on the thermal evolution of the structure of polymetallosiloxanes formed by base-catalyzed (NH_4OH) hydrolytic polycondensation of ethyl silicate with zinc(II) or lead(II) salts was studied.

In synthesis of polymetallosiloxanes by the sol–gel method, the anion of the starting salt determines the rate and depth of its hydrolytic polycondensation with ethyl silicate and also the composition, structure, and properties of the resulting metal–silica gels at common temperatures [1]. However, the effect of anions of metal salts on solid-state transformations of the resulting polymetallosiloxanes on their annealing was not studied. Such data would show how the heat treatment of the synthesized metal–silica gels and materials based on them, performed within a wide temperature range, affects their structure and properties.

EXPERIMENTAL

The starting chemicals were commercial ethyl silicate-40 (ES) (partially hydrolyzed tetraethoxysilane) and the lead and zinc salts $PbCl_2$, $Pb(NO_3)_2$, $Pb(OCOCH_3)_2 \cdot 3H_2O$, $ZnSO_4 \cdot 7H_2O$, $ZnCl_2$, $Zn(NO_3)_2 \cdot 6H_2O$, and $Zn(OCOCH_3)_2 \cdot 2H_2O$.

The choice of these salts was governed by the ability of lead(II) and zinc(II) salts to affect the crystallization of amorphous silica phases of polymetallosiloxanes at relatively low temperatures, as it was found earlier [2]. We used 2-propanol as an organic solvent. The molar ratio ES : H_2O : $(CH_3)_2CHOH$ was 1 : 8 : 4. The process was carried out as follows: A metal salt was dispersed in aqueous ammonia at 35.0 ± 0.5 °C within 1 h. The resulting dispersion was added to an ES solution in 2-propanol, also heated to 35.0 ± 0.5°C, with continuous stirring, and the mixture was stirred for an additional 1 h. For the gelation completion, the system was allowed to stand for a day at room temperature without stirring. The resulting products of hydrolytic polycondensation were thoroughly washed by decanting and dried to a xerogel state for 16 h at 120 ± 5°C. Then they were studied by X-ray diffraction analysis (DRON-3) and IR spectroscopy (a Specord IR-75 spectrophotometer, KBr pellets).

After heat treatment in air for 3.5 h at 900°C, the amorphous phase of plumbo- and zincosiloxanes actively crystallizes to form several modifications of silicon dioxide (Tables 1, 2). This is confirmed by the appearance of well-defined strong reflections cor-

responding to β-cristobalite (interplanar spacings *d* 0.403, 0.313, 0.283, 0.248, 0.246, 0.211, 0.201, 0.192, 0.186, 0.168, 0.160, 0.153, 0.141, and 0.136 nm) and γ-tridymite (*d* 0.430, 0.381, 0.321, 0.296, 0.230, and 0.184 nm), which were identified by comparison with the reference data [3]. The lines corresponding to α-tridymite (*d* 0.228, 0.195, and 0.152 nm) and willemite (*d* 0.349, 0.263, and 0.232 nm) are also present in the X-ray patterns of zincosiloxanes. Willemite is formed by the thermal reaction of SiO_2 with ZnO (product of dissociation of the sorbed zinc salt) [2]. The formation of SiO_2 crystal modifications is apparently induced by lead(II) or zinc(II) atoms incorporated in the siloxane structure as Si–O–M–O–Si (M = Pb or Zn) fragments and also by salts of these metals sorbed in the polysiloxane matrix. As noted above, this is primarily determined by the nature of the introduced metal and by high molecular homogeneity of the resulting systems [2]. Highly dispersed lead(II) and zinc(II) oxides formed by thermal decomposition of the starting salts, being highly reactive in phase transformations (Hedwall effect), are also catalytically active.

The crystallization of the amorphous silica phase of polymetallosiloxanes also depends on the conditions of their synthesis (the cation and anion of the starting salt, pH of the reaction medium, and reaction temperature). This is confirmed by variations of the intensity I/I_0 of the characteristic maxima in the corresponding X-ray patterns of metallosiloxanes (Tables 1, 2).

The catalytic effect of lead salts at pH 11 of the reaction medium on the formation of the major phase (β-cristobalite) decreases in the order $PbCl_2$ (100%) > $Pb(OCOCH_3)_2$ (67.0%) > $Pb(NO_3)_2$ (64.3%), corresponding to a decrease in the thermal stability of the salts. This is proved by the reflection intensities I/I_0 calculated relative to the intensity of the major peak (*d* = 0.403 nm) in the X-ray pattern of plumbosiloxane obtained from $PbCl_2$, taken as 100% for all the systems. However, at pH 12 the catalytic effect of the salts decreases in another sequence: $Pb(NO_3)_2$ (100%) > $PbCl_2$ (70%) > $Pb(OCOCH_3)_2$ (44%). As a whole, plumbosiloxanes crystallize after annealing much more actively if the sol–gel process is carried out at pH 11.0 (Table 1).

When zinc(II) salts are used in the sol–gel process at pH 12.0, crystalline phases in zincosiloxane are formed more actively. After the synthesis at pH 11.0, zincosiloxanes show similar tendency to crystallize only when zinc nitrate and acetate are used (most readily dissociating on heating to form ZnO). With

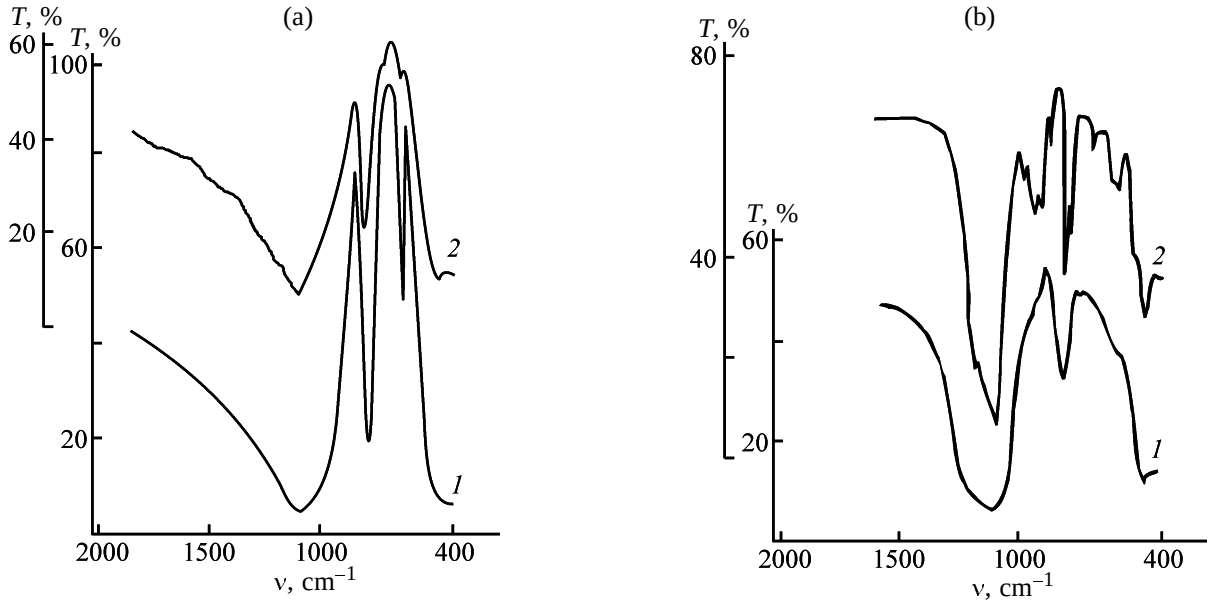

Fig. 1. IR absorption spectra of (a) plumbosiloxanes obtained from $PbCl_2$ and (b) zincosiloxanes obtained from $ZnCl_2$ after heating at 900°C for 3.5 h. (*T*) Transmission and (ν) wave number. pH: (*1*) 11 and (*2*) 12.

zinc sulfate and chloride (most stable thermally), the crystallization of the system is insignificant. With $ZnCl_2$ as the starting salt, β-cristobalite is not noticeably formed in the xerogel. Zincosiloxanes differ from plumbosiloxane by the higher content of crystalline phases. Except for β-cristobalite and γ-tridymite, these are α-tridymite and willemite (Zn_2SiO_4). The content of the major phases of γ-tridymite and willemite essentially depends on the conditions of the sol–gel synthesis (the zinc salt anion and pH of the reaction medium).

This conclusion is also supported by the IR data, in particular, by the fact that the typical spectra contain well-defined strong absorption bands at 969, 917, 890, 853, 790, 752, 677, 613, and 507 cm^{-1} (Figs. 1a, 1b). However, direct determination of the majority of the forming phases by IR spectroscopy is severely complicated by the overlap of the absorption bands characteristic for all high-temperature SiO_2 forms in the range 400–1200 cm^{-1}. In this connection, only cristobalite was identified in the IR spectra by the absorption band at 615 cm^{-1}, characteristic of only this SiO_2 modification [4]. Its content in the products of the sol–gel synthesis was estimated from the optical density *D* of this band in the maximum [4]. In the IR spectra of the plumbosiloxanes obtained, this band is somewhat shifted toward lower frequencies owing to a change in the spacial orientation of the silicon–oxygen tetrahedra of cristobalite in the presence of other crystalline phases. The value of *D* for this band is consistent with the results of the X-ray phase analysis demonstrating how the crystallization of the system depends on the anions of the starting lead and zinc salts and on pH of the reaction medium. Thus, the content of cristobalite in plumbosiloxanes after heat treatment is always higher if the synthesis was carried out at pH 11.0, and not 12.0, of the starting reaction medium. The content of all the crystalline phases after the heat treatment of the zincosiloxanes obtained from $ZnSO_4$ and $ZnCl_2$ (most thermally stable) at pH 11.0 is considerably lower.

This is confirmed also by variation of *D* for the absorption band in the region of 800 cm^{-1}, characteristic of practically all silica modifications [4, 5].

Table 3. Optical density *D* of the absorption bands at 615/800 cm^{-1} for plumbo- and zincosiloxanes after heating at 900°C for 3.5 h in relation to the conditions of their preparation

Starting salt	*D* at indicated pH of reaction medium during synthesis	
	11	12
$PbCl_2$	0.26/0.63	0.03/0.34
$Pb(NO_3)_2$	0.18/0.41	0.15/0.38
$Pb(OCOCH_3)_2$	0.19/0.43	0.02/0.26
$ZnCl_2$	–/0.23	0.06/0.28
$ZnSO_4$	0.01/0.46	0.09/0.71
$Zn(NO_3)_2$	0.12/0.42	0.15/0.55
$Zn(OCOCH_3)_2$	0.14/0.65	0.13/0.45

Depending on the structure of other crystalline phases formed, this band is shifted to 780–797 cm^{-1} in the spectra of zincosiloxanes and to 776–789 cm^{-1} in the spectra of plumbosiloxanes. The data obtained indicate that *D* of this band for plumbo- and zincosiloxanes is always higher in the case of more crystallized systems (Table 3). These data correlate with the I/I_0 ratios in the X-ray diffraction patterns.

Thus, by varying the anions of the starting lead(II) or zinc(II) salts and pH of the reaction medium during the sol–gel process, we can control the crystallization and phase composition of the basic amorphous polysiloxane matrix of metal–silica compounds.

CONCLUSIONS

(1) High-temperature crystal transformations of amorphous silica phases of plumbo- and zincosiloxanes (metal–silica compounds) obtained by a sol–gel method from ethyl silicate and a metal salt in 2-propanol in the presence of NH_4OH depend on the salt anion and pH of the medium.

(2) The major phases formed upon the heat treatment (900°C, 3.5 h) of metal–silica compounds are β-cristobalite in the case of plumbosiloxanes and γ-tridymite and willemite in the case of zincosiloxanes.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Application of the Hertz–Langmuir Equation to Studying the Kinetics of Dehydration of Solid Compounds in Air

B. V. L'vov and V. L. Ugolkov

Received January 19, 2005

Abstract—A simple and reliable method was suggested for studying thermal dehydration of solid substances. The method is based on the application of the Hertz–Langmuir equation to determining the rate of decomposition in air and on the use of the third-law method for calculating the enthalpy of the process.

Two fundamentally different approaches to the interpretation of the exponential temperature dependence of the rate of thermal decomposition of solid substances are known. The first of them it based on the Arrhenius hypothesis, which assumes that only the active part of reagent molecules participate in a reaction. According to the Maxwell–Boltzmann distribution, this part is an exponential function of temperature. The second approach is based on classical studies by Hertz and Langmuir that revealed proportionality between the rate of evaporation and the equilibrium vapor pressure, which, in turn, depends exponentially on temperature.

It is well known [1] that the first approach was transferred to the theory of solid-phase reactions from the kinetics of homogeneous reactions without proper theoretical substantiation. As a result, the kinetic parameters of the Arrhenius equation (preexponential factor A and activation energy E) lost their physical sense. Attempts of use the simple Polanyi–Wigner equation followed by application of the transition state (or activated complex) theory developed by Eyring, Evans, and Polanyi were restricted only to rather approximate estimates of the preexponential factor [1]. Moreover, within the framework of this approach, the main relationships of decomposition reactions determining the mechanism of nucleation, autocatalytic development of the reactions, deceleration of the decomposition in the presence of gaseous products, low evaporation coefficients for many substances, Topley–Smith effect, and kinetic compensation effect remain without quantitative interpretation. The lack of the quantitative theory and the stagnation in this field have been admitted by leading experts [2].

Much greater success in solution of the above-listed problems has been reached by using the Hertz–Langmuir approach developed in [3–9]. The observation of dissociative evaporation of a number of metal nitrates [4, 5] by quadrupole mass spectroscopy gave impetus to the development of this ideology, widely applied earlier to comparative study of decomposition rates of solid substances by methods of Langmuir and Knudsen [10–12]. It has allowed extending this mechanism to all solid compounds. As a result, in view of two other assumptions, the developed concept [6, 8] is based on the following propositions: (1) the initial stage of thermal decomposition consists in congruent dissociative evaporation of the reagent; (2) initial components of the decomposition can differ from equilibrium products; (3) the energy liberated during condensation of the low-volatile product in the reaction zone partly reduces the enthalpy of the overall decomposition reaction (including the condensation stage) as compared to the enthalpy of the initial stage of the dissociative evaporation.

Of the above-listed assumptions, the first assumption provokes the greatest doubts or objections of opponents of this concept. The following reasons are usually advanced. What is the reason for the low-volatile product to pass into vapor, if it should be in the condensed state at a decomposition point according to its thermochemical characteristics? In this case, it is forgotten that the question is not the evaporation of the product, but the dissociative evaporation of the starting compound. Furthermore, it is silently assumed in this case that the starting reagent is allotted by the information on the thermochemical properties of the reaction system, which allows the thermodynamically optimal decomposition pathway to be selected. There-

fore, for example, when Ag_2O decomposes, silver atoms remain in their initial positions defined by the oxide crystal lattice, and Zn and Cd atoms pass into the gas phase in the cousre of the decomposition of ZnO and CdO. It is difficult to agree with these anthropomorphic notions. It is more logical to assume that solid decomposition products are formed by collisions and condensation of low-volatile particles (atoms and molecules) appearing in the free state in the gas phase as a result of the decomposition by a uniform mechanism of congruent dissociative evaporation.

One more argument against extending the mechanism of dissociative evaporation to thermal decomposition of any compounds is the supposedly low probability of the existence of rather complicated molecules in the gas phase, in particular, of molecules of many metal salts formed by the thermal decomposition of crystal hydrates. This reason is disproved by the data obtained recently by mass spectrometry. On the basis of systematization and generalization of the data published in Russia and other countries and of the results of own long-term studies of the composition of vapor of borates, aluminates, carbonates, silicates, nitrates, phosphates, sulfates, hydroxides, chromates, and other binary oxides, Kazenas [13] concluded: "...the discovery of molecules of new types has completely refuted the notion on the high-temperature vapor as a medium poor of molecular species. In particular, it was found that the molecular composition of vapor–gas phases of a number of chemical compounds and their mixtures is much more complicated and more manifold than it seemed earlier."

Nevertheless, verification (direct and indirect) of the dissociative evaporation as the first step of thermal decomposition of solid compounds remains an urgent problem on the pathway of the further development of the Hertz–Langmuir approach and its application to the kinetics of solid-phase reactions. This is the subject of our study. Also, we offer a simple and reliable method of studying dehydration reactions. It consists in the application of the Hertz–Langmuir equation to determining the dehydration rates in air and in the use of the third law for calculating the reaction enthalpy. To show experimentally the possibility of widely applying the method suggested, we chose hydrated compounds of different classes: $Li_2SO_4 \cdot H_2O$ and $3MgO \cdot 4SiO_2 \cdot H_2O$ (talc).

Let us consider some aspects of the theory used in this study. The third-law method is based on the application of the fundamental equation of chemical thermodynamics:

$$\Delta_r H_T^0 = T(\Delta_r S_T^0 - R\ln K_e), \quad (1)$$

where $\Delta_r H_T^0$ and $\Delta_r S_T^0$ are the enthalpy and entropy of the decomposition and K_e is the equilibrium constant.

If reagent R decomposes (according to the mechanism of dissociative evaporation) into gaseous products A and B with simultaneous condensation of low-volatile component A, i.e.,

$$R(s/l) \rightarrow aA(g)\downarrow + bB(g), \quad (2)$$

the equilibrium constant is

$$K_e = P_A^a P_B^b. \quad (3)$$

The equivalent partial pressure P_{eq} (bar) of product A can be found from the Hertz–Langmuir equation through the maximal decomposition rate J ($kg\,m^{-2}\,s^{-1}$):

$$P_{eq} = \frac{(2\pi\overline{M}RT)^{1/2} J}{\gamma M_B}, \quad (4)$$

where $\gamma = 10^5$ Pa bar^{-1} corresponds to the factor of recalculation of pressure from pascals to bars; $\overline{M}$ is the gometric mean of the molar weights of primary products

$$\overline{M} = (M_A^a M_B^b)^{1/(a+b)} = (M_A^a M_B^b)^{1/\nu}, \quad \nu = a + b. \quad (5)$$

Taking into account the stoichiometric coefficients of reaction (2), the equilibrium constant under high-vacuum conditions (equimolar decomposition mode) [6, 8] is described by Eq. (6):

$$K_e = P_A^a P_B^b = (b/a)^b P_{eq}^\nu. \quad (6)$$

In the presence of excess gaseous product B in the reactor (isobaric decomposition mode), we have

$$K_e = P_A^a P_B^b = P_{eq}^a P_B^b. \quad (7)$$

In the case of dissociative evaporation of a reagent, the parameter E in Arrhenius equation is related to the reaction enthalpy as follows [6, 8]: for the equimolar mode,

$$E^e = \Delta_r H_T^0/\nu = \Delta_r H_T^0/(a + b), \quad (8)$$

and for the isobaric mode,

$$E^i = \Delta_r H_T^0/(\nu - b) = \Delta_r H_T^0/a. \quad (9)$$

In the first case, the parameter E corresponds to the

reaction enthalpy per mole of primary products, i.e., to the molar enthalpy, and in the second case, to the reaction enthalpy per mole of the products except for the component present in excess.

The requirement of the maximal decomposition rate or, in other words, of the decomposition from the free surface in the equimolar mode means the absence of any diffusion limitations for the removal of the gaseous product (or products) from the surface of the decomposing reagent. In the case of dehydration, H_2O vapor is the only gaseous product. Other primary products (or product), being low-volatile, immediately condense. To eliminate diffusion limitations for the removal of H_2O vapor, it is necessary to use high vacuum in the reactor.

In the presence of excess H_2O vapor in the reactor (isobaric mode), the conditions of the removal of H_2O liberated during the decomposition are of no significance, as the external pressure of H_2O vapor is much higher than its equivalent pressure. This feature opens a remarkable possibility for the realization of the decomposition from the free surface (after Langmuir) in the presence of any foreign gas, in particular, in air. In fact, the presence of air should not affect the decomposition rate, as diffusion limitations for H_2O vapor removal under isobaric conditions are insignificant, as noted above, and all the low-volatile primary dehydration products instantaneously condense. This means that. in the presence of H_2O vapor in the reactor, the Hertz–Langmuir equation can be used to estimate the equivalent partial pressures of primary dehydration products not only in a vacuum or under low pressure, but also at atmospheric or even higher pressure of a foreign gas. Certainly, this conclusion is valid only under conditions of congruent dissociative evaporation of hydrates when, according to Eqs. (6) and (7), primary decomposition products are described by the laws of the equilibrium thermodynamics, in particular, by the law of mass action. If this is the case, the enthalpies determined by Eq. (6) for a high vacuum and by Eq. (7) for air should be equal.

It is evident from Eq. (1) that the determination of the enthalpy by the third-law method suggests the possibility of calculating the reaction entropy. At first sight, this can seriously restrict the application of this method. Fortunately, the situation in this field has considerably changed within the last 40 years. The standard entropies S^0_{298} and the corresponding temperature increments $S^0_T - S^0_{298}$ for the majority of substances were calculated and published in the tabulated form in several handbooks. Nevertheless, such data for several low-volatile molecules (in particular, of metal salts) in thegaseous state are lacking. The most common approach to the estimation of the reaction entropies in these cases is based on the similarity of the molar entropies $\Delta_r S^0_T/\nu$ for decomposition of various compounds. The recent analysis [8] revealed certain difference in $\Delta_r S^0_T/\nu$ for compounds decomposing to free metal atoms and to metal-containing molecules. The mean value of $\Delta_r S^0_T/\nu$ appeared to be 136 ± 9 J mol^{-1} K^{-1} in the first case and 160 ± 9 in the second. The uncertainty in $\Delta_r S^0_T/\nu$ (± 9 J mol^{-1} K^{-1}) results in an error in the enthalpy and parameter E of about 3%. Therefore, against the background of the total, random, and fixed errors, the effect of this factor is insignificant [9]. Furthermore, these values can be recalculated as soon as $\Delta_r S^0_T/\nu$ values are refined.

EXPERIMENTAL

The essence of the experiments consisted in determining the equilibrium constants of dehydration under high-vacuum conditions (in the absence of H_2O vapor in the reactor) and in air (in the presence of H_2O vapor in the reactor) with the aim of subsequently calculating reaction enthalpies. The sample weight loss per unit time $\Delta m/\Delta t$ and its temperature were measured with STA 429 and STA 449 Netzsch thermoanalyzers with TG and TG + DSC units, respectively. Open crucibles of internal diameter 5.7 mm and height 4.0 mm were used. The materials under study were $Li_2SO_4 \cdot H_2O$ (analytically pure grade) crystals grown at the laboratory and transparent pieces of talc mica (without inclusions) of thickness 0.2–0.5 mm. The composition of substances was preliminarily checked by the weight loss on heating. The surface area of samples S_0 was estimated with an MPB-2 ($\times 24$) microscope.

Experiments in a vacuum were carried out with an STA 429 analyzer. The chamber was evacuated up to a pressure of $n \times 10^{-8}$ bar with roughing and diffusion pumps. The measurements were carried out at continuous pumping under isothermal conditions. The experiments in air were carried out with both analyzers. The partial pressure of H_2O vapor was estimated by indications of a digital thermohygrometer (moisture percentage) and by H_2O saturated vapor pressure at room temperature.

The rate of heating the samples from room temperature to an intermediate temperature (5 K below the final temperature) was 4 deg min^{-1} for $Li_2SO_4 \cdot H_2O$ and 30 for talc. The heating rate from the intermediate

* Calculated by formulas (8) and (9).

to the final temperature was 1 deg min^{-1}. The furnace was heated at a chosen temperature for 5–10 min until a steady-state decomposition rate was attained. The change in the surface area of samples was taken into account in the calculations. We have found experimentally that the relative decrease in the surface area is proportional to $(1 - \alpha_m)^{2/3}$), where α_m is the decomposition degree at the moment of measurement. This dependence can be attributed to decreasing size of crystals. All primary signals ($\Delta m/\Delta t$) were corrected for the idle signal (0.02–0.07 $\mu g\,s^{-1}$), which depended on temperature and pressure and was measured independently with an empty crucible. The temperature was measured with a Pt–Pt/10% Rh thermocouple placed under a crucible bottom. The temperature variations during the measurement (usually 15–30 min) did not exceed ±0.2 K.

The experimental conditions and calculated enthalpies for both compounds are given in Table 1, and the enthalpy calculated for $Li_2SO_4 \cdot H_2O$ from the data of [14, 15], in Table 2. The averaged enthalpies and parameters E for $Li_2SO_4 \cdot H_2O$ and talc are given in Table 3. The entropy of dehydration of $Li_2SO_4 \cdot H_2O$ was calculated using $\Delta_r S_{298}^0/\nu$ = 175.9 $J\,mol^{-1}\,K^{-1}$ determined in [7]. For talc, we used the approximate value $\Delta_r S_T^0/\nu$ = 160 $J\,mol^{-1}\,K^{-1}$, which is valid for compounds decomposing to molecular products. The number of moles of primary products of talc decomposition is eight; therefore, $\Delta_r S_T^0$ = 1280 $J\,mol^{-1}\,K^{-1}$. The results obtained allow the following conclusions.

The most significant fact is the closeness of $\Delta_r H_T^0$ values obtained in a vacuum and in air (Table 1); hence, the primary step of the dehydration corresponds to the following mechanism of dissociative evaporation

$$Li_2SO_4 \cdot H_2O(s) \rightarrow Li_2SO_4(g)\downarrow + H_2O(g), \quad (10)$$

$$3MgO \cdot 4SiO_2 \cdot H_2O(s) \rightarrow 3MgO(g)\downarrow + 4SiO_2(g)\downarrow + H_2O(g). \quad (11)$$

In the case of talc, the condensation products are enstatite ($MgSiO_3$) and amorphous SiO_2 form [16], which also agrees well with the mechanism of the decomposition by dissociative evaporation–condensation. It is difficult to imagine that enstatite and amorphous silicon dioxide can be formed otherwise than by vapor deposition. Somewhat higher $\Delta_r H_T^0$ values for vacuum result from sample self-cooling under the conditions when the only source of its heating is radiation of crucible walls. In the case of $Li_2SO_4 \cdot H_2O$ at 330–360 K, the difference in $\Delta_r H_T^0$ and correspondingly in the sample temperatures in a vacuum and in air attains 10%. When talc is decomposed at 1220–1290 K, the difference is only 5%, which is attributable to the difference in the radiation power, which is known to be proportional to temperature raised to the fourth power. The measured rate of the dehydration in air practically rules out the influence of self-cooling on the measured $\Delta_r H_T^0$ because of the preferential contribution of the gas thermal conductivity to the sample heating.

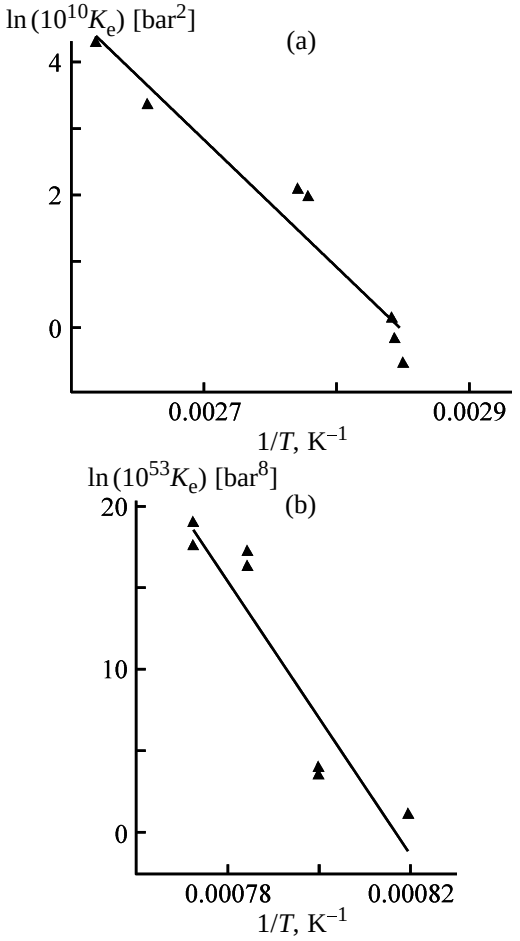

Fig. 1. Logarithm of the equilibrium constant K_e [(a) bar^2 and (b), bar^8] as a function of reciprocal temperature T for the decomposition of (a) $Li_2SO_4 \cdot H_2O$ and (b) talc in air.

The relative standard error in the determination of $\Delta_r H_T^0$ for both reagents is about 1% (Table 3). It confirms the high accuracy of the third-law method, which was theoretically justified earlier [8, 9]. In the case of the second-law method, the standard error is greater by more than an order of magnitude: $\Delta_4 H_T^0 = 160 \pm 27$ and 3500 ± 500 kJ mol^{-1} for $Li_2SO_4 \cdot H_2O$ and talc, respectively (Fig. 1). This difference agrees with the theoretical estimation. In fact, the difference in the accuracy of the results is determined by the ratio $T_{max}/(T_{max} - T_{min})$, where T_{max} and T_{min} are the maximal and minimal temperatures of the measurements. In the case of $Li_2SO_4 \cdot H_2O$ and talc, this ratio is 382/31 ≃ 12 and 1295/74 ≃ 17, respectively.

The enthalpy of $Li_2SO_4 \cdot H_2O$ dehydration in a vacuum, calculated by the third-law method from the data of [14, 15] (Table 2), practically coincides with our data for vacuum (Table 1). The average values are 208 and 209 kJ mol^{-1} K^{-1}, respectively. However, as mentioned above, both these results are overestimated owing to self-cooling. The only published value of E^i for talc dehydration [16] is 423 ± 17 kJ mol^{-1} (in Ar containing H_2O), which agrees well with the result of this study, E^i = 3995 kJ mol^{-1} (Table 3).

Unfortunately, the suggested method is inapplicable the decomposition of metal hydroxides. This is due to the presence of about 0.003% CO_2 in air, which reacts with metal oxides with partial formation of thermally stable carbonates. This conclusion was checked by the example of $Mg(OH)_2$ (brucite) dehydration. At 650 K, the apparent decomposition rate appeared to be 20–30 times less than the expected value (in the absence of CO_2 in reactor).

CONCLUSIONS

(1) A method was developed for determining the enthalpies of dehydration of various crystal hydrates (except for metal hydroxides). The method is simple, fast, precision, and free from errors caused by the self-cooling effect. It is based on the application of the Hertz–Langmuir equation to measuring the dehydration rates in air and of the third-law method to calculating the enthalpy. The values of $\Delta_r H_T^0$ found for $Li_2SO_4 \cdot H_2O$ and talc are 190.2 ± 1.5 and 2793 ± 34 kJ mol^{-1}, respectively.

(2) The equality of the enthalpies of $Li_2SO_4 \cdot H_2O$ and talc dehydration measured in a high vacuum (equimolar decomposition mode) and in air (isobaric mode) confirms the mechanism of dissociative evaporation of these compounds with simultaneous condensation of low-volatile products according to schemes (10) and (11).

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Solubility of Sodium Sulfate in a Mixed Solvent Water–Methyldiethanolamine at 25 and 35°C

Yu. A. Anufrikov, N. D. Fedicheva, and G. L. Kuranov

St. Petersburg State University, St. Petersburg, Russia

Received November 29, 2004

Abstract—The solubility of sodium sulfate in a mixed solvent water–methyldiethanolamine at 25 and 35°C was studied experimentally using the gravimetric method and gravimetric acid–base titration. The solubility diagrams obtained for the first time were compared with those of sodium sulfate in binary solvents monoethanolamine–water and diethanolamine–water.

Aqueous methyldiethanolamine (MDEA) solutions are widely used as sorbents of acid gases, such as hydrogen sulfide, carbon dioxide, and sulfur oxides. In industrial installations, the absorption of acid gases is frequently complicated by formation of strong electrolytes exerting the salting-out effect. For example, in a gas flow containing sulfur trioxide, the following process takes place in an aqueous MDEA solution:

$$SO_3 + H_2O + 2MDEA \rightarrow (MDEAH)_2SO_4.$$

The forming methyldiethanolammonium sulfate decreases the solubility of acid gases in an aqueous MDEA solution. The subsequent regeneration of the amine with a base yields sodium sulfate as by-product:

$$(MDEAH)_2SO_4 + 2NaOH \rightarrow 2MDEA + 2H_2O + Na_2SO_4.$$

This salt exerts the strong salting-out effect on acid gases [1, 2]. Therefore, when the content of Na_2SO_4 in an aqueous MDEA solution becomes high, this salt should be removed from the solution. In this context, it becomes necessary to know the Na_2SO_4 solubility in the MDEA–H_2O binary solvent. These data are of not only applied but also scientific importance, as giving new information on the phase equilibria in systems constituted by a salt and a mixed solvent.

In this study we determined the Na_2SO_4 solubility in the system at 25 and 35°C. The temperature of 35°C, at which the Na_2SO_4 solubility in water is maximal [3], was chosen as the upper temperature limit. The Na_2SO_4 solubility in the mixed solvent MDEA–H_2O was not measured previously.

EXPERIMENTAL

Anhydrous Na_2SO_4 (analytically purity grade), MDEA containing more than 99% main substance (Aldrich), chemically pure grade barium chloride and 5 wt % hydrochloric acid, $AgNO_3$ (pure grade), and Methyl Red indicator were used without additional purification. All solutions were prepared in freshly distilled water.

A mixture (about 50 ml) of Na_2SO_4 and MDEA was charged into a round-bottom flask and agitated in a temperature-controlled shaker to attain the thermodynamic equilibrium, i.e., to obtain a saturated solution of the salt in the binary solvent. To preset the overall composition of the mixture, each component was weighed with an accuracy of 0.1 mg. The equilibration time was determined in the course of the kinetic experiment by taking liquid phase samples at 12-h intervals and determining the content of Na_2SO_4 and MDEA in them. In solutions containing up to 30 wt % MDEA, the equilibration took 3 days; in those containing 30–50 wt % MDEA, 4 days; and in those with the amine concentration above 50 wt %, 5 days. The long equilibration time is due to the high viscosity of MDEA solutions.

The Na_2SO_4 concentration was determined gravimetrically. To do this, the sulfate ion was precipitated in the form of $BaSO_4$. The samples for the analysis were transferred into tightly closed weighing bottles with a pipet equipped with a finely porous filter on the tip to avoid ingress of small crystals of the bottom phase. Then, the bottles were weighed with an accuracy of 0.1 mg. The volume of the test samples was from 0.5 to 6 ml, depending on the Na_2SO_4 concentration. It corresponded to formation of 0.3 g of

1070-4272/05/7803-0386© 2005 Pleiades Publishing, Inc.

$BaSO_4$ and was estimated in a preliminarily experiment. The weighed samples were transferred into beakers, and their pH was adjusted with 10% HCl (1 ml). Then, they were heated to 70°C, and a 5% $BaCl_2$ solution was added dropwise with vigorous stirring. The precipitate obtained was kept for 3 h to mature, filtered through an ashless paper filter (blue tape), and repeatedly washed in warm water. The filters with the precipitate dried in air were placed into quartz crucibles, which were calcined to constant weight, ashed, and calcined in a muffle furnace at 900°C for 4 h. The calcination time was determined experimentally: longer calcination did not further change the weight of the crucibles and their contents.

The MDEA concentration was determined by the adapted procedure of the gravimetric acid–base titration. From 0.5 to 6 ml of the test solution was sampled into a conical flask with a ground-glass neck. To the weighed solution, 30 ml of water and Methyl Red indicator were added. After that, the test solution was titrated with an HCl solution (0.1 mol kg^{-1} H_2O). The volume of the test solution was chosen so that about 20 ml of the HCl solution was spent for the titration. This volume ensured sufficient experimental accuracy and was convenient to fix the color transition point (from yellow to crimson). The amount of the acid spent for titration was determined to within 0.1 mg by weighing. To standardize the titrant, the chloride ions were precipitated in the form of AgCl by the standard procedure [4] and determined gravimetrically.

The composition of the solid phase was determined by the Schreinemakers method. In the procedure used, Schreinemakers path was passed from the point of the liquid phase composition through the point of the overall composition preset in preparation of the three-component mixture.

Each concentration of Na_2SO_4, determined gravimetrically, and MDEA, determined titrimetrically, was an averaged result of three replicate measurements; the scatter of the results did not exceed 0.3 rel. %.

This method was checked by determining the Na_2SO_4 and MDEA concentrations in a ternary solution of a known composition. The preset and experimentally determined concentrations coincided within 0.2 rel. %.

Our experimental results are presented in Table 1, and the compositions of the saturated solutions, along with the overall compositions used in construction of the Schreinemakers paths, in Table 2. The solubility diagrams in the Na_2SO_4–MDEA–H_2O system, constructed from the data obtained, are shown in Fig. 1.

35	21.33	14.13	18.79	20.75	Na_2SO_4
	30.45	8.325	27.37	17.66	Na_2SO_4
	48.37	1.811	44.36	9.979	Na_2SO_4
	64.09	0.418	59.44	8.264	Na_2SO_4

The saturated solution coexists with the crystal hydrate $Na_2SO_4 \cdot 10H_2O$ in the range of the MDEA concentrations below 15 wt % at 25°C. As the MDEA concentration is increased, the solid phase changes for anhydrous Na_2SO_4. At 35°C, the solid phase coexisting with the saturated solution over the entire range of the MDEA concentrations is anhydrous Na_2SO_4. The presence of the crystal hydrate at 25°C and its absence at 35°C is in agreement with the data on the $Na_2SO_4 \cdot H_2O$ binary system [3], according to which the saturated aqueous Na_2SO_4 solution coexists with the

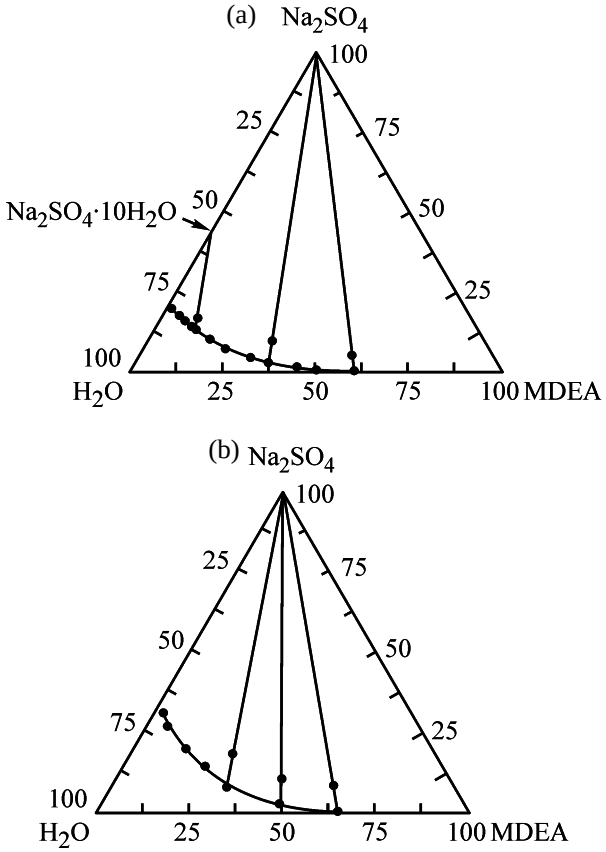

Fig. 1. Solubility diagrams (wt %) of the MDEA–Na_2SO_4–H_2O system. Temperature (°C): (a) 25 and (b) 35; the same for Fig. 2.

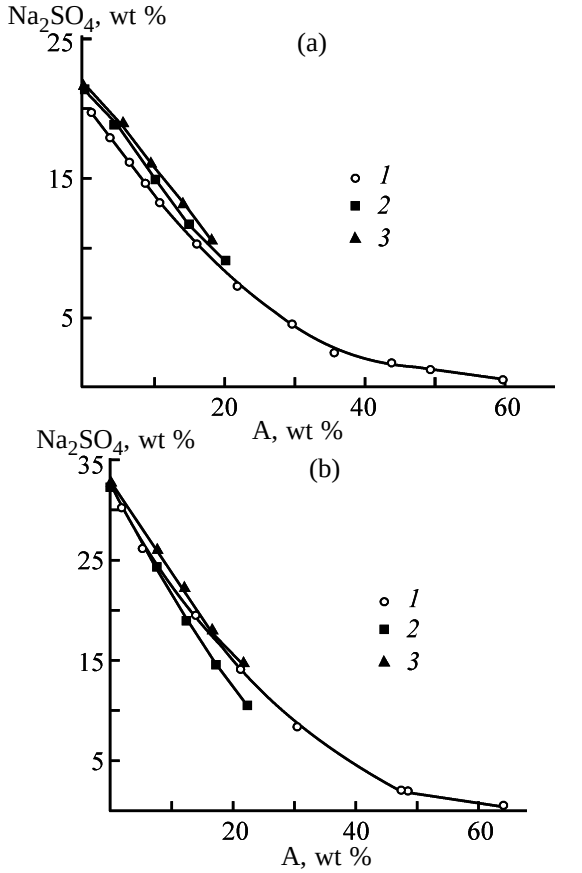

Fig. 2. Solubility isotherms of Na_2SO_4 in mixed solvents (*1*) MDEA–H_2O, (*2*) MEA–H_2O, and (*3*) DEA–H_2O. (A) amine.

$Na_2SO_4 \cdot 10H_2O$ solid phase up to 32.38°C; above this temperature, this crystal hydrate decomposes.

As noted above, published data on the solubility in the Na_2SO_4–MDEA–H_2O system are lacking. The solubility of Na_2SO_4 in aqueous solutions of monoethanolamine (MEA) and diethanolamine (DEA) was studied in [5, 6]. The experimental results of our study, along with the known data for the above systems, are plotted in Fig. 2. As seen, the Na_2SO_4 solubilities in the binary solvents MEA–H_2O and DEA–H_2O are close. The solubility of Na_2SO_4 in the mixed solvent MDEA–H_2O is lower than in both the above binary solvents. At 35°C, the solubility in the DEA–H_2O system is higher than in the MEA–H_2O system. The solubility isotherm of Na_2SO_4 in the mixed solvent MDEA–H_2O at 35°C lies between the isotherms taken in the other two systems and is closer to the Na_2SO_4 solubility curve in the DEA–H_2O solvent.

The comparison of the solubility diagrams at 25 and 35°C, obtained in this study, shows that, in the range of the MDEA concentrations 0–40 wt %, the Na_2SO_4 solubility at 35°C is considerably higher. As the amine concentration is increased, the solubility of the salt in the MDEA–H_2O binary solvent decreases and the temperature dependence of the solubility becomes less pronounced. At an MDEA concentration of about 50 wt %, the solubility curves for both temperatures virtually merge together, with the solubility in this region being about 1.5 wt % and tending to zero at higher MDEA concentrations. The low solubillity of Na_2SO_4 in concentrated MDEA solutions can be of interest for practice, since these solutions, as less corrosive than those of other alkanolamines, recently found use as sorbents of acid gases [7]. Probably, the low solubility of Na_2SO_4 in concentrated aqueous MDEA solutions will allow their use for sorption of acid gases without additional treatment to remove Na_2SO_4.

CONCLUSIONS

(1) Experimental data on the solubility of Na_2SO_4 in the MDEA–H_2O binary solvent at 25 and 35°C were obtained.

(2) The compositions of the solid phase coexisting with the saturated solution were determined by the Schreinemakers method.

(3) Qualitative trends in the influence of temperature on the solubility in the ternary system were revealed.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Mutual Solubility of Components and Critical Solution Points in the System Water–Isopropyl Alcohol–*n*-Dodecane in the Temperature Range 5–120°C

S. I. Sinegubova, K. K. Il'in, and D. G. Cherkasov

Chernyshevskii Saratov State University, Saratov, Russia

Received June 30, 2004

Abstract—The mutual solubility of components and critical solution points in the ternary system water–isopropyl alcohol–*n*-dodecane were studied by a visual-polythermal technique at saturated vapor pressure in the temperature range 5–120 °C. The mixture composition in the critical solution point was studied in relation to temperature.

The mutual solubility of components in ternary systems water–aliphatic alcohol–*n*-alkane was studied by numerous researchers. In [1], the mutual solubility of components in 19 ternary systems was analyzed in relation to the molecular structure of particular components and features of intermolecular interactions. The isothermal and polythermal solubility diagrams of several systems of this kind were studied in detail in [2–5]. It was shown in these papers that the critical solution point is an important characteristic of the phase diagram, because its location reflects the mutual solubility of components and their interaction in the system. Therefore, in studying the mutual solubility of liquid compounds, the location of the critical solution point in the phase diagram and factors influencing the system composition in this point should be determined. The temperature effect on the mixture composition in the critical solution point at a constant pressure was studied only for a few ternary systems and in a narrow temperature range.

In this study we examined the influence of temperature on the mutual solubility of components and the composition of the critical point in the system water–isopropyl alcohol–*n*-dodecane at saturated vapor pressure in the temperature range 5–120°C. This system was not studied previously.

EXPERIMENTAL

All the compounds used in our experiments were thoroughly purified. Water was purified on a DEM-20 MERA-POLNA double-distiller. The initial isopropyl alcohol (chemically pure grade) containing 99.8% main compound was dried over calcined K_2CO_3 for a day, decanted, and then distilled on a 0.3-m Vigreux column, and the fraction with bp 82.2–82.4°C was collected. The purified isopropyl alcohol was stored over molecular sieves (4 Å). *n*-Dodecane (chemically pure grade) was dried over molecular sieves (4 Å) and used without further purification. All the liquids were identified by their boiling point, refractive index, and density. These characteristics were in good agreement with the reference data [6].

The temperature of the phase transition from a two-phase mixture ($l_1 + l_2$) to a homogeneous state (l) $l_1 + l_2 = l$ in the ternary systems was determined in sealed test tubes by the visual polythermal technique [7] with ±0.1°C accuracy. The required temperature was maintained with a Mechanic Medingen U-10 thermostat and was monitored with calibrated decimal mercury thermometers in the temperature ranges 0–50, 50–100, and 100–150°C. The relative accuracy of determining the composition of the coexisting equilibrium phases did not exceed ±0.5%.

The compositions of the ternary system in the critical solution points were determined by the phase volume ratio technique [8]. We chose such compositions of ternary mixtures water–isopropyl alcohol–*n*-dodecane at which the mixture exhibited the critical opalescence in the vicinity of the critical solution point (±0.1 C) and separated into two liquid phases of equal volume. The critical behavior of the systems under consideration was studied in sealed graduated test tubes. The phase volumes were determined with an accuracy of about 5%.

1070-4272/05/7803-0390© 2005 Pleiades Publishing, Inc.

The critical solution point was considered to be equilibrium if, in approaching from both the higher and lower temperatures, the equal values were obtained.

In studies of mutual solubility of components in the ternary system (Fig. 1), their trigonal phase diagrams were built with 15 sections as follows. Sections *I–III*: constant water to isopropyl alcohol weight ratio [(*I*) 80 : 20, (*II*) 50 : 50, and (*III*) 36 : 64] and varied *n*-dodecane content; sections *IV–XIII*: constant isopropyl alcohol to *n*-dodecane weight ratio [(*IV*) 80 : 20, (*V*) 75 : 25, (*VI*) 70 : 30, (*VII*) 60 : 40, (*VIII*) 55 : 45, (*IX*) 50 : 50, (*X*) 45 : 55, (*XI*) 40 : 60, (*XII*) 30 : 70, and (*XIII*) 20 : 80] and varied water content; sections *XIV* and *XV*: constant dodecane to water weight ratio [(*XIV*) 43 : 57 and (*XV*) 21 : 79] and varied isopropyl alcohol content.

The polytherms of the mutual solubility of the components in the ternary systems, built with fifteen sections of the phase diagrams, have similar shape: the solubility curve separates the field of homogeneous solutions from the field of separation into two liquid phases (not illustrated). Of particular interest are the polytherms of systems corresponding to sections *VI–XI* in which the critical solution points were determined. For systems located on these and several similar sections, the critical solution points and the corresponding system compositions were determined by the phase volume ratio technique. Figure 2 shows the water and *n*-dodecane content in the critical solution points in relation to temperature.

The curves in this plot are the orthogonal projections onto the composition–temperature planes of the critical solution curve located on the surface of the three-dimensional region of separation of the ternary systems into two phases in the prismatic phase diagram.

The mutual solubility of components and the system composition in the critical points were determined from the polythermal curves by graphic interpolation technique at 5.0, 10.0, 20.0, 25.0, 30.0, 40,0, 50.0, 60.0, 70.0, 80.0, 90.0, 100.0, 110.0, and 120.0°C. These data for 5.0, 25.0, 50.0, 80.0, and 120.0°C are presented in the table and Fig. 1. The isotherms of the mutual solubility of the components at these temperatures are shown in Fig. 1. The *CC* curve is the orthogonal projection of the critical solution curve of two-phase systems onto the base of the prismatic phase diagram. These results show that the mutual solubility of the components increases with increasing temperature.

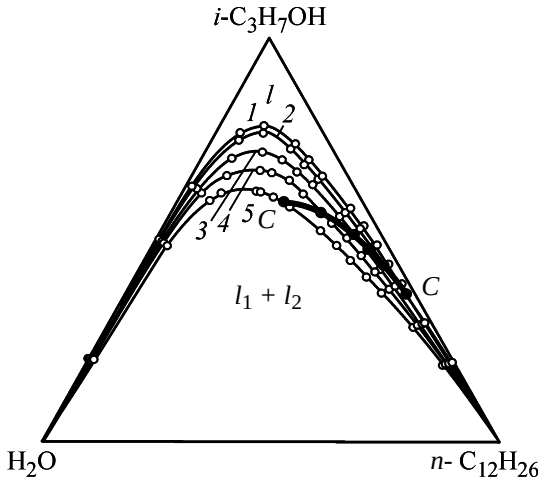

Fig. 1. Isotherms of mutual solubility of components in the system water–isopropyl alcohol–*n*-dodecane at (*1*) 5.0, (*2*) 25.0, (*3*) 50, (*4*) 80.0 and (*5*) 120.0 °C. (*CC*) critical solubility curve.

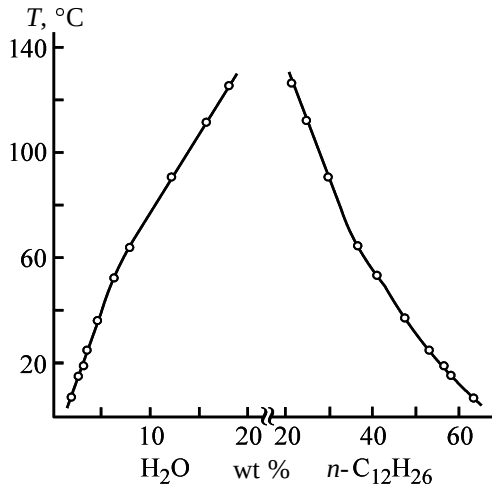

Fig. 2. Temperature dependence of the water and *n*-dodecane content in the critical solution points of the system water–isopropyl alcohol–*n*-dodecane.

Figure 2 shows that, with increasing temperature, the critical mixtures are enriched in water and depleted of dodecane. As a result, the critical solution points shift toward the maximum of the binodal curves (Fig. 1). At 5.0 and 25.0°C (curves *1, 2*), the critical points are located in the vicinity of the triangle side corresponding to the binary system *n*-$C_{12}H_{26}$–*i*-C_3H_7OH, virtually on the tangent to the binodal curve passing from the *n*-$C_{12}H_{26}$ apex. According to an approach to analysis of multiphase multicomponent systems developed by Mertslin [9], this kind of binodal curve shows that, in the ternary systems under consideration, the molecular interactions typical of the binary system water–isopropyl alcohol prevail.

* Critical solution point.

At the highest temperature (120°C), the critical solution point shifts to the maximum of the binodal curve (Fig. 1, curve *5*). According to the Mertslin approach, this means that, on heating of the ternary system from 5 to 120°C, the intermolecular interactions governing the phase behavior change from those typical of the binary system water–isopropyl alcohol to the interactions typical of the system *n*-dodecane–isopropyl alcohol. We believe that the shift of the critical solution points with increasing temperature is caused by breakdown of isopropyl alcohol hydrates with weakening of interactions between isopropyl alcohol and water molecules in the ternary system.

CONCLUSIONS

(1) The mutual solubility of components in the ternary system water–isopropyl alcohol–*n*-dodecane and the composition of this system in the critical solution point were determined in the temperature

range 5.0–120°C. The mutual solubility of the components increases with temperature.

(2) It was suggested that, in heating the system water–isopropyl alcohol–*n*-dodecane, the shift of both the critical solution point and the binodal maximum is caused by the replacement of the intermolecular interactions typical of the binary system water–isopropyl alcohol by those typical of the system *n*-dodecane–isopropyl alcohol, due to breakdown of isopropyl alcohol hydrates.

(3) The phase diagrams of the system water–isopropyl alcohol–*n*-dodecane in a wide temperature range can be used in extraction practice and as reference data.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Salting-Out of *n*-Propyl Alcohol with Potassium Nitrate from Aqueous Solutions

S. I. Sinegubova, D. G. Cherkasov, and K. K. Il'in

Chernyshevskii Saratov State University, Saratov, Russia

Received December 6, 2004

Abstract—The solubility of components and critical phenomena in the ternary system constituted by potassium nitrate, water, and *n*-propyl alcohol were studied by the visual polythermal method in the temperature range 25–80°C. The temperature of formaiton of the critical node of the monotectic equilibrium (critical solution–solid phase) and the solution compositions corresponding to the critical solution points at different temperatures were determined. The isothermal solubility diagrams of the system were constructed and the distribution coefficients of *n*-propyl alcohol at different temperatures were calculated. A comparative analysis of the salting-out effect exerted by potassium nitrate on aqueous solutions of *n*-propyl alcohol and isopropyl alcohol was done.

The salting-out of *n*-propyl alcohol from aqueous solutions with various salts has been studied by many researchers [1–4]. However, data on the influence of alkali metal nitrates on the phase separation of mixtures constituted by water and propanol are lacking. In this study we examined the phase equilibria and critical phenomena in the ternary system $KNaO_3$–H_2O–C_3H_7OH in the temperature range 25–80°C to reveal the temperature dependences of the salting-out effect.

EXPERIMENTAL

The phase equilibria in the ternary system KNO_3–H_2O–*n*-C_3H_7OH were studied by the visual polythermal method [5]. Experimental procedures and pretreatment of potassium nitrate and water have been described in detail in [6]. Chemically pure grade *n*-propyl alcohol (containing more than 99.5% main substance) was used without purification, since its constants (T_b = 97.4°C, n_D^{20} = 1.3850) coincided with the reference data [7]. KNO_3 and *n*-C_3H_7OH were stored over calcined $CaCl_2$ in desiccators protected from direct light.

The compositions of the component mixtures were varied along ten sections of the concentration triangle of the system under study. The component mixtures belonging to sections *I*–*VIII* had a varied content of KNO_3 and the constant weight ratio of *n*-propyl alcohol to water: (*I*) 10 : 90, (*II*) 24 : 76, (*III*) 37 : 63, (*IV*) 50 : 50, (*V*) 58 : 42, (*VI*) 71 : 29, (*VII*) 83 : 17, and (*VIII*) 90 : 10. The component mixtures belonging to section *IX* had the constant content of the salt (30.00 wt %) and the varied weight ratio of *n*-propyl alcohol to water, whereas the component mixtures along section *X* had the varied content of alcohol (up to 18 wt %) and the constant weight ratio of KNO_3 to water (65 : 35).

For all the sections, polytherms of the phase states of the system were plotted. The polytherms of sections *IX* and *X* allowed determination of the temperature at which the critical node of the monotectic equilibrium (critical solution–solid phase) is formed, which corresponds to the onset of phase separation in the system (Fig. 1). The polytherm of the phase states along section *IX* comprises four curves which converge to a common point and delimit four fields of phase states, those of unsaturated solutions *l*, saturated solutions $l + S$, phase separation $l_1 + l_2$ (l_1 is alcohol phase and l_2, aqueous phase), and monotectic equilibrium $l_1 + l_2 + S$. The solid phase is potassium nitrate. The polytherm of section *X* has two fields of phase states, $l + S$ and $l_1 + l_2 + S$. In going from the saturated into the monotectic state, critical phenomena in the system of two liquid phases were observed in both sections. The region of critical points corresponding to the compositions of the solution with a critical opalescence is encircled with a dashed line, and the critical point corresponding to a mixture with equal volumes of liquid phases is denoted by a large circle and letter *C*. Evidently, this point *C* corresponds to a mixture composition belonging to the critical node *CS* (critical solution–solid phase), which appears in

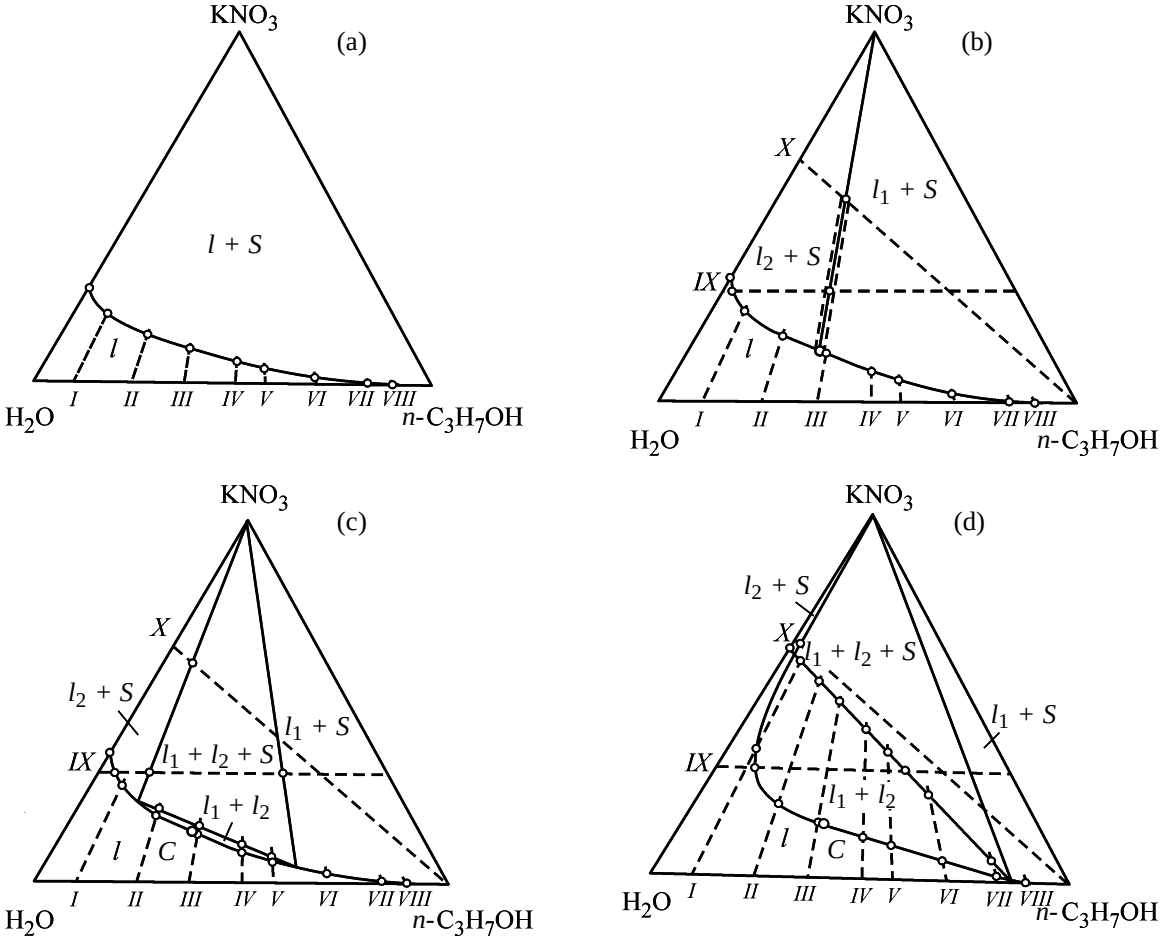

Fig. 2. Isotherms of the phase states of the KNO_3–H_2O–*n*-C_3H_7OH system at (a) 25.0, (b) 32.1, (c) 35.0, and (d) 80.0°C.

the field of saturated solutions at 32.1°C. This temperature corresponds to the onset of the phase separation in the system.

The temperature dependence of the solution composition corresponding to the critical solution point was found. For this purpose, we studied the component mixtures belonging to additional sections and having a varied content of KNO_3 and the constant weight ratio of water to the alcohol. We found that the composition of the critical solution changes only slightly with temperature (Table 1).

The polytherms and the temperature dependences of the composition of the critical solution were used to plot the isothermal phase diagrams of the system at 25.0, 32.1, 35.0, 50.0, and 80.0°C. At temperatures in the range from 25.0 to 32.1°C, a simple diagram of KNO_3 solubility in mixtures of water and *n*-propyl alcohol is observed. For example, at 25.0°C, there is a field of homogeneous solutions *l*, separated by a smooth curve of solubility from the field of saturated solutions $l + S$ (Fig. 2a). At 32.1°C, a critical point *C* appears on the solubility line (Fig. 2b). This point corresponds to a mixture in which two liquid phases, $l_1 + l_2$, have identical compositions and properties. As the critical liquid phase *C* is in equilibrium with the solid phase *S* (KNO_3), there appears a critical node *CS* of the monotectic equilibrium. The composition of the critical liquid phase *C* of the node *CS* was determined graphically in the concentration triangle from the point of interception of the critical node with the solubility line.

As the temperature is raised, the critical node transforms, as seen from the isotherm at 35.0°C (Fig. 2c), into a monotectic triangle $l_1 + l_2 + S$, with the adjacent field of phase separation $l_1 + l_2$ with the critical solution point *C* and the fields of saturated solutions $l_2 + S$ and $l_1 + S$. As the temperature is raised further, the isotherms of phase states do not change qualitatively, but the fields of the monotectic state and phase separation increase in size, and the fields of saturated solutions become narrower, as seen from the diagram at 80°C (Fig. 2d).

Table 2. Compositions of the liquid phases of the monotectic equilibrium and distribution coefficients K_d of *n*-propyl alcohol in the ternary system KNO_3–H_2O–*n*-C_3H_7OH

* Composition of liquid phase in the critical node of the monotectic equilibrium (critical solution–solid phase).

The results obtained in determining the solubility of the system components are listed in Table 1. Data on the solubility of KNO_3 in water were taken from a reference book [8]. The compositions of the liquid phases of the monotectic equilibrium (Table 2) were found graphically by plotting the triangles of the monotectic equilibrium on the plane of the concentration triangle at different temperatures (Fig. 3). The dashed line *aCb* (Fig. 3), which reflects the variation of the compositions of the equilibrium liquid phases of the monotectic with temperature, consists of two branches. The composition of the aqueous phase l_2 varies along branch *Ca* and that of the organic phase, along branch *Cb*. As the temperature increases, the aqueous phase is enriched with the salt and depleted of the alcohol, and the organic phase is enriched with the alcohol and depleted of water and the salt.

The distribution coefficient K_d of the alcohol was calculated as the ratio of the concentrations of the alcohol in the organic and aqueous phases of the monotectic equilibrium (Table 2). The fact that the distribution coefficient grows with temperature indicates that the effect of salting-out of *n*-propyl alcohol with potassium nitrate from aqueous solutions is enhanced. Evidently, this is due to decomposition of alcohol hydrates [9, 10] and to a significant increase in the concentration of KNO_3 in the aqueous phase.

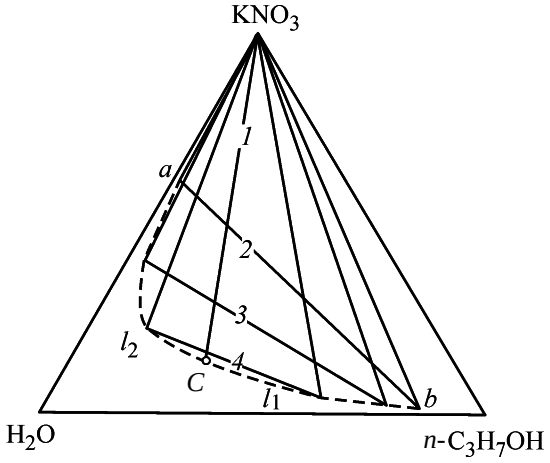

Fig. 3. Variation with temperature of the compositions of the liquid phases of the monotectic equilibrium and of the position of the monotectic triangle in the KNO_3–H_2O–*n*-C_3H_7OH system. T (°C): (*1*) 32.1, (*2*) 35.0, (*3*) 50.0, and (*4*) 80.0.

Comparison of the results obtained in the polythermal studies of phase equilibria in the KNO_3–H_2O–*n*-C_3H_7OH and KNO_3–H_2O–*i*-C_3H_7OH [6] systems revealed an analogy between the topological transformations of their phase diagrams with temperature. The difference is in the onset temperature of phase separation: 32.1°C in the system with *n*-propyl alcohol and 47.2°C in that with isopropyl alcohol. At equal temperatures and concentrations, the excess enthalpy of mixing in the H_2O–*n*-C_3H_7OH system at relatively low alcohol concentrations is less negative than in the H_2O–*i*-C_3H_7OH system [11]. This indicates that the interactions between H_2O and isopropyl alcohol are stronger. Apparently, this fact is responsible for a decrease in the onset temperature of phase sepaation and for a higher distribution coefficient of the alcohol in the KNO_3–H_2O–*n*-C_3H_7OH system compared to that in the KNO_3–H_2O–*i*-C_3H_7OH system (Table 3).

Table 3. Distribution coefficients K_d of alcohol and temperature of the onset of phase separation in the ternary systems H_2O–KNO_3–*n*-C_3H_7OH (*i*-C_3H_7OH)

Alcohol	K_d at indicated T, °C		T_{CS},* °C
	50.0	80.0	
n-C_3H_7OH	19.6	56.1	32.1
i-C_3H_7OH	5.5	33.6	47.2

* (T_{CS}) Temperature of formation of the critical node of the monotectic equilibrium.

CONCLUSIONS

(1) The phase equilibria in mixtures of components along ten sections in the composition triangle of the ternary system constituted by potassium nitrate, water, and *n*-propyl alcohol were studied in the temperature range 25–80°C by the visual polythermal method. The temperature corresponding to the onset of phase separation in the system is 32.1°C.

(2) The distribution coefficient of *n*-propyl alcohol between the liquid phases of the monotectic equilibrium increases with temperature.

(3) At equal temperatures in the range 50–80°C, the effect of salting-out of *n*-propyl alcohol from aqueous solutions with potassium nitrate is stronger than that of isopropyl alcohol. In the system with *n*-propyl alcohol, the temperature of formation of the critical node of the monotectic equilibrium is lower than in that with isopropyl alcohol.

Abstract—Liquid–vapor equilibrium in the binary subsystems of the ethylbenzene–*o*-xylene–α-methylstyrene–*p*-vinyltoluene–dicyclopentadiene–indene system was predicted using UNIFAC group model and studied experimentally. To assess the reliability of parameters, the liquid–vapor equilibrium was studied experimentally in the ternary systems and compared with the calculated data.

Petroleum polymeric resins (PPRs) are widely used as a rosin substitute and in production of paintwork materials, wooden fiberboards, adhesive solutions, and anticorrosive coatings. Waste and side products of petroleum-chemical production, and, first of all, liquid products of hydrocarbon pyrolysis are the raw materials for PPR production [1].

Unsaturated reactive hydrocarbons are the resin-forming components. Their content in the raw material should be no less than 30%. In addition, it may contain admixtures decreasing the quality of the polymers synthesized, which makes necessary appropriate pretreatment of the raw material.

The requirements to the raw material are determined by the properties of PPR formed, polymerization conditions, and catalytic systems used, which allows selection of the method of the raw material preparation. As a rule, distillation is used to separate pyrocondensate components.

Ethylene and propylene monomers are gaseous products of the pyrolysis of hydrocarbon raw material, in particular, straight-run naphtha. The residual (after ethylene or propylene separation) pyrocondensate contains a lot of components with unsaturated bonds, namely, styrene, α- and β-methylstyrenes, vinyltoluenes, allylbenzene, dicyclopentadiene, indene, and indan in a mixture with such solvents as toluene, xylene, ethylbenzene, propylbenzene, and cumene. High-molecular-weight resinous products can also be present. This pyrocondensate can be used to prepare PPRs (which are the components of varnishes and paints) after removal of solvents, dicyclopentadiene (DCPD), and tars.

Although DCPD is unsaturated hydrocarbon and hence a resin-forming component, its presence in the raw-material is undesirable. The point is that powdered aluminum chloride used as a catalytic system polymerizes DCPD to form insoluble in PPR cross-linked polymers, which is inadmissible. High content of DCPD favors formation of the intensely colored polymerizate, which is also undesirable.

With regard to the above facts, the raw material preparation includes distillation of highly resinous liquid products of the pyrolysis of straight-run naphtha with high content of oligomers and monomers.

To develop the process for distillation separation of the pyrocondensate, we have analyzed the known properties of substances comprising PPR [2, 3]. Many components of the mixture to be separated have close boiling point, which makes it impossible to solve the task by the elementary distillation. The mixture contains thermolabile components, capable of polymerization, which requires addition of polymerization inhibitors and reduced pressure in the distillation column.

Preliminarily, we reduced the dimension of the initial concentration space by discrimination of certain homologs, isomers, and components with low concentrations [4]. To develop the process for separation by distillation, the system ethylbenzene (EB)-*o*-xylene (*o*-X)–styrene (S)–α-methylstyrene (α-MS)–*p*-vinyl-

toluene (*p*-VT)–DCPD–indene (I) was taken as an initial system.

The development of a process for separation of the above mixture requires the information on the liquid–vapor equilibrium (LVE) in binary systems constituting the total system. For the initial seven-component mixture, the number of binary subsystems is 21. In the case of *o*-X–S and EB–S subsystems, the data on LVE are known [5, 6]. For certain systems, such data were obtained experimentally by the method described in [5] at P = 760 mm Hg; for the other subsystems, they were predicted using UNIFAC group model.

In the first stage of the experimental study, the initial substances were purified [7–9]. The purity was

checked by the boiling point, refractive index, and chromatographically on an LKhM-80 chromatograph, model 1, with a catharometer as a detector and with temperature programming. A Separon porous polymer was used as a chromatographic phase. The composition of the mixture analyzed was calculated by normalization of the peak areas with regard to correction factors [10].

The liquid–vapor equilibrium we studied as the dependence of the boiling point on the liquid–phase composition under the isobaric conditions (*X*–*P*–*T*) at 760 mm Hg using the Gillespie circulating device [5].

The binary systems were prepared gravimetrically with 10^{-4} g error at 100–120-g weight of samples. The boiling point was measured with a mercury thermometer with a 0.1°C error, with correction for the pressure and projecting mercury column [5, 9].

The results of the experiments on LVE are listed in Table 1.

For certain binary subsystems, the data on LVE were obtained using UNIFAC group model. Fragmentation of molecules into group components was standard and unambiguous; the parameters of group interaction were taken from [11].

To describe and predict the liquid–vapor equilibrium in binary and multicomponent systems and to calculate the distillation process, we examined the temperature dependence of the vapor pressure of the individual substances using the Antoine equation:

$$\log P_0 = A - B/(C + T),$$

where P_0 is the vapor pressure (mm Hg); *T*, temperature (°C); *A*, *B*, and *C*, constants of Antoine equation.

The Antoine equation constants were calculated using published data [12] within the 5–760 mm Hg range; their values are shown in Table 2.

All the seven binary systems are azeotropic, some of them are close to ideal, and the other systems approach the square diagonal at low or high concentrations of the low-boiling component. Typical dependences of the vapor composition on the liquid composition in the systems studied are shown in the figure.

The experimental, previously published, and predicted (UNIFAC) data on LVE in the binary systems we described by the Wilson equation [13] using the software developed at the Karpov Research Physicochemical Institute. The Wilson parameters obtained are so-called major dimensionless parameters.

Table 2. Constants of Antoine equation

A set of parameters of binary interaction lies in the basis of the mathematical model of the liquid–vapor phase area for the mixture studied; it is necessary for performing computer experiments on distillation. The parameters of binary interaction for binary subsystems of the mixture studied (λ_{12} and λ_{21}) and the average and maximal boiling point deviations are listed in Table 3.

As seen, the calculated data reasonably agree with the experimental and pseudo-experimental data, since the average and maximal deviations do not exceed 1% relative to the boiling point of the components.

The reliability of the parameters obtained can be assessed by simulation of LVE in the ternary systems and comparison of the results obtained with the experimental data.

The LVEs in the ternary subsystems were studied experimentally. For a limited number of points of the

concentration field, we determined the dependences of the boiling points on the liquid phase composition by the above method. The results are listed in Table 4.

To simulate liquid–vapor equilibria in the ternary systems, we used a set of the parameters of the binary interaction in the Wilson equation (Table 3). The calculated boiling points in the ternary systems are listed in Table 4. As seen, the calculated boiling points reasonably agree with the experiment (the difference between them does not exceed of 1°C), confirming the reliability of the parameters of the binary interaction.

CONCLUSIONS

(1) The parameters of the Antoine equation for calculating the vapor pressure of the individual substances at various temperatures were determined.

(2) The mathematical description of the experimental and pseudo-experimental data was performed. The set of parameters of binary interaction between the components of the mixture studied was obtained, allowing simulation of the liquid–vapor equilibrium in multicomponent systems and realization of computer experiments on distillation.

(3) The reliability of the binary interaction parameters was confirmed by the comparison of the calculated and experimental values describing the equilibrium in the ternary systems.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Solubility of Adipic Acid in Organic Solvents and Water

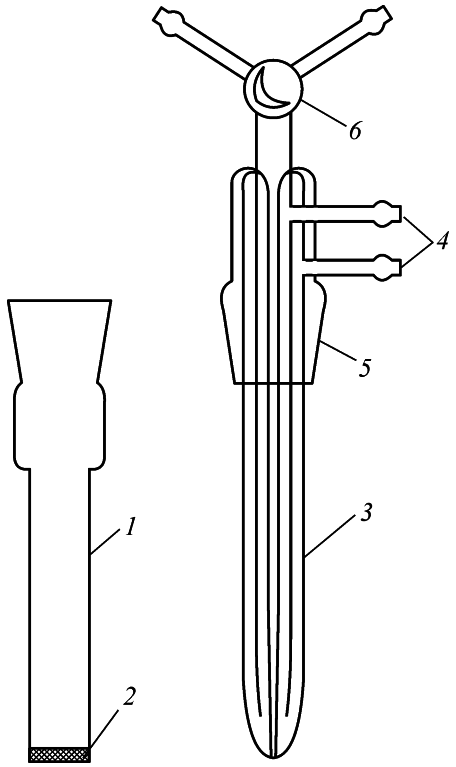
A. N. Gaivoronskii and V. A. Granzhan

Khimtekhnologiya State Research and Designing Institute of Chemical Engineering, Severodonetsk, Lugansk oblast, Ukraine

Received December 22, 2004

Abstract—The solubility of adipic acid in methanol, ethanol, propanol, isopropanol, *n*-butanol, *tert*-butanol, acetone, 1,4-dioxane, acetic acid, and water was measured within the 0–60°C temperature range. A sampler for determination of the temperature dependence of the solubility of solids in liquids by the isothermal method was suggested. The thermodynamic parameters of solution of adipic acid in the above solvents were calculated. The dependence of the solubility on the solvent and temperature was considered.

Adipic acid (AA) is a large-capacity product used mainly in fiber production. The solubility of solids in liquids is one of the most important process parameters and is of scientific interest for the development of the solution theory.



EXPERIMENTAL

Analytically pure grade adipic acid was recrystallized twice from water and dried at 120°C. Its melting point was 151.5±0.2°C, which agrees with the most reliable published data [1]. Chemically pure and analytically pure grade organic solvents were dried by standard procedures [2]. Acetone and alcohols were kept for a day over drierite and then distilled. 1,4-Dioxane was kept over KOH for two weeks, refluxed over sodium metal for a day, and then distilled. Acetic acid had mp 16.6°C after twofold freezing. The water content in solvents was no higher than (wt %): 0.04 in methanol, 0.08 in ethanol, 0.06 in propanol, 0.06 in isopropanol, 0.08 in *n*-butanol, 0.08 in *tert*-butanol, 0.02 in acetone, 0.02 in 1,4-dioxane, and 0.1 in acetic acid. The water content in acetic acid was determined using the melting point depression curve [3] and in the other solvents, by Fischer titration. Double-distilled water was used.

The AA solubility was determined by the isothermal method. The thermodynamic equilibrium between excess solid phase at the solvent was attained by continuous agitation and a constant temperature with a device consisting of a U-10 ultrathermostat and a mechanical stirrer. The stirrer was mounted on the thermostat lid.

To determine the solubility, adipic acid and a solvent were charged into 100–200-ml flasks with ground-glass stoppers. The flasks were fixed on a coupling rod and introduced into a thermostat. The flask contents were stirred by reciprocal motion of the flask, provided by a synchronous electric motor (e.g., SD-54 motor with 60 rpm rotation speed) equipped with a crank system. The temperature was kept constant to within ±0.1°C.

To measure the solubility by the isothermal method, solution samples should be taken for analysis in

Sampler: (*1*) tube, (*2*) glass frit. (*3*) temperature-controlled pipet, (*4*) connecting tubes, (*5*) conical ground-glass joint, and (*6*) stopcock.

Methanol	0.0218	0.0306	0.0422	0.0576	0.0775	–
Ethanol	0.01618	0.0212	0.0326	0.0453	0.0624	0.1146
Propanol	0.01014	0.01569	0.0232	0.0338	0.0485	0.0953
Isopropanol	0.01238	0.01913	0.0287	0.0422	0.0601	0.1125
Butanol	0.00861	0.01305	0.01934	0.0284	0.0411	0.0829
tert-Butanol	–	–	0.0503	0.0649	0.0825	0.1259
Acetone	0.00650	0.00941	0.01351	0.0193	0.0274	–
1,4-Dioxane	–	0.0242	0.0347	0.0487	0.0670	0.1215
Acetic acid	–	–	0.01731	0.0250	0.0362	0.0731
Ideal solubility	0.00376	0.00630	0.01009	0.01592	0.0245	0.0548

definite time intervals up to attaining the thermodynamic equilibrium (e.g., formation of the saturated solution). The solution is in contact with adipic acid crystals and should be filtered. This is done using various samplers equipped with a glass frit [4–6]. In addition, when the temperature of the solution exceeds the room temperature, it is necessary to prevent crystallization in the solution during sampling. Our sampler (see figure) solves both these problems.

The sampler consists of a tube *1* with a glass frit *2* and a temperature-controlled pipet *3*. Before sampling, tubes *4* are attached to a thermostat for attaining the temperature of the solution studied, and the pipet is inserted into tube *1* and fixed with a conical ground-glass joint *5*. After heating for 3–5 min, the sampler is introduced into the flask, and the saturated solution is sampled into the pipet through a stopcock *6* using a water-jet pump or rubber bulb. The sample is transferred into a beaker for weighing and the subsequent analysis.

The equilibrium between the solid and liquid phases in all cases was attained within less than 2 h, which follows from the constancy of AA concentration in several successively taken samples.

The concentration of AA in the saturated solution was determined gravimetrically. The volume of the solution samples was chosen so that the dry precipitate weight was 0.2–0.5 g [7]. After weighing the bottles with the solution samples, the solvent was removed by evaporation in two steps. Initially the weighing bottles were heated on a temperature-controlled plate in an exhaust hood at 50°C up to visual disappearance of the liquid. Then, AA was dried to constant weight at 80°C. Such a technique prevents the possible AA loss caused by spraying when the solution is boiled. Each solubility value is an average of three measurements. The maximal relative error in the solubility determination at a confidence probability of 0.95 is 0.5. The results of solubility determination are listed in Table 1. For comparison, the published data on the AA solubility in water are given in Table 2 [8–10].

The data on the AA ideal solubility calculated by the modified Schroeder equation [11] are listed in Table 1. As seen, the AA solubility in all the solvents studied except water exceeds the ideal solubility. The negative deviations from the ideality are substantial and may be caused by specific interactions between the solute and solvent. The enthalpies of AA solution were calculated from the temperature dependence of the solubility. The free energy of solution is

$$\Delta G = -RT\ln a. \quad (1)$$

Table 2. Solubility of adipic acid in water

Acetone	11.44	–0.0430	–0.00022
Water	16.00	–0.0408	–0.00077

For poorly soluble, weakly dissociating substances, the activity a can be replaced by its mole fraction x [12], and then

$$\Delta G = -RT\ln x. \quad (2)$$

To check the validity of such substitution, we determined the degree of AA dissociation in water using the Ostwald dilution law. The AA dissociation constant in water was taken from Dobos handbook [13]. The α values obtained assuming the dissociation constant to be temperature-independent are given in Table 3. The solution ionic strengths I produced by the ionized fraction of AA are also listed in Table 3. The dependence of the AA activity coefficient on the solution ionic strength was determined in [14] from the solubility in water in the presence of electrolytes. The calculated activity coefficients γ are listed in Table 3. As seen, they only slightly differ from unity, and hence Eq. (2) can be used for calculating ΔG.

Since the AA dissociation constants in the chosen organic solvents should be substantially lower than in water, Eq. (2) is also applicable to the other solvents.

The temperature dependence of ΔG is approximated by a quadratic equation:

$$\Delta G = A + B(T - 273.15) + C(T - 273.15)^2. \quad (3)$$

The coefficients of Eq. (3) are listed in Table 4.

Then, using the known thermodynamic equations, we calculated ΔS and ΔH of solution (see Table 5). In all the cases, the enthalpies of solution are positive and hence the enthalpies of solvation do not exceed the enthalpies of the molecular crystal lattice. In the series of normal alcohols, the AA solubility decreases from methanol to butanol, and the enthalpy of solution increases. In other words, in the series of normal alcohols, the interaction of AA molecules with solvent molecules becomes weaker. For the most part of solvents studied, this interaction becomes weaker with increasing temperature. Thus, an interesting fact is observed: the enthalpy growth in one case is accompanied by a decrease in the solubility and in the other case, by its increase.

The enthalpy of solution characterizes only the energetic aspects of the solute–solvent interaction. However, the interaction between solvent molecules, determining the solvent structure, also changes upon dissolution; this factor also affects the dissolution. The joint analysis of the thermodynamic characteristics of AA dissolution shows that both the enthalpy and entropy components increase in the series of normal alcohols. The enthalpy component changes to a greater extent than the entropy component. As a result, the interaction between AA and alcohol molecules becomes weaker in this series. With increasing temperature, the entropy component increases faster than the enthalpy component, and ΔG decreases. Hence, the temperature affects more strongly the solution structure, whereas the alcohol molecule size affects more strongly the energy of intermolecular interactions.

For isopropyl and *tert*-butyl alcohols, the enthalpy component decreases with increasing temperature, while the entropy component increases, i.e., both components of the free energy favor dissolution, which explains their anomalous position in the alcohol series.

It should be noted that the entropy component increases to the greatest extent in water and acetone. The AA solubility in these solvents is the lowest as compared to the solubility in the other solvents studied. This means that the water and acetone structures are fairly stable at the temperatures studied and that AA dissolution actively breaks these structures. The structure of liquid *tert*-butyl alcohol is weak, and AA molecules weakly affect the level of its ordering.

CONCLUSIONS

(1) A sampler for studying the solubility of solids in liquids by isothermal method is developed.

(2) Solutions of adipic acid in organic solvents are characterized by negative deviation from the ideality, which suggests specific interactions between the solute and solvent.

(3) Thermodynamic characteristics of adipic acid solution depend on both the temperature and solvent.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Polythermal Study of the Systems $M(ClO_4)_2$–H_2O (M^{2+} = Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+})

Abstract—The solubility polytherms in the systems for which the cryoscopic data are lacking were measured. The structural models of the electrolyte solutions were discussed on the basis of the solubility polytherms.

Unique properties of eutectic compositions of solutions and salt melts make them important for metallurgical applications. They are widely used in modern technology [1] to improve the quality of metal production and obtain materials with prescribed properties. The overwhelming majority of physicochemical studies concerning formation of natural salts is based on the thermodynamic principles and, as theoretical background, uses the phase diagrams of water–salt systems corresponding in the composition to natural brines [2, 3].

The solubility polytherm is the dependence of the freezing point of a solution on the solute concentration. In the certain range of the concentrations (dilute solution) it is described by the Raoult's law, which is valid for any binary system. However, as the solute concentration is increased, a deviation from the linearity followed by a change in the behavior of the curve above the eutectic concentrations is observed, i.e., the freezing point of a solution increases with the concentration. In addition, the supereutectic branch can have additional singularities, depending on how many (two or more) crystal hydrates of the salt are formed.

The solubility isotherm represents in the graphical form the Raoult's law and the deviations from it and reflects the dynamics of structural processes in a solution as its concentration increases. The developed structural models of aqueous electrolyte solutions are based on comparison of the character of changes in physicochemical properties with the solubility polytherm of the salt. With this approach, regions of the predominance of different structures corresponding to the structure of the solid phase crystallizing from the solution with dereasing temperature can be revealed over the entire concentration range of existence of the solution [4].

In the region of subeutectic concentrations, water as a major component determining the solution structure crystallizes from the solution upon cooling. On cooling of supereutectic solutions, the solute in the form of a crystal hydrate or anhydrous salt precipitates as the bottom phase. This means that in the supereutectic region a certain structural type of the associates termed cybotactic group [4, 5] dominates in a solution. Water becomes a solute and a component of this group. For some salts, the solubility polytherm, apart from the eutectic, contains one or several singularities (peritectics). They separate the region of the concentrated solution into the regions of predominance of the corresponding crystal hydrates.

The way of formation and the origin of the eutectic remain still an open question stimulating much interest. The whole set of the data obtained by many researchers shows the existence of two principal concepts. According to one of them, the eutectic is a mechanical mixture of solid components (in the case of an aqueous solution, these are crystals of salt and ice) having constant composition and melting point. According to this traditional concept, the eutectic is formed owing to the short-term local deviations from the average composition of the solution. According to the other concept, the eutectic is a chemical compound [1].

As known, the solution of eutectic composition (at 25°C) is characterized by the following specific properties.

(1) The isotherms of the viscosity and proton magnetic relaxation rate (which is the measure of the water mobility), taken for solutions of salts forming crystal hydrates, undergo an inversion in the region of eutectic concentrations, which is not the case for solutions of anhydrous salts [6, 7].

1070-4272/05/7803-0409© 2005 Pleiades Publishing, Inc.

(2) The isotherms of the specific electrical conductivity of electrolyte solutions pass through a maximum at a concentration coinciding within 1–2 wt % with the eutectic composition. The maximum is observed for solutions of salts forming crystal hydrates. The presence of the maximum is due to structural transformation of the surrounding medium, rather than to strengthening of the interaction between the ions moving in it. This is noted in all the relevant papers [1, 5].

(3) The X-ray diffractometry of salt solutions shows that the solution of eutectic concentration is the most disordered [8].

(4) It is significant that, at concentrations corresponding to the eutectic composition, the relative partial molal entropy of water passes through a maximum, which is a consequence of the strongest disordering [9, 10].

According to the results of this study, the probable cause of the behavior of all the characteristics (presence of singularity points in the curves) is the change in the kind of the prevailing structures in the solution in the eutectic point [11–14].

In this study, we determined the previously unknown solubility polytherms of the systems $M(ClO_4)_2$–H_2O, where M^{2+} is Mg^{2+}, Ca^{2+}, Sr^{2+}, or Ba^{2+}. We determined the eutectic concentrations of the solutions, the composition of the crystal hydrates, and the fraction of 'free water' (i.e., water not incorporated in crystal hydrate) in the eutectic. The correlation between the latter parameter and the water activity in the eutectic solution at 25°C is discussed.

The choice of the salts was dictated by the following reasons. As known, the perchlorate ion has a highly symmetrical (tetrahedral) structure, low electron-donor and proton-acceptor power, and relatively low polarizability; it is very stable in solution. Owing to these properties, the perchlorate ion does not form any acido complexes with the metal cations and is not involved in the protolytic reactions of water in the vicinity of perchlorate ion, which makes its salts convenient objects for study.

EXPERIMENTAL

The metal perchlorates were prepared from the corresponding analytically pure grade carbonates (Ca^{2+}, Sr^{2+}, Ba^{2+}, and Mg^{2+}) and 57% perchloric acid (chemically pure grade) and were recrystallized two times from distilled water. Concentrated solutions of the salts were prepared; these were analyzed for the content of metal cations and ClO_4^- anions.

The ClO_4^- content was determined by the ion-exchange chromatography with a KU-2 resin, followed by pH-metric titration of perchloric acid with a borax solution. The content of M^{2+} (M^{2+} is Ca^{2+}, Mg^{2+}) was determined by EDTA titration. The content of strontium and barium ions was determined gravimetrically after precipitation in the form of sulfates. The error in determining the concentrations did not exceed 0.5%. Less concentrated salt solutions were prepared by dilution of the concentrated stock solutions. The freezing point was determined by the visual polythermal method.

The reaction vessel was cooled with liquid nitrogen. The cooling rate was varied within 0.3–1 deg min^{-1}. The freezing points (as averaged results of three measurements) are listed in Table 1. The cryoscopic data at $T > 0$°C were taken from a reference book [15].

The composition of the crystal hydrates $Mg(ClO_4)_2 \cdot nH_2O$ and $Ca(ClO_4)_2 \cdot mH_2O$ formed from the above solutions was determined in the region of negative temperatures. Test solutions of the known concentration belonging to the supereutectic region were cooled until the formation of crystals, which were then filtered at a temperature from –18 to –20°C. After that, the sample was passed through an ion-exchange column packed with KU-2 resin and the content of the ions was determined by pH-metric titration with a borax solution. The analysis results were used to calculate the number of molecules in the crystal hydrate.

According to the polythermal measurements, all the solutions studied, except that of strontium perchlorate, form simple eutectic systems. Barium perchlorate has an eutectic at a higher temperature (–33°C) compared to the other salts (Table 2). Apparently, this is due to weak interaction of this salt with water.

The eutectic compositions of calcium, strontium, and barium perchlorate solutions are close (4.2, 4.0, and 4.02 mol/1000 g H_2O, respectively). Magnesium perchlorate differs from this group in that it forms an eutectic at m = 3.35 mol/1000 g H_2O, which is not surprising because of its stronger tendency to hydration. Then, at first glance, it would seem that the eutectic concentration depends on the cation. However, as will be shown below, the main attention must be paid to the number of water molecules incorporated in the crystal hydrate crystallizing in the supereutectic region.

The solubility polytherm of strontium perchlorate also has the specific features deserving more detailed discussion. Strontium perchlorate is one of the least studied perchlorates of Group II metals. The unusual property of this salt consists in its tendency to vitrify in the region of supereutectic concentrations. This is reflected by a dashed line drawn in the range from 5.50 to 6.25 mol/1000 g H_2O (Fig. 1). In this concentration region, the solution became thick on cooling and its viscosity grew until the onset of vitrification. Above 6.25 mol/1000 g H_2O, the solid crystal hydrate precipitated again as the bottom phase. Evidently, the 5.5 m solution corresponds to the peritectic composition.

There is an opinion in the literature that, in solutions of strontium perchlorate (capable of forming acido complexes), saturated with respect to tetrahydrate, the amount of water not involved in the coordination with Sr^{2+} is very small, and even this water is hardly free [16]. Latysheva [16] believes that this water, most probably, plays the role of bridges binding $Sr(H_2O)^{2+}$ and ClO_4^- ions into a continuous viscous structure, which is responsible for the tendency of solutions to high degree of supersaturation. James and Culter [17] studied the spectral properties of $Sr(ClO_4)_2$ and calculated the parameters of the perchlorate ion

Table 2. Eutectic concentrations m_{eut}, number of water molecules in crystal hydrate n, fraction of free water in the eutectic N_w, and water activity in the eutectic at 298 K for the systems studied

Substance	m_{eut}	n	N_w	$a_{w_{298}}$

from the data obtained. They came to the conclusion that contact ion pairs exist at concentrations above 5.5 mol/1000 g H_2O. As seen, the opinions of different authors about the speciation of this salt in solution are contradictory. However, the concentrations at which the specific effects are observed are the same.

We believe that complexes and ion pairs in concentrated strontium perchlorate solutions can be formed by the so-called structure-induced processes occurring owing to the solution microheterogeneity, rather than by the commonly accepted traditional mechanism [18]. From our viewpoint, the existence of two structural modifications, α-$Sr(ClO_4)_2$ and β-$Sr(ClO_4)_2$, of this salt, revealed by X-ray phase analysis, is the most probable origin of the vitrification. Though these are the modifications of the solid anhydrous salt, it may be suggested that the similar structural modifications exist for the crystal hydrate whose structure dominates in the vitrification region. This assumption can account for the observed vitrification. This phenomenon is also known for solutions of other salts, i.e., calcium chloride, which also have several structural modifications and is readily vitrified.

It is important that the difference between the eutectic and peritectic temperatures in the polytherm is small, i.e., there exists a fairly large region of the structural constancy in which the parameters and properties do not change. This assumption is also supported by Fig. 2 illustrating the dependences of the relative dynamic viscosity on the concentration of strontium perchlorate solutions within the range 0.5–6.5 mol/1000 g H_2O at 25 and 50°C. As seen, the two dependences corresponding to different temperatures are very close, i.e., increasing the temperature of the strontium perchlorate solution affects only slightly the relative dynamic viscosity. However, the curves show inversion, although it is observed in a certain region rather than point; the curves coincide in the region from 4 to 5.6 mol/1000 g H_2O, i.e., between the eutectic and the peritectic. Because the eutectic and peritectic solutions in the strontium perchlorate–water system considered here and in other similar systems tend to vitrify and have a low freezing point, determination of the bottom phase compositions becomes difficult.

The number of water molecules incorporated in the crystal hydrate is related to the fraction of free water N_w by

$$N_w = (55.51 - nm_e)/55.51,$$

where n is the number of water molecules in the crystal hydrate; m_e, eutectic concentration (mol/kg H_2O); and 55.51, the amount of water (moles) in 1 kg of the water.

In this study, the numbers n for magnesium and calcium perchlorates were determined to be 8 and 6, respectively. The published data [15] show that the obtained values are the common hydration numbers of the salts of these metals. For example, in calcium halides, chlorate, iodate, and nitrite $n = 6$, and in magnesium iodide, most closely resembling perchlorate, $n = 8$.

The calculated N_w values, 0.503 and 0.546 for magnesium and calcium perchlorates, respectively, are close to the water activities $a_{w_{298}}$ at 298 K, 0.499 and 0.525, respectively, obtained from the water vapor pressure in [19]. This similarity has been observed previously [20].

For barium and strontium perchlorates, the compositions of the bottom phases formed just above the eutectic concentration are unknown. The phase diagram of strontium perchlorate has a peritectic. We suggest that, in the range 4–5.5 mol/1000 g H_2O, the hexahydrate is the major structure. In such a case, $N_w = 0.570$, which is close to the corresponding value of the water activity at 298 K (0.599). In the barium perchlorate polytherm, there are no other singularities in the supereutectic region. Therefore, it may be suggested that, just as the concentration of 4 mol/1000 g H_2O is exceeded, the tetrahydrate becomes the major structure. Then, $N_w = 0.710$ and the corresponding value of the water activity is equal to 0.691.

The fraction of water not incorporated in the crystal hydrate (free water) in the eutectic is close to the value of water activity in the eutectic solution. Thus, N_w and $a_{w_{298}}$ in the eutectic solution at 25°C are interconnected through the number of water molecules *n* in the crystal hydrate precipitating into the bottom phase just above the eutectic concentration. This relationship is confirmed for the perchlorate solutions of zinc group metals and for perchloric acid. The results obtained are listed in Table 2.

CONCLUSION

In eutectic solutions, the fraction of water not incorporated in the crystal hydrate (free water) is close to the water activity in the eutectic solution at 298 K. This makes it possible, in particular, to estimate the composition of the crystal hydrate precipitated in the supereutectic region.

SORPTION AND ION-EXCHANGE PROCESSES

Recovery of Nickel Ions from Dilute Solutions by Electrodialysis Combined with Ion Exchange

Yu. S. Dzyaz'ko, L. M. Rozhdestvenskaya, and A. V. Pal'chik

Abstract—The possibility of using inorganic ion exchangers based on zirconium hydrophosphate and a weakly cross-linked cation-exchange resin for continuous purification of dilute nickel-containing solution by a combined method of electrodialysis and ion exchange was studied.

A promising technique for recovery of Ni^{2+} ions from dilute solutions is a combined method of electrodialysis and ion exchange (electrodeionization), which enables continuous purification of a solution, simultaneously with reagent-free regeneration of the ion exchanger used [1–3]. Unfortunately, the use of this method is limited by the low mobility of Ni^{2+} in the ion exchanger phase [4] and by the possibility of formation of sparingly soluble hydroxo compounds on the surface of the ion-exchange materials [5]. In addition, presence of hardness ions markedly lowers the degree of recovery of heavy metal ions [6].

To overcome these difficulties, it is primarily necessary to choose an appropriate ion exchanger. The factors predetermining the performance of an ion-exchange material in electrodeionization processes are its high sorption capacity and selectivity, as well as a high mobility of absorbed ions. Among the known ion exchangers, the best in kinetic properties are weakly cross-linked sulfonic ion-exchange resins [7]. High sorption capacity and selectivity with respect to heavy metal ions are exhibited by inorganic ion exchangers such as, e.g., zirconium hydrophosphate (ZHP) [8].

The aim of this study was to assess the possibility of using these ion exchangers in electrodeionization purification of Ni^{2+}-containing solutions.

EXPERIMENTAL

ZHP samples with varied content of functional groups were synthesized for the study. The procedure used to obtain sample ZHP-1.1 included preparation of a hydrogel of zirconium dioxide by the reaction of a 1 M solution of $ZrOCl_2$ with an equal volume of a mixed solution containing glycerol (1.4 M), hexamethylenetetramine (2 M), and urea (2 M). The resulting hydrogel wax treated with 5 M H_3PO_4 at 373 K for 1 h. Sample ZHP-1.2 was prepared similarly, but with the concentration of urea in the solution used to precipitate zirconium dioxide equal to 6 M. In addition, the hydrogel was dried at 333 K prior to phosphatization.

The particles of the ion exchangers obtained were nearly spherical. The 0.2–0.5-mm fraction was taken for the study.

The elemental composition of the samples was determined by dissolving them in concentrated H_2SO_4, with the subsequent photometric analysis of the resulting solution [9]. The water content was found from the loss of mass by the ion exchanger after heating at 373 K for 2 h. The average pore diameter was calculated from nitrogen adsorption isotherms obtained with a Tristar 3000 adsorption analyzer [10]; the total cation-exchange capacity, concentration of cation-exchange groups, and pK of their dissociation were determined by potentiometric titration [11, 12].

The procedures described in [13] were used to study the Dowex 50WX-2 sulfonic ion exchanger (0.2–0.5-mm fraction) containing a cross-linking agent in an amount of 2%. Its total exchange capacity was determined by treating the resin with 0.1 M NaOH for 20 min with the subsequent titration of the excess alkali. The apparent volume of the H^+- and Ni^{2+}-substituted forms was determined volumetrically. The content of water in the resin was evaluated by the loss of mass upon drying over P_2O_5.

To study the kinetics of sorption of Ni^{2+} ions by

1070-4272/05/7803-0414 © 2005 Pleiades Publishing, Inc.

the "thin bed" method, a weighed portion of the sample was placed in the form of a single bed between two grids fixed at the end of a glass tube 1.5 cm in diameter, connected to a pump. Then, a 0.1 M solution of $NiSO_4$, acidified with H_2SO_4 to pH 3, was passed through the ion exchanger bed in the direct-flow mode for a certain time. The linear flow velocity of the solution was 0.14 m s^{-1}. After the required time elapsed, the ion exchanger was washed with deionized water and nickel(II) ions were eluted with an H_2SO_4 solution. The content of desorbed Ni^{2+} ions in the eluate was determined by the atomic-absorption method on a PUY UNICAM SP 9 spectrophotometer.

The sorption isotherms were obtained by treating the ion exchangers under static conditions with individual $NiSO_4$ and $CaCl_2$ solutions with initial concentrations of 1×10^{-4}–0.1 M. The ion exchanger : solution volume ratio was 1 : 100, and the time of contact, 24 h. After the equilibrium was established, the solution was separated from the ion exchanger and the concentration of the Ni^{2+} and Ca^{2+} in it was determined by the atomic-absorption method. The ion exchanger was treated with 2 M H_2SO_4 and the content of the ions in the eluate was found similarly.

The electrodeionization was studied on a setup comprising a three-chamber electrodialysis cell, three independent liquid circuits, current source, and measuring instruments (Fig. 1) [2]. Platinum electrodes were in the side compartments of the cell, and the ion exchanger bed, in the central compartment. The effective area of the membranes and electrodes was 24 cm^2 (1.5×6 cm), and the ion exchanger bed thickness, 1 cm. CMI-7000 cation-exchange and AMI-7001 anion-exchange heterogeneous membranes (Membrane International) or two Nafion-117 cation-exchange homogeneous membranes (Du Pont) were used.

To avoid a change in the volume of the organic ion exchanger in the course of electrodeionization, the resin was preliminarily converted into a partially nickel-substituted form by treatment with a 0.1 M solution of $NiSO_4$ at a 1 : 100 resin-to-solution volume ratio. The inorganic ion exchanger, whose volume remains unchanged upon conversion into the substituted form, was not treated preliminarily with a nickel-containing solution.

The $NiSO_4$ solution or a combined solution containing Ni^{2+}, Ca^{2+}, and Mg^{2+} ions was fed from the input vessel into the central compartment in the direct-flow mode. The forming solution was delivered into the output vessel. Acid solutions were circulated through the electrode compartments at a flow velocity of 1.67×10^{-2} m s^{-1}. The volume of the acid solution

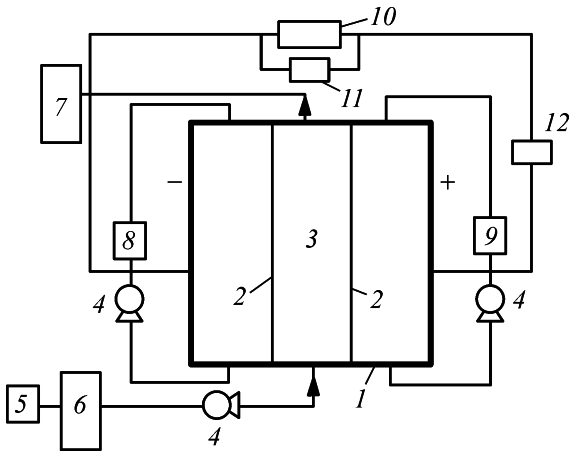

Fig. 1. Electrodeionization setup: (*1*) three-chamber cell, (*2*) ion-exchange membranes, (*3*) ion exchanger bed, (*4*) pumps, (*5*) thermostat, (*6*) vessel with the starting solution, (*7*) vessel with a purified solution, (*8*) vessel with the catholyte, (*9*) vessel with the anolyte, (*10*) current source, (*11*) voltmeter, and (*12*) ammeter.

in each compartment was 200 cm^3. In a separately specified case, the catholyte was additionally acidified in the course of the experiment in order to prevent formation of a sparingly soluble precipitate in the cathode compartment and on the membrane on the cathode side.

The electrodeionization purification of solutions was performed in the voltage stabilization mode. The solutions in the cathode and anode compartments and at the outlet of the central compartment were sampled at fixed intervals of time.

The sorption and electrodeionization were studied at 298 ± 0.05 K.

The parameters of the ion exchangers are listed in Table 1. It can be seen that the ZHP samples synthesized have a developed mesoporous structure. The total cation-exchange capacity of these materials considerably exceeds that of Dowex WX-2. At the same time, the content of water in the cation-exchange resin and inorganic ion exchangers is approximately the same. In contrast to the case of ZHP, conversion of the organic cation exchanger into the Ni^{2+}-substituted form is accompanied by a substantial decrease in its volume.

It should also be noted that ZHP-1.1 sample, which contains a certain amount of hydrophosphate ions in addition to dihydrophosphate ions, contains a larger amount of P(V) than ZHP-1.2. Nevertheless, the total cation-exchange capacity of ZHP-1.1 is substantially lower, and the p*K* value of functional groups, higher than those of ZHP-1.2.

Table 1. Parameters of ion exchanger samples

Parameter	ZHP-1.1	ZHP-2.2	Dowex 50WX-2
Zr : P molar ratio	0.53 : 1	0.92 : 1	–

Dowex 50WX-2	3.00×10^2	3.10×10^{-4}	10.00	7.20×10^{-11}

The structural-sorption properties of ion exchangers determine the rate of ion exchange. Figure 2 shows kinetic curves of Ni^{2+} sorption, which have the form of the dependence of $\bar{c}_{Ni}/\bar{c}_{Ni,\infty}$ on the time of sorption t, where $\bar{c}_{Ni}$ and $\bar{c}_{Ni,\infty}$ are the contents of Ni^{2+} reached after a certain time and at $t = \infty$, respectively. Preliminarily, it was established that the rate of sorption from a 0.1 M solution of $NiSO_4$ is independent of the flow velocity. This suggests that the sorption rate at the given solution concentration is controlled by internal diffusion [12].

The effective diffusion coefficient $\bar{D}_{Ni}$ was calculated by the equation [12]

$$\bar{D}_{Ni} = 0.03\bar{d}/4t_{0.5}, \quad (1)$$

where $t_{0.5}$ is the exchange half-time, and $\bar{d}$ is the particle diameter.

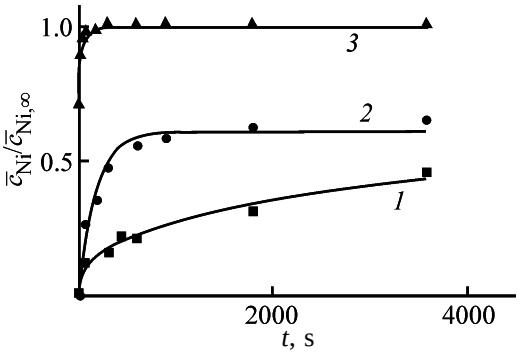

Fig. 2. Degree of completion of Ni^{2+} sorption, $\bar{c}_{Ni}/\bar{c}_{Ni,\infty}$, on (*1*) ZHP-1.1, (*2*) ZHP-1.2, and (*3*) Dowex 50WX-2 ion exchangers vs. time t.

The values of $\bar{c}_{Ni,\infty}$, $t_{0.5}$, and $\bar{d}$, as well as the effective diffusion coefficients of Ni^{2+}, calculated by Eq. (1), are listed in Table 2. The diameter of resin particles was evaluated taking into account the change in volume: in conversion into the Ni^{2+}-substituted form, a 30% decrease in volume corresponds to a decrease in the particle diameter by a factor of 1.13.

Table 2 shows that the mobility of Ni^{2+} in a weakly cross-linked ion-exchange resin considerably exceeds that in inorganic ion exchangers. This is due to the fact that water filling voids in resins of this kind retains a more or less liquid structure and absorbed ions can freely move in the liquid [12]. In ion exchangers of the ZHP type, water molecules are mostly associated with functional groups via hydrogen bonds [14]. In this case, the ions sorbed are transferred by hoppings from one group to another. The higher mobility of cations in ZHP-1.2 ion exchanger, compared to ZHP-1.1, is apparently associated with the higher acidity of the functional groups and, according-

ly, with a shorter distance between the dissociated groups.

Further studies were carried out with ion exchangers in which the mobility of Ni^{2+} is the highest: Dowex 50WX-2 and ZHP-1.2. Figure 3 shows Ni^{2+} and Ca^{2+} sorption isotherms in the form of dependences of the equivalent fraction of M metal ions in the ion exchanger phase, $\bar{\gamma}_M$, on the equivalent fraction of M in solution, γ_M. The quantity $\bar{\gamma}_M$ was calculated by the formula

$$\bar{\gamma}_M = \frac{z_M \bar{m}_M}{z_M m_M + z_H \bar{m}_H}, \quad (2)$$

where $\bar{m}$ is the molal concentration of cations in the ion exchanger; z, charge; and subscript H corresponds to hydrogen ions.

The concentration of H^+ in the ion exchanger was calculated from the total cation-exchange capacity (Dowex 50WX-2) or from the concentration of dissociated groups at certain pH values (ZHP-1.2). The equivalent fraction of metal ions in solution was determined using a formula similar to (2).

As seen from Fig. 3, the sorption isotherms for Dowex 50WX-2 are typical of strongly acidic ion exchangers: the $\bar{\gamma}_M$–γ_M curves steeply ascend at low solution concentrations. In the case of a moderately acidic ion exchanger ZHP-1.2, a significant increase in sorption is observed in more concentrated solutions. Nevertheless, the inorganic ion exchanger absorbs mostly Ni^{2+} in dilute solutions. For the ion-exchange resin, the differences in the sorbability of Ni^{2+} and Ca^{2+} become more pronounced as the solution concentration increases.

Also, we examined the possibility of electrodeionization purification of Ni^{2+}-containing solutions with ZHP-1.2 and Dowex 50WX-2 ion exchangers. In the first set of experiments, heterogeneous membranes (cation-exchange CMI-7000 and anion-exchange AMI-7001, Membrane International) were used to separate the cathode and anode spaces from the central compartment. A 3 M solution of HCl was circulated through the cathode compartment, and a 3 M solution of H_2SO_4, through the anode compartment. The solution being purified contained 0.17 or 1 mol m^{-3} of $NiSO_4$. The flow velocity of the solution was 1.46×10^{-3} m s^{-1}, and the cell voltage, 10 V.

The results obtained are listed in Table 3 and shown in Fig. 4, which illustrates the dependence of the amount of Ni^{2+} in the catholyte, $n_{Ni,c}$, on the time of electrodeionization. As seen from Fig. 4 and

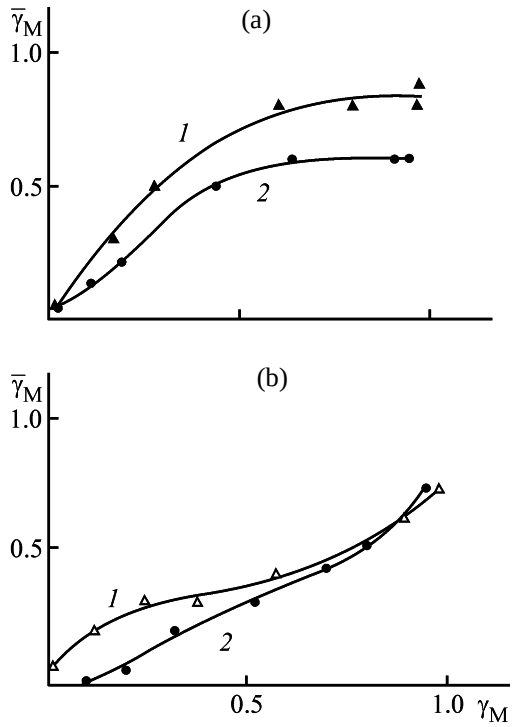

Fig. 3. Sorption isotherms of (*1*) Ni^{2+} and (*2*) Ca^{2+} from individual solutions for (a) Dowex 50WX-2 and (b) ZHP-1.2 ion exchangers. ($\bar{\gamma}_M$) Equivalent fraction of metal ions in the ion exchanger and (γ_M) equivalent fraction of metal ions in solution.

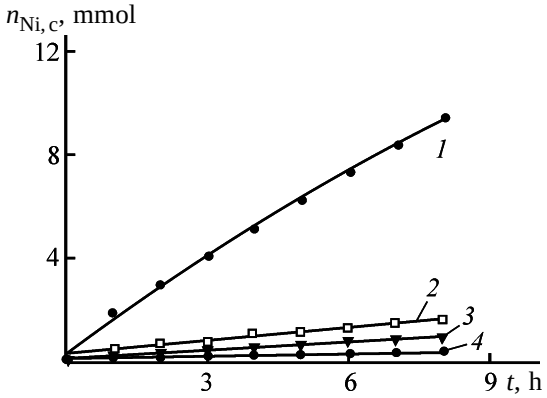

Fig. 4. Amount of Ni^{2+} in the catholyte, $n_{Ni,c}$, vs. time t of electrodeionization of individual solutions containing (*1*, *3*) 1 and (*2*, *4*) 0.17 mol m^{-3} of Ni^{2+}. Ion exchanger: (*1*, *2*) Dowex 50WX-2 and (*3*, *4*) ZHP-1.2.

Table 3, for the cation-exchange resin, the rate of transfer of Ni^{2+} into the cathode compartment somewhat decreased during the first 2 h, with the current simultaneously increasing. This was, apparently, due to a certain decrease in the concentration of metal ions in the ion exchanger phase. Further, the flux of Ni^{2+} into the catholyte and the current remained unchanged. No deposit was formed on the cation-exchange mem-

Table 3. Electrodeionization recovery of Ni^{2+} from solutions of various compositions

brane. An analysis of the material balance demonstrated that the amount of Ni^{2+} absorbed by the ion exchanger in unit time is equal to the amount of Ni^{2+} arriving at the cathode compartment. The acidification of the solution formed in the central compartment was due to diffusion of the acid across the anion-exchange membrane [2, 15].

In the case of the ZHP-1.2 ion exchanger and a $NiSO_4$ concentration of 1 mol m^{-3}, both the rate of Ni^{2+} transfer across the cation-exchange membrane and the current slightly decrease in the course of time. This is, apparently, due to conversion of the ion exchanger into the cation-substituted form, and also to formation of a deposit on the cation-exchange membrane. At a lower solution concentration, the flux of Ni^{2+} into the catholyte and the current remained virtually unchanged. In all cases, no reduction of Ni^{2+} at the cathode was observed.

As seen from Table 3, the most effective is the organic weakly cross-linked cation exchanger. With this resin, the highest degree of solution purification and the highest current efficiency are achieved. Therefore, we assessed the possibility of using this material for continuous recovery in a direct-flow mode of Ni^{2+} ions from a combined solution containing, in addition, hardness ions.

In these experiments, Nafion-117 cation-exchange membranes were placed between the central compartment and electrode chambers. The use of these membranes is due to the need to preclude the concentration polarization at low voltages and to provide a lower acidity of the solution being purified. A 1 M solution of HCl was circulated through the cathode chamber, and a 1 M solution of H_2SO_4, through the anode chamber. Every 20 h, a 10 cm^3 portion of concentrated HCl was added to the catholyte. The electrodeionization was performed continuously for 80 h at 5 V and a flow velocity of the solution being purified equal to 4.10×10^{-3} m s^{-1}. The efficiency of electrodeionization with ion-exchange resins increases with the flow velocity of the solution being purified [3]. In this connection, the solution flow velocity was

raised when passing from an individual solution to a combined solution.

Figure 5 shows how $n_{Ni,c}$ depends on the time of electrodeionization (solid lines). It can be seen that not only Ni^{2+} but also Ca^{2+} and Mg^{2+} arrived at the catholyte. No reduction of Ni^{2+} at the cathode or formation of a deposit in the central compartment was observed. The current density increased from 20 to 36 A m^{-2} during the first 2 h and then remained unchanged. The acidity of the dialyzate was constant during the experiment (pH 4).

If the catholyte was not additionally acidified, Ni^{2+} reduction commenced at the cathode after approximately 43 h because of the decrease in the concentration of the acid in the cathode compartment. In the process, the current decreased, and the pH of the solution in the central compartment increased dramatically (Table 3), which was accompanied by intensive formation of hydroxo compounds of Ni^{2+} on the membranes and ion exchanger particles. The amount of Ni^{2+} in the catholyte decreased because of the deposition of Ni^{2+} onto the cathode, and the rate of transfer of Ca^{2+} and Mg^{2+} into the cathode chamber diminished virtually to zero (Fig. 5, dotted lines).

The results obtained enable certain estimates of the transport of Ni^{2+} into the catholyte. Under conditions of forced convection, the flux of Ni^{2+} across the cation-exchange membrane, $\bar{\bar{N}}_{Ni}$, associated with the transport through the solution, is determined by migration of ions in the solution bulk, N_{Ni}^{migr}, and by diffusion across the layer of the solution at the membrane surface, N_{Ni}^{dif} [16]:

$$\bar{\bar{N}}_{Ni} = N_{Ni}^{migr} + N_{Ni}^{dif}. \quad (3)$$

The diffusion flux exceeds that associated with migration by a factor γ, where γ is the charge ratio of the cation and anion. In the case of a binary symmetric electrolyte $NiSO_4$, $\gamma = 1$ and, consequently, $\bar{\bar{N}}_{Ni} = 2N_{Ni}^{migr}$ (the current does not reach its limiting value) or $\bar{\bar{N}}_{Ni} = 2N_{Ni}^{dif}$ (limiting and "overlimiting" current). In turn,

$$N_{Ni}^{migr} = u_{Ni}\bar{\bar{c}}_{Ni}\,\mathrm{grad}\,\bar{E}, \quad (4)$$

$$N_{Ni}^{dif} = k_{Ni}(c_{Ni} - c_{Ni}^{0}), \quad (5)$$

where u_{Ni} and k_{Ni} are the mobility and mass-transfer coefficient of Ni^{2+}; c_{Ni} and c_{Ni}^{0}, concentrations of cations in the solution bulk and the near-membrane layer, respectively; and $\mathrm{grad}\,\bar{E}$, the voltage drop across the central compartment of the cell.

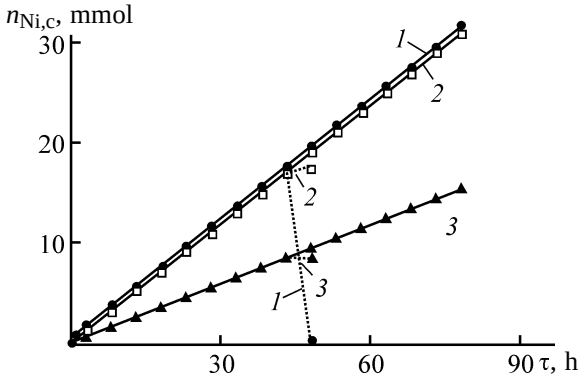

Fig. 5. Amount of metal ions in the catholyte, $n_{Ni,c}$, as a function of the time τ of electrodeionization of a combined solution with (solid lines) and without (dashed lines) additional purification. Dowex 50WX-2 resin. Cation: (*1*) Ni^{2+}, (*2*) Ca^{2+}, and (*3*) Mg^{2+}.

The value of $\mathrm{grad}\,\bar{E}$ was calculated by the formula

$$\mathrm{grad}\,\bar{E} = \frac{E(E_c - E_a)}{l}, \quad (6)$$

where E, E_c, and E_a are the cell voltage and potentials of the cathode and anode, respectively; and l, width of the central compartment.

In this calculation, the voltage drop in the rather concentrated solutions filling the compartments and in membranes whose thickness is considerably less than 1 mm was disregarded. As indicated by voltammetric measurements, $E_c + E_a$ is 1.8 V.

The thickness δ of the near-membrane layer can be found from an empirical relationship [12]

$$\delta = 0.05\,d^{0.16}(w/v)^{-0.84}, \quad (7)$$

where w and v are the linear flow velocity and viscosity of the solution. With account of the fact that $k_{Ni} = D_{Ni}/\delta$ (D_{Ni} is the diffusion coefficient of Ni^{2+} in solution), $D_{Ni} = 6.49 \times 10^{-10}$ $m^2\,s^{-2}$, $v = 8.99 \times 10^{-7}$ $m^2\,s^{-2}$ [18], the mass-transfer coefficients for Ni^{2+} are 2.28×10^{-5} ($w = 1.46 \times 10^{-3}$ m s^{-1}) and 5.50×10^{-5} m s^{-1} ($w = 4.10 \times 10^{-3}$ m s^{-1}).

The concentrations c_{Ni} were evaluated as average solution concentrations at the inlet and outlet of the central compartment (Table 3). The migration fluxes were calculated using Eq. (4), taking into account that $u_{Ni} = 4.99$ $m^2\,V^{-1}\,s^{-1}$ [18], and the diffusion fluxes corresponding to the limiting conditions were found

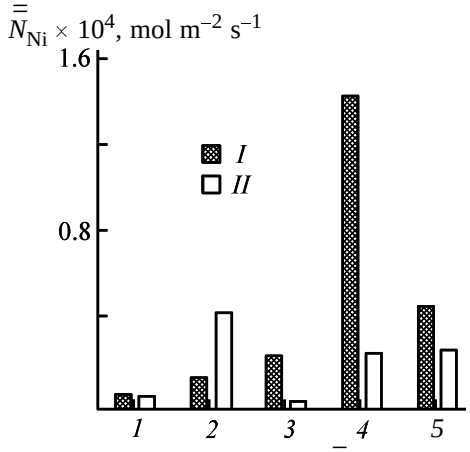

Fig. 6. Ni^{2+} flux into the catholyte, $\bar{\bar{N}}_{Ni}$, associated with transport (*I*) through ion exchanger–solution system and (*II*) through the solution. Ion exchanger: (*1, 2*) ZHP-1.2 and (*3, 5*) Dowex 50WX-2. Solution (mol m^{-3}): individual, containing (*1, 3*) 0.17 and (*2, 4*) 1 Ni^{2+}; and (*5*) a combined solution containing 1 Ni^{2+}, 1 Ca^{2+}, and 0.5 Mg^{2+}.

as $k_{Ni}c_{Ni}$. As follows from Table 3, the diffusion fluxes calculated for the case of electrodeionization at 10 V are smaller than the migration fluxes, and, consequently, the current exceeded the limiting values. At 5 V, $N_{Ni}^{dif} < N_{Ni}^{migr}$ and the electrodeionization mode corresponded to the "sublimiting" current.

The results obtained make it possible to calculate quantitatively the flux of Ni^{2+}, associated with their transport through the electrolyte across the membrane (Fig. 6). It can be seen from this figure that the calculated values of $\bar{\bar{N}}_{Ni}$, corresponding to fluxes through the solution, are somewhat lower than those obtained experimentally. At the same time, the flux through the ion exchanger–solution system, found experimentally for Dowex 50WX-2 resin, well exceeds that calculated theoretically. Hence follows that the use of ion exchangers based on zirconium hydrophosphates in electrodeionization purification of nickel-containing solutions is inexpedient, because ions are mostly transferred through solution as a result of the low mobility of Ni^{2+} in the ion exchanger phase.

The use of weakly cross-linked ion-exchange resin Dowex 50WX-2 markedly improves the efficiency of solution purification because of the possible ion transport in the ion exchanger. If the acidity of the catholyte is maintained constant, the purification in the direct-flow mode can be performed continuously. Acidification of the catholyte at regular intervals of time makes it possible to avoid formation of sparingly soluble nickel(II) hydroxo compounds on the surface of membranes and ion exchangere particles, observed in [3].

CONCLUSIONS

(1) The kinetic method was used to determine the mobility of nickel ions in a Dowex 50WX-2 weakly cross-linked cation-exchange resin and inorganic cation exchangers based on zirconium hydrophosphates. It was found that the highest diffusion coefficient of Ni^{2+} is achieved for the organic cation exchanger (7.20×10^{-11} m^2 s^{-1}), whereas for inorganic cation exchangers this parameter is 2–3 orders of magnitude lower.

(2) The sorption of Ni^{2+} and Ca^{2+} on ion exchangers was studied. It was shown that, in the case of weakly concentrated solutions, the inorganic ion exchanger mostly sorbs Ni^{2+}, whereas the ion-exchange resin equally effectively absorbs both Ni^{2+} and Ca^{2+}.

(3) The possibility of using ion exchangers for electrodeionization recovery of nickel(II) ions from solutions was assessed. It was established that, in the case of an inorganic ion exchanger, the transport of Ni^{2+} mostly occurs via solution. At the same time, the highest degree of solution purification and current efficiency are obtained with Dowex 50WX-2, which is due to predominant transport of Ni^{2+} via the ion exchanger. Thus, the main criterion to be used in selecting an ion-exchange material is the mobility of ions in its phase.

(4) Maintaining constant the acid concentration in the catholyte enables continuous electrodeionization purification of a solution and minimizes the probability of formation of sparingly soluble hydroxo compounds of Ni on the surface of ion-exchange materials.

(5) Foreign double-charged cations are transported, together with nickel(II) ions, across the bed of the Dowex 50WX-2 resin. Further development of a technique for purification of nickel-containing solutions should, apparently, be based on weakly cross-linked ion-exchange resins with a higher selectivity toward ions of this metal, compared to Dowex 50WX-2.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption Purification of Aqueous Ammonium Molybdate To Remove Tungsten Impurities with a Cation Exchanger Containing Pyrocatechol Functional Groups

Abstract—The sorption of molybdenum(VI) and tungsten(VI) from weakly alkaline and neutral solutions with PK-S cation exchanger containing pyrocatechol functional groups was studied. The possibility of selective recovery of tungsten(VI) impurities from aqueous ammonium molybdate with PK-S resin was examined.

Tungsten impurities strongly affect the properties of metallic molybdenum. Among techniques commonly used for molybdenum purification to remove tungsten (extraction of molybdenum from its hydrogen chloride solutions [1], sublimation of molybdenum oxychloride [2], etc.), the simplest and the most efficient is ion-exchange sorption allowing the selective removal of tungsten impurities from aqueous ammonium molybdate (AM). For example, tungsten can be removed from aqueous molybdenum-containing solutions by sorption on hydrated polyvalent metal oxides [3] or on certain anion exchangers [4]. It is known that polyhydric phenols such as pyrocatechol coordinate with molybdenum(VI) and tungsten(VI) and that the tungsten(VI) complexes are stronger than those of molybdenum(VI) [5]. Therefore, PK-S cation exchanger of the condensation type containing pyrocatechol functional groups [6] shows promise for purification of aqueous molybdate solutions to remove tungsten impurities.

In this work we tested PK-S cation exchanger containing pyrocatechol functional groups for purification of aqueous ammonium molybdate to remove tungsten(VI) impurities.

EXPERIMENTAL

In our experiments we used PK-S cation exchanger in the H^+ form with the total cation-exchange capacity of 8.7 mg-equiv g^{-1}, prepared at the Kazmekhanobr Institute, Almaty. The sorption experiments were carried out under static and dynamic conditions. In the static experiments, the sorbent (g) to liquid phase (ml) ratio was 1 : 100. The sorption time was 5–7 days. The dynamic experiments were carried out in 20-ml glass columns with the height to diameter ratio of 15 : 1. In these experiments, aqueous molybdate solutions to be purified to remove tungsten were passed through the column at a rate of 0.7–1.0 column volume per hour. The molybdenum(VI) content in solutions was determined spectrophotometrically [6]. The pH was measured on an I-120 pH meter equipped with an ESL-47-07 glass electrode and an EVP-AM-3 silver chloride reference electrode. The ion-exchange sorption of tungsten(VI) was studied with tungsten-185 tracer added as aqueous sodium tungstate. The activity (count rate) was measured on a KRK-1-01A device equipped with a BDIB-01-1 counter and a PSO2-4 scaling unit.

The acidity is the main factor governing the state of molybdenum(VI) and tungsten(VI) in aqueous solutions. The dissociation of the phenolic functional groups of PK-S cation exchanger and their coordination with metals under consideration also strongly depend on the acidity. Therefore, we first studied how the ion-exchange sorption of molybdenum(VI) and tungsten(VI) from their 0.01 M solutions containing 1 M ammonium sulfate on PK-S cation exchanger depends on pH. Figure 1 shows that molybdenum(VI) and tungsten(VI) are sorbed on PK-S not only from acidic but also from alkaline solutions and their sorption decreases with increasing pH. It seen that the sorption of tungsten(VI) starts at a higher pH than that of molybdenum. These data suggest that, in the pH range corresponding to stronger sorption of tungsten(VI), tungsten(VI) impurities can be separated from large amounts of molybdenum(VI) with PK-S cation exchanger. To check this hypothesis, we studied

1070-4272/05/7803-0422 © 2005 Pleiades Publishing, Inc.

sorption of tungsten(VI) impurities (0.01 M) from 1 M aqueous ammonium molybdate.

Figure 2 shows that PK-S cation exchanger, indeed, sorbs tungsten(VI) from aqueous solutions containing large amounts of ammonium molybdate. The plot of the tungsten sorption vs. pH passes through a maximum at pH ~ 9.

It is known that at pH 9 both molybdenum and tungsten are present in aqueous solutions in the form of monomeric anions MoO_4^{2-} and WO_4^{2-}, respectively. We believe that these anions are sorbed on PK-S cation exchanger by the mechanism of complexation with the phenolic hydroxy groups in the *ortho* position relative to each other

$$Ar(OH)_2 + MO_4^{2-} + 2H^+ \rightleftarrows ArO_2MO_2 + 2H_2O, \quad (1)$$

where Ar is the benzene ring and M is molybdenum or tungsten.

It is known that tungsten and molybdenum form strong complexes with polyhydric phenols and the complexation occurs even in alkaline solutions [5]. The phenolic groups coordinate with tungsten(VI) more strongly than with molybdenum(VI) and the tungsten complexes start to form at higher pH. As a result, the sorption of tungsten(VI) on PK-S cation exchanger start at higher pH than the sorption of molybdenum(VI) (Fig. 1). Equation (1) shows that acidification of solutions should strengthen the coordination of phenolic groups with molybdenum(VI) and tungsten(VI). Therefore, with decreasing pH, the sorption capacity of the PK-S resin for tungsten increases. However, at certain pH, the pyrocatechol groups of the resin start to coordinate with molybdenum(VI) also. Because the molybdenum(VI) content in the solutions considerably exceeds the tungsten content, molybdenum starts to displace tungsten from the resin. Furthermore, in acidification of solutions containing molybdenum(VI) and tungsten(VI), mixed Mo(VI)–W(VI) polyanions are formed at pH < 8 [8].

The coordination of the phenolic groups of PK-S resin with tungsten(VI) is manifested in the IR spectra (Fig. 3). The IR spectra of all the samples of PK-S resin contain a strong broad absorption band of bending vibrations of water molecules and phenolic OH groups (~1620 cm^{-1}) and the absorption band of C=C stretching vibrations of the benzene ring (1520 cm^{-1}) [8]. The IR spectra of PK-S resin in the H^+ form contains an absorption band of the bending vibrations of the phenolic group (1440 cm^{-1}), a broad absorption band of C–O stretching vibrations of the phenolic groups (~1300 cm^{-1}), and an absorption band of

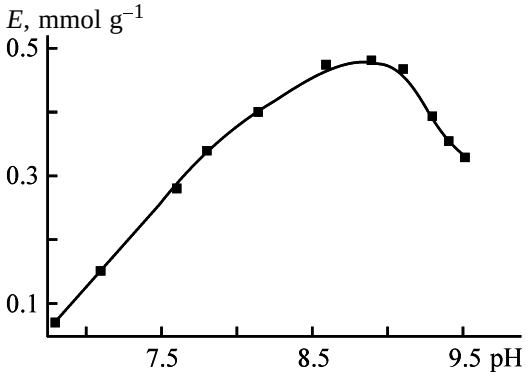

Fig. 2. Influence of pH on the sorption capacity of PK-S cation exchanger for tungsten(VI) in sorption from its 0.01 M solution containing 1 M $(NH_4)_2MoO_4$.

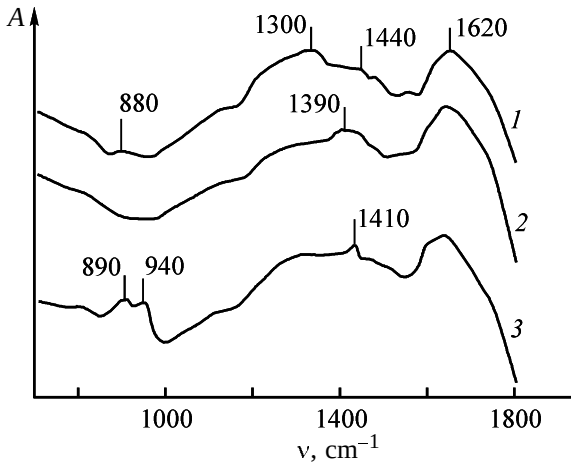

Fig. 3. IR spectra of PK-S cation exchanger in the (*1*) H^+ and (*2*) Na^+ forms, and (*3*) of PK-S resin saturated with tungsten(VI) from 0.05 M aqueous Na_2WO_4 at pH 9.0 to the sorption capacity of 1.4 mmol g^{-1}. (ν) Wave number and (*A*) absorption.

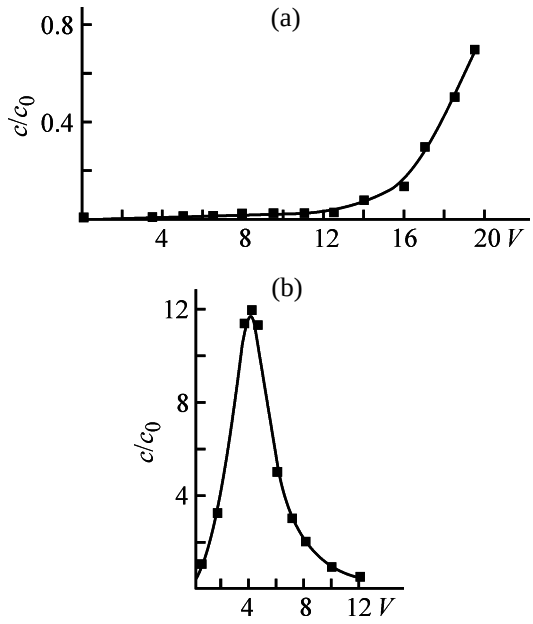

Fig. 4. (a) Breakthrough curves for tungsten(VI) sorption on PK-S resin from 1 M aqueous $(NH_4)_2MoO_4$ containing 0.1 g l^{-1} tungsten(VI) and (b) curve of tungsten(VI) desorption from PK-S with 0.5 M aqueous NaOH. (c/c_0) Ratio of the tungsten(VI) concentration at the column outlet and its concentration in the initial solution; (V) solution volume passed though the column (number of resin bed volumes).

the out-of-plane vibrations of the phenolic groups at ~880 cm^{-1}. The IR spectrum of PK-S resin in the Na^+ form contains no absorption bands at 1440, 1300 and 880 cm^{-1}, but a new absorption band of the ionized phenolic groups Ar–O^- appears at 1390 cm^{-1}. The IR spectrum of PK-S saturated with tungsten(VI) differs from that of the resin in the Na^+ form: the absorption band of vibrations of the ionized phenolic groups becomes narrower and shifts towards shorter waves by approximately 20 cm^{-1} (~1410 cm^{-1}), apparently due to coordination of the phenolic groups with tungsten. This spectrum contains also two new absorption bands of W–O vibrations at 890 and 940 cm^{-1} [10, 11].

Our dynamic sorption experiments showed that PK-S cation exchanger ensures efficient purification of concentrated aqueous ammonium molybdate to remove tungsten impurities. Figure 4 shows the breakthrough curve for tungsten sorption from aqueous solution containing 1 M $(NH_4)_2MoO_4$ (chemically pure grade) and tungsten impurities (0.1 wt % relative to molybdenum) and the curve of tungsten desorption with 0.5 M aqueous sodium alkali. The tungsten was desorbed with aqueous NaOH, since aqueous ammonia desorbs tungsten incompletely. We found that treatment of aqueous ammonium molybdate containing tungsten impurities with PK-S cation exchanger decreases the tungsten content by a factor of no less than 100. Unfortunately, PK-S cation exchanger as well as most of the other cation exchangers of the condensation type are poorly stable in alkaline solutions. As a result, in the course of desorption of tungsten from PK-S with aqueous NaOH, the resin degrades and the eluate becomes yellow-brown.

CONCLUSION

PK-S cation exchanger with the pyrocatechol functional groups selectively sorbs tungsten(VI) impurities from aqueous ammonium molybdate. The treatment of 1 M aqueous ammonium molybdate with this resin decreases the tungsten content in the solution by a factor of no less than 100.

Abstract—The influence exerted by a calcium hydroxide additive introduced into the negative electrode on the serviceability of a sealed nickel–zinc battery with a nickel oxide electrode fabricated from spherical nickel hydroxide on a foamed-nickel support was studied.

It was established in a study of processes governing the cycling life of a sealed nickel–zinc (SNZ) battery that the most important limitations are imposed by transport and incorporation of zinc into the structure of a nickel oxide electrode (NOE) in amounts leading to its gradual degradation and accelerated "loss of shape" by the zinc electrode.

The incorporation into nickel hydroxide of a part of zinc(II) transferred to the positive electrode leads to unbalance of migration and diffusion flows of $Zn[OH]_4^{2-}$ ions directed toward the NOE in charging and in the opposite direction in discharge. Therefore, to decelerate the accumulation of zinc in the NOE, the following is necessary. The fraction of $Zn[OH]_4^{2-}$ ions, which are involved, in parallel with OH^- ions, in current transport, is to be lowered and the gradient of their concentration, which appears in charging between the zones of the reactions in the negative and positive electrodes, is to be diminished to the maximum possible extent. Both these goals are achieved by lowering the equilibrium concentration of $Zn[OH]_4^{2-}$ in the electrolyte. However, of high importance in this case are physicochemical parameters of the NOE (porosity and structure of its pore space, electrical conductivity of the active paste), which determine the current distribution in the electrode and concentration changes in the electrolyte filling the pore space. These parameters affect the stability of the zincate complex and the rate of incorporation of zinc into the structure of nickel hydroxide. Zinc is incorporated into the layered structure of nickel hydroxide in the form of a cation in battery charging in the localized interlayer space, with hydrogen bonds [1] and covalent bonds [2] formed to give $Ni_{1-x}Zn_x(OH)_2$ or $Ni_{1-x}Zn_xOOH$ complexes.

In particular, the accumulation of incorporated zinc in pressed electrodes with a foamed-nickel (FN) support, which contain electrically conducting components, is 1.5–2 times slower than that in electrodes with a metal–ceramic support [1].

However, with nickel oxide electrodes of the FN type used in a battery and, simultaneously, the initial KOH concentration lowered from 7 to 6 M, it was impossible to make longer the cycling life of SNZ batteries. This was due to a decrease in the concentration of the electrolyte in the course of cycling to 3–3.5 M and the resulting deterioration of the serviceability of the electrodes [3, 4].

These results demonstrated that, to improve to an even greater extent the service life of a sealed nickel–zinc (NZ) battery, it is necessary to diminish the solubility of the zincate complex without any further decrease in the concentration of OH^- ions in the zone of the negative electrode, e.g., upon introduction of a $Ca(OH)_2$ additive into the zinc electrode.

The introduction of $Ca(OH)_2$ into the zinc electrode in order to make longer the service life (in cycling) of an NZ battery was first suggested by A.A. Zhulidov [5]. The battery developed by him for miner's lamps had a prolonged, by that time, cycling life of up to 250–300 cycles.

In recent years, it has been suggested to introduce a $Ca(OH)_2$ additive into the zinc electrode in the form of a sparingly soluble calcium zincate in order to make longer the cycling life of an NZ battery [6–8].

Calcium zincate is a complex compound, which is not stoichiometric [6], but in equilibrium with a 20% KOH solution has a definite composition: $Ca(OH)_2 \cdot 2Zn(OH)_2 \cdot 2H_2O$. The complex is formed upon mixing of $Ca(OH)_2$ with ZnO in an alkaline medium

and prolonged keeping in the absence [6] or in the presence [7] of catalysts. In an electrolyte with 0 to 30% KOH, the amount of ZnO that is in equilibrium with a solution of potassium zincate and calcium zincate is 2–3 times lower than that in the case of its equilibrium with KOH [6]. However, as the content of KOH and calcium zincate increases, the solubilities of ZnO in these compounds approach each other to become equal at a KOH concentration of 8 M (34 wt %).

A question arises in practical use of calcium zincate additives as to whether it is appropriate to use it in finished form or as separate components. This is because calcium zincate mostly decomposes in charging and is formed again in discharge only partially [8]. The amount of the material present as separate components depends on the discharge conditions and on the period of time during which the battery is in the discharged state.

In this study, a $Ca(OH)_2$ additive to ZnO was introduced in the form of separate components in amounts closely corresponding to the composition $Ca(OH)_2 \cdot 2Zn(OH)_2 \cdot 2H_2O$ (batteries 1). In parallel with the experimental batteries we tested control batteries containing no $Ca(OH)_2$ additive. The initial concentration of KOH in the electrolyte was 6 (batteries 1, 2) and 7 M (Table 1, batteries 3).

EXPERIMENTAL

The basic parameters of the sealed nickel–zinc batteries are listed in Table 1.

The experimental and control batteries under study differed in the composition of the active pastes of the negative electrode and the capacity ratio of the negative and positive electrodes.

The active paste of the negative electrodes of all the batteries was fabricated with thorough mixing of the components. In batteries 1, the amount of $Ca(OH)_2$ in the mixture was 22 wt %. The mixture contained about 10 wt % excess of ZnO, relative to its content in calcium zincate. In all the variants, the pressed positive electrodes used were fabricated by pasting the active mass on the FN support and subsequent pressing.

The capacity ratio of the active pastes of the negative and positive electrodes in batteries 1, with a $Ca(OH)_2$ additive, is smaller than that in batteries 2 and 3. This is so because part of ZnO in the negative electrode of batteries 1 is replaced with $Ca(OH)_2$ (at a thickness equal to that of electrodes in batteries 2, with a HgO additive).

The batteries were formed in a ventilated state (with an opened low-pressure valve). The modes of charging and discharge of the batteries in the forming and subsequent cycles are listed in Table 2. The forming mode was chosen so that, at the beginning of the

subsequent cycling, the active paste contained no less than 20% oxidized phase in the charged state and 30–40% reduced phase, when discharged.

The charging current in forming was 3 A, and that in cycling, 5 A in the first stage and 1.5 A in the second. The final charging voltage was 2.05 V in forming, and 1.98 V for batteries 1 and 1.93 V for batteries 2 and 3, in cycling. The discharge current was 5 A in forming and 6 A in cycling. The final discharge voltage was 1.2 V.

As seen from Table 2, the forming of batteries 1 was hindered, which required two additional forming cycles.

Measurements demonstrated that the way in which potentials vary in forming of positive electrodes of the batteries is the same for all the batteries. The charging potential of negative electrodes with a $Ca(OH)_2$ additive in batteries 1 is higher and especially steeply increases when charging is commenced, which indicates that the ohmic component of the polarization is significant.

In further studies of sealed batteries (with pressure gages on cover), the charging and discharge voltages and the internal pressure associated with accumulation of oxygen and hydrogen were measured. In doing so, it was kept in mind that the difference in battery voltages in the initial period of cycling is due to specific features of processes occurring in the negative electrode and the battery capacity is determined by the positive electrode, which has a lower calculated capacity (Table 1).

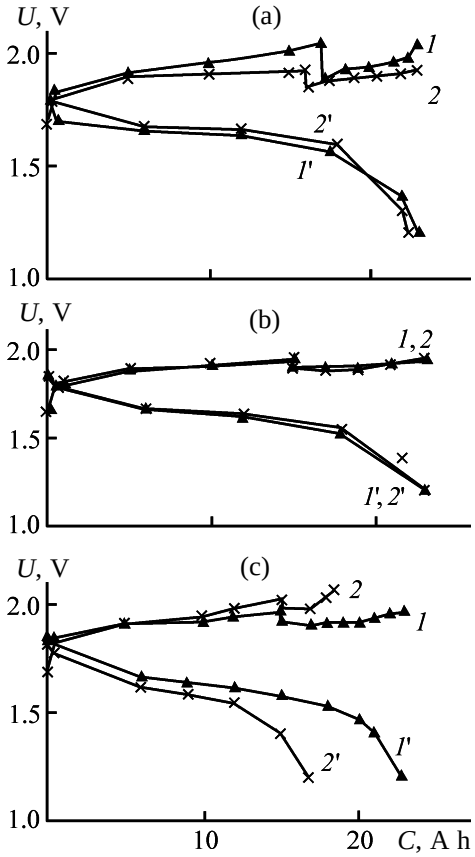

Fig. 1. Voltage U of NTsG-25 batteries (*1*, *1*') 1 and (*2*, *2*') 2 in (*1*, *2*) charging and (*1*', *2*') discharge in the course of cycling. (*C*) Discharge capacity. Cycle: (a) 35th, (b) 100th, and (c) 170th. Additive to the zinc electrode (%): (*1*, *1*') 22 $Ca(OH)_2$ and (*2*, *2*') 0.9 HgO + 0.25 PbO.

At the beginning of cycling, <30–40 cycles, the charging voltage of batteries 1 with a $Ca(OH)_2$ additive was higher than that in batteries 2 (Fig. 1a). At the instant when the current is switched on, the voltage increases abruptly. A stronger increase in voltage is also observed for batteries 1 in the final stage of charging, when a larger part of zinc(II) is reduced and further reduction of the remaining part of the oxidized phase (ZnO) is hindered because its contact with the current-carrying support may be disrupted in the presence of $Ca(OH)_2$. The charging and discharge voltages of batteries 1 and 2, respectively, become closer by the 50th cycle and virtually completely coincide by the 100th cycle (Fig. 1b).

However, the situation changes after 160–180 cycles. The manner in which the charging voltage and discharge capacity vary in batteries 1 remains the same, but in batteries 2 the voltage increases in the course of charging more steeply, which leads to a shorter time of their charging and to the resulting decrease in the discharge capacity (Fig. 1c). It has been established [2] that the deteriorating chargeability of batteries 2 results from the hindrance to the anodic process at the positive electrode, which arises during this stage of cycling.

The variation of the gas pressure in batteries 1 (Fig. 2) exhibited specific features characteristic of batteries with NOE fabricated from spherical nickel hydroxide [9]. The build-up of pressure in these batteries, preserved during the first 30–40 cycles, is due to predominant accumulation of hydrogen. This is associated with the low rate of its oxidation on the NOE, which originally has a smoothened and denser surface [9]. Beginning with 30th–40th cycle, the evolved H_2 is oxidized on the NOE virtually completely because of the loosening of the surface layer of the active paste, and the pressure within the batteries is due to the evolution of oxygen, being determined by the rate of its absorption at the zinc electrode. In further cycling, the pressure varies narrowly at around

Table 3. Content of KOH in the electrolyte and accumulation of zinc in the NOE of the NTsG-25 batteries under study in different cycles

Battery	Initial electrolyte concentration, M (g l^{-1})	Cycle	KOH concentration		Content of zinc	
			M	g l^{-1}	in electrolyte, g l^{-1}	in NOE, $[Zn/Ni(OH)_2]_2$, %
1	6 (336)	90th	2.9	163	4.6	5.2
		220th	2.8	158	–	–
2	6 (336)	70–90th	3.0	168	8.0	7.8
		218th	2.95	166	–	–
3	7 (392)	90th	4.8	269	12.6	9
		200th	–	–	–	10.6
		286th	4.5	250	12	11.6

0.6×10^2 kPa, which indicates that the zinc electrode containing a $Ca(OH)_2$ additive can actively react with oxygen evolved at the NOE.

The charging and discharge capacities of batteries 1 and 2 vary similarly in the initial stage of cycling (Fig. 3), although the time of their stabilization is longer in batteries 1. Probably, this is due to gradual formation of the calcium zincate phase. By the 40th–50th cycle, the charging capacities of both kinds of batteres attain the same level, whereas the discharge capacity of batteries 1 with a $Ca(OH)_2$ additive is higher, which is presumably due to the better chargeability of the positive electrode. This result can be attributed to an increased overvoltage of O_2 evolution in the presence of calcium(II) [10].

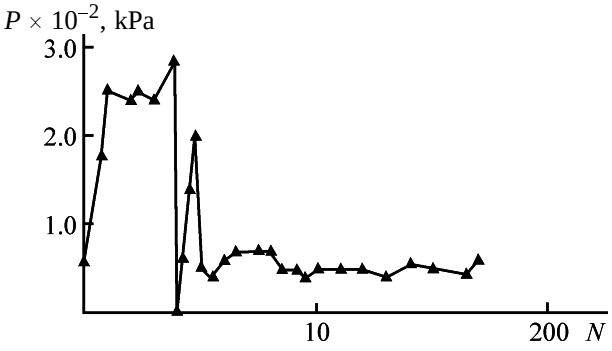

Fig. 2. Variation of the internal pressure in NTsG-25 battery 1 with a $Ca(OH)_2$ additive to the negative electrode. (*P*) Pressure and (*N*) number of cycles.

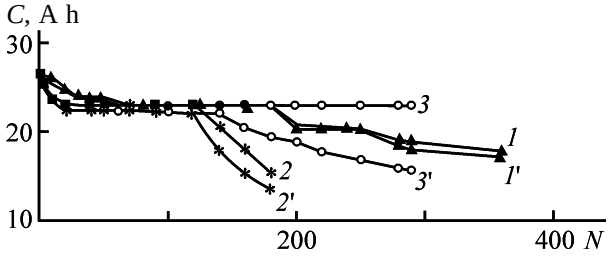

Fig. 3. Variation of (*1*–*3*) charging and (*1*'–*3*') charge capacity *C* of NTsG-25 batteries *1*–*3* with various additives to the negative electrode and at different concentrations of KOH in the electrolyte. (*N*) Number of cycles. Additive (%): (*1*, *1*') 22 $Ca(OH)_2$ and (*2*, *2*', *3*, *3*') 0.9 HgO + 0.25 PbO. Initial KOH concentration (M): (*1*, *2*) 6 and (*3*) 7.

The charging and discharge capacities first start to decrease in batteries 2 with a lowered initial concentration of KOH (6 M). Their service life does not exceed 200 cycles. At a higher initial concentration of KOH (7 M), the decrease in the battery capacity (to 0.6 C_{in}), observed in batteries 3 after 160–180 cycles, was slower and the service life was 300 cycles.

In batteries containing a $Ca(OH)_2$ additive, the capacity decreased only slightly in the course of cycling to 360 cycles at a change in the electrolyte composition similar to that in batteries 2.

These results can be understood on the basis of data on changes in the electrolyte composition in the batteries under study and on accumulation of zinc in the NOE (Table 3).

The concentration of KOH in the electrolyte in batteries 1 and 2 reaches a constant value by the 70th cycle and then varies only slightly. In batteries 3, it reaches a rather high level. The service life of this kind of batteries is limited by the accumulation of zinc in the NOE in amounts exceeding 10% $Zn/Ni(OH)_2$.

The decrease in the capacity of batteries 2 is due to the low steady-state concentration of hydroxide ions. At a similar, to batteries 2, change in the concentration of OH^- ions, batteries 1 retain a stable capacity because of the presence of $Ca(OH)_2$ and calcium zincate, which serve as an additional source of hydroxide

ions in the zone of the occurring reactions. The accumulation of zinc in the NOE of this kind of batteries is slow because of the lower concentration of $Zn(OH)_4^{2-}$ in the electrolyte, which results in that their service life is longer.

According to results of a chemical analysis, cycling leads to transfer of not only zinc(II), but also calcium(II), into the active paste of the NOE in batteries 1. At a very low content of calcium(II) in the electrolyte of a charged battery (0.07 g l^{-1}) by the 90th cycle, 0.112 g of calcium(II) was transferred into the active paste of the NOE, which corresponds to 0.37 g of calcium zincate. At such a low concentration of calcium(II) in the electrolyte, it transport may occur only via diffusion in the form of a complex and decomposition of this complex in the reaction of zinc with nickel hydroxide. It was found from the ratio of the transferred amounts of zinc(II) and calcium(II) that zinc is transferred into the NOE of batteries containing a $Ca(OH)_2$ additive mainly in the form of zincate ions at an insignificant fraction of its transport by calcium zincate formed in the course of cycling.

CONCLUSIONS

(1) Calcium hydroxide introduced into the negative electrode of a sealed nickel–zinc battery is an additional source of hydroxide ions in the zone of the occurring reactions. In the course of cycling, it reacts with zinc oxide and thereby gradually transforms into calcium zincate.

(2) The reduced phase of a zinc electrode containing calcium zincate actively reacts with oxygen evolved at the nickel oxide electrode, which results in that the internal pressure of oxygen in the sealed battery is not high.

(3) The transport of zinc(II) by $Zn(OH)_4^{2-}$ ions becomes slower in the presence of calcium zincate because of its lower equilibrium concentration in the electrolyte. Calcium zincate is involved in the transport of zinc(II) in the nickel oxide electrode as a result of its diffusion in the form of a complex.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Formation of Surface Oxides in Electrode Polarization of Fibrous Carbon Materials in a Sulfuric Acid Solution and Their Influence on Ion-Exchange and Electrochemical Properties of These Materials

V. I. Varentsova and V. K. Varentsov

Institute of Solid-State Chemistry and Mechanochemistry, Siberian Division, Russian Academy of Sciences, Novosibirsk, Russia

Received May 19, 2004

Abstract—Formation of surface oxides in the course of cathodic and anodic polarization of fibrous carbon materials in a 0.25 M sulfuric acid solution and their influence on the cation- and anion-exchange properties of fibrous carbon materials, steady-state electrode potential in a 0.1 M sodium sulfate solution, and electrodeposition of copper from a sulfuric acid solution were studied.

The use of fibrous carbon materials (FCMs) in technical electrochemistry has proved to be effective in manufacture of electric power sources, electrodeposition, recovery of noble, rare, and nonferrous metals from mineral and secondary raw materials, and deactivation of toxic compounds and liquid waste in various branches of industry [1–3]. In prolonged operation of FCM electrodes, problems necessarily arise, associated with the change of their properties in cyclic and nonstationary processes [1, 3, 4]. It has been shown previously that preliminary electrode treatment of some FCMs in acid and alkaline solutions leads to a significant change in the morphology of carbon fibers and in the mass, electrical conductivity, and steady-state electrode potential of FCMs. All these factors can strongly affect further use of FCMs in electrochemical processes [5–7].

Published data suggest that the change in the FCM properties is due to formation of oxide compounds on the surface of carbon compounds in the course of electrode treatment. The existence of oxide compounds on the surface of carbon materials has long been known, and a considerable attention is being given to a study of these materials because of their pronounced influence on the catalytic, ion-exchange, adsorption, and other properties of carbon materials [8–15].

Surface oxide compounds are produced in reaction of carbon materials with atmospheric oxygen without formation of an independent phase. Surface oxides are nonstoichiometric, but enter into chemical reactions characteristic of bulk compounds because of the presence of a chemical bond. A fruitful way to study surface compounds is to identify them with functional groups known from organic chemistry. Thanks to this approach, carboxy, phenol, carbonyl, and lactone surface oxides have been identified. The identification was the most reliable for carboxy and phenol groups [10, 11, 14, 15]. A distinctive feature of carbon materials is the possibility of widely varying the composition and relative concentrations of surface oxides, which leads to variation of their surface properties in a wide range. Depending on the conditions and method of treatment, carbon materials can adsorb from solutions both acids and alkalis; the steady-state electrode potential of carbon materials in electrolyte solutions varies by several hundreds of millivolts [11, 13].

The most flexible way to modify the surface properties of carbon materials is the electrochemical method [11, 13–15]. Data concerning the application of electrode treatment of FCMs for modification of their surface properties are scarce [14, 15]. It was shown in [14] that the surface properties of carbon fibers subjected to anodic and chemical treatment are identical. By contrast, it was found in [15] that the amount of phenol groups, involved in the esterfication reaction, on the surface of anodically oxidized fibers considerably exceeds that on the surface of chemically and thermally oxidized fibers.

1070-4272/05/7803-0430© 2005 Pleiades Publishing, Inc.

The goal of this study was to determine the composition of oxide compounds formed on the FCM surface in cathodic and anodic polarization in an H_2SO_4 solution and their influence on the ion-exchange and electrochemical properties of FCMs.

EXPERIMENTAL

As objects of the study we chose carbonized (graphite content ~85 wt %) woven (AMT, AUT, knitted fabric) and nonwoven (NT-1) fibrous carbon materials. The electrode polarization in the galvanostatic mode was carried out using a B5-49 dc power source, with the solution circulated by a pp-304 peristaltic pump through the electrode volume with an overall surface area of 2 cm^2 on a setup described schematically in [5]. A platinum wire served as an anode, and a perforated titanium or platinum plate, as a current lead. After treatment, the electrode was washed with distilled water to constant pH and dried at 80–100°C. The variation of the ion-exchange properties of FCMs was monitored by absorption of an acid or alkali from solutions, and that of electrochemical properties, by the change in the steady-state electrode potential and by the efficiency of electrodeposition of copper(II) from a sulfuric acid solution.

The steady-state electrode potential was measured in 0.1 M Na_2SO_4, without drying of the FCM, with an OP-265/1 pH-meter relative to a saturated silver chloride electrode and recalculated to the hydrogen scale. Copper(II) was electrodeposited from a solution of composition (g l^{-1}): copper(II) 0.15 and sulfuric acid 25, on the setup used for FCM treatment. The efficiency of the process was evaluated by the degree of copper(II) electrodeposition from solution, α,

$$\alpha = (c_0 - c_\tau)/c_0 \times 100,$$

where c_0 and c_τ are the initial and final concentrations of copper in solution, g l^{-1}.

The amount of surface oxides was determined using the neutralization reaction, by the procedure described in [16]. The method of separate determination of surface oxide groups [10, 11, 16] is based on the different activities of surface oxides with respect to bases with different strengths. NaOH is used to neutralize carboxy and phenol groups, and $NaHCO_3$, carboxy groups, with the amount of phenol groups found from the difference.

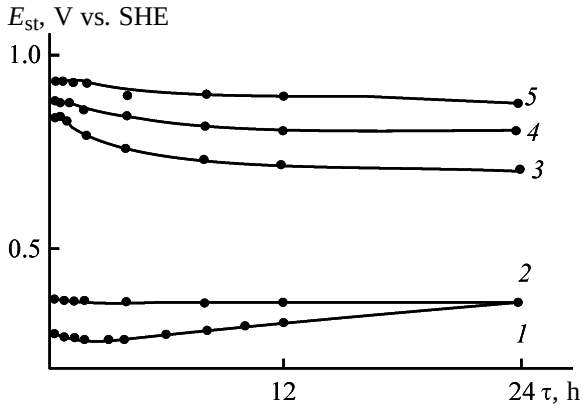

Table 1 lists the results obtained in measuring the amount of ion-exchange groups on the surface of carbon fibers after the anodic polarization of FCM. It can be seen that the amount of ion-exchange groups and the relative amounts of cation- and anion-exchange groups vary with the conditions of electrode treatment. As a result of anodic treatment under the conditions studied, FCMs acquire cation-exchange properties. Under the conditions of cathodic polarization, both cation- and anion-exchange groups can be found on the FCM surface.

Table 1. Amount n of anion- (a/e) and cation-exchange (c/e) groups on the FCM surface after an electrode treatment in a 0.25 M H_2SO_4 solution. Current density I = 500 A m^{-2}, electrolysis duration τ = 2 h

The influence exerted by the conditions of electrode polarization on the composition and ratio (relative amounts) of cation-exchange groups (carboxy and phenol) on the surface of FCM fibers was studied with NT-1 as example. Table 2 shows that, by varying the conditions of electrode polarization, one can affect not only the amount of cation-exchange groups, but also the ratio of carboxy and phenol groups. In a cathodic treatment, the amount of carboxy groups remains unchanged and that of phenol groups decreases, with the extent of this decrease depending on the conditions of cathodic treatment. Changing the cathodic current density exerts a stronger influence than the duration of treatment. In anodic polarization, the amount of phenol groups increases by a factor of 1.5–2, and that of carboxy groups, by a factor of more than 8. As the current density increases, the amount of phenol groups grows by ~35%, and the amount of carboxy groups is independent of the conditions of anodic polarization. The ratio of phenol and carboxy groups varies from 0.75 to 4.3, depending on the conditions of electrode treatment.

It should be noted that the ability of an FCM sub-

Steady-state electrode potential E_{st} of an NT-1 FCM vs. time τ of keeping in a 1 M Na_2SO_4 solution after (*1*, *2*) cathodic and (*3*–*5*) anodic polarization of the FCM in an H_2SO_4 solution. Steady-state electrode potential of the initial NT-1 sample +0.37 V. Polarization current density (A m^{-2}): (*1*, *5*) 1000, (*2*, *4*) 500, and (*3*) 250. Polarization time (h): (*1*, *2*, *4*, *5*) 1–3 and (*3*) 1.

jected to electrode polarization to absorb alkali from solution remains virtually unchanged if, upon sorption of NaOH, the samples are neutralized with acid and washed with water, and alkali is again sorbed after that.

The state of the surface of FCM fibers strongly affects the steady-state electrode potential of FCM, E_{st}, and the extent to which it changes upon an electrode treatment [5–7]. In the presence of atmospheric oxygen at the interface between the carbon material and the aqueous electrolyte solution, E_{st} must be determined, depending on the solution pH, by the electrochemical equilibria

$$O_2 + 4H_3O^+ + 4e = 6H_2O \text{ (acid medium)},$$

$$O_2 + 2H_2O + 4e = 4OH^- \text{ (alkaline medium)}.$$

However, this is virtually not the case because carbon materials are not inert toward oxygen and suffer from corrosion to give surface oxides. The contribution from the formation of surface oxides to E_{st} can be evaluated by subjecting the FCM to preliminary cathodic or anodic polarization, thereby changing the amount and ratio of the surface oxides. The figure shows how E_{st} of NT-1 varies after a cathodic or anodic polarization of NT-1 in a 0.25 M H_2SO_4 solution.

The figure shows that cathodic treatment has a little effect on E_{st}, with only a slight negative shift of E_{st} observed at a treatment current density of 1000 A m^{-2}. On keeping an NT-1 sample in a solution for 24 h, E_{st} returns to its initial value. The negative shift of E_{st} is due to desorption of oxygen from the FCM surface in cathodic polarization, and its return to the initial value on keeping in a solution, to chemisorption of oxygen [5, 7, 11, 13]. After a cathodic treatment, the amount of acidic surface oxides decreases, with a pronounced decrease (by a factor of 2) observed for samples subjected to cathodic polarization at a current density of 1000 A m^{-2} (Table 2). On keeping such a sample in a 0.1 M Na_2SO_4 solution for 24 h, 0.3 mg-equiv g^{-1} of acidic complexes was found on its surface, which is close to the value characteristic of the initial NT-1 (Table 2). An anodic treatment of NT-1 in a sulfuric acid solution strongly shifts E_{st} in the positive direction from the value attained in 0.1 M Na_2SO_4, even at a low anodic current density. As the treatment current density increases, the positive shift of E_{st} becomes more pronounced, reaching a value of 0.68 V. It has been assumed that the shift of E_{st} upon anodic polarization of NT-1 results from formation of oxide compounds on the NT-1 surface [6]. The amount of surface oxides found after an anodic treatment of NT-1 confirms this assumption (Table 2).

Total amount	0.32	0.90/1.06	1.02
Phenol	0.26	0.39/0.53	0.50
Carboxy	0.06	0.51/0.53	0.52

Thus, it follows from the results obtained that the steady-state electrode potential attained by an FCM upon its electrode treatment in an aqueous electrolyte solution is largely determined by the presence of surface oxides on the surface of carbon fibers.

As noted previously [6], anodic treatment of FCM results in that their electrical conductivity decreases, with the parameters of metal recovery on electrodes of this kind markedly impaired. It can be seen from

Table 3. Change in the mass Δm and electrical conductivity χ of NT-1 and in the amount n of surface oxides upon an electrode polarization in a 0.25 M H_2SO_4 solution

Polarization	Δm, %	χ, S cm^{-1}	n, mg-equiv g^{-1}
Initial sample	–	0.041	0.32
Anodic	+14.5	0.011	0.90
Anodic, followed by cathodic	+25	0.040	0.50

Table 4. Degree α of electrolytic recovery of copper(II) from solution in relation to conditions of preliminary electrode treatment of NT-1 in a 0.25 M H_2SO_4 solution

Treatment	i, A m^{-2}	τ, h	α, %
Initial sample	–	–	56.0
Anodic	500	1	41.7
Cathodic	500	1	57.0

the data obtained that the reason for the decrease in the electrical conductivity of FCMs is formation of surface oxides. This is also manifested in a significant increase (by 15–19%) in the mass of FCM samples [6]. The data in Table 2 suggest that cathodic treatment of samples subjected to anodic polarization can regenerate the FCM properties.

Table 3 shows how successive anodic-cathodic treatment affects the NT-1 properties. The current density of anodic and cathodic polarization was 500 A m^{-2}, and the time of treatment at each polarization, 1 h. Table 3 shows that cathodic treatment of an anodically polarized FCM restores its electrical conductivity, the positive gain in mass decreases by more than 80%, and the amount of surface oxide groups becomes smaller.

The results of experiments on electrolytic recovery of copper(II) from a sulfuric acid solution on an electrode of this kind at a current density of 500 A m^{-2} are listed in Table 4. The electrolytic recovery of copper(II) was performed at a current density of 500 A m^{-2} in the course of 20 min, because, as shown in [17], the contribution of concurrent reduction of hydrogen ions was at a minimum under these conditions.

Table 4 shows that the degree of electrolytic recovery of copper(II) onto an FCM electrode regenerated by cathodic polarization in an H_2SO_4 solution reaches values characteristic of the initial FCM. This result is important for application of FCM electrodes to processes associated with electrolytic recovery of metals, their subsequent anodic dissolution, and repeated use of fibrous carbon electrodes.

CONCLUSIONS

(1) The amount of ion-exchange groups on the surface of the fibrous carbon materials studied depends on the conditions of electrode treatment; as a result of anodic polarization, the materials acquire cation-exchange properties.

(2) The amount of cation-exchange (phenol and carboxy) groups on the NT-1 surface was determined. Depending on the polarization conditions, their total amount varies within a factor of 2–3.5, and their ratio, from 0.75 to 4.3.

(3) The steady-state electrode potential of fibrous carbon materials depends on the composition and amount of oxide groups on their surface. An increase in the amount of acidic surface oxides leads to a shift of E_{st} by 0.68 V in the positive direction.

(4) Cathodic treatment of samples subjected to anodic polarization can regenerate the properties of fibrous carbon materials.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

A New Procedure for Preparing Perfluoroalkoxypropanoic Acid Fluorides

Abstract—Condensation of perfluoro carboxylic acid fluorides with hexafluoropropene epoxide in the presence of *N,N,N',N'*-tetraalkyldiaminomethanes was studied.

Perfluoroalkoxypropanoic acid fluorides (PFPAFs) are starting compounds for preparing perfluoroalkyl vinyl ethers (monomers for fluoro rubbers, elastomers, vulcanizates with high heat, ozone, and weather resistance), emulsifiers, fluorinated surfactants, chemically and thermally stable liquids, lubricating oils, and polymeric materials [1].

Procedures for preparing PFPAFs are based on the reaction of hexafluoropropene epoxide (HFPE) with perfluoro carboxylic acid fluorides (PFAFs) in polar aprotic solvents in a wide temperature range (from –80 to 200°C) in the presence of various catalysts, e.g., alkali metal halides [2], quaternary ammonium salts [3], tris(dimethylamino)difluorophosphorane [4], sulfonium salts [5], tetraalkylurea [6], and *N,N,N',N'*-tetraalkyldiaminodifluoromethane [7].

As a rule, reactions with low-boiling PFAFs, e.g., with carbonyl fluoride, trifluoroacetyl fluoride, or pentafluoropropionyl fluoride, are performed at a pressure ranging from 0.7 to 24 atm. As solvents are used mixtures of polar aprotic solvents [dinitriles of saturated aliphatic dicarboxylic acids (C_5–C_8), dimethyl ethers of polyethylene glycols $CH_3O(CH_2CH_2O)_n \cdot CH_3$, n = 2–6] [8] or of polar aprotic (acetonitrile, diglyme) and nonpolar (pentane, hexane, cyclohexane, or a halogenated alkane, e.g., trifluorotrichloroethane) solvents [7]. The PFPAF yield in these procedures does not exceed 50%, being in some cases as low as 6–12%.

In this work, with the aim to increase the reaction selectivity, we studied the conditions of condensation of HFPE with PFAFs according to the scheme

$$R_F COF + CF_3CF\!-\!CF_2 \longrightarrow R_F CF_2OCFCOF,$$

(O bridge; CF$_3$ branch)

where R_F = F, CF_3, C_2F_5, $CF_3(CF_2)_3$, $HCF_2(CF_2)_3$, $CF_3(CF_2)_5$, $CF_3(CF_2)_7$, $BrCF_2$, or $C_2F_5OCF_2$.

In the process, we used new catalysts, *N,N,N',N'*-tetraalkyldiaminomethanes $R^1R^2NCH_2NR^3R^4$ (see table), where R^1–R^4 are linear or branched alkyls (C_1–C_6) or perfluoroalkyls (C_1–C_6), C_2H_4OH groups, or fragments forming with the nitrogen atom a heteroring containing one more nitrogen atom or an oxygen atom. Examples are bis(dimethylamino)methane, bis(diethylamino)methane, dipiperidinomethane, dimorpholinomethane, and bis[di(β-hydroxyethyl)amino]methane.

Condensation of HFPE with PFAF is performed in a polar aprotic solvent (acetonitrile or diglyme) in the presence of a nonpolar perfluorinated solvent (perfluoroheptane, perfluorooctane, perfluoromethylcyclohexane, perfluoroethylcyclohexane, perfluorodecalin, perfluoro-2-methyldecalin) acting as extractant for the forming PFPAF.

We found that the optimal catalyst concentration is 10–15 wt %; with its lower amounts, the yield of the target product decreases, and with larger amounts the PFPAF yield does not increase further.

The starting components, HFPE and PFAF, are taken in a molar ratio from 1 : 1 to 1 : 2. Under these conditions, the reaction mainly yields the monoaddition product, with a minor impurity (~1–3 wt %) of the HFPE isomerization product, pentafluoropropanoic acid fluoride.

The synthesis is performed in a stirred vessel at ambient pressure. The condensation product formed in the process is extracted with the organofluorine solvent. After the reaction completion, the PFPAF is distilled off from the extract, and the nonpolar organofluorine solvent is reused. The reaction products are

identified by ^{19}F NMR spectroscopy. The yield of perfluoroalkoxypropanoic acid fluorides is 97–99% (see table).

Under these conditions, HFPE oligomers and products of addition of two or more HFPE molecules to PFAF are not formed.

The condensation of HFPE with PFAF in the presence of *N*,*N*,*N*',*N*'-tetraalkyldiaminomethanes involves intermediate formation of dialkylaminofluoromethane generating fluoride ion [9] which, in turn, initiates formation of perfluoroalkoxide anion by the reaction with PFAF. The perfluoroalkoxide anion reacts with HFPE as a nucleophilic agent to form the corresponding PFPAF:

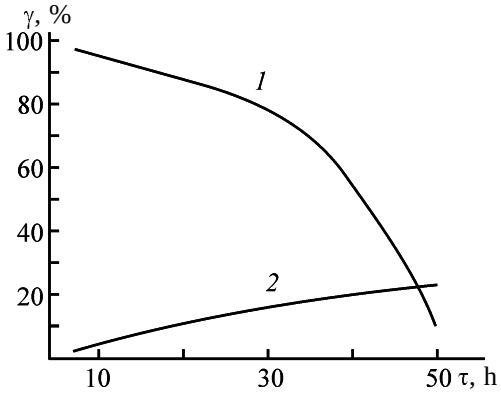
$$R_FCOF + CH_2(NR_2)_2 \rightarrow R_FCONR_2 + R_2NCH_2F$$

$$\rightleftarrows R_2NCH_2^+ + F^-,$$

$$R_FCOF + F \rightleftarrows R_FCF_2O^-,$$

$$R_FCF_2O^- + CF_3\underset{\diagdown\,O\,\diagup}{CF}{-}CF_2 \longrightarrow R_FCF_2OCFCF_2O^-$$
$$\Big|$$
$$CF_3$$

$$\rightleftarrows R_FCF_2OCFCOF + F^-.$$
$$\Big|$$
$$CF_3$$



With the condensation of carbonyl fluoride with HFPE in the presence of bis(diethylamino)methane (BDEAM) as example [solvent acetonitrile, extractant perfluoro-2-methyldecalin (PFMD) or perfluorooctane (PFO)], we examined the dependence of the catalyst activity on the reaction time (see figure).

It is seen that the conversion of HFPE into perfluoromethoxypropanoic acid fluoride (curve *1*) decreases from 98 to 21% in the interval from 6 to 45 h, and after 50-h operation of the catalyst it does not exceed 2–3%. In the same period, the conversion of HFPE into pentafluoropropanoic acid fluoride increases from 2–3 to 20–21%.

These results show that the useful life of the catalyst in the system CH_3CN–PFMD–BDEAM is 37–40 h on the average. After 48.5 h, the catalyst activity appreciably decreases: The conversion of HFPE decreases to 40%.

It was also interesting to test the new catalyst in oligomerization of HFPE. The reaction is performed in the presence of bis(diethylamino)methane in a polar aprotic solvent (diglyme) at –40 to –30°C. The ^{19}F NMR spectra of the reaction products demonstrate selective formation of HFPE tetramer (n = 4).

The mechanism of HFPE oligomerization involves isomerization of HFPE by attack of the electrophilic carbon atom of HFPE with a lone electron pair of the nitrogen atom in tetrasubstituted bis(diethylamino)methane, resulting in cleavage of the C–O bond in the epoxy ring and rearrangement of the unstable intermediate perfluoroalkoxide anion into pentafluoropropion-

Catalyst activity as a function of the reaction time τ. (γ) Conversion of HFPE into (*1*) perfluoromethoxypropanoic and (*2*) pentafluoropropanoic acid fluorides.

yl fluoride. The latter reacts with HFPE to form addition products:

$$CF_3CF_2COF + n\,CF_3CF(O)CF_2 \xrightarrow{F^-} CF_3CF_2CF_2O(CFCF_2O)_{n-2}CFCOF.$$

EXPERIMENTAL

Bis(diethylamino)methane was synthesized in a 3-l three-necked flask equipped with a reflux condenser and a dropping funnel. The flask was charged with 200 g of paraform and approximately 700 ml of water; the mixture was stirred to obtain a unifom suspension and heated to 90°C to dissolve the paraform. After cooling to 30–40°C, 1.15 kg of diethylamine was added, the mixture was cooled to 20–25°C, and NaOH was added in portions. After stirring for 2–3 h, the mixture was distilled. Diethylamine and water were removed at 55–100°C, and bis(diethylamino)-methane was distilled at 110–112°C. The distilled product was dried over NaOH or KOH. Yield 1.75 kg (69%). The other catalysts were prepared similarly.

The condensation of HFPE with PFAF was performed in a three-necked flask equipped with a stirrer, a reflux condenser (cooled to –30°C), a dropping funnel, and a bubbler for feeding HFPE and gaseous PFAFs. The reactant amounts, reaction conditions, and yields of the target products are listed in the table.

The products were identified by ^{19}F NMR spectroscopy (Bruker WP-80 device, 80 MHz, internal reference hexafluorobenzene).

CONCLUSIONS

(1) A procedure was developed for selective preparation of perfluoroalkoxypropanoic acid fluorides in a quantitative yield. The procedure involves new catalysts, *N,N,N',N'*-tetraalkyldiaminomethanes, and extraction of the forming reaction products with nonpolar organofluorine solvents.

(2) Oligomerization of hexafluoropropene epoxide in the presence of *N,N,N',N'*-tetraalkyldiaminomethanes yields the hexafluoropropene epoxide tetramer as the major product.

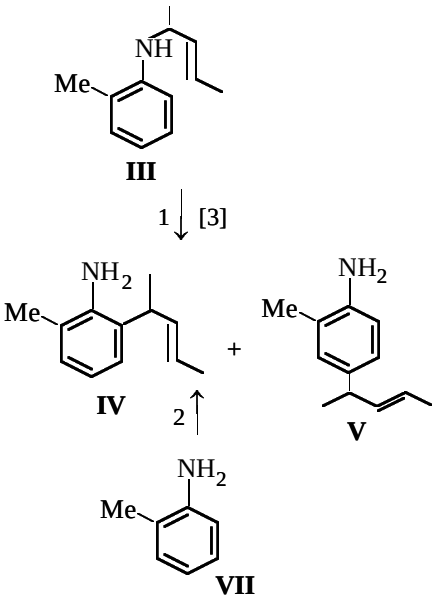
ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis of 6-Methyl-4-(1-methyl-2-buten-1-yl)-2-(2-cyclohexen-1-yl)- and 6-Methyl-4-(1-methyl-2-buten-1-yl)-2-(1-cyclohexen-1-yl)anilines

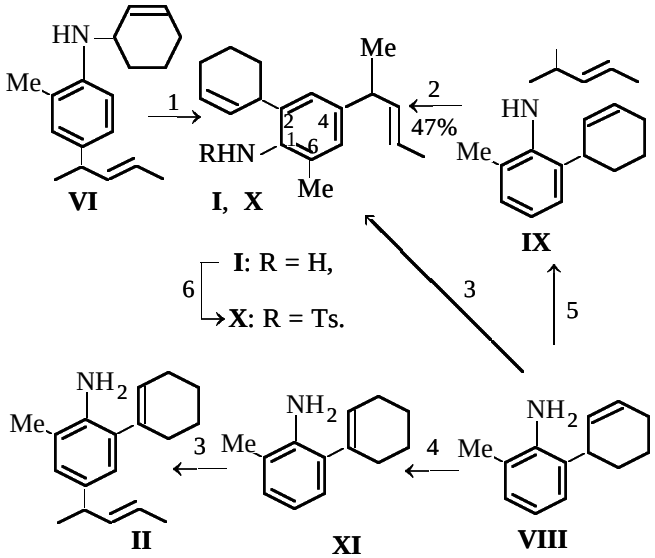
R. R. Gataullin, R. R. Ishberdina, A. M. Sotnikov, and I. B. Abdrakhmanov



Institute of Organic Chemistry, Ufa Scientific Center, Russian Academy of Sciences, Ufa, Bashkortostan, Russia

Received July 2, 2004; in final form, December 2004

Abstract—Alkenylation of 6-methyl-2-(2-cyclohexen-1-yl)- and 2-(1-cyclohexen-1-yl)anilines with piperylene in the presence of $AlCl_3$ and transformation of the resulting cyclohexenylanilines into carbazole structures were studied.



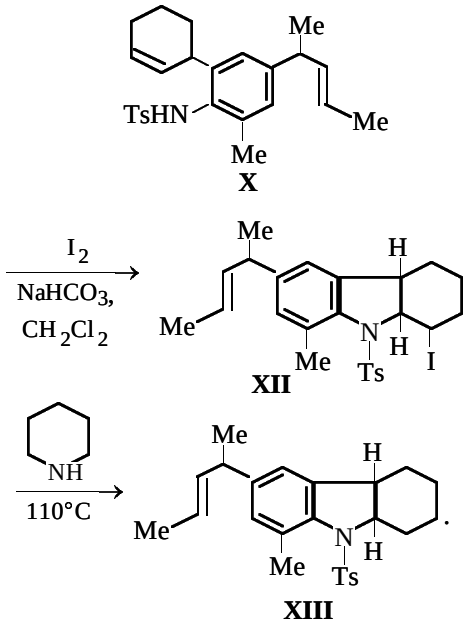
Major attention is given to synthesis of heterocyclic systems of the pyridocarbazole series, as such derivatives (e.g., ellipticine, olivacine, and their isomers) show antitumor activity. One of the main routes to such compounds involves as intermediates 6-substituted carbazoles or their partially hydrogenated analogs [1] prepared from 2-cyclohexenylanilines [2].

To develop a procedure for preparing amines **I** and **II**, which are key substances in the synthesis of olivacine and its isomers, we examined several routes. Aromatic Claisen amino rearrangement of **III** yields amines **IV** and **V** [3]:

Conditions and reagents: (1) HCl, then excess toluidine, 140°C; (2) piperylene, $AlCl_3$, benzene, 135°C, 3 h.

The ratio of the *ortho* and *para* isomers is approximately 85 : 15; therefore, cyclohexenylation of the minor *para* isomer **V** followed by the rearrangement of the resulting N-substituted product **VI** into the desired amine **I** is of little preparative use:

Conditions and reagents: (1) HCl, then excess **V** or *o*-xylene, 140°C; (2) HCl, then excess **VIII**, 165–170°C, 6 h; (3) piperylene, $AlCl_3$, benzene, 135°C, 3 h; (4) KOH, 300°C, 1 h; (5) 3-chloro-2-pentene; (6) TsCl, Py, 20°C.



In alkenylation of toluidine **VII** with piperylene in the presence of excess $AlCl_3$, the isomer ratio **IV** : **V** becomes inverse (15 : 85), but the problem of their separation remains.

The reaction of cyclohexenyltoluidine **VIII** with 3-chloro-2-pentene yields *N*-pentenyl derivative **IX**.

1070-4272/05/7803-0438 © 2005 Pleiades Publishing, Inc.

Heating of the hydrochloride of **IX** at 170°C also gives dialkenylaniline **I** in 47% yield based on the reacted amine **VIII**. Alkenylation of **VIII** with piperylene in the presence of $AlCl_3$ appeared to be the most efficient; the yield of **I** was 88%. Cyclohexenylaniline derivatives with the vinyl location of the double bond can be successfully used for the synthesis of relatively complex heterocyclic systems of the carbazole series. Proceeding with such studies [5], we also performed alkenylation of aniline **XI** with piperylene in the presence of $AlCl_3$. The product is formed in 85% yield by heating of **VIII** with KOH at 300°C. The reaction of amine **XI** with piperylene gives compound **II** in 87% yield.

The reaction of amine **I** with TsCl in pyridine gives *N*-tosyl derivative **X**, which, when treated with electrophilic agents (in particular, with molecular iodine), yields hexahydrocarbazole system **XII**, with the double bond in the methylbutenyl moiety remaining intact. Refluxing of **XII** in piperidine results in *trans* elimination with the formation of tetrahydrocarbazole **XIII** in 90% yield:

The compositions and structures of the compounds prepared were proved by IR and NMR spectroscopy and by elemental analysis.

EXPERIMENTAL

The ^1H and ^{13}C NMR spectra were taken on a Bruker AM-300 spectrometer (operating frequencies 300 and 75 MHz, respectively; solvent $CDCl_3$; internal reference TMS), and the IR spectra, on a UR-20 spectrometer. The product purity was monitored on a Chrom-5 chromatograph (stationary phase SE-30 on Chromaton N-AW-DMCS, 1200 × 3-mm column, flame ionization detector, heating rate 12 deg min^{-1}, carrier gas He). Qualitative analysis was performed with Sorbfil UV 254 plates (Lyuminofor Private Company, Krasnodar, Russia), eluent CH_2Cl_2. A mixture of *cis* and *trans* isomers of piperylene (Kaustik plant, Sterlitamak, Bashkortostan, Russia) was used for alkenylation without additional purification.

6-Methyl-4-(1-methyl-2-buten-1-yl)-2-(2-cyclohexen-1-yl)aniline I. (a) A 17-ml pressure vessel was charged with 1 g of aniline **VIII**, 10 ml of benzene, 0.69 g of $AlCl_3$, and 0.68 g of piperylene. The mixture was heated on an oil bath at 135°C for 3 h and cooled to room temperature, after which 30 ml of 20% aqueous NaOH was added, the mixture was stirred, 30 ml of benzene was added, and the organic phase was separated and dried over KOH. The solvent was evaporated to a minimal volume (2–3 ml). Yield of amine **I** after chromatographic purification on a short (1 × 1 cm) silica gel column (eluent hexane) 1.2 g (88%).

(b) To 35 g of amine **VIII** was added 9.5 g of 3-chloro-2-pentene. After the condensation completion (GLC monitoring of reaction mixture samples treated with a NaOH solution), the mixture was heated on an oil bath at 160–170°C. The consumption of **IX** was monitored by GLC. After the rearrangement completion, the mixture was cooled and neutralized with 20% aqueous NaOH (50 ml); the organic layer was dried over KOH. Vacuum distillation gave 20 g of the unchanged amine **VIII** (42% conversion) and 9.6 g (47% based on the reacted amine **VIII**) of dialkenylated product **I**, bp 140–145°C (2 mm Hg).

(c) To 32.37 g of **V** was added 14.9 g of 3-bromo-1-cyclohexene. The mixture was heated on a water bath at 90°C for 1 h and cooled to room temperature; 50 ml of 20% aqueous NaOH was added, and the mixture was shaken in a separating funnel. The organic layer was dried over KOH, filtered, and saturated with gaseous HCl. The resulting hydrochloride of **VI** was heated in excess amine **V** or in *o*-xylene at 140°C until aniline **VI** disappeared (GLC monitoring of reaction mixture samples neutralized with a NaOH solution). After the isomerization completion, the mixture was cooled to room temperature, 100 ml of 20% aqueous NaOH was added, the mixture was shaken in a separatory funnel, and the organic phase was dried over KOH. Vacuum distillation gave 15 g of the unchanged amine **V** and 10.8 g (42% based on

the reacted amine **V**) of dialkenylaniline **I**, bp 140–145°C (2 mm Hg).

6-Methyl-4-(1-methyl-2-buten-1-yl)-2-(1-cyclohexen-1-yl)aniline II was prepared similarly to **I** by procedure (a) from 1 g of **XI**; yield 1.19 g (87%).

***N*-Tosyl-6-methyl-4-(1-methylbut-2-en-1-yl)-2-(2-cyclohexen-1-yl)aniline X.** To a solution of 1.27 g of amine **I** in 10 ml of pyridine was added 1.7 g of *p*-toluenesulfonyl chloride. The mixture was allowed to stand at room temperature for 24 h, 0.5 ml of H_2O was added, the mixture was stirred for 30 min, and the solvent was vacuum-evaporated. The residue was diluted with 5 ml of H_2O and 50 ml of CH_2Cl_2. The organic phase was separated, washed with 30 ml of 5% HCl and water (2 × 10 ml), and dried over $MgSO_4$. After vacuum evaporation of the solvent, 2 g of crude **X** was obtained; the product slowly solidified in air and was sufficiently pure for the subsequent syntheses. Recrystallization from EtOH gave 0.63 g of crystalline **X**, mp 124–126°C (from EtOH). An additional 0.4-g crop of **X** was obtained from the mother liquor after its prolonged storage; mp 126–130°C.

6-Methyl-2-(1-cyclohexen-1-yl)aniline XI. 6-Methyl-2-(2-cyclohexen-1-yl)aniline (10 g) [3] and KOH (10 g) were heated for 1 h on a silicone bath (300°C) in a steel test tube equipped with a reflux air condenser. After cooling, the product was decanted from KOH and vacuum-distilled. Yield 9.5 g (95%), bp 118–120°C (3 mm Hg).

***N*-Tosyl-1-iodo-6-(1-methyl-2-buten-1-yl)-1,2,3,-4,4a,9a-hexahydrocarbazole XII.** To a solution of 0.41 g of amide **X** in 20 ml of CH_2Cl_2, we added 0.85 g of $NaHCO_3$ and 0.51 g of I_2. After the complete consumption of the starting amide **X** (~6–7 h), the precipitate was filtered off, and the solution was washed with 10% aqueous $Na_2S_2O_3$ (2 × 20 ml) and water (2 × 10 ml) and dried over $MgSO_4$. The solvent was vacuum-evaporated. Compound **XII** was obtained as an amorphous mass; yield 0.51 g (95%), R_f 0.4 (eluent CH_2Cl_2).

***N*-Tosyl-6-(1-methyl-2-buten-1-yl)-3,4,4a,9a-tetrahydrocarbazole XIII.** A solution of 0.377 g of 1-iodohexahydrocarbazole **XII** in 3 ml of piperidine was heated at 110°C for 3 h. After the dehydroiodination completion, the solvent was vacuum-evaporated, and the residue was dissolved in 50 ml of CH_2Cl_2 and washed with water (2 × 20 ml). The organic phase was dried over Na_2SO_4, and the solvent was vacuum-evaporated; yield of **XIII** 0.26 g (90%), R_f 0.7 (eluent CH_2Cl_2).

CONCLUSIONS

(1) Alkenylation of 6-methyl-2-(2-cyclohexen-1-yl)- and -2-(1-cyclohexen-1-yl)anilines with piperylene in the presence of $AlCl_3$ gives the corresponding 4-(1-methyl-2-buten-1-yl)anilines in 87–88% yields.

(2) The reaction of the synthesized 6-methyl-2-(2-cyclohexen-1-yl)-4-(1-methyl-2-buten-1-yl)aniline with I_2 gave iodohexahydrocarbazole in 95% yield. On refluxing in piperidine, it transformed into the tetrahydrocarbazole in 90% yield.

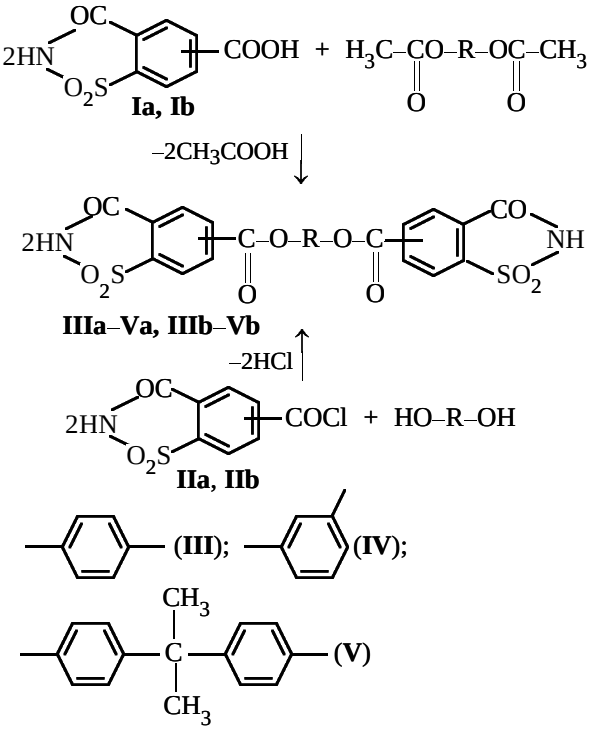
ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis of Diester Disulfimides from Saccharinmonocarboxylic Acids and Aromatic Diols

T. A. Aslanov, U. M. Mamedli, and A. M. Guliev



Institute of Polymeric Materials, National Academy of Sciences of Azerbaijan, Sumgait, Azerbaijan

Received January 13, 2005

Abstract—The reactions of saccharinmonocarboxylic acids with bisphenol acetates and of saccharinmonocarboxylic acid chlorides with bisphenols yielded the corresponding diester disulfimides.

Diester disulfimides are used as monomers for preparing poly(ester sulfimides) [1]. Diester diimides are usually prepared by ester interchange of trimellitimide methyl esters with glycols [2]. In particular, diester diimides containing aromatic fragments were prepared from trimellitic acid imide and bisphenol acetates [3]. Such products can also be prepared by reactions of trimellitimide chloride with aromatic diols.

Here we report on the synthesis of diester disulfimides **IIIa**–**Va** and **IIIb**–**Vb**. These compounds can be formed both by reactions of saccharin-5(or 6)-carboxylic acid **Ia** or **Ib** with bisphenol acetates [4] and by reactions of saccharin-5(or 6)-carboxylic acid chloride **IIa** or **IIb** with bisphenols:

Diester disulfimides **IIIa**–**Va** and **IIIb**–**Vb** prepared by both routes are identical, according to analytical data and spectra. Their characteristics are given in the table.

Synthesis of diester disulfimides **IIIa**–**Va** and **IIIb**–**Vb** from saccharinmonocarboxylic acid **Ia** or **Ib** and bisphenol acetates was performed in diphenyl ether at 270–280°C for 3 h until the release of acetic acid was complete. Yield of the target product 85–90%.

In the reactions with saccharinmonocarboxylic acid chlorides, triethylamine was added to the bisphenol solution (2 mol per mole of bisphenol) to bind the released HCl.

The composition and properties of **IIIa**–**Va** and **IIIb**–**Vb** were confirmed by elemental analysis and IR spectroscopy [5]. The IR spectra of **IIIa**–**Va** and **IIIb**–**Vb** contain absorption bands at 1760–1720 (C=O groups of saccharin ring); 1370–1300 and 1200–1180 (SO_2); 1300–1250 and 1120–1100 (ester C–O–C); and 3350–3310 cm^{-1} (NH).

Diester disulfimides **IIIa**–**Va** and **IIIb**–**Vb** are readily soluble in aprotic solvents (DMAA, DMSO, DMF, *N*-methylpyrrolidone).

EXPERIMENTAL

Diester disulfimides IIIa and IIIb derived from hydroquinone acetate III. A flask was charged with 22.7 g (0.1 mol) of saccharinmonocarboxylic acid **Ia** and 38.8 g (0.2 mol) of hydroquinone diacetate dissolved in 100 ml of diphenyl ether. The mixture was stirred at 270–275°C for 3 h. The released acetic acid was collected in a trap. The resulting mixture was dissolved in acetone, and the product was precipitated with distilled water. The gray crystalline powder

Vb	87	259–261	$C_{31}H_{22}O_{10}N_2S_2$	56.70/57.58	2.25/3.40	4.30/4.354	9.90/9.90	646

obtained was dried at room temperature and then in a vacuum oven to constant weight.

Diester disulfides **IIIb**, **IVb**, and **Vb** were prepared similarly from resorcinol diacetate, diphenylolpropane diacetate, and saccharinmonocarboxylic acid **Ia** or **Ib**.

Saccharinmonocarboxylic acid chloride IIa and IIb. A mixture of 2.1 g (0.01 mol) of PCl_5 and 2.27 g (0.01 mol) of saccharinmonocarboxylic acid **Ia** or **Ib** was stirred. The mixture spontaneously warmed up to 40–45°C, after which it was heated at 90–95°C for 2 h. After adding dry benzene, the mixture was filtered, and the precipitate was washed with chloroform and benzene, recrystallized from a mixture of toluene and acetone, and dried in a desiccator. Yield 70–75%; T_m = 260°C; M = 245.5.

Found, %: C 39.42; H 1.68; N 5.61; S 14.00; Cl 15.05. $C_8H_4O_4NSCl$.
Calculated, %: C 39.10; H 1.63; N 5.70; S 13.03; Cl 14.46.

Preparation of diester disulfimides IIIa–Va and IIIb–Vb from saccharinmonocarboxylic acid chloride. A mixture of 24.5 g (0.1 mol) of saccharinmonocarboxylic acid chloride **IIa**, 22.8 g (0.05 mol) of diphenylolpropane, and 10.1 g (0.1 mol) of triethylamine in 50 ml of dry toluene was stirred at 25–30°C for 1.5–2 h. A dark product formed. After the reaction completion, 100 ml of distilled water was added, and the mixture was filtered through a glass frit. The product was dried at room temperature and then in a vacuum oven to constant weight. Yield of diester disulfimide **Va** 85%.

Diester disulfimides **IIIa**, **IVa**, and **IIIb**–**Vb** were prepared from saccharinmonocarboxylic acid chloride similarly.

The starting compounds were purified as described in [6].

CONCLUSION

Previously unknown diester disulfimides derived from saccharin-5(or 6)-carboxylic acid and aromatic diols (hydroquinone, resorcinol, diphenylolpropane) were prepared. These compounds can be used as monomers for preparing poly(ester imides).

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Ethylbenzene Oxidation in the Presence of Acetic Anhydride

I. M. Nosacheva, O. A. Revkov, and A. L. Perkel'

Kuzbass State Technical University, Kemerovo, Russia

Received May 28, 2004; in final form, December 2004

Abstract—The kinetics of formation and subsequent transformation of the products of ethylbenzene oxidation in the presence of acetic anhydride at 100°C was studied by solution of the inverse kinetic problem.

Secondary hydroperoxides are the main primary molecular intermediates of liquid-phase oxidation of saturated aliphatic, alicyclic, and some alkylaromatic hydrocarbons [1–4]. These intermediates can further react with carboxylic acid anhydrides (important products of oxidative degradation of saturated hydrocarbons and their oxygen derivatives) [4, 5].

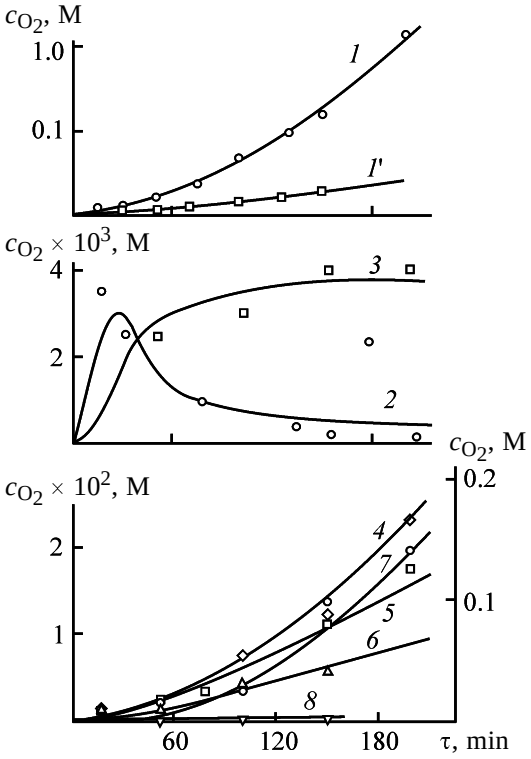
Carboxylic acid anhydrides react with hydroperoxides to form peroxy esters [4–7]. Synthesis of peroxy esters of secondary hydroperoxides and their properties are poorly studied. This is probably due to the fact that peroxy esters of secondary hydroperoxides are substantially less stable than those of primary and especially tertiary hydroperoxides and decompose even at low temperatures [6, 7].

In this work we studied the kinetics of ethylbenzene (EB) oxidation in the presence of acetic anhydride (AA). 1-Phenylethyl hydroperoxide formed in EB oxidation reacts with AA to form 1-phenylethyl peroxyacetate. In this study we examined the main relationships in formation and subsequent reaction of 1-phenylethyl peroxyacetate.

EXPERIMENTAL

Ethylbenzene (pure grade) was treated with concentrated sulfuric acid to remove oxygen-containing compounds [8] and then was distilled in an argon flow. As determined by gas–liquid chromatography, the concentration of methylphenylcarbinol and acetophenone in the resulting product was lower than 0.003 and 0.005 wt %, respectively.

Acetic anhydride (analytically pure grade) was purified by distillation after conversion of the acetic acid impurity into methyl acetate by the reaction with diazomethane.



The total peroxide content in the EB oxidation products was determined colorimetrically after treatment of the sample with the reagent containing Fe^{2+} and *N*,*N*-dimethyl-*p*-phenylenediamine [9]. The content of 1-phenylethyl peroxyacetate (PEPA) was calculated as the difference between the content of 1-phenylethyl acetate (PEA) in the sample reduced with triphenylphosphine and in the oxidized sample. Acetic anhydride was decomposed with a methanol–pyridine mixture (1 : 1 v/v) immediately after the sampling. The content of 1-phenylethyl hydroperoxide (PEHP) was determined as the difference between the total peroxide content and the PEPA content. To determine the content of benzoic acid by GLC, it was converted into methyl benzoate by treatment with diazomethane. The GLC analysis of nonperoxide products of EB oxidation was performed at 140°C on a 2000 × 3-mm column; stationary phase 15% Carbowax-6000 on Chromaton N-AW-DMCS, internal reference nitrobenzene.

Ethylbenzene was oxidized in a manometric unit under the conditions of the kinetic control of the oxygen uptake.

The parameters of the kinetic equations were calculated by the least-squares procedure using the Delphi 5.5 program. A set of differential equations was solved in each step by the fourth-order Runge–Kutta method.

Peroxy esters of secondary hydroperoxides are thermally unstable and can be studied only under special conditions [6, 7] which substantially differ from the conditions of hydrocarbon oxidation. The general features of formation and subsequent transformations of peroxy esters of secondary hydroperoxides under the autooxidation conditions were studied with an example of PEPA. This compound was prepared *in situ* by reaction of AA introduced into the reaction

1070-4272/05/7803-0443 © 2005 Pleiades Publishing, Inc.

(*1*') Kinetic curves of oxygen uptake in EB oxidation at 100°C in the absence of AA and kinetic curves of (*1*) total accumulation of the products of EB oxidation at 100°C in the presence of AA and accumulation of (*2*) PEHP, (*3*) PEPA, (*4*) AP, (*5*) MPC, (*6*) BAl + BAc, (*7*) PEA, and (*8*) BAc. (C_{O_2}) concentration of absorbed oxygen and the oxidation products and (τ) time. (*1*–*7*) Calculated curves and (*1*', *8*) experimental curves.

mixture with PEHP formed in radical-chain oxidation of EB.

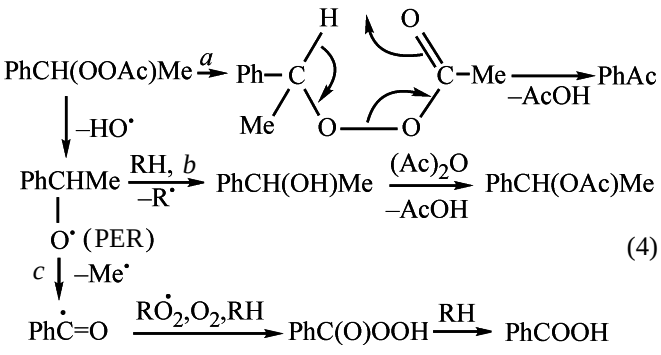
Ethylbenzene was oxidized with oxygen at 100°C in the absence of AA and in the presence of 1.1 M AA. The experimental kinetic curves of oxygen uptake (in the absence of AA), total accumulation of the EB oxidation products, and accumulation of PEHP, PEPA, methyphenylcarbinol (MPC), acetophenone (AP), PEA, benzaldehyde (BAl) + benzoic acid (BAc), and BAc are shown in the figure.

The rate of ethylbenzene oxidation to form PEHP at 100°C in the absence of AA is almost constant (see figure)

$$PhCH_2Me \xrightarrow{RO_2^*,\ O_2,\ RH} PhCH(OOH)Me\ (PEHP). \quad (1)$$

Clearly, PEHP decomposition under these conditions is slow and is initiated mainly by chain generation. The rate of radical-chain oxidation of EB is described by the equation [1, 2]

$$-d[RH]/d\tau = k_p(2k_t)^{-0.5}[RH](w_i^0)^{0.5}, \quad (2)$$



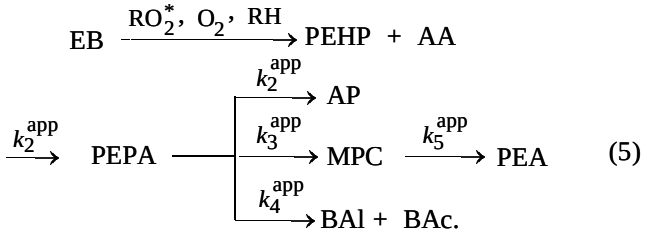
where k_p and $2k_t$ are the rate constants of chain propagation and termination, respectively; w_i^0 is the rate of initiation by chain generation.

Substitution of $k_p(2k_t)^{-0.5} = 22.2 \times 10^{-4}$ l mol$^{-0.5}$ s$^{-0.5}$ [2], the rate constant of radical-chain oxidation of EB in the absence of acetic anhydride ($w_{rc} = 3.9 \times 10^{-6}$ mol l^{-1} s^{-1}), and [RH] = 8.2 M into Eq. (2) gives $w_i^0 = 4.5 \times 10^{-8}$ mol l^{-1} s^{-1} at 100°C.

The kinetic curve of oxygen uptake in the presence of AA is more complex. In the first steps, the curve is typical of an autocatalytic process and then it becomes linear (see figure). Along with PEHP, PEPA is accumulated by acylation of PEHP with AA:

$$PhCH(OOH)Me \xrightarrow[-AcOH]{(Ac)_2O} PhCH(OOAc)Me\ (PEPA). \quad (3)$$

Acceleration of EB oxidation in the presence of AA is due to increasing contribution of degenerate branching caused by homolytic decomposition of PEPA. Probably, radical decomposition of PEPA in the course of BE oxidation is faster than that of the initial PEHP [5]. The main oxidation product of EB in the presence of AA is AP. Its yield is substantially higher than that in thermal oxidation of EB at 120°C in the absence of AA [2]. We suggest that AP is formed by pericyclic transformation of PEPA [scheme (4), pathway *a*]. The relative yield of MPC in the presence of AA (see figure) is substantially lower than that in the absence of AA [2]. Probably, methylphenylcarbinol is formed by the reaction of 1-phenylethoxy radical (PER) with EB and partially reacts with AA to form PEA [scheme (4), pathway *b*]. Clearly, homolytic decomposition of PEPA yields BAl which is further oxidized to BAc [scheme (4), pathway *c*].



(4)

Calculated rate constants of formation and transformations of PEPA in EB oxidation in the presence of AA

i	$k_i \times 10^4$		$k_i' \times 10^2$		$(k_i'/k_i) \times 10^2$
	s^{-1}	$l\ mol^{-1}\ s^{-1}$	$l\ mol^{-1}\ s^{-1}$	$l^2\ mol^{-2}\ s^{-1}$	
0	10.00		0.19		1.90
1		9.57		16.68	174
2	32.5		0.76		2.34
3	6.13		0.22		3.59
4	2.52		0.0016		0.063
5		2.57		0.000	0.00

Thus, EB oxidation in the presence of AA can be described by the following kinetic scheme:

(5)

Kinetics of reactions (1), (3), and (4) can be described by the following set of equations:

$$-d[EB]/d\tau = k_p(2k_t)^{-0.5}[EB](w_i^0) + k_0^{app}[PEPA]^{-0.5}, \quad (6)$$

$$d[PEHP]/d\tau = k_p(2k_t)^{-0.5}[EB](w_i^0) + k_0^{app}[PEPA]^{-0.5} - k_1^{app}[PEPA][AA], \quad (7)$$

$$d[PEHP]/d\tau = -k_1^{app}[PEPA][AA] - (k_2^{app} + k_3^{app} + k_4^{app})[PEPA], \quad (8)$$

$$d[AP]/d\tau = k_2^{app}[PEPA], \quad (9)$$

$$d[MPC]/d\tau = k_3^{app}[PEPA] - k_5^{app}[MPC][AA], \quad (10)$$

$$d([BAl] + [BAc])/d\tau = k_4^{app}[PEPA], \quad (11)$$

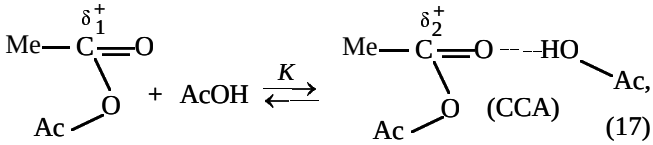
$$d[PEA]/d\tau = k_5^{app}[MPC][AA], \quad (12)$$

$$-d[AA]/d\tau = k_1^{app}[PEHP][AA] + k_5^{app}[MPC][AA], \quad (13)$$

$$d[AA]/d\tau = k_1^{app}[PEHP][AA] + (k_2^{app} + k_3^{app} + k_4^{app})[PEPA] + k_5^{app}[MPC][AA], \quad (14)$$

$$\Delta[O_2] = [EB]_0 - [EB] = [PEHP] + [PEPA] + [AP] + [MPC] + [BAl] + [BAc] + [PEA], \quad (15)$$

where [X] is concentration of the reactants, M; $[O_2]$, amount of oxygen taken up, M; k_1^{app}–k_5^{app} are the apparent rate constants of the steps of reaction (5); and k_0^{app} is the apparent rate constant of initiation by PEPA decomposition.



Since formation and subsequent transformations of 1-hydroxycyclohexyl peroxydodecanoate are acid-catalyzed [10, 11], we suggest that the corresponding apparent rate constants can depend on the acetic acid (AAc) concentration

$$k_i^{app} = k_i + k_i'[AAc], \quad (16)$$

where k_i is the autocatalytic constant.

The rate constants calculated by solution of the inverse kinetic problem are presented in the table, and the calculated kinetic curves are shown in the figure.

As seen from the figure, the calculated kinetic curves fit well the experimental results (the sum of squares of the deviations is 4.9×10^{-4}). Comparison of the rate constants shows that the conversion of PEPA into AP is about 75%. Although all k_i^{app}, except for k_5^{app}, depend on the AAc concentration, the autocatalytic contribution to reactions steps, as indicated by the k_i'/k_i ratio (see table), noticeably differ. The influence of AAc on acylation of PEHP with AA is the most pronounced. Clearly, the catalytic effect in this case is caused by formation of AAc–AA (CCA) complex which is more reactive than the free anhydride with respect to the nucleophilic attack of the hydroperoxide ($\delta_2^+ > \delta_1^+$):

(17)

$$(CCA) + PEHP \underset{}{\overset{k_2''}{\rightleftarrows}} PEPA + AAc, \quad (18)$$

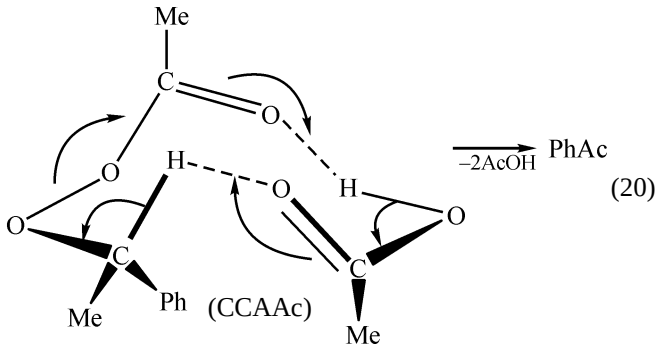
where k_2'' is the rate constant of reaction of PEHP with CCA and K is the equilibrium constant of reaction (17).

Taking into account reactions (17) and (18), the PEHP consumption can be described by the kinetic equation of an autocatalytic reaction

$$-d[PEHP]_{cat}/d\tau = k_2'' K[AAc][AA][PEHP]$$

$$= k_2'[AAc][AA][PEHP]. \quad (19)$$

Hence, $k_2' = k_2'' K$.



Acylation of MPC with AA should be seemingly also acid-catalyzed. However, our previous kinetic study of this reaction in chlorobenzene at 80–110°C [12] shows that AAc has no effect on this reaction. The k_5^{app} determined in this study (2.57×10^{-4} l mol^{-1} s^{-1}) is close to $k_5^{app} = 2.66 \times 10^{-4}$ l mol^{-1} s^{-1} calculated from the dependence $\ln k_0 = (10.9 \pm 2.9) - (59\,300 \pm 8900)/RT$ [12].

The reason of this distinction is not clear. We assume that it is due to the fact that the steric hindrance in the attack of the carbon atom of the carbonyl group in CCA by the hydroxy group of MPC is stronger than that in the reaction of CCA with the hydroperoxy group of PEHP.

The influence of AAc in the step of PEPA decomposition is weaker than that in the step of its formation. The ratio k_i'/k_i (table) shows that the contribution of the autocatalytic reaction to the overall process is substantially lower [particularly, in the case of reaction (4, pathway *c*)] than in the case of decomposition of 1-hydroxycyclohexyl peroxydodecanoate (intermediate of Baeyer–Villiger oxidation of cyclohexanone with peroxylauric acid) [10, 11]. The ratio of the constants for heterolytic rearrangement of 1-hydroxycyclohexyl peroxydodecanoate (α-hydroxy peroxy ester) into lactone (18°C) is 17.3, whereas for the homolytic decomposition it is 41.8 [11]. Probably, decomposition of the peroxy ester is less acid-sensitive than that of α-hydroxy peroxy ester owing to lower probability of the decomposition by the mechanism of relay proton transfer [10, 11].

We suggest that the decomposition mechanism of PEPA in the cyclic complex with AAc (CCAAc) to form AP (20) is similar.

The apparent rate constant of initiation by homolytic decomposition of PEPA (k_0^{app}) (see table) is almost independent of the presence of acetic acid.

(20)

This constant should be related, by definition, to the apparent rate constants of PEPA decomposition into MPC and BAl by the equation

$$k_0 + k_0'[AAc] = 2e(k_3 + k_3'[AAc]) + (k_4 + k_4'[AAc]), \quad (21)$$

where e is the coefficient of radical escape from the solvent cage.

At [AAc] = 0.2 M, substitution of the constants in Eq. (21) gives $e = 0.57$ which is close to the known value ($e = 0.6$) for aromatic solvents [13].

Thus, carboxylic acid anhydrides substantially catalyze decomposition of secondary hydroperoxides and change the decomposition mechanism. Contrary to the previous data [7], about 25% of the peroxy ester of the secondary hydroperoxide decomposes homolytically, i.e., this compound initiates the radical-chain oxidation but to a lesser extent as compared to peroxy esters of tertiary hydroperoxides [7, 14]. Since carboxylic acid anhydrides are consumed mainly by reactions with hydroperoxides [4], formation and decomposition of peroxy esters of secondary hydroperoxides can contribute significantly to both initiation of oxidation of organic compounds and formation of carbonyl-containing products.

CONCLUSIONS

(1) Acetic anhydride substantially catalyzes radical-chain oxidation of ethylbenzene at 100°C. The primary molecular product of ethylbenzene oxidation, 1-phenylethyl hydroperoxide, decomposes via 1-phenylethyl peroxyacetate formation to give mainly acetophenone by the pericyclic mechanism.

(2) Acceleration of ethylbenzene oxidation in the presence of acetic anhydride is due to homolytic decomposition of the peroxy ester into methylphenylcarbinol and benzaldehyde.

(3) Acetic acid formed in acylation of the hydroperoxide and peroxy ester decomposition catalyzes

both peroxy ester formation and, to a lesser extent, its decomposition.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Modification of *L*-α-Polyglutamic Acid with Xanthene Dyes via γ-Carboxy Groups of Amino Acid Residues

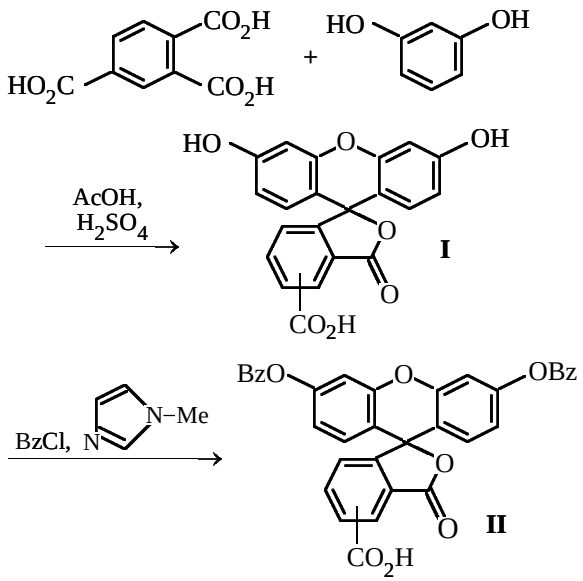
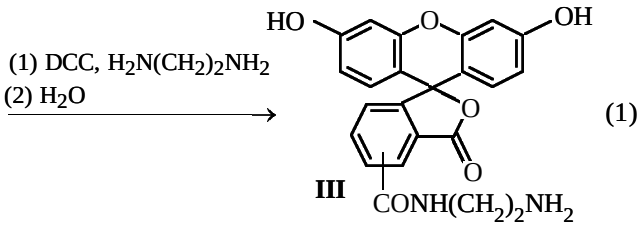
Abstract—Modification of *L*-α-glutamic acid with xanthene dyes (rhodamine and fluorescein) and the optical properties of the incorporated luminophores were studied.

Photosensitive natural proteins, as a rule, are photosensors and energy converters. Light absorption with dye fragments in proteins results in transfer of the electronic excitation energy, which is modeled well by interaction of a donor–acceptor pair upon irradiation of a simple protein [1, 2].



The researchers' interest was focused on photochromic and photosensitive polypeptides; this was reflected in a number of reviews and summarizing papers [3–5]. Polyamino acids are similar in properties to natural peptides; they can change conformation under the influence of even a weak external action, which results in changes in the physicochemical, physical, and mechanical properties of the macromolecule as a whole [3].

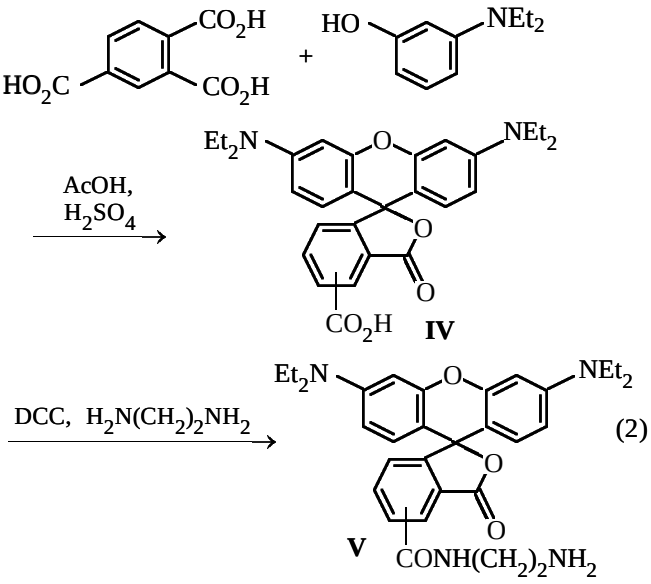
Previous luminescence studies demonstrated the possibility of nonradiative energy transfer between 9-aminoacridine (radiation donor) and 4-amino-*N*-phenylnaphthimide (radiation acceptor) in a polymer matrix upon laser irradiation [6]. Proceeding with these studies, we prepared in this work a model of an α-helical biopolymer, suitable for studying the migration of the energy of electronic excitation of the luminescing groups in the macromolecule, the changes in the chain conformation occurring under external impacts, and the formation of intra- and intermolecular contacts.



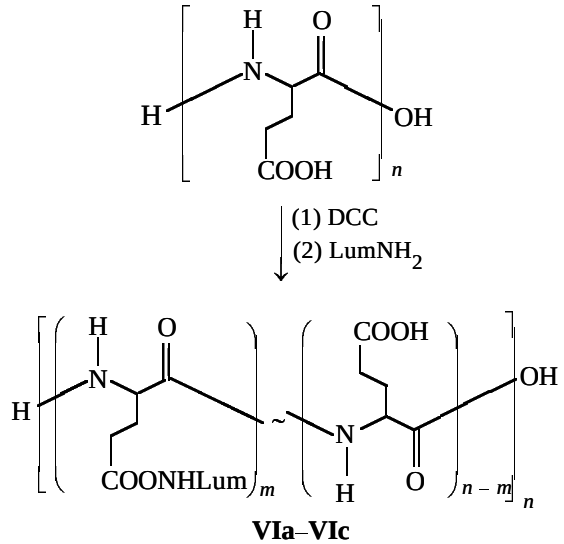
Polyglutamic acid (PGA) is a comprehensively studied protein model. It contains free γ-carboxy groups capable of polymer-analogous transformations; therefore, it can be a convenient biopolymer matrix for modification with dyes. For our experiments, we chose xanthene dyes: fluorescein (Fl) and rhodamine (Rh), taking into account the fact that the luminescence maximum of Fl (radiation donor) corresponds to the absorption maximum of Rh (radiation acceptor) [7].

Modification of γ-carboxy groups of PGA with luminophores was performed by formation of an amide bond. To this end, it was necessary to introduce primary amino groups into Fl and Rh. To preserve the optical properties of the luminophores, the functional group was separated from the dye core by an aliphatic hydrocarbon spacer.

5(6)-Carboxyfluorescein **I** was prepared by condensation of trimellitic acid with resorcinol. To protect the hydroxy groups, compound **I** was converted into 3',6'-dibenzoyl-5(6)-carboxyfluorescein **II**, whose reaction with dicyclohexylcarbodiimide (DCC) and ethylenediamine gave 5(6)-(2-aminoethylcarbamoyl)-fluorescein **III**:

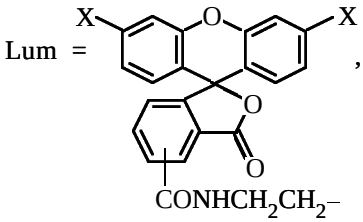


1070-4272/05/7803-0448 © 2005 Pleiades Publishing, Inc.



(1)

5(6)-Carboxy-*N*,*N*,*N*',*N*'-tetraethylrhodamine **IV** was prepared from trimellitic acid and 3-(diethylamino)phenol. Its subsequent reaction with DCC and ethylenediamine gave 5(6)-(2-aminoethylcarbamoyl)-*N*,*N*,*N*',*N*'-tetraethylrhodamine **V**:



(2)

Taking into account our experience in introducing various dyes into PGA [8, 9], we performed the polymer-analogous transformations of the PGA γ-carboxy groups using dicyclohexylcarbodiimide:

VIa–**VIc**

(3)

where X = OH, $m \approx 13$ (**a**); X = NEt_2, $m \approx 10$ (**b**); X = OH or NEt_2, $m \approx 10$ (**c**); $n \approx 40$.

In all the reactions we used *L*-α-polyglutamic acid of molecular weight 5200 ($n \approx 40$) [8]. The regular structure of the modified macromolecule could be attained at the maximal degree of the polymer modification with the dye. For this purpose, we initially performed computer simulation (GAMESS program) of the target molecules: amides derived from PGA and modified Fl **III** and Rh **V**. We found that the content and arrangement of the dyes in the polypeptide chain are governed by steric factors. The maximal content of Fl in the polypeptide corresponds to modification of every third amino acid molecule with the dye. The bulkier Rh derivative can be introduced only in every fourth amino acid fragment. Taking into account these results, we chose appropriate component ratios.

We also prepared the polyamino acid containing both dyes in the chain simultaneously (compound **VIc**). Successive addition of the dyes to the γ-carboxy group of PGA resulted in a random, virtually uncontrollable distribution of the dyes in the polymer matrix. Therefore, our choice was to introduce **III** and **V** simultaneously. Since Rh contains bulkier diethylamino substituents, we expected that alternation of the Rh and Fl substituents separated by at least two free amino acid units would be sterically favorable and chose the corresponding component ratio. The reaction progress was monitored by TLC and indirectly by formation of the reaction by-product, dicyclohexylurea (DCHU). Its total amount corresponded to the complete conversion of the dyes. Comparison of the chromatograms of the reactants, product, and reaction mixture showed the absence of residual amounts of unchanged dyes **III** and **V**.

To obtain the same yield of the modified polymer (~60%), the reaction of PGA with **V** (60 h) took longer time, compared to the reaction with **III** (36 h).

The content of the chromophores in PGA was determined by ^1H NMR and electronic spectroscopy. In the first case, we compared the integral intensities of the signals of the aromatic protons (7.6–8.1 ppm) of the dyes and methylene (β-CH_2, 2.25 ppm; γ-CH_2,

Electronic absorption and fluorescence spectra of compounds in a 10% solution of triethylamine in DMSO

Compound	λ_{max}^{abs}, nm (log ε)	λ_{max}^{fl}, nm
III	521.5 (4.07)	565
V	558 (4.05)	587
VIa	523 (4.06)	552
VIb	566 (4.05)	605
VIc	531 (4.06), 587 (4.00)	563, 612

2.65 ppm) protons of PGA [9]. Using the optical method of successive dilutions, we estimated the dye content in the polymer from variation of the solution absorption at λ_{max}. The results obtained by both methods were consistent and corresponded to 33 mol % content of Fl and 25 mol % of Rh in PGA. The total content of Fl and Rh in **VIc** was 26 mol %. The absorption spectra of the compounds recorded at different concentrations show that the content of the fragments of the two dyes in the polymer is approximately equal.

The electronic absorption and luminescence spectra of **III**, **V**, and **VIa**–**VIc** were recorded in ethanol, DMSO, and DMSO–triethylamine mixture (10 wt %) (see table). In the absence of a base, the Fl derivatives lose the capability for the luminescence. This feature can be used in subsequent studies of the behavior of luminescing biopolymers in media with different pH values. The parameters of the electronic absorption and luminescence spectra of the compounds are given in the table.

In binding of the dyes with PGA, the long-wave absorption maxima of Fl and Rh are shifted bathochromically by 1.5 and 8 nm, respectively. The emission maximum of Fl is shifted hypsochromically by 13 nm, and that of Rh, bathochromically by 18 nm. As a result, the Stokes shift of Fl after the reaction with PGA decreased by 15 nm, and that of Rh increased by 10 nm. Thus, compounds **VIa** and **VIb** preserve the properties of the donor–acceptor pair: The emission maximum of the Fl derivative (radiation donor, 552 nm) is close to the absorption maximum of the Rh derivative (radiation acceptor, 566 nm).

EXPERIMENTAL

The IR spectra were recorded on a UR-20 spectrophotometer (mulls in mineral oil), and the ^{1}H NMR spectra, on a Bruker WP-400SY spectrometer (400 MHz, reference TMS). The electronic absorption spectra were taken on a Jasco videc 510 spectrophotometer, and the luminescence spectra, on an Edinbourgh Injfr. 549 spectrofluorimeter with the time-resolved photon counting in the pulse mode; the mass spectrum was taken on a Kratos MS 50 TS spectrometer (chemical ionization, 3 eV). The reaction progress and the homogeneity of the products were monitored by TLC on UV-254 plates (UV development).

Polyglutamic acid (M ~5200, n = 40) was prepared by the *N*-carboxy anhydride method from *N*-benzoyloxycarbonyl-*L*-glutamic acid γ-methyl ester (Sigma) [10].

5(6)-Carboxyfluorescein I. A mixture of trimellitic acid (5.0 g, 23.8 mmol), resorcinol (5.4 g, 47.6 mmol), and glacial acetic acid (1.4 ml) was heated with stirring at 185°C for 15 min, 1.0 g of concentrated H_2SO_4 was added dropwise, and the mixture was heated to 210°C and stirred at this temperature for 30 min. Then the mixture was cooled, crushed, and boiled with 20 ml of water for 10 min. The precipitate was filtered off, washed with water, and recrystallized from ethanol; yield of **I** 4.64 g (52%), R_f = 0.70 (EtOH–$CHCl_3$, 1 : 50). Electronic absorption spectrum (EtOH): λ_{max} = 492 nm (log ε = 4.40).

3',6'-Dibenzoyl-5(6)-carboxyfluorescein II. To a solution of **I** (4.0 g, 10.6 mmol) in 30 ml of dry pyridine, we added dropwise with stirring 1-methylimidazole (0.9 g, 10.6 mmol) and benzoyl chloride (6.6 g, 47.2 mmol). The mixture was stirred for 1 h, evaporated to a volume of 10 ml, and diluted with 100 ml of 1 M HCl. The light yellow precipitate was filtered off, washed on the filter with 1 M HCl (2 × 30 ml) and cold water, and dried in air. Yield of **II** after recrystallization from glacial acetic acid 6.8 g (60%), R_f = 0.80 (EtOH–$CHCl_3$, 1 : 25).

5(6)-(2-Aminoethylcarbamoyl)fluorescein III. Compound **II** (3.0 g, 5.43 mmol) and dicyclohexylcarbodiimide (1.0 g, 5.43 mmol) were dissolved in DMF (20 ml); the solution was stirred for 5 min. The resulting solution was added in portions with stirring to a solution of ethylenediamine (0.64 g, 8.15 mmol) in DMF (10 ml). The mixture was stirred for 1 h, the DCHU precipitate was filtered off, and the solvent was distilled off in a vacuum. A solution of NaOH (0.43 g, 10.8 mmol) in water (10 ml) was added, the mixture was refluxed for 30 min, and the precipitate was filtered off, washed on the filter with water, and dried in air. Yield of **III** 1.66 g (73%), R_f = 0.75 (AcOH–water, 3 : 1). Electronic absorption spectrum (EtOH): λ_{max} = 500 nm (log ε = 4.10).

^{1}H NMR spectrum (δ, ppm, $CDCl_3$): 2.89–3.02 br.d (2H, NH_2), 3.23–3.65 m (2H, C$H_2$$NH_2$), 3.75–

4.00 m (2H, CONHCH_2), 6.12 br.s (2H, OH), 7.27–8.68 m (9H, arom. CH), 9.02 br.d (1H, CONH).

Found, %: C 66.18, 66.10; H 4.08, 4.14; N 6.62, 6.65. $C_{23}H_{18}N_2O_6$.
Calculated, %: C 66.02; H 4.33; N 6.69; *M* = 418.405.

5(6)-Carboxy-*N,N,N',N'*-tetraethylrhodamine IV. Trimellitic acid (2.0 g, 9.5 mmol), 3-(diethylamino)phenol (3.1 g, 19.0 mmol), and glacial acetic acid (3.2 ml) were mixed and heated in a heat-resistant test tube at 185°C for 15 min with stirring, after which concentrated H_2SO_4 (0.4 ml) was added dropwise, and the mixture was heated to 210°C and stirred at this temperature for 30 min. The resulting mixture was cooled, ground, and boiled for 10 min with 20 ml of water, after which 10% NaOH was added to neutral reaction, and the precipitate was filtered off, washed with water, and recrystallized from ethanol–water (2 : 1). Yield of **IV** (red-violet crystals) 3.01 g (65%), R_f = 0.30 (AcOH–water, 1 : 4). Electronic absorption spectrum (EtOH): λ_{max} = 541 nm ($\log\varepsilon$ = 4.64).

5(6)-(2-Aminoethylcarbamoyl)-*N,N,N',N'*-tetraethylrhodamine V. Compound **IV** (3.0 g, 6.16 mmol) and dicyclohexylcarbodiimide (1.14 g, 6.16 mmol) were dissolved in DMF (20 ml); the mixture was stirred for 5 min. The resulting solution was added in portions with stirring to a solution of ethylenediamine (0.72 g, 9.25 mmol) in DMF (10 ml). The mixture was stirred for 1 h, the DCHU precipitate was filtered off, and the solvent was distilled off in a vacuum. The residue was triturated with 10 ml of 25% ammonia, and the resulting crystals were filtered off, washed with water, and dried in air. Yield of **V** 2.28 g (70%), R_f = 0.40 (AcOH–water, 1 : 3). Electronic absorption spectrum (EtOH): λ_{max} = 547 nm ($\log\varepsilon$ = 4.58). Mass spectrum (*m*/*z*): 529 $[M + 1]^+$ (100%).

Found, %: C 70.16, 70.21; H 6.92, 6.98; N 10.50, 10.45. $C_{31}H_{36}N_4O_4$.
Calculated, %: C 70.43; H 6.86; N 10.60; *M* = 528.653.

γ-Amide of *L*-α-polyglutamic acid and 5(6)-(2-aminoethylcarbamoyl)fluorescein VIa. Polyglutamic acid (3.9 g, 0.03 mol of monomeric units) was dissolved in DMF (15 ml); a solution of **III** (4.6 g, 0.011 mol) in DMF (15 ml), dicyclohexylcarbodiimide (2.27 g, 0.011 mol), and pyridine (1 drop) were added, and the mixture was kept at 0°C for 2 h and then was allowed to stand at room temperature. The reaction progress was monitored by TLC. After the reaction completion (36 h), the DCHU precipitate was filtered off, and the solvent was distilled off in a vacuum. The residue was dissolved in ethyl acetate, the solution was filtered, and the filtrate was vacuum-evaporated. The residue was reprecipitated from chloroform with diethyl ether and dried in a vacuum. Yield of **VIa** 4.7 g (60%), R_f = 0.13 (BuOH–AcOH–water, 4 : 1 : 1). IR spectrum (ν, cm^{-1}): 3100–2700 br, 3340 br (OH, NH), 1700 (C=O), 1670 (amide I), 1620 (C=C), 1550 (amide II).

γ-Amide of *L*-α-polyglutamic acid and 5(6)-(2-aminoethylcarbamoyl)-*N,N,N',N'*-tetraethylrhodamine VIb was prepared similarly from PGA (3.9 g, 0.03 mol of monomeric units), **V** (4.4 g, 0.008 mol), and dicyclohexylcarbodiimide (1.65 g, 0.008 mol). The reaction was complete in 60 h; yield 4.9 g (60%); R_f = 0.10 (BuOH–AcOH–water, 4 : 1 : 1). IR spectrum (ν, cm^{-1}): 3100–2700 br, 3340 br (OH, NH), 1700 (C=O), 1670 (amide I), 1620 (C=C), 1550 (amide II).

Mixed γ-amide of *L*-α-polyglutamic acid and 5(6)-(2-aminoethylcarbamoyl)fluorescein and 5(6)-(2-aminoethylcarbamoyl)-*N,N,N',N'*-tetraethylrhodamine VIc was prepared similarly from PGA (3.9 g, 0.03 mol of monomeric units), **III** (2.09 g, 0.005 mol), **V** (2.64 g, 0.005 mol), and dicyclohexylcarbodiimide (2.27 g, 0.011 mol). Yield of **VIc** 4.1 g; R_f = 0.30 (BuOH–AcOH–water, 4 : 1 : 1). IR spectrum (ν, cm^{-1}): 3370, 3000–2600 (NH, OH), 1700 (C=O), 1670 (amide I), 1620 (C=C), 1540 (amide II).

CONCLUSIONS

(1) *L*-α-Polyglutamic acid was modified with covalently bound xanthene dyes, rhodamine and fluorescein, containing primary amino groups; the degree of substitution of the pendant γ-carboxy groups of the substrate depends on the steric factors.

(2) Luminophores linked via amide bond to *L*-α-polyglutamic acid preserve their optical properties; the emission maximum of fluorescein (552 nm) virtually corresponds to the absorption maximum of rhodamine.

ACKNOWLEDGMENTS

The study was performed within the framework of the Multifunctional Smart Polymers project, New Chemical Materials and Products program of the RF Ministry of Education and within the framework of B0025 UNTs project (Supramolecular Chemistry and High Technologies for Preparing New Materials) of the Integration Federal Target Program.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

The Use of IR Spectra for Estimating the Boiling Points and Molecular Weights of Monohydric Aliphatic Alcohols

V. V. Vazhev and M. K. Aldabergenov

Kostanai State Teacher's Training College, Kostanai, Kazakhstan

Received December 9, 2004

Abstract—The use of transformed IR spectra as descriptors of molecular structure in estimating the boiling points and molecular weights of alcohols was studied. No additional data on molecular structure are required for the estimation.

The boiling point T_b is a fundamental characteristic of organic compounds; therefore, development of methods of its theoretical estimation attracts much attention for a long time. Numerous additive methods for estimation of T_b were suggested, but the most widely used is the QSPR (Quantitative Structure–Property Relationships) method, whose current status can be judged from published reviews [1, 2]. The majority of studies on estimating T_b concerns hydrocarbons or heterogeneous systems containing hydrocarbons and other low-polarity molecules. Much less attention was given to simulation and estimation of T_b of highly polar substances. This is apparently caused by the fact that the traditionally used descriptors of molecular structure (mainly topological indices) insufficiently adequately reflect the structural features of molecules responsible for formation of hydrogen bonds in solutions. In particular, the QSPR studies of T_b of alcohols were made only in a few papers [3–9]. The model constructed in [3] for a small set of 37 monohydric alcohols was characterized by the correlation coefficient between experimental and evaluated boiling points R = 0.978 and standard deviation S = 7.4988. For the same subjects, Yang *et al*. in a later study [4] obtained R = 0.9837 and S = 6.35. For the set of 29 alcohols Galvez *et al*. obtained R = 0.979 and S = 3.63 [5]. Recently [6] it was found that, for a small set of 54 saturated alcohols, R = 0.9945 and S = 4.26. For 58 alcohols, Randic and Basak [7] constructed a series of models, the best of which had R = 0.9943 and S = 3.891. For 106 monohydric alcohols, Cao and coworkers [8] constructed a model with R = 0.9899 and S = 4.5727. The highest quality of estimation with R = 0.9960 and S = 3.814 was reached by Ren for 108 alcohols [9].

Here we studied the possibility of estimating T_b and molecular weight of monohydric alcohols using their IR spectra as descriptors of molecular structure. Previously the IR spectra were successfully used in estimating chromatographic retention indices of a set of substances of various classes, among them alcohols [10], and normal boiling points of alkanes [11]. The possibility of determining the molecular weights of compounds from the IR spectra was not considered previously.

EXPERIMENTAL

We used the IR transmission spectra in the gas phase and the boiling points of monohydric aliphatic alcohols with the number of carbon atoms from 2 to 12, available from the server of the National Institute of Standards (NIST, USA) [12]. The training sample contained 60 substances, and the control sample, 40. Before the calculations, the spectra were normalized by the formula

$$d_{ij} = h_{ij}\left(\sum_{k=1}^{k=n} h_{ik}\right)^{-1}, \quad (1)$$

where d_{ij} are operating values of descriptors used in calculations; n, number of points in the IR spectrum; and h_{ij}, transmission in the spectrum of substance i in point j.

A part of spectra in the range 550–3798 cm^{-1} was used; in this range, the spectrum was interpolated linearly with a step of 4 cm^{-1}; the number of points in the spectrum n = 813. Elements d_{ij} form a matrix of descriptors D in which submatrices of training sample A and control sample C can be distinguished. In our case, the number of descriptors (813) exceeds the number of substances in the training sample (60) and the problem of choice of the least correlated descriptors, well-known in estimation, arises. A new

Table 1. Indexes of correlation between the experimental and calculated boiling points and molecular weights of alcohols

Characteristic	Index of correlation	Whole set	Sample	
			training	control
T_b	R	0.9972	0.9976	0.9963
	S	2.268	2.324	2.129
M	R	0.9896	0.9974	0.9693
	S	3.441	1.929	4.751

approach to solving of this problem was suggested in [13]. Here we present the expression used for the calculations:

$$p = CV_r\Gamma_r^{-1}U_r^T b, \quad (2)$$

where p is the sought-for vector consisting of characteristics of the control sample; b, vector consisting of characteristics of the training sample of substances; U, matrix consisting of eigenvectors of matrix AA^T; V, matrix consisting of eigenvectors of matrix A^TA; and Γ, diagonal matrix of nonzero singular numbers coinciding for both matrix products.

The subscript is the estimated rank of the descriptor matrix $r(A)$; it denotes that r highest eigenvalues and the corresponding eigenvectors are used. For comparison of the results obtained with published data, the submatrix of descriptors in Eq. (2) was completed with the submatrix of training sample A and, correspondingly, vector b was completed with vector p. This procedure is equivalent to constructing a correlation model from the training sample and estimating the characteristics of both control and training samples. Calculations were performed using the PROGROC software (PROGram RObustness Calculation) developed by us [13]. The quality of estimation was characterized by the correlation coefficient R between the estimated and experimental values and by the standard deviation S.

The dependence of the correlation coefficient for T_b of the whole set of substances on the estimated rank of the matrix of descriptors is shown in Fig. 1.

The maximum $R = 0.9972$ for T_b is reached at $r = 54$, standard deviation $S = 2.268$. The results of estimation of T_b and molecular weight at this rank are shown in Figs. 2 and 3.

The quantitative characteristics of the corresponding correlation dependences are listed in Table 1.

A part of the results obtained in estimating T_b

Table 2. Experimental and estimated from the IR spectra boiling points of alcohols (K) for the control sample

Substance	T_b, K		Difference
	experiment	calculation

2,2-Dimethyl-3-pentanol	409.00	409.50	–0.57
2-Methyl-3-ethyl-3-pentanol	432.15	432.70	–0.55
2-Ethyl-1-hexanol	456.00	456.11	–0.11
3-Methyl-2-pentanol	407.00	405.50	1.50
2,5-Dimethyl-3-hexanol	431.00	430.33	0.67
2-Octanol	453.00	454.14	–1.14
2,3-Dimethyl-2-pentanol	410.65	411.42	–0.77
4-Methyl-1-heptanol	455.85	454.04	1.81

of alcohols, related to the control sample only, are presented in Table 2.

The maximal error is observed for isopropanol and reaches 5.84 K. The error distribution for T_b of alcohols (Fig. 4) is close to the normal distribution, which confirms the reliability of the model; 71% of deviations of the calculated boiling points are in a narrow range (±2 K).

The above data show that our estimation of T_b of alcohols is better than the best published results obtained with the commonly used statistical characteristics.

CONCLUSIONS

(1) The use of normalized IR spectra as descriptors of molecular structure allows simultaneous estimation of the boiling point and molecular weight of alcohols in one numerical experiment.

(2) The quality of estimation is characterized by the correlation coefficient between the experimental and estimated boiling points $R = 0.9972$ and standard error of the estimate $S = 2.268$. For the molecular weight, $R = 0.9896$ and $S = 3.441$.

(3) The important feature of the suggested approach is the possibility of estimating the characteristics of unknown compounds without identification, using only their IR spectra.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

The Use of Mass Spectra for Estimating the Melting Points of Esters

V. V. Vazhev and M. K. Aldabergenov

Kostanai State Teacher's Training College, Kostanai, Kazakhstan

Received December 9, 2004

Abstract—The possibility of using low-resolution mass spectra as descriptors of molecular structure in estimating the melting points of 79 esters was studied.

The melting point T_m is one of the most important characteristics of organic compounds. In synthesis of new compounds it is determined first among other physicochemical characteristics, since it is used for identifying the compound and checking its purity. Experimental determination of T_m requires fairly large amounts of high-purity sample and in many cases is complicated by low thermal stability of substances. In this connection, approximate estimation of T_m is an urgent problem.

A recognized leader in estimation of various physicochemical characteristics is the QSPR (Quantitative Structure–Property Relationships) method based on a search for correlation equations relating the target characteristic and certain molecular characteristics (topological, electronic, etc.) of the compounds from a training sample. The resulting equations are used for further estimation of characteristics of other compounds. The topological indices, which are the invariants of the matrix of the graph reflecting the molecular structure, are mainly used as molecular characteristics. The estimation quality is characterized by the correlation coefficient R between the estimated and experimental values and standard deviations S. Published reviews [1, 2] show that the estimation accuracy in many characteristics already approaches the experimental accuracy. The melting point, whose estimation quality should be considered up to now as insufficient, is among a few exceptions (Table 1) [3–12].

A low accuracy of the models is caused in some cases by poor accuracy of experimental values used in training samples. In particular, sometimes the presence of small impurities can significantly decrease T_m. The other reason is that, as compared to, e.g., the boiling point, T_m is governed by additional factors related to the features of the crystal lattice. Although T_m is a function of the structure, up to now there are no fairly general and accurate methods for its estimation on the basis of molecular structure. The commonly used characteristics of molecular structure cannot reflect numerous factors governing T_m.

Here we studied the possibility of estimating T_m of esters from the mass spectra. Previously it was shown that the mass spectra can be successfully used to estimate the chromatographic retention indices of a set of substances of various classes, among them esters [13], and standard boiling points of alkanes [14].

We used low-resolution mass spectra of 79 esters with the number of carbon atoms from 2 to 15, available from the server of the National Institute of Stan-

Table 1. Results of estimating the melting points of various substances from published data

Substance class	Number of substances	R	S	References
Aniline derivatives	42	0.941	24.6	[3]
Alkanes	90	0.977	16.0	[4]
Alkanes	366	0.9584	17.9	[5]
Benzene derivatives	443	0.9150	30.19	[6]
Polychlorobiphenyls	209	0.9055	–	[7]
Alkanes	74	0.7632	22.14	[8]
Bromides of pyridine derivatives	126	0.888	–	[9]
Bromides of imidazole derivatives	104	0.9712	–	[10]
Organic sulfides	150	0.9381	21.93	[11]
Sulfonates	226	0.8911	23.66	[11]
1,2,3-Diazaborine derivatives	72	0.9257	16.78	[12]

dards (NIST, USA) [15]. The T_m values were taken from the site of the University of Akron (USA) [16] and PhysProp database [17]. The training sample contained 55 substances and the control sample, 24 substances. Among all the mass spectra of the set used, there are 189 nonzero vectors of peak intensities in the range of the ratios *m*/*z* from 2 to 244. To obtain operating values of descriptors, before calculations, the mass spectra were preliminarily transformed by the formula

$$d_{ij} = h_{ij} m_{ij} \left(\sum_{k=1}^{k=n} h_{ik} m_{ik} \right)^{-1}, \quad (1)$$

where d_{ij} are the operating values of the descriptors used in calculations; *n*, number of peaks; h_{ij}, their relative intensities; *I*, substance number; *j*, peak number; and m_{ik}, ratio of the weight of *k*th ion to its charge in the *i*th molecule.

Elements d_{ij} form the matrix of descriptors *D* consisting of submatrices of training *A* and control *C* samples. For estimatoin, we used the matrix equation suggested in [18]:

$$p = CV_r \Gamma_r^{-1} U_r^T b, \quad (2)$$

where *p* is the sought-for vector of characteristic values of the control sample; *b*, vector of characteristics values of the training sample of substances; *U*, matrix consisting of the eigenvectors of matrix AA^T; *V*, matrix consisting of the eigenvectors of matrix A^TA; and Γ, diagonal matrix of nonzero singular numbers coinciding for both matrix products.

The subscript is the estimated rank of the descriptor matrix *r*(*A*); it denotes that *r* largest eigenvalues and the corresponding eigenvectors are used. For comparison of the results obtained with published data, the submatrix of descriptors in Eq. (2) was completed with the submatrix of training sample *A* and, correspondingly, vector *b* was completed with vector *p*. This procedure is equivalent to construction of a correlation model from the training sample and estimation of the characteristics of both control and training samples. The calculations were carried out using the PROGROC (PROGram RObustness Calculation) software [18].

The dependence of the correlation coefficient between the experimental and calculated T_m values for the overall set of substances on *r*(*A*) (estimated rank of descriptor submatrix) is presented in Fig. 1.

The maximum value $R = 0.986$ is reached at *r*(*A*) = 52. The results of estimating T_m of esters at this rank are presented in Table 2 and Fig. 2.

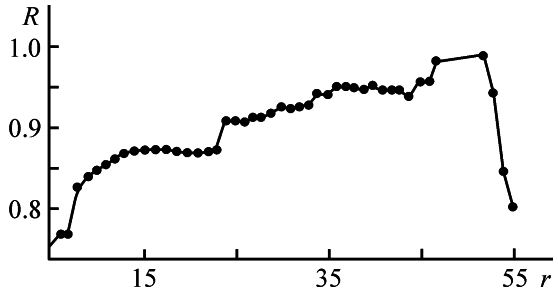

Fig. 1. Correlation coefficient *R* between experimental and calculated T_m as a function of estimated rank of descriptor submatrix *r*(*A*).

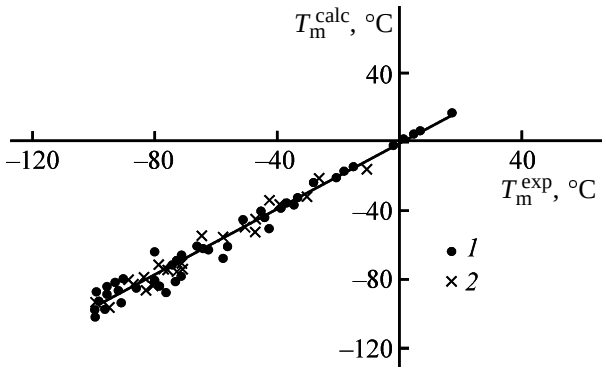

Fig. 2. Correlation between experimental (T_m^{exp}) and calculated from the mass spectra (T_m^{calc}) melting points of esters. Sample: (*1*) training and (*2*) control.

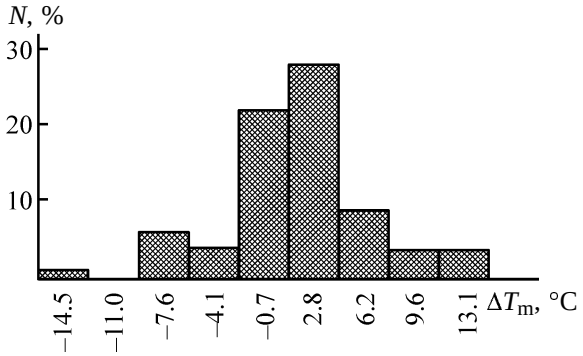

Fig. 3. Error distribution histogram for estimating the melting point T_m of esters. (*N*) Incidence.

The error distribution histogram for the estimation, shown in Fig. 3, is close to the normal distribution.

The quantitative characteristics of correlations between the experimental and calculated T_m values are listed in Table 3.

It should be noted that the accuracy of the results obtained in estimating the melting points of esters

exceeds the accuracy of estimating the T_m for compounds of different classes.

CONCLUSIONS

(1) The use of normalized mass spectra as descriptors of molecular structure allows estimation of melting points of esters with the correlation coefficient $R = 0.986$ between the experimental and estimated melting points and standard deviation $S = 5.01$.

(2) The advantage of the approach developed is that, for estimating a substance characteristic, it is sufficient to have only the mass spectrum of the substance.

Table 3. Characteristics of correlation between experimental and calculated melting points of esters

Characteristic of correlation	Whole set	Sample	
		training	control
R	0.986	0.9860	0.983
S	5.01	5.34	4.37
Average standard deviation	3.7	3.8	3.6

Abstract—A method is suggested for relating the relative permittivity, ionization potential, polarizability, and linear dimensions of nonpolar molecules. This was demonstrated for the example of inert gases, some spherical- and symmetric-top molecules, and linear molecules.

Taking into account the polarizability of organic molecules and ions is important when describing quantitatively the mechanisms and rates of nonradical reactions. The energy of intermolecular dispersion interaction is directly related to the polarizabilities of molecules under consideration. The influence of the dispersion interaction on the reactivity was analyzed in [1–6]. The polarizabilities are commonly determined by extrapolation methods from the refractive index (using the Lorentz–Lorenz formula) and from the relative permittivities of substances. The most accurate values of the molecular polarizability can be obtained from the above parameters determined for the gaseous state, i.e., the case in which the contribution of intermolecular interactions can be neglected.

In analysis of models of the molecular polarizability, attention is attracted by the fact that the influence exerted by the field of the induced dipole on the atomic polarization is disregarded in the literature concerned with nonpolar molecules. An attempt to consider this factor was made in [7]. However, an important point is that the field of the induced dipole is considered in a superposition with that of the permanent dipole for polar molecules. Atoms are regarded as isotropically polarized points, and the induced dipole moment of a molecule is represented as

$$\mu_i = A_i\left[E_i - \sum_{\substack{j=1\\ i\neq j}}^{N} T_{ij}\mu_j\right], \qquad (1)$$

where A_i is the polarizability tensor of ith atom, and T_{ij} is the tensor of a field created by the induced dipole, which can be written in the matrix form as

$$T_{ij} = -\frac{3}{r^5}\begin{bmatrix} x^2 - r^2/3 & xy & xz \\ xy & y^2 - r^2/3 & yz \\ xz & yz & z^2 - r^2/3 \end{bmatrix}, \qquad (2)$$

where r is the distance between ith and jth atoms; x, y, z, components of the vector running from point i to point j in the Cartesian coordinates. The expression in the brackets reflects the total field at ith atom, constituted by the externally applied field and the field of all induced dipoles of the system. However, this model gave a good (within 10%) agreement with experiment for medium polarizabilities and an unsatisfactory agreement for the main components of polarizability and anisotropy. This concept was further developed in [8], with anisotropic effects included, and then in [9], where the repulsion of electrons was taken into account.

Further complication and modification of the model, made in [10, 11], failed to improve significantly the agreement between the quantities mentioned. The last study employing this model and some of its preceding modifications was performed in 1999. The average and principal components of polarizability, calculated in this study for amino acids and peptides, coincided with the expected values only within an order of magnitude. This is natural, because the field of the induced dipole for polar molecules is three orders of magnitude lower than the field of the permanent dipole. Therefore, the model of polarizability of nonpolar molecules, suggested here, does not use tensor quantities, but is based on the relationship between the polarizability and the ionization potential. The idea of establishing such a relationship has been reflected in the literature [13–16]. However, this rela-

1070-4272/05/7803-0461 © 2005 Pleiades Publishing, Inc.

tionship has not been substantiated theoretically and only empirical relations between the experimental and calculated ionization potentials U and polarizabilities α have been obtained in the forms

$$\alpha = a/U^3 + b \quad (3)$$

and

$$\alpha = c/U^\gamma, \quad (4)$$

where a, b, c, and γ are variable parameters. The degree of the correlation was not specified in [15] and was found to be 0.98 in [13, 14, 16]. It was mentioned in [13, 14] that the degree of the correlation strongly depends on the set of atomic radii, used in the calculations. The dependences were constructed using the commonly known relationship between the polarizability of a charged sphere and its volume (radius) and the apparent dependence of the ionization energy on the atomic radius. The existence of a relationship between the polarizability and volume was shown for molecules only in [17].

The aim of this study was to establish a relationship between the polarizability and the ionization potential of nonpolar molecules. The calculation was performed by taking into account the mutual influence of the fields of the induced charges within a molecule. The induced dipole moment of a unit volume of an insulator placed in a uniform external electric field E is given by

$$P = \alpha\varepsilon_0 n_0 E, \quad (5)$$

where α is the polarizability coefficient; m_0, volume concentration of molecules; and ε_0, permittivity of free space. The polarizability coefficient is related to the relative permittivity ε of a nonpolar gas by the Clausius–Mosotti formula

$$\alpha = \frac{3}{n_0}\frac{\varepsilon - 1}{\varepsilon + 2} \approx \frac{\varepsilon - 1}{n_0}. \quad (6)$$

The induced dipole moment per molecule is equal to

$$\mu = \alpha\varepsilon_0 E. \quad (7)$$

Let us represent this dipole as two equal charges q with opposite signs, spaced by a distance l not exceeding the linear dimensions of the molecule. The electric field strength at positions of the induced charges will be changed by the presence of a field associated with the charge of the opposite sign:

$$E_q = \frac{E}{\varepsilon} - \frac{q}{4\pi\varepsilon_0 l^2}. \quad (8)$$

As the field strength increases from zero to E, the work of forces associated with the external field

$$\int_{l(E)}^{l(E)} q E_q \,\mathrm{d}l = \alpha\varepsilon_0 \int_0^E \frac{E^2}{l}(1/\varepsilon - \alpha/4\pi l^3)\frac{\mathrm{d}l}{\mathrm{d}E}\,\mathrm{d}E \quad (9)$$

is at a minimum at

$$\alpha\varepsilon = 4\pi l^3, \quad (10)$$

or if

$$\mathrm{d}l/\mathrm{d}E = 0. \quad (11)$$

Let us assume that, in the case of ionization in a constant electric field, the induced dipole moment of the molecule reaches the value

$$\mu_\mathrm{i} = el, \quad (12)$$

where e is elementary charge, and the field strength in ionization is proportional to the ionization potential U related to the molecular size, i.e., the maximum distance by which the induced charges can be spaced,

$$E_\mathrm{i} = fU/l. \quad (13)$$

Then, if the condition (10) is satisfied, the proportionality factor f can be found from

$$f = (e/\varepsilon_0 U)^{1/2}[n_0/16\pi^2(\varepsilon - 1)]^{1/6}. \quad (14)$$

Analysis of values of f for various substances shows that it is close to unity only for the helium atom and hydrogen molecule. For other nonpolar substances, this factor is within the range from 0.8 for benzene to 1.3 for carbon tetrachloride. This means that formulas (10) and (14) are inadequate as applied to a calculation of the properties of nonpolar substances. If the condition (11) is satisfied, the factor f can be found from the equation

$$f = (4e/\pi\varepsilon_0 Ul)^{1/2}\{1 + [1 + 2(\varepsilon - 1)/\pi n_0 l^3]^{1/2}\}^{-1}, \quad (15)$$

to be in the range from 0.91 to 1.17 for inert gases, a number of linear molecules, and spherical- and symmetric-top molecules. Thus, taking into account the influence exerted by the field of the induced charge

with the opposite sign in Eq. (8) makes it possible to relate the ionization potential, linear dimensions of molecules, and relative permittivity of nonpolar gases by a dimensionless coefficient close to unity.

Below is given the table that lists the experimental values of the linear sizes of a number of molecules, relative permittivities, and ionization potentials. Also given are proportionality factors found by formula (15). The atomic radius for inert gases and the maximum internuclear distance plus the atomic radius of the terminal atom for molecules of various types served as a linear size of molecules. Data on the density, relative permittivity, internuclear distances, atomic radii, and ionization potentials were taken, for the sake of uniformity, from a single source [18]. The only exception is CF_4, for which the density and relative permittivity were taken from [19]. The densities of carbon tetrachloride, carbon disulfide, and benzene were found by the van der Waals equation at a given temperature, with the use of critical parameters.

These data suggest the following. For inert gases, the relative deviation of the factor f from the average value is at a maximum (10%). This deviation is <7% for spherical-top molecules, 4% for diatomic and linear molecules, and ≤3% for symmetric-top molecules. This gives reason to use formula (15) for calculating the ionization potential of nonpolar molecules at a known relative permittivity and, vice versa, to find the relative permittivity (and, consequently, the polarization too) from the ionization potential. The second opportunity is of practical importance, because different experimental values of the ionization potentials of molecules, found in the literature, are commonly in good agreement. Further, we intend to extend the applicability domain of formula (15) to calculation of the polarizability of ions with a symmetric electronic configuration ensuring the absence of a dipole moment. It is necessary to use, instead of the ionization potential, the electron affinity for anions and the second ionization potential of a neutral molecule for cations.

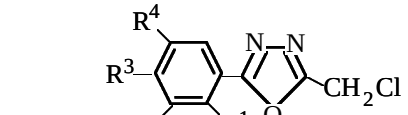
Abstract—The reactions of 1,1-dimethylhydrazine, methylhydrazine, and hydrazine hydrate with 5-aryl-2-chloromethyl-1,3,4-oxadiazoles were studied. The structures and compositions of the final products were confirmed by ^{1}H NMR spectroscopy and elemental analysis.

Hydrazine and its derivatives attract great interest of researchers [1] owing to wide use of these compounds in medicine (antitubercular, antitumor, and other drugs), agriculture (plant growth regulators and stimulants), and industry (production of synthetic fibers, films, coatings, etc.) [2–5].

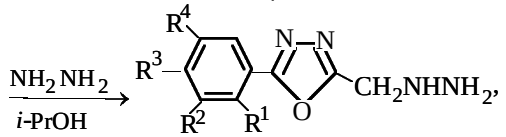
5-Aryl-2-chloromethyl-1,3,4-oxadiazoles, aromatic five-membered heterocycles, are key fragments of various drugs (antiviral agents, antidepressants, etc.) [6]. At the same time, introduction of a hydrazine fragment may enhance their biological activity.

Our goal was synthesis of previously unknown 5-aryl-2-hydrazinomethyl-1,3,4-oxadiazoles, 5-aryl-2-(1-methylhydrazino)methyl-1,3,4-oxadiazoles, and 5-aryl-2-(1,1-dimethylhydrazinio)methyl-1,3,4-oxadiazole chlorides, which are of interest as potentially bioactive substances and agents for further fine organic synthesis.

Accessible 1,3,4-oxadiazole substrates for nucleophilic substitution of chlorine by hydrazine, methylhydrazine, and 1,1-dimethylhydrazine fragments are 2-chloromethyl-5-phenyl-1,3,4-oxadiazole **I**, 2-chloromethyl-5-(2,4-dimethoxyphenyl)-1,3,4-oxadiazole **II**, 2-chloromethyl-5-(2-chlorophenyl)-1,3,4-oxadiazole **III**, and 2-chloromethyl-5-(3,4,5-trimethoxyphenyl)-1,3,4-oxadiazole **IV** [7–9]:



I–**IV**



where $R^1 = R^2 = R^3 = R^4 = H$ (**I**); $R^2 = R^4 = H$, $R^1 = R^3 = MeO$ (**II**); $R^1 = Cl$, $R^2 = R^3 = R^4 = H$ (**III**); $R^2 = R^3 = R^4 = MeO$, $R^1 = H$ (**IV**).

It is known that 5-aryl-2-chloromethyl-1,3,4-oxadiazoles react with amines and methylmercaptoacetyl derivatives selectively with the replacement of Cl in the 2-chloromethyl group [8, 9].

We found that compounds **I**–**IV** react with hydrazine hydrate in 2-propanol at 55–65°C strictly selectively to give 2-hydrazinomethyl-5-phenyl-1,3,4-oxadiazole **V**, 2-hydrazinomethyl-5-(2,4-dimethoxyphenyl)-1,3,4-oxadiazole **VI**, 2-hydrazinomethyl-5-(2-chlorophenyl)-1,3,4-oxadiazole **VII**, and 2-hydrazinomethyl-5-(3,4,5-trimethoxyphenyl)-1,3,4-oxadiazole **VIII** in 67, 23, 25, and 75% yields, respectively.[1] Note that compounds **I**–**IV** react with hydrazine hydrates at different rates depending on substituents in the aromatic ring. The reactions of hydrazine hydrate with **I**–**IV** take 5, 6, 4, and 3 h, respectively. Compounds **V**–**VIII** are isolated as poorly crystallizing hygroscopic crystals.

I–**IV**

V–**VIII**

[1] The synthesis conditions and yields of **V**–**XVI** are given in Table 1; the melting points and analytical data, in Table 2; and the ^{1}H NMR data, in Table 3.

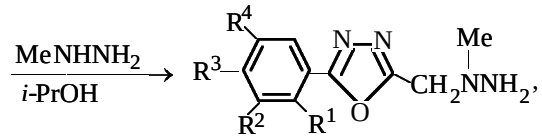
Table 1. Conditions, yields, and products of reactions of **I**–**IV** with hydrazine hydrate, methylhydrazine, and 1,1-dimethylhydrazine

Compound	Ratio*	*T*, °C	τ, h	Product	Yield, %
I	1/2.5[a]	55–65	5	**V**	67
II	1/2.5[a]	55–65	6	**VI**	23
III	1/2.5[a]	55–65	4	**VII**	25
IV	1/2.5[a]	55–65	3	**VIII**	75
I	1/2.5[b]	80–83	5	**IX**	55
II	1/2.5[b]	50–60	5	**X**	45
III	1/2.5[b]	80–83	4	**XI**	56
IV	1/2.5[b]	50–60	4	**XII**	85
I	1/1.2[c]	55–60	5	**XIII**	68
II	1/1.2[c]	55–60	6	**XIV**	84
III	1/1.2[c]	55–60	18	**XV**	71
IV	1/1.2[c]	55–60	7	**XVI**	80



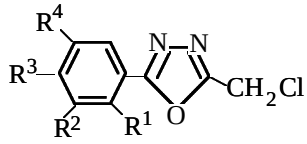
* Component indicated in the denominator: [a] hydrazine, [b] methylhydrazine. and [c] 1,1-dimethylhydrazine.

where $R^1 = R^2 = R^3 = R^4 = H$ (**I**, **V**); $R^2 = R^4 = H$, $R^1 = R^3 = MeO$ (**II**, **VI**); $R^1 = Cl$, $R^2 = R^3 = R^4 = H$ (**III**, **VII**); $R^2 = R^3 = R^4 = MeO$, $R^1 = H$ (**IV**, **VIII**).

The reactions of **I**–**IV** with methylhydrazine were performed in 2-propanol at 50–60 or 80–83°C. The reactions gave 2-(1-methylhydrazino)methyl-5-phenyl-1,3,4-oxadiazole **IX**, 2-(1-methylhydrazino)methyl-5-(2,4-dimethoxyphenyl)-1,3,4-oxadiazole **X**, 2-(1-methylhydrazino)methyl-5-(2-chlorophenyl)-1,3,4-oxadiazole **XI**, and 2-(1-methylhydrazino)methyl-5-(3,4,5-trimethoxyphenyl)-1,3,4-oxadiazole **XII** in 55, 45, 56, and 85% yields, respectively. With **I** and **III**, 1-methylhydrazine reacts at 80–83°C within 5 and 4 h, and with **II** and **IV**, at 50–60°C within 5 and 4 h, respectively. Compounds **IX**–**XII** are noncrystallizable hygroscopic oils:

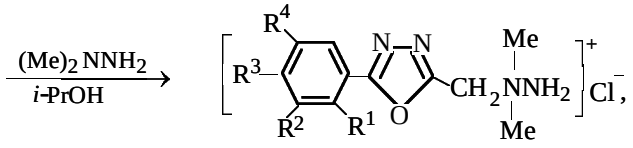
I–**IV**

IX–**XII**



where $R^1 = R^2 = R^3 = R^4 = H$ (**I**, **IX**); $R^2 = R^4 = H$, $R^1 = R^3 = MeO$ (**II**, **X**); $R^1 = Cl$, $R^2 = R^3 = R^4 = H$ (**III**, **XI**); $R^2 = R^3 = R^4 = MeO$, $R^1 = H$ (**IV**, **XII**).

The analytical data (Table 2) for **V**–**XII** unambiguously show that hydrazine and methylhydrazine react with **I**–**IV** along the monoalkylation pathway, i.e., the starting compounds react in an equimolar ratio.



The occurrence of monoalkylation is provided by a 2.5-fold excess of hydrazine hydrate and methylhydrazine in the mixture of the starting components (Table 1). A broadened signal of amine protons at 4.62–4.68 ppm (2H) in the ^{1}H NMR spectra of **IX**–**XII** is an unambiguous evidence of the regioselective alkylation of monomethylhydrazine at the methyl-substituted nitrogen atom (Table 3).

It is known that 1,1-dimethylhydrazine reacts with aliphatic and aromatic chlorides strictly at the N^1 atom to form quaternary ammonium salts [10].

The reactions of **I**–**IV** with 1,1-dimethylhydrazine occurred selectively as nucleophilic substitution of the chlorine atom. The reactions were performed in 2-propanol and gave the corresponding quaternary hydrazinium salts 2-(1,1-dimethylhydrazinio)methyl-5-phenyl-1,3,4-oxadiazole chloride **XIII**, 2-(1,1-dimethylhydrazinio)methyl-5-(2,4-dimethoxyphenyl)-1,3,4-oxadiazole chloride **XIV**, 2-(1,1-dimethylhydrazinio)methyl-5-(2-chlorophenyl)-1,3,4-oxadiazole chloride **XV**, and 2-(1,1-dimethylhydrazinio)methyl-5-(3,4,5-trimethoxyphenyl)-1,3,4-oxadiazole chloride **XVI** in 68, 84, 71, and 80% yields, respectively. All the salts **XIII**–**XVI** are hygroscopic and water-soluble:

I–**IV**

XIII–**XVI**

where $R^1 = R^2 = R^3 = R^4 = H$ (**I**, **XIII**); $R^2 = R^4 = H$, $R^1 = R^3 = MeO$ (**II**, **XIV**); $R^1 = Cl$, $R^2 = R^3 = R^4 = H$ (**III**, **XV**); $R^2 = R^3 = R^4 = MeO$, $R^1 = H$ (**IV**, **XVI**).

The ~2-ppm downfield shift of the amine proton signal (2H) to 6.65–6.82 ppm in the ^{1}H NMR spectra of **XIII**–**XVI** relative to **V**–**VIII** (4.88–4.97 ppm) and **IX**–**XII** (4.62–4.68 ppm) indicates that the positive charge is localized on the dimethyl-substituted nitrogen atom, i.e., a quaternary hydrazinium salt is formed (Table 3).

Thus, compounds **I**–**IV** readily undergo nucleophilic substitution and are convenient starting compounds for preparing various hydrazine-containing compounds. All the hydrazine derivatives prepared are potenitally bioactive and can be brought into further transformations.

EXPERIMENTAL

The ^{1}H NMR spectra were taken on a DPX-300 spectrometer (300 MHz, DMSO-d_6, internal reference TMS). The elemental analysis was performed on a Hewlett–Packard automatic C, H, N analyzer. The melting points were determined with a PTP device. The TLC analysis was performed on Silufol UV-254 plates (eluent chloroform–methanol, 9 : 1, development under UV light or with iodine vapor).

5-Aryl-2-hydrazinomethyl-1,3,4-oxadiazoles V–VIII (general procedure). A solution of 1.5 g of 100% hydrazine hydrate in 10 ml of 2-propanol was added with stirring to a solution of 2 g of **I**–**IV** in 40 ml of 3-propanol. The reaction temperatures and times are given in Table 1. The resulting mixture was cooled, excess 2-propanol was distilled off, and the precipitate was filtered off and dried in a desiccator.

5-Aryl-2-(1-methylhydrazino)methyl-1,3,4-oxadiazoles IX–XII (general procedure). A solution of 1 g of methylhydrazine in 10 ml of 2-propanol was added with stirring to a solution of 2 g of **I**–**IV** in 3 ml of 2-propanol. The reaction temperatures and times are given in Table 1. The resulting mixture was cooled, excess 2-propanol was distilled off, and the remaining oily liquid was dried in a desiccator.

5-Aryl-2-(1,1-dimethylhydrazinio)methyl-1,3,4-oxadiazole chlorides XIII–XVI (general procedure). A solution of 1 g of 1,1-dimethylhydrazine in 10 ml of 2-propanol was added with stirring to a solution of 3 g of **I**–**IV** in 40 ml of 2-propanol. The reaction temperatures and times are given in Table 1. The resulting mixture was cooled, excess 2-propanol was distilled off, and the precipitate was filtered off and dried in a desiccator.

CONCLUSIONS

(1) Hydrazine and methylhydrazine react with 5-aryl-2-chloromethyl-1,3,4-oxadiazoles with the substitution of chlorine to form the corresponding hydrazino and methylhydrazino derivatives.

(2) 1,1-Dimethylhydrazine reacts with 5-aryl-2-chloromethyl-1,3,4-oxadiazoles with the substitution of chlorine to form the corresponding quaternary hydrazinium salts.

Abstract—The changes in the structural organization of solutions of *N,N*-dimethylhexadecylammonium salt of the polyamido acid based on 3,3',4,4'-diphenyltetracarboxylic dianhydride and *o*-tolidine in a dimethylacetamide–dioxane mixed solvent during 24-h keeping at room temperature were studied by polarized light scattering. The stability of the salt solutions was studied as influenced by the composition of the mixed solvent, chemical nature of its components, and molecular weight of the polymer.

In our previous work [1] we carried out light-scattering and viscometric studies of the structure formation and revealed supramolecular associative structures in dilute solutions of comb-shaped *N,N*-dimethylhexadecylammonium salt PAA–C_{16} of polyamido acid based on 3,3',4,4'-diphenyltetracarboxylic dianhydride and *o*-tolidine (PAA DP-T) in a mixed dimethylacetamide (DMAA)–benzene solvent. The PAA–C_{16} solutions at the 50 : 50 solvent : precipitant volume ratio and the concentration of 1 mM are used for preparing ultrathin polyimide (PI) films by the Langmuir–Blodgett (LB) technique [2]. As known, solutions of salts obtained by PAA neutralization with a long-chain tertiary amine are prepared immediately before formation of LB films [3], since even within several hours their performance characteristics get deteriorated: Films thereof are strongly defective and heterogeneous. We showed that keeping 0.5% solutions of PAA–C_{16} in a 50 : 50 DMAA–benzene mixture significantly modifies their supramolecular structure, namely, their microheterogeneity and microordering [1] tend to increase. It seemed reasonable to study how variations of the structure of the PAA–C_{16} solutions during 24-h keeping depend on the composition of the mixed solvent, chemical nature of its components, and molecular weight M of the polymer.

As known, the consumers' properties of the polyimide macrofilms formed from PAAs are virtually unaffected by the molecular weights M within 50 000–200 000. However, films prepared from PAAs with $M < 50\,000$ do not exhibit the required physicomechanical characteristics [4], but, at the same time, these salts do not form a supramolecular structure in dilute solutions, as demonstrated by our control tests. Therefore, we chose solutions (0.4 g dl^{-1}) of salts based on a PAA with a comparatively high molecular weight M = 135 000 (sample 1) and on a low-molecular-weight PAA with M = 50 000 (sample 2). The ratio γ of the components of the DMAA–dioxane mixed solvent was varied around practically used compositions: 55 : 45, 50 : 50, and 48.4 : 51.6.

EXPERIMENTAL

Polyamido acid DP-T was synthesized as a 10% solution in DMAA by the standard procedure [4]. The monomers for synthesis of PAA and *N,N*-dimethylhexadecylamine were purified by vacuum distillation. Solvents DMAA and dioxane were dried over calcium hydride and distilled. The PAA salts were prepared in two steps. First, 1% solutions of PAA and the tertiary amine in the DMAA–dioxane mixture of the desired composition were prepared separately. Then, immediately before the experiment, they were mixed in the amounts corresponding to 1 : 2 molar ratio of the PAA unit to amine; the resulting solution was diluted to the desired concentration by the solvent of the same composition. After 30 min, an equilibrium was established, and the solution was placed into a measuring cell and kept at a constant temperature for 20 min. The intensities of the polarized V_V and depolarized H_V components of the light scattered by the PAA–C_{16} solutions at the scattering angles θ of 40°–140° were measured on an FPS-3M photoelectric light-scattering instrument at the wavelength λ = 578 nm. Benzene was used for calibration. For nonpolarized light at

Table 1. Intrinsic viscosity of DP-T polyamido acid and its salt PAA–C_{16} as influenced by the mixed solvent composition

DMAA : dioxane volume ratio	Intrinsic viscosity, dl g^{-1}	
	DP-T	PAA–C_{16}
100 : 0	3.00	2.15
55 : 45	2.50	1.65
50 : 50	2.40	1.50
48.4 : 51.6	2.25	1.35

this wavelength, the Rayleigh ratio for benzene was 13.06×10^{-6} cm^{-1}. The intrinsic viscosity [η] of the polymer macromolecules was determined in a capillary Ubbelohde viscometer at 20°C. The time of outflow of the mixed solvent was 90–100 s. Table 1 lists the intrinsic viscosities of PAA and the PAA salt in the mixed solvent of different compositions. The molecular weight of the samples of the initial PAA in DMAA was determined by the light scattering method at the angle of 90°. The supramolecular structure of the solutions was quantitatively analyzed by the polarized light scattering method in terms of the Debye–Stein statistical theory [5].

The Debye–Stein statistical theory connects the experimentally determined Rayleigh ratios for the vertically R_V and horizontally R_H polarized components of the scattered light and the structural characteristics of the scattering polymeric medium by the relationships

$$R_V - \frac{4}{3}R_H = 4\pi K_0^4 \langle \eta \rangle \int_0^\infty \gamma(r) \frac{\sin(2KrS)}{2KrS} r^2 \, dr, \quad (1)$$

Angular plots of (*1*, *2*) $(V_V - 4H_V/3)^{-1/2}$ and (*3*, *4*) $(H_V)^{-1/2}$ for the PAA–C_{16} salt sample in the DMAA–dioxane mixed solvent at γ = 55 : 45. (*1*, *3*) Initial samples and (*2*, *4*) samples kept for 24 h.

$$R_H = \frac{4}{15} 4\pi K_0^4 \langle \delta^2 \rangle \int_0^\infty f(r) \frac{\sin(2KrS)}{2KrS} r^2 \, dr, \quad (2)$$

where $K = K_0 n$; n, refractive index of the medium; $K_0 = 2\pi/\lambda$; r, distance between two elementary scattering volumes; $S = \sin^2(\theta/2)$; $\gamma(r)$, correlation function of the polarizability fluctuation; $f(r)$, correlation function of the mutual orientation of the optical axes of the elementary scattering volumes.

Using the exponential correlation functions $\gamma(r) = \exp(-r a_V)$ and $f(r) = \exp(-r/a_H)$, it is possible to obtain the following parameters of the scattering medium: a_V and a_H, correlation radii of the polarizability fluctuation and orientation, respectively; $\langle \eta^2 \rangle$, mean squared polarizability fluctuation, and $\langle \delta^2 \rangle$, mean squared optical anisotropy density. Since the exponential correlation function of the orientation is related to the angle θ_{ij} between the optical axes of two arbitrarily chosen optical elements, it is possible to determine the factor of local orientation F within the areas confined by the radius $r = a_V$ [6]:

$$F = (\cos^2 \theta_{ij}) a_V = [1 + 2\exp(-a_V/a_H)]/3. \quad (3)$$

Thus, the isotropic parameters $\langle \eta^2 \rangle$ and a_V characterize the degree of the density heterogeneity of the system and the correlation size of the microheterogeneities, and anisotropic parameters $\langle \delta^2 \rangle$ and a_H, the degree of ordering of the system and sizes of the ordered areas.

For all the tested solutions of the PAA–C_{16} salt samples in a mixed solvent, we obtained the experimental plots of $(H_V)^{-1/2}$ and $(V_V - 4H_V/3)^{-1/2}$ vs. $\sin^2(\theta/2)$ (see figure). From the slopes of the approximating straight lines and the intercepts, we calculated four statistical structural parameters of the scattering system [5] and the local orientation factor F [6], using the exponential correlation function. Table 2 lists the statistical parameters characterizing the structure of the solutions of the two samples of the PAA–C_{16} salt with different molecular weighs M in the DMAA–dioxane mixtures. Also, Table 2 lists the molecular weights M of the initial PAAs that were used for preparing the PAA–C_{16} salts studied.

We showed previously [1] that PAA DP-T forming the backbone of the salt dissolves completely and that amide solvents are thermodynamically good for *o*-tolidine-based PAA macromolecules. Upon addition of dioxane to the solution, the thermodynamic quality of the solvents is deteriorated, and the macromolecular globule gets contracted, which decreases [η] for

Table 2. Structural characteristics of the PAA–C_{16} salt solutions in the DMAA–dioxane mixed solvent at c = 0.4 g dl^{-1}

both PAA and the PAA–C_{16} salt (Table 1). However, when dissolved, comb-shaped PAA–C_{16} salts prepared from PAA form molecular-dispersed solutions neither in amide solvents nor in their mixtures with benzene or dioxane, which suggests that these are associated systems [7]. Intermolecular association may be realized via long side aliphatic chains of the tertiary amine.

Table 2 shows that the difference between the statistical parameters characterizing the structural organization of the PAA salt solutions in mixed solvents with close compositions substantially exceeds the measurement inaccuracy.

It is known that, with deteriorating thermodynamic quality of the solvent, the polymer–polymer interactions are enhanced, which is responsible for contraction of the macromolecular globule and an increase in the segment density [8]. It was found experimentally that, with increasing proportion of the precipitant, the structural changes in solutions of associated macromolecules are manifested in an increase in the microheterogeneity of the solution, i.e., in the mean squared density of the optical polarizability $\langle\eta^2\rangle$ in parallel with a decrease in the size of the associative formations a_V. Such a behavior was revealed for PAA solutions in mixed solvents [9].

In dilute PAA–C_{16} salt solutions, the parameter $\langle\eta^2\rangle$ also increased with increasing proportion of precipitant (dioxane) in the mixed solvent, but this was accompanied by an increase in a_V (Table 2). Increase in the proportion of dioxane results in contraction of the backbone of PAA–C_{16} for which dioxane is precipitant [10]. This is responsible for increases in the optical density of the macromolecular globule and in the corresponding $\langle\eta^2\rangle$ parameter. Evidently, contraction of the globule enhances interaction between the long side aliphatic branches of the tertiary amine. This favors association in solution, which increases a_V.

We found that all the PAA–C_{16} salt solutions that we studied exhibit microanisotropic properties. The calculated anisotropic structural parameters, the mean squared density of the optical anisotropy $\langle\delta^2\rangle$ and the mean correlation radius of orientation of the scattering elements of the volume a_H, vary insignificantly with the mixed solvent composition. The local order factor F fluctuates around 0.4, which is typical for dilute polymer solutions [6].

Since the PAA salt solutions in mixed solvents of close compositions differ substantially in the structural organization, it can be expected that, during keeping, these solutions will behave differently as well. Table 2 shows that, during 24-h keeping at room temperature, the statistical parameters characterizing the supramolecular structure of the PAA–C_{16} salt solutions significantly vary, whatever the composition of the mixed solvent studied, with the solvent composition and the molecular weight M of the initial PAA.

For the solution of the high-molecular-weight sample no. 1 in the mixed solvent at the DMAA : dioxane ratio γ of 55 : 45 and 50 : 50, all the structural parameters tend to decrease within 24 h, and the mean correlation radius of orientation of the scattering elements of volume a_H remains virtually unchanged. This suggests homogenization of the solution. The local orientation factor F remains virtually unchanged. For the system with a maximal amount of the precipitant (γ = 48.4 : 51.6), when the polymer still occurs in solution, the mean squared polarizability fluctuation $\langle\eta^2\rangle$ decreases by a half within 24 h, and the parameter a_V remains unchanged within the accuracy. Thus, the size a_V of the associative formations remains unchanged with time, but their density decreases, that is, the solution becomes more homogeneous. The correlation size of the ordered areas a_H noticeably decreases and, therefore, the degree of ordering of the

associative formations, characterized by the factor *F*, decreases.

As the system approaches the precipitation point (γ = 48.4 : 51.6), the instability of the structural organization of the solutions is manifested stronger than for the other systems: The parameter $\langle\eta^2\rangle$ decreases almost by a half, and a_H also significantly decreases. Thus, not only homogenization but also disordering of the structure of the associative formations take place, probably owing to a decrease in the degree of mutual orientation of the side fragments of the macromolecules.

Studies of the structural organization of solutions of mesogenic PAA in amide solvents showed that, in the course of keeping, the diamine and dianhydride components of the monomeric unit undergo mutual ordering, which increases the optical anisotropy density [10]. In the PAA–C_{16} salt solution at γ of 55 : 45 and 50 : 50, the development of this process is precluded by side aliphatic chains which create steric hindrance to mutual approach of the PAA backbone segments. However, as the system approaches the precipitation point, the polymer–polymer interaction is strengthened, and this favors mutual approach of the monomeric units, thus enhancing the order at the microlevel. This can be responsible for a certain increase in the parameter $\langle\delta^2\rangle$ during keeping of the solutions of sample no. 1 of the PAA–C_{16} salt in the solvent with γ = 48.4 : 51.6.

We showed previously [9] that the structural organization of the systems studied, quantitatively characterized by statistical parameters, depends on the molecular weight *M* of the polyamido acid. In view of the fact that the solutions of polymers with different molecular weights *M* strongly differ in the structural features at identical concentrations, it is important to compare the supramolecular organizations of the solutions for which the polymer concentrations are identical and molecular weights *M* differ. This is the more important, since, in practice, Langmuir–Blodgett films are usually prepared from solutions with one, fixed, polymer concentration.

To elucidate how the structural organization of the PAA–C_{16} salt solutions is influenced by the molecular weight *M*, we compared the characteristics of two samples in mixed solvents of the same concentration (γ = 50 : 50). For the high-molecular-weight sample no. 1 within 24 h of keeping, both isotropic ($\langle\eta^2\rangle$ and a_V) and anisotropic ($\langle\delta^2\rangle$ and a_H) parameters decrease insignificantly, i.e., the solutions become more homogeneous in density and more disordered (Table 2). In contrast to sample no. 1, a low-molecular-weight sample no. 2 exhibits a qualitatively different pattern of variation of the structural parameters on keeping: The parameters $\langle\eta^2\rangle$ and a_H tend to significantly increase, while the two other parameters, to significantly decrease (Table 2). An increase in $\langle\eta^2\rangle$ suggests that the heterogeneity of the solution of sample no. 2 tends to increase with time, which can be due to an increase in the density of the monomeric units inside the associative formations. Increase in the correlation size of the ordered areas a_H suggests an increase in the degree of ordering in system 2 with time. For a low-molecular-weight sample, a lower mean density of the monomeric units in the molecular globule and a more unfolded chain can create more favorable conditions for the mutual ordering of the side aliphatic chains [11] of the polymer and solvent molecules, incorporated into the associative formation. This is manifested in an increase in the orientation correlation radius a_H and local orientation factor *F*. Ordering of long side chains, in turn, results in a decrease in the equilibrium flexibility of the macromolecules [11], which can be manifested experimentally in an increase in the microheterogeneity $\langle\eta^2\rangle$.

Comparative analysis of the behavior of the PAA–C_{16} solutions suggests that solutions of low-molecular-weight salts have a less stable structure than high-molecular-weight samples. This should be taken into account when applying solutions of low-molecular-weight PAA–C_{16} salts in formation of Langmuir–Blodgett films.

Comparison of the changes in the structural organization of the PAA–C_{16} salt solution in DMAA–benzene and DMAA–dioxane mixtures revealed a marked difference in their supramolecular organization and stability. In particular, within 24 h of keeping, solutions of the high-molecular-weight salt in the DMAA–benzene mixture undergo substantial structural changes, which are manifested in increases in $\langle\eta^2\rangle$ and a_H by a factor of 1.5–2. By contrast, in solutions of the high-molecular-weight salt in the DMAA–dioxane mixture the structural characteristics slightly decrease. Morphological changes in time, similar to those in the PAA–C_{16}–DMAA–benzene system, are exhibited in the DMAA–dioxane system only by the low-molecular-weight sample.

CONCLUSIONS

(1) A comparative analysis of the structural organization was carried out for solutions of high-molecular-weight samples of PAA–C_{16} in mixed dimethyl-

acetamide–dioxane solutions of various compositions. The homogeneity of these solutions is the higher, the smaller the proportion in them of the precipitant, dioxane. The mean density of the associative formations and their statistical size tend to decrease with time, like the mean squared anisotropy density and the size of the ordered areas. This means that solutions of high-molecular-weight PAA–C_{16} become more homogeneous and disordered.

(2) The structural organization and behavior with time, exhibited by the PAA–C_{16} salt solutions in solvents with identical compositions, depend on the molecular weight M of the PAA: Solutions of the low-molecular-weight sample of the comb-shaped salt become more heterogeneous and microordered with time.

(3) In the case of the high-molecular-weight PAA–C_{16} salt and the mixed solvent with a composition close to that corresponding to precipitation of the polysalt, the dimethylacetamide–dioxane system can be more advantageous than the dimethylacetamide–benzene system from the viewpoint of the stability of solutions. This should be taken into account in preparing Langmuir–Blodgett films.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Preparation of Branched Poly(Methyl Methacrylate) Using a Macroinitiator Based on Cobalt(II) 3-Allylpentane-2,4-dionate

Abstract—Cobalt(II) 2-allylpentane-2,4-dionate, when used as an initiator of methyl methacrylate polymerization, yields a polymer containing metal chelate groups and exhibiting the properties of a macroinitiator capable of initiating secondary polymerization with the formation of branched high-molecular-weight methyl methacrylate polymers with a low polydispersity.

Polymers containing functional groups in the chain can be used in various processes [1]. Recently we suggested a procedure for preparing functional polymers starting from transition metal vinyl β-diketonates [2]. The presence of a double bond in these compounds allows their copolymerization with vinyl monomers, and the radical-generating metal chelate ring exhibits initiating power. Initiation with transition metal β-diketonates has been described in sufficient detail in [3]; however, no data are available on initiation with polymers containing β-diketonate fragments in pendant chains. Macroinitiators based on peroxides were reported in [4, 5]. They are of interest for preparation of branched and graft polymers and for cross-linking and modification of polymers [6].

In this work we studied polymerization of methyl methacrylate (MMA) initiated with a cobalt(II) vinyl β-diketonate and some characteristics of the resulting polymers.

EXPERIMENTAL

As initiator we used cobalt(II) 3-allylpentane-2,4-dionate [APD-Co(II)] [7]. Polymerization was performed in a solution of dimethylformamide (DMF) and dimethyl sulfoxide (DMSO) at 70°C. In these solvents, the attainable concentration of the chelate is higher than in bulk polymerization. Furthermore, donor solvents should exert an activating effect on the polymerization. The monomer concentration was 5.32 M in all the experiments. The initiator concentration in DMF solutions was 1 wt %, and in DMSO solutions, 2 wt % based on the monomer. The polymerization was performed in ampules. The reaction kinetics was studied by the method of dry residue.

To calculate the content and length of the grafted chains, the polymerization was performed in two steps. In the first step, we isolated polymers formed at incomplete conversion (from 13.0 to 19.9%). Since initiation and copolymerization with the chelates occurred simultaneously, we obtained an MMA polymer containing metal chelate groups in the pendant chains. The polymers were reprecipitated two times with a tenfold excess of ethanol. For the samples obtained, we determined the cobalt(II) content and the molecular-weight characteristics.

In the second step, the polymers obtained were used as macroinitiators (MIs) in MMA polymerization. We determined the molecular-weight characteristics of the resulting graft polymers. The content and mean length of the grafted chains were determined by comparison of the matrix polymer prepared in the first step with the graft polymer formed in the second step. The cobalt(II) content was determined with a Saturn atomic absorption spectrometer equipped with an LSP-1 lamp (analytical line of Co 240.7 nm). The molecular weights of the polymers were determined by gel permeation chromatography on a Waters-200 chromatograph using Waters monodisperse polystyrene references. The branched PMMA was subjected to fractional precipitation in the benzene–petroleum ether system at 20°C. The molecular weights of the fractions were estimated from their intrinsic viscosities [η].

The polymerization of MMA initiated with APD-Co(II) was performed at 70°C to various conversions (Table 1). In DMF solutions at a chelate concentration of 1 wt %, the polymerization rate is fairly high (the rate of thermal polymerization in the bulk was 1.1%

per hour). The cobalt(II) content in the polymer substantially decreases with increasing conversion, which may be due to exhaustion of the polymer in the course of the polymerization. Therefore, the polymer samples taken at low conversions contain more metals and hence are more active as macroinitiators. Copolymerization of the initiator with MMA yields a copolymer with metal chelate groups.

Since APD-Co(II) contains two ligands, each with a C=C bond, it is a diene monomer. Therefore, the copolymerization can be accompanied by cross-linking through unchanged double bonds. The metal atoms present in the monomer can also effect cross-linking [8]. The chelate groups incorporated in the copolymer form active centers behaving as branching centers. The branches can also contain chelate groups and undergo further branching. Therefore, the polymers listed in Table 1 will contain two types of chelate groups: converted groups which formed branches and unchanged groups which can act as initiation centers after isolation of the polymers. The degree of the polydispersity of the polymers is high. One of the polymers contained a small (1.5%) low-molecular-weight fraction (M_n = 2800, M_w = 3500, M_w/M_n = 1.28) whose formation may be associated with the inhibiting effect of β-diketonates [2].

The polymerization in DMSO shows similar trends. However, in this case the mean reaction rates were very high, and the Co(II) content in the polymer reached 1 wt %. Furthermore, a cross-linked product was obtained when the polymerization was performed for 1.5 h. Additional experiments showed that the cross-linked polymer was always formed in both solvents at the chelate concentration of 2 wt %, polymerization time of >1.5 h, and temperature of 70°C. From the cobalt(II) content in the polymer and M_w of the polymers, we calculated the cobalt content per macromolecule N_{Co}; the results confirm the participation of the chelate in the copolymerization with MMA as comonomer.

The polymers prepared by the above procedure were used as initiators of graft polymerization of MMA (Table 2), which was performed in the bulk.

* (n) Number of grafting sites, ($\overline{M}_{gr}$) mean molecular weight of grafted chains, and ($M_{t.gr}$) total molecular weight of grafted chains.

As already noted, a part of the metal chelate groups incorporated in the macroinitiator formed branchings even in the step of its preparation. Such groups will not initiate secondary polymerization. This is indicated by the fact that a high cobalt(II) content in MI (Table 1) does not always ensure higher rate of secondary polymerization. A similar phenomenon was observed previously with MIs containing peroxy groups of the same thermal stability. Nevertheless, the reaction rates are fairly high in all the cases. It is interesting that a cross-linked fraction formed in the MI sample with the highest Co content (DMF solution). The molecular weights of the graft polymers exceeded those of the initial macroinitiators by more than an order of magnitude, suggesting high degree of grafting. It should be emphasized that the degree of polydispersity of the graft polymers is relatively low (<3) and in all the cases lower than that of the initial MIs. This may be due to weaker inhibiting effect of the β-diketonate groups incorporated in the polymer, which is caused by steric factors and diffusion limitations. Therefore, the chain termination on an MI will be weaker than on the monomeric chelate; as a result, the polydispersity will decrease. In the case of peroxy MIs, the degree of polydispersity was more than 10 [4]. This fact demonstrates an advantage of MIs based on β-diketonates.

Comparison of data from Tables 1 and 2 allows determination of the content and length of the grafted chains. Considering the mechanism of initiation with monomeric cobalt(II) vinyl β-diketonates, we can expect that the metal chelate groups incorporated in the polymer will initiate graft polymerization. Then the amount of the cobalt atoms in the macromolecule (Table 1) will determine the limiting amount of the grafting sites (Table 3). The exceptions are the metal chelate groups that already formed graftings in the step of MI preparation. However, the amount of such groups can be reduced to a minimum by decreasing the time and temperature of MI preparation. From data in Table 3, we calculated the total and mean molecular weights of the grafted chains in the macromolecule. Thus, MIs prepared under similar conditions but at different conversions (from 14.5 to 19.9%) only slightly differ in the number of grafting sites (from 18 to 22). The mean molecular weight of the grafted chains is (2.53–3.66) × 10^5, which amounts to 34–54% of the molecular weight of the macroinitiator. Thus, comb-shaped polymers with a high molecular weight of the grafted chains were obtained. The total weight of the grafted chains is many times higher than the weight of the macroinitiator.

It is known that grafting of monomers onto a polymer matrix containing a peroxy fragment yields, along with the graft product, also the thermopolymer and the homopolymer (owing to participation in the polymerization of a small radical formed by cleavage of the peroxy bond) [4]. The presence of large amounts of these polymers appreciably impairs the properties of the graft products. The mechanism suggested previously in [9] does not involve formation of a small radical in initiation with MIs based on cobalt(II) β-diketonates; therefore, the graft product should be mainly contaminated with the thermopolymer. To confirm this assumption, we fractionated the graft polymer obtained on MI-2. The results are listed in Table 4.

The sample was separated into three fractions, and the intrinsic viscosity [η] and molecular weight of each fraction were determined. For the nonfractionated sample, [η] = 6.04. Calculation of the intrinsic viscosity of this sample from [η] of separate fractions and their relative content (by weight) gave [η] = 6.17. Thermal polymerization of MMA at 70°C occurs at a rate of 1.1% h^{-1}, and the intrinsic viscosity of the resulting polymer is 5.81. If the rate of the polymerization initiated with MI-2 is 4.3% h^{-1} (Table 2), then the relative content of the thermopolymer in the sample should be 25.6%. The same conclusion follows from the results of the gravimetric analysis. Comparison of these data with the characteristics of fraction II shows that it is the thermopolymer. Hence, fraction I of the highest molecular weight is the graft polymer. Fraction III remains unidentified. Presumably, this

Table 4. Results of fractionation of the secondary polymer obtained on MI-2

Fraction	$[\eta]$, dl g^{-1}	$M_\eta \times 10^{-6}$	Content of fraction, %	Molecular weight		
				$M_n \times 10^{-6}$	$M_w \times 10^{-6}$	M_w/M_n
I	7.39	6.00	58.0	–	–	–
II	5.34	3.83	26.0	–	–	–
III	3.09	1.81	16.0	–	–	–
Nonfractionated sample	6.04	4.54	–	2.2	6.1	2.77

lowest-molecular-weight fraction is formed by termination of the propagating chains on MI chelate fragments. Thus, the graft polymer does not contain MMA homopolymer, which confirms the initiation mechanism suggested in [9]. The high degree of polydispersity (>10) of the graft polymers prepared with MIs of peroxy type may be due to the presence of the homopolymer.

Table 4 also shows that the molecular weight of fraction I (graft polymer) is 33% higher than that of the nonfractionated sample. The calculations of the lengths of the grafted chains were based on data for nonfractionated samples, and even in this case the molecular weight of the grafted chains reached 54% of that of MI. Thus, actually the molecular weight of the grafted chains is, apparently, almost equal to that of the polymer.

CONCLUSIONS

(1) Branched methyl methacrylate polymers were obtained with macroinitiators containing cobalt(II) diketonate fragments in the pendant chains.

(2) The number and mean molecular weight of the grafted chains were calculated. The polymers obtained are comb-shaped with the molecular weight of the grafted chains close to that of the macroinitiator and have a low degree of polydispersity.

(3) Examination of the fractional composition of the graft polymer showed that the polymer blend contained no homopolymer that could form by secondary polymerization. This fact furnishes additional information on the mechanism of initiation with cobalt β-diketonates.

Abstract—The conducting properties of composites prepared by deposition of polyaniline layers on the surface of porous polyethylene films from dispersions and by polymerization *in situ* were studied.

Conducting polymers such as polyacetylene, polyaniline (PANI), polypyrrole, polythiophene, and their derivatives are novel promising materials attracting researchers' attention [1, 2]. They are used in membrane processes, electric batteries, and new types of electronic and optoelectronic devices, and also as sensitive elements in modern sensor systems, antistatic agents, and microwave absorbers. Due to relatively high intrinsic conductivity and chemical stability, and also to diverse and simple preparation procedures, polyaniline is the most promising conducting polymer [3, 4]. However, low strength, brittleness, and very poor solubility hinder utilization and treatment of PANI. These disadvantages can be effectively overcome by preparing composites containing PANI as conducting component [5, 6]. Development of methods for preparing composites consisting of conducting layers on various supports is an urgent problem. When the composites are used as membranes, the resistance of the supports to the mass transfer should be minimal, and porous materials containing through channels meet this requirement.

In this work we used porous polyethylene (PE) supports, because they exhibit good mechanical properties and high chemical resistance with respect to organic solvents, acids, and alkalis.

We studied the electrical and mechanical properties of composites consisting of PANI layers deposited on porous PE film supports. Since in service these composites can be exposed to thermal treatment, we also studied their thermal-deformation behavior and structural transformations.

EXPERIMENTAL

The required porous films were prepared from high-density polyethylene (M_w 1.4×10^5, M_w/M_n 6–8, and mp 132°C). The porous structure was formed by uniaxial extension of the film prepared by extrusion of the melt with subsequent annealing [7]. The total porosity of the resulting 20-μm films was 40%. These porous films contained through channels (180–360 nm in diameter) [7, 8] and had developed rough surface [9, 10] providing high adhesion of the films to the layers deposited.

The PE/PANI composites were prepared by two procedures: by chemical oxidative polymerization from aniline solutions directly on the porous film surface [PE/PANI(*in situ*)] and by deposition of a polyaniline dispersion on the film surface [PE/PANI (disp.)].

To prepare the PE/PANI(*in situ*) systems, the porous PE film was immersed into the reaction mixture containing aniline hydrochloride (0.2 M), ammonium peroxodisulfate (0.25 M), and excess hydrochloric acid (1 M). The polymerization time was varied from 8 min to 2 days. Then, the resulting film was dried in a vacuum at room temperature. The polymerization was carried out at 5 and 20°C.

The colloidal PANI dispersion was prepared as follows. To a solution of dodecylbenzenesulfonic acid (0.1 M, 100 ml), we successively added aniline (0.01 mol) and a solution of ammonium peroxodisulfate (0.01 mol) in deionized water (5 ml). The polymerization was carried out at room temperature for

PE/PANI(disp.)	26	70	5	7×10^{-6}

* (T_p) Polymerization temperature.

4 h. The size of the PANI particles was 5–30 nm [11]. To prepare the PE/PANI(disp.) system, the porous PE film was placed in the colloidal dispersion for 4 h and then dried at room temperature. The PANI content in the samples was determined gravimetrically.

The surface electrical conductivity of the composites (conductivity in the direction parallel to the film surface) was measured by the standard four-point method, and the through conductivity (conductivity from one film surface to the other), by the two-disc procedure.

The mechanical properties of the porous PE films and composites were studied on an R-5 tensile-testing machine. The strength, elastic modulus, and relative elongation at break were calculated from the stress–strain curves recorded at uniaxial extension of the samples (2×30 mm) at a rate of 100% min^{-1}. The strength was determined as the maximal (breaking) force related to the initial cross-section of the sample. The elastic modulus was determined at 0.5% strain. The mechanical properties of the porous PE films and composites were determined in directions parallel and perpendicular to the direction of extension of the porous support.

The thermomechanical properties were studied at uniaxial extension of the films at a heating rate of 10 deg min^{-1}. These tests were carried out in a vacuum to exclude oxidation of the films.

The heat of melting and melting point of the films were determined by differential scanning calorimetry on a DSM-2 microcalorimeter at a heating rate of 16 deg min^{-1}.

Kinetics of formation of polyaniline layers on the surface of porous PE films. The samples with various content of PANI were prepared by polymerization *in situ* at 20°C. Formation of the PANI film on the porous support surface is described by the kinetic dependence shown in Fig. 1. As seen, after certain induction period (~5 min), PANI is formed fairly rapidly in the first ~0.5 h, then the formation rate sharply decreases and the content of PANI in the composite changes insignificantly with increasing polymerization time. The thickness of the PANI layer at a polymerization time of 48 h was about 1 μm.

Electrical conductivity of porous PE supports with polyaniline layers. The porous structure of PE films is formed under the conditions of complex effects, and, as a result, they exhibit pronounced anisotropy [12, 13]. Therefore, we studied how the surface conductivity of the composites depends on the direction with respect to the orientation axis of the film. Our experimental results showed no dependence of the surface conductivity on the film orientation, i.e., the resulting PANI layers are uniform.

An electron-microscopic study showed that, when the monomer polymerization procedure is used, the PANI layer appears not only on the PE film surface but also on the pore walls, forming conducting bridges between the surfaces of the composite and thus providing the through conductivity of the sample. As seen from Table 1, the through conductivity is lower than the surface conductivity by several orders of

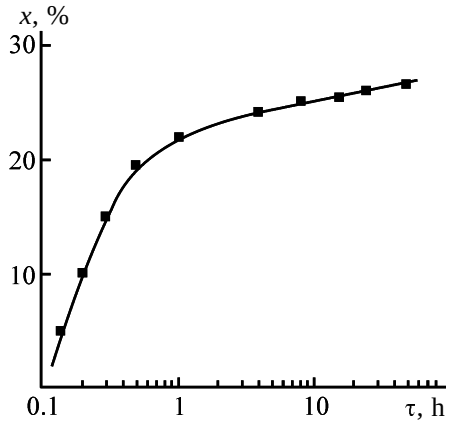

Fig. 1. Content of PANI x in the composite as a function of the polymerization time τ; polymerization *in situ* at 20°C.

* Data recorded in direction parallel/perpendicular to the support extension axis.

magnitude, which can be explained by the complex structure and tortuosity of the through channels.

The conductivity of the PE/PANI(*in situ*) systems prepared at 20°C is plotted in Fig. 2 vs. PANI content. With increasing content of PANI, the surface conductivity of the samples first increases and then becomes constant at a PANI content of ~20%. The flattering-out of this dependence suggests formation of the conducting uniform surface layer. When the content of PANI is below 5%, the conducting polymer does not form a continuous coating, and the conductivity of this sample is close to that of the PE film support.

As in the case of the surface conductivity, the dependence of the through conductivity on the content of PANI flattens out at a PANI content of ~20%. This is due to the fact that, with a further increase in the PANI content, the thickness of the surface layer increases, whereas the structure of the conducting phase in the porous support bulk remains unchanged.

It is known [14, 15] that lower polymerization temperatures favor formation of PANI with more ordered structure and, as a result, with a higher conductivity. Indeed, polymerization at 5°C allows preparation of the PE/PANI systems with higher conductivities than that of the systems prepared at 20°C (Table 1).

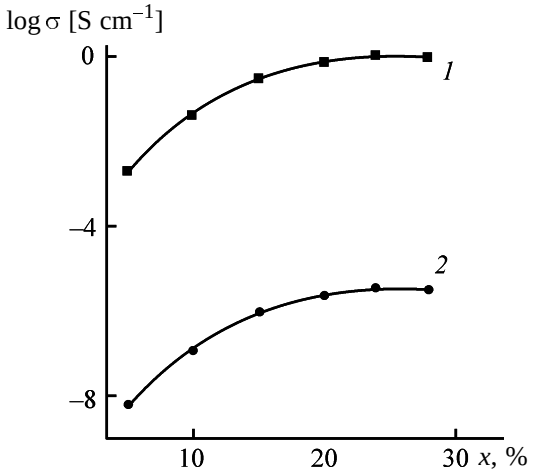

Fig. 2. (*1*) Surface and (*2*) through conductivity σ of the PE/PANI composites prepared by polymerization *in situ* at 20°C as functions of the PANI content *x*.

Our results show (Table 1) that the conductivities of the composites prepared by deposition of the PANI dispersions are comparable with those of the composites prepared by polymerization, despite considerably higher content of PANI.

Thus, polymerization *in situ* and deposition of the dispersion on the support surface yield the composites with the surface conductivity close to that of the free PANI films (1–40 S cm^{-1} [2]), which suggests that the PANI layers formed by these procedures are defect-free and uniform.

Mechanical properties of the porous PE films coated with polyaniline layers. Our study of the mechanical properties of supports and composites showed that the oriented structure of the porous PE films causes anisotropy of mechanical properties, which is retained in the composites on their base. As seen from Table 2, the strength and relative elongation at break in the direction of the film extension are greater by an order of magnitude than the corresponding values measured in the direction perpendicular to the extension axis.

After the polymerization deposition of the PANI layers, the strength and elasticity of the porous PE films (both in the extension direction and perpendicularly to it) slightly decrease, whereas the elastic modulus increases (Table 2). These systems are characterized by high adhesion of the PANI layers to the porous support, and no exfoliation was observed even at the sample break. From our viewpoint, this fact suggests that the monomer penetrates not only into the support pores, but also in the intercrystallite space, and polymerization provides formation of the continuous phase of the conducting polymer both on the support surface and in its bulk.

In extension of the composites containing layers prepared from PANI dispersion, exfoliation of the layers was observed even at low strains, i.e., the composites lost their uniformity. In this case, low adhesion of the layers to the porous support is due to the fact that dispersion particles, whose size is greater than that of the monomer molecules, cannot penetrate into the pores and no continuous skeleton of the conducting polymer in the porous support bulk is formed.

Thus, only polymerization *in situ* as a procedure for preparing PANI layers on porous PE supports yields the composites combining high electrical properties of the conducting polymer with high mechanical stability of the support polymer.

Thermomechanical properties of porous PE films coated with polyaniline layers. Since the structure of the PE films is oriented, they exhibit shrinkage in the orientation direction. It was found [9, 16] that the thermal-deformation stability of porous films increases after deposition of polyaniline layers; as a result, shrinkage of these systems starts at higher temperatures and the degree of shrinkage in the entire temperature range is significantly smaller as compared to the porous supports. In this work we studied the deformation behavior of porous PE supports with PANI layers under a load in the course of heating.

The thermomechanical curves for porous materials (Fig. 3, curve *1*) and composites PE/PANI(*in situ*) and PE/PANI(disp.) (Fig. 3, curves *2*–*4*) were recorded under a tensile load of 0.2 MPa. The behavior of all the samples under this load is typical for ordered systems containing flexible-chain polymers: the shrinkage is maximal at temperatures close to the melting point of PE (T_m^{PE}), and at heating above this temperature sharp elongation followed by the break is observed. As seen from Fig. 3, shrinkage of the composite materials in the entire temperature range is smaller than that of the porous supports. This suggests that PANI layers stabilize the structure of the PE supports.

Higher thermal-deformation stability of the PE–PANI(*in situ*) systems as compared to PE/PANI(disp.) composites is due to the fact that, in contrast to the supports coated with PANI dispersion, in the first case a more rigid PANI skeleton strongly fixed on the support surface is formed.

The thermal-deformation stability of the samples prepared by PANI polymerization at 5°C is higher as compared to the samples formed at 20°C, because a more compact and ordered PANI layer is formed at the lower temperature; this fact is confirmed by higher conductivity of this layer.

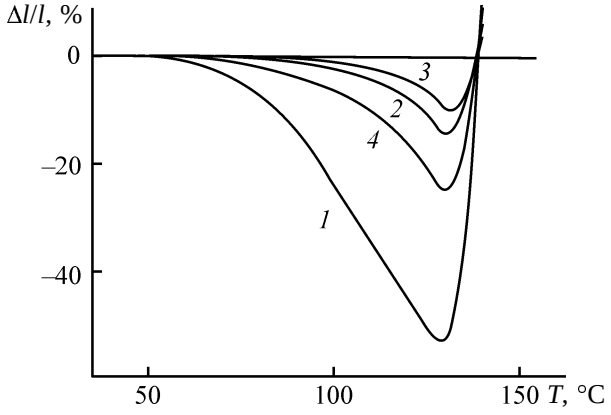

Fig. 3. Relative elongation $\Delta l/l$ of the (*1*) porous films, PE/PANI(*in situ*) systems polymerized at (*2*) 20 and (*3*) 5°C, and (*4*) PE/PANI(disp.) composites under a tensile load of 0.2 MPa as a function of temperature *T*.

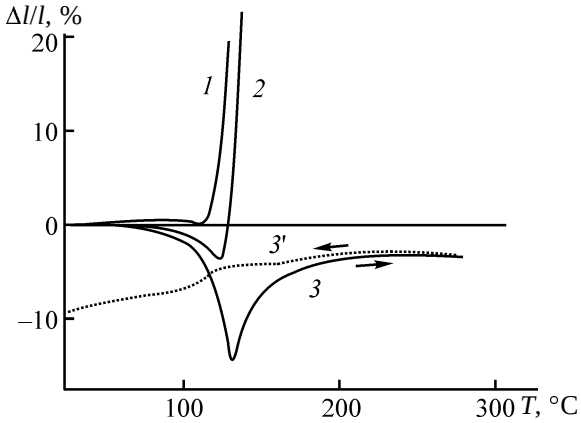

Fig. 4. Relative elongation $\Delta l/l$ of the PE/PANI(*in situ*) systems polymerized at 5°C under a load of (*1*) 1.0, (*2*) 0.5, and (*3*, *3*') 0.05 MPa as a function of temperature *T*.

The thermomechanical curves of PE/PANI(*in situ*) composites recorded under various tensile loads are shown in Fig. 4. Under medium loads (in the experimental range studied) of 0.1–1.0 MPa, shrinkage of the PE/PANI(*in situ*) sample up to the break is observed upon heating to T_m^{PE} (Fig. 4, curve *2*). It should be noted that the shrinkage decreases with increasing tensile load, and no shrinkage of the sample and even small elongation was observed under a tensile load of 1 MPa (Fig. 4, curve *1*). The behavior of the composite upon heating under a tensile load of 0.05 MPa (Fig. 4, curve *3*'), and less was quite different: the samples stand the load and do not change their size in a wide temperature range above T_m^{PE}. The plateau in the thermomechanical curves in the 180–300°C range confirms this. Preservation of the sample integrity

Table 3. Thermal characteristics of the porous PE supports and the PE/PANI composites

Sample	T_m^{PE}, °C	ΔH, J g^{-1}
Porous PE support	132	180
PE/PANI(*in situ*), T_p, °C:		
20	133	166
5	134	158
PE/PANI(disp.)	132	180

in this temperature range (where PE is already molten) is due to the fact that the load acts on the three-dimensional skeleton of the rigid-chain PANI polymer spreading, according to the electron microscopic data, through the bulk of the PE support. The section of thermomechanical stability is observed only for PE/PANI(*in situ*) composites polymerized at 5 and 20°C, and no effect was observed for PE/PANI(disp.) systems.

The data on mechanical relaxation [17] showed that, when PANI is heated to 200°C, the mobility of the polymer chains decreases, which, in the authors' opinion, is due to the formation of weakly cross-linked structures. With PE samples [18], no thermal effects except melting at ~130°C were observed in the TGA curves recorded upon heating to 300°C in a vacuum. Hence, the mechanical stability of the PE/PANI(*in situ*) composites in the 180–300°C range is due to the cross-linking of PANI. Irreversible changes in the PANI layer structure are confirmed by the curve of the sample cooling (Fig. 4, curve *3*'). The run of this curve is essentially different from that registered upon heating, and its shape is typical for cross-linked systems. At repeating of the heating–cooling cycles, the shape of curve *3*' (Fig. 4) remains unchanged. This fact indicates that the irreversible changes caused by cross-linking of the PANI polymer occur at first heating of the system.

Structural transformations of the porous supports coated with PANI layers upon heating. Since the PE/PANI(*in situ*) composites do not melt and preserve their integrity upon heating to the temperatures above T_m^{PE}, their structural transformations were studied by DSC.

Our experimental results showed (Table 3) that the heat of PE melting ΔH in the PE/PANI(*in situ*) composites is lower than that of the PE support (these values were calculated taking into account the weight fraction of PE in the composite). Moreover, after formation of the PANI layer, the melting peak shifts toward higher temperatures by 1–2°C. Since the PE film is oriented, we suggest that heating of the PE/PANI(*in situ*) composites does not cause formation of an isotropic melt and certain orientation of the polymer is preserved owing to fixation of the PE chains by the rigid PANI skeleton. Specifically these structural features in the course of melting hinder passing of the PE chains into the equilibrium state, decreasing the heat and increasing the temperature of PE melting in the PE/PANI(*in situ*) composites. Our assumption is confirmed by the data of wide-angle X-ray scattering [16], which showed that the PE/PANI(*in situ*) samples exhibit the oriented structure after their heating to the temperatures higher than T_m^{PE} by several tens of degrees and subsequent cooling to room temperature.

As seen from Table 3, these effects (decrease in the heat of melting and increase in the melting point) are more pronounced for the systems polymerized at 5°C than for those prepared at 20°C, i.e., the PE chains are more strongly fixed in the PANI skeleton in the course of the low-temperature process.

It should be noted that the heat and temperature of melting of PE in the PE/PANI(disp.) systems correspond to those determined for the uncoated porous PE films. This fact confirms that no PANI skeleton is formed in this case, and the PANI layer prepared from a dispersion does not affect the characteristics of PE melting.

CONCLUSIONS

(1) Polymerization *in situ* of the polyethylene–polyaniline systems yields a continuous three-dimensional phase of the conducting polymer both on the surface and in the bulk of the porous support, providing surface and through conductivity of the composites.

(2) The resulting polymers combine the electrical properties of the conducting polymer and high mechanical properties of the porous support.

(3) Formation of the rigid polyaniline skeleton strongly increases the thermal-deformation stability of the polyethylene/polyaniline systems prepared by polymerization *in situ* as compared to the porous support.

Abstract—Specific features of initiated oxidation of polyisoprene and polyisoprene–polybutadiene blends in chlorobenzene solution were studied in relation to the supramolecular state of the polymer in solution.

Available data [1–5] show that the mechanisms of oxidation of low- and high-molecular-weight compounds have much in common. Nevertheless, there are certain differences associated primarily with the structural features of the polymers and their state in solution. Polymer solutions are nonuniform, and conditions of diffusion of oxygen molecules into a macromolecular globule are different, which gives rise to supramolecular effect in oxidation of polymers and polymer blends in solution.

EXPERIMENTAL

Polyisoprene (PI) and polybutadiene (PB) were purified by double reprecipitation with ethanol from solution in chlorobenzene (CB). Chlorobenzene was purified as described in [2]. The initiator, dicyclohexyl peroxydicarbonate (DCPDC), was recrystallized from toluene. The polymer solution was prepared at 40°C for 4 h with inert gas bubbling. Solutions of polymer blends were prepared by mixing the solutions of the individual polymers of equal concentration in the required proportion. The initiator was added just before the kinetic experiment. The initiation rate constant k_i for dicyclohexyl peroxydicarbonate was taken from [6].

The rate of initiated oxidation of the polymers was determined in a manometric unit from the oxygen uptake. The solution in the reaction vessel was stirred at 60°C with a magnetic stirrer (200 rpm). No apparent oxidation of CB at 60°C was observed (no oxygen uptake), which allows us to neglect the solvent oxidation in the experiments on initiated oxidation of PI and PI–PB blends in solution.

The kinetic curve of oxygen uptake with PI in CB is linear and is independent of the liquid phase volume and of the stirring rate, which indicates that the oxidation is kinetically controlled.

Viscometric studies of solutions of the polymers and their blends were performed with an Ubbelohde viscometer by the standard procedure [6].

The dependence of the PI oxidation rate on the PI content in solution is plotted in Fig. 1a. As seen, with increasing content of the polymer the oxidation rate grows nonlinearly. A similar pattern was observed previously in [2] for initiated oxidation of PE and PP and in [7] for oxidation of PB in CB.

By plotting the experimental data in the ln–ln coordinates, we determined the reaction order with respect to the polymer, $n = 0.32$. The order with respect to the polymer of the previously studied liquid-phase oxidation of PB in CB was 0.35.

The observed trends can be explained taking into account the structural changes occurring in the polymer solution. Viscometric studies of solutions of PI in CB, performed at the same temperature as that of the oxidation runs, show that the transition (crossover) from a dilute solution containing discrete macromolecular globules which do not interact with each other to a semidilute solution occurs for PI at a concentration $c^* = 1$ g dl^{-1} (Fig. 1b). Thus, as for the previously studied PB, in a dilute polymer solution, when the sequence of oxidation events occurs within one globule, the oxidation rate appreciably grows with an increase in the total polymer content in the solution (Fig. 1a, portion *1*).

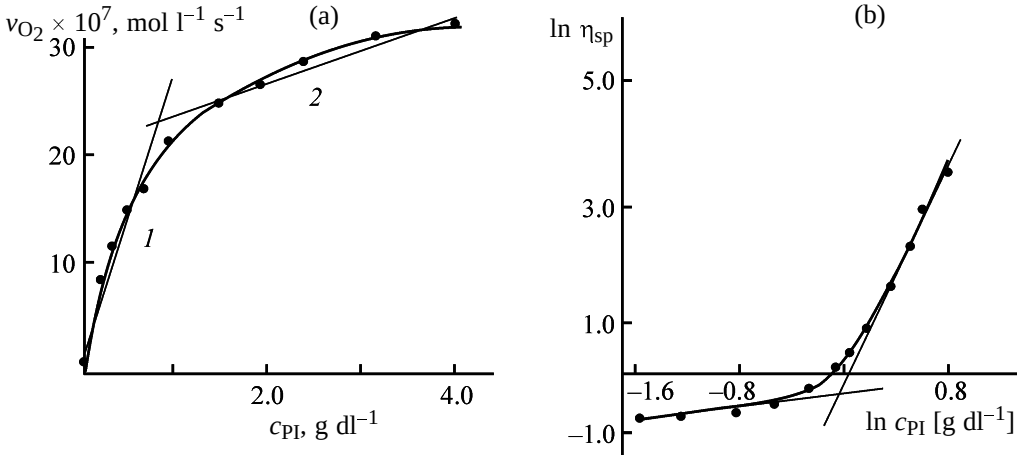

Fig. 1. (a) Oxidation rate v_{O_2} and (b) specific viscosity η_{sp} as functions of the PI concentration in chlorobenzene c_{PI}.

On passing beyond the crossover range, areas with local densification of units arise, hindering the diffusion of oxygen into the system. As a result, the influence of the solution concentration on the rate of PI oxidation becomes substantially weaker (Fig. 1a, portion *2*).

The dependence of the rate of PI oxidation in CB solution on the initiator concentration, as in the case of PB solutions, is indicative of the linear termination (Fig. 2) occurring, apparently, on the solvent molecules.

Thus, the transition from a dilute to a semidilute solution, accompanied by the development of reversible aggregation of macromolecules at PI concentrations $c > c^*$, is manifested as a change in the slope of the dependence of the PI oxidation rate on the PI concentration in CB solution.

In solutions of polymer blends, different kinds of supramolecular structures can form, depending on what contacts are preferable: polymer 1–polymer 1 and polymer 2–polymer 2 (homoaggregates), or polymer 1–polymer 2 (heteroaggregates). The type of the aggregates, if they form, will be one of the decisive factors (along with the general characteristics of the conformational and supramolecular state of the polymers in solution) affecting the physicochemical properties of the system.

There are indications in the literature that the kind of the forming aggregates can be judged from the deviations of the viscosity of a polymer blend solution from the additive values [8]. As a rule, positive deviations suggest formation of heteroaggregates, and negative deviations, formation of homoaggregates. Figure 3a shows that only dilute solutions of PI–PB blends show no deviations of the relative viscosity from the additive values.

In going to semidilute solutions (beyond the crossover point), the relative viscosities of the polymer blends become lower than the additive values. These facts suggest that, whereas in dilute solutions PI and PB, showing a low thermodynamic affinity, do not noticeably interact with each other, in semidilute solutions PB and PI form homoaggregates.

This change in the supramolecular structure of the polymer blend is manifested in the dependence of the rate of initiated oxidation of the blend. Figure 3b shows that only in a dilute solution the oxidation rate is an additive function of the relative content of the polymers. In going to semidilute solutions containing interacting, aggregated polymer globules, the oxidation rate becomes a nonadditive function of the blend composition. The higher the concentration of the polymers, i.e., the stronger the tendenct to form homo-

aggregates, the larger the deviations of the oxidation rate from the additive values. The fact that the rate of the initiated oxidation of a polymer blend in the region of aggregated solutions is appreciably lower compared to the solutions of the individual polymers is apparently due to increased density of packing of the macromolecular segments in the homoaggregates forming in the blend. This, in turn, causes significantly hinders the duffusion of oxygen to macromolecular units.

Thus, our results show that the rate of oxidation of polymers and polymer blends in solution is largely determined by the supramolecular structure of the solution.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Polyelectrolyte Complexes of Fibroin with Chitosan

E. S. Sashina and N. P. Novoselov

St. Petersburg State University of Technology and Design, St. Petersburg, Russia

Received September 23, 2004

Abstract—Fibroin–chitosan polyelectrolyte complexes are studied by X-ray diffraction, IR spectroscopy, and scanning calorimetry. Mechanical characteristics and the swellability of the blend films at various pHs are examined.

The polysaccharide chitosan is a chitin deacetylation product exhibiting fungicidal and bactericidal activities [1]. Blends of chitosan with uncharged polymers such as polyvinyl alcohol and polyesters, and also polyelectrolyte complexes with carboxymethyl cellulose, alginate, carboxymethyl chitin, and other polyelectrolytes were studied [2–7]. In these complexes, chitosan behaves as a weak polymeric base (pK_a 6.3 [6]).

At present, polymer blends of chitosan with fibroin are being studied. Fibroin is a weak polymeric acid (isoelectric point at pH 4.0–5.0) [8]. When mixing dialyzed aqueous salt solutions of fibroin with chitosan solutions in dilute acids [9, 10], pH-sensitive polymeric complexes are formed, which can be used in the form of films or gels as separating membranes, microcapsules, medicinal implants, and catalysts.

In this work we studied synthesis and properties of chitosan–fibroin blend films prepared from hexafluoro-2-propanol solutions.

EXPERIMENTAL

In the work we used *Bombyx mori* silk fibroin pretreated to remove sericin and fatty, waxy, and mineral compounds, and cut into short fibers 3.6 mm long and 34.6 μm in diameter. The fibers were dissolved in aqueous 6 M LiBr at 60°C and dialyzed across a semipermeable membrane. The dialyzed fibroin solution was dried at room temperature to obtain a film and then allowed to stand in a vacuum at 40°C for 4–6 h.

Chitosan was purchased from Dalwoo-Chitosan Co. Ltd. (Korea) (degree of deacetylation 95%; moisture content 7.5%; viscosity at 25°C of 2% solution in 2% acetic acid 30.8 mP).

As a solvent we used 1,1,1,3,3,3-hexafluoro-2-propanol (HFP) from Merck (main product content 99%; bp 58°C; ρ_4^{20} 1.615–1.618 g cm^{-3}).

The polymers were dissolved in HFP at room temperature to obtain a clear solution of the desired concentration. The resulting solution was then vacuum-filtered (Buchner funnel) through a glass filter no. 1. Equimolar polymer solutions were mixed for 1 h with continuous stirring to obtain the desired polymer weight ratio. As a result, stable clear solutions were formed.

Films were prepared by pouring the solutions onto a foil, which was followed by removing the solvent. The resulting films were 0.4–0.6 μm thick. Some of the films were treated with methanol for 30 min and then air-dried. Mechanical characteristics of the films were determined using an Instron tensile-testing machine in accordance with DIN EN ISO 527-3 standard. Swelling of the films in distilled water and buffer solutions at pH 2.0 and 4.0 was studied gravimetrically. The films were kept in solution at room temperature for 30 min (this time was demonstrated to be sufficient to reach the maximal swelling). The degree of swelling Δw (%) was estimated as

$$\Delta w = (w_1 - w_0)/w_0 \times 100,$$

where w_0 and w_1 are the weights of the film before and after swelling (g).

The density of the films was measured on an AccuPyc 1330 V2.01 He pycnometer (the United States). The film morphology was examined in a polarized light using an Olympus U-SMAD-2 BX-50 JVC microscope (magnification ×200). The infrared spectra of the films were recorded on an IFS25 spectrometer (Bruker). Thermal analysis was carried out on a

Mettler Toledo Star scanning calorimeter with heating from 25 to 350°C at a rate of 10 deg min^{-1} under nitrogen (N_2 flow rate 50 ml min^{-1}). X-ray diffraction patterns were obtained on a Bruker D8 Advance diffractometer.

Scanning calorimetry is widely used for studying interpolymer interactions in blends. For incompatible polymers, two glass transition points, characteristic of individual components, are observed in blends, whereas blends formed by compatible polymers are characterized by single glass transition point (T_{gt}), depending on the component ratio. This point can be estimated by the Fox equation [11]:

$$1/T_{gt} = w_1/T_{gt1} + w_2/T_{gt2},$$

where T_{gt}, T_{gt1}, and T_{gt2} are the glass transition points of the blend, polymer 1, and polymer 2, respectively; and w_1 and w_2, weight fractions of the components in the blend.

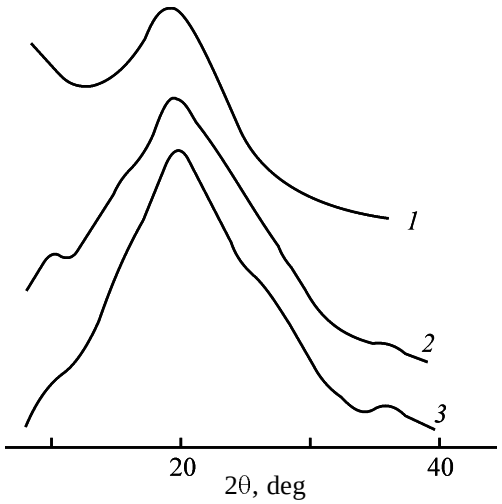

Fig. 1. X-ray diffraction patterns of the films: (*1*) fibroin, (*2*) 1 : 1 blend, and (*3*) chitosan. (2θ) Bragg angle.

The results of thermal analysis of fibroin, chitosan, and their blends are given in Table 1. The DSC curve of straight fibroin shows an endothermic peak near 78°C (T_{1f}), which is associated with removal of adsorbed water. The endothermic effect near 152°C (T_{2f}) is caused by glass transition of amorphous fibroin, which is followed by a weak exothermic effect due to transition of the amorphous phase into β-folded crystalline structure [12]. The endothermic peak at 246°C reflects molecular motion in α-crystals of the polymer, which is observed only for straight fibroin and for the blend containing 80% fibroin. Finally, the endothermic peak at 280°C ($T_{f.deg}$) is caused by thermal degradation of the disordered β-structure.

The DSC curve of chitosan shows endothermic peaks associated with removal of adsorbed water (T_{1ch} = 101°C), devitrification (T_{2ch} = 165°C), and onset of thermal degradation at 262°C ($T_{ch.deg}$).

The blend films demonstrate common thermal effects T_1, T_2, and T_{deg}, suggesting compatibility of the components. The deviation of the experimental glass transition points T_{gt} from those estimated by the Fox equation was within 15%. On passing to the blends with a chitosan content of 20 to 40%, T_{gt} and glass transition enthalpy decrease, which can attributed to decreased size of amorphous domains between the crystallites as a result of formation of a more homo-

geneous structure at the indicated component ratio.

The formation of a more homogeneous and, presumably, more ordered structure is demonstrated by X-ray diffraction patterns of the films obtained from chitosan, fibroin, and 1 : 1 mixed solutions (Fig. 1). The interplanar spacings in the crystal lattices of the polymers are given in Table 2. The X-ray diffraction pattern of 100% fibroin shows only a halo at 2θ 20.4°. The film of 100% chitosan shows a typical pattern with weak peaks at 2θ 19.5° and 10°. For the blend film, we observed an increased peak at 2θ 10° and a very weak peak at 2θ 15.6°, suggesting formation of a modification of chitosan with more closely packed straightened chains.

The pH dependence of the swellability of the fibroin, chitosan, and blend films is given in Table 3. The measurements were carried out with the untreated films and those modified by treatment with methanol. As seen, the swellability increases in parallel to the chitosan content in the films, depending on pH: the maximal swellability was observed at pH 2.0; at a chitosan content above 40 wt % and pH 2.0, the films become soluble. The increase in the swellability is caused by protonation of the amino groups of chitosan in acidic solutions, resulting in weakened intermolecular interaction. The swellability of straight fibroin depends on pH insignificantly. It slightly decreases at pH 4.0, i.e., near the isoelectric point. The minimal swellability in the system was observed at a chitosan content of 30 wt %. At this component ratio, one may suggest the strongest intermolecular interaction causing formation of a more homogeneous structure.

Modification of the films with methanol decreases the swellability by a factor of about three at all the experimental pHs, which is probably due to formation of the β-folded crystalline structure of fibroin [13] and hydrogen bonding between chitosan and fibroin. Analysis of the published data [14–16] shows that the α- and β-conformations can be easily distinguished by their characteristic absorptions in the IR spectra. The spectrum of fibroin shows characteristic Amide I (C=O), Amide II (bound N–H, C–N), Amide III (C–N, bound N–H, CH_3–C), Amide IV, and Amide V bands. On passing from the α-spiral to β-folded structure, the frequencies of the Amide I and II bands generally decrease by 10–30 cm^{-1}, and those of Amide III and V, on the contrary, increase. It is more difficult to distinguish α- and randomly globular conformations by IR spectra. Table 4 shows the Amide I and II absorption bands in the IR spectra of blend films before and after methanol treatment.

The observed shift of the Amide I and II bands of fibroin toward lower frequencies after methanol treat-

Table 5. Mechanical properties of fibroin–chitosan films

Chitosan content, wt %	Breaking stress, N mm^{-2}	Elongation at break, %	Density, g cm^{-3}
–	37.2	4.1	1.37
21	40.3	6.9	1.53
32	43.7	5.6	1.55
53	39.7	7.7	1.39
100	41.0	7.5	1.42

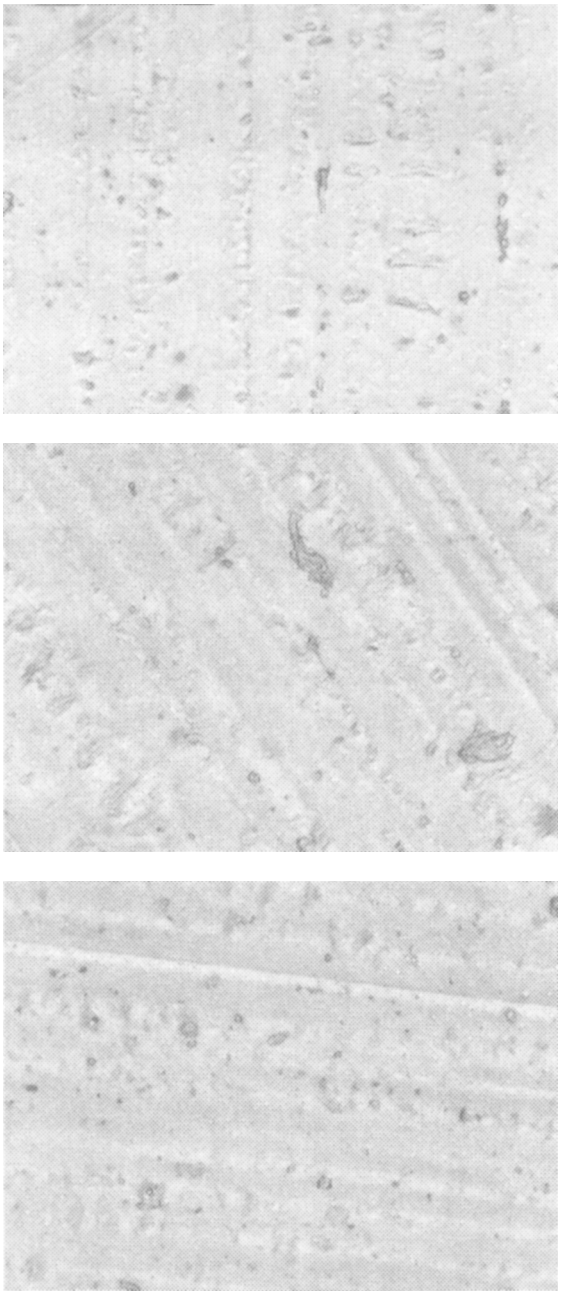

Fig. 2. Photomicrographs of films: (a) fibroin, (b) 1 : 1 blend, and (c) chitosan.

ment confirms the transformation into the β-folded structure.

The mechanical characteristics of the fibroin–chitosan films at various component ratios are given in Table 5. The increase in the density and strength of the films at a chitosan content of about 30 wt % supports the hypothesis stated earlier that this composition is characterized by the strongest intermolecular interaction.

Figure 2 shows the photomicrographs of fibroin, chitosan, and 1 : 1 fibroin–chitosan blend films. As seen, the blend film is quite homogeneous with no coarse particles dispersed throughout the bulk and no noticeable phase separation.

CONCLUSIONS

(1) Fibroin–chitosan blends exhibit common glass transition point, suggesting compatibility of these polymers. Interpolymer interaction initiates formation of more ordered structures, which is the most pronounced at a chitosan content of 20–40 wt %.

(2) Methanol treatment of the films initiates formation of the β-folded conformation of fibroin and interpolymer H-bonding, which is reflected in reduced swellability.

ACKNOWLEDGMENTS

The authors are grateful to Dr. R.-U. Bauer, Director of the Thuringian Institute of Textile and Plastics, for affording an opportunity to carry out experimental studies.

Received December 27, 2004

Abstract—Particle-size distribution of wood resin, sulfate lignin, and their mixtures in aqueous alkaline solutions (pH 12.7) at 293–333 K was described in the framework of the thermodynamic model. The increase in the average particle size and the broadening of the distribution are caused by an increase in the energy of thermodynamic fluctuations.

To develop a theory of sulfate delignification of wood and to solve applied urgent problems of pulp and paper industry, we studied previously colloidal chemical properties of aqueous alkaline solutions of sulfate lignin, wood resin, and their mixtures [1–3]. We found that the systems are heterogeneous, containing mainly nanoparticles, and tend to aggregate with changing temperature. We also proved formation of coagulation compounds in solutions containing sulfate lignin and wood resin [3]. These compounds are unstable not only at temperature changes but also in the presence of electrolytes [4].

Here we continue our study of particle-size distribution of wood resin, sulfate lignin, and their mixture in colloidal aqueous alkaline solution. The aim of this study is to describe statistically the particle-size distribution of these substances and their mixtures in strongly alkaline solutions (pH 12.7) at 293–333 K.

EXPERIMENTAL

Solutions of sulfate lignin and wood resin were prepared as follows. Sulfate lignin and wood resin were extracted from birch chips with dioxane and diethyl ether, respectively. The extracts were dried to constant weight and treated by the conventional procedure of sulfate cooking. Sulfate lignin was recovered from the solution with sulfuric acid and the resin was extracted with dichloroethane. The samples were dried again to constant weight by evacuation at 323 K and dissolved in aqueous solutions of sodium hydroxide (pH 12.7) at 363 K. The concentration of birch resin and sulfate lignin was 0.27 and 2.5 wt %, respectively.

The particle-size distribution of the dispersions at 293, 313, and 333 K was studied by dynamic light scattering. The measurements were performed on a Coulter Nr. 4 correlator of dynamic light scattering (Coultronic, France). Operation of the device and calculation of the size of diffusing particles were described in our previous papers [1–3]. Based on the results obtained, the particle-size distribution curves (Fig. 1) were constructed. The distribution was simulated using the reversible aggregation model [5–7].

The model of reversible aggregation suggests formation of steady-state microstructures by aggregation of identical particles into metastable clusters (aggregates). In the liquid state, these aggregates are closely packed and are characterized by definite lifetime, i.e., aggregates form and decompose with time (reversibility conditions). Thus, the composition of aggregate ensembles fluctuates steadily. In instantaneously frozen liquid, we will have only one of numerous thermodynamically equivalent configurations. In the framework of this model, using the thermodynamic principles, we suggested to describe the relative distribution of aggregates $n(y)$ by the following equation [5–7]:

$$h(y) = ay^q \exp(-y\Delta u_0/kT), \quad (1)$$

where a is the normalization factor; q, dimension of space where particles aggregate; $y\Delta u^0$, aggregation energy defined as the product of the aggregate size and the standard aggregation energy Δu^0; k, Boltzmann constant; and T, absolute temperature. Equation (1) is the canonical Gibbs distribution [8] modified on the assumption that the aggregation energy depends on the aggregate size. This equation is known as the Γ-distribution [8]. As seen from Eq. (1), ag-

gregation is initiated by thermal fluctuations with energy kT.

Previously the model of reversible aggregation was successfully used to describe statistical ensembles of colloidal particles of carbon black and their clusters in compounded rubber [6], ordered liquid crystal phase in the course of transition of isotropic liquid to the nematic phase [9–11], and microdomains of glassy polymers in chemical reactions [12–15].

The particle-size distribution of wood resin particles at 293 K is shown in Fig. 1a as a dotted curve. As seen from Fig. 1a, the particles form a statistical ensemble described by Eq. (1) (continuous line) at $q = 3$ (three-dimensional space). The other parameters (a, Δu_0) of the distribution are presented in the table. The experimental particle-size distributions of wood resin at 313 and 333 K were treated similarly. The distribution parameters at the indicated temperatures are given in the table. As seen from the table, the particle-size distributions at different temperatures are described by Eq. (1) at constant standard aggregation energy.

As follows from Eq. (1), the most probable (average) particle size in the statistical ensemble can be expressed as the normalized population mean of the distribution My

$$My = \frac{\int_0^\infty yh(y)\mathrm{d}y}{\int_0^\infty h(y)\mathrm{d}y} = \frac{(q+1)kT}{\Delta u_0} = 4kT/\Delta u_0, \quad (2)$$

and the distribution width (rms deviation from the average) can be expressed as $(Dy)^{1/2}$, where Dy is the normalized variance:

$$(Dy)^{1/2} = [M(y^2) - (My)^2]^{1/2} = [(q+1)^{1/2}kT]/\Delta u_0 = 2kT/\Delta u_0. \quad (3)$$

According to Eqs. (2) and (3), My and $(Dy)^{1/2}$ are inversely proportional to $\Delta u_0/kT$. If Δu^0 is constant, the increase in the average particle size of the resin and the broadening of the distribution with increasing temperature (see table) will be due to an increase in the energy of thermal fluctuations (parameter kT) governing formation of a statistical ensemble.

The particle-size distribution of sulfate lignin at 293 K is shown in Fig. 1b. In this case, the particles form two partially overlapped statistical ensembles. This distribution is described by Eq. (1) modified for the case of polynomial distribution [11, 14, 15].

$$h(y) = \sum_i^{i=N} a_i y_i^q \exp(-y_i \Delta u_{0i}/kT), \quad (4)$$

where $N = 2$ is the number of statistical ensembles. The average particle size in each ensemble is described by Eq. (5) derived from Eq. (2):

$$My_i = 4kT/\Delta u_0, \quad (5)$$

and the distribution width is described by Eq. (6) derived from Eq. (3):

$$(Dy_i)^{1/2} = 2kT/\Delta u_{0i}. \quad (6)$$

The distribution calculated by Eq. (4) is shown in

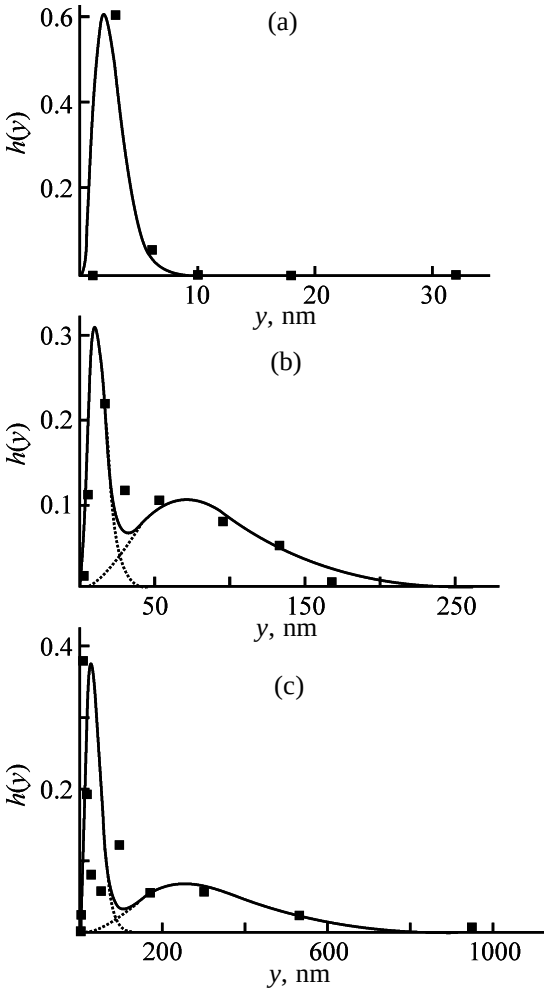

Fig. 1. Experimental particle-size (y) distribution $h(y)$ of (a) birch resin, (b) sulfate lignin, and (c) their mixture in aqueous alkaline solution (pH 12.7) at T = 293 K and the distribution simulated by Eqs. (1) and (4).

Fig. 1b as a continuous line; the distributions of separate ensembles are shown by the dotted lines. Both ensembles have the common starting point on the abscissa (y = 0). Hence, the second ensemble (with larger average particle size) is based on the statistical elements of the first ensemble (with smaller average particle size), i.e., these is a hierarchical system of two statistical ensembles of lignin particles.

The statistical parameters of the distribution, the distribution width, and the average particle size in the ensembles, calculated, respectively, form Eqs. (5) and (6) and simulating the experimental particle size distribution of lignin at 293, 313, and 333 K, are presented in the table. As in the case of the resin, the distribution of statistical ensembles of lignin particles is broadened and the average particle size in each ensemble increases with temperature owing to intensification of thermal fluctuations (see table). It should be noted that, at all temperatures, the average particle size of lignin in the first ensemble is larger by almost an order of magnitude than that of the resin particles. This indicates that the supramolecular structures (clusters) of the polymer (lignin) are larger than those of the oligomer (resin).

In the third part of this work we described the particle size distribution in a solution containing the resin and sulfate lignin in a 1 : 9 ratio. The experimental particle size distribution in this system (dotted line) and the results of its simulation by Eq. (4) are shown in Fig. 1c. As in the previous case, the particles of this mixture form two hierarchic statistical ensembles. The distribution parameters of these ensembles and their average particle size are presented in the table together with the results of statistical treatment of the experimental data for this mixture at 313 and 333 K.

As in the case of resin and lignin particles aggregated in ensembles, the statistical ensembles of particles of their mixtures are broadened and their average size increases with temperature (see table). It should be noted that, in the examined temperature range, the average particle size of ensembles formed in the mixture is substantially larger than the sum of the average sizes of resin and lignin particles. This is likely due to thermal coagulation of particles in the mixture, which increases with temperature.

CONCLUSIONS

(1) Particle size distribution of birch resin, sulfate lignin, and their mixtures (1 : 9) in aqueous alkaline solutions (pH 12.7) at 293, 313, and 333 K was studied by dynamic light scattering.

(2) Resin particles form a single statistical ensemble, and particles of lignin and its mixture with the resin form two statistical ensembles which can be described in the framework of the model of reversible aggregation.

(3) The fact that the distribution is broadened and the average particle size increases with temperature is caused by an increase in the energy of thermal fluctuation governing formation of statistical ensembles.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Corona-Poled Electrets Based on Vinyl Chloride/Vinyl Acetate Copolymer–Zinc White Composites

M. F. Galikhanov and R. Ya. Deberdeev

Kazan State Technological University, Kazan, Tatarstan, Russia

Received April 28, 2004; in final form, December 2004

Abstract—Electret properties of vinyl chloride/vinyl acetate copolymer and its composites with zinc oxide are studied.

Diverse engineering applications of electrets (electrical analogs of permanent magnets) [1–4] stimulate searching for novel electret materials and developing electrets with stable characteristics. In this respect, the most promising are composite materials consisting of two or more chemically dissimilar materials with an interface between them, which are capable of Maxwell–Wagner polarization. However, the trends in electrical polarization of plastics are not thoroughly understood even for some comparatively simple binary systems. In this connection, it is of interest to study the features of electrical polarization in filled polymers.

It is a standard technique of electret charging to inject charge carriers generated in a corona discharge. Among the advantages of this method are technical simplicity and fairly high process rate. The mechanism of such a polarization involves injection of charge carriers (electrons, ions) into a polymeric dielectric and their trapping by impurities and structural defects [1, 2]. Corona-discharge polarization is used for nonpolar polymers to obtain high-performance electrets.

On the contrary, electret charging in polar polymers proceeds through dipolar-group and dipolar-segmental polarization [4].

Previously we demonstrated with an example of ethylene/vinyl acetate copolymers that the stability of corona-poled electrets decreases with increasing polarity of the polymer [5], which is caused by migration of the charge carriers from the surface of a polymeric material and by relaxation. The degree of depolarization is controlled by the specific volume conductivity of the material γ_V, which is the lower, the higher the content of polar groups in the polymer. However, the initial surface charge density σ_{eff} in corona-poled electrets based on polar polymers is higher compared to nonpolar polymers. As the polarity of the copolymer increases, the starting σ_{eff} initially increases and then slightly decreases. In [5], our interpretation was that, when entering the surface layer of a polymer sample, the charge carriers polarize the nearest dipoles (polar groups), initiating orientation of the dipoles in the field of the injected charge. The oriented dipoles are traps for the injected charges, attracting and retaining them by Coulombic forces. The higher the content of polar (acetate) groups in a polymer, the higher the content of the traps and the initial surface charge density. Liberation of the charge carriers from the surface traps occurs more intensively than from the bulk traps, which is due to increased charge carrier concentration in the surface layer and, therefore, higher conductivity of the polymer [5]. This mechanism is supported by data of [6] that the major part of charge carriers injected to a polar polymer is localized in the surface layer, so that their concentration in the bulk is negligible.

Earlier we have patented a process for manufacturing a coating based on a corona-poled electret prepared from vinyl chloride/vinyl acetate copolymer (VCVAC), having stable high charge [7]. In this work we studied the electret effect in filled VCVAC.

EXPERIMENTAL

In the work we used A-15-0 random VCVAC (weight fraction of chlorine 52.5%) [TU (Technical Specifications) 6-01-1181–87] and ZnO with a particle size of 2–4 μm and specific surface area of 3–4 $m^2 g^{-1}$.

The polymer with mixed with the filler at 135 ± 5°C for 3 min using a laboratory roll mill. Samples in the form of 0.8–1.2-mm-thick plates were fabricated by

1070-4272/05/7803-0496© 2005 Pleiades Publishing, Inc.

pressing at 170 ± 5°C according to GOST (State Standard) 12 019–66. The samples were polarized by corona charging using an electrode with 196 pointed needles uniformly arranged on a 7 × 7-cm square. The distance between the sample and electrode was 20 mm; polarizing voltage, 35 kV; and polarization time, 90 s. The samples were preheated at 90°C for 10 min in an oven prior to polarization.

The surface potential of the electrets U_e was measured at 24-h intervals by the contactless induction method using a vibrating electrode according to GOST 25 209–82. The observation time was 1 year. The time elapsed since the onset of polarization to the first measurement was 1 h. The electrets were stored at room temperature in the nonshorted state. The effective surface charge density σ_{eff} was estimated [2] as

$$\sigma_{eff} = U_c \varepsilon \varepsilon_0 / \delta,$$

where U_c is the compensating voltage (V); ε, permittivity of the composite; ε_0, dielectric constant equal to 8.854×10^{-12} F m^{-1}; and δ, sample thickness (m).

The charge relaxation time τ was determined as the time in which the surface potential of the samples decreased by a factor of *e* (~2.71).

After 1-year storage, we recorded the thermally stimulated current (TSC) spectra of the samples at a heating rate of 5 deg min^{-1} using a specially designed cell equipped with blocking electrodes and Teflon spacer [3, 4].

The TSC data were then compared with the results of DTA analysis (Q-1500 D derivatograph; samples 150 ± 50 mg; heating rate 5 deg min^{-1}).

The dependence of the surface potential of the VCVAC corona-poled electret on the storage time is a curve with a minimum (Fig. 1, curve *1*). The initial decline of the surface potential is due to charge relaxation.

Evidently, the observed abrupt decline of the potential in the period from the 80th to 160th day is caused by shielding of the electret charge by the water molecules adsorbed from air on the surface. In the course of the experiment, the indicated period fell on the season of the maximal humidity. As the humidity decreased, a considerable fraction of water desorbed from the surface of the electret, and surface potential increased after 300 days of storage. The decrease in the charge with increasing humidity and its subsequent restoration is typical of the conventional electrets [8]. At the same time, the charge relaxation rate

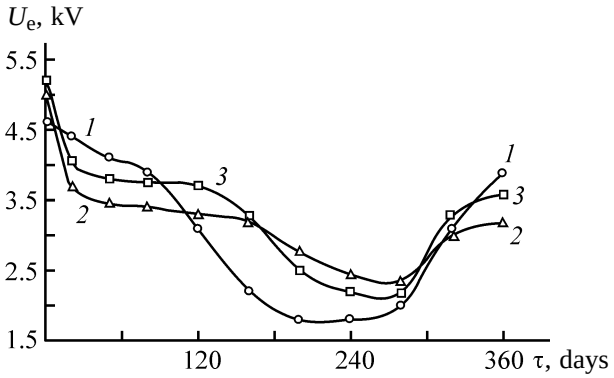

Fig. 1. Variation with storage time τ of the surface potential U_e of (*1*) VCVAC corona-poled electret and (*2, 3*) composites with ZnO. ZnO content (vol %): (*2*) 4 and (*3*) 8.

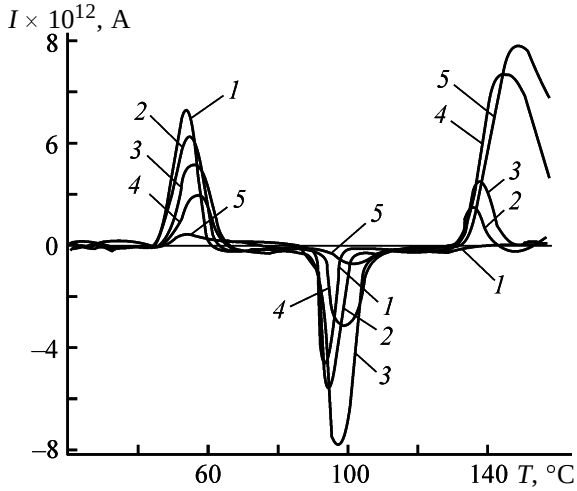

Fig. 2. Thermally stimulated depolarization current spectra of corona-poled electrets: (*1*) VCVAC and (*2–5*) VCVAC–ZnO composites. (*I*) Current and (*T*) temperature. ZnO content (vol %): (*2*) 2, (*3*) 4, (*4*) 6, and (*5*) 8.

at increased humidity increases, which can be attributed to an increase in the surface conductivity of the polymeric samples and preferential relaxation of the homocharge in the surface and near-surface layers of the electret [9, 10].

Analysis of the TSC spectra of the copolymer (Fig. 2, curve *1*) revealed two levels of trapping. The first-level traps are destroyed at 60–65°C, which corresponds to the glass transition point as determined by DTA. Presumably, at this temperature, the hindrances to rotation of dipolar groups are overcome, which results in the decay of the dipolar-group or dipolar-segmental polarization [3]. The activation energy of charge relaxation W_a corresponding to this peak was estimated by the Garlick–Gibson method [2] to be about 0.70 eV.

The presence of a negative current peak suggests that the second trapping level decays at 95–105°C,

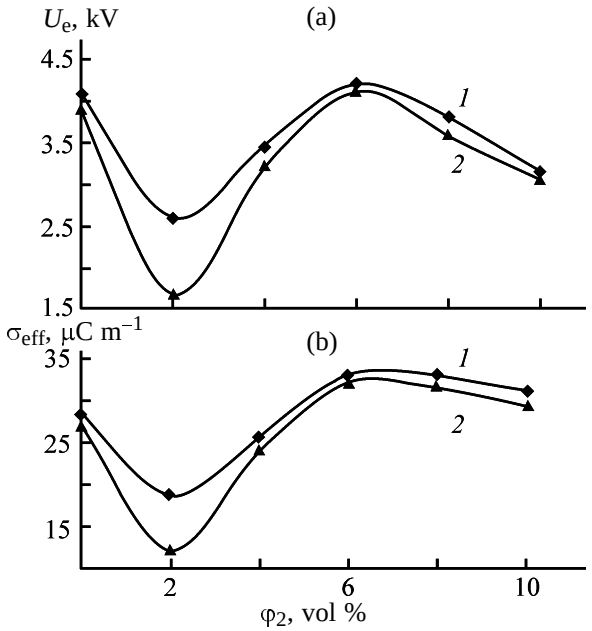

Fig. 3. (a) Surface potential U_e and (b) effective surface charge density σ_{eff} in ZnO-filled VCVAC as functions of the filler content φ after (*1*) 50 and (*2*) 350 days of storage.

which corresponds to the viscous-flow transition observed in the DTA curve. At these temperatures, the intermolecular physical and hydrogen bonds are broken, which results in liberation of the injected charge. The W_a of this process is about 1.30 eV, which suggests that the charge carriers are localized in deep wells, thus imparting stable high surface potential to the polymer.

The TSC data show that the observed stable high charge on the corona-poled VCVAC electrets is caused by the external and dipolar-group types of polarization, the polarization by virtue of the injected charge controlling the quantity of the charge, and the dipolar polarization, its stability. Preheating the polymer to 90°C prior to corona charging transfers it into the hyperelastic state, when the dipolar groups become capable to be oriented in the polarizing field, and on cooling, to be frozen with formation of a heterocharge.

In polarization of filled VCVAC in the corona discharge field, charge carriers are trapped at the interfaces. According to the Maxwell–Wagner effect, accumulation of charges on the interfaces is caused by different conductivities of the phases in heterogeneous samples. Let us analyze the mechanism of polarization in VCVAC–ZnO composites from this standpoint.

It was demonstrated in the previous studies of the effect of a conducting filler on the electret properties in polar polymers [4, 11–13] that increasing filler loading initially increases and then decreases the electret effect. Pinchuk *et al*. [14] observed only a decrease in TSC on adding 0.5 wt % of ultradisperse sialon-like particles in butyral resin.

Our experiments showed that filling with ZnO affects the electret properties of VCVAC: with increasing ZnO content in the copolymer, the surface potential (Fig. 3a) and effective surface charge density of the electrets (Fig. 3b) seccessively pass through a minimum and a maximum.

The initial decrease in the surface potential is probably due to perfection of the supramolecular VCVAC structure at low ZnO loading. Filling of polymers always alters the supramolecular structure, i.e., the size, shape, and size distribution of structural blocks, as well as the packing density of macromolecules. Being in low concentration, finely dispersed solid fillers may serve as nucleating agents [15]. Furthermore, fillers significantly affect the flexibility of kinetic units of macromolecules and their relaxation time.

The subsequent increase in U_e and σ_{eff} is probably due to changing type and depth of the energy traps for the injected charges with filling. In the presence of reactive fillers, carboxy, carbonyl, and other groups could be generated in the macromolecules, primarily at the polymer–filler interface. Furthermore, mechanochemical activation of the material in the course of composite preparation could generate free radicals [16], also capable to serve as energy traps for the charges.

Starting from the ZnO content of 6 vol %, the observed deterioration of the electret characteristics of the composites can be attributed to increase in their conductivity, which controls the decay rate of the electret surface potential.

To check these hypotheses for consistency, we analyzed the TSC spectra of the filled composites. The spectra show changes in the intensity and position of the TSC peaks relative to those typical of straight VCVAC and also the appearance of a new high-temperature peak at 130–150°C. At small ZnO content (2 vol %) we observed a decrease in W_a of the energy traps to 0.65 and 0.7 eV for the first and second types of the traps, respectively, which is caused by decreasing flexibility of the macromolecules in the presence of the filler and, as a result, by hindered rotation of the dipolar groups (Fig. 2, curve *2*). Presumably, this is due to adsorption of the copolymer macromolecules on the filler particles with formation of interfacial layers characterized by decreased flexibility of structural units of the copolymer. Furthermore, the presence of the filler intensifies mechanical degradation of the copolymer in the course of composite preparation,

which could decrease the amount of groups capable of serving as traps for the injected charges and, at the same time, intensifies trapping of the injected charges in the traps formed in the course of mechanically activated degradation.

The formation of new types of traps at the copolymer–filler interface, associated with manifestation of the Maxwell–Wagner effect, increases the fraction of charge carriers in high-energy traps, as demonstrated by the occurrence of a new level of trapping of the injected charge carriers, whose decay is observed at 130–150°C (Fig. 2). The activation energy of charge relaxation from traps of this type increases, depending on the ZnO content, from about 0.55 (2 vol % ZnO) to 1.90 eV (10 vol % ZnO), thus improving the electret characteristics of the composites (Fig. 3).

The appearance of a new peak in the TSC spectra, caused by filling, is well known. For example, in polyamide–fiber glass composites, the appearance of a low-temperature thermally stimulated depolarization current peak was observed at about 55°C [17]. This peak was assigned to charging of defects on the fiber glass surface or at the polymer–filler interface.

Nevertheless, low W_a of traps in the initial VCVAC limits the polarization in highly loaded composites. Without question, this is favored also by increased conductivity of such composites.

CONCLUSIONS

(1) Vinyl chloride/vinyl acetate copolymer exhibits high initial surface charge density.

(2) Filling with zinc oxide imparts stability to the polarized state of the polymer, typical of the Maxwell–Wagner polarization.

Abstract—The major relationships in the Toms effect in direct crude oil emulsions differing in the dispersed phase concentration were studied on a modified turbulent rheometer with anionic copolymer of acrylamide as the polymer additive. The Toms effect was studied as influenced by the polymeric additive concentration and shear stress.

One of the most important and urgent problems currently faced by the oil extraction industry is development of efficient, scientifically sound power-saving technologies accelerating high-speed pipeline transportation of hydrocarbon raw materials [1, 2]. Unlike laboratory experiments, real processes yield a water-rich end product, which creates additional problems. In view of the fact that the water enrichment of the extracted crude oil tends to increase with increasing time of exploitation of wells [3], this necessitates a search for new methods of intensifying the transportation of hydrocarbon raw materials. This concerns not only dehydrated but also water-enriched oil-containing dispersed systems with a complex composition, above all, direct (oil-in-water) and reverse (water-in-oil) emulsions [4, 5].

In this situation, much promise is offered by polymeric additives (PAs) introduced into the dispersion medium in minor amounts in order to reduce the hydraulic resistance in turbulent streams of disperse systems (Toms effect). The Toms effect was most successfully applied to dehydrated oil [6, 7]. Good performance of PAs can be illustrated by the results of the tests on the 125-km long Tikhoretsk–Novorossiisk main crude oil pipeline with the internal diameter of the pipe of 0.8 m [8]. With nonpolar high-molecular-weight polyhexene in the concentration of 8 g cm^{-3} as additive, the oil transportation was considerably accelerated owing to a 20% decrease in the friction loss.

Good performance of polyolefin-based nonpolar polymeric additives as turbulence "quenchers" in oil streams was also confirmed by experiments on pumping dehydrated oil through the Aleksandrovskoe–Anzhero–Sudzhensk main pipeline (oil density 850 kg m^{-3}; kinematic viscosity 5×10^{-6} m^2 s^{-1}; Reynolds number Re = 3.5×10^5 at shear stress of 3 Pa) [9].

The promise of ionic and nonionic water-soluble (co)polymers for decreasing the hydrodynamic resistance in oil-containing disperse systems is understood to a much lesser extent. There are only fragmentary data confirming the suitability for this purpose of water-soluble polymer additives [10] whose essential properties need to be characterized more precisely [11]. At the same time, development of technologies of high-speed transportation of oil streams using water-soluble PAs is well justified: They showed the best performance in development and application of industrial technologies intensifying high-speed transportation of water streams [12, 13].

Here, we continue our previous studies [14] by quantitatively analyzing the Toms effect as influenced by the concentration of water-soluble PAs (anionic copolymers of acrylamide) and by the velocity of the turbulent streams of direct oil emulsions.

EXPERIMENTAL

Crude oil from Novosheshminsk site (Tatarstan) served as the main component of the dispersed phase of the emulsions. At 20°C, the oil had the kinematic viscosity $\nu = 210 \times 10^{-6}$ m^2 s^{-1} and density $\rho_4^{20} =$ 910 kg m^{-3}. The viscosity of oil was decreased by preliminary dilution with kerosene [Volgograd Refin-

1070-4272/05/7803-0500© 2005 Pleiades Publishing, Inc.

ery, Technical Specifications (TU) 3840158-10–90] to the 3 : 1 volume ratio. Diluted oil in all the experiments was characterized by $\nu = 23.5 \times 10^{-6}$ m^2 s^{-1} and density $\rho_4^{20} = 880$ kg m^{-3}. A water-soluble anionic surfactant, sodium alkylbenzenesulfonate (Sulfonol), served as stabilizer of direct emulsions. Direct emulsions with different compositions were prepared by the following procedure. The calculated amounts of distilled water, oil, and stabilizer (2% of the volume of dispersed phase, oil) were thoroughly stirred with a magnetic stirrer until formation of the primary emulsion. The resulting emulsion was additionally stabilized by ultrasonication with a UZDN-1 ultrasonic disperser (working frequency 22 kHz, total time of ultrasonication 15 min).

The size of the dispersed phase particles in the emulsions, as estimated by optical microscopy, did not exceed 1.5×10^{-6} m. This made the resulting emulsions fairly resistant to aggregation and sedimentation.

An anionic copolymer of acrylamide with sodium acrylate (Alcoflood 1175 A), available from Allied Colloids, the United Kingdom, with the molecular weight $M = 10.8 \times 10^6$ and 21.5% content of ionic units served as the polymeric additive.

The Toms effect was studied on a modified turbulent rheometer with a glass capillary (1.66×10^{-3} m in diameter and 0.6 m long). Figure 1 shows the schematic of the setup. The experiment consisted in the following. Thick-walled steel 350 cm^3 reservoir *1* was filled with 300 cm^3 of the liquid under study. Using gas cylinder *2* with valve *3* and reducer *4*, an excess pressure was created in receivers *5* and was monitored by manometer *6*. At the preset time, electric drive of valve *7* was switched on, which, in turn, opened valve *8*. The liquid flew via capillary *9* from reservoir *1* into receiver *10* under pressure. After 2 s, the valve closed automatically. The amount of the liquid that flew out of reservoir *16* was measured with an A&D (Japan) electronic balance *11*.

The Toms effect T was calculated by the relationship

$$T = (m - m_0)/m_0,$$

where m and m_0 are the masses of the consumed emulsion with and without PA additive, respectively [15, 16].

The reduced Toms effect T/c was calculated by the formula [16]

$$T/c = (m - m_0)/m_0 c,$$

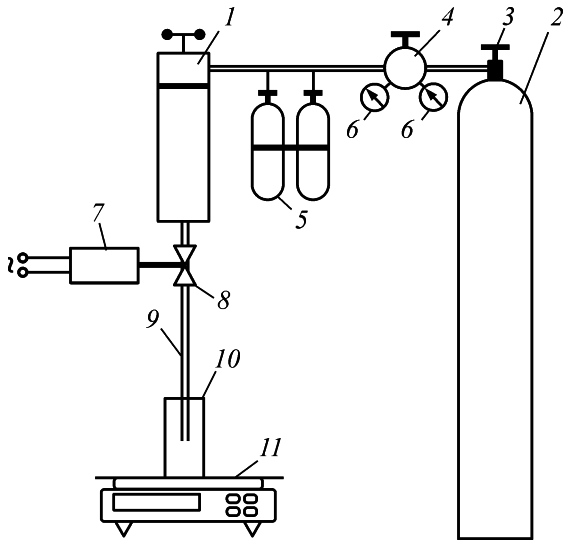

Fig. 1. Schematic of the setup for studying the Toms effect. For comments, see text.

where c is the PA concentration.

The polymer adsorption A was estimated from the difference in the concentrations of the copolymer before (c) and after (c_x) its contact with the dispersed phase particles, using the calibration plot of the specific viscosity vs. the concentration $\eta_{sp} = f(c)$. The copolymer concentration in the aqueous phase of the emulsion was determined viscometrically after the oil was separated on an OPN-8 centrifuge at 8000 rpm. To correctly measure the viscosity when plotting the calibration curve, we used as the aqueous medium the aqueous mother liquor yielded by centrifugation of the emulsion. The reason was that the aqueous phase of the emulsions contains a relatively large amount of the ionic stabilizer, anionic surfactant, able of markedly affecting the size of the macromolecules of anionic copolymer of acrylamide and, thus, the viscosity numbers n_{sp}/c of the copolymer solutions analyzed. With the aqueous mother liquor as the aqueous medium, in all the reference aqueous solutions of the copolymer the concentration of the surfactant not bound with the dispersed phase was identical to that in the oil emulsion analyzed. This precluded possible complications in the viscosity analysis due to the difference in the surfactant concentrations in the reference [used for plotting the $\eta_{sp} = f(c)$ calibration curve] solutions of copolymers and in the aqueous phase of the emulsion.

Viscometric studies were carried out in an Ubbelohde viscometer with the capillary diameter of 0.54×10^{-3} m.

The macroscopic Toms effect is determined by a

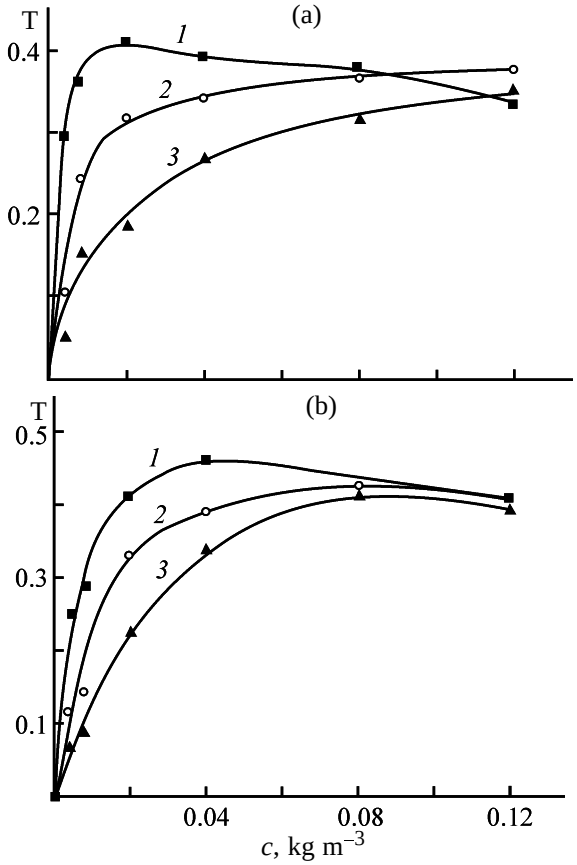

Fig. 2. Toms effect T as a function of the polymeric additive concentration *c* for (a) 15% direct oil emulsion and (b) water at the pressure *p* of (*1*) 5, (*2*) 10, and (*3*) 15 atm.

large number of active parameters of the system, governed primarily by the nature of the PA, polymeric medium, and hydrodynamic features of the turbulent stream of the liquid [12, 13]. Principal complications in quantitative analysis of the experimental data and, especially, in judging the detailed mechanism of this phenomenon arise in changing from true solutions to multicomponent heterophase systems exhibiting synergistic and antagonistic effects [15]. In this study, we examined how the Toms effect T in direct oil emulsions differing in the content of the dispersed phase (5, 10, 15, and 20 vol %) varies with the stream velocity and concentration of the water-soluble PA. Figure 2a illustrates the concentration dependence of T, as well as the interrelation between T and external pressure *p*, when the emulsion is pumped through the capillary (we will note that *p* is proportional to the shear stress τ), with the 15% oil emulsion as an example. For oil emulsions with other compositions, the T = $f(c)$ and T = $f(p)$ dependences were similar. Table 1 lists the main hydrodynamic characteristics of the direct oil emulsions in the presence of various amounts of PA.

It should be noted that, for the systems of interest, the Reynolds numbers Re significantly exceed the critical value of 2.3×10^3, which suggests the turbulent flow regime in the emulsions analyzed. Figure 2a and Table 1 show that, at high concentrations, T flattens out. This suggests that, with increasing PA concentrations, the contribution to the resulting Toms effect from the successively added portions of the polymer tends to decrease. This is clearly illustrated by a decrease in the parameter T/*c* with increasing polymer concentration (Table 1). The pattern is similar not only for direct oil emulsions but also for aqueous solutions of the copolymer (Fig. 2b). This can be due to the existence of a certain optimal concentration of the macromolecules c_{opt} in the stream zone occurring in the immediate vicinity of the internal surface of the capillary. Further increase in the copolymer concentration above 0.002–0.004 wt % is not accompanied by an increase in c_{opt} and only markedly increases the dynamic viscosity of the aqueous dispersion medium, which, naturally, decreases T and T/*c*. It is clear from Figs. 2a and 2b and Table 1 that T tends to decrease with increasing p within a wide range of the PA concentrations.

The influence of the external pressure on the capability of PA to decrease the hydraulic resistance of turbulent streams of direct oil emulsions can be understood most clearly from comparison of the dependences of T/*c* (for fixed *c* and *p*) on the composition of the emulsion (Fig. 3). There is no significant difference in the dependences of the parameters T and T/*c* on the external pressure *p* in purely aqueous media and in direct oil emulsions differing in the dispersed phase composition. Thus, the empirically established interrelation between T and *p* is not directly related to the heterophase nature of the system.

Another factor responsible for a decrease in T with increasing *p* may be mechanical degradation of the macromolecules of the copolymers in turbulent streams and direct oil emulsions. Mechanical degradation accompanied by rupture of the C–C bonds of the macromolecules decreases the average molecular weight *M* of the copolymer. This, naturally, decreases the effective size of the macromolecular globules. Under mechanical degradation, this should be accompanied by decreases in such macroscopic parameters as T and T/*c* [16] to the greater extent, the higher the pressure *p* in the turbulent rheometer. Special experiments showed that the viscosity numbers of the aqueous solutions of the copolymer before and after passing through the capillary of the rheometer at the

pressures of 5, 10, and 15 atm differed by no more than 3%.

Thus, under the actual conditions, mechanical degradation of the macromolecules in the turbulent stream cannot be primarily responsible for a decrease in T with increasing p.

The experimental $T = f(p)$ dependence can with a good reason be accounted for by the specific features of the mass transfer and of the conformation of the macromolecules in turbulent streams, especially in view of the fact that these features are common for aqueous solutions and oil emulsions. A specific feature of the mass transfer in turbulent streams is formation in close proximity of the capillary walls of a special parietal zone of stream (extending by no more than several tens of micrometers). In this zone, the concentration of the PA macromolecules (as well as of the dispersed phase particles) can markedly differ from the concentration in the bulk [12, 15]. Certainly, the rheology of the turbulent streams of direct oil emulsions is also strongly affected by the conformation of the macromolecules. This is manifested, above all, in a significant difference in the size and shape of the macromolecular globules in the laminar and turbulent streams, especially in view of the velocity gradient in the transverse and longitudinal directions in turbulent streams [17, 18]. Under the experimental conditions, another factor affecting the conformation

of the macromolecules of the copolymer is a fairly high thermodynamic and kinetic flexibility of the units in the macromolecules of the acrylamide copolymers [19].

Common knowledge suggests that the hydrodynamic characteristics of the oil emulsions are also markedly affected by the specific features of the structure of the dispersed phase particles (Fig. 4). This is primarily due to the specific aggregation state (liquid) of these particles, as well as to the occurrence in their structure of complex structural units (CSUs) (Fig. 4), comprised of a solid core and an adsorption–solvation layer [14].

The aggregate of the dispersed phase particles is surrounded by an electrical double layer (EDL) consisting of adsorption layer *II* of the potential-determining ions (anions of the stabilizer) and adsorption *III* and diffusion *IV* layer of counterions (primarily Na^+ cations). Because of the transverse-longitudinal velocity gradients in the turbulent streams, the changes in the oil emulsions are observed not only in the diffusion part *IV* of the EDL. Complex deformation of the aggregate *I* is due to transition from a sphere to, e.g., an ellipse, disk, or cylinder. Evidently, the change in the shape of the aggregate is accompanied by relaxation changes in structural elements *II* and *III*. These changes are accompanied by charge density redistribution on the surface of the dispersed phase particles, which affects, in particular, the electrokinetic potential. Such rearrangement of the structural elements of the dispersed phase particles is accompanied by a change in the balance of the potential energies of attraction U_{att} and repulsion U_{rep} both between the dispersed phase particles and in their interaction with the charged internal surface of the capillary. Naturally, the changes in the shape of the dispersed phase particles and in the balance of the forces U_{att} and U_{rep} should substantially affect such macroscopic parameters as T and T/c. The current knowledge of the inherent relationships in the turbulent flow processes in direct oil emulsions allows us to speculate only about some correlations rather than about rigorous quantitative relationships in the heterophase systems under consideration.

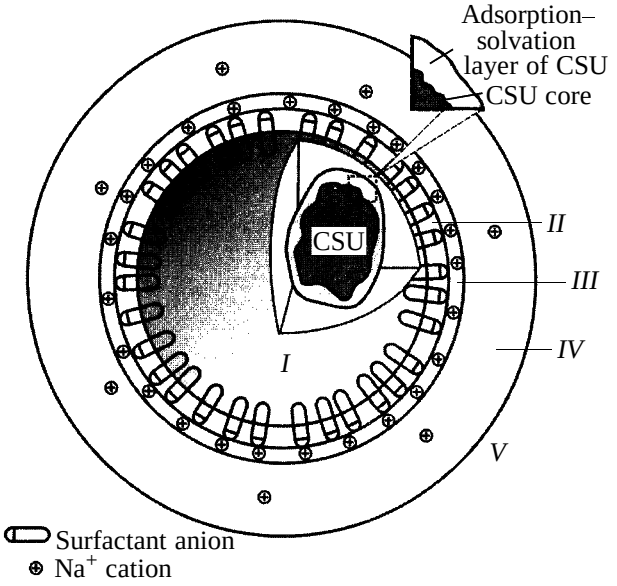

Fig. 4. Schematic picture of the oil particle in direct emulsion: (*I*) dispersed phase aggregate, (*II*) adsorption layer of the potential-determining ions, (*III*) adsorption layer of the counterions, (*IV*) diffusion layer of the counterions, and (*V*) dispersion medium (aqueous solutions of surfactants and electrolytes).

More rigorous conclusions about the relationships in the turbulent flow of direct oil emulsions in the presence of PA requires, in the first stage of analysis, knowledge of the effective concentrations of the PA in the dispersion (aqueous) medium and on the surface of the dispersed phase particles and, hence, data on adsorption of the macromolecules on the dispersed phase particles [20]. Table 2 presents selected data concerning adsorption in the 10% direct oil emulsion. Compared to adsorption of anionic copolymers of acrylamide on solid model adsorbents like ocher and kaolin with negatively charged dispersed phase particles [21], the coefficient A of adsorption of close in composition anionic copolymers of acryalmide on the oil particles is much smaller. This is due to two

factors, namely, a high density of the negative charge on the dispersed phase particles, generated by the anions of the stabilizer, and the already mentioned specific features of the interface surface (liquid state of aggregation), which creates additional problems with fixing negatively charged macroions of the polymeric additive on the oil particle surface [20].

CONCLUSIONS

(1) Water-soluble anionic copolymers of acrylamide, introduced into direct oil emulsions, sharply (by up to 50%) decrease the hydraulic resistance of turbulent streams.

(2) The influence of the polymeric additive concentration and the turbulent stream velocity of direct oil emulsions on the Toms effect was analyzed quantitatively. Reduced Toms effect is only weakly dependent on the composition of direct oil emulsions and is close to that of purely aqueous media.

Abstract—Effects of mechanical abrasion and applied shock in the presence of cellulolytic enzyme and NaOH on the yield and properties of peat lipids are studied.

Plant raw materials, among them peat, are structured composites containing fat- and water-soluble compounds, and their specific features should be taken into account in developing efficient processes for recovering bioactive components. Cell walls of plants consist essentially of lipids. To destoy and dissolve spacer lipid structures, solvent extraction is mostly used.

Mechanical treatment also promotes degradation of the lipid structures, thus facilitating subsequent recovery of water-soluble components. Mechanochemical treatment not only initiates degradation of the lipid structures, but also provides transportation of a chemical just into cells [1, 2]. Study of the evolution in the composition and properties of lipids in the course of such a treatment is of particular interest in view of their applications as a source of bioactive substances and development of physiological action preparations [3–5].

In this study we examined the effect of mechanochemical treatment on the composition and properties of lipids from high-moor and valley peats.

EXPERIMENTAL

As raw material we used peat of two kinds: high-moor peat of the Temnoe deposit (Tomsk oblast) classified with the peat-moss group with low degree of degradation (5 wt %) and low ash content (4 wt %), and valley wood peat of the Taganskoe deposit (Tomsk oblast) with high degree of degradation (30 wt %) and high ash content (25 wt %).

Mechanochemical treatment of peat was carried out in mill activators of two types: VTsM-10 flow vibratory vapart mill activator and APF-4 planetary mill with 10-mm steel balls in both cases. In the VTsM-10 mill activator, the ball acceleration was 180 m s^{-2} and treatment time, 2 min, and in the APF-4 planetary mill, 200 m s^{-2} and 2 min. These apparatuses differ in the nature (abrasion and applied shock, respectively) and intensity of action. Peat sample preparation was performed under various conditions: no mechanical treatment; mechanical activation, but no chemicals; and mechanical activation in the presence of chemicals [cellulolytic enzyme celloviridine (CV) or solid alkali].

Lipids were extracted from the initial activated peat samples with chloroform under stirring for 1 h. Then the solvent was removed in a rotary evaporator at 30°C and a residual pressure of 0.5 Pa [6].

The content of antioxidants c_{AO} and inhibiting rate constants k_7 were determined from the data on the kinetics of oxidation of cumene at 60°C and constant initiation rate $W_i = 6.8 \times 10^{-8}$ mol l^{-1} s^{-1}. As an initiator we used azobis(isobutyronitrile). The experiments were carried out on an automated gasometric system for measuring microconsumption of oxygen. The bubble volume was constant (10 ± 0.2 μl) throughout the experiment. The time dependence of the amount of oxygen consumed was processed using a specially designed computer program and was represented as an integral kinetic curve (Fig. 1) divided into linear sections: (1) linear circuit break and (2) uninhibited oxidation. In semilogarithmic coordinates, the first section represents a straight line characterized by specific induction period τ. The AO concentration (mol kg^{-1}) was calculated from the relationship

$$c_{AO} = W_i\tau/P,$$

where W_i is the initiation rate (mol l^{-1} s^{-1}); τ, experimental induction period (s); and P, concentration of the sample to be analyzed (kg l^{-1}).

The inhibition rate constants $^1k_7$ and $^2k_7$ were estimated from the parameters of the corresponding linear sections of the kinetic curve [7–9].

The composition of normal and isoprene hydrocarbons was studied by TLC on Silufol plates and also by GLC (24-m capillary column, SE-54 stationary phase, programmed heating from 100°C at a rate of 3 deg min^{-1}).

Mechanical activation, particularly in the presence of chemicals (NaOH and CV), affected the yield and characteristics of the major components of peat. Previously we studied the effect of abrasion action on the group and fraction composition of peat and catalytic properties of water-soluble and humic preparations [10, 11]. It was demonstrated that mechanochemical activation increases the yield and catalytic activity of humics. The extent and direction of transformations in lipids in relation to the kind of peat and conditions of mechanical activation can be judged from the changes occurring in the composition of liposoluble components and their antioxidant properties.

Our results reveal that the yield of lipids strongly depends on the activation conditions of peat (Table 1).

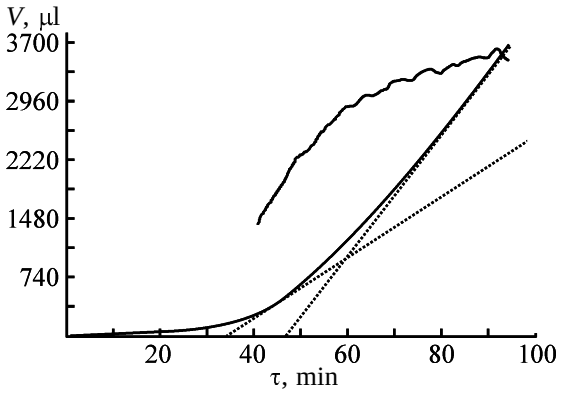

Fig. 1. Kinetic curve of initiated oxidation of cumene in the presence of lipids from high-moor peat. (*V*) Volume of oxygen consumed and (τ) treatment time.

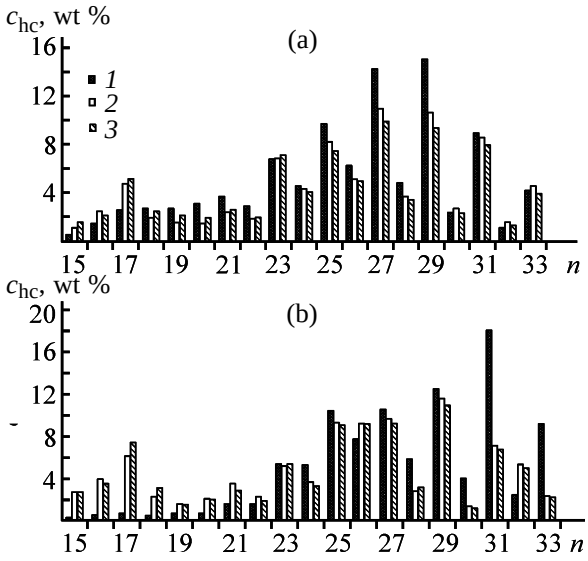

Fig. 2. Chain-length distribution of normal hydrocarbons in lipids of (a) high-moor and (b) valley peat activated in VTsM-10. (c_{hc}) Hydrocarbon concentration and (*n*) number of carbon atoms. Peat: (*1*) initial, (*2*) mechanically activated (no chemicals), and (*3*) activated in the presence of the enzyme.

Activation of high-moor and valley peat in VTsM decreased the yield of lipids c_l, the trend being more pronounced for high-moor peat. Valley wood peat is characterized by low content of liposoluble components; their yield slightly decreases upon activation, depending on the activation conditions. The increase in the yield of lipids after shock activation in APF-4 in the presence of CV can be attributed to degradation of the base cellulose and hemicellulose network in the initial raw material and also to facilitated interaction with the solvent. Activation of both high-moor and valley peat in the presence of NaOH decreases the total yield of liposoluble components by virtue of formation and removal of water-soluble compounds. This phenomenon can be explained taking into account the structure of lipid molecules representing glycoglycerolipids. On the one hand, they consist of long-chain hydrophobic hydrocarbon fragments and, on the other hand, of more compact hydrophilic fragments related to alcohols, carbohydrates, acids, and phenols. Such amphiphilic molecules form associates whose degradation depends on the kind of chemicals and mechanical activation.

Mechanical activation primarily affects long hydrocarbon chains of lipids as the most thermodynamically unstable fragments of the indicated associates [12]. Gas–liquid chromatographic analysis of peat lipids revealed the presence of normal alkanes C_{15}–C_{33} with dominating odd hydrocarbons over the range C_{23}–C_{33}. Isoprene hydrocarbons are represented essentially by pristane (*i*-C_{19}) and phytane (*i*-C_{20}). The relative concentrations of hydrocarbons c_{hc} and their chain-length distribution in lipids depend on the kind of peat and activation procedure. Figure 2 clearly shows that, for the samples obtained from activated peat, the concentration maximum in the distribution curve is shifted toward shorter-chain hydrocarbons, and a second maximum appears near C_{17}. These alkanes are formed as a result of cleavage of C–C bonds in long aliphatic chains. Changes in the composition of hydrocarbons during activation can be characterized by the parameters given in Table 2. A decrease in the odd index K_{odd} and C_{17}/C_{27} ratio and an increase in the concentration of normal alkanes C_{15}–C_{17} characterize the extent of mechanochemical degradation [13, 14]. In valley peat, the maximal degradation is observed for paraffins C_{31}–C_{33}, resulting in a considerable increase in the yield of alkanes C_{15}–C_{17}. Activation of valley peat in the presence of NaOH resulted in considerable transformation of hydrocarbons (Table 2). The content of alkanes C_{15}–C_{17} and C_{17}/C_{27} ratio increased by a factor of 10. The parameters *n*-C_{17}/*i*-C_{19} and *n*-C_{18}/*i*-C_{20} decreased in the activated peat samples, suggesting increase in the content of pristane and especially of phytane as a result of isomerization.

Lipids are characterized by high content of antioxidants inherited from peat-forming plants and transformed as a result of biochemical reactions occurring in peat deposit. The antioxidant activity in lipids is exhibited by compounds with labile hydrogen atom (phenols, carotinoids, and amino acids). In lipids separated from both kinds of peat, we found two groups of antioxidants (AO_1 and AO_2) different in their reactivity, which is typical of natural compounds. Table 1 includes the inhibition rate constants ${}^1k_7$ and ${}^2k_7$ determined to within 10% and characterizing the reactivity of AO_1 and AO_2. The data on the antioxidant activity show that, in lipids separated from untreated peat, AO_1 and AO_2 exhibit similar ${}^1k_7$ and ${}^2k_7$. In all the samples activated in VTsM-10, the amount of AO_1 and ${}^1k_7$ increased, whereas the AO_2 content and reactivity mostly decreased (Table 2).

Activation of peat in APF-4 strongly increased the total content of antioxidants, primarily by virtue of increasing AO_2 content (Table 1). The reactivity of antioxidants was found to be lower than in the case of activation in VTsM, as demonstrated by lower ${}^1k_7$ and ${}^2k_7$. The maximal content of antioxidants was found in lipids separated from peat activated in the presence

Table 2. Evolution of the composition of alkanes in lipids in the course of activation of peat

Peat	n-C_{17}/n-C_{27}	ΣC_{15}–C_{17}	n-C_{17}/i-C_{19}	n-C_{18}/i-C_{20}	K_{odd}

0.5 wt % CV	0.79	13.7	1.49	0.85	1.88
3.0 wt % NaOH	0.83	13.9	1.36	0.80	1.51

of NaOH. The final rate of uninhibited oxidation of cumene changed after full consumption of antioxidants. Most of the peat lipids decreased the oxidation rate after completion of the induction period [5]. Activation of both kinds of peat in VTsM imparts additional antioxidant capacity to lipids. Table 1 shows that the final oxidation rate amounts to 108–125 ml min^{-1}. Lipids from peat activated in APF reduce the final oxidation rate, suggesting that, depending on the conditions, activation results in degradation of terminal alkyl radicals in the lipid associates with formation of new associates different in their antioxidant characteristics.

CONCLUSIONS

(1) The yield and composition of lipids depend on the conditions of mechanical activation of peat. The yield slightly increases in the presence of celloviridine under shock activation and decreases in all other cases.

(2) Mechanochemical activation results in degradation of high-molecular-weight n-alkanes C_{27}–C_{33} in lipids of high-moor and valley peat with formation of shorter-chain hydrocarbons (C_{15}–C_{17}).

(3) Mechanochemical activation of high-moor and valley peat increases the total antioxidant content in lipids. Activation in the vibratory vapart mill increases the amount of antioxidants of higher reactivity, whereas shock activation produces antioxidants of lower reactivity.

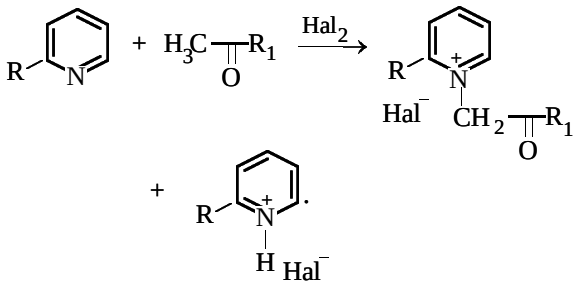
Pyridinium Halides and Their Mixtures as Inhibitors of Steel Corrosion in Sulfuric Acid Solutions

R. I. Yurchenko, S. V. Ivashchenko, T. N. Pilipenko, and I. S. Pogrebova



Kiev Polytechnic Institute, National Technical University of Ukraine, Kiev, Ukraine

Received October 15, 2004

Abstract—Mixtures of 1-acylmethylpyridinium halides with equimolar amounts of pyridinium halides were prepared by the Ortoleva–King reaction. The inhibiting effect of various pyridinium halides and their mixtures on corrosion of steel in sulfuric acid solutions was studied.

Previously we found [1, 2] that some of 1-phenacylmethylpyridinium bromides are relatively effective inhibitors of the acid corrosion of steel, especially at elevated temperatures. These compounds were prepared by alkylation of appropriate pyridine derivatives with ω-bromoacetophenones.

Corrosion inhibitors of this type can be prepared by the Ortoleva–King reaction [3], i.e., the reaction of pyridine derivatives, iodine, and compounds containing labile hydrogen atoms. Since pyridine and its derivatives act as both reagents and acceptors of the forming hydrogen halide, this reaction gives, along with the desired pyridinium salts, also the corresponding pyridinium halides. For example, the reaction of pyridine, acetophenone, and bromine yields an equimolar mixture of 1-phenacylmethylpyridinium bromide and pyridinium bromide:

When the solubility of the resulting salts is strongly different, they can be separated to prepare individual 1-acylmethylpyridinium halides. For example, treatment with alcohol of the salt mixture formed in the reaction of pyridine or 2-methylpyridine with acetophenone in the presence of bromine or iodine allows preparation of the corresponding 1-phenacylmethylpyridinium bromides and iodides with high yields. In many cases, the Ortoleva–King reaction strongly simplifies synthesis of 1-acylmethylpyridinium halides: it can be performed in one step without using halomethyl ketones (lacrimators) and allows preparation of pyridinium salts that cannot be obtained by common methods. Moreover, this reaction yields acylmethylpyridinium halides in mixtures with pyridinium halides, which can enhance their corrosion-protective effect [4].

EXPERIMENTAL

The synthesis was performed according to the procedure described in [3]. The corrosion-protective effect of the compounds prepared was evaluated using the coefficients of corrosion deceleration γ and degree of corrosion protection Z, calculated from the weight loss of 08KP steel samples in 3 M sulfuric acid at 20 and 60°C and inhibitor concentration of 1×10^{-2} M (see table).

The coefficient of corrosion inhibition of 1-phenacylmethylpyridinium bromide (I-1) at 20°C is 11.3 [1]. This compound is formed by the Ortoleva–King reaction from pyridine, acetophenone, and bromine in a mixture with pyridinium bromide and the coefficient of corrosion inhibition of this mixture (inhibitor I-1a) is as high as 18.0. In the case of iodine, the reaction yields 1-phenacylmethylpyridinium iodide (I-2) and pyridinium iodide; the first compound, when isolated pure, exhibits the coefficient of inhibition of 17.7 at 20°C. The coefficient of corrosion inhibition of the resulting mixture (I-2a) is 24.3. In the case of 1-phenacylmethyl-2-methylpyridinium bromide (I-3), the coefficients of corrosion inhibition are 15.5 and 209.1 [1], and for its mixture with

Coefficients of corrosion inhibition γ and degree of corrosion protection *Z* of 08KP steel in 3 M H_2SO_4 in the presence of acylmethylpyridinium halides (I-1–I-8) and their mixtures with the corresponding pyridinium halides (I-1a–I-8a)

Inhibitor	20°C		60°C		Inhibitor	20°C		60°C	
	γ	*Z*, %	γ	*Z*, %		γ	*Z*, %	γ	*Z*, %
I-1	11.7	91.45	–	–	I-1a	18.0	94.44	–	–
I-2	17.7	94.35	–	–	I-2a	24.3	95.88	–	–
I-3	15.5	93.55	209.1	99.52	I-3a	21.4	95.33	237.8	99.58
I-4	19.6	94.90	223.9	99.55	I-4a	22.5	95.56	250.3	99.60
I-5	–	–	–	–	I-5a	23.1	95.67	594.6	99.83
I-6	–	–	–	–	I-6a	22.0	95.45	237.9	99.58
I-7	21.4	95.33	333.8	99.70	I-7a	23.1	95.67	464.0	99.78
I-8	–	–	–	–	I-8a	25.0	96.00	864.9	99.88

2-methylpyridinium bromide, 21.4 and 237.9 at 20 and 60°C, respectively.

The reaction with acetone can be performed through one or two methyl groups. The reaction of 2-methylpyridine, acetone, and bromine or iodine in a 2 : 1 : 1 ratio yields the corresponding 1-acetylmethylpyridinium bromide (I-4) or iodide (I-5) in a mixture with 2-methylpyridinium bromide or iodide (I-4a and I-5a). We failed to isolate pure compounds I-4 and I-5 because of their close solubilities with the corresponding pyridinium salts. Pure I-4 was prepared by a common procedure, i.e., by alkylation of 2-methylpyridine with α-bromoacetone. The reaction of pyridine or 2-methylpyridine, acetone, and bromine or iodine (4 : 1 : 2 molar ratio) yields bis-salts (I-6–I-8) in the form of mixtures with the corresponding pyridinium salts (inhibitors 1-6a–I-8a, respectively). Pure I-7 was prepared by treatment of the reaction mixture with alcohol. As seen from the table, the corrosion-protective power of I-7a is higher than that of individual compound I-7 by a factor of 1.5.

Our experimental results show that the corrosion-protective effect of 1-phenacylmethylpyridinium halides increases in the presence of equimolar amounts of the corresponding pyridinium halides and on passing from bromine to iodine. This trend is the most pronounced at elevated temperatures. The products of reaction of pyridine or 2-methylpyridine with acetone and iodine (I-5a, I-7a, and I-8a) are the most effective inhibitors exhibiting at 60°C the coefficients of corrosion inhibition of 594.6, 464.0, and 864.9 and the degrees of corrosion protection of 99.83, 99.48, and 99.88%, respectively:

R = CH_3, Hal = Br (I-4, I-4a); I (I-5, I-5a)

R = H, Hal = Br (I-6, I-6a), I (I-7, I-7a)

R = CH_3, Hal = I (I-8, I-8a)

CONCLUSIONS

(1) The Ortoleva–King reaction essentially simplifies synthesis of 1-acylmethylpyridinium halides exhibiting corrosion-protective properties and allows preparation of pyridinium salts that are difficultly accessible by common procedures.

(2) The inhibiting effect of the mixtures of pyridinium salts formed by the Ortoleva–King reaction is stronger than that of the individual acylmethylpyridinium halides. The best inhibitors at a concentration of 1×10^{-2} provide the coefficients of corrosion

inhibition and the degrees of corrosion protection of 08 KP steel at 60°C in 3 M sulfuric acid of 464.0–864.9 and 99.58–99.88%, respectively.

Degradation of Cellulose Triacetate upon Irradiation with Accelerated Electrons

V. Yu. Kasimova, S. S. Mnatsakanov, and A. G. Sirota

St. Petersburg State University of Movie and Television, St. Petersburg, Russia

Received December 9, 2004

Abstract—The radiation-chemical yield G of degradation of cellulose triacetate was calculated from the viscometric data. The radiation dose providing formation of cellulose triacetate with the modified structure and with the desired reactivity was determined.

The properties of irradiated cellulose and its derivatives were extensively studied [1–8], as these polymers are of principal importance in industry, medicine, and agriculture. Owing to high content of oxygen, cellulose has low radiation resistance. Breakdown of the polymer chain (degradation) is the main result of irradiation of cellulose and its derivatives, which decreases the degree of polymerization and changes structural and mechanical properties, solubility, and reactivity.

In contrast to other cellulose esters and ethers, the effect of irradiation on cellulose acetates (CAs) is poorly studied [7, 8]. At the same time, irradiation of CA can yield an ideally compatible modifier and plasticizer of the acetate film. Insignificant amounts of the irradiated polymer, when added to the film-forming CA solution, can change the supramolecular polymer structure and, in particular, the packing density of macromolecules in the films.

EXPERIMENTAL

In our work we used cellulose triacetate (CT) prepared by the heterogeneous procedure (Svema). Before irradiation, the polymer was dried at 105°C. The cellulose samples were irradiated in air on an ILU-6 installation with accelerated electrons (1.9 MeV) at a dose rate of 0.18 kGy s^{-1}. The sample thickness was 2.5 mm. The samples were irradiated to doses D of 40, 70, and 150 kGy. The viscometric measurements were carried out at 25°C with an Ubbelohde viscometer according to the procedure given in [9] using trichloromethane; the outflow time of the pure solvent was t_0 = 53.7 s. The intrinsic viscosities [η] of the samples are given below:

D, kGy	[η], dl g^{-1}
–	1.83
40	0.80
70	0.56
150	0.29

The polymer degradation can be described using the statistical method [1, 10, 11]. The radiation-chemical yield G of degradation can be calculated from the dependence of the number-average molecular weight of the polymer $\overline{M}_n$ on the absorbed radiation dose [1]:

$$(\overline{M}_n)^{-1} - (\overline{M}_n^0)^{-1} = \frac{GD}{10^2 N_A}, \quad (1)$$

where $\overline{M}_n^0$ is the initial number-average molecular weight of the polymer, D is the radiation dose (eV), and N_A is the Avogadro number.

In this work, all the molecular weights of the CT

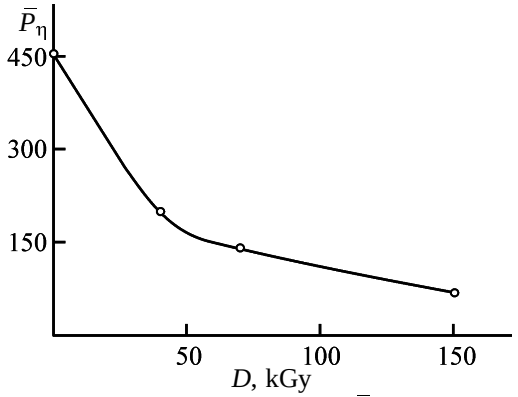

Fig. 1. Degree of CT polymerization $\bar{P}_\eta$ as a function of the radiation dose D.

1070-4272/05/7803-0514© 2005 Pleiades Publishing, Inc.

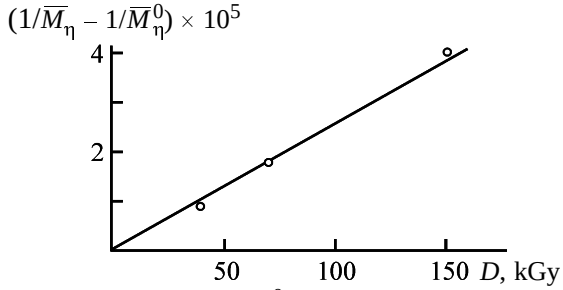

Fig. 2. Plot of $1/\overline{M}_\eta - 1/\overline{M}_\eta^0$ vs. the absorbed radiation dose D.

samples were determined from the viscosity of the dilute solutions. For CT in trichloromethane, the coefficient K in the Mark–Kuhn–Houwink equation and coefficient α are 1.4×10^{-5} and 1 [12], respectively. The dependence of the viscosity-average degree of CT polymerization $\overline{P}_\eta$ on the radiation dose is shown in Fig. 1.

The viscosity-average molecular weight $\overline{M}_\eta$ can be determined using $\overline{M}_n$ from the following equation [11]:

$$\overline{M}_\eta = \overline{M}_n[(\alpha + 1)\Gamma(\alpha + 1)]^{1/\alpha}. \quad (2)$$

At $\alpha = 1$, $\Gamma(\alpha + 1) = 1$ and $\overline{M}_\eta = 2\overline{M}_n$. Then the yield of degradation G can be calculated as follows:

$$(\overline{M}_\eta)^{-1} - (\overline{M}_\eta^0)^{-1} = \frac{GD}{2 \times 10^2 N_A}, \quad (3)$$

where $\overline{M}_\eta^0$ is the viscosity-average molecular weight of the polymer.

The dependence of $1/\overline{M}_\eta - 1/\overline{M}_\eta^0$ on the absorbed radiation dose is shown in Fig. 2. As in the case of cellulose [1], this dependence is linear. The degradation yield calculated from the curve tangent is 4.7 break events per 100 eV. As expected, this value is smaller than that in the case of cellulose, because the acetyl groups decelerate the polymer degradation.

CONCLUSIONS

(1) The radiation-chemical yield of degradation of cellulose triacetate is relatively high, and its radiation modification is feasible.

(2) Since relatively low-molecular-weight polymers are used to prepare film materials, 40-kGy dose seems to be sufficient. Irradiation of cellulose triacetate to higher doses is undesirable, because it can change moisture absorption and mechanical properties of the resulting material.

OBITUARIES

Nikolai Andreevich Kaluzhskii (1925–2005)

Nikolai Andreevich Kaluzhskii, one of the most prominent organizers of the domestic aluminum industry, honored science worker, doctor of technical science, and professor, died of a severe illness on January 9, 2005, at the age of 79. He had headed for many years the All-Union Research and Design Institute of Aluminum, Magnesium, and Electrode Industries (VAMI).

Kaluzhskii was born on November 15, 1925, at Smorodino village (Kursk oblast) into an office workers' family. He started to work in the war years at the age of sixteen. From January 1943 till March 1944 he served in the Soviet Army and took part in action. After being severely wounded, he was demobilized and continued his education.

In 1951, Kaluzhskii graduated with a first-class honors degree from Leningrad Polytechnic Institute as an engineer-metallurgist. During the following three years, he worked his way up from a foreman to production manager at the electrolysis shop of the aluminum plant in Novokuznetsk. Kaluzhskii took part in starting-up the Nadvoitsy aluminum plant (Karelia) in 1954 and became its director in 1956.

From 1960 till 1966 Kaluzhskii occupied executive positions in the Council of Ministers of the Republic of Karelia and in the regional committee of the communist party. Beginning in 1966, and for more than 25 years, Kaluzhskii had been director of VAMI in Leningrad. Designs were made and production facilities were put in service at virtually all aluminum plants constructed in our country in the post-war years under his supervision and with his direct involvement. A particular pronounced contribution was made by Kaluzhskii to the development of theoretical foundations of aluminum manufacture with the use of high-power electrolyzers with burnt anodes. In his doctoral dissertation defended in 1976, Kaluzhskii thoroughly substantiated the feasibility of application of elec-

trolyzers with burnt anodes, operating at currents of up to 260 kA, in the aluminum industry. Kaluzhskii's achievements in equipping with high-performance process apparatus, designing, and putting in operation the Bratsk, Krasnoyarsk, Tajik, and Sayany aluminum plants are remarkable.

Kaluzhskii was a prominent scientist in the field of chemical technology, electrochemistry of melts, powder metallurgy, and composites. He was the author of more than 100 scientific publications, made 95 inventions, and obtained a large number of patents in various countries.

Kaluzhskii was decorated for his research, production, and organizational achievements with high state awards and prizes of the Council of Ministers of the USSR and Government of Russia.

HISTORY OF CHEMISTRY AND CHEMICAL TECHNOLOGY

Professor Aleksei Lavrent'evich Potylitsyn (to 160th Anniversary of His Birthday)

A.L. Potylitsyn, one of the closest disciples and followers of D.I. Mendeleev, professor of Warsaw University, and later professor, director, and honorary member of Novaya Aleksandriya Institute of Agriculture and Forestry, devoted his research to solution of one of the most important problems of physical chemistry in the second half of the XIX century, that of the driving force of chemical reactions, i.e., chemical affinity, and ways to measure this quantity.

Aleksei Lavrent'evich Potylitsyn was born on March 16 (28), 1845, in Krasnoyarsk into the family of a junior officer of the Yenisei Cossack regiment. The youth received his primary education at Irkutsk military college (military pre-gymnasium), which did not give its graduates the right to enter higher-school institutions. Having graduated from the college, Potylitsyn remained there as a teacher and started to prepare, on his own, for a full gymnasium course examination. In July 1865, at the age of 20, he went to St. Petersburg and, in August of the same year, successfully passed the entrance examination at Larin gymnasium, one of the best male gymnasia of the city. In September 1865, Potylitsyn became a student of Medical-Surgery (later, Military-Medical) Academy. However, he soon went to the natural department of the physicomathematical faculty of St. Petersburg University. At those years, among the teachers of chemical disciplines were A.A. Voskresenskii (1809–1880), N.N. Sokolov (1826–1877), and D.I. Mendeleev (1834–1907), and N.A. Menshutkin (1842–1907) just commenced his pedagogical activities. A.M. Butlerov (1828–1886) became a professor of the University in 1868. As noted by F.F. Selivanov, the author of the only sufficiently full biographical essay about Potylitsyn's life [1], Mendeleev became the favorite teacher of Aleksei Lavrent'evich. The area of Potylitsyn's research was determined already in his student years. At the end of 1872, he graduated from the University and continued studies of the mutual displacement of substances in chemical reactions at Mendeleev's laboratory. In September 1873, Potylitsyn became a staff member (laboratory assistant) at Menshutkin's laboratory, but continued the already commenced studies in his free time. In the autumn of

1876, the young scientist was sent to France, because he was in the state of acute tuberculosis, for treatment and familiarization with works of French chemists. The most favorable impression was produced on Potylitsyn by his acquaintance with A.E. Saint-Clair Deville (1818–1881), a rather well known chemist and member of the Paris Academy of Sciences. In the late summer of 1878, Potylitsyn returned to Russia and resumed his interrupted service and research activities. Together with working at the University, he taught chemistry at the Pavel military college and wrote a textbook on chemistry for higher military educational institutions, which later ran into eight editions.

In December 1879, at the VI Congress of Russian natural scientists and physicians in St. Petersburg, Potylitsyn delivered a report "On the Action of Hydrogen on Halide Salts of Silver and on the Maximum Work Rule," which was of considerable interest for such well-known chemists as Mendeleev, Menshutkin, and G.G. Gustavson (1843–1908). In 1880, after Potylitsyn successfully defended the dissertation "On Methods for Measuring the Chemical Affinity" at St. Petersburg University, a master's degree in chemistry was conferred on him. As was customary in

1070-4272/05/7803-0517 © 2005 Pleiades Publishing, Inc.

those years, the full text of the dissertation was published as a separate edition (St. Petersburg, 1880, 155 pp.). In the same year, he made, together with Mendeleev, a trip to the Caucasus, to familiarize himself with oil fields. As a result of this, and two later (1884 and 1891) trips, Potylitsyn carried out a number of studies concerned with oil and its by-products.

In January 1881, Potylitsyn was appointed a professor of the Institute of Agriculture and Forestry at Novaya Alaksandriya (Lublin province, Poland), and already in July 1882, he was transferred to Warsaw University as an extraordinary professor of chemistry. During his work in Warsaw (1882–1895), Potylitsyn delivered lectures and carried out a large number of studies. In 1886, after Potylitsyn defended his dissertation "On the Importance of the Heat of Salt Formation for Double-Decomposition Reactions" at St. Petersburg University, the degree of a doctor of chemistry was conferred on him. The text of the dissertation was also published (Warsaw, 1888, 101 pp.) In the same year, Potylitsyn becomes an ordinary professor. However, he was appointed director of the Novo-Aleksandriya Institute in September 1895.

In 1900, in view of the difficulties with his family and deterioration of his health, Potylitsyn retired and went to live first to Warsaw and then to St. Petersburg.

The principal area of Potylitsyn's research was, in fact, formulated in his master's dissertation: methods for measuring the chemical affinity. The list of Potylitsyn's scientific publications can be found in [1]. His research activities were analyzed in sufficient detail in the monographs [2–5] and papers by B.Ya. Rozen [6] and R.B. Dobrotin [7]. The main, but far from being the only, objects of Potylitsyn's research were reactions of mutual displacement of halogens from halo derivatives of a number of metals. He studied in detail the reactions of mutual displacement of chlorine and bromine from their compounds with metals. The principal experimental result was that the percentage of displacement of one halogen by another under the experimental conditions was determined. The analysis of the results obtained was based on the position of an element under consideration in Mendeleev's periodic table.

Potylitsyn's experiments convincingly confirmed, among other things, that the reactions occurring with heat release do not go to completion. Thus, it was demonstrated experimentally that the maximum-work principle formulated by M. Berthelot (1827–1907) requires a better definiteness and has applicability limits. It is inapplicable to, in the first place, reactions occurring with consumption of heat.

As noted by Dobrotin [7], the importance of Potylitsyn's experimental studies is not limited to restrictions of the maximum-work principle. A major achievement of the scientist was wide use of data obtained in analysis of reaction equilibria for finding a rational measure of the chemical affinity. Potylitsyn also formulated the concept of the influence exerted by temperature on the direction in which the equilibrium is shifted. This was done before J. van't Hoff (1852–1911) published his studies in this area [1, 8].

Potylitsyn was a strong supporter of Mendeleev's standpoint concerning the principal problems of chemistry at that time and, in particular, the hydrate theory of solutions. It is noted in Potylitsyn's biography [1] that he was keenly interested not only in science, but also in literature and arts (and primarily fine arts).

Potylitsyn died of tuberculosis on February 25 (March 10), 1905, in St. Petersburg. In an article devoted to the death of his disciple, Mendeleev wrote that the name of Aleksei Lavrent'evich Potylitsyn as a chemist-researcher and pedagogue should be preserved in Russian memory. Of particular importance, in Mendeleev's opinion, are Potylitsyn's investigations concerned with the limits to chemical reactions, displacement of one halogen with another, and influence exerted by heats of formation on the course of chemical transformations.

==========

Errata

The authors made the following corrections to the article published in *Zh. Prikl. Khim.*, 2003, vol. 76, no. 11, pp. 1901–1905 (*Russ. J. Appl. Chem.*, 2003, vol. 76, no. 11, pp. 1850–1854).

In formula (7), ω_i/M_i should be replaced by $\omega_i M_i$.

The conclusion should be formulated as follows.

CONCLUSION

The reduced Toms effect in direct oil emulsions in media differing in the ionic strength depends on the molecular weight polydispersity in a complex manner, passing through extrema. This is due to nonadditivity of the contributions from the samples of the copolymer with different molecular weights to the resulting macroscopic Toms effect.

In *Russ. J. Appl. Chem.*, 2005, vol. 78, no. 1, p. 101 and Contents, the name of one of the authors was erroneously given as P. M. Hockridge. Correct is F. M. Hawkridge.

REVIEWS

Toms Effect in Model and Real Systems

V. A. Myagchenkov and S. V. Chichkanov

Kazan State Technological University, Kazan, Tatarstan, Russia

Received November 25, 2004

Abstract—Selected data on use of macromolecular compounds (polymers) as additives that diminish the hydraulic resistance of turbulent fluid flows (Toms effect) are presented. Theoretical and applied (concerning mainly oil production) aspects of the phenomenon are considered.

General evidence concerning the Toms effect. Polymers have played the key role in the development of numerous branches of industry; they can be rightfully named among the motive forces of the technological progress [1]. One of interesting and, at the same time, insufficiently studied phenomena associated with the successful application of polymers is the Toms effect: decrease in the hydraulic resistance of turbulent fluid flows upon introduction of small amounts of macromolecular polymers (on the order of 10^{-3}–10^{-4} wt %) [2, 3]. As a consequence, the flow rate increases at a constant pressure or the pumping pressure decreases at a constant flow rate of the fluid. This phenomenon has been named the Toms effect by the name of the scientist who was the first to study it systematically. This effect, which can be manifested in both aqueous and organic media, is of a particular importance in those branches of industry, in which it is necessary to transport large volumes of fluids, e.g., in oil production in pumping of water, oil, oil products, and oil emulsions (of both direct and reverse types).

History of discovery. A minor amount of guar (polymer of vegetable origin, a variety of caoutchouc) accidentally found its way into a fluid flow in oil pumping through a pipe at an oil refinery in the United States [4]. After that, the maintenance staff noticed that the pumps transporting the oil started to work with a reduced load. Naturally, this phenomenon attracted interest. Primarily, all the events exhibiting any even remote analogy were analyzed. It was found that, occasionally, the speed of ships unexpectedly increased, at a constant driving power, in sea regions with large amounts of plankton of animal or vegetable origin and, after a certain time, returned to its original value. A similar behavior was observed in experiment tanks in tests with rapidly moving ship models, when, in a repeated test with the same model after a certain interval of time, its resistance changed significantly.

The first scientist to commence a serious study of the enigmatic phenomenon was an English chemist B.A. Toms, who reported in 1948 the results of his experiments with dilute solutions of macromolecular polymers with a linear structure of molecules. In these experiments, the friction resistance in a turbulent flow decreased by 50–80% [5].

A comprehensive analysis of the set of experiments carried out by Toms revealed the reason for the dramatic increase in the speed of ships in regions with a high content of plankton. It was found that seaweeds and microorganisms excrete macromolecular compounds (biopolymers), which, when present in water even at low concentrations, markedly reduce the resistance to a body moving in it at a high speed. Subsequent studies revealed that a strong effect is observed not only for biopolymers, but also for polyoxyethylene (POE) and a number of other synthetic water-soluble polymers. It was found experimentally that, in particular, the resistance of water containing even an exceedingly low amount of POE (~0.002% and less) to a rapidly moving body decreased by 30–40%.

This phenomenon primarily attracted the interest of scientists and engineers working in areas of military technology, associated with hydrodynamics. For example, according to by no means complete data, more than 30 foreign scientific institutions were engaged in studies of the influence exerted by polymer additives on the turbulent fluid flow already in 1970. At present, the researchers' interest in this largely enigmatic phenomenon remains keen. A great success in studies of the Toms effect has been achieved by Russian and foreign research teams. The Toms

1070-4272/05/7804-0521 © 2005 Pleiades Publishing, Inc.

effect has found a wide application in oil-production and oil-refining industries, fire engineering, and medicine.

Main hypotheses for the mechanism of the effect. The issues associated with the mechanism of the Toms effect still give rise to heated discussions. Several tens of hypotheses for the possible mechanism have been suggested. These hypotheses for the most part interpret rather one-sidedly only separate aspects of the phenomenon, whereas a theory that would describe in a unified way the mechanism of the Toms effect has not been developed yet.

Let us consider further the most interesting and important studies of the Toms effect, aimed to establish its fundamental aspects.

The rheodynamics of a flow of dilute solutions of POE through thin capillaries has been studied by Naumchuk by methods of laminar and turbulent rheometry with the use of images of fluid flow lines in various radial zones of the flow [6]. On the basis of the experimental results obtained, an original model of the turbulent flow of polymer solutions was suggested. A flow without polymer additives is turbulized by strong outbreaks of a fluid from the laminarized boundary sublayer of a fluid, situated near the wall, into the center of the flow. Introduction of a polymer into the flow results in that strong outbreaks from the "viscous" boundary layer become simply unfavorable for purely energetic reasons. As a result, turbulent momentum transfer in a macroscopic fluid flow becomes less probable, and this leads to a decrease in the hydrodynamic resistance. To confirm the assumptions made, the author presents data obtained in studying the profiles of longitudinal velocity gradients and the dynamic birefringence appearing near the wall surface. A comprehensive analysis of the information obtained shows with certainty that macromolecules undergo conformational changes under the action of longitudinal velocity gradients arising in fluid flows.

It has been established in a study of the influence exerted by polymer additives (POE and guar resin) on the frequency characteristics of near-wall pressure pulsations arising in a flow around rough surfaces that the hydraulic resistance becomes lower because of the decrease in the frequency levels of near-wall pressure pulsations [7, 8].

The turbulent flow of dilute polymer solutions has been the subject of [9]. Based on modern concepts of turbulence and diffusion and on his own experimental data, the author of this study suggested an integrated method for calculation of parameters of a turbulent boundary layer with polymer additives. This method makes it possible to calculate the longitudinal distributions of the friction characteristics, characteristic values of the flow thickness, and effective concentration of the polymer additive.

It was shown that polymer additives strongly rearrange the flow in the inner region of the boundary layer, thereby making thicker the viscous sublayer. In addition, the calculation methods suggested make it possible, in the author's opinion, to give certain recommendations concerning the introduction mode of a polymer additive into the flow and to prognosticate the magnitude and nature of the decrease in the hydraulic resistance in engineering calculations and in interpretation of the results of model experiments.

Also of interest and original in their goal are studies by Kulik [10]. He examined, in addition to individual polymers, the influence exerted by damping coatings (based on organosilicon rubbers) on the magnitude of the decrease in the hydraulic resistance of a turbulent flow. It was established that, depending on the properties of a material chosen, a monolayer damping coating may either reduce or raise the hydraulic resistance coefficient. It was shown that the decrease in the hydraulic resistance is due to scattering of the limiting contour of "turbulent energy" by the wall and to a decrease in the density of pressure pulsations at the wall. Kulik gave a new, but in certain respects disputable interpretation of the results obtained in experiments with polymer additives (POE). He analyzed in ample detail the mechanism of action of damping coatings, which is based on damping of pressure pulsations just in the near-wall zone of the turbulent flow. Having done so, he made, when passing to polymer additives, an insufficiently reasonable assumption that hypothetical spatial structures exist in the polymer solution. Structured polymers disintegrate in the field of shear and pulsating stresses, thereby making larger the number of actively working macromolecules. To advantages of Kulik's works should be referred that he was the first to perform a systematic study of the joint action of damping coatings and polymer additives, which makes lower the hydraulic resistance of turbulent flows. It was, in particular, shown that the effects are additive at low polymer doses, whereas at high doses, the magnitude of the decrease in friction becomes considerably larger than the sum of the effects caused by separate use of a coating and a polymer additive.

An important contribution to studies of the mechanism of the Toms effect has been made by foreign scientists. For example, Tiederman and Reischman

developed a computer model of propagation of the velocity profile in a turbulent polymer flow [11]. Virk and Suraiya [12] calculated, based on their own experimental data obtained by means of spectrophotometry, the thickness of the near-wall diffusion (elastic) layer, which reduces the turbulent friction. The studies by Lumley [13] and Hinch [14] have also been devoted to a theoretical substantiation of the Toms effect. In addition to the theoretical studies by Tiederman and Reischman, interesting experimental data on the distribution of the velocity profile in a turbulent flow with polymer additives have been obtained by the photographic method and Doppler anemometry [15, 16].

In [17], the influence exerted by the polymer additive on the coefficient of turbulent diffusion, which is a positive factor in interpretation of experimental data obtained in analyzing the Toms effect in other studies. Finally, an important stage in the development of the theory of the influence exerted by polymers on the near-wall turbulence is the publication by Ayyash and McComb [18], who could form a layer of adsorbed polymer on the inner surface of a tube.

Proceeding from the structural inhomogeneity of the medium, Kalashnikov [19] correlated the decrease in the hydraulic resistance with the presence of polymer associates in any solution. In this case, a polymer solution is regarded as a suspension (even comparative data for real suspensions and polymer solutions are given), and the decrease in the hydraulic resistance depends on the concentration, size, and structure of associates. This statement is also confirmed by the fact that the size of the associates is well comparable with the maximum transverse size of near-wall vortices. This enables the associates to dissipate the energy of vortices and thereby to reduce the turbulent friction [20]. The author maintains that it is owing to the formation of macromolecular associates in solution that the Toms effect starts to be manifested only after the critical molecular weight of $(0.2–0.3) \times 10^6$ and more is reached. The point is that polymers with a lower molecular weight cannot form associates in solution and, consequently, do not serve as hydrodynamically active additives. In the author's opinion, which is far from being indisputable, data of his experiments indicate that "anomalous" effects arising in a flow of solutions of polymers with a high molecular weight are due to aggregation of macromolecules.

Brestkin [21] analyzed dynamic phase transitions in a flow of polymer solutions and experimentally confirmed that a strong asymmetry appears in coils of macromolecules of a flexible-chain polymer with $M = 10^6$ and more when a longitudinal hydrodynamic field is generated in a dilute solution. Similar experiments were carried out by de Gene in a study of the conformation of macromolecules in solution in the case of a turbulent flow [22]. He established that macromolecules undergo a transition from a coil to an unrolled conformation of the type of a strongly straightened macromolecule.

Povkh and Stupin [23] suggested their own interpretation of the mechanism by which the hydraulic resistance is reduced via resonance absorption of the turbulent energy by polymer macromolecules. They modeled the macromolecule with a formation composed of N statistical segments. Upon introduction of external perturbations, the macromolecule shows a set of relaxation times (or intrinsic absorption frequencies). In the case of a turbulent flow of fluids, turbulent pulsations of a certain frequency arise in the fluids. These pulsations are characterized by the so-called spectrum of turbulent perturbations. At a certain instant of time, when the frequency of turbulent perturbations becomes equal to the first intrinsic frequency of the macromolecule, macromolecules start to exhibit resonance absorption of the turbulent energy, with the result that the intensity of velocity pulsations decreases. The authors planned and carried out experiments on heat exchange in a flow of water and dilute polymer solutions. Originally, they assumed that, if macromolecules suppress perturbations (breakouts) from the near-wall region, then the heat-transfer coefficient must also decrease. Their experiments with aqueous solutions of polyacrylamide (PAA) confirmed, on the whole, the assumption made.

The influence exerted by polymer additives on heat-exchange processes has been studied by Khabakhpasheva [24]. She also concluded that, when a polymer additive finds its way into the immediate vicinity of the tube wall, the intensity of pulsations of the velocity component perpendicular to the wall strongly decreases. As a result, the thickness of the transition layer increases and, therefore, its thermal resistance becomes higher.

Among theoretical studies of the turbulent mass exchange in the presence of polymer additives, mention should be made of that by Mikhailu [25]. When calculating the parameters of a mass exchange in aqueous solutions of macromolecular polymers, he came to conclusions similar to those reported in [24].

Factors that affect the magnitude of the Toms effect. Despite the differences in the interpretation of the mechanism of the phenomenon, all researchers

emphasize that the Toms effect starts to be manifested already at Reynolds numbers Re $(2–4) \times 10^3$, i.e., in the boundary region in a transition from the laminar flow mode to the turbulent one. It will be recalled that

$$\mathrm{Re} = \rho v d/\eta,$$

where ρ and η are the density and viscosity of the fluid; v, flow velocity; and d, inner diameter of the tube (capillary) [26].

As the Reynolds number increases, the efficiency of a polymer additive in making lower the hydraulic resistance of the flow becomes higher, but only up to a certain value of Re. It was shown in [27] that, for laminar flows of polymer solutions (PAA; Re $\le 2.3 \times 10^3$), the magnitude T of the Toms effect is either zero or negative, i.e., polymer additives lead to an increase in the effective viscosity and, naturally, do not act as agents reducing the resistance to the flow. At Re > $(3–5) \times 10^3$, the Toms effect comes into play and, as Re increases, the magnitude of the Toms effect grows until Re becomes equal to Re_{cr}. At Re > Re_{cr}, T is constant (and even somewhat decreases), i.e., the effect is the strongest at Re_{cr}.

Prior to passing to a detailed analysis of the factors that affect the magnitude of the Toms effect, it should be noted that this magnitude can be evaluated in different ways and, therefore, severe difficulties are encountered in making comparative estimates. The most frequent was use of methods based on measuring the flow rate of a fluid that passed through a capillary (or a tube) [28–31] or on determining the resistance factor for a cylinder rotating within another cylinder on standard instruments of the Reotest type [32]. Also, measurements of the Toms effect by unconventional techniques have been reported. For example, this effect can be evaluated by comparing the maximum distances to a target in its "shooting" with a fluid jet in the presence of a polymer and without it [33]. Upon introduction of a polymer additive, this distance increased because of the "spreading" of the water jet. Abroad, methods based on measuring the parameters of a flow around bodies of various shapes [34, 35] and the resistance forces in rotation of flat discs relative to each other (with the fluid in between) [36] are used to characterize the effect. The fluid flow lines are commonly visualized by "dyeing" the flow with various dyes, with subsequent photographing of its certain zones [37], and by laser anemometry, which yields a real pattern of velocity profiles in any part of the flow [38]. In medicine and physiology, experiments are performed *in vivo*, i.e., on animals. The blood circulatory system of rats, dogs, or cats is used as a model "setup" that is far from being standard [39]. In these experiments, a manifestation of the Toms effect is judged from an increase in the rate of blood circulation or from a decrease in the arterial blood pressure.

Despite the wide variety of methods used to study the Toms effect, most of researchers prefer to analyze the rheological properties of aqueous polymer solutions by modeling the pipeline transport of a fluid with tubes or capillaries. In this case, either the fluid flow rate or the pressure difference between the tube ends is fixed or the flow parameters are used to calculate the coefficient of the hydraulic resistance to the flow [31, 40–44]. Such an experimental procedure is preferable to another technique, which measures the effective viscosity of polymer solutions at high shear stresses on instruments of the "cylinder-in-cylinder" type [45]. The reason is that there are no convenient criteria for a comparative assessment of the mass-transfer process and the subsequent processing and interpretation of the data obtained are inevitably complicated in the case of a viscometric monitoring of the process.

The decrease in the hydraulic resistance of a turbulent flow becomes noticeable when the molecular weight of the polymer introduced reaches a value $M \sim 10^4$.

Studies of the influence exerted by the molecular weight M of PAA [46–49] lead to the same conclusion: the Toms effect is the more pronounced, the higher the molecular weight of the polymer introduced. For the overwhelming majority of water-soluble polymers, the Toms effect is negligible or lacking at all at $M < 1 \times 10^4$.

In studying the influence exerted by the molecular properties of a polymer additive on the extent to which the hydraulic resistance of turbulent flows is reduced, the effect of such an important parameter of the polymer as its molecular weight polydispersity remained virtually unexamined [50].

In comparative analysis of the efficiency of various polymers in lowering the hydraulic resistance of a flow, it is advisable to use the reduced Toms effect, $\gamma = \mathrm{T}/c$. Here c is the polymer concentration; T, magnitude of the Toms effect, evaluated by comparing the mass flow rates of the fluid in its flow through a capillary in the turbulent mode:

$$\mathrm{T} = (m - m_0)/m_0,$$

m_0, mass flow rate of pure water; and m, mass flow rate of water with a polymer additive [31, 50]. A cor-

rect analysis of the dependences $\gamma = f(F)$ was performed for the example of ionogenic (cationic) statistical copolymers of acrylamide in the absence of complications associated with the inconstancy of the composition α of the copolymers, with the conditions $\overline{M}$ = const and $\bar{\alpha}$ = const satisfied (Fig. 1). As a quantitative characteristic of the M polydispersity was used the Schultz parameter F [51]:

$$F = \overline{M}_m/\overline{M}_n - 1,$$

where $\overline{M}_m$ and $\overline{M}_n$ are the mass-average and number-average molecular weights, respectively.

The complex, extremal nature of the $\gamma = f(F)$ dependences for the acrylamide copolymers studied is due to nonadditivity of the contributions of separate fractions to the resulting effect, which is favored by ionogenic (acrylate) main-chain links preset in the polymer additive.

Important results have been obtained in this field by Berman [52, 53]. Berman used in his studies narrow (with respect to molecular weight) fractions of a polymer (POE), obtained by gel-chromatography. He particularly emphasized that nonfractionated polymer samples with an unknown molecular-weight distribution were used in most of his experiments when studying the hydraulic resistance. This is an additional complicating factor in making an adequate estimate of the influence exerted by the molecular weight on the magnitude of the Toms effect. In Berman's opinion, it is important to trace in experiments of this kind the contribution of a separate macromolecule (or a group of macromolecules with the same molecular parameters) to the total reduction of the hydraulic resistance. It was shown in his experiments that the magnitudes of the Toms effect for fractionated and nonfractionated samples with the same average molecular weight may differ significantly. Having made a thorough analysis of the experimental data obtained, Berman concluded that, in the case of a nonfractionated polymer, the major contribution to the reduction of the hydraulic resistance is made by minor amounts of fractions with the largest molecular weight.

It can be well seen from the very concept of the Toms effect that its magnitude also strongly depends on the concentration of the polymer additive. It is virtually a common opinion of all researchers that the efficiency of a polymer as an agent reducing the hydraulic resistance of a turbulent flow increases as its concentration becomes higher. The efficiency of the polymer additive increases until a certain critical concentration is reached, after which the magnitude of the Toms effect starts to decrease gradually.

Figure 2 shows as an example a typical concentration dependence of the magnitude of the Toms effect for aqueous solutions of watersoluble (co)polymers of varied nature [54].

Pokryvailo and Gol'bina [7] studied the influence exerted by polymer additives on the intensity and frequency spectrum of pressure pulsations in a turbulent flow. Samples of POE, sodium carboxymethyl cellulose (Na-CMC), and guar resin were used in their experiments. An analysis of the results of the experiments demonstrated that for each polymer there is an optimal concentration at which the pressure pulsations are quenched to the greatest extent. The most effective among the polymers studied were solutions of POE and guar resin. Na-CMC solutions did not reduce the friction and even raised the flow resistance in some cases.

The conclusion that there exists an optimal polymer concentration c_{opt} in solution was also made by Manzhai *et al.* [55] in a study of the hydrodynamic

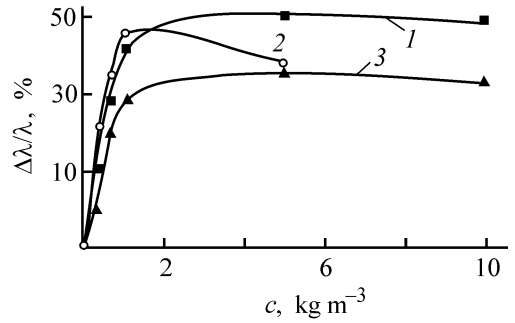

Fig. 3. Decrease in the hydraulic resistance, $\Delta\lambda/\lambda$ vs. the concentration c of natural caoutchouc in oil. Molecular weight $M \times 10^5$: (*1*, *3*) 2.4 and (*2*) 5.5. Shear stress (Pa): (*1*) 240 and (*2*, *3*) 120.

efficiency of polyisoprene samples in a turbulent flow of dry oil. On carrying out a set of experiments with polyisoprene samples of varied molecular weight introduced into and oil-containing dispersed system, the authors revealed a dependence of the optimal concentration on the molecular weight of the polymer additive. After c_{opt} is reached, the efficiency of the polymer additive "damping" the turbulence of the flow decreases (Fig. 3).

In some cases, practical application of polymers to reduce the resistance encounters difficulties associated with the fact that macromolecular polymers undergo mechanical destruction under certain conditions. In the case of a developed turbulent flow, the destruction is the most intensive [56], which automatically leads to a pronounced decrease in the magnitude of the Toms effect. Therefore, it is, in some cases, advisable to use polymers in closed-circulation systems, especially at a fast turbulent flow of fluids with large Reynolds number ($Re > 10^4$) [2].

An important contribution to investigation of dynamic processes of destruction of polymer solutions in a turbulent flow has been made Frenkel and Brestkin [21, 57]. A special emphasis was placed in these studies on analysis of the dynamics of conformational transitions in macromolecules in a longitudinal mode of solution flow. A study of the destruction products by means of chromatography led to a conclusion that, despite the decrease in the molecular weight in the course of destruction, the Schultz parameter characterizing the polydispersity in molecular weight does change significantly.

Data on destruction of polymers in a turbulent flow have also been reported by Makogon *et al.* [58, 59]. PAA and POE solutions were passed through a capillary and the resulting solutions were studied by the light-scattering method and sedimentation-diffusion analysis. The author concluded that, in addition to a simple decrease in the molecular weight of samples in solution, there also occur processes in which intra- and intermolecular cross-links are formed under the action of the hydrodynamic field. This leads to a decrease in the thermodynamic flexibility and effective dimensions of macromolecules and, consequently, their efficiency as turbulent flow "dampers" becomes lower.

In a study of the destruction of a solution of polyisobutylene in oil on a setup of the "cylinder-in-cylinder" type, Patterson *et al.* [60] made the following generalizations: (1) the extent of destruction is the greater, the higher the shear rate and (2) the strongest destruction is observed at comparatively low temperatures.

It is known that the resistance of a polymer additive to mechanical destruction is closely associated with the chemical structure of a polymer. Layec-Raphalen [61] made an attempt to reveal this relationship in experiments on circulation of a number of flexible-, moderately flexible (PAA and POE), and rigid-chain (xanthane) polymers in a system of pipelines and made a conclusion that rigid-chain polymers (xanthane) are more stable against destruction than POE and PAA.

Undoubtedly, a more in-depth and comprehensive analysis of the fundamental aspects of the destruction of polymer additives in a turbulent fluid flow will contribute to elimination of difficulties in practical application of polymer additives in industrial processes of high-rate transportation of fluids (e.g., in circulation systems).

The existence of a strong dependence of the hydrodynamic resistance of turbulent flows on the size $(\bar{h}^2)^{0.5}$ of macromolecular coils has been demonstrated on a vast body of experimental data. Therefore, it would be expected that, with water-soluble polymer additives used, the parameters T and $\gamma = T/c$ should depend on the pH value and ionic strength of the medium, and on the content of active components (surfactants, electrolytes, etc.) in it. This assumption has been confirmed by a large number of experiments with model and real systems.

There is no commonly accepted opinion concerning the influence exerted by the pH value. Some researchers have noted a pronounced enhancement of the Toms effect with increasing pH of the medium [47, 48, 62, 63]. This occurs if an increase in the pH value is accompanied by a simultaneous rise in the size $(\bar{h}^2)^{0.5}$ of macromolecular coils of the polymer. A sufficiently versatile and well-reasoned standpoint can be noted for another group of researchers, who believe that the maximum magnitude of the Toms

effect is observed in a neutral or weakly alkaline aqueous medium [64–66].

A considerable attention to the influence exerted by the pH value on the magnitude of the Toms effect has been given by Makogon, Klenin, and Povkh [45, 58, 59, 67]. They carried out a comparative study of the structure and thermodynamic activity of aqueous PAA solutions with different degrees of hydrolysis and various pH values and noted that the viscosity numbers of nonhydrolyzed PAA remained virtually unchanged in the pH range 2–10. No experiments have been carried out at pH > 10, because, in this case, PAA hydrolyzes already in the stage of solution preparation. The strong dependence of the reduced viscosity on the pH value was observed for samples of hydrolyzed PAA. It was found that macrocoils have the smallest size in an acid medium because of the presence of hydrogen bonds between un-ionized carboxy groups. At pH 8, the coils of macromolecules were the largest owing to an increase in the degree of ionization and to appearance of electrostatic repulsion forces between acrylate ions along the chain of the copolymer macromolecule. In an alkali medium, the size of macrocoils starts to decrease again because of the shielding of charged carboxy groups by sodium counterions, and, as a result, the repulsion forces between negatively charged main-chain links become weaker. Data on the conformational states of the macromolecules were compared with hydrodynamic parameters of turbulent flows in media with varied pH values. For those pH values at which the macromolecules of hydrolyzed PAA became smaller, a decrease in the magnitude of the Toms effect was observe; in distilled water, the reduction of the hydraulic resistance was at a maximum (Fig. 4).

In [68], the relationship between the magnitude of the Toms effect and the conformational state of macromolecules of cationic copolymer of acrylamide in neutral, acid, and alkaline aqueous media was subjected to a quantitative comparative analysis.

To summarize this series of investigations, it may be stated that the dependence of the size $(\bar{h}^2)^{0.5}$ of macromolecular coils (and, consequently, also that of the magnitude of the Toms effect) on the pH value of the solutions is largely determined by the chemical nature of (co)polymers being analyzed and invites a more detailed study for each class of polymers, separately.

As the ionic strength I of a solution increases, the Toms effect becomes less pronounced [30, 32]. In [69, 70], the influence exerted by the ionic strength of a solution (with respect to NaCl) on the magnitude of the Toms effect for hydrolyzed PAA was

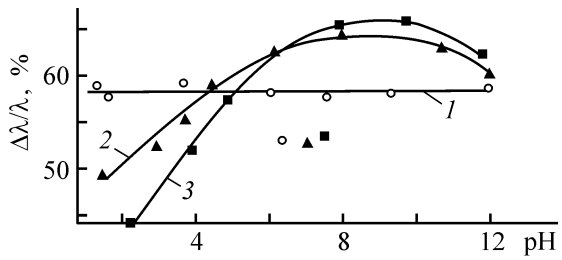

Fig. 4. Reduction of the hydrodynamic resistance, $\Delta\lambda/\lambda$, vs. pH value. c = 0.004 kg m^{-3}, $M = 6 \times 10^6$, shear stress 33 Pa. (*1*) Nonhydrolyzed PAA, (*2*) HPAA (α = 12.5%), and (*3*) HPAA (α = 16.8%).

studied at varied shear strength. It was shown that the magnitude of the Toms effect depends on the size $(\bar{h}^2)^{0.5}$ of macromolecules. The authors call special attention to the correlation between the dependences of the parameters T and $(\bar{h}^2)^{0.5}$ on the electrolyte concentration. It is also noted that introduction of salts changed the conformational state of macromolecules not only in the inner regions of the fluid flow, but also in a thin fluid layer at the phase boundary, which, naturally, reflected upon the magnitude of the resultant macroscopic Toms effect [70, 71].

In some cases, the key contribution to the dependence of the magnitude of the Toms effect on I is made not only by the conformational state of the copolymer macromolecules, but also by parameters of the near-wall layer at the inner wall of a capillary or a tube along which the fluid flows [72, 73].

Studies of the concentration dependences of the magnitude of the Toms effect for samples of hydrolyzed polyacrylamide (HPAA) with different degrees of hydrolysis, α, revealed a complex, ambiguous type of $T = f(\alpha)$ dependences [73] (Fig. 5). One more distinctive feature of the curves in Fig. 5 is that they

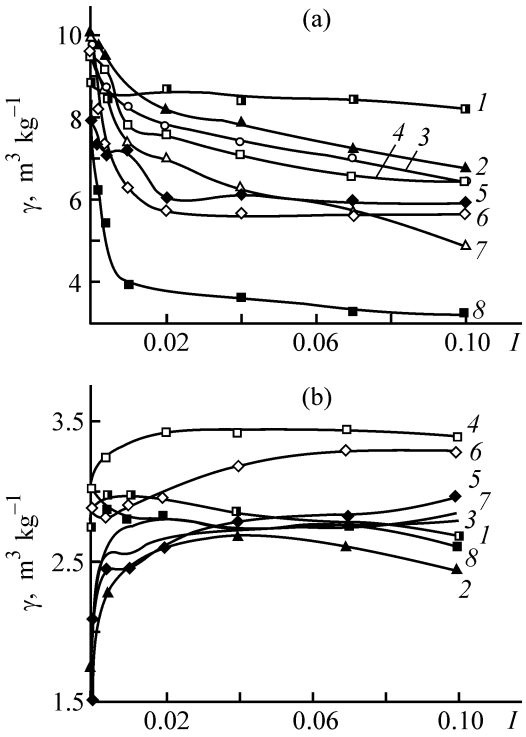

Fig. 6. Reduced Toms effect γ vs. the ionic strength *I* for (*1–5*, *7*, *8*) anionic copolymers of acrylamide with various degrees of hydrolysis and (*6*) Alcoflood 1175-A reference sample (α = 21.5 mol %, $M = 10.8 \times 10^6$). Copolymer concentration *c* (kg m^{-3}): (a) 0.03 and (b) 0.1. Degree of hydrolysis (mol %): (*1*) 10.33, (*2*) 22.20, (*3*) 63.70, (*4*) 47.93, (*5*) 41.02, (*7*) 36.20, (*8*) 1.50.

exhibit a clearly pronounced peak. This is attributed by the authors primarily to processes involving macroanions in the zone of the most effective damping of the arising turbulence waves, which is, specifically, the local volume of the fluid flow in the immediate vicinity of the capillary walls. With account of the type of fluid motion in this zone, the local concentration of macroanions and the size and shape of macromolecular coils are significantly different from those in the initial solution, in the absence of a turbulent fluid flow. It is this concept of the turbulent flow of a polymer solution that may logically lead to such notion as the optimal concentration ("saturation" concentration) c_{opt} of the polymer in the near-wall zone of the flow. Raising the polymer concentration to above a certain critical value (which was about 0.003% for the polymers studied) makes higher the dynamic viscosity in the flow, rather than c_{opt}, with the result that the efficiency of the polymer component in damping the turbulence of a solution decreases (as also does the magnitude of the Toms effect).

To illustrate the important role of the processes occurring in the near-wall zone of the capillary, the $\gamma = f(I)$ dependences were analyzed for two concentration "sections" in Figs. 6a, 6b. For this purpose, two polymer concentrations $c = c_{cr} = 0.003\%$ and $c = 0.01\%$ were chosen on the assumption that differences in the influence exerted by the electrolyte dose on the magnitude of the Toms effect are the most pronounced just at these concentrations. Indeed, the types of the dependences for the copolymer concentrations of 0.003 and 0.01% are fundamentally different. A steady decrease in the first case (Fig. 6a) and, contrariwise, an increase in the reduced Toms effect, $\gamma = T/c$, (and, consequently in the parameter T [54], too, because c = const in this set of experiments), in the second (Fig. 6b) were observed as the ionic strength became higher. It should be noted that, for all the systems studied, the dependence of the dynamic viscosity on the ionic strength of the solution was of the type characteristic of flexible-chain polymers, i.e., the viscosity decreased as the ionic force became higher.

One of the most probable reasons why the reduced Toms effect is more pronounced for systems with $c = 0.01\%$ may be associated with a decrease in $(\overline{h}^2)^{0.5}$ and dynamic viscosity at higher *I* and with a local increase in the intensity of transition of a part of macromolecules from the regions of the solution that are remote from the walls of the limiting contour into the near-wall region, which makes c_{opt} higher.

The magnitude of the Toms effect is affected not only by the ionic strength of the solution, but also by the nature of the electrolyte, which was clearly demonstrated in [72]. This study was concerned with the influence of multicharged ions on the magnitude of the Toms effect, with anionic and cationic copolymers of acrylamide used as polymers. It was found that the magnitude of the Toms effect is affected not only by the electrolyte concentration, but also, strongly, by the nature of a multicharged ion. For example, the magnitude of the Toms effect dramatically decreased for the cationic copolymer of acrylamide as the concentration of the electrolyte with a multicharged anion ($K_4[Fe(CN)_6]$) became higher, and decreased stepwise for anionic copolymers of AA as the concentration of $FeCl_3$ increased. The source of the experimentally observed strong antagonistic effects for the above-mentioned binary formulations constituted by an ionogenic copolymer and a polyvalent electrolyte is the selective electrostatic interaction of charged parts of macroanions (macrocations)

with polyvalent cations Fe^{3+} ($[Fe(CN)_6]^{-4}$ anions). This interaction leads to a dramatic decrease in the root-mean-square size of macromolecular coils and to their subsequent globulization.

The joint influence of the pH value and the ionic strength of a solution on the magnitude of the Toms effect was analyzed. Polyacrylic acid was used as a polymer object, and the ionic strength of the solution was adjusted with NaCl and $MgCl_2$ salts. Mainly the range of low pH values was studied. It was found that addition of small amounts of NaCl (up to 10^{-2} M) has virtually no effect on the extent to which the hydraulic resistance decreased in the whole range of pH values. At the same time, replacing the electrolyte with $MgCl_2$ led, all other conditions being the same, to a significant decrease in hydraulic resistance, especially at high pH values. A possible reason for the behavior observed, mentioned by researchers, is interaction of double-charged ions of magnesium with macromolecules of polyacrylic acid, which results in a substantial decrease in electrostatic repulsion forces between separate negatively charged groups of a macromolecule. This makes smaller the macromolecular coils and, consequently, reduces the magnitude of the Toms effect.

It is noteworthy that the above data on the influence exerted by the pH value and the ionic strength of a solution on the magnitude of the Toms effect are particularly important for the oil industry, which has, more and more frequently, to deal with highly mineralized formation water (with a mineralization as high as 200–300 g l^{-1}), which may have widely varying pH values and contain salts of varied nature [75]. Therefore, knowledge of the salt composition and pH value of the formation water is necessary even for a semiquantitative prognostication of the macroscopic effect produced by a particular polymer reagent.

In most cases, real dispersed objects are complex, multicomponent systems, whose various components may affect in a certain way the resulting macroscopic effect. Among components of this kind are surfactants, which can exert a strong influence both on the physicochemical parameters of fluids and on the conformational state of macromolecules. Despite that this area of research is a matter of particular current interest, the number of reports on systematic studies of this problem is insufficient.

In [31, 76–80], the influence exerted by the nature and concentration c_s of a surfactant in the dispersion medium on the resultant Toms effect was evaluated and the main conditions for the appearance in systems

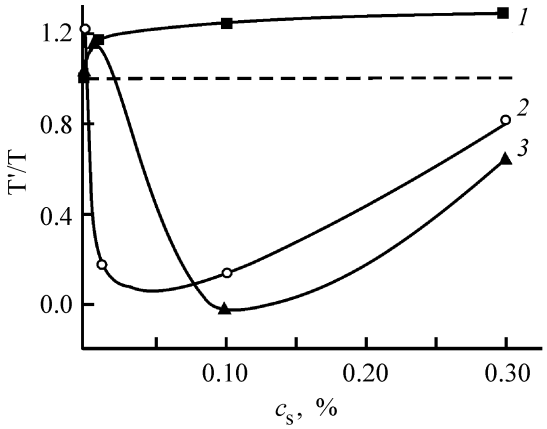

Fig. 7. Parameter T'/T vs. the surfactant concentration c_s for the binary mixtures (*1*) HPA + nonionogenic surfactant, (*2*) C + anionic surfactant, and (*3*) HPAA + cationic surfactant.

of this kind of a synergism and antagonism in the action of the components of binary polymer–surfactant mixtures were analyzed. The occurrence of these effects is indicated by the data in Fig. 7. A binary formulation composed of HPAA and a nonionogenic surfactant exhibits a weakly pronounced synergism, and those constituted by a cationic copolymer (C) and an anionic surfactant and by HPAA and a cationic surfactant, an antagonism in the action of the components. With account of the presence of two active components, HPAA and a surfactant, are contained in the system being analyzed, the magnitudes T' of the Toms effect for the binary formulations polymer–surfactant were calculated by the formula

$$T' = (m' - m_0)/m'_0.$$

In the expression, the prime means that the corresponding parameter was determined in an aqueous solution of a surfactant (for each fixed concentration of the surfactant).

The experimentally observed steep fall in the values of the parameter T'/T at surfactant concentrations of 0.05–0.1% is due not only to a decrease in the size of macromolecular coils as a result of selective interactions between an anion and a cation of a cationic surfactant or between a cation and an anion of an anionic surfactant. It also results from formation of dense globular associates composed of macromolecules with immobilized molecules or micelles of the surfactant. The visually observed, or indicated by results of optical measurements, strong turbidization of solutions of ionogenic copolymers of acrylamide in the presence

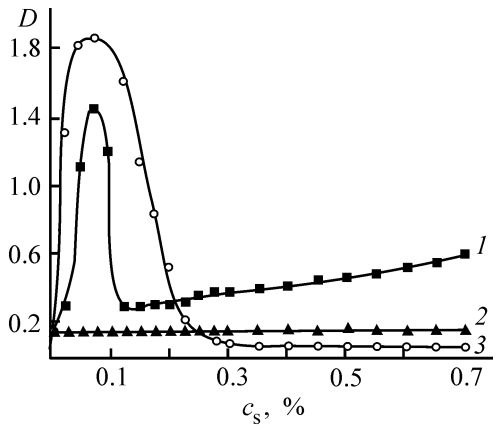

Fig. 8. Optical density D vs. the surfactant concentration c_s for binary mixtures constituted by (*1*) HPAA + cationic surfactant, (*2*) HPAA + nonionogenic surfactant, and (*3*) C + anionic surfactant. (Co)polymer concentration $c = 0.1$ kg m^{-3}, wavelength 400 nm.

of minor amounts of a surfactant (Fig. 8, curvers *1* and *2*) confirms that compact globular structures composed of macromolecules of the polymer and a surfactant are formed in the system.

Of indubitable practical interest are the results of studies [29, 81, 82] in which the resistance to the flow decreased when a surfactant with a concentration exceeding the critical micelle concentration (CMC) was introduced into a solution. For example, rod-like micelles were observed in solution when a surfactant was used as an additive [82]. It was noted that the flow structure was nearly laminar upon addition of the surfactant.

Of theoretical and practical importance are studies in which binary polymer formulations were used as additives. Data on the reduction of the hydraulic resistance of a flow with binary polymer formulations composed of polymers of varied nature were reported in [54, 78, 83, 84]. It was noted that both synergism and antagonism in the action of the components may arise in the general case in formulations of this type. The highest efficiency in the "quenching" of the turbulence of a flow is observed for the POE–HPAA and POE–C mixtures, and the lowest, for the HPAA–C mixture. The manifestation of antagonism in the action of the components of the last binary mixture can be accounted for by formation of a dense, compact, and hydrodynamically inactive interpolymer complex.

Model binary polymer formulations composed of samples of the same polymer but having different molecular weights have been studied [50, 68]. The authors call attention to the nonadditive contributions from separate fractions of the polymer to the resultant effect of reduction of the hydraulic resistance of aqueous flows.

The turbulent outflow of solutions of CMC, PAA, and xanthane polymer and of their mixtures has been studied [28]. Primary attention was given to the relationship between their rheological properties and the Reynolds number. In [85], experimental data on joint use of formulations with POE and a surfactant were reported, but, unfortunately, no attempt was made to evaluate the efficiency of action of separate components in order to determine whether or not there is a synergism (or an antagonism) in the system.

Application of the Toms effect in petroleum engineering. In the development of new industrial technologies, polymers have found wide use in virtually each stage of production, transportation, and treatment of oil [40]. One of the most original, unexpected, and effective ways to use polymers in oil production has been their application as agents that quench turbulence in a fluid flow in aqueous, organic, and aqueous-organic media. The use of the Toms effect made it possible to reduce the time of well-boring and make lower the power consumption by pumps maintaining the seam pressure at a prescribed level, and markedly diminish the expenditure for transportation of oil and oil products [3].

At present the following polymers are the most frequently used to quench turbulence in aqueous media in oil production: (1) (co)polymers of acrylamide (cationic, anionic, nonionogenic), (2) cellulose and its derivatives (carboxymethyl cellulose, oxyethyl cellulose, etc.), (3) POE, etc.

Among the polymers listed above, the highest efficiency is observed for polyacrylamide and POE. The technological advantage of polyacrylamide over POE is due to its higher resistance to destruction in quenching of the flow turbulence and to the fact that the amount of its industrial manufacture exceeds that of POE, and its cost is lower. Therefore, polyacrylamide have found the widest use, both in our country and in the rest of the world, as an agent reducing the hydraulic resistance of aqueous turbulent flows [2, 3].

Natural cellulose-based polymers are also commonly accepted as active agents for reduction of the hydraulic resistance of water, but their efficiency is not as high as that of POE and polyacrylamide. However, their use in those cases when they serve several purposes simultaneously is justified if account is taken of the difference between their cost and that of polyacrylamide (and POE). For example, use of cellulose esters to stabilize drilling agents in oil and gas pro-

duction makes it possible to raise simultaneously the drilling rate and the flow rate of solutions without any increase in the power of the apparatus used [2, 40].

In addition to aqueous media, the Toms effect is also widely used in hydrocarbon media. Its application made it possible to solve an important problem of making higher the rate of transportation of fluids in transfer of oil, oil emulsions, and commercial oil products. The most widely used as effective turbulence-quenching agents for these systems are such polymers as polyethylene and copolymers of ethylene (in particular, a copolymer of ethylene and vinyl acetate: Sevilen), polybutadiene, polyisoprene, and polystyrene and its derivatives [86–88].

It is necessary to distinguish additives lowering the turbulence of a flow and those of the depressor type among the large number of reagents that intensify transportation of oil and oil products via pipes, because the mechanisms of their action are different.

Polymer additives were first used industrially to reduce the hydraulic resistance when transporting low-viscosity oils via the Trans-Alaska pipeline in 1979. This was the CDR additive, a solution of polyolefins in a hydrocarbon solvent, manufactured by Conoco Speciality Products, Inc. [86]. In 1991, the first domestic additive acting as turbulence-quenching agent was manufactured at Tomsk Petrochemical Combine (VIOL, 10% solution of a copolymer of α-olefin in heptane) [89].

The problem of the mechanism of the Toms effect in hydrocarbon media is rather ambiguous. In particular, studies by scientists from Ufa, Movsumadze and Mastobaev, are known in Russia [90, 91]. They believe that the polymer is adsorbed on particles of oil and thereby stabilizes its flow by reducing the internal friction. Of certain interest are their generalizing papers devoted to separate aspects of application of reagents differing in the functionality of action and chemical nature (surfactants, polymers and formulations on their basis) in pipeline transport of oil and oil products [92, 93].

Studies by Chelintsev and co-authors are known in Russia and abroad [88]. They reported not only experimental data on application of various reagents, but also the most important aspects of the mathematical modeling of the pipeline transport of oil and oil products containing these reagents.

The most important characteristics of polybutylene as a turbulence-quenching agent were analyzed in [94]. In particular, the main parameters that affect

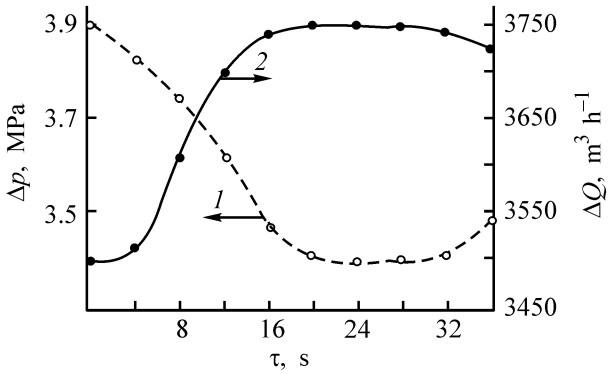

Fig. 9. Variation with time τ of (*1*) pressure drop Δ*p* and (*2*) volumetric flow rate Δ*Q* of oil at a part of the Tikhoretsk–Novorossiisk pipeline in the case of a continuous introduction of a polymer additive into the oil being transported.

the Toms effect: the molecular weight of a polymer, its concentration, and the nature of a solvent, were studied.

In [95, 96], the reduction of friction of a turbulent flow in hydrocarbon media with various polymer additives, with the decrease in friction being as large as 40% and more, was briefly reviewed.

The influence exerted by the concentration and molecular weight of polyhexene-1 on the magnitude of the Toms effect in real and model hydrocarbon media was considered in [41, 42]. The authors analyzed the main reasons for the frequent inconsistency of results obtained in laboratory and in industrial tests and present the necessary criteria to be used in a scientifically substantiated choice of a polymer additive in order to achieve the strongest effect. To confirm their theoretical concepts, the authors of these publications performed a successful experiment on reducing the energy expenditure in transfer of oil via the Tikhoretsk–Novorossiisk pipeline with a total length of 125 km (pipe diameter 0.8 m), which is clearly illustrated by Fig. 9.

At present, the quality of oil obtained from wells that have worked for a long time steadily decreases. In particular, this is manifested in the increased watering of oil [97]. Most frequently, an emulsion of oil with formation water is obtained from a well instead of oil. This emulsion has a high sedimentation and aggregative stability. Therefore, the negative tendency toward an increase in the water content of oil in the course of the service life of wells is combined with another, even more complicated problem of separating water from oil. Oil emulsions are separated at special stations for integrated treatment of oil (UKPN), as

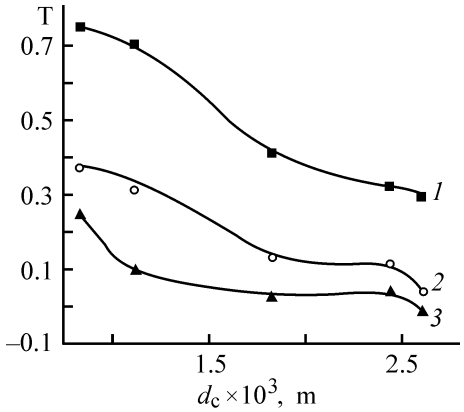

Fig. 10. Parameter T vs. capillary diameter d_c at a pressure P of 15 atm in the rheometer tank. Capillary length L (m): (*1*) 0.6, (*2*) 0.15, and (*3*) 0.075.

well as in intermediate stages of collection and transportation of the product obtained from wells to UKPN [98]. In this context, the question of how the transportation of oil emulsions can be accelerated is rather acute, because the viscosity of these emulsions is very high and distances to which they are to be transported may be as long as several tens of kilometers. Therefore, studies of the conditions for the most rational use of the Toms effect in high-speed transportation of reverse and direct emulsions of oil are of current interest and, undoubtedly, their results will be in demand in the near future. However, information about reduction of the hydraulic resistance of a flow in reverse oil emulsions is still exceedingly scarce and contradictory. For example, it was noted in [40], without describing the experimental procedure, that the hydraulic resistance to a turbulent flow of watery oil can be reduced by introducing minor amounts of aqueous solutions of polyacrylamide, with a dispersing agent (surfactant) added to achieve a homogeneous distribution of the aqueous phase (with the polymer additive) in the hydrocarbon medium.

In the USSR, experiments of pipeline transfer of high-solidifying oil on the industrial scale were performed. It was found that continuous introduction of a 0.2–0.5% solution of polyacrylamide (1.5–3.0 g of dry substance per 1 ton of oil) raises the throughput of an oil pipeline by 20%, with the amount of paraffin deposits on the inner surface of pipes simultaneously reduced [99].

Recently, separate publications have appeared in which a method for transportation of heavy oil in the form of a direct emulsion stabilized with an aqueous solution of a surfactant has been suggested [100–103]. In some cases, it is recommended to transfer high-solidifying crude oil in a rather original way, with continuous supply of water into the annular space near the pipeline wall [100]. Thereby there occurs layer transportation of oil on a water substrate. As a result, the expenditure for transfer of crude oil in this way is considerably lower than that for transfer of oils in the pure form. Despite that the transportation of oil in a mixture with an aqueous phase is seemingly complicated, the methods suggested are promising because introduction of rather small (relative to the target product) amounts of a polymer into the aqueous phase will further reduce the expenditure for transportation.

With account of the fact that transportation of crude oil and oil products in the form of direct and reverse emulsions is undoubtedly promising in economical and ecological regards, rheological aspects of a turbulent flow of direct oil emulsions with water-soluble polymers as additives [104–109]. It was noted that the manner in which the most important parameters of both the polymer additive (chemical nature of repeated links, molecular weight, concentration, molecular-weight and compositional polydispersity) and the dispersion medium (ionic strength, pH value, presence of active components of the type of surfactants) for unconcentrated direct oil emulsions (10–25%) is similar to that of the aqueous medium in some respects. However, the presence of particles of the dispersed phase, oil, in the aqueous medium leads to a number of interesting features. The most important of these is that the magnitude of the Toms effect decreased as the concentration of the dispersed phase became higher. This was attributed by the authors to the occurrence of adsorption processes on the surface of particles of the dispersed phase, which lead to a certain decrease in the concentration of the polymer in the dispersion medium. This effect is more pronounced for POE, which exhibits a high surface activity, and less so for (co)polymers of acrylamide. In addition to the factors mentioned above, the influence exerted by the flow velocity of the oil emulsion on the magnitude of the Toms effect was also studied [109]. A certain decrease in the magnitude of the Toms effect at higher transfer rates was observed experimentally. This can be attributed to a possible distortion of the spherical shape of particles of the dispersed phase (and, consequently, to a change in other parameters of particles of the dispersed phase) [110] upon a transition from the laminar mode of flow of direct oil emulsions to a turbulent mode.

Undoubtedly, not only the properties of a polymer additive and dispersion medium, but also the velocity of the turbulent flow and geometric parameters of the limiting contour affect the magnitude of the Toms

effect. The influence exerted by these factors on the Toms effect in direct oil emulsions and in a purely aqueous medium was studied in [109, 111]. Experiments were carried out on a modified turbulent rheometer with replaceable glass capillaries, which made it possible to vary widely their length and diameter. Based on the experimental data obtained with a set of glass capillaries, the authors made a conclusion that the parameters T and γ increase as the capillary becomes longer, and its diameter, smaller (Fig. 10).

It should be especially noted that, irrespective of the length and diameter of the capillaries, the manner in which the magnitude of the Toms effect depends on the active parameters of the system remained unchanged, with only the "scaling factor" (for T and γ) varied.

Other areas of manifestation of the Toms effect. In addition to the oil-producing industry, the Toms effect has found use in other areas: in fire extinguishing, for making longer the range of water jets from water cannons; in stone cutting, for intensifying the water-jet cutting of marble and granite flagstones; in shipbuilding, for raising the velocity of ships and submarines; and in biology and medicine [2–4].

The question of the possible manifestation of the Toms effect in living organisms has long escaped the attention of researchers. Only in the early 1970s, there appeared first experimental studies devoted to application of macromolecular polymers in experimental medicine and physiology. It was found that a natural biopolymer with a high molecular mass, C26, which is contained in blood, can lower the hydrodynamic resistance in a flow of blood [112]. Erythrocytes of blood also contain a macromolecular component that can be involved in the reduction of the resistance to a blood flow. In addition to natural polymers, synthetic polymers have also been used to diminish the resistance to a blood flow. Low-toxic water-soluble polymers (POE, polyacrylamide, and polyvinylpyrrolidone) was employed for this purpose [113].

Despite the comprehensive studies in this field, the issue of manifestation of the Toms effect in living organisms remains open to question and is far from being clear. The principal feature of application of polymers is that, in most cases, the turbulent flow does not virtually occur in its pure form in the circulatory system of animals (the Reynolds number in large arteries in the human circulatory system is, on average, as small as 100–1000, which, according to formal criteria, corresponds to a laminar flow mode [114]). Many physiologists note that the blood flow in the circulatory system is pulsating, rather than stationary. In the strongly branched network of resistive (resistance-creating) vessels, deviations from the laminar flow mode appear in the zone of branching (in the so-called initial portions) and constriction of blood vessels. These deviations give rise to local hydraulic resistances in the blood stream. In addition, the size of erythrocytes contained in blood are comparable with the diameter of the smallest vessels, which introduces additional "perturbations" into the flow in chaotic motion of erythrocytes in these vessels. Just these conditions have led physiologists to a conclusion that the Toms effect can be manifested in the circulatory system of animals.

However, the question as to whether or not the Toms effect does exist in living organisms, or the above-described effect caused by introduction of a polymer occur for some other reasons remains disputable. One thing is apparent, a more in-depth study of the fundamental aspects of this phenomenon in the field of biomedicine will favor development of new effective ways to control the dynamics of blood circulation and unconventional methods for improving the efficiency of the presently existing and new medicinal agents.

CONCLUSION

A sufficiently large number of experimental and theoretical studies have been devoted to various aspects of investigation and application of the Toms effect in aqueous and hydrocarbon media. Despite this circumstance, the influence exerted on the Toms effect by such most important parameters of copolymers as their molecular weight and compositional dispersity remain insufficiently studied and open to question. The same applies to the active parameters of a dispersion medium (nature of solvent, which is more important for organic media; nature and concentration of surfactants; ionic strength; pH value; and presence of impurities). The information about the influence exerted on the resultant macroscopic effect by binary formulations of the polymer–polymer, polymer–surfactant, and polymer–electrolyte types is scarce. This is so despite that just binary additives of this kind exhibit both synergism and antagonism, which is particularly important in passing from modeling to real systems. Most of researchers use model systems, distilled water, individual hydrocarbons, or organic fluids, as "convenient" objects of study. However, real objects (e.g., direct and reverse emulsions) are more complex multicomponent mixtures whose separate ingredients can strongly affect the resultant Toms effect, which is unclear and unpredictable in-

most cases. Therefore, studies of these problems are of indisputable practical interest and their results will find use, and some of these, in the nearest future. These issues become particularly important in development of industrial technologies for fast transportation of dispersed oil systems, including their direct and reverse emulsions, via pipelines.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Potassium-Reduced Tantalum Powders

V. N. Kolosov, M. N. Miroshnichenko, V. M. Orlov, and T. Yu. Prokhorova

Abstract—Properties of powders produced by potassium-reduction of tantalum from K_2TaF_7 were studied.

High-purity tantalum powders with a developed surface, which are necessary for manufacture of high-capacitance volume-porous capacitors, are mostly produced by metallothermic reduction from potassium heptafluorotantalate (K_2TaF_7). The role of the reducing metal is, as a rule, played by sodium:

$$K_2TaF_7(l) + 5Na(l) = Ta(s) + 5NaF(l) + 2KF(l). \quad (1)$$

Reaction (1) gives NaF (5 mol), which has a low solubility. Of interest is use of potassium as a reducing agent:

$$K_2TaF_7(l) + 5K(l) = Ta(s) + 7KF(l), \quad (2)$$

because only KF having a very high solubility is formed in reduction by reaction (2) in addition to powdered Ta. This would make it possible to decrease by more than an order of magnitude the amount of water necessary for removing salts from the reaction mass and favor their utilization [1]. In addition, this would facilitate production of powders with an exceedingly low content of sodium ($c_{Na} \le 2 \times 10^{-4}$ wt %), which is important for making lower the leakage current [2], one of the most important quality characteristics of capacitors.

The aim of this study was to examine properties of tantalum powders obtained with potassium used as a reducing metal.

EXPERIMENTAL

Tantalum(V) was reduced by reaction (2) by delivering liquid potassium and a flux to the surface of a K_2TaF_7 melt (liquid-phase reduction) [3]. Potassium heptafluorotantalate with a content of metallic impurities of less than 0.001 wt % for each impurity was used. Chemically pure KCl served as a flux for varying the concentration of K_2TaF_7 in the melt and lowering the melting point. It should be noted that use of other halides is undesirable in the given case. Use of KF as the flux would lead to a high melting point of the final melt, and addition of NaCl would result in formation of a sparingly soluble NaF in the melt via an exchange reaction with KF.

The experimental setup is shown schematically in Fig. 1. The stock composed of K_2TaF_7 and a flux was charged into a nickel vessel *1* and placed in the retort-reactor *2*. Potassium was available in an amount necessary for the reduction in a container *3*. After being assembled, the retort was placed in a furnace and

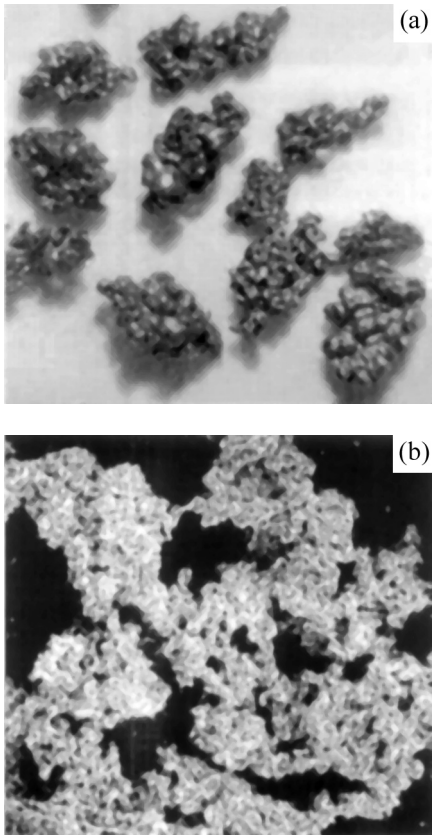
heated in a vacuum, with the temperature of the stock gradually raised. When the residual pressure decreased to approximately 5 Pa, the temperature was raised to melt the salts, the rabble *4* was lowered, and the melt was agitated until the melt was homogenized. Then, liquid potassium was delivered into the reactor via a pipe *5* under continuous agitation. The process was performed in the temperature range 750–850°C. After the reduction was complete, the reactor was cooled to room temperature. The tantalum powder formed was separated from the reaction products by hydrometallurgical treatment [1].

The specific surface area of the powders obtained was determined by the BET static adsorption method on a FlowSorb II 2300 installation. A morphological analysis of the powders was made with a SEM LEO-420 electron microscope. Anodes fabricated from the powders were sintered at 1650°C for 30 min. The anodes were oxidized at 80°C in a 1% H_3PO_4 solution to a voltage of 70 V and kept at this voltage for 3 h. The characteristics of the anodes were measured using the commonly accepted procedure.

The study was performed at a molar ratio K_2TaF_7 : KCl in the stock equal to 1, 2, and 3. The initial melting point of mixtures of this kind was in the range 725–775°C, and that after the completion of reduction was 730–820°C, depending on the content of KCl. Accordingly, the reduction process was performed in the temperature range 750–850°C. The results obtained indicate that replacing sodium with potassium as a reducing metal leads to a significant change in the granulometric composition of the resulting powders. With potassium used, up to 30% of the tantalum obtained was in the form of spongy mass with agglomerates more than 200 μm in size (Fig. 2a). At the same time, agglomerates of this kind are virtually absent upon reduction with sodium, irrespective of the process conditions. Finer particles of the powders had the same morphology as those of the powder produced by sodium reduction: equiaxed dendrite-like particles (Fig. 2b).

The formation of a spongy mass in reduction of Ta and Nb was observed by the authors of [4, 5], who developed the theory of electron-assisted reduction reactions [6]. According to this theory, metallothermic reduction involves not only electron transfer resulting from a direct physical contact between the reactants (see scheme). Also possible is an indirect electron transfer via an external circuit, without any direct contact (pathway b). In the authors' opinion, just mechanism b leads to formation of a spongy mass. However, such an explanation is hardly valid in the case



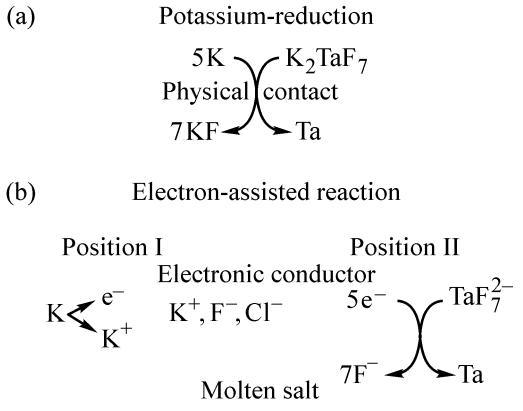


Fig. 2. Morphology of potassium-reduced tantalum powders. (a) Spongy mass, 20× magnification; (b) dendrite-like particles, 1000× magnification.

in question, because the spongy mass was formed in the solution bulk, rather than at reactor walls, in the case of a liquid-phase reduction with agitation.

Scheme of possible reaction pathways in metallothermic reduction.

It is more probable that the aggregative state of the reducing metal was the factor affecting the morphology of the product formed. The heat effect of reactions (1) and (2) involving Na and K in the liquid

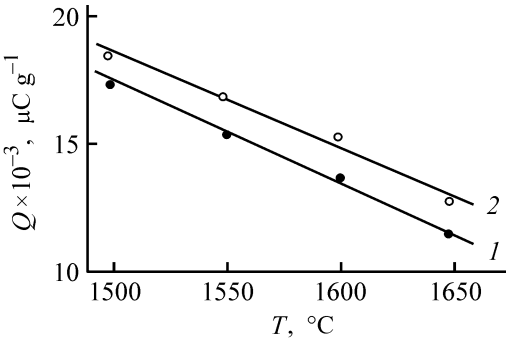

Fig. 3. Specific charge Q of the anodes vs. the sintering temperature T. Powders produced by reduction with (*1*) potassium and (*2*) sodium from a melt composed of KCl and 14 mol % K_2TaF_7.

state is about 1240 and 110 kJ kg^{-1} stock, respectively. As the potassium-induced reduction occurred at a temperature exceeding the boiling point of potassium (760°C), it may be assumed that the potassium vapor is involved in the reaction. In this case, the heat effect of reaction (2) is considerably higher (about 1850 kJ kg^{-1} stock). This may result in a substantial local overheating of the zone of powder particle formation, which favors growth of coarser and better faceted particles and their sintering. To minimize the involvement of the potassium vapor in the reaction, experiments with a stock with K_2TaF_7 : KCl : NaF = 1 : 4 : 2 and K_2TaF_7 : KCl = 1 : 6 molar ratios were carried out. This made it possible to perform reduction at a temperature of about 750°C, i.e., below the boiling point of potassium. The reduction carried out under these conditions resulted in a significant change in the properties of the Ta powder formed. Despite that the bulk density of the powder decreased by a factor of 2–2.5, the surface area remained virtually unchanged and was smaller than that of sodium-reduced powders obtained under the identical conditions. Accordingly, the specific charge of the anodes was lower, too (Fig. 3). A positive factor was that the leakage current of the anodes decreased by a factor of 1.5–2. A morphological analysis demonstrated that the >100-μm fraction of the powder obtained under these conditions is virtually completely composed of lamellate scaly particles. In the case of reduction in a melt containing NaF, which leads to an increase in the surface tension, the amount of this fraction was about 40%, of which 11% were more than 200 μm in size. As established previously, particles of this shape result from the formation of a metallic film on the surface of the melt [7]. In the case in question, the bath temperature measured in the bulk exceeded the freezing point of the melt only slightly. With account of thermal radiation, the temperature of the melt surface was even lower, which reflected upon the surface tension. The higher surface tension could favor formation of a considerable amount of scaly particles [8].

Thus, the study demonstrated that use of potassium as a reducing agent for obtaining tantalum powders from K_2TaF_7 makes it possible to simplify washing of the metal to remove salts, to diminish the content of Na in the powders, and to lower the leakage current of anodes. However, a considerable part of the powder formed is represented by a fraction unsuitable for capacitor anodes. Use of potassium as a reducing agent may be feasible if this part of the powder serves to produce a compact metal.

CONCLUSIONS

(1) It was found that replacing sodium as a reducing metal with potassium strongly affects the granulometric composition and morphology of the powders obtained. The potassium-reduction produced a considerable amount of spongy aggregates and resulted in a decrease in the yield of a powder suitable for fabrication of capacitor anodes.

(2) Reduction with potassium led, all other conditions being the same, to a decrease in the specific surface area of the powders obtained and resulted in that the anode capacitance became lower by 5–10% and the leakage current of the capacitor anodes decreased by a factor of 1.5–2.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Spontaneous Decomposition of Industrially Manufactured Sodium Hypochlorite Solutions

I. P. Sizeneva, N. B. Kondrashova, and V. A. Val'tsifer

Institute of Technical Chemistry, Ural Division, Russian Academy of Sciences, Perm, Russia

Received December 16, 2004; in final form, November 2004

Abstract—Spontaneous decomposition of industrially manufactured aqueous solutions of sodium hypochlorite was studied. The rate constants of the decomposition reactions were calculated for different pH values.

In view of the exceedingly high toxicity and volatility of metallic mercury (MPC for habitats 0.0003 mg m^{-3}) [1] and its wide use, the problem of efficient salvation in tackling with possible mercury spillage events remains a matter of current interest. For this purpose, new demercurization methods are being developed and the already existing techniques are being improved. At present, the most widely used methods are those in which mercury is oxidized with strong oxidizing agents [2, 3]. In developing a demercurizer, with industrially manufactured sodium hypochlorite (HC) solutions as an oxidizing agent, it became necessary to assess the stability of solutions of this kind in storage and to study the oxidizing activity of these industrial solutions at various pH values.

HC solutions are nonequilibrium systems that undergo spontaneous decomposition. The problem of spontaneous decomposition of HC solutions has been extensively studied. The influence exerted by the concentration, temperature, and acidity on decomposition processes has been analyzed and the possible mechanisms and kinetic characteristics of decomposition have been reported [4–8]. In the known studies, solutions of both calcium and sodium HC were examined. Model solutions have been mostly studied, with the HC solutions having low concentrations: 0.01–0.20 M in terms of active chlorine.

The aim of this study was to assess the stability of industrially manufactured concentrated HC solutions in order to determine the maximum shelf life of solutions of this kind. Another goal was to determine the kinetic characteristics of real solutions used to prepare the demercurizing agent.

The choice in developing the demercurizer was made in favor of sodium HC, taking into account its availability as a solution, high content of active chlorine, and high stability against decomposition in an alkaline medium (compared with calcium HC) [9]. The behavior of the solutions was analyzed at two temperatures, 25 and 35°C, in view of the regional climatic conditions (the maximum summer temperature is not, as a rule, higher than 35°C).

EXPERIMENTAL

As object of study served industrially manufactured (Berezniki Soda Plant Open Joint-Stock Company) sodium HC solution with a concentration of 180–200 g l^{-1} in terms of active chlorine. Model solutions were prepared by passing at (0–5°C) Cl_2 obtained by reacting chemically pure hydrochloric acid with $KMnO_4$ through a NaOH solution containing no carbonates. The excess amount of the alkali was about 20 g l^{-1}. The reaction vessel was cooled with a mixture of NaCl and ice. The pH values of the solutions were measured with an EV-74 ionometer with glass and silver chloride electrodes.

In stability studies, the alkaline (pH 13.5) HC solutions under study were thermostated in hermetically sealed polyethylene jars for 3 months. The pH value of the solutions remained virtually constant, irrespective of the duration and temperature of experiments, because of the presence of an excess amount of NaOH in the HC solutions.

The dependence of the degree of HC decomposition on the pH value was studied at 25 and 30°C.
