Table 1 shows that 93–97% of lignin and 81–90% of resin, recovered from wood in kraft cooking, are in black liquor. The ratios of the content of residual lignin and resin DTO were 2.7 : 0.43 and 1.8 : 0.49 in the pulp obtained in cooking of birch wood without additives and with addition of 3 wt %; 0.95 : 0.37 and 1.0 : 0.16 in that produced in cooking of aspen wood; and 1.8 : 0.52 and 1.4 : 0.6 in that formed in cooking of the blend. These ratios show that the content of lignin and resin in the pulp after cooking with addition of distilled tall oil decreases in such a manner that their ratio in the pulp after recovery varies insignificantly or remains the same as in the cooking without additives.

In the data listed in Table 1, it is assumed that the resin substances are completely recovered from pulp in the extraction and the residual content of lignin, which is insoluble in methylene chloride under the conditions of determination of the resin content, remains the same.

The variations in the ratios of the contents of residual lignin and resin in the pulp after kraft cooking of birch and aspen woods and their mixture without addition and with addition of 1, 2, and 3% DTO (see Fig. 1) illustrate the main differences in the influence

exerted by increasing amounts of DTO on the decrease in the content of lignin and resin. In cooking of aspen wood without additives, the minimum content of lignin and resin was reached, and, with increasing amount of additives, it did not noticeably vary. In cooking of a blend of birch and aspen wood (50 : 50), the average content of lignin and resin (curve *3*) was mainly governed by the fraction of the birch wood.

To obtain new data on the composition of the samples studied, we recorded their Fourier IR spectra in the range 1450–1800 cm^{-1}, in which the characteristic bands of guaiacyl and syringyl rings of lignin, resin residues, uronic acids, and other components predominantly lie.

The spectra of all the samples contain a weak band of carbonyl groups (C=O) at 1740 cm^{-1} and characteristic bands at approximately 1600, 1540, and 1510 cm^{-1}, related to various vibration modes of aromatic structures of the residual lignin. A mathematical processing for improvement of the spectral resolution (deconvolution and differentiation) showed that the band in the range of 1510 cm^{-1} is a superposition of two bands at 1515 and 1502 cm^{-1} related to vibrations of guaiacyl (G) and syringyl (S) aromatic rings.

Data on the relative intensities of characteristic bands of lignin aromatic structures and carbonyl groups in the spectra of the pulp samples (Table 2) allow estimation of changes in the content and structure of residual lignins, caused by addition of distilled tall oil and extraction of resinous substances with methylene chloride.

Comparison of the intensity of the bands at 1600 and 1510 cm^{-1} shows that the strongest changes are observed with the band at 1510 cm^{-1} and, hence, with the content of aromatic rings of lignin in the structure of the kraft pulp samples. The intensity of the band at 1600 cm^{-1} varied in the same direction as the intensity of the band at 1510 cm^{-1}, but its variations were significantly less pronounced. The intensity of this band shows a good total correlation with the parameter of Clason lignin. The relative intensity of the band at 1600 cm^{-1} closely correlates (r 0.98) with the content of the residual lignin in the pulp, which confirms the possibility of using Fourier IR spectroscopy for development of a sensitive quantitative spectral method of noninvasive analysis for the lignin content at its low content in the pulp.

In the course of delignification, the most pronounced changes in the spectra are associated with tensities of the bands at 1600, 1515, and 1502 cm^{-1}; a decrease in the in the behavior of their intensities depends on the kind of a sample.

The most pronounced differences were observed in the ratios between the intensities of the absorption bands of guaiacyl (G) rings at 1515 cm^{-1} and syringyl (S) rings at 1502 cm^{-1} and, hence, in the content of these structural units in residual lignins (Table 2, parameter G/S). Based on these ratios, it can be noted that the content of guaiacyl structures in the residual lignin of kraft aspen pulp was, on the average, higher than that in the residual lignin of birch pulp and the highest content of guaiacyl structures was observed in the pulp samples with addition of 3 wt % DTO.

The intensities of weak bands at 1740 and 1540 cm^{-1} decrease in the sample of birch pulp after deresination and increase in the sample obtained with addition of 3% DTO. This fact suggests that these bands of lignin overlap with the bands of resinous substances of pulp. The intensity of the absorption band at 1740 cm^{-1} is somewhat higher than that of the band at 1540 cm^{-1}, which is caused by the apparent superposition of the absorption bands of lignin and uronic acids whose content in the pulp is significantly higher than that of esters of neutral resinous substances and carbonyl groups in them. The practical use of these bands for monitoring changes in the content and composition of resin in the samples is, however, difficult because of the above features.

CONCLUSION

The high correlation coefficient of the relative intensity of the characteristic band of lignin with

the content of residual lignin and high the sensitivity of these bands to changes in the content of guaiacyl and syringyl structures allowed quantitative estimation of the content of residual lignin and assessment of its structural transformations in kraft birch and aspen pulp by Fourier IR spectroscopy in situ without its recovery from wood fibers.

Abstract—The kinetics of bleaching with potassium peroxoborate of waste from rice production (straw and husk), untreated and treated with water, acid, and sodium hydroxide, was studied.

DOI: 10.1134/S1070427206100272

Production of husked rice groats involves formation of large-tonnage wastes. These wastes can be a source for production of various types of products for chemical, medical, food, textile, paper, construction, and other branches of industry [1–5]. Rice straw has long been used as a raw material for production of the cellulose material [6]. Development of environmentally safe procedures for bleaching of lignocellulose materials without using chlorine-containing reagents is a topical problem [7–9].

This study proceeds with examination of wastes from rice production and considers the possibility of using potassium peroxoborate (PPB) for bleaching of rice straw (RS) and husk (RH).

EXPERIMENTAL

We chose for the study the RS and RH samples prepared from rice of the Darii-8 strain cultivated in Primorskii krai in 2002 [10]. The straw was milled to particles with a length of 3–5 cm, the husk was fractionated, and particles with a size of no less than 2 mm were taken. The raw material was washed with water and dried at 60°C. The content of inorganic and organic components of the initial raw material has been determined previously [2–4] and is as follows (%): 12 and 88% for RS and 20 and 80%, respectively, for RH.

As a bleaching agent we used PPB containing 20% available oxygen O_{av} whose synthesis is described in [11]. We studied the effect of PPB on the samples of the initial raw materials and their residues after treatment (extraction) with water, hydrochloric acid (1 N), and sodium hydroxide (1 N) at the volume ratio solid : liquid = 1 : 13, treatment duration of 1 h, and temperature of 90°C. The residual raw materials after the extraction of soluble substances were filtered off, washed with water, and dried to constant weight at 60°C. The composition of the extracts was studied in [4]. The samples were bleached at the optimal temperature of 95°C, with the concentration of PPB varied from 6 to 12 g l^{-1}, and the process duration, from 5 to 60 min.

The rate of PPB decomposition was estimated from variation of the O_{av} content in the solution, determined by permanganatometric titration [12], and was calculated from the ratio $\ln[c_0/(c_0 - c_x)]$, where c_0 is the initial concentration of O_{av} in the solution, and $(c_0 - c_x)$ is the concentration of available oxygen undecomposed by the time τ. The rate constants of O_{av} decomposition were evaluated from the rate equation of a first-order reaction [13]. The bleaching power of PPB was estimated on a Specol device by the procedure described in [14]; freshly calcined magnesium oxide was used as reference. We analyzed the spectrophotometric curves of the reflection coefficient ρ in the wavelength range 400–700 nm. The results are listed in Tables 1 and 2 and shown in Figs. 1–4.

the course of RS bleaching are listed in Table 1. The kinetic curves illustrating the linear dependence of the O_{av} concentration on time are shown in Fig. 1.

The results obtained suggest that, as the PPB concentration in aqueous solution increases, the rate of O_{av} decomposition grows both in the presence of RS and without it; in the process, the solution pH varies in the range 8.9–9.6. The decomposition of O_{av} proceeds more actively in the first 30 min.

Depending on the PPB concentration and bleaching duration, the rate constants of O_{av} decomposition decrease from 0.99×10^3 to 0.42×10^3 and from 1.84×10^3 to 0.85×10^3 s^{-1} (Table 1; Fig. 1, curves *1*, *3*), respectively. The degree of O_{av} decomposition by the end of bleaching for these systems is 88.93 and 95.26%. In the presence of RS, both the reaction rate and the rate constant of O_{av} decomposition increase (Fig. 1, curves *2*, *4*). By the end of peroxide bleaching (τ = 60 min), the rate constants of O_{av} decomposition decrease to 0.58×10^3 (Table 1, sample no. 2) and 0.96×10^3 s^{-1} (Table 1, sample no. 4). The degree of O_{av} decomposition is 93.68 and 96.84%, respectively.

the presence of treated RS samples (Table 1, Fig. 2) shows that the bleaching of raw materials depends on the procedure of their pretreatment (aqueous, acidic, or alkaline). For example, the rate constants of O_{av} decomposition in bleaching of RS treated with acid or alkali by the end of peroxide bleaching are 0.65×10^3 and 0.58×10^3 s^{-1} (Table 1, sample nos. 6, 7). In this case, the degree of PPB decomposition is 90.51 and 87.35%, respectively, which is lower than that in decomposition of pure PPB (95.26%).

In the course of bleaching of RS pretreated with water, acid, or alkali, the solution color and pH (in the range 8.9–10.5), and also the weight of the cellulose product (≤24%) after bleaching vary depending on pretreatment of straw (Table 2).

A comparison of the effect of PPB on RS shows that the maximum rate of O_{av} decomposition in the solution is observed in bleaching of the initial RS and the minimum rate, for RS treated with NaOH (Fig. 2, curves *2*, *5*). With respect to the influence of the procedure of preextraction of soluble substances from straw on the rate of PPB decomposition in the course of bleaching, the samples of raw materials can be ranked in the following order: RS(init) > RS(H_2O) > RS(HCl) > RS(NaOH).

Rice husk. The RH bleaching with PPB proceeds somewhat differently (Table 1, Fig. 3), compared to

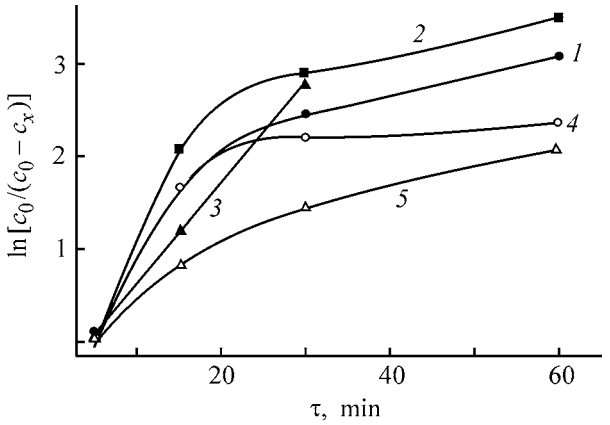

Fig. 2. Kinetic curves in the coordinates $[\ln(c_0/c_0 - c_x)]$–time of thermal decomposition of O_{av} τ in solutions containing PPB and RS. (*1*) Without RS (Table 1, sample no. 3); RS: (*2*) initial (sample no. 4), (*3*) treated with H_2O (sample no. 5), (*4*) treated with HCl (sample no. 6), and (*5*) treated with NaOH (sample no. 7).

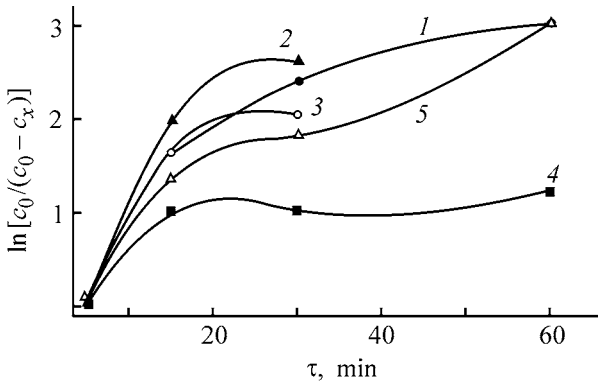

Fig. 3. Kinetic curves in the coordinates $[\ln(c_0/c_0 - c_x)]$–time τ of thermal decomposition of O_{act} in solutions containing PPB and RS. (*1*) Without husk (Table 1, sample no. 3); RH: (*2*) initial (sample no. 8), (*3*) treated with H_2O (sample no. 9), (*4*) treated with HCl (sample no. 10), and (*5*) treated with NaOH (sample no. 11).

straw bleaching and depends on the procedure of husk pretreatment.

The kinetic curves of thermal decomposition of PPB show that the maximum rate of O_{av} decomposition is attained, as in the experiments with RS, in bleaching of the initial RH (Fig. 3, curve *2*), and the minimum rate, in bleaching of the husk subjected to acid treatment (not alkaline, as for RS) (Fig. 3, curve *4*). With respect to variation of the rate of O_{av} decomposition in bleaching with PPB, the raw materials can be ranked in the following order, depending on the pretreatment procedure: RH(init) > RH(H_2O) > RH(NaOH) > RH(HCl).

The degree of O_{av} decomposition in the PPB solution is 65.22% for RH(HCl) and 84.19% for RH(NaOH) (Table 1). The maximum degree of O_{av} decomposition is observed in bleaching of RH(init): 92.89%.

A comparison of the rate constants of PPB decomposition (Table 1) shows that they are close in bleaching of the initial samples of RH and RS, 2.22×10^3 and 2.30×10^3 for τ = 15 min and 1.64×10^3 and 1.61×10^3 s^{-1} for τ = 30 min, respectively, and decrease with increasing duration of PPB action on the raw materials, irrespective of the pretreatment procedure.

Bleaching of RH subjected to alkaline or acid treatment proceeds without changes in the solution pH (Table 2), contrary to the solutions with the initial RH or RH treated with water, in which pH changes from 9.0 to 10.4. After bleaching, the weight of the cellulose product decreases, depending on the procedure of pretreatment of the raw materials, to 19.6%.

Thus, the study of bleaching of wastes from rice production with PPB shows that, in the presence of untreated RS and RH, the constant of O_{av} decomposition increases, whereas in the case of RS and RH pretreated with water and acid and alkali solutions, the rate constant of O_{av} decomposition decreases.

The spectrophotometric curves recorded before and after bleaching of the samples (Fig. 4, curves *1–4*) show that the reflection coefficient of bleached samples of RH and RS, ρ, increases. The highest ρ is observed for RS subjected to acid treatment and RH treated with alkali (Fig. 4, curves *2*, *4*). These data correlate with the maximum concentration of water-soluble substances extracted from raw material during its pretreatment and subsequent bleaching (Table 2).

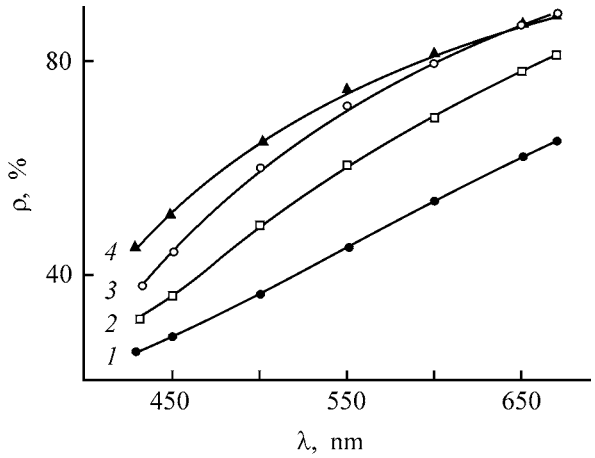

Fig. 4. Reflection coefficient ρ vs. wavelength λ for the samples of raw materials (Table 1) without and after bleaching. (*1*) Initial unbleached RH, (*2*) RH treated with NaOH and bleached with PPB (sample no. 11), (*3*) RS treated with NaOH and bleached with PPB (sample no. 7), and (*4*) RS treated with HCl and bleached with PPB (sample no. 6).

Thus, our study demonstrated that the use of PPB as a bleaching agent for wastes from rice production (straw and husk) is not only possible, but also efficient. The necessary condition for improvement of the whiteness of fibrous intermediates is pretreatment: acid for straw and alkaline for husk; in this case, RS is bleached more efficiently than RH. This pretreatment of the raw material is favorable for milder bleaching, due to the decrease in the rate of O_{av} decomposition in the solution. The data obtained allow recommendation of potassium peroxoborate in design of a new chlorine-free procedure for synthesis of cellulose-containing materials from wastes formed in rice production.

The kinetic studies of bleaching of plant raw materials with potassium peroxoborate were performed in the pH range 8.9–13 (the pH was adjusted by adding a NaOH solution to the system) for the systems with the best whiteness index, PBB + RS(HCl) and PPB + RH(NaOH). The results obtained are listed in Table 3.

The results of our study show that the pH affects the O_{av} decomposition in solution more strongly than does an increase in the bleaching duration. In the pH range 8.9–13, the O_{av} decomposition accelerates during a short period of time (τ = 5 min) for all the systems. The increase in pH from 10 to 12 in sys-

		13.0	11.37	4.08	1.98	96.74	97.45	97.23

tems 1 and 2 (Table 3) leads to a rise in the rate constants of decomposition by more than a factor of 2 (3.80×10^3 and 7.70×10^3, and 3.42×10^3 and 7.93×10^3 s^{-1}, respectively). The degree of O_{av} decomposition in the solution at given pH values is 68.09 and 90.07% for PPB without plant raw materials and 64.19 and 90.77% in bleaching of RH treated with alkali solution.

In bleaching of RS treated with HCl solution, a similar change in the solution pH results in an increase in the rate constant of O_{av} decomposition by an order of magnitude (1.11×10^3 and 10.01×10^3 s^{-1}, respectively, at pH 10 and 12, τ = 5 min). In this case, the degree of O_{av} decomposition is 28.37 and 95.04%, respectively.

Further increase in the solution pH to 13 only slightly affects the rate constants of decomposition for all the systems studied, since the available oxygen has decomposed practically completely. Therefore, an increase in the bleaching duration to 30 min at the same pH decreases the rate constant of O_{av} decomposition.

Thus, our studies showed that a pH not exceeding 12 is optimal for bleaching of plant raw materials.

CONCLUSIONS

(1) The kinetics of the thermal decomposition of high-peroxide potassium peroxoborate containing 20% of available oxygen in aqueous solutions in the course of bleaching of rice straw and husk was studied in relation to the type of raw materials, procedure of its pretreatment, solution pH, and process duration. It was found that potassium peroxoborate is efficient for bleaching of wastes from rice production.

(2) The straw treated with a solution of hydrochloric acid (the rate constant of available oxygen decomposition varies from 0.05×10^3 to 0.65×10^3 s^{-1}) and husk treated with alkali solution (the rate constant varies from 0.32×10^3 to 0.85×10^3 s^{-1}) are the most susceptible to oxidation. The optimum time interval of bleaching of the raw materials is 30 min.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Wastes from Woodworking Industry as a Filler for a Cable Sheathing Compound

L. K. Mal'kevich and L. Ya. Tsarik

Irkutsk State University, Irkutsk, Russia

Received December 16, 2006

Abstract—The suitability of an alternative filler for a cable polyvinyl chloride plastic compound was studied. Physicomechanical, chemical, and relaxation properties and inflammability of plastic compound were analyzed in relation to the filler content.

DOI: 10.1134/S1070427206100284

Composites of wood and polyvinyl chloride (PVC) can be subdivided into two groups: composites based on polyvinyl chloride plastic and on plastic compounds [1]. Highly-filled composites for building industry have been developed [2].

As fillers for cable sheathing compounds we tested wastes from woodworking industry (WWI). The main attention was focused on the O-40 cable plastic compound for wire and cable sheaths, which is the product of deep processing of PVC.

In this study, we examined the effect of a filler alternative to chalk, the waste from woodworking industry, and developed the formulations of this plastic compounds.

EXPERIMENTAL

Fine sawdust (WWI) was taken because of its practical importance as filler of polymeric materials [3]. Fine sawdust meets the requirements to the fillers, such as filler purity, absence of inclusions, high dispersity, light color (which does not affect the pigment color), chemical stability, and low specific density.

Six formulations with various contents of sawdust filler were prepared under the conditions close to those used in the component ratios in these samples are listed in Table 1. The formulations with WWI filler were developed on the basis of the compositions of commercial plastic compounds containing suspension polyvinyl chloride of S 7058-M brand as binder. This binder is a homogeneous white powder without smell and taste; it is used in production of light- and heat resistant cable sheathing compounds, high-strength pipes, specialty linoleum, plasticized films, and artificial leather. Dioctyl phthalate (DOP), which is the main plasticizer for PVC, is a transparent colorless

oily liquid with slight odor; bp 340°C (6 mm Hg), mp –40°C. The separated chalk (white powder) was used as filler for S 7058–M PVC. Light and thermal stabilization of PVC was performed using lead oxosulfate (LOS) $PbO \cdot PbSO_4 \cdot H_2O$ (white powder, mp 977°C, ρ 7.0–7.1, insoluble in water, greases, and oils). Calcium stearate $(CH_3(CH_2)_{16}COO)_2Ca$ (CaSt) is a PVC stabilizer, which can be used as a lubricant at PVC processing (white nontoxic powder, mp 175°C, density of technical-grade product 1.035). Antimony(III) oxide Sb_2O_3 (special-purpose fire-retardant additive) shifts the ignition point of PVC by 10°C. The sawdust (WWI) consists of yellowish particles (0.2–1.0 mm size and 11% moisture content).

Also, formulations were modified with various technological additives (lubricants, odorants), which, being added in amounts even smaller than the stabilizers, do not affect the polymer properties.

The resulting formulations were exposed to extrusion treatment at the laboratory of the Sayanskkhimplast Joint-Stock Company, and their strength and relative elongation at break were measured in accordance with GOST (State Standard) 11 262–80. In the course of the tests, the load and relative elongation at break were measured.

The chemical stability of the samples to various aggressive liquids was studied; three samples of each plastic compound were placed in 40% NaOH, 45% H_2SO_4, 60% HNO_3, 70% CH_3COOH, NH_4OH and some household solvents; after 1-day exposure, changes in the samples were analyzed.

In this study, we examined the effect of the new filler on the inflammability of the plastic compound, using sample no. 3 with chalk, and nos. 3 and 4 with sawdust. The inflammability group of the samples was determined in accordance with GOST 12.1.044–89 on an OTM device. The combustion delay was measured with a stopwatch at the instant of attainment of the self-combustion. The electrical resistivity of the coke residues of the burnt polymer materials was measured using an experimental setup consisting of a press, a press mold, and an ohmmeter.

The relaxation properties upon deformation of the composites were studied on a tensile-testing machine in accordance with the procedure described elsewhere [4].

The optimal composition of OP-40 sheathing compound is as follows (wt %): PVC 43.75, DOP 31.65, chalk 22.2, LOS 1.18, CaSt 0.8, and Sb_2O_3 0.42. In the first stage of the study, we examined the samples with different contents of chalk. New formulations were prepared by substitution of chalk with fine sawdust (Table 1).

The results of the first stage of our study showed a direct dependence of the compound properties on the content of the common filler (chalk). The data on the strength and relative elongation are listed in Table 2. Comparison of the results for the composites containing sawdust with GOST showed that sample nos. 3–6 (Table 1) are unsuitable for preparing sheathing compounds.

Changes in the sample properties after chemical treatment are shown in Table 3. Among the samples

Table 4. Time τ of attainment of the indicated combustion gas temperature

Sample no.	Time τ, s, of attainment of attainment of indicated temperature, °C					
	200	250	300	350	400	600
3, chalk	66	79	84	88	90	100
3, sawdust	52	70	81	87	91	99
4, sawdust	71	86	91	105	107	113

containing chalk, sample no. 4 with the highest chalk content appeared to be the most unstable to nitric acid. Sample nos. 1 and 2 are the most stable to chemical treatment, but sample no. 1 contains no chalk. All the samples containing sawdust were stable to degradation. Thus, addition of the sawdust filler does not affect the chemical properties of the plastic compound, whose integrity and initial shape do not change in both concentrated acids and alkalis. This phenomenon is independent of the sawdust content. When immersed in concentrated solutions, the sawdust either becomes charred in concentrated sulfuric acid or swells in NaOH and HNO_3; as a result, the solution acquires the natural color of the wood fiber. The optimal chemical properties (i.e., the highest chemical stability) among the samples containing the new filler are exhibited by sample no. 2.

Polyvinyl chloride cable plastic compound is designed to prepare wire and cable sheaths that operate, depending on the plastic compound brand and design of the wire and cable, at temperatures of –60 to +70°C, and to 105°C for IT-105 compound. It is known that the main disadvantage of many plastics is their instability under heat treatment. Soft PVC plastics (plasticized PVC, plastisols) contain considerably larger amounts of more inflammable plasticizing agents than do rigid plastics (polyvinyl chloride plastic). In this study, we examined inflammabil-ity of materials in relation to the content of the new filler using sample no. 3 with chalk and nos. 3 and 4 with sawdust (Table 1).

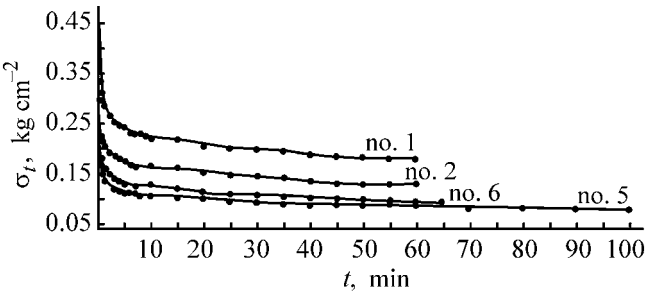

Fig. 1. Stress relaxation curves for sample nos. 1, 2, 5, and 6 containing sawdust. (σ_t) Stress and (t) time.

The combustion delay for the samples studied was as follows, s: no. 3 (chalk) 17, no. 3 (sawdust) 14, and no. 4 (sawdust) 13. With increasing combustion delay, the inflammability of the material decreases. As seen, the combustion delay decreases in the series of samples studied, which is obviously due to the increasing content of the combustible material in the PVC composite. As can be seen from the test for the inflammability group, the weight loss of all the three samples exceeded 60% [76.3, 86.7, and 85.8% for sample nos. 3 (chalk), 3 (sawdust), and 4 (sawdust), respectively], i.e., the resulting composites belong to the class of highly inflammable and combustible materials. The maximal temperatures of the flue gas and the time of their attainment are listed in Table 4. With increasing sawdust content, the time of the sample heating becomes longer. This is probably due to the fact that the sawdust particles, being charred upon heating, form some "insulation" barrier preventing transport of the pyrolysis products into the combustion area. The heat is also consumed for the release of water and its evaporation. The water vapor hinders diffusion of atmospheric oxygen to the combustion area, and thus decelerates degradation.

The electrical resistivity of the coke residue of the polymeric materials was as follows (mΩ): 25, 1000, and 500 for sample nos. 3 (chalk), 3 (sawdust), and 4 (sawdust), respectively. The slowest temperature increase was observed for sample no. 4, and its specific electrical resistivity is lower than that of sample no. 3.

The equilibrium and relaxation moduli and relaxation time of the samples containing chalk were E_∞ 0.28–0.45 kg cm^{-2}, E_{rel} 0.675–1.17 kg cm^{-2}, and τ 6.1–9.3 s. The experimental data on the samples containing sawdust are shown in Fig. 1. The equilibrium and relaxation moduli and relaxation time of the samples containing sawdust were E_∞ 0.28–0.39 kg cm^{-2}, E_{rel} 0.66–0.90 kg cm^{-2}, and τ 8.4–14.4 s.

On adding solid fillers, the mobility of macromolecules in the boundary layer decreases due to steric hindrance caused by the solid surface and interaction of the polymer with this surface. This changes the re-

laxation properties. A decrease in the molecular mobility upon filling makes longer the average relaxation time; it increases with the degree of filling and filler dispersity and with decreasing flexibility of macromolecules.

Since addition of the filler not only changes the properties of the composite but also reduces its price, we calculated the per ton cost of all the samples. Sample no. 4 was the least expensive among the composites containing chalk. Since the sawdust is a waste from woodworking industry (i.e., no special production is required), only the transport charges should be taken into account in production of plastic compounds filled with sawdust. Sample no. 6 with the highest content of sawdust is the least expensive material.

It should be noted that sample no. 4 is the least expensive among all the composites studied, though its stability with respect to chemical treatment is the lowest. Hence, composite no. 4 can be used for preparing plastic compounds to be used in nonaggressive media, and this production would be profitable. Plastic compounds prepared from composite nos. 1 and 2 (Table 1) can operate in aggressive media, but it should be noted that the strength of sample no. 1 corresponds only to the first grade, and plastic compound prepared from these composites would require greater capital investments.

The composites were selected taking into account not only the economic parameters but also the plastic compound properties. In this study, the compound quality of the plastic was evaluated using only two parameters (strength and relative elongation at break) taken from GOST 5960–72 for the plastic compound of O–40 brand. Chemical characteristics also affect the sample quality. Thus, the quality of a plastic compound was assessed in our studies by its strength, relative elongation, and chemical stability. All these three parameters are summarized in Fig. 2 relative to sample no. 1, whose strength, relative elongation, and chemical stability were taken as unity.

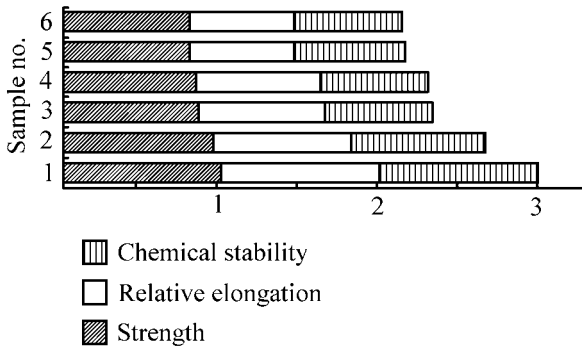

Fig. 2. Mechanical properties and chemical stability of the samples Sample no. 1–6.

As can be seen from Fig. 2, sample no. 1 exhibits the best properties, but it contains no filler, which is an essential drawback, because the filler is an obligatory component of the plastic compounds. Among all the other samples, sample no. 2 containing sawdust (5.2 wt %) is the best (Table 1).

CONCLUSIONS

Polyvinyl chloride is compatible with a new filler, waste from woodworking industry. Sawdust can be used as a filler of O-40 plastic compound. The effect of the filler content on the properties of the plastic compound was examined.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Alkali Resistance of Cured Rolivsans and Glass-Reinforced Plastics Based on Them

B. A. Zaitsev, G. I. Khramova, I. D. Shvabskaya, and I. V. Balanina

Institute of Macromolecular Compounds, Russian Academy of Sciences, St. Petersburg, Russia

Received April 25, 2006

Abstract—The effect of strongly alkaline media on the strength and heat resistance of thermosetting polymers and plastics prepared by thermal transformations of Rolivsans (cross-linking and cyclizing polyfunctional aromatic ethers with terminal styrene and methacrylate groups) was studied.

DOI: 10.1134/S1070427206100296

Rolivsans, thermosetting castable resins of a new type, are used for preparing various polymeric and composite materials highly resistant to heat and to aggressive agents, including hot sulfuric acid and solutions of HF [1–7]. Rolivsans are low-viscosity (containing no solvents) unsaturated monomer–oligomer systems formed by chemical transformations of di[4-(1-hydroxyethyl)phenyl] ether with methacrylic acid, catalyzed by strong acids [3, 8–10].

When heated to 120–250°C and higher temperatures, Rolivsans are cured to form heat-resistant network polymers. The first step of thermal curing (120–170°C) involves three-dimensional radical copolymerization of unsaturated monomeric and oligomeric components via terminal methacrylate and styrene-like (vinylaromatic) groups, to give a primary polymer network. Heating to 170–220°C induces cleavage of methacrylate cross-links to give, first, methacrylic acid units and then tetralone and anhydride units (polycyclization) in the course of solid-phase rearrangements. The formation of the final heat-resistant structure of cured Rolivsans is complete at 240–260°C; the resulting nonporous polymers and plastics exhibit high hardness and heat resistance [11–13].

It is known that common heat-resistant heterocyclic polymers (e.g., aromatic polyimides, bismaleimides, polycyanurates), which are widely used in modern engineering, show poor hydrolytic stability, especially in alkaline media [14, 15]. The practical interest in alkali-resistant polymeric materials is also associated with the use of rods of glass-reinforced plastics based on polyester resins in concrete structures in building. These rods have certain advantages over the common steel reinforcement. However, concretes and cements undergo hydration in the course of service, which gives rise to an alkaline medium (pH ~12) exerting a prolonged destructive effect on the polyester binder [7].

We expected that the high cross-linking density and high content of aromatic and tetralone rings in the structure of cured Rolivsans would enhance the hydrolytic stability of these thermosets and of reinforced plastics based on them. To evaluate the alkali resistance of these materials, we examined their behavior in alkaline solutions.

EXPERIMENTAL

Experiments were performed with Rolivsan samples prepared according to [10]. Their characteristics are listed in Table 1. Exclusion liquid chromatography of Rolivsan samples was performed with a Waters gel permeation chromatograph at 20°C, using columns packed with Ultrastyrogel (500 Å) and toluene as eluent. The number-average molecular weights $\bar{M}_n$ were determined with a Hitachi–Perkin–Elmer 115 vapor osmometer. The unsaturation of the samples was evaluated with an ADS-3 ozonizer at 0°C, solvent CCl_4.

The cured (cast) samples were prepared by casting into brass molds, and glass-reinforced plastics, by hot pressing of T-10-80 glass fabric sheets impregnated with Rolivsans in a mold at a pressure of 1 kgf cm^{-2}, followed by thermal curing in the temperature range 150–260°C at a heating rate of 5 and 7 deg h^{-1}. The shear elastic modulus G' and mechanical loss

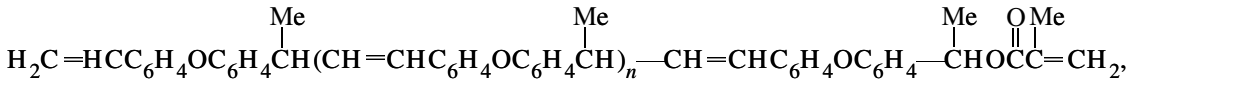
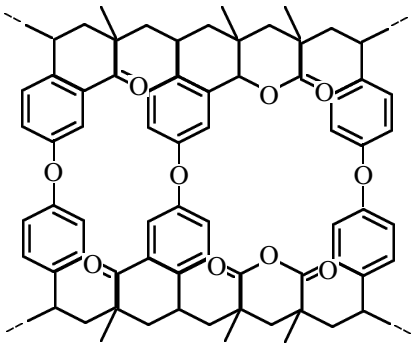
II	14 ± 3	23 ± 4	23 ± 4	39 ± 5	1 ± 0.1	0.56	420	1.592	2500



* Mol >C=C< per 100 g of product.

tangent tan δ were measured with a reverse torsion pendulum with an oscillation frequency of 0.25–0.50 Hz in the temperature range 15–400°C; the sample size was (36–38) × (4.2–5.6) × (1.7–2.0) mm.

To test the samples for alkali resistance, we prepared a standard alkaline buffer (pH 12) from aqueous solutions of NaOH (0.1 M), NH_2CH_2COOH (0.1 M), and NaCl (0.1 M). The samples were cut into 40 × 2.5 × (1.0–1.5)-mm strips, weighed, and placed in flasks containing alkaline buffer solutions; each flask was connected to a reflux condenser and to a tube packed with CaO to prevent penetration of CO_2 into the system in the course of prolonged tests. Samples were kept in the alkaline solution at room temperature; for prompt evaluation of the hydrolytic stability, samples were additionally heated at the boiling point (~102°C) for a definite time. Then the samples were washed with distilled water, dried to constant weight, and weighed, after which the breaking bending stress was measured and compared to the initial value.



As shown in [3, 9–11], Rolivsans consist of the following unsaturated aromatic compounds:

and also of antioxidants (products of alkylation of phenolic compounds with monomers M1 and M2 and with oligomer OL).

Thermal transformations of Rolivsans and their components M2 and M3 (cross-linking, polycyclization) yield thickly cross-linked glassy polymers having the following polycyclic structure [11, 13]:

Preliminarily finely divided (powdered) samples of cured Rolivsan and a model polymer prepared by three-dimensional polymerization of M2 were treated with aqueous–dioxane solutions of KOH at the boiling point for 7 h. An IR study of the samples before and after the treatment confirmed the stability of the chemical structure (backbones, tetralone units, diphenyl oxide bridges) of the cured Rolivsan and model polymer (poly-M2), despite severe testing conditions [3, 16].

The characteristics of the initial Rolivsans used for preparing glassy (nonporous) polymers and glass-reinforced plastics are listed in Table 1. Tables 2 and 3 show how alkaline solutions affect the strength of the block polymers and glass-reinforced plastics prepared from Rolivsans of various compositions. To accelerate the hydrolytic degradation, samples were kept for various intervals of time at room temperature and additionally at the boiling point of the alkaline solution.

Table 2. Effect of the alkaline medium (pH 12) on the strength of cured Rolivsans

*** Cured at a heating rate of 5 deg h^{-1}.

**** Cured at a heating rate of 7 deg h^{-1}.

It could be expected [15] that alkaline treatment would induce hydrolytic degradation leading to a decrease in the strength of network polymers and plastics prepared by curing of Rolivsans. However, it should be borne in mind that cured Rolivsans having a high network density and containing mainly low-polarity units and groups do not noticeably swell in water and weakly swell in the majority of common solvents [3, 17, 18]. Therefore, the effect of an alkaline buffer solution containing surfactants on the strength of the polymers and plastics could be primarily associated with the adsorption of surfactants [15]. The subsequent hydrolytic degradation occurred mainly under the external diffusion–kinetic control, i.e., in the surface layers of the polymer sample.

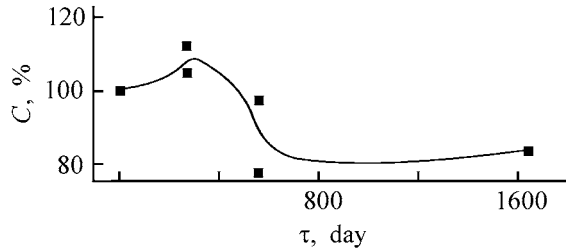

Fig. 1. Relative strength C of cured Rolivsans vs. time τ of their treatment with an aqueous buffer solution (pH 12) at 20°C, according to data from Table 2.

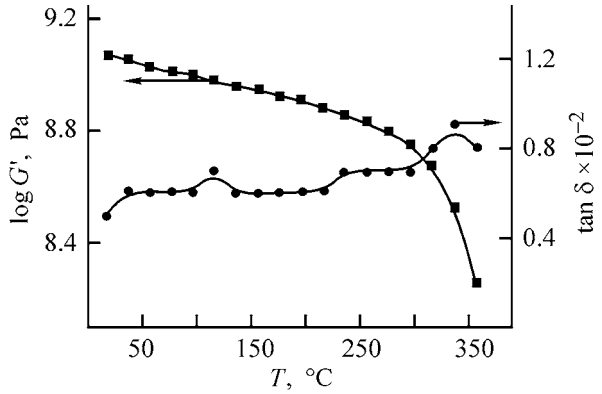

Fig. 2. Dynamic shear modulus log G' and mechanical loss tangent tan δ vs. temperature T for composition II thermally cured at a heating rate of 5 deg h^{-1}.

Table 2 shows that a combined (accelerated) action of the alkaline solution by alternating prolonged keeping at room temperature and boiling (equivalent time of testing at 20°C, estimated by the van't Hoff rule [19], varies from 9 months to 4.5 years) does not lead to failure of the thermosets. The cast samples still preserve a high strength. Furthermore, the strength even appreciably increases during the first 9 months of alkaline treatment, after which it starts to gradually decrease, i.e., the relative strength passes through a maximum (Fig. 1). A similar effect of an original increase in strength under the action of chemically active media has been described in the literature [15]. In the given case, this can be explained as follows. As can be seen from the results of a dynamic mechanical analysis (DMA) (Fig. 2), cured Rolivsans are rigid (low mechanical loss tangent) and have high heat resistance (~340°C). Apparently, they contain microcracks which give rise, under an applied force, to increased local stresses and appearance of a main crack, which causes

Table 3. Effect of alkaline medium (pH 12) on the strength of glass-reinforced plastics based on Rolivsans

Conditions of alkaline treatment, time, days/T, °C	τ, days (years)	σ_b^{20}, MPa	C, %	σ_b^{250}, MPa	C, %	σ_b^{20}, MPa	C, %	σ_b^{250}, MPa	C, %
	Composition I*					Composition I**

** Cured at a heating rate of 5 deg h^{-1}.

failure of the sample. Thus, microcracks impair the strength of a sample whose external layers are subject to extension at bending. Base hydrolysis induces cleavage of ester cross-links and opening of anhydride rings on the sample surface, which decreases the network density and improves the deformation-strength properties of the surface layers. Such a chemical modification of the surface does not promote formation of new microcracks but, by contrast, leads to erosion of the edges of the already existing microcracks. In the process, the local stresses decrease and become more uniformly distributed over the sample surface. The decrease in the breaking force with the further progress of degradation (hydrolysis) is apparently due to a decrease in the cross section of the polymer sample.

As expected, glass-reinforced plastics were found to be more sensitive than the block (unfilled) polymers to the effect of an alkali medium (Table 3), because the reinforcing aluminoborosilicate glass fibers of the glass fabric (E glass) degrade under the action of acids and alkalis [20]. Nevertheless, glass-reinforced plastics still retain no less than a half of their initial strength (σ_0^{20} 20) after prolonged treatment (~4.5 years) with an alkaline solution. Apparently, the access of an alkali to glass fibers coated with the binder (cured Rolivsan) is strongly hindered. Table 3 also shows that the breaking bending stresses of the glass-reinforced plastic before and after the alkaline treatment, with loading at 250 (σ_0^{250}, σ_t^{250}) and 20°C (σ_0^{20}, σ_t^{20}), essentially differ. It was noted above that a decrease in the polymer network density and erosion of microcracks in the surface layers after alkaline treatment lead to a decrease in the local glass transition points and, as a result, to the surface plasticization in high-temperature tests. Therefore, a seemingly unexpected trend is observed (Table 3): The hydrolytic degradation of the plastic can result in an appreciable enhancement of its high-temperature strength (or in its slight decrease).

CONCLUSIONS

(1) Heat-resistant network polymers and plastics prepared by thermal curing of Rolivsans exhibit high hydrolytic resistance in a strongly alkaline medium. After keeping at 20°C for 105 days, combined with refluxing at 102°C for 6 days in aqueous-alkaline buffer solutions (pH 12), the plastics still retain approximately 50–80% of their initial bending strength.

(2) Alkaline treatment under certain conditions noticeably enhances the strength of cured Rolivsans and glass-reinforced plastics based on them. The effect is caused by partial hydrolytic degradation of cross-links in the surface layers of the plastics, leading to a decrease in the polymer network density, in the concentration of microcracks (with their partial elimination), and in the local glass transition points. As a result, surface plasticization is observed, increasing the breaking bending stress in high-temperature tests.

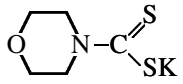
Abstract—Results of thermochemical studies of a new compound, potassium morpholinodithiocarbamate, are presented. The enthalpies of its solution in water at various dilutions and the specific heat at 173–348 K were examined by the experimental methods of isothermal and dynamic calorimetry.

DOI: 10.1134/S1070427206100302



Bioactive substances forming the basis of medicinals are of particular importance for the human life. To compounds of this kind also belong morpholine derivatives, which occupy a prominent place among the known analgesics, antiarrythmatics, antidepressants, etc. [1].

Studies of the thermodynamic properties of bioactive substances and their derivatives are of high theoretical and practical importance for their directed synthesis and for revealing the relationship between their structural and energy-related characteristics.

In this context, we performed a calorimetric study to determine the enthalpies of solution in water of a new compound, potassium morpholinodithiocarbamate, and its specific heat in the temperature range 173–348 K.

EXPERIMENTAL

The sample under study was potassium morpholinodithiocarbamate[1] of chemically pure grade, T_{decomp} = 230°C, empirical formula $C_5H_8NOS_2K$, molecular weight 201.3434. The structural formula of the compound is as follows:

The enthalpy of solution of this compound was studied on a DAK-I-IA automated differential calorimeter under isothermal conditions (25°C) at various dilutions (1 : 18000, 1 : 36000, and 1 : 72000 moles of compound per moles of water). The theory and practice of calorimetric studies was described in detail in [2–5]. The technical parameters of the calorimeter are as follows: working temperature range 25–200°C, ampule volume 8 cm^3, sensitivity in the mode of a direct measurement of the thermal electromotive force not worse than 0.012 μV, error in measurement of heat effects not exceeding 2.0%. Heat effects were recorded with a KSP-4 potentiometer, and also using an IP-4 precision integrator. The time of preliminary thermostating was 2 h. The substance under study was placed in a metallic ampule, which was inserted into a metallic cartridge with the solvent.

The operation of the device was checked by measuring the enthalpy of solution of thrice recrystallized KCl at dilutions of 1 : 1600, 1 : 2400, and 1 : 3200 (moles of salt per moles of water). The value obtained at 25°C, ΔH_{sol} = 17780 ± 262 J mol^{-1}, is in a good agreement with the reference values reported in [6, 7].

The experimental errors and the homogeneities of their variances were calculated using the Student and Cochran criteria [8].

The significance level of the criteria employed was 5%. The regression line had the following parameters:

	0.0008	0.2482	62.47
	0.0008	0.2454	61.76
	$\Delta\overline{H}^m_3 = 62.19 \pm 0.45$		

$a_0 = 1.820$, $b_0 = 22.41$, $a = 1.780$. The sought-for regression equation has the form

$$Y = 1.780 + 22.41x.$$

The linearity hypothesis is satisfied by the inequality $F_{exp} = 40.97 < 243.9$.

As the optimal confidence probability was chosen $\alpha = 0.95$.

Table 1 lists the results of a calorimetric analysis of the enthalpies of solution in water of the compound under study.

As can be seen in Table 1, an endothermic effect is observed in dissolution of potassium morpholinodithiocarbamate in water, which demonstrates predominance of the energy of the crystal lattice over that of solvation of the constituent ions of the compound.

Further, the experimentally obtained average values of the enthalpies of solution of the compound under study at the specified dilutions were extrapolated to infinite dilution to calculate the standard enthalpy of solution of the compound in an infinitely diluted aqueous solution. According to [9], $\Delta H^m_{sol} = f\sqrt{m}$ (m is the molal concentration). Based on the data obtained, we found that the dependence of the enthalpy of solution (kJ mol^{-1}) of potassium morpholinodithiocarbamate on the molal concentration is described by the expression

$$\Delta H^m_{sol} = 54.18 + 295.17\sqrt{m}. \quad (1)$$

The standard enthalpy of solution of $C_5H_8NOS_2K$ in an infinitely diluted aqueous solution is 54.2 ± 0.4 kJ mol^{-1}.

The specific heat of potassium morpholinodithiocarbamate was studied with an IT-S-400 dynamic calorimeter in the temperature range 173–348 K. Liquid nitrogen was used as a cooling agent. The duration of measurements covering the whole temperature range, including experimental data processing, was about 2.5 h. The maximum rated error of the device was ±10%. The device was calibrated by determining the thermal conductivity K_{th} of the heat meter [10, 11]. For this purpose, several runs were performed with a copper sample and empty ampule.

The specific heat was measured in accordance with the technical characteristics of the device at intervals of 25 K.

A sample to be studied was placed in the metallic ampule of the measuring cell and heated by the continuous flow of heat through the heat meter. The time lag of the ampule temperature with respect to the base temperature was measured at intervals of 25 K.

As in the case of calibration, five parallel runs were performed with the compounds under study at each temperature (at 25-K intervals). The results obtained were averaged and processed by the methods of mathematical statistics [8].

At each measurement temperature, the root-mean-square deviation $\overline{\delta}$ was calculated for the averaged values of the specific heat, and the random component of the error, $\mathring{\Delta}$, was determined for molar values of the specific heat.

The results obtained in the study of the specific heat are listed in Table 2.

Table 2. Specific heat ($C_p \pm \bar{\delta}$) and mole heat capacity ($C_p^0 \pm \mathring{\Delta}$) of potassium morpholinodithiocarbamate

T, K	$C_p \pm \bar{\delta}$, J g^{-1} K^{-1}	$C_p^0 \pm \mathring{\Delta}$, J mol^{-1} K^{-1}	T, K	$C_p \pm \bar{\delta}$, J g^{-1} K^{-1}	$C_p^0 \pm \mathring{\Delta}$, J mol^{-1} K^{-1}
173	0.6977 ± 0.0138	140 ± 8	273	0.8596 ± 0.0231	173 ± 13
198	0.7244 ± 0.0208	146 ± 12	298.15	0.9955 ± 0.0268	200 ± 15
223	0.7557 ± 0.0198	152 ± 11	323	1.0673 ± 0.0224	215 ± 13
248	0.8148 ± 0.0163	164 ± 9	348	1.1047 ± 0.0281	222 ± 16

The data in Table 2 were used to derive the equation describing the temperature dependence of the specific heat of the compound in the temperature range under study (J mol^{-1} K^{-1})

$$C_p^0 = -(86.3 \pm 5.84) + (825.7 \pm 55.9) \times 10^{-3}T + (25.1 \pm 1.70) \times 10^5 T^2. \quad (2)$$

To calculate the standard enthalpy of formation of potassium morpholinodithiocarbamate, we first estimated its standard heat of combustion by the Karas and Frost methods [12], which are the best suitable for taking into account the contributions of various groups to the heat of combustion. The averaged enthalpy of combustion of $C_5H_8NOS_2K$ in the liquid state, found by these two methods, is –3024 ± 82 kJ mol^{-1}.

Using the average value of the enthalpy of combustion by the reaction

$$2C_5H_8NOS_2K_{(l)} + 17.5O_{2(g)} = 10CO_{2(g)} + 8H_2O_{(l)} + N_{2(g)} + 4SO_{2(g)} + K_2O_{(s)} - \Delta H^0_{comb} \quad (3)$$

we calculated, on the basis of the Hess cycle, the value of $\Delta_f H^0_{298.15}$ for $C_5H_8NOS_2K_{(l)}$, equal to –541.3 kJ mol^{-1}. The values of $\Delta_f H^0_{298.15}$ for $CO_{2(g)}$, $H_2O_{(l)}$, $N_{2(g)}$, $SO_{2(g)}$, and $K_2O_{(s)}$, necessary for the calculation, were taken from the reference book [13].

In view of the fact that $C_5H_8NOS_2K$ is in the crystalline state at 298.15 K, it was necessary to calculate its standard enthalpy of formation in the solid state. For this purpose, the melting heat of the compound under study was evaluated [14]:

$$\Delta H_m / T_m = 20.72 \times 10^{0.00324M}. \quad (4)$$

The value of ΔH_m, found for $C_5H_8NOS_2K$ by Eq. (5), is 46.8 kJ mol^{-1}.

Using the equation

$$\Delta_f H^0_{298.15} C_5H_8NOS_2K_{(s)} = \Delta_f H^0_{298.15} C_5H_8NOS_2K_{(l)} - \Delta H_m, \quad (5)$$

we calculated the standard enthalpy of formation of crystalline potassium morpholinodithiocarbamate to be –588.2 kJ mol^{-1}.

CONCLUSIONS

(1) The enthalpy of solution of a new morpholine derivative, potassium morpholinodithiocarbamate, in water was studied and its standard enthalpy of solution in an infinitely diluted aqueous solution was determined (54.2 ± 0.4 kJ mol^{-1}).

(2) The method of dynamic calorimetry was used to measure the temperature dependence of the specific heat of $C_5H_8NOS_2K$ in the temperature range 173–348 K), C_p^0 (298.15 K) was found, and the equation describing the dependence $C_p^0 \sim f(T)$ for the compound in this temperature range was derived.

(3) The enthalpies of combustion (–3024 ± 82 kJ mol^{-1}) and melting (46.8 kJ mol^{-1}) and the standard heats of formation of liquid (molten) (–541.3 kJ mol^{-1}) and crystalline (–588.2 kJ mol^{-1}) potassium morpholinodithiocarbamate were calculated using indirect methods.

The data on the thermochemical and thermodynamic properties of the new morpholine derivative, obtained in this study, are of interest for physicochemical modeling of the technology of development of medicinals and for determining their structural, energetic, and bioactivity characteristics.

BRIEF COMMUNICATIONS

Acceleration of the Diffusion of Aqueous $CoCl_2$ Solutions in Porous-Glass Membrane in the Presence of Alkali Metal Chlorides

E. S. Stromova and V. N. Pak

Hertzen State Pedagogical University, St. Petersburg, Russia

Received June 29, 2006

Abstract—The diffusion coefficients of a 0.1 M aqueous solution of cobalt(II) chloride in a porous-glass membrane with a predominant pore radius of 45 nm in the presence of 0.5–3.0 M of lithium, potassium, and cesium chlorides were determined. Specific features of the influence exerted by the type of accompanying electrolytes on the rate of diffusion transport of $CoCl_2$ were considered.

DOI: 10.1134/S1070427206100314

Commonly, the diffusion rate of electrolytes in microporous glass membranes is markedly lower than that in free solutions [1–7]. This fact is reflected by several reports [4–6] of the "size" dependence of the diffusion coefficient on the radius of transport channels, r_p:

$$D = D_0 \exp(-K_p/r_p). \quad (1)$$

Here D_0 is found by the extrapolation $r_p \to \infty$ and the parameter K_p characterizes the effective thickness of the near-wall structured solution layer with hindered diffusion.

At the same time, it is possible that the membrane transport of water–salt solutions can be considerably accelerated by introduction of accompanying electrolytes having high diffusion mobility. To the authors' knowledge, this opportunity has not been subjected to reliable experimental verification. The reason is, in part, that the results of such a verification would hardly be obvious, primarily because of the decrease in the activity of the main substance in the presence of accompanying substances.

This study is concerned with the influence exerted by the nature and concentration of 1 : 1 electrolytes (LiCl, KCl, and CsCl) on the rate of diffusion mass-transfer of cobalt(II) chloride in porous-glass membrane. The existence of Co^{2+} cations in aqueous solutions in the form of stable hexa-aqua complex $[Co(H_2O)_6]^{2+}$, possibility of their direct photometric determination, and negligibly small adsorption on the silica surface [8] strongly simplify the formulation and solution of the problem by making it possible to distinguish the nature and concentration of supporting electrolytes as the main potential factors influencing the diffusion coefficient.

The porous-glass membrane with a predominant pore radius r_p = 45 nm and porosity δ = 31.3% was hermetically fixed between the feeding and receiving cells. Working solutions with a constant concentration of $CoCl_2$ (0.5 M) and a concentration of alkali metals within the range 0.5–3.0 M were used. The dynamics of the diffusion transport of $CoCl_2$ was judged from the results of a direct photometric determination of the amount of Co^{2+} ions in the receiver cell at a wavelength λ_{max} = 510 nm [9]. It is important to note that the profile of the absorption band peaked at 510 nm was completely preserved over the entire range of concentrations of the supporting electrolytes on both sides of the membrane, which indicates that the form of the $[Co(H_2O)_6]^{2+}$ cation being transferred remains unchanged. The diffusion was measured at 20°C under continuous agitation of the solutions. A steady-state flow across the membrane was attained in all cases 20–30 min after the beginning of a run. The fact that linear time dependences of the amount of $CoCl_2$ transferred, Q–τ, were observed made it possible to determine the diffusion rate and diffusion coefficients by using the first Fick's law

$$dQ/d\tau = DS\delta\Delta c/h. \quad (2)$$

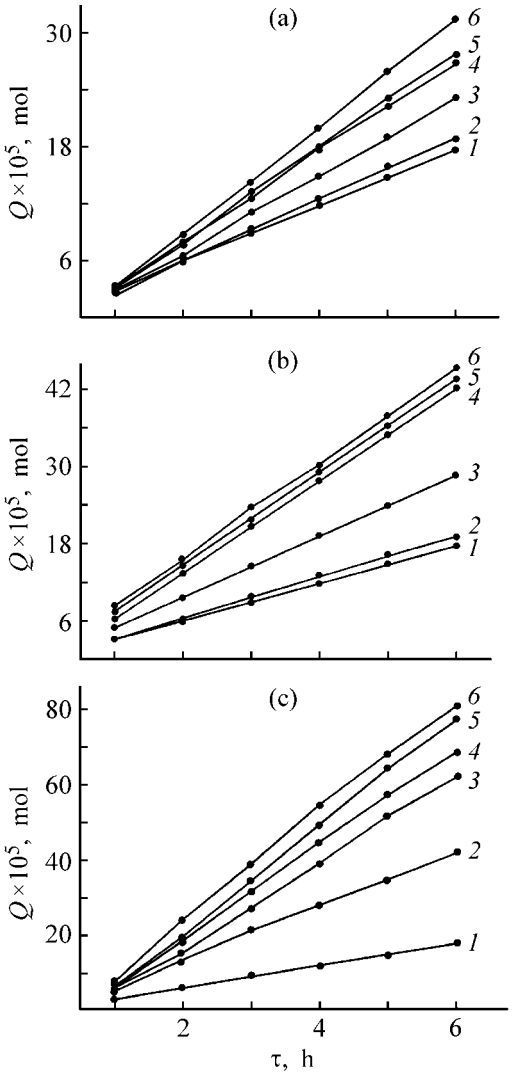

Fig. 1. Amount Q of $CoCl_2$ transferred across the membrane vs. time τ for (*1*) its 0.5 M solution and for solutions containing (a) LiCl, (b) KCl, and (c) CsCl. Solution concentration (M): (*2*) 0.5, (*3*) 1.0, (*4*) 1.5, (*5*) 2.0, and (*6*) 3.0.

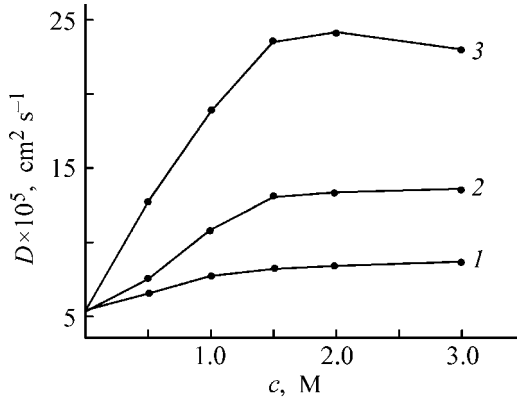

Fig. 2. Membrane diffusion coefficient D of cobalt(II) chloride vs. concentration c of (*1*) LiCl, (*2*) KCl, and (*3*) CsCl solutions.

Here $S\delta$ is the free cross-section of a membrane, equal to its geometric area with a correction for the porosity; $\Delta c/h$, the difference of solution concentrations before and after the membrane of thickness h.

Because the $CoCl_2$ concentration in the receiving cell, $c_{out} \sim 10^{-3}$ M, was considerably lower than that in the feeding cell (c_{in}), the gradient in Eq. (2) was taken in all the experiments to be $\Delta c/h \cong (c_{in} - c_{out})/h \cong c_{in}/h$.

The kinetic dependences in Fig. 1 reflect the reliably recorded acceleration of the diffusion of cobalt(II) chloride, caused by an increase in the concentration of the supporting electrolytes. The degree of their activating action strongly increases in the order LiCl–KCl–CsCl, which provides in the last case an increase in the rate of the $CoCl_2$ transport across the membrane by more than a factor of 4. The character and extent of the influence exerted by alkali metal chlorides on the $CoCl_2$ mobility is even more clearly reflected by the dependences shown in Fig. 2. The increase in the diffusion coefficient, caused by the presence of supporting electrolytes, is more than considerable and, on the whole, corresponds to the increase in their intrinsic mobility in the above order, which is determined by the decrease in the effective size of hydrated cations [10]. Thus, it is apparent that cobalt chloride is involved in the high-intensity diffusion flow of the accompanying salts, and this involvement is the more pronounced, the higher their concentration.

It should be noted that, in all cases, the $CoCl_2$ diffusion coefficient mainly increases within the range bounded by the concentration of the supporting electrolytes (~1.5 M) (Fig. 2). This feature is to a certain extent consistent with the known decrease in the viscosity of aqueous KCl solutions in thin quartz capillaries, which ceases at a concentration of about 1 M [11, 12]. This gives reason to believe that the principal factor governing the nature of diffusion and the degree of its acceleration is the specific interaction of salts of alkali metals with water in the pore space of the membrane. It is well known [10] that the viscosity of free CsCl solutions is lower at any concentration than that of water; the K^+ cation causes only a weakly pronounced disintegration of its structure, whereas Li^+ is a positively hydrated ion. Accordingly, the run and relative positions of the curves describing the dependences of the membrane diffusion coefficient of $CoCl_2$ on the concentration of supporting electrolytes (Fig. 2) are determined by the decrease in the viscous resistance of pore solutions and by the increase in diffusion mobility in the order LiCl–KCl–CsCl.

CONCLUSIONS

(1) An increase in the concentration of alkali metal chlorides in the range 0.5–3.0 M is accompanied by acceleration of the $CoCl_2$ diffusion transport in glass membrane, and the degree of this acceleration grows in the order Li–Cl–KCl–CsCl.

(2) The most probable factor responsible for the influence exerted by accompanying electrolytes on the mass transfer of $CoCl_2$ is the specific interaction of alkali-metal cations with water from the pore space of the membrane.

Abstract—Experimental data demonstrate that a study of accelerated aging can enable prognostication of the working capacity and storage life of polymeric formulations used in aircraft components on the basis of changes in thermogravimetric constants of these polymeric formulations.

DOI: 10.1134/S1070427206100326

To determine whether or not promising polymeric composite materials can be used in aircraft components, it is necessary to know, with account of exploitation requirements, their real service and storage life.

Only prolonged full-scale tests give reliable results in assessment of the aging of polymeric composites, but, frequently, these results are out of date by the time they are obtained. A way to make aging studies of polymeric formulations shorter is to intensify the action of climatic factors and develop accelerated laboratory techniques simulating various climatic conditions [1].

To perform scientifically substantiated accelerated studies, it is necessary to make a quantitative assessment of the correlation between the effect of climatic factors and changes in physicochemical and, consequently, performance characteristics of a polymeric composite material.

Despite the wide variety of diverse factors that impair the durability and working capacity of polymeric aircraft components, the key role is attributed to the action of radiation, temperature, and oxygen on the polymeric composites [2, 3].

Chemical transformations that occur in polymers in the course of aging mainly belong to the following two processes: structuring and destruction of macromolecules in a material. The first process leads to cross-linking of separate chains of the polymer to give 3*D* structures. This improves the strength of the polymeric composite, but it becomes rigid and brittle and loses elasticity, which, naturally, results in loss of the required performance characteristics. The second process, destruction, leads to rupture of molecular chains and reduces the molecular weight of the polymer, with the result the polymeric composite becomes soft and sticky and loses its mechanical strength and, consequently, fails to satisfy the performance requirements. Therefore, the basic problem of stability of a polymeric composite against aging should be assessed on the basis of changes in its chemical structure under the action of ambient conditions (ionizing radiation, temperature, oxygen).

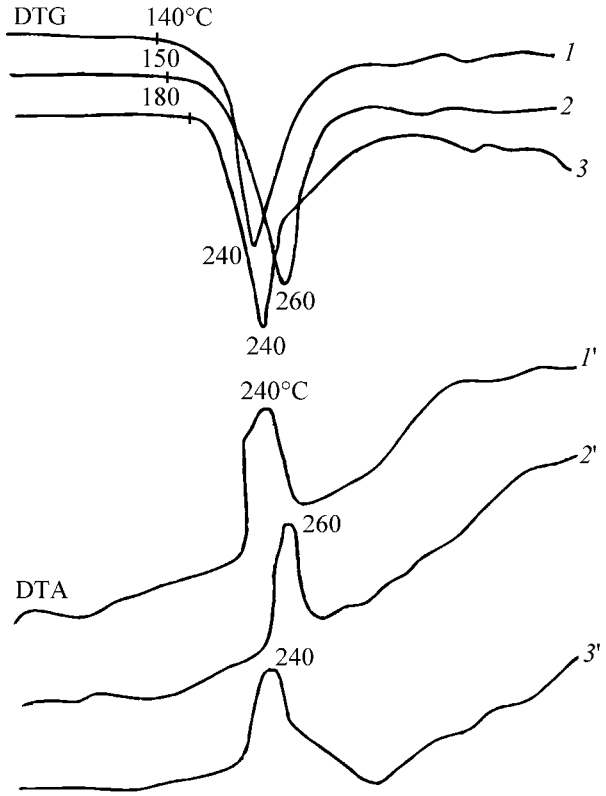
In this study, we chose as an object of analysis a polymeric formulation composed of a copolymer of vinyl chloride and vinyl acetate (A–15–OM), urethane prepolymer (SKU–PFL), and triisocyanate (TT–75), at an NCO/OH ratio of 1.2. We introduced diphenylsilanediol (DPSD) into the polymeric formulation as an additional cross-linking compound.

We chose as a criterion for assessing changes in the chemical structure the effective activation energy E_A of thermooxidative destruction of the polymeric formulation, found from thermogravimetric characteristics.

The thermogravimetric characteristics were determined in a dynamic thermogravimetric analysis (DTG), combined with differential thermal analysis (DTA), on an MOM derivatograph (Hungary) in air, with the temperature raised at a rate of 2.5–5°C/min in the range 100 – 600°C. The kinetic parameters of thermooxidative destruction were determined by a procedure we developed.

The working capacity of the polymeric composite was assessed on the basis of changes in tribological parameters determined by the required performance under severe climatic conditions.

To confirm our choice, we studied how the cross-linking compound DPSD, which allows purposeful modification of the structure of the polymeric composite, affects the thermooxidative destruction of the formulation. This was done by analysis of changes in the effective activation energy (see figure).



As can be seen from the figure, introduction of a DPSD additive changes the shape of the thermogravimetric curves and shifts the temperature peaks, which indicates that the structure of the polyurethane formulation changes and, consequently, so does the effective activation energy of thermooxidative destruction.

An additional, particularly important factor is that the introduction of a cross-linking compound affects both the structure of the composite being formed and the working capacity of polymeric aircraft components. The experimental results we obtained are listed in Table 1.

It can be seen from Table 1 that the modification of the physicochemical properties of the polymeric formulation upon introduction of the cross-linking compound changes the activation energy of thermooxidative destruction of the formulation.

In addition, the working capacity of the polymeric composite under severe climatic conditions also changes, with there existing a certain activation energy below which the working capacity of the polymeric formulation starts to fall steeply and its physicochemical properties degrade. Therefore, it was of interest to find out whether derivatographic analysis can be used to prognosticate the durability or service life of polymeric formulations by determining how the activation energy changes in the course of destruction of a polymeric formulation in its accelerated aging under heating or irradiation and by extrapolating the rate or time of the reaction to real aging conditions.

Previous studies have shown that polymeric composites subjected to the action of ionizing radiation change their physicochemical properties and, consequently, their working capacity under severe climatic conditions. Therefore, it was of interest to analyze

Thermogravimetric curves for a polyurethane formulation with varied content of DPSD. DPSD content (wt %): (*1*, *1'*) 0, (*2*, *2'*) 10, and (*3*, *3'*) 15.

changes in the activation energy of thermooxidative destruction of a polymeric formulation under exposure to ionizing radiation (Co^{60} gamma photons). Table 2 lists the experimental data we obtained.

It can be seen that the ionizing radiation causes accelerated aging of the polymeric formulation and changes its structure, and it is this fact that leads to a decrease in the activation energy of thermooxidative destruction.

Thus, the results we obtained demonstrate that processes of accelerated aging can be studied in order to prognosticate the service capacity and storage life

	500 Gy	169.94	1500

of polymeric composites for aircraft components on the basis of changes in the effective activation energy of thermooxidative destruction of the corresponding polymeric composite materials.

Table 3 lists the results obtained in a study of how the activation energy of thermooxidative destruction changes in the course of accelerated aging of polymeric formulations.

As can be seen from Table 3, the activation energy decreases in accelerated aging, and does so to varied extent for different polymeric materials. Therefore, the results obtained make it possible to prognosticate the real service life of polymeric composites in aircraft components by comparing the activation energies obtained with those determined previously for known polymeric formulations. Thus, the procedure we developed can be used for comparative evaluation of the time during which the performance characteristics of polymeric formulations are preserved. This should be done by establishing a correlation between the accelerated and natural aging processes.

In addition, analysis of the results obtained suggests that the derivatographic technique allows identification of aircraft components by the composition of a polymeric formulation and enables prognostication of the performance characteristics of polymeric formulations of the same composition. This is so because there exists a clearly pronounced correlation between the results of assessment of the working capacity of a polymeric formulation and its activation energy of thermooxidative destruction. The results obtained in the study were confirmed by full-scale tests of aircraft components.

CONCLUSIONS

(1) A correlation was established between the working capacity and storage life of polymeric composites, on the one hand, and changes in derivatographic constants, on the other.

(2) It was shown that changes in the effective activation energy of thermooxidative destruction of polymeric formulations in accelerated aging can be used to prognosticate the time during which the performance characteristics of the aircraft components fabricated from these formulations are preserved.

Abstract—The mechanism of the rearrangement of polyarylene benzimidoates into *N*-phenyl-substituted aromatic polyamides and poly(*N*-arylenebenzamides) was studied.

DOI: 10.1134/S1070427206100338

Previously we have studied macromolecular rearrangements of polyarylene benzimidoates (PABIs) [1, 2] heated to 260–340°C without solvent or to 240°C in diphenyl ether. Depending on the PABI structure, the reaction products are either *N*-phenyl-substituted aromatic polyamides (*N*-PAPAs) or poly(*N*-arylenebenzamides) (P-*N*-BAs). The transformation follows the schemes

Ia–Ig **IIIa–IIIg**

IId–IIk **IVd–IVk**

where X = *p*-C_6H_4 (**a**), *m*-C_6H_4 (**b**), (*p*-$C_6H_4)_2O$ (**c**); Y = *p*-C_6H_4 (**d**), *m*-C_6H_4 (**e**), (*p*-$C_6H_4)_2CMe_2$ (**f**), (*p*-$C_6H_4)_2SO_2$ (**g**); Z = *p*-C_6H_4 (**h**), *m*-C_6H_4 (**i**), (*p*-$C_6H_4)_2O$ (**j**), (*p*-$C_6H_4)CH_2O$ (**k**). Hereinafter, the first literal index in the compound designations refers to fragment X in compounds **I** and **III** and fragment Z in compounds **II** and **IV**, and the second literal index, to fragment Y.

The resulting polymers exhibit high resistance to thermal oxidative degradation, good solubility, and relatively low softening point. The structures of the polymers were confirmed by instrumental methods, but the reaction mechanism remained unclear. Therefore, the goal of this study was to elucidate the mechanism of the rearrangement of PABIs into *N*-PAPAs and P-*N*-BAs.

To this end, we mixed compounds **Ia**–**Id** and **IIk**–**IIf** in a 1 : 1 ratio. The rearrangement was performed in diphenyl ether for 20 h at 240°C. The reaction product was subjected to thermomechanical analysis (Fig. 1). Two transitions to the viscous-flow state were revealed in the TMA curve. Taking into account that the depolymerization and cross-linking did not occur, block copolymers were absent initially and were not formed in the process, and the polymer was fully X-ray-amorphous, these two transitions should be assigned to the glass transitions of the two polymers [3, 4]. The artificially prepared analogous blend of the rearrangement products showed an essentially similar TMA curve, suggesting the intramolecular reaction mechanism. Otherwise, a single random co-

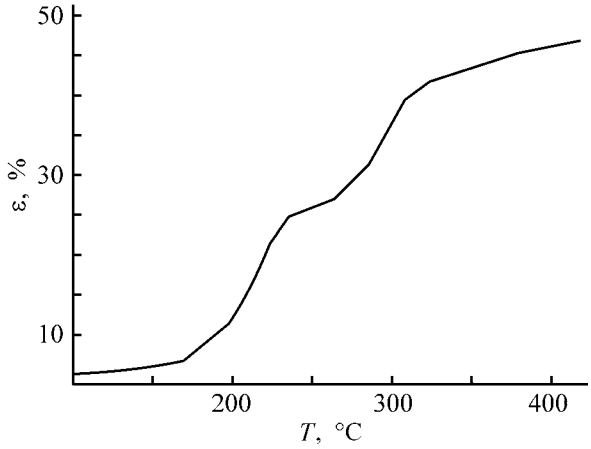

Fig. 1. TMA curve: (ε) strain and (*T*) temperature.

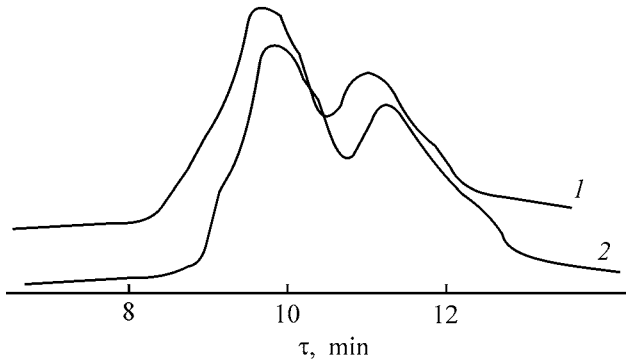

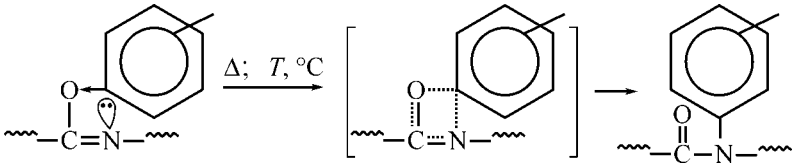

Fig. 2. Gel chromatograms of (*1*) PABI **Ic**–**Ie** and (*2*) its rearrangement product, *N*-PAPA. (τ) Time.

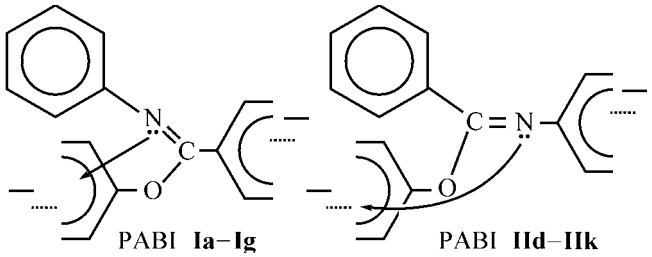
polymer would be obtained, and the TMA curve would show a single glass transition point.

We examined PABI **Ic**–**Ie** and its rearrangement product, *N*-PAPA, by gel permeation chromatography (Fig. 2). The GPC curve of PABI shows a characteristic bimodal molecular-weight distribution, which does not change essentially in going to *N*-PAPA. Furthermore, the polymers have virtually equal molecular weights: M_w 29 120 and 28 970, M_n 16 850 and 16 300 for the PABI and *N*-PAPA, respectively. Thus, the rearrangement does not involve cleavage of the polymer chain.



A model compound, benzanilimino ester, also undergoes an intramolecular rearrangement into *N*-phenylbenzamide by the known mechanism of the Chapman rearrangement [5].

These facts show that the mechanism of the rearrangement of the low- and high-molecular-weight compounds is similar and starts with the nucleophilic attack on the aromatic ring by the nitrogen atom. The nitrogen migrates by the intramolecular pathway via a four-membered transition state:

The rearranging fragment of a macromolecule can form such a transition state if it is compact and the chain is flexible.

In view of the aforesaid, it becomes clear why PABIs **I** rearrange more slowly (see table) than PABIs **II**. The main difference between these polymers is in the position of the rearranging fragment in the polymer chain:

PABI **Ia**–**Ig** PABI **IId**–**IIk**

PABIs **I** rearrange more slowly because the reactive fragment is oriented along the chain, whereas in PABIs **II** it is more compact; furthermore, the pendant group is more mobile than units in the back-bone [6].

Our results show that, in diphenyl ether, more flexible polymers rearrange faster than more rigid polymers, whereas in the melt, the rigid polymers rearrange faster.

EXPERIMENTAL

A thermomechanical analysis was performed on a Zetlin device at a constant load of 0.08 MPa and heating rate of 5 deg min^{-1}.

The X-ray phase analysis was performed on a D-8 Advance diffractometer (Bruker AXS), Cu_{K_α} radiation, graphite monochromator.

Gel permeation chromatography of polymers was performed on a Waters chromatograph, using columns packed with U-Styrogel Linear; refractometric detector, solvent tetrahydrofuran, T = 20°C, flow rate 0.3 mol min^{-1}; Maxima data processing system, calibration against polystyrene references.

The PABIs were prepared in a 50-ml three-necked flask equipped with a stirrer and inlet and outlet tubes for argon. The flask was successively charged in an argon flow with 0.01 mol of bisphenol and *N*-methyl-2-pyrrolidone; the mixture was homogenized. Then 0.02 mol of triethylamine and 0.01 mol of imidoyl chloride were added with vigorous stirring. The homogenized reaction mixture was heated to 170–180°C. After the lapse of 17–18 h, the product was precipitated into 2% aqueous ammonia, filtered off, washed

with a 1% solution of sodium bisulfite and with water, and vacuum-dried at 60–70°C to constant weight.

P-*N*-BAs and *N*-PAPAs were prepared by rearrangement of the corresponding PABIs in an Ar atmosphere in a melt and in DPE.

CONCLUSIONS

(1) The rearrangement of polyarylene benzimidoates in the melt and in diphenyl ether occurs by the intramolecular mechanism, without cleavage of the polymer chain and similarly to the rearrangement of the model benzanilimino ester, whose mechanism consists in the nucleophilic substitution in the aromatic ring.

(2) In diphenyl ether, more flexible polymers rearrange faster than more rigid polymers, whereas in the melt, more rigid polymers rearrange faster.

Abstract—Complexation between chitosan and Levomycetin antibiotic and the possibility of formation of complexes of stoichiometric composition was studied.

DOI: 10.1134/S107042720610034X

Because of the low toxicity and biological activity, natural polysaccharides, chitin and chitosan, are of particular interest for medical applications [1–4]. Owing to its film-forming ability, chitosan can be used to produce coatings for temporal protection and treatment of wounds and burns [5, 6]. Recent studies have shown that chitosan is promising as a polymer matrix, carrier of medicinals, which makes their action longer and toxicity lower [7, 8]. In this context, synthesis of chitosan complexes with medicinals exhibiting antimicrobial activity for treatment of burns and open is an urgent task.

The aim of this study was to examine the complexation of chitosan (CTS) and the antimicrobial preparation Levomycetin (LM) and to obtain on their basis films with controlled release of the active medicinal.

EXPERIMENTAL

CTS obtained from shells of Far-Eastern crabs with initial number-average degree of polymerization (P_n) of 860, degree of deacetylation in the range 70–75%, and humidity of 4.5% was used in the study. Levomycetin, a pharmaceutical preparation, was taken without additional purification (as purchased). The IR spectra were recorded on a Specord-M 80 spectrophotometer in KBr pellets and in films. The ^{1}H NMR spectra were measured in an HCl solution in D_2O on a Bruker AM 300 instrument. The UV spectra of the samples in 1% acetic acid were measured on a Specord M-40 spectrophotometer. The pH values of the solutions were determined with an ANION 4100 pH-meter. The specific rotation [α_D^{25}] was measured on a Model 141 Perkin–Elmer polarimeter. The compounds synthesized were purified to remove unreacted levomycetin by double reprecipitation from solution into isopropyl alcohol, with the subsequent washing of the precipitate with isopropyl alcohol. Films were produced from a solution of the CTS–LM complex with a 1 : 1 molar ratio of components in 1% acetic acid by casting on glass with subsequent drying in air at room temperature. A three-layer film was produced by successive castings on glass of a 2% solution of chitosan, a 2% solution of CTS–LM complexes (at 1 : 1 molar ratio), and again a 2% chitosan solution. After each casting, the substrate was dried in air at 25°C and, finally, the resulting three-layer film was heated at 80°C for 1.5 h. To study the release of the medicinal, the films were placed in a test tube filled with a 0.01 N KOH solution (10 ml, pH 10). The release of the medicinal was monitored with a Specord M-40 spectrophotometer by the absorption band at λ = 260 nm.

Levomycetin is a broad-spectrum antibiotic [9]. It has the structure of a neutral compound containing no charged groups, which makes impossible any specific ionic interaction between LM and the polymer matrix under study. However, the presence of two hydroxy and one amide groups enables formation of hydrogen bonds between the medicinal and chitosan.

The electronic spectrum of LM at its concentration of 1×10^{-4} M in 1% acetic acid contains one absorption peak at 270 nm. On addition of a comparable amount of chitosan to the solution, the intensity of the LM absorption peak increases and its position shifts to shorter wavelengths by 8–10 nm. The spectral changes indicate that chitosan affects the electron system of LM and a complex compound is formed. It was found using the isomolar series method [10] that the ratio of the stoichiometric coefficients for the CTS–LM complex is 1 : 1 (Fig. 1). The complexation constant (β_c) was calculated by the method of molar ratios [10] to be $(2.4 \pm 0.3) \times 10^4$ l mol^{-1}.

The complexes of CTS with LM were isolated, purified, and studied by IR, UV, and ^{1}H NMR spectroscopies; their angles of rotation were also determined. The electronic spectra of the polymer complexes show a shift of the absorption peak of LM in the CTS–LM complex to lower wavelengths, compared with that in the LM spectrum (λ_{max} = 258–260 and 270 nm, respectively). Chitosan has no absorption in this spectral range. The absorption bands at 1730 cm^{-1}, characteristic of stretching vibrations of the carbonyl group of substituted amine, and at 1580 cm^{-1}, associated with stretching vibrations of the benzene ring in LM, appear in the IR spectra of the complexes. In addition, the IR absorption peaks of OH groups are shifted to lower frequencies by 30–50 cm^{-1} (3250–3150 cm^{-1}), and those of C–O groups of glycoside, by 10–15 cm^{-1} (1200–1000 cm^{-1}). This confirms that intermolecular hydrogen bonds are formed between the molecules of the medicinal and chitosan. Comparison of the ^{1}H NMR spectra of CTS, LM, and CTS–LM complex shows that the proton signals from the complex are shifted downfield (σ_H 3.21 ppm for the complex and 3.01 ppm for CTS). In this case, the redistribution of the electronic density, caused by the complexation, results in the downfield shift of the H^2 peak. The values of the specific rotation [α_D^{25}] were determined for CTS, LM, and CTS–LM complex to be +23.0, +3.5, and +1.0, respectively.

Changing the molar ratio between the components of the complex from 1 : 0.25 to 1 : 3 and raising the time and temperature of complexation affect the content of the medicinal in the reaction products only slightly (Table 1).

The kinetics of LM release was monitored by the accumulation of the medicinal in a KOH solution. On submerging CTS–LM films (one- and three-layer) in an aqueous–alkaline solution, their swelling occurs. A typical kinetic curve of LM release from a one-layer CTS–LM film formed at 25°C is shown in Fig. 2.

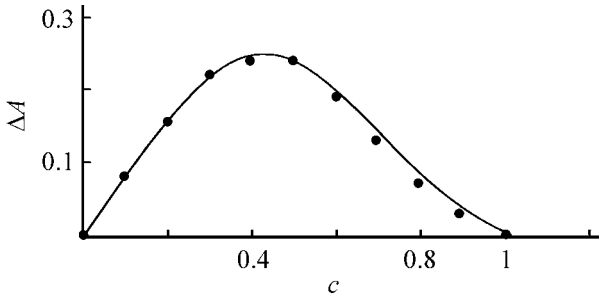

Fig. 1. Isomolar diagram. [CTS] + [LM] = 5×10^{-4} M, pH 4.1, l = 1 cm. (ΔA) Change in optical density, $c = c_{LM}/(c_{LM} + c_{CTS})$.

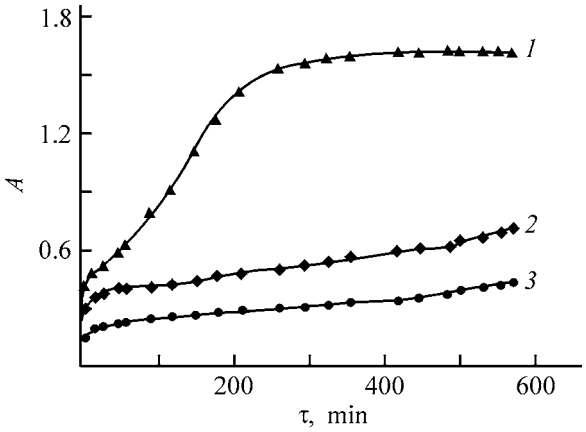

Fig. 2. Kinetic curves of LM release from films based on the CTS–LM complex. (A) Optical density and (t) time. Film: (*1*) one-layer (T = 25°C), (*2*) three-layer (T = 80°C), and (*3*) one-layer (T = 80°C).

The complete release of LM from this film takes 6.5 h. The time of complete release of LM is about 12 days for a three-layer film and markedly decreases (to about 7 days) for a heated one-layer film. At the same time, the complete release of LM from a film prepared

Table 1. Influence of the complexation conditions on the content of the medicinal in reaction products

CTS–LM molar ratio	τ, h	T, °C	LM content of the complex, %
1 : 1	2	60	0.8
1 : 1	6	60	1.3
1 : 1	10	60	1.4
1 : 1	24	60	1.7
1 : 0.25	6	60	1.2
1 : 0.5	6	60	1.3
1 : 2	6	60	0.8
1 : 3	6	60	1.2
1 : 1	6	20	0.7
1 : 1	6	40	1.0
1 : 1	6	90	1.4

Table 2. Dependence of the effective rate constants of LM release on the conditions of formation of films based on the CTS–LM complex

Film	T, C°	$k_{eff} \times 10^{-3}$, s^{-1}
One-layer	25	–4.30
"	80	–1.10
Three-layer	80	–0.87

by mechanical mixing of 2% acetate solutions of LM and CTS takes 30 min. The effective rate constant of LM release (Table 2) was found by plotting the kinetic curves in the coordinates of the equation

$$\ln [A]_t = \ln [A]_0 - k_{eff}\tau,$$

where A is the optical density, and τ, the time of LM release.

It can be seen from the data of Table 2 that the rate of LM release is higher for films formed at 25°C. Probably, a decrease in the rate of release from heated films is due to structural changes in the polymer matrix in the course of the heat treatment. Thus, the rate of LM release from the films depends on their preparation conditions.

The experimental data obtained show that use of polymer coatings based on CTS–LM complexes provides quite acceptable terms of a continuous release of the medicinal into a wound, i.e., allows a prolonged action of the medicinal during several days.

CONCLUSIONS

In a study of some aspects of complexation between chitosan and Levomycetin, the conditions of controlled release of the medicinal from a polymer coating were chosen and the formation of complexes of the stoichiometric composition was revealed.

Abstract—A method was developed for synthesis of high-purity tris(trimethylsilyl) borate by reaction of trimethylacetoxysilane with powdered boric acid.

DOI: 10.1134/S1070427206100351

Tris(trimethylsilyl) borate $B(OSiMe_3)_3$ (TMSB) is used as a monomer and comonomer in production of polyorganyl borosiloxane caoutchoucs for improving their technical parameters, as a catalyst for polymerization processes, and as an adsorbent of neutrons. It is recommended as a means of protection of surfaces subjected to action of an electric arc and as a half-product in synthesis of silicon-and-boron-containing compounds [1]. High-purity TMSB has been suggested by the authors for use in the microelectronic technology for plasmochemical deposition of thin layers of boron-doped silicon dioxide, with a boron content of 1.5 to 10 wt % [2].

Previously, TMSB has been synthesized in a 20% yield by heating hexamethyldisiloxane with B_2O_3 in an autoclave at 350°C or by boiling trimethylchlorosilane with H_3BO_3 (yield 26.5%) [3].

The yield of TMSB could be raised to 81% on heating hexamethyldisilthiane with boric acid to 120°C [4]. However, use of the difficultly accessible and foul-smelling hexamethyldisilthiane is unfeasible for industry. The reaction of hexamethyldisilazane with ammonium borate in a solvent [5] or with boric acid at 110–120°C in the course of 10 h [6] produced TMSB in 40 and 72% yields, respectively.

To be used in micro- and optoelectronics, TMSB should be of special purity. This forced the authors to develop a method for synthesis of high-purity TMSB by heating trimethylacetoxysilane with powdered boric acid of chemically pure grade at 110°C:

$$B(OH)_3 + 3MeCOOSiMe_3 \rightarrow B(OSiMe_3)_3 + 3MeCOOH.$$

A mixture of 20 g (0.15 mol) of trimethylacetoxysilane and 3 g (0.05 mol) of finely ground boric acid of chemically pure grade was heated at 110°C for 1 h. After acetic acid was evaporated (8.4 g, 97%), the residue was distilled in a vacuum. The yield of TMSB was 7.95 g (95%), bp 70°C (19 mm Hg), $n_d^{20} = 1.3865$, in agreement with published data [3]: bp 48°C (5 mm Hg), $n_d^{20} = 1.3860$.

According to GLC data, TMSB purified by rectification in a vacuum on a quartz column is free of even trace amounts of organic impurities. According to the results of an atomic-absorption analysis, the content of metals (Na, K, Ca, Fe, Ni, Co, etc.) does not exceed 10^{-5}–10^{-6} wt % for each of the metals.

CONCLUSION

A method for synthesis of high-purity tris(trimethylsilyl) borate for micro- and optoelectronics in a 92% yield was developed. The method is based on the reaction of trimethylacetoxysilane with powdered boric acid of chemically pure grade at 110°C for 1 h, with the subsequent purification of the product by rectification in a vacuum.

Abstract—Physicochemical and catalytic properties of H-pentasils in *m*-xylene isomerization and toluene methylation were studied.

DOI: 10.1134/S1070427206100363

Control of the zeolite pore size and acid properties by elimination of the strongest acidic centers and by variation of their nature is one of probable ways to modify the catalytic and molecular-sieve properties of zeolites. Chemical modification of the zeolite surface with compounds of B, Mg, P, Si, etc. [1–3], which have a para-orienting effect upon the activity of zeolite catalysts in transformations of aromatic hydrocarbons, is promising in this respect.

Since pentasil-type high-silica zeolites offer wide opportunities in oil refining, it is interesting to study how modification of such zeolites with a phosphorus compound will affect their catalytic and physicochemical characteristics in *m*-xylene isomerization and toluene methylation.

EXPERIMENTAL

Pentasil-type zeolite with a SiO_2/Al_2O_3 molar ratio of 58 was used. It was converted into the NH_4 form by ion exchange as in [4] and then into the H form by thermal decomposition of the NH_4 form for 4 h at 500°C. Catalysts modified with 0.5–4 wt % phosphorus were prepared by impregnation of the zeolite H form with ammonium hydrophosphate for 6 h at 80°C. The samples were dried in air for 16 h, then for 4 h in a desiccator at 110°C, and finally calcined in a muffle for 4 h at 550°C.

The catalysts obtained were subjected to chemical analysis, X-ray phase analysis, and adsorption analysis and studied by IR spectroscopy.

The IR spectra were recorded on a Specord spectrophotometer. Zeolites were compacted into thin pellets containing 6–8 mg of the substance per square centimeter. Before adsorption, they were heated in a vacuum for 2 h at 500°C. Adsorption of pyridine was performed at room temperature and saturated vapor pressure. The IR spectra in the region of aluminosilicate framework vibrations were recorded with samples pelletized with KBr. Adsorption measurements were performed by the method described in [4].

The experiments were performed on a flow-type device with a fixed catalyst bed (4 cm^3), in a plug-flow reactor, at atmospheric pressure within the 250–450°C range, volumetric flow rate of the raw material of supply 1 h^{-1}, and m-$C_6H_4(CH_3) : H_2$ and $C_7H_8 : CH_3OH : H_2$ molar ratios of 3 : 1 and 2 : 1 : 2, respectively. The reaction products were analyzed chromatographically [5].

The X-ray phase analysis showed that the crystalline structure of the zeolite is preserved during modification with ammonium hydrophosphate. The IR study confirmed this conclusion. In the region of aluminosilicate framework vibrations (400–1300 cm^{-1}), which are the most sensitive to the degree of crystallinity of the zeolite, the bands of the external Si–O– bonds at 550–560 and 790–800 cm^{-1} remain virtually unchanged upon modification with phosphorus. An increase in the intensity of the high-frequency branch of the asymmetrical stretching band (1000–1100 cm^{-1}) may be due to interaction of phosphorus atoms with structural aluminum atoms [6].

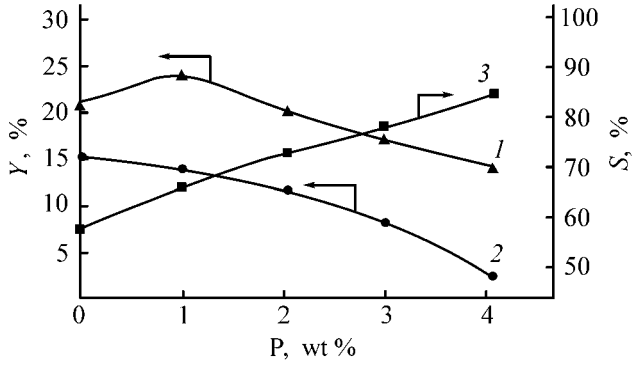

Fig. 1. Yield Y of (*1*) *p*-xylene and (*2*) *m*-xylene, and (*3*) selectivity S with respect to *p*-xylene vs. the phosphorus content of H-pentasil.

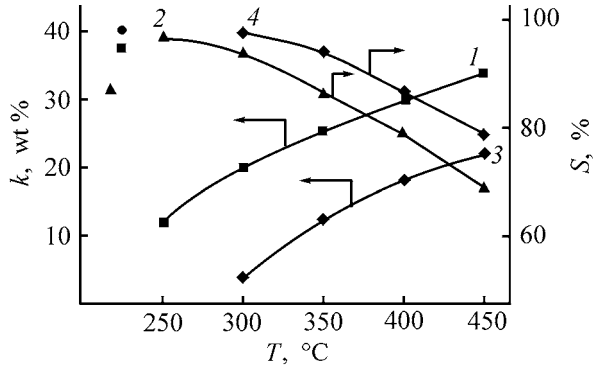

Fig. 2. Conversion k of (*1*) *m*-xylene and (*3*) toluene, and selectivity S with respect to *p*-xylene vs. temperature T in (*4*) isomerization of *m*-xylene and (*2*) methylation of toluene.

Analysis of the activity and selectivity of the modified catalysts shows that the phosphorus content strongly affects the *m*-xylene isomerization and toluene methylation. As can be seen from Fig. 1, the yield of *p*-xylene somewhat grows as the phosphorus content increases to 1.0 wt %. At a phosphorus content higher than 2 wt %, the *p*-xylene content noticeably decreases, but the para-selectivity substantially increases (from 70 to 85%). A different trend is observed for *o*-xylene. An increase in the phosphorus content decreases the *o*-xylene content within the entire range of phosphorus contents and, especially at those higher than 2 wt %. For example, the *o*-xylene yield decreases from 12.0 to 1.2% when the phosphorus content is raised from 2 to 4%. In this case, the condensate is enriched in *p*-xylene, i.e., the selectivity with respect to *p*-xylene formation increases.

Adsorption of water and benzene vapors on H-pentasils (HP) modified with phosphorus (P/P_s = 0.1, T = 20°C)

Zeolite	Adsorption, $cm^3\ g^{-1}$	
	H_2O	G_6H_6
NP	0.078	0.046
0.5% P/NP	0.071	0.040
1.0% P/NP	0.059	0.031
2.0% P/NP	0.043	0.023
3.0% P/NP	0.018	0.0084
4.0% P/NP	0.0083	0.0037

The temperature dependence of the *m*-xylene and toluene conversion and selectivity with respect to *p*-xylene on H-pentasil modified with 4 wt % phosphorus is shown in Fig. 2. As seen, a decrease in the conversion of *m*-xylene and toluene is accompanied by an increase in the para-selectivity of the catalyst. At 250°C and 12% conversion of the aromatic hydrocarbon, the selectivity with respect to *p*-xylene reaches 95%. This shows that *p*-xylene is the primary product of *m*-xylene isomerization and toluene methylation on the phosphorus-containing zeolite.

The differences in the distribution of the products of *m*-xylene isomerization and toluene methylation and in the selectivity of the reaction on modified pentasils become more understandable when the results obtained are considered from the viewpoint of control of the reaction rate by diffusion into the volume. Reactions in zeolites occur with the diffusion rate determined by the shape and size of both the reacting molecules and zeolite channels (configuration diffusion) [5]. In this case, the increased selectivity with respect to *p*-xylene can be accounted for by the higher diffusion rate of *p*-xylene molecules, which have a smaller kinetic diameter than molecules of *m*- and *o*-xylenes, in the channels of the modified pentasil.

Indeed, the modification with phosphorus is accompanied by a chemical reaction with the zeolite, as judged from a substantial decrease in the intensity of absorption of zeolite OH groups in the IR spectra of the modified samples as compared to the initial zeolite. In addition, polymeric structures of –P–O–P– type probably appear during modification [6], along with PO_4 fragments formed in reactions of phosphorus compounds with zeolite OH groups, which undoubtedly affects the accessibility of the zeolite channels. This, in turn, decreases the zeolite sorption capacity (see table) and is reflected in molecular-sieve properties of pentasil in reactions sensitive to the pore size: *m*-xylene isomerization and toluene methylation.

It is known that a change in the number and strength of acid centers is the main reason for variation of the catalytic activity of zeolites [7]. Since the isomerization is catalyzed by Brønsted acid centers faster than by Lewis centers, a decrease in the Brønsted acidity and a change in the ratio of Brønsted to Lewis acidic centers will affect the catalyst activity [8].

The IR spectra of the initial zeolite and that modified with ammonium hydrophosphate (Fig. 3) show that the band at 3615 cm^{-1} in the region of the stretching vibrations of the strongly acidic bridging OH groups is observed in the spectra of all the samples studied. Its intensity substantially decreases with an increase in the phosphorus content of the sample. This fact suggests that phosphorus partially dealuminates the zeolite and thus neutralizes acid centers situated at entrances into channels or at their intersections [6]. Thus, modification of zeolites with phosphorus decreases the total concentration of hydroxy groups.

In the region of pyridine bending vibrations (1440–1700 cm^{-1}), the spectra of all the samples contain the following pyridinium ion (PyH^+) bands: a band at 1550 cm^{-1} corresponding to Brønsted acid centers (B centers), band at 1450 cm^{-1} belonging to Lewis acid centers (L centers), and band at 1490 cm^{-1}, belonging to B and L centers; their intensity decreases with the phosphorus content increasing from 1.0 to 4.0 wt %. Thus, not only the amount of strong acid centers decreases, but also the ratio of L to B centers increases more substantially, which is probably a reason for the change in the activity and selectivity of the catalysts modified with phosphorus.

Thus, our study showed that modification with phosphorus affects not only the concentration, but also the nature and properties of the active centers in zeolite. In addition, the zeolite channels become narrower. All these facts affect the adsorption and diffusion characteristics of the catalysts, which largely determine the high selectivity with respect to formation of *p*-xylene.

CONCLUSION

Chemical modification of H-pentasil with ammonium hydrophosphate redistributes acid centers and decreases the zeolite sorption capacity. The ratio of Lewis to Brønsted acid centers increases and the zeolite channels become narrower, which makes higher the catalyst selectivity with respect to *p*-xylene.

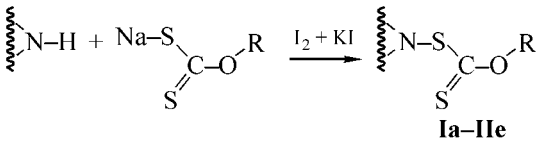
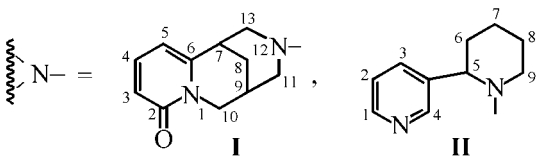
Received November 2, 2005

Abstract—*S*-Amino derivatives of *O*-alkyldithiocarbonic acid were prepared by oxidative condensation of certain alkaloids with sodium xanthates. Some of the compounds synthesized exhibit fungicidal activity.



DOI: 10.1134/S1070427206100375

Alkali metal xanthates are widely used as additives to lubricating oils [1], flotation agents for dressing of various mineral ores [2], and complexing agents [3]. Their effect on the central nervous system and on redox processes in a human body has been examined [4].



The properties of numerous sodium xanthate derivatives showing promise for development of new pesticides have been studied [5]. However, no data are available on the compounds derived from sodium xanthates and natural alkaloids anabasine and cytisine, whose insecticidal and fungicidal properties are well known [6].

Therefore, we studied the oxidative condensation of cytisine and anabasine with a series of sodium xanthates.

The oxidative condensation of sodium xanthates, prepared according to [7], with cytisine and anabasine was performed in an aqueous solution in the presence of I_2 (in 20% KI solution) by the scheme

Ia–IIe

I **II**

where R = C_2H_5 (**a**), C_3H_7 (**b**), $(CH_3)_2CH$ (**c**), C_4H_9 (**d**), $(CH_3)_2CHCH_2$ (**e**).

To determine the optimal reaction conditions, we examined the influence of temperature on the yield of the target products. With compound **Ia** as an example, we performed a series of experiments at temperatures varied in the range 0–80°C.

We found that the highest yield of **Ia**, 86%, is attained at 40°C. At lower temperatures, sodium xanthates are oxidized too slowly, and the yield of **Ia** decreases to 12%; at higher temperatures (60–80°C), the products form an intractable tar. As for the influence exerted by the structure of the alkyl substituent in sodium xanthates, the yields of the target products decrease with an increase in its size and with its branching: C_2H_5– > C_3H_7– > $(CH_3)_2CH$– > C_4H_9– > > $(CH_3)_2CHCH_2$–.

The yields of the anabasine derivatives are considerably lower than those of the cytisine derivatives. This trend may be due to the presence of a bulky pyridyl fragment with a conjugated system in the α-position of the piperidine ring in anabasine. As shown in [8], the anabasine molecule can exist in the form of two stable equatorial conformers produced by rotation of the pyridyl and piperidyl substituents about the C–C bond linking the two rings. At a certain steric orientation of the pyridyl fragment, its π-electron system can interact with the lone electron pair of the piperidyl nitrogen atom, thus decreasing the reactivity of the anabasine molecule.

Compounds **Ia**–**Ie** and **IIa**–**IIe** are crystalline substances readily soluble in many organic solvents.

The structures of **Ia**–**Ie** and **IIa**–**IIe** were confirmed by IR and ^{1}H NMR spectroscopy, and their compositions, by elemental analysis. The IR spectra of **Ia**–**Ie** and **IIa**–**IIe** contain strong bands in the range 1135–1130 cm^{-1}, assigned to the C=S bond [9], and bands at 796–816 cm^{-1} characteristic of C–S stretching vibrations [9].

In the NMR spectra of **Ia**–**Ie**, the protons of the alkaloid core give signals in the expected regions of the spectrum [10]. Three groups of low-field signals belong to protons of the α-pyridone ring. The signals at 7.20 ppm correspond to H^2 ($J_{H^2H^3}$ 8.0 Hz), and a doublet at 6.32 ppm, to H^1 ($J_{H^1H^2}$ 10.0 Hz). A complex multiplet at 3.20–4.40 ppm corresponds to the axial and equatorial protons at C^7. The H^8 protons appear as a doublet at 2.38 ppm. The H^4 and H^6 protons give a group of lines in the range 2.98–3.10 ppm. The methylene H^5 protons appear as a complex multiplet centered at 1.96 ppm. The methyl group of the alkoxy fragment gives a multiplet at 1.18 ppm, and the methylene group, at 4.08 ppm.

Comparison of the spectra of **Ia**–**Id** with that of the starting cytisine shows that the signals of the protons at C^8 and $C^{8'}$ are appreciably shifted. This is apparently due to the fact that the lone electron pair of the adjacent nitrogen atom, occupying the equatorial position in cytisine, becomes axial on replacement of the hydrogen atom by the xanthate group. As a result, the delocalization of the lone electron pair to the antibonding orbital of the C–H bond becomes possible, which results in a stronger shielding of these protons.

In the ^{1}H NMR spectra of **IIa**–**IIe**, the signals of the pyridine ring protons H^1, H^2, H^3, and H^4 are observed in the low field. The H^1 proton gives a doublet at 8.80 ppm; H^4, a doublet at 8.79 ppm; H^3, a quartet at 8.10 ppm; and H^2, a quartet at 6.74 ppm. The methylene protons of the piperidine ring gives a complex multiplet at 3.47–3.80 ppm; the methine proton, a signal at 3.92–4.05 ppm; and the methylene protons remote from the N atom, a multiplet at 1.8–2.5 ppm.

Some of compounds **Ia**–**Ie** and **IIa**–**IIe** were tested for the fungicidal activity. *Fusarium oxysporum* and *Botrytis cinerea* phytopathogenic fungi were used as test cultures. The fungicidal activity was evaluated by the intensity of development of microorganisms on the cultural medium, compared to control experiments without addition of the xanthate derivatives.

We found[1] that *S*-(*N*-anabasinyl) derivative of *O*-isopropoxydithiocarbonic acid **IIc**, tested in vitro, shows a pronounced fungicidal activity against *Botrytis cinerea* (69–74% growth suppression). This compound also showed a pronounced activity against *Fusarium oxysporum* (56–67% growth suppression).

The results were confirmed by biological test statements. Compound **IIc** was recommended for further comprehensive studies as a promising pesticide for agriculture.

EXPERIMENTAL

The IR spectra were recorded on an Avatar-320 spectrometer (KBr pellets), and the ^{1}H NMR spectra, on a Tesla BS-587 spectrometer (operating frequency 80 MHz, C_6D_6, internal reference HMDS). The melting points were determined with a Boëtius heating

[1] Tests were performed at the Research Institute of Plant Protection, Almaty.

stage. The reaction mixtures were analyzed, and the product purity checked, by TLC on Silufol UV-254 plates (eluent benzene–acetone, 1 : 1 by volume).

***S*-(*N*-Cytisinyl) *O*-ethyl dithiocarbonate Ia.** A 0.25-l round-bottomed flask equipped with a mechanical stirrer and a dropping funnel was charged with 0.6 g (0.003 mol) of cytisine and 0.52 g (0.003 mol) of sodium xanthate in 30 ml of water. Then the mixture was heated to 40°C, and a saturated solution of iodine in 20% aqueous KI was added dropwise with stirring. The precipitate was filtered off and recrystallized from EtOH–H_2O (1 : 1).

***S*-(*N*-Anabasinyl) *O*-ethyl dithiocarbonate IIa** was prepared similarly from 0.5 g (0.003 mol) of anabasine and 0.52 g (0.003 mol) of sodium xanthate in 30 ml of water.

The other alkaloid xanthate derivatives were prepared similarly; their characteristics are listed in the table.

CONCLUSIONS

(1) *S*-Amino derivatives of *O*-alkyldithiocarbonic acids were prepared by oxidative condensation of cytisine and anabasine with sodium xanthates.

(2) It was found that *S*-(*N*-Anabasinyl) *O*-isopropyl dithiocarbonate exhibits pronounced fungicidal activity.

Abstract—Modification of polyacrylamide under mild conditions was studied.

DOI: 10.1134/S1070427206100387

Wastes from ore dressing enterprises, concentrated in sludge precipitation tanks of various designs and in sludge ponds, occupy large fields and pollute surface and underground waters and open reservoirs. From the safety viewpoint, processing of finely dispersed coal sludge from sludge ponds and precipitation tanks should improve the environmental situation around ore dressing enterprises.

One of the key problems of flotation is precipitation of fine (smaller than 30 μm) particles, which pass, in the case of modern processing procedures, into the final tailings with the mineral component. Owing to the absence of inexpensive and efficient reagents for concentration of coal fines by flotation, low-ash wastes are discharged into precipitation tanks, which causes of additional loss of the coal combustible mass.

In this study, we examined the possibility of enhancing the flocculation activity of domestic polyacrylamide (PAA), which is the most widely used flocculant with a well-developed production technology.

EXERIMENTAL

A large number of parameters that affect the structure formation in the course of polymer modification should be taken into account. Because of this circumstance, preparation of modified PAA with specified flocculation properties by the reaction of PAA with reactive monomers is a rather difficult problem. These parameters include the type and distribution of charged groups in the polymer chain, chain length, charge density, degree of branching and microstructure of macromolecules, polymer-monomer molar ratio, pH of the medium, temperature, pressure, etc. [1].

Taking into account the above factors, we chose the modification pathway making the structure more branched. PAA was modified with α-propylene chlorohydrin (1-chloro-2-propanol). The reaction of the initial PAA (molecular weight 1×10^6) with the above reagent was performed by the procedure reported in [2]. The resulting modified polyacrylamide (MPAA) was tested in clarification of coal-clay disperse systems. For these purpose, we used coal sludges from the sludge dump of the processing plant, which contains a mixture of coking coals of K, KO, and KS brands. These sludges were preliminarily concentrated using a hydrosizer [3]. The hydrosizer allows preparation of an enriched coal concentrate with permissible ash content and increased ash content in the rock material. After treatment of the coal suspension with the initial ash content A^d = 32.5% in the hydrosizer, we obtained a concentrate with ash content A^d = 10–11%. Then, the coal-clay suspension was treated with a flocculant. The initial coal sludge was sieved (mesh size 800 μm), and, after treatment in the hydrosizer, we obtained a coal-clay suspension with a mean geometrical diameter of particles of the dispersed phase of 2.25 μm (Fig. 1).

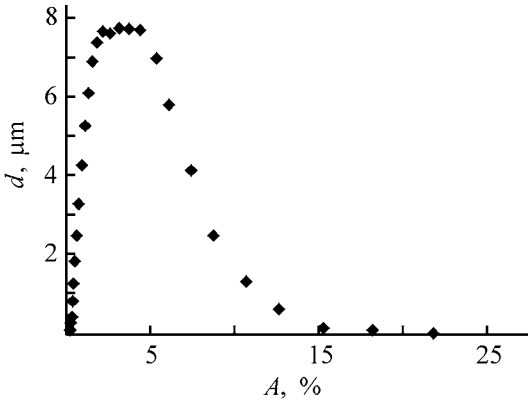

Fig. 1. Particle size distribution of the coal-clay suspension. (*d*) Particle diameter and (*A*) number of particles.

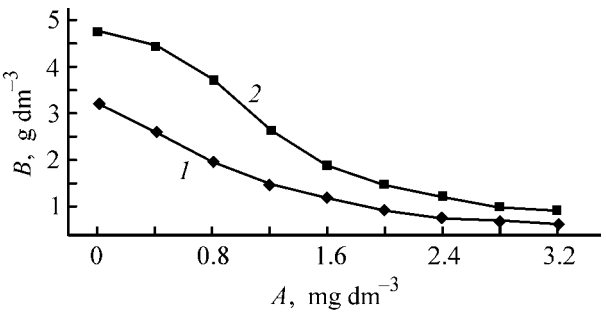

Fig. 2. Weight of the dry residue, *B*, in the clarified coal-clay suspension vs. the flocculant concentration *A*. Flocculant: (*1*) MPAA and (*2*) PAA.

The size distribution of the coal particles was determined on an Analysette-22 device.

The major mineral component of the coal-clay suspension is the clay material. The concentration process of the coal sludge in the laboratory hydrosizer is characterized by the following parameters (%): ash content in the initial coal sludge, A^d 32.6; ash content in the concentrate, A^d 10.5; ash content in the washed coal-clay suspension, A^d 67.8; water content of the concentrate, W^a 23; water content of the flocculated precipitate, W^a 25; yield of the dry concentrate, X_α 78; and yield of the dry coal-clay dispersion, X_α 17.

The flocculation activity of PAA and MPAA was evaluated by the procedure described elsewhere [4]. The dependence of the weight of the dry residue in the clarified coal-clay suspension on the content of flocculant is shown in Fig. 2. As seen, the flocculation activity increases on passing from PAA to MPAA. The flocculation process, as influenced by the flocculation activity of polymers, was described using the following mathematical model. Changes in the content of the solid phase (SP) in the coal-clay suspension with time in the course of treatment with a flocculant are described by

$$dc/dt = -Kcc_f, \quad (1)$$

where $c = c(t)$ is the total content of the solid phase (SP) in the coal-clay suspension (g dm^{-3}); c_f, flocculant concentration (mg dm^{-3}); and K, scaling factor, generally dependent on the total concentration of the solid phase and on the flocculant concentration.

The same equation can be written for each ith fraction of the SP particles, with c_i substituted for c. By integrating Eq. (1) at $t = 0$ and $c = c_0$, we obtained the following equation:

$$c = c_0 e^{-Kc_f t}, \quad (2)$$

where $\tau = 1/Kc_f$ is the relaxation time, i.e., the time in which the content of SP decreases by a factor of e.

The particle size distribution of the coal-clay suspension (Fig. 1) shows that the size of the SP particles is in the range of applicability of the Stokes law [5]. Our calculations using Eq. (2) for a flocculant concentration of 0.4 mg dm^{-3} (Fig. 2) show a decrease in the SP content by a factor of 1.8 and 3.1 in 102 and 53 s for PAA and MPAA, respectively. Analysis of the experimental and calculated data shows that the modified flocculant increases the rate of SP precipitation.

CONCLUSION

Modification of polyacrylamide with α-propylene chlorohydrin enhances the flocculation properties of the modified polymer, which can be used to clarify the return water in concentration of coal sludges with a hydrosizer.

Henri Étienne Sainte-Claire Deville (To 150th Anniversary of the Development of the First Industrial Method for Production of Aluminum)

DOI: 10.1134/S1070427206100399

A French scientist, Professor Henri Étienne Sainte-Claire Deville is among the most outstanding chemists of the second half of the XIX century. A member of Paris Academy of Sciences (since 1861), president of the French Chemical Society (1863) and foreign corresponding member of Imperial St. Petersburg Academy of Sciences (since 1869), he laid foundations of quite a number of scientific areas, primarily in the field of applied inorganic chemistry. One of the main deeds of the scientist is the development of the first industrial method for production of aluminum (1856).

At the turn of the XIX century (1800), A. Volta (1745–1827), an Italian physicist, created the first chemical current source (Volta's column battery) and thereby opened up wide opportunities for analysis of the effect of electric current on various substances. One of the best known researchers of the early XIX century, English physicist and chemist H. Davy (1788–1829), a member of London Royal Society (since 1803) and honorary foreign member of St. Petersburg Academy of Sciences (since 1826), was among the first to commence electrochemical experiments. Having carried out a detailed study of the decomposition of water, Davy was the first to isolate metallic potassium (1807) and sodium (1808) by electrolysis of their molten hydroxides. Davy's studies aroused considerable interest and further served as a basis for development of industrial techniques for production of these metals. Later, Davy isolated barium, strontium, calcium, and magnesium by electrolysis of their molten hydroxides, but failed to obtain aluminum from its oxygen-containing compounds.

Aluminum was first isolated in the free state at the beginning of 1825 by a Danish physicist H.C. Oersted (1777–1851), who developed methods for obtaining aluminum chloride and for reduction of aluminum with a potassium amalgam. Metallic aluminum was obtained in a small amount from the forming aluminum amalgam by distillation without access of air. In 1827, a German physicist F. Wöler (1800–1882)

continued Oersted's experiments by replacing potassium amalgam with metallic potassium in the vapor state. Wöler's studies lasted long and only by 1845 the first stage in the history of aluminum was complete: although the metal was not obtained in a compact form, its amount was sufficient for determining its basic physical and chemical properties.

Thus, Davy was the first to formulate the task of obtaining in the free state an as yet unknown metal, named by him, in advance, aluminum. Oersted was the first to obtain aluminum, but he did not study its properties and did not specify the conditions of his experiments. Wöler not only isolated aluminum, but also determined its most important properties.

It was necessary to find a method for industrial manufacture of the metal and to specify areas of its practical use. This task was successfully accomplished in 1854, nine years after the final Wöler's work, by Henry Sainte-Claire Deville, who used the less expensive and more accessible sodium instead of potassium.

H. Sainte-Claire Deville was born on March, 11, 1818, in the island of Saint-Thomas (Virgin Islands, West-Indies) into the family of the French consul and, simultaneously, ship owner. He received his primary classical education in Paris and finished a medical institute in the same city (doctor of medicine, 1843). Even earlier, however, H. Sainte-Claire Deville took a great interest in chemistry, primarily under the influence of lectures delivered by professor L. Thenard (1777–1857, member of Paris Academy of Sciences since 1810, honorary foreign member of St. Petersburg Academy of Sciences since 1826), organized a private chemical laboratory, published in 1839 his first scientific study in the field of chemistry of natural compounds, and carried out a number of additional studies in this area.

In 1845, H. Sainte-Claire Deville occupied, by recommendation of Thenard, the position of a professor of chemistry and, simultaneously, became dean of a faculty at the University of Besanc'on (eastern France), one of the oldest universities of the country (founded in 1423).

An excellent experimenter, H. Sainte-Claire Deville continued, together with teaching and despite the lack of appropriate conditions, his scientific activities. The first years of his work were devoted to organic chemistry; however, already in 1849 he performed an original inorganic synthesis, obtained nitric anhydride by treating fry silver nitrate with chlorine. Having done so, he dispelled the opinion of that time that monobasic acids have no anhydrides.

In 1851, a French chemist A. Balard (1802–1876, member of Paris Academy of Sciences since 1844) was elected a professor at Collége de France, and H. Sainte-Claire Deville, who already became known by that time, occupied his position at Ecole Normale Superieure in Paris. This educational institution was engaged in training of teachers for secondary schools and, unfortunately, did not have sufficient conditions for scientific work. H. Sainte-Claire Deville did much for improvement of the laboratory improvement. He worked at Ecole Normale Superieure for for thirty years. It is during this period of time that all his diverse scientific studies were performed. In 1851–1853, H. Sainte-Claire Deville paid a considerable attention to improvement of methods for analysis of minerals and, in particular, silicates and carbonates. This refined the scientist's concepts concerning reactions at high temperatures in inorganic systems and gave him an impetus to devise and improve methods for production of metals and their purification to remove impurities. Based primarily on works of his predecessors, Davy, Oersted, and Wöler, H. Sainte-Claire Deville set to study aluminum. By that time, metallic potassium became less expensive and more accessible, which allowed H. Sainte-Claire Deville to perform large-scale experiments. Accounts of these experiments were rendered to Paris Academy of Sciences in 1854 and aroused a considerable interest. Professor J.B.A. Dumas (1800–1884, member of Paris Academy of Sciences, foreign corresponding member of St. Petersburg Academy of Sciences since 1845), a prominent scientist and public figure, demonstrated samples of aluminum and described properties of the metal to Emperor Napoleon III (1808–1873, Emperor of France in 1852–1870). Beginning from that time, H. Sainte-Claire Deville's works aimed to devise an industrial technology for manufacture of aluminum were fully financed by the State. A major success was that potassium was replaced, as a reducing agent, with metallic sodium, which is considerably simpler and safer in use. To reduce the cost of sodium, H. Sainte-Claire Deville developed a new technology for its manufacture. A mixture of anhydrous sodium carbonate, coal, and chalk was heated in tubular iron furnaces, with sodium produced in the vapor state and condensed in a cooler. This method was considerably more economical than that used before, in which sodium hydroxide served as the raw material. Another important achievement was that the readily volatile aluminum chloride was replaced with the double salt $AlCl_3 \cdot NaCl$. To obtain this salt, dry chlorine was passed over hot mixture of alumina, sodium chloride, and coal. The double aluminum sodium chloride formed in the vapor state was condensed and cooled.

It should be noted that metallic aluminum can be obtained from the double salt $AlCl_3 \cdot NaCl$ by electrolysis. This possibility was noticed in 1854, virtually simultaneously and independently, by H. Sainte-Claire Deville and R.W. Bunsen (1811–1899, foreign member of St. Petersburg Academy of Sciences), a professor of Heidelberg University in Germany. The equipment used by both researchers in studies of electrolysis of a molten double chloride was nearly the same: experiments were performed in porcelain crucibles at about 200°C. In Bunsen's studies, both electrodes were made of carbon, whereas H. Sainte-Claire Deville used a carbon anode and a platinum cathode. Aluminum was deposited as a thin layer on the platinum cathode and was scraped-off at regular intervals of time and remelted. H. Sainte-Claire Deville attempted to obtain aluminum by electrolysis of other molten electrolytes, but, at that time, such experiments could not go beyond the laboratory scale, because it was impossible to produce considerable amounts of electric power. Nevertheless, H. Sainte-

Claire Deville's experiments in France and Bunsen's in Germany undoubtedly affected the later development of an industrial technology for manufacture of aluminum by electrolysis of cryolite–alumina melts (1886).

In the middle of the XIX century, the chemical technique for industrial manufacture of aluminum was the only possible. Beginning in 1856, more than 200 tons of the metal was produced during more than thirty years by reduction of aluminum chloride in the form of the double salt $AlCl_3 \cdot NaCl$ by the method devised by H. Sainte-Claire Deville, and the price of the metal was steadily decreasing. Already at the World Exhibition in Paris in 1855, chemically produced aluminum was demonstrated as a commercial product. Twelve aluminum slugs of the metal, with a total weight of 12 kg, were demonstrated. At a regular meeting of the French Academy of Sciences on October 13, 1856, professor Dumas reported that production of aluminum went beyond the stage of research and became an industrial process. France was the first country that set up production of aluminum on the industrial scale.

Originally, the alumina necessary for production of the $AlCl_4 \cdot NaCl$ salt was obtained by calcination of ammonium alum $NH_4Al(SO_4)_2 \cdot 12H_2O$; later, bauxites served as the raw material. Bauxites were processed into alumina by a method close to the present-day sintering technique. Crushed bauxite was mixed with powdered soda and the mixture was calcined in a flame surface to give sodium aluminate. The mass extracted from the furnace was leached with water, and the resulting pure solution of sodium aluminate was treated with carbon dioxide under agitation, with an aluminum hydroxide precipitate formed.

The history of discovery of aluminum and its industrial production by H. Sainte-Claire Deville's method were described in a monograph by Debard [1] and in later publications [2–4]. The contribution of Oersted and Wöler to the development of the aluminum production technology was considered in detail by Goldschmidt [5, 6].

H. Sainte-Claire Deville was primarily a scientist and a pedagogue. Together with teaching at Ecole Normale Superieure, he delivered lectures on chemistry at Paris University (Sorbonne) in 1853 to 1866, by invitation of professor Dumas. After the industrial manufacture of aluminum was organized, H. Sainte-Claire Deville continued intensive scientific studies of processes for isolation of other elements. Because sodium and aluminum became well accessible, the scientist used these elements as reducing agents. In a joint study with Wöler, H. Sainte-Claire Deville obtained by reduction of boron oxide with sodium an amorphous modification of boron in the form of a powder. Soon after, having changed the experimental conditions and using aluminum as a reducing agent, he obtained boron in the crystalline form and synthesized boron nitride. By reduction of silicon chloride vapor with aluminum, H. Sainte-Claire Deville obtained crystals of silicon (1856). Later (1863), the scientist suggested a faster and more convenient method for production of crystalline silicon from its fluorosilicate. By treating potassium fluorotitanate with a sodium vapor in the atmosphere of hydrogen, H. Sainte-Claire Deville and Wöler obtained titanium [7]. To perform high-temperature studies, H. Sainte-Claire Deville designed and fabricated laboratory furnaces using various kinds of fuel. During the period of his intensive scientific activities (1850–1880), he was a leading specialist in high-temperature inorganic chemistry.

In 1859–1861, H. Sainte-Claire Deville and his closest co-worker H.G. Debray (1827–1888, member of Paris Academy of Sciences since 1877) took part, at request of the Russian government, in the development of methods for refinement of Ural platinum. A Russian academician, B.S. Jacoby (1801–1874), acted as intermediate in the negotiations. Thirty-two kilograms of crude platinum, 16 kg of platinum in the form of coins minted in Russia, and 8 kg of crude iridium were shipped to France. The French scientists devised a method for refining platinum and isolating platinum group metals. They were the first to fuse platinum in a considerable amount (12–15 kg), and to obtain platinum ingots. A detailed report on the accomplished work was published in Russia in Gornyi Zhurnal (Mining Journal) [8]. Studies by H. Sainte-Claire Deville and Debray in the field of refining of platinum group metals were highly appreciated by specialists. Commissioned by the International Committee for Weights and Measures, they fabricated international prototypes of the meter and kilogram from a platinum alloy with 10% iridium (1872).

In 1857, H. Sainte-Claire Deville commenced studies in the field of thermal dissociation of substances, which were later recognized as classical. According to a Russian scientist N.N. Beketov (1827–1911, academician of St. Petersburg Academy of Sciences since 1886), who worked at H. Sainte-Claire Deville's laboratory during a business trip (1858), these studies "constituted a historical epoch in the development of chemistry" [9, 10]. In his paper "On dissociation or spontaneous decomposition of substances under

the action of heat" [11], which became widely known, the scientist demonstrated that, when heated, steam does decompose into oxygen and hydrogen. In his later studies (1859–1861), H. Sainte-Claire Deville noted that water vapor decomposes not only at the melting point of platinum (1750°C), but also at that of silver (950°C) [9]. In a series of lectures on this subject, published in Paris in 1866, the scientist suggested that "the phenomenon of spontaneous decomposition of water ... should be named dissociation." According to H. Sainte-Claire Deville, this definition refers only to those cases in which "decomposition occurs partially and at a temperature lower than that corresponding to a complete disintegration of the compound," i.e., the cases of reversible decomposition, whose products again interact when the forces causing the decomposition are removed [9]. In an experimental study of equilibria, H. Sainte-Claire Deville suggested and successfully used the method of their "quenching." The studies of the French scientist, devoted to thermal dissociation, were of primary importance for the further development of the theory of thermal equilibria.

In the Russian scientific literature, H. Sainte-Claire Deville's studies in the field of thermal dissociation were first analyzed by V.F. Alekseev (1852–1919) in "Essay on the Modern State of Chemical Mechanics" [12]. The scientific activities of Alekseev were considered in a previous publication by Morachevsii [13]. H. Sainte-Claire Deville's works exerted a strongest influence on the development of experimental research and their thermodynamic assessment.

The main results of H. Sainte-Claire Deville's scientific activities can be briefly formulated as follows.

He developed and implemented on the industrial scale a chemical method for manufacture of aluminum (reduction of the double salt $AlCl_3 \cdot NaCl$ with metallic sodium);

independently of Bunsen, demonstrated the possibility of aluminum recovery at low temperatures by electrolysis of chloroaluminate melts;

together with Wöler, was the first to isolate boron, silicon, and titanium in pure form and obtained some compounds of these elements;

widely used metallic sodium as a reducing agent and developed a method for its production, which markedly reduced its price; was the first to use aluminum as a reducing agent;

made a major contribution to the development of a laboratory equipment that enabled high-temperature studies;

together with Debray, developed a technology for platinum refinement with recovery of platinum group metals and was the first to fuse platinum;

discovered the phenomenon of thermal dissociation.

Owing to H. Sainte-Claire Deville's efforts, the chemical laboratory at Ecole Normale Superieure became one of the best known European scientific centers, visited by scientists from various countries. Students were actively involved in research, especially in studies of dissociation processes. The scientific legacy of the scientist is huge. In addition to being engaged in the above-mentioned principal areas of research, H. Sainte-Claire Deville carried out numerous studies in analytical chemistry and performed high-temperature syntheses of a large number of minerals (apatite, ruby, sapphire, zircon, etc.).

In October 1876, H. Sainte-Claire Deville suffered a severe loss, his elder brother Charles (born in 1814), a specialist in geology and meteorology and member of the French Academy of Sciences, died. The brothers were on very friendly terms, they together leaved their parents in West-Indies in 1828 and came to Paris. Despite the difference in age, they together received their secondary education. The loss of the brother strongly affected H. Sainte-Claire Deville's health and mental state. He died on July 1, 1881, at Boulogne sur Seine not far from Paris and was buried near his brother. The commemoration speech at the meeting of the French Academy of Sciences on July 4, 1881, was delivered by Louis Pasteur (1822–1895, member of numerous academies of the world, honorary foreign member of St. Petersburg Academy of Sciences), an outstanding chemist and microbiologist and a close friend of H. Sainte-Claire Deville [14].

Among the known publications, that by Gernez [15] describes the life and scientific and pedagogical activities of H. Sainte-Claire Deville in most detail. More concise evidence can be found in [7], brief articles [16, 17], and encyclopedias and biographical reference books. A popular description of certain episodes of H. Sainte-Claire Deville's life is contained in a book by M. Manolov [18].

Scientific Legacy of N.N. Semenov: A Breakthrough into the Future

DOI: 10.1134/S1070427206100405

The title of this article fully corresponds to the name of the International conference devoted to the 110th anniversary of Academician N.N. Semenov (1896–1986). Over 800 scientists and students took part in this conference.

Semenov was the founder and permanent head of the Institute of Chemical Physics, Academy of Sciences of the USSR, in 1931–1986. In 1956 he (jointly with S. Hinschelwood) was awarded a Nobel Prize for the development of the theory of branched chain reactions. He had been publishing these works since 1928. Semenov was one of the founders of chemical physics and biochemical physics as sections of natural sciences. He significantly contributed to the development of chemical kinetics as a tool for studying mechanisms of chemical and biochemical processes.

The conference was organized by the Russian Academy of Sciences (RAS), Ministry of Education and Science of the Russian Federation, Lomonosov State University in Moscow (MGU), Moscow City Government, Semenov Foundation for Science Development, and Joint Institute of Chemical Physics (OIKhF).

The conference proceeded according to a two-day program on April 14–15, 2006 (Semenov was born on April 16, 1896).

On the first day, the conference proceeded in the Big Hall of the Russian Academy of Sciences. The opening of the conference was attended by leading scientists of the Russian Federation and representatives of UNESCO and Moscow Government. A large number of telegrams were addressed to the conference and, in particular, that the from President of the Russian Federation V.V. Putin.

Four plenary presentations were held on the first day of the conference.

RAS Academician V.E. Fortov devoted his presentation to the development of chemical physics under extreme conditions. Prof. J.-M. Lehn (France) characterized the current status of supramolecular chemistry, chemical physics, and chemical kinetics. Prof. J Polanyi (Canada) presented modern views in the field of quantum chemistry and chemical kinetics of gas-phase processes. Special interest was evoked by the presentation of RAS Academician V.P. Skulachev, concerned with radical forms of oxygen (mithochondrias and aging processes), and its discussion.

On the second day, the conference proceeded in the Big Hall of the main building of MGU. There were two sessions. The morning session included three plenary presentations and one discussion. RAS Academician A.E. Shilov delivered a lecture on some modern achievements in chemical physics and biomimetics. The second presentation was concerned with problems of light, energy, and natural photosynthesis (M. Gretzel, Switzerland). The presentation by S. Sarisiftsy, Austria, was focused on problems of accumulation of solar energy and its transformation into electricity (organic solar batteries). This was followed by round table debates on the subject "Fundamental science for power generation" (it should be reminded that Semenov for many years headed in the USSR the Scientific Council for solar energy accumulation).

The evening session on the second day of the conference included presentations on the prospects for development of high school (universities and institutes). It should be mentioned that Semenov established in 1944 the Chair of Chemical Kinetics at the Chemical Faculty of MGU and headed it till 1986. Two presentations concerning the future of higher education in various countries were made by Prof. R. Loughline, US.

The session concluded with round table debates on the subject "Higher Education in XXI Century", whose participants suggested diversified (occasionally, conflicting) ideas.

As a part of the conference, a number of events were organized:

informal meeting of Russian and foreign scientists with Russian young scientists and students;

meetings of Nobel Prize Laureates with representatives of the Semenov International Foundation for Science Development;

exhibition devoted to the 110th anniversary of Academician Semenov at the MGU Museum in the New Library building.

The conference demonstrated that the ideas and solutions suggested by Semenov in his time were further developed by many scientists from various countries.

All-Russia Conference of Young Scientists and Second School "Oxidation, Oxidative Stress, and Antioxidants"

DOI: 10.1134/S1070427206100417

The All-Russia Conference of Young Scientists and Second School "Oxidation, Oxidative Stress, and Antioxidants" was held on June 1–3, 2006, at the Semenov Institute of Chemical Physics, Russian Academy of Sciences (IKhF RAN). It was devoted to the 90th anniversary of Academician N.M. Emanuel' and the 110th anniversary of his teacher, Nobel Prize Laureate Academician N.N. Semenov.

The conference was organized by IKhF RAN, Emanuel' Institute of Biochemical Physics (IBKhF RAN), and Institute of Problems of Chemical Physics, Russian Academy of Sciences (IPKhF RAN). The Organizing Committee was headed by Academician A.A. Berlin, Director of IKhF, and Corresponding Member of the Russian Academy of Sciences (RAS), S.D. Varfolomeev, Director of IBKhF. Over 100 scientists from 15 research centers of CIS took part in the conference.

The session was opened by Academician A.A. Berlin who made a presentation devoted to the 110th anniversary of Academician Semenov. A special attention was given to the school created by Semenov, disciples of this school, and their contribution to science. The discussion on oxidation processes included a presentation by G.E. Zaikov (IBKhF RAN), focused on the practical implementation of the results of the research conducted by Academician N.M. Emanuel' and his disciples (Research–Development–Production).

On the second day of the work of the conference, 4 plenary presentations were made, devoted to the development of ideas and views concerning the role of free radicals and peroxide oxidation in biology and medicine (E.B. Burklakova, IBKhF RAN); reactivity of antioxidants of radical reactions (E.T. Denisov, IPKhF RAN); role of nitrogen oxides in oxidation processes (A.F. Vanin, IKhF RAN); and theoretical and applied aspects of the chemistry of phenolic antioxidants (V.B. Volevaya, IBKhF RAN).

Young scientists prepared numerous poster presentations, whose discussion was followed by an extensive discussion of the subject "What is antioxidant," headed by Burlakova and O.T. Kasaikina, IKhF RAN.

On the third day of the work of the conference, two sessions were held. At the morning session, S.D. Varfolomeev, RAS Corresponding Member, made a presentation concerning the role of enzymes in the development and suppression of oxidative stress. The presentation by Kasaikina was focused on the oxidation of complex multicomponent systems, with a special emphasis on pro- and antioxidative effects, and that by N.P. Pal'mina (IBKhF RAN), on the peroxide oxidation of lipids by biological membranes. The morning session concluded with another poster session.

During the evening session, the conference participants heard and discussed presentations devoted to the antioxidative properties of natural components of cells in vitro and in vivo (L.N. Shishkina, IBKhF RAN); synergism and antagonism in mixed compositions of bioantioxidants (N.M. Storozhok, Medical Academy, Tyumen); and numerical analysis of the chemical reaction mechanism of the α-tocopherol-inhibited peroxidation of methyl linoleate (L.A. Tavadyan, Nalbandyan Institute of Chemical Physics, National Academy of Sciences of Armenia, Yerevan). The last presentation was focused on the kinetic significance of individual stages of the processes.

This was followed by an analysis and discussion of all the poster presentation made at the conference (a total of nearly 70), mostly prepared by young scientists. All these presentations concerned various aspects of the kinetics and mechanism of oxidation of organic compounds of various classes (with both low and high molecular weight). The general discussion at this session was aimed to decide what is a more efficient pathway for stabilization: deactivation of radicals or nonradical utilization of peroxides with deactivation of catalysts (enzymes). The conclusion was that each factor plays a significant role, and its share depends on the nature of organic compounds and catalysts.

The work of the conference demonstrated that young people are gradually returning to science; the scientific level of the presentations corresponds to the current world standard.

The conference participants decided to hold the next conference in 2008 at IKhF RAN and IBKhF RAN.

REVIEWS

Sadykov, S.B., *Avtoklavnaya pererabotka nizkosortnykh tsinkovykh kontsentratov* (Autoclave Processing of Low-Grade Zinc Concentrates),

Yekaterinburg: Ural. Otd. Ross. Akad. Nauk, 2006, 541 pp.

DOI: 10.1134/S1070427206100429

In the scale of its manufacture, zinc occupies the third place among nonferrous metals, being exceeded in this regard only by aluminum and copper. The demand for zinc steadily grows; the main areas of its use are as follows: deposition of protective coatings, and primarily those on steel articles; manufacture of brass, bronze, and alloys for die casting; and production of chemical goods.

The favorable situation in the world market of zinc promotes development of additional facilities for its manufacture from domestic raw materials in the Republic of Kazakhstan. In the construction of the Balkhash zinc plant with an annual design output of 100 thousand tons of zinc, the unique technology of autoclave leaching, previously not used in Kazakhstan or other CIS countries, has been implemented. The book by S.B. Sadykov, which probably should be better classed with industrial-technological literature, covers three principal areas: (i) analysis of the present-day state of world's production of zinc with account of the role played by autoclave hydrometallurgy, (ii) examination of the potentialities of the autoclave leaching in decomposition of low-grade zinc concentrates, and (iii) search for optimal solutions in the implementation of the new technological process.

Sadykov's book, published under scientific editorship of S.S. Naboichenko, a known specialist in hydrometallurgy and corresponding member of the Russian Academy of Sciences, comprises an introduction, six chapters grouped into three parts, conclusion, and three supplements. The brief introduction (pp. 3–5) formulates the problems discussed in the book. The first part of the book (chs. 1, 2; pp. 7–110) starts with a discussion of the situation in the world market as of the beginning of 2004. The state of production in the countries that are leading manufacturers of zinc is considered, as well as that in the CIS countries and, separately, in Kazakhstan, where the main manufactures of zinc is OAO Kaztsink. This company, organized in January 1997, performs the whole production cycle, from geological surveys to mining works, mining and dressing of the ore, and metallurgical processing of the concentrate to give zinc and lead as final products. In 2004, Kaztsink company manufactured 279 thousand tons of refined zinc. All plants of the company are situated on the territory of the Republic of Kazakhstan. The first part of the book also analyzes in detail the experience gained in autoclave processing of zinc concentrates at a number of foreign plants (Canada, Germany, Japan).

The second part of the book (chs. 3–5, pp. 113–411) discusses the results of studies of the autoclave technology for processing of zinc concentrates in Kazakhstan (Kazakhmys plant). The autoclave leaching is based on the interaction of components of a crushed concentrate with sulfuric acid and oxygen to give the corresponding sulfates and elementary sulfur. The author presents the results of numerous experiments with both single- and double-stage leaching. All the experimental data obtained are presented with exhaustive completeness, including numerous analysis of various products (solutions and solid phases) to determine a large number of elements and material balances of the leaching stages. The good agreement between the data for zinc, copper, iron, lead, and sulfur in input and output materials in autoclave leaching indicates that the procedures used for sampling and analysis are reliable. Also considered are the results of laboratory studies (ch. 3) and large-scale tests (ch. 4). The same part of the book gives a general description of a design of a plant for processing of zinc concentrates by the autoclave technology (ch. 5).

The third part of the book (ch. 6, pp. 413–494) describes in detail the implementation of the technology including the autoclave leaching at Balkhash zinc plant in the pre-startup period.

In the conclusion (pp. 413–494), the author emphasizes once more that nonferrous metallurgy is one of the leading branches of industry in the economy of

the Republic of Kazakhstan. The increasing demand for zinc in the world market makes feasible industrial use of zinc concentrates of comparatively poor quality, with a lowered content of zinc (40–45%) and increased content of copper (3–5%) and lead (1–3%). In accordance with the foreign technological practice, it is advisable to use, when processing concentrates of this kind, the autoclave leaching with the subsequent purification of the resulting solutions to remove impurities and electrolysis in the final stage.

Supplements I, II, and III (pp. 515–527, 528–540, and 541–579) present, respectively, the generalized results of stand tests of autoclave leaching of the zinc concentrate at Kazakhmys plant, per-operation balances of the autoclave-hydrometallurgical technology for manufacture of zinc, and technological regulation for processing of solutions produced in autoclave leaching.

The author summarized and discussed a vast material of technological nature. The book is well published and includes a large number of tables, as well as technological schemes and photographs. The book is primarily intended for engineers and technicians at plants and research and design institutions engaged in use and development of hydrometallurgical technologies. It may be of use for students of metallurgical specialties in the pregraduate stage. Sadykov has accomplished a large and valuable work.

Thermally Expanded Graphite: Synthesis, Properties, and Prospects for Use

A. V. Yakovlev, A. I. Finaenov, S. L. Zabud'kov, and E. V. Yakovleva

Engels Technological Institute, Saratov State Technical University, Engels, Saratov oblast, Russia

Received April 13, 2006

Abstract—Results obtained in synthesis of thermally expanded graphite by chemical and electrochemical methods with sulfuric and nitric acids are summarized. The possibility of controlling the properties of thermally expanded graphite compounds in electrochemical synthesis is demonstrated. The existing and promising application areas of thermally expanded graphite are analyzed.

DOI: 10.1134/S1070427206110012

Graphite and various composite materials based on graphite, including graphite intercalation compounds (GICs), are widely used in a variety of fields of science, technology, and industry. Some GICs with acids and salts are used to obtain thermally expanded graphite (TEG), which has the form of a foamed carbon structure [1] and is used to produce low-density carbon materials and articles [2–6]. Similarly to graphite, TEG is chemically inert and heat-resistant. Its electrical conductivity and thermal conductivity are determined by the porous structure of the material and may widely vary [7–9]. An important distinction of TEG from all other powder-like carbon materials is its ability to form carbon articles without any binder. Thermally expanded graphite is well rolled into a flexible graphite foil [10], compacted into gaskets and seal rings [11–13], and introduced into the composition of multifunctional composites [14–17]. Thanks to a unique combination of properties of the material and to the possibility of their purposeful modification, seals, linings, catalysts, adsorbents, fireproofing composites, flexible heaters, and many other TEG-based articles are rather widely used in modern high-tech industries. The high chemical and thermal stability, combined with controllable electrical and thermal conductivity, porosity, and developed specific surface area create prerequisites for development of multifunctional materials.

The general principle underlying various methods for production of TEG consists in intercalation of substances or compounds, which either are themselves converted into gases upon rapid heating or give gaseous decomposition products, into the interlayer spaces of graphite [18, 19].

Numerous methods for GIC synthesis have been developed [20–22]. They are commonly subdivided into chemical (including vapor- or gas-phase synthesis and liquid-phase intercalation) and electrochemical, including galvanostatic or potentiostatic oxidation.

According to [23], the stages of GIC are the following: (1) transport of a substance to be introduced to the surface of the graphite host; (2) its adsorption by the surface, accompanied by separation of the substance to be introduced from that serving as a transporting agent; (3) intercalation into the host; (4) diffusion within the host; and (5) reaction between different intercalation stages.

Rudorff [24, 25] determined the fundamental aspects of the process of acid intercalation of graphite. The main specific feature of the process is the stepwise intercalation and the necessary presence of an oxidizing agent. The chemical model of GIC formation presumes occurrence of conjugated reactions of oxidation and intercalation [24]:

$$pC + [Ox] \rightarrow C_p^+ + [Ox]^-, \quad (1)$$

$$C_p^+ + A^- + m\mathrm{HA} \rightarrow C_pA^- \cdot m\mathrm{HA}. \quad (2)$$

The necessity for presence of an oxidizing agent is due to the low redox potentials of systems containing most of the acids being introduced, which cannot withdraw electrons from the graphite network. An exception is provided by nitric and perchloric acids, which are self-intercalating agents [26]. Initially, the oxidizing agents change the composition of oxygen-containing surface functional groups (SFGs) at terminal atoms of graphite layers [7, 19, 27]. The transfer

of electrons from graphite networks lowers the Fermi level of graphite, and the C_p^+ macrocation is formed in the carbon layers [reaction (1)]. The change in the SFG composition and the presence of charge on the graphite planes favor wedging of the interplanar spaces at edges of a carbon particle, which creates conditions for electrostatic drawing-in of acid anions [reaction (2)], i.e., for the direct occurrence of the intercalation process.

A particular place among acceptor GICs is occupied by compounds with sulfuric and nitric acids, graphite bisulfate and graphite nitrate. This is due to their high practical importance, because they serve as starting products for synthesis of thermally expanded graphite. The chemical method for synthesis of graphite bisulfate consists in oxidation of graphite with an H_2SO_4 solution additionally containing an oxidizing agent (Ox) [28, 29]:

$$24n\mathrm{C} + \mathrm{Ox}^z + m\mathrm{H_2SO_4} \rightarrow \mathrm{C}_{24n}^+ \cdot \mathrm{HSO_4^-} \cdot (m-1)\mathrm{H_2SO_4} + \mathrm{HOx}^{(z-1)}. \quad (3)$$

As oxidizing agents can serve a wide variety of compounds: CrO_3, $K_2Cr_2O_7$, $(NH_4)_2S_2O_8$, HNO_3, $KMnO_4$, H_2O_2, O_3, etc. The rate of formation and the stage of the resulting graphite bisulfate depend on the H_2SO_4 concentration and on the nature and content of the oxidizing agent in the solution [24, 29–31]. The dynamics of graphite bisulfate formation, with such oxidizing agents as HNO_3 and $KMnO_4$ involved, was studied for the first time by the potentiometric method in [32, 33]. Plateaus at potentials of 1.0 and 1.3 V (vs. SHE) were observed on the potentiometric curves obtained during chemical synthesis. These plateaus correspond, according to the results of X-ray phase analysis (XPA), to the formation of stage III of graphite bisulfate and to transformation of stage II of graphite bisulfate into stage I.

The mechanism of graphite nitrate formation by chemical oxidation in 96% nitric acid was described in [34]. The sequence of reactions, with account of the adsorption and reduction of HNO_3, formation of graphite macrocations, and their neutralization via penetration of NO_3^- into the interlayer space, can be represented as the following set of reactions:

$$\mathrm{HNO_3} \rightarrow \mathrm{HNO_{3(ads)}}, \quad (4)$$

$$2\mathrm{HNO_{3(ads)}} \rightleftarrows \mathrm{H_2O} + \mathrm{NO_{3(ads)}^-} + \mathrm{NO_2^+}, \quad (5)$$

$$\mathrm{NO_{2(ads)}^+} + n\mathrm{C} \rightarrow n\mathrm{C}^+ + \mathrm{NO_{2(ads)}}, \quad (6)$$

$$\mathrm{NO_{2(ads)}} \rightarrow \mathrm{NO_{2(g)}}, \quad (7)$$

$$n\mathrm{C}^+ + \mathrm{NO_{3(ads)}^-} + m\mathrm{HNO_{3(ads)}} \rightarrow \mathrm{C}_n^+ \cdot \mathrm{NO_3^-} \cdot m\mathrm{HNO_3}. \quad (8)$$

Reaction (5) in the adsorbed form is similar to the well-known dissociation of pure HNO_3 and gives rise to strongly electrophilic nitronium ions NO_2^+. Reaction (6) shows that the NO_2^+ ion captures an electron from the graphite lattice to be desorbed as NO_2 [reaction (7)]. As a result, graphite acquires a positive charge and draws in nitrate ions with solvate HNO_3 ligands to become electrically neutral.

As regards the possible composition of the resulting graphite nitrate, published evidence is contradictory [28, 34–37], in contrast to that for graphite bisulfate. According to the data for graphite nitrate, its composition is described by the general formula also characteristic of other graphite compounds with acids: $C_{24n}^+ \cdot NO_3^- \cdot 2HNO_3$, where n = 1, 2, 3, ... are intercalation stages. In addition, X-ray and electron diffraction analyses revealed that a small number of water molecules forming their own sublattice are present between carbon layers [37]. The ideal stoichiometry for this case is $C_{4.3n}HNO_3 \cdot mH_2O$ for nth stage, where $m < 0.07$ [37], which agrees with the chemical analysis data.

In [38–42], a strict correlation between the redox potential of a system under study and the number of a stage of the forming GIC was revealed by potentiometry for the graphite–H_2SO_4–Ox and graphite–HNO_3–H_2O systems. In addition, the concentration ranges in which various stages of graphite bisulfate and graphite nitrate are formed were determined. Under the conditions of chemical synthesis, the threshold intercalation concentrations of the acids are approximately 63% for H_2SO_4 and 75% for HNO_3. Weaker acids, e.g., H_3PO_4 and $H_4P_2O_7$, can be intercalated into the graphite host only at a 100% concentration of an acid [24]. Weak protonic acids, e.g., H_3BO_3, cannot be intercalated into graphite.

The chemical method is rather technologically and instrumentally simple [28]. However, changes in the concentration of an acid and, to a greater extent, in that of the oxidizing agent in the course of intercalation predetermine inhomogeneity of the graphite nitrate composition and make synthesis difficultly controllable. In addition, the compounds obtained are contaminated with the oxidizing agent and products of its reduction. This circumstance, combined with the high concentration of the acids, requires a gross expenditure of water for hydrolysis and washing of the final product.

To conclude the consideration of the liquid-phase method for synthesis of acceptor-type GIC, it can be

stated that the presence of an oxidizing agent and the effect of its potential on the degree of intercalation indicate that GICs are synthesized by the electrochemical mechanism.

The electrochemical method has a number of advantages over the chemical technique: it is environmentally safer, the compound obtained is not contaminated with the oxidizing agent and products of its reduction, and synthesis can be performed in a controlled mode, which makes it possible to obtain with high precision a product of the required composition and diminishes the expenditure of the acid. The electrochemical synthesis is used to produce GICs with inorganic and organic acids, such as H_2SO_4, HNO_3, $HClO_4$, H_2SeO_4, $HReO_4$, CF_3COOH, and HCOOH [24, 25, 43–48].

The electrochemical synthesis of graphite bisulfate is based on anodic oxidation of graphite in H_2SO_4 solutions of a sufficient concentration. The following stages of the synthesis can be distinguished [24, 28, 35, 49, 50].

(1) Induction period, i.e., SFG oxidation accompanied by buildup of stresses in carbon networks and their wedging from the sample surface.

(2) Introduction of the intercalate, which consists in electrochemical formation of carbon macrocations and diffusion of acid ions and molecules into interlayer spaces:

$$nC - e \rightarrow C_n^+ \xrightarrow{3.5H_2SO_4} C_n^+HSO_4^- \cdot 2.5H_2SO_4 + H^+, \quad (9)$$

to the point of maximum saturation of the graphite host ($C_{21}^+ \cdot HSO_4^- \cdot 2.5H_2SO_4$).

(3) Overoxidation of stage I graphite bisulfate with partial deformation of carbon layers by one of the following reactions [49, 51, 52]:

$$C_{24}^+HSO_4^- \cdot 2.5H_2SO_4 \rightarrow 2C_{12}^+ \cdot 2HSO_4^- \cdot 1.5H_2SO_4 + H^+ + e, \quad (10)$$

$$C_{24}^+HSO_4^- \cdot 2H_2SO_4 \rightarrow C_{24}^+ \cdot 0.5S_2O_8^{2-} \cdot 2H_2SO_4 + H^+ + e, \quad (11)$$

$$C_{24}^+HSO_4^- \cdot 2H_2SO_4 \rightarrow 3(C_8^+ \cdot HSO_4^-) + 2H^+ + 2e. \quad (12)$$

According to [53, 54], overoxidation in the presence of a sufficient amount of H_2O_2 in the electrolyte may lead to formation of graphite oxide $C_n^+(OH)^- \cdot yH_2O$.

(4) Oxidation of water to oxygen released in the form of O_2, CO, and CO_2 [55]. In moderately concentrated H_2SO_4 solutions, this stage may occur in parallel to the first three, with a number of soluble organic compounds as possible products of carbon oxidative breakdown [54]. The rate of GIC formation decreases with the H_2SO_4 concentration [36, 56].

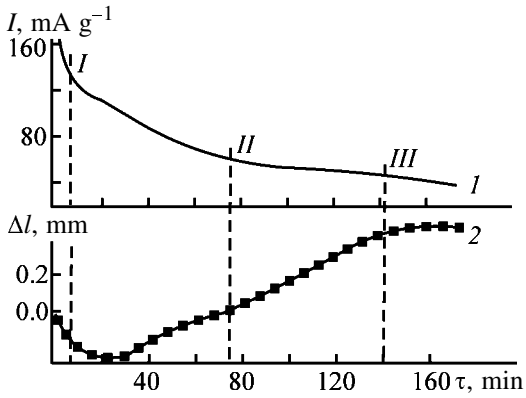

Fig. 1. Variation of (*1*) current *I* and (*2*) piston shift Δl with time τ in potentiostatic synthesis [E_a = 2.42 V (vs. SHE)] of graphite bisulfate in 96% H_2SO_4.

The above-described fundamental aspects of the electrochemical synthesis of graphite bisulfate have been mainly revealed in preparative experiments with samples of pyrolytic graphite. Taking into account that dispersed natural graphite is predominantly used to obtain thermally expanded graphite, we made a comprehensive study of electrochemical intercalation of graphite electrodes in sulfuric and nitric acid electrolytes.

An induction period was experimentally revealed from variation of the thickness of the graphite layer in anodic treatment in sulfuric acid (Fig. 1) [57]. It corresponds to the time elapsed before dashed line *I*. In this stage, the friction force between carbon particles becomes weaker and the graphite layer is densified (Fig. 1, negative Δl) due to oxidation of surface groups and to charging of the electrical double layer. Then, anodic intercalation leads to an increase in interlayer spacings and, accordingly, to a rise in the volume of graphite particles and to an upward shift of the piston (graphite layer thickness increases). XPA data confirm that the graphite bisulfate phase is absent during the induction period [57].

According to [58, 59], the potentials of formation of various stages of graphite bisulfate from dispersed graphite somewhat exceed analogous values for GICs synthesized from pyrolytic graphite [49, 50] (Table 1). The possibility of synthesis of various stages of graphite bisulfate by anodic treatment of dispersed graphite and of their subsequent "overoxidation"

electrode in concentrated H_2SO_4 mostly depends on the anode potential, whereas the composition and properties of the compounds obtained are governed by the amount of the electricity passed. In electrochemical synthesis of graphite bisulfate, the distribution of the overall anode current among intercalation, overoxidation, and oxygen evolution processes is strongly affected by the concentration of the sulfuric acid electrolyte [50, 58, 60–62]. Despite certain contradictions in interpretation of experimental data, it is possible to reveal general aspects, which consist in a shift of the threshold intercalation potential and of the formation potentials of graphite bisulfates of various stages in the positive direction with dilution of the electrolyte (Fig. 2). Thus, it can be stated that an increase in the fraction of water in the electrolyte favors anodic overoxidation of graphite bisulfate to give compounds that approach graphite oxide in their properties.

Of no less importance is the effect of temperature on the electrochemical intercalation of graphite. According to [60], the threshold intercalation potential and the potentials of stage conversion (III → II and II → I) steadily increase (at a rate of 1.9–2.8 mV K^{-1}), together with the intercalation rate, in electrochemical synthesis of graphite bisulfate in 96% H_2SO_4 as temperature is raised from 0 to 80°C. A similar trend was observed in [61, 63].

In electrochemical synthesis of graphite nitrate, all the basic aspects of stages of anodic oxidation are the same as in the case of graphite bisulfate. According to [64], graphite nitrates of various stages can be synthesized by anodic oxidation of graphite (Table 3).

According to [64–66], electrochemical oxidation of graphite can yield graphite nitrate of classical composition in HNO_3 solutions with concentrations of no less than 55–65%. In these electrolytes, formation of graphite nitrate stages has been recorded only upon a short-time anodic treatment, with an amount of electricity passed in the process not exceeding

Table 4. Variation of the volume of a dispersed graphite electrode with time in anodic potentiostatic treatment in 13.5 M HNO_3

2.0	0	1	11	29	40	61	52

60 mA h g^{-1}. An increase in the amount of electricity yields defective structures of the type of graphite oxide, which can be formed in HNO_3 solutions that contain about 20% H_2O [54]. In the opinion of Shapranov and Yaroshenko [54], intercalation and hydrolysis occur in 20–55% HNO_3 solutions simultaneously, which favors oxidation of a sample, e.g., by the reaction

$$C^+_{24n}\cdot NO^-_3\cdot 2HNO_3 + 3yH_2O$$

$$\rightarrow C^+_{24n}\cdot(1 - y)NO^-_3\cdot yOH^-\,2(1 - y)HNO_3\cdot 2yH_2O, \quad (13)$$

where $y < 1$.

The electrochemical method allows use of more dilute HNO_3 solutions for GIC synthesis [67, 68]. In particular, graphite nitrate can be obtained at concentrations in the range 1–70% [68]. To obtain GIC, dispersed graphite was subjected to polarization with anodic current in the range 0.5–4.0 A, with 66–440 mA h g^{-1} imparted. However, the publication cited presents only evidence of general technological nature, with no data on the occurring chemical processes and chemical composition of GIC reported.

The analysis made in our studies confirmed that the electrochemical oxidation of graphite in 59% HNO_3 occurs in stages similar to those described for graphite bisulfate. In particular, it was confirmed that there exists an induction period whose duration becomes somewhat shorter as the anodic polarization potential is raised [69]. A strong increase in the volume of the graphite electrode is due to intercalation and GIC formation. After the intercalation process is complete and the volume of the graphite anode ceases to grow, currents corresponding to overoxidation of the GIC formed continue to be observed in the potentiostatic curves (Table 4).

At higher anode potentials, an increase in the volume of the graphite electrode upon conversion of graphite into GIC becomes faster, but the strongest swelling is, by contrast, observed at lower potentials (2.0 V is the potential of oxygen evolution in 59% HNO_3 [70]). This circumstance can be understood with account of the fact that the probability of formation of graphite oxide grows with the anode potential. The theoretically possible (as determined by the interplanar spacings) increase in the graphite volume upon formation of graphite bisulfate should be 30% larger than that upon conversion of graphite into graphite oxide. Consequently, it may be assumed that graphite nitrate subject to hydrolysis is predominantly formed at E_a = 2.0 V, and compounds of the type of graphite oxide, at E_a = 2.3 V.

Thus, it has been shown experimentally that the qualitative composition of the products of anodic oxidation of graphite is determined by the electrolyte concentration, specific amount of the electricity passed, and potential of anodic polarization. In this context, it is preferable to perform electrochemical synthesis of GIC in the potentiostatic mode [71], which makes the process more controllable, diminishes gas evolution, and saves electric power by 10 to 50%.

After determining the dynamics of the electrochemical treatment process at different anodic polarization potentials [72], it becomes possible to find the minimum necessary time of anodic treatment to give GICs of various compositions (Table 5). The theoretical amount of electricity necessary for graphite nitrate formation was determined using the Faraday law. It should be noted that, in anodic oxidation of graphite, the current efficiency does not exceed 65% and markedly decreases at potentials exceeding the oxygen evolution potential (1.8–2.0 V) [70]. As follows from Table 5, synthesis of GIC is only possible at $E_a > 1.8$ V even at a low intercalate concentration. The theoretical value of Q necessary for overoxidation of GIC is about 380 mA h g^{-1}. It would be expected that, in anodic treatment of graphite, the electrical conductivity will substantially decrease upon conversion of GIC into graphite oxide. This will lead to a dramatic fall of currents and will eliminate part of the graphite anode from the process. According to [54], electrochemical synthesis of a graphite oxide of the composition $C_8O_2(OH)_2$ is virtually impossible. In-

Table 5. Time necessary for imparting the theoretically necessary capacity Q_{theor} in synthesis of GICs of various compositions at different potentials E of anodic treatment of graphite in 59% HNO_3

Charge of macrocation	Q_{theor}, mA h g^{-1}	Time, min, at indicated E, V (vs. SHE)								
		1.7	1.8	1.9	2.0	2.1	2.2	2.3	2.4	2.5
C_8^+	350	–	–	–	–	–	–	240	180	150

C_{18}^+	46	–	54	33	30	25	18	16	15	11
C_{27}^+	31	–	30	19	17	13	9	9	8	6
C_{36}^+	23	–	13	9	8	6	4	4	4	3

deed, even imparting $Q > 800$ mA h g^{-1} leads only to formation of intermediate forms of graphite oxide ($C_{24n}^+ \cdot OH^- \cdot 2H_2O$, where $n < 1$) because of a decrease in the current efficiency and an increase in the resistivity of the compounds obtained. In addition, prolonged anodic polarization makes higher the probability that hydrolysis will occur directly in the course of GIC synthesis [reaction (13)].

The available experimental data on the mechanism and conditions of electrochemical synthesis of GIC made it possible to formulate the basic principles of development of continuous reactors for synthesis of GIC with acids from dispersed graphite [73]. The originality of the design consists in that the gap between the anode current lead and the diaphragm on the rotating drum has a variable width (Fig. 3). The narrowest gap (compression zone) corresponds to the induction period of the reaction, and its further widening, to GIC synthesis accompanied by an increase in volume. Graphite and the forming GIC are transported along the gap by retractable blades. The blades are pushed out of the drum by springs or by spokes connecting diametrically opposite blades into pairs, with a special slide guide mounted in the upper part of the electrolyzer. This installation can use as an electrolyte both sulfuric and nitric acids. The electrode and structural materials for both systems were experimentally selected. It is recommended to use in sulfuric acid the 12Cr18Ni10Ti stainless steel as a stable material [74]. Titanium is an appropriate structural material and as a cathode in nitric acid electrolytes [75]. Platinum or platinum-plated titanium should be necessarily used as the anode current lead [76]. The diaphragm can be made of a polyvinyl chloride filter cloth, which is inert toward corrosive media and possesses high retentive properties. The attenuation coefficient of diaphragms of this kind does not exceed 2.5–4. The tests performed confirmed the working capacity and high reliability of the design and the possibility of performing GIC synthesis in a continuous automated mode [77]. Alternative reactor designs, which enable GIC synthesis from nonstratifying graphite–acid suspensions, have also been developed [78, 79].

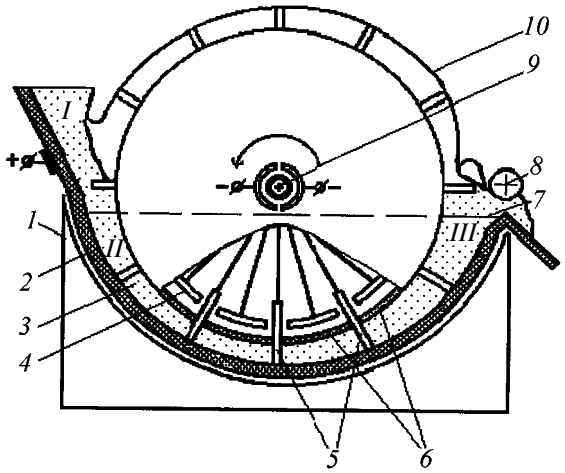

Fig. 3. Schematic of a drum electrolyzer: (*1*) electrolyzer case, (*2*) anode current lead, (*3*) graphite bed, (*4*) cathode, (*5*) blades, (*6*) diaphragm, (*7*) electrolyte level, (*8*) GIC remover, (*9*) shaft, and (*10*) blade guide. (*I–III*) Zones of charging, compression, and GIC discharge, respectively.

GICs synthesized by the chemical and electrochemical methods contain residual amounts of acids and oxidizing agents, both directly in their composition and on the surface in the form of adducts. To remove the residues, GIC are washed with water to pH 5–7. The specific expenditure of water for washing of graphite nitrate and graphite bisulfate is about 100 and 600 ml per gram of the product, respectively. As a result, the intercalating layer is totally replaced with hydroxide ions and water [29]:

$$C_{24n}^+ \cdot A^- \cdot 2HA + 3H_2O \rightarrow C_{24n}^+ \cdot OH^- \cdot 2H_2O + 3HA. \quad (14)$$

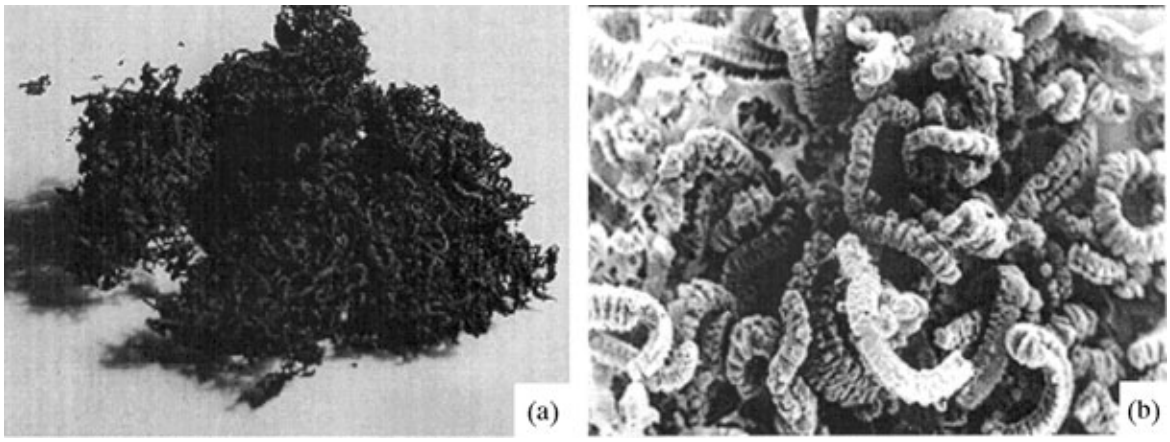

Fig. 4. Thermally expanded graphite. Magnification: (a) 1 and (b) 20.

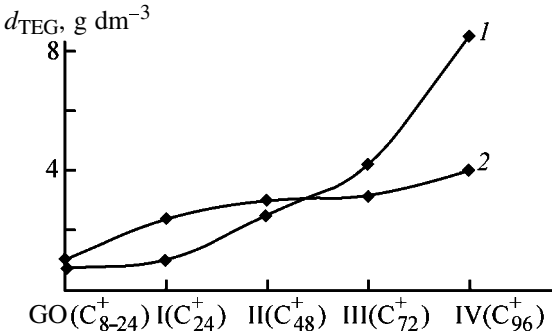
In addition, a GIC containing sulfur or nitrogen in the highest oxidation state can, when brought in contact with water, oxidize it with an increase in the oxygen concentration in the GIC. Oxygen can be present in various carbonyl, carboxy, and phenol groups on the surface of the graphite host or can form covalent bonds with neighboring carbon atoms. The thus produced and dried at 60–100°C hydrolyzed GICs (HGICs) are used to obtain thermally expanded graphite.

The mechanism of thermal expansion of GIC still remains a matter of discussion [80–84]. Makhorin et al. [80] assumed that carbon networks break down after fast removal of a certain amount of intercalating particles from the interlayer space of the graphite host, with neighboring planes disintegrated. In [81, 82], the process of thermal expansion of graphite was regarded as a phase transition caused by removal of the intercalating agent from GIC. The degree of foaming depends on the synthesis conditions and composition of the resulting GIC, as well as on the structure and size of particles of the starting carbon raw material. Chung [81] believes that the size of grains of the starting graphite should exceed 75 μm, with the crystallite size of no less than 75 nm. It is assumed most frequently that fast heating of GIC gives rise to a pressure (280–720 atm) between layers of carbon networks in graphite [83], and this pressure has a dispersing effect. Deintercalation of the graphite host occurs via layer edges and the existing defects, with the layers ruptured and shifted. At high heating rates this leads to formation of foam-like structures. An increase in the dispersity and defectiveness of graphite leads to a decrease in the internal interlayer pressure and, consequently, to a decline in the degree of expansion.

According to [84], the expansion originally involves cleavage of crystallites along the *c*-axis into thin packets-ribbons consisting of a small number of atomic planes, with their simultaneous deformation, to give a 3D folded structure. The resulting wormlike and cylindrical particles have a closed surface, within which residual decomposition products are contained (Fig. 4). The wormlike shape of particles of foamed graphite is due to opening of planar carbon networks wedged at the edge surface of a crystallite by surface groups. The basic technological characteristic of TEG is its bulk density d_{TEG}, which largely depends on preparation conditions and may vary widely, from 1–5 to 20–100 g dm^{-3} [7, 8, 80, 85]. According to experimental data, there exists a certain relationship between the composition of a GIC and its capacity for thermal expansion (Fig. 5). The greatest practical demand is for TEG with bulk densities of less than 7 g dm^{-3}. In addition, electrochemical oxidation of graphite in HNO_3 has been used to obtain GIC that can be thermally expanded even at 200–250°C to give a TEG with a bulk density of less than 2 g dm^{-3} [86].

At present, the overwhelming fraction (up to 50000 tons per year) of TEG is processed into a flexible graphite foil and compacted articles (see the



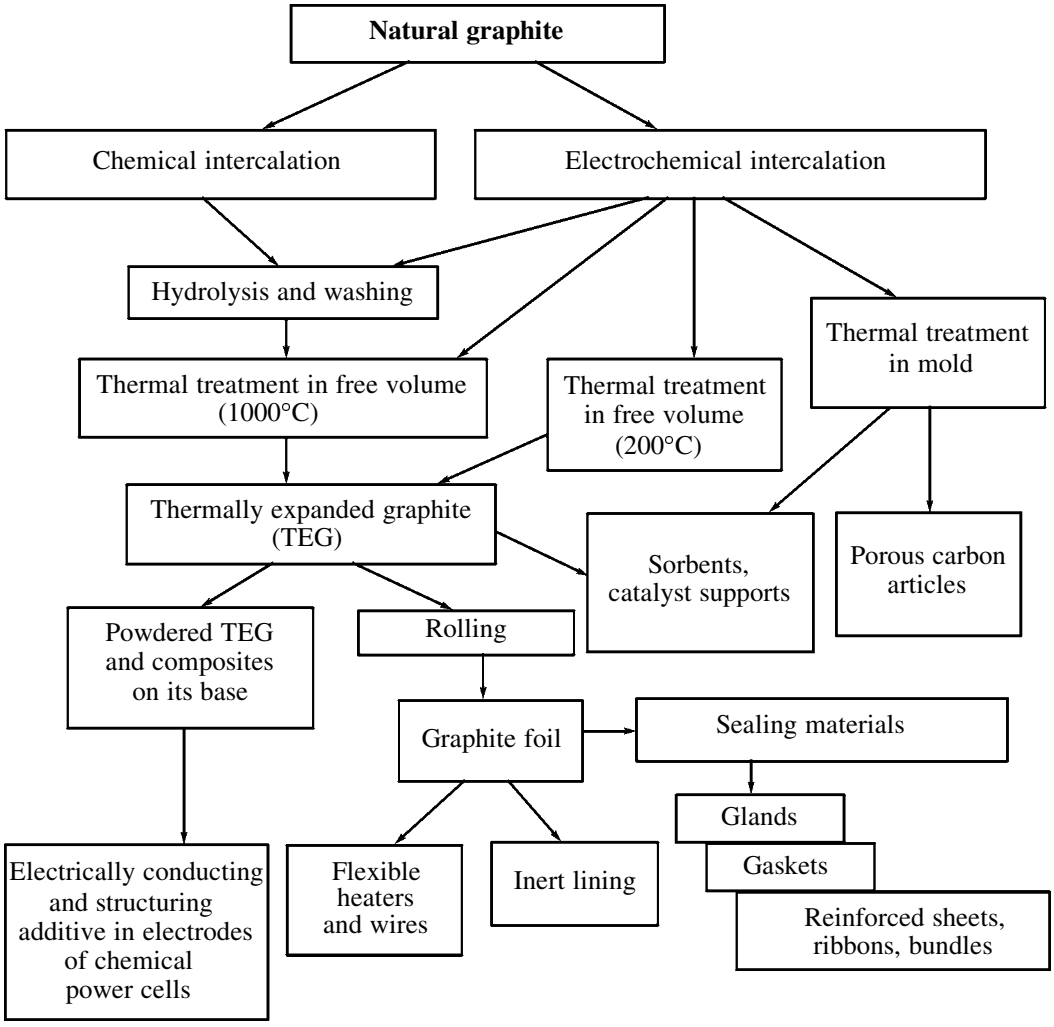


Fig. 5. Bulk density d_{TEG} of thermally expanded graphite in relation to the macrocation composition and GIC stage. (*1*) Graphite bisulfate and (*2*) graphite nitrate.

General scheme of synthesis of thermally expanded graphite and its subsequent processing into articles and materials

general scheme of synthesis and processing of TEG). The foil is obtained on a set of rolls in the same cycle with thermal treatment without introduction of a binder. This yields roll materials with a thickness of 0.15–1.5 mm, density of 0.7–1.3 g cm^{-3}, tensile strength of 4–7 MPa, and electrical resistivity of $(0.3–0.7)\times10^{-4}$ Ω m [10]. Owing to their high inertness toward corrosive media and thermal stability, combined with elasticity and plasticity, TEG-based materials everywhere replace such conventional sealing and laying materials as asbestos, Poronite, fluoroplastic, copper, and lead. Their use is especially effective in chemical and oil-and-gas machine building [12], fuel-and-energy complex [13, 87], and municipal service, which provides a decrease in the accident rate, diminishes the expenditure for equipment repairing, and improves the environmental safety.

It is known [14, 88] that TEGs are used as electrically conducting and structuring additives in electrodes of lithium chemical power cells to improve their specific characteristics; fluorination of TEG yields active reagents of chemical power cells; and their modification with metals serves to control their thermal and electrical conductivity [90]. According to [91, 92], TEG powders are effective adsorbents of oil products (sorption capacity 10–80 g g^{-1}) and certain metal cations (sorption capacity for hardness cations 0.42 mg-equiv g^{-1} [93]). The possibility that carbon materials, including TEG, can be used as catalysts and catalyst supports was reported in [94].

The most promising way to make articles of TEG, with its highly porous structure preserved, is thermal expansion of GIC in a gas-permeable mold with prescribed dimensions (chemical compaction). In this case, fabrication of articles of complex shape, with the density, porosity, and other properties of the material controlled, becomes possible because of the spatial

entanglement of particles of the expanding graphite [15, 89]. The above properties can be varied by changing the filling factor of the mold. In addition, the article properties can be varied widely by introducing carbon fibers and binders (pitch, phenol tars, metal oxides) into GIC before thermal treatment or by reinforcing the host produced from TEG with pyrocarbon from the gas phase [15]. A particular type of application is characteristic of composites containing intercalated graphite. The process of its thermal expansion under the action of open flame or heating results in the formation of a noncombustible thermally insulating coating, with simultaneous evolution of CO and CO_2, which decelerates and suppresses burning. Composites of this kind in the form of roll materials, pastes, and varnishes have been named active fireproofing materials [5, 17]. The presently manufactured domestic materials are used to protect electric cables, fabricate fire-resistant doors and partitions, and fireproof building constructions.

CONCLUSION

Comprehensive studies of the electrochemical synthesis of graphite intercalation compounds to be processed into thermally expanded graphite, design of a novel equipment for continuous anodic treatment of a dispersed carbon material, and its implementation as working laboratory and industrial installation revealed real prerequisites for the development of a new highly efficient technology that can yield thermally expanded graphite with controllable properties for various fields of science and technology.

Abstract—The wetting of the potassium chloride surface by water-soluble polymers and polymer–surfactant complexes, which is highly important for granulation of potassium chloride, was studied. The efficiency of the wetting process was analyzed using a polymer–surfactant combination in comparison with individual polymers.

DOI: 10.1134/S1070427206110024

At present, the international market of mineral fertilizers imposes the following basic requirements on their physicomechanical properties: the grain size of a fertilizer should have a narrow distribution; the grains should be spherical and have a smooth surface, high crushing and wear resistance, low moisture content, resistance to caking, high resistance to moisture absorption, and low dust content [1–3]. A permanent problem in manufacture of potassium fertilizers and, especially, in their shipping to consumers is dusting of potassium chloride. Dust fractions of fertilizers are released into the atmosphere in handling, make difficult the work of the service personnel, contaminate the environment, and deteriorate the quality of fertilizers in storage.

Finely grained flotation potassium chloride presently manufactured by Belarus'kalii Production Association, Republican Unitary Enterprise, contains a considerable amount of dust particles. The dusty fraction is delivered together with the main product to compaction. The presence of dust, whose surface is hydrophobized by amines (organic reagents used in the industrial process), complicates compaction, lowers the output capacity, raises the energy expenditure, and impairs the quality of grains. The problem can be solved by separating the dust and performing granulation to obtain a commercial product. The granulation consists of a set of physicochemical and physicomechanical processes that provide formation of particles with certain size, shape, structure, and physical properties. Various methods for granulation of dispersed materials are known; however, the only presently existing way to granulate potassium fertilizers is compaction [4–7]. The efficiency of granulation is determined by the process parameters and by use of binder liquids. In a comparison of techniques used for granulation of dispersed systems (compaction and pelletizing), the authors of [3–5] believe that use of effective binder additives is especially important in pelletizing because of the absence in this case of any external pressure in the granulation process.

The interaction of a binder liquid with particles of the dispersed phase begins with surface wetting. A good wetting, which provides a fuller contact over a large surface area, predetermines the high efficiency of the binding action of an additive. In the general case, the wetting is governed by the properties of a liquid (viscosity, density, surface tension) and a material (capillary radius, nature of the substance, state of the surface). The properties of the material (dustlike fractions of flotation potassium chloride), namely, its high dispersity and hydrophobic surface, require a specific approach to the choice of binder materials. Experiments demonstrated that, in the case in question, use of the conventional binders based on water-soluble polymers (polyvinyl alcohol, carboxymethyl cellulose, polyvinyl acetate) is inefficient. According to electron-microscopic data, grains formed from finely dispersed potassium chloride are inhomogeneous and have the form of a combination of dust particles and clots of a polymer binder.

The aim of this study was to examine the possibility of control over wetting of potassium chloride by using complexes based on water-soluble polymers and surfactants of varied nature.

EXPERIMENTAL

As water-soluble polymers were used commercial samples of acrylamide (co)polymers of Praestol brand (Stockhausen, Germany): nonionic polyacrylamide (N) and anionic (A) and cationic (C) polyelectrolytes. The anionic polyelectrolytes were high-molecular-weight copolymers (molecular weight of 14×10^6 according to manufacturer's data) of acrylamide with sodium acrylate, with a 20% content of ionic units. The cationic polyelectrolytes, copolymers of acrylamide with trimethylammoniopropylacrylamide chloride had a molecular weight of about 9×10^6 and contained 20% ionic units.

Oxyethyl alcohol was used as a nonionic surfactant (S_N); sodium octanesulfonate, as anionic surfactant (S_A); and cetylpyridium chloride, as cationic surfactant (S_C).

Potassium chloride of chemically pure grade, used in the study, was ground to a finely dispersed state corresponding in particle size to the dustlike fraction (1200–1500 $cm^2\ g^{-1}$). The surface of potassium chloride was hydrophobized with aliphatic amine chlorides of Flotigam S brand. Creating a monomolecular layer at a specific surface area of about 100 $cm^2\ g^{-1}$ requires about 20 g of amine per ton of potassium chloride [8]; for finely dispersed fractions this amount is 270–300 g t^{-1}. At amine doses of 50, 100, and 200 g t^{-1}, the fraction of the hydrophobized surface is 15–20, 30–35, and 60–70%, respectively. According to laboratory tests, the industrial samples of the dustlike fraction contained 60 to 270 g t^{-1} of amine.

To evaluate the efficiency of wetting of the potassium chloride surface, a procedure for estimating the spreading velocity of drops of the same volume over the surface of densified finely dispersed material was developed. Samples of potassium chloride ground to the state of a dust (fraction with a particle size of less than 0.2 mm) were prepared under identical conditions (humidity, temperature, time, and force of compaction). The variation of the drop diameter was recorded by measurements under a Telemik-1 microscope (Russia–Japan) with a tenfold magnification at certain intervals of time, and the velocity of drop spreading over the surface was evaluated (Fig. 1). The wetting efficiency (D_w) was calculated as the ratio between the spreading velocity of a drop of

a liquid under study to that of a drop of distilled water over the sample surface.

The interaction in systems based on polymers and surfactants was studied by viscometry (using an Ostwald viscometer with a capillary diameter of 0.63 mm) and by measuring the surface tension by the ring detachment method to within ± 0.2 mJ m^{-2}. In the experiments, the same volume of a surfactant solution of varied concentration was added to a certain volume of a polymer solution of prescribed concentration, at various relative amounts of polar groups of the polymer and a surfactant.

The wetting of the hydrophobized surface of potassium chloride with distilled water and polymer solutions was evaluated in relation to the amount of amine. It was found that the spreading velocity of drops sharply decreases at an amine content of 300 g t^{-1}, i.e., under the conditions of virtually complete hydrophobization of the surface. Therefore, the effect of reagents (polymers, surfactants, and mixtures of these) on the wetting efficiency was studied at the maximum content of amine (300 g t^{-1}).

The adsorption layers formed by amine chlorides on the surface of potassium chloride contain surface-active ions with hydrophobic radicals directed away from the surface. In treatment of potassium chloride with water-soluble polymers, this hinders surface wetting and prevents uniform distribution of polymer solutions. To improve the wetting, a preliminarily prepared mixture of aqueous solutions of polymers and surfactants of varied nature was used. Mixing of solutions of an anionic polyelectrolyte and cationic surfactant leads, at any component ratio, to precipitation. Therefore, the rheological and surface-active properties and the wetting efficiency were not studied for this system.

Table 1 lists data characterizing the wetting efficiency of the potassium chloride surface by aqueous solutions of polymers mixed with surfactants. It can be seen that the wetting efficiency increases to varied extent for all combinations of polymers with surfactants, with the exception of $A–S_A$ and $C–S_C$ mixtures. The wetting efficiency is the highest with the oppositely charged polymer and surfactant and with nonionic components ($N–S_N$). Addition of even an insignificant amount of a surfactant to the polymer (polymer/surfactant ratio = 1 : 0.005) leads to an increase in the wetting efficiency by 9–11%. It may be assumed that the improvement of the wetting capacity is due to interaction between components and to formation of polymer–surfactant complexes. As the ratio of the interacting groups of the components starts to exceed 1 : 1, the wetting efficiency remains virtually unchanged, which indicates that there exists a limiting degree of interaction of the components.

It is known that, in wetting of powdered materials, drops expand in all directions and fill pores between separate particles. At invariable properties of the material and wetting conditions, the rate of capillary suction is determined by the properties of the liquid and, in particular, by its viscosity and surface tension [3, 5]. Therefore, the rheological and surface-active properties of solutions of polymers and their mixtures with surfactants of varied nature were studied.

It was found that the viscosity of aqueous solutions of a mixture of a cationic polyelectrolyte and anionic surfactant decreases relative to that of the starting polymer (by a factor of more than 3 at the equimolar polymer/surfactant ratio) (Table 2). As there is no dilution in the system (the surfactant concentration changes at an invariable volume), the changes observed may be due to interaction between the components and to complexation. As the concentration

of the surfactant in the mixture increases, its adsorption on oppositely charged polymer macromolecules becomes more pronounced. This is accompanied by a decrease in the polyelectrolyte charge and in the size of polymer macromolecules and by the resulting lowering of the viscosity of the solutions. A decrease in viscosity is also observed on mixing aqueous solutions of a nonionic polymer with a nonionic surfactant (Table 2). In this case, the change in the viscosity of the mixture, compared with the individual polymer, is due to interaction of the nonionic groups of the components via hydrogen bonds.

A comparison of the rheological properties of $A–S_N$, $N–S_A$, $N–S_C$, and $C–S_N$ mixtures and individual polymers demonstrated that the viscosity decreases, on the average, by 10% at a component ratio of 1 : 1. Taking into account that polymer macromolecules contain 20% ionic groups, the rest of the groups can be involved in formation of hydrogen bonds with surfactant molecules.

It is known [9] that the macromolecules are hydrophobized and their surface activity increases in complexation as a result of the interaction between the hydrophilic groups of the polymers and surfactants (electrostatic or via hydrogen bonds). In the case in question, studies revealed a decrease in the surface tension of aqueous solutions of polymers upon addition of a surfactant. In treatment of potassium chloride, the aqueous solution of the polymer–surfactant complex comes in contact with the salt. The presence of the low-molecular-weight surfactant affects the surface-active properties of the polymer complex. In this context, the effect of the salt in various concentrations on the surface tension of solutions of 1 : 1 polymer complexes was studied (Table 3).

As seen from Table 3, the surface tension of the solutions decreases as the concentration of the low-molecular-weight salt becomes higher. This is due to a change in the solvent (water) structure, a decrease in the degree of hydration of complex species, and the resulting enhancement of their adsorption on the potassium chloride surface [10]. As the concentration of the low-molecular-weight electrolyte is raised to 20%, the surface tension of the solutions grows, which may be due to rearrangement of the complex species, but remains lower than that of the aqueous solutions.

Figure 2 shows magnified images of drops of an aqueous solution of a polymer and of a mixture of the cationic polyelectrolyte and anionic surfactant (1 : 1 ratio of ionic groups), taken at regular intervals of time (2 min).

Table 2. Variation of the relative viscosity of aqueous solutions of polymer–surfactant mixtures with the ratio of the ionic groups of the components (the viscosity of the individual polymers is taken as unity)

Polymer/surfactant ratio	Relative viscosity	
	$C–S_A$	$N–S_N$

20.0	63.5	62.6	62.7	68.3

The drop of the aqueous solution of the complex (Fig. 2a) wets the potassium chloride surface better than does that of the individual polymer (Fig. 2b). The presence of the surfactant favors distribution of the liquid over the surface, which improves the binding properties of the polymer in further processing (granulation) of potassium chloride.

The results obtained were used in practice in granulation of a finely dispersed flotation potassium chloride. The introduction of surfactants into the solution of a polymer binder improved the grain strength by a factor of 2.5 and raised the output of the target fraction by 12% on average.

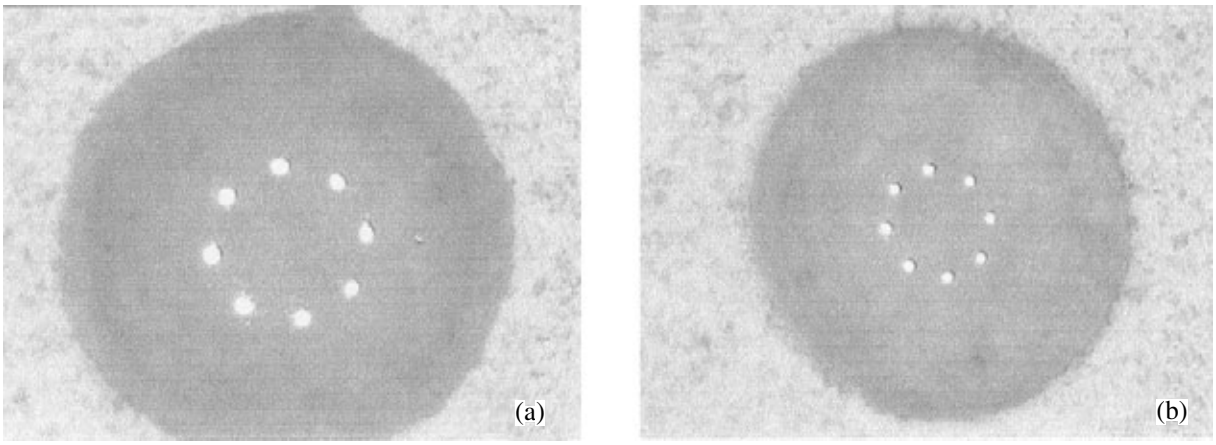

Fig. 2. Photographs of drops of (a) 1 : 1 C–S_A mixture and (b) aqueous solution of C.

CONCLUSIONS

(1) The wetting efficiency of the hydrophobized surface of finely dispersed potassium chloride by aqueous solutions of polymeric binders increases if complexes based on polymers and surfactants are used. This is due to a change in the colloid-chemical properties of the solutions: decrease in viscosity and increase in surface activity.

(2) Surfactants serve as a kind of interlayer between the hydrophobic surface of potassium chloride particles and the hydrophilic solution of a binder, which has a positive effect in the stage of component mixing on the distribution of the binder over the particle surface and, further, on the physicomechanical properties of fertilizer grains.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Autoclave Breakdown of Zircon with Ammonium Fluorides

V. V. Guzeev and A. N. D'yachenko

Abstract—Autoclave breakdown of zircon with ammonium fluorides was studied.

DOI: 10.1134/S1070427206110036

Zircon is one of the main mineral sources of zirconium materials, but the technology of its breakdown and processing is still labor-consuming, and much efforts are made to improve it.

The classical industrial methods of breaking down zirconium concentrates are sintering with fluosilicates and chlorination. Numerous studies summarized in [1] were devoted to zircon fluorination; however, it did not gain industrial application. The fluoride technology allows the scheme of the zirconium product processing to be reduced considerably, but high cost and corrosive behavior of HF and F_2, and also SiF_4 liberation restrain industrial application of these reagents.

In this study we examined the autoclave breakdown of zircon with ammonium fluorides.

Unlike fluorine and hydrogen fluoride, ammonium fluorides are very convenient to use, as these are solid crystalline substances under normal conditions. Ammonium fluorides can be obtained from metal fluorides by the action of ammonia water, which is the basis for conversion and recycling of ammonium fluorides.

Ammonium fluoride is known to react slowly with zircon [2, 3]. At temperatures below 240°C, the reaction rate is negligible and the degree of breakdown is unsatisfactory for the industrial use, whereas at higher temperatures ammonium fluoride evaporates with decomposition.

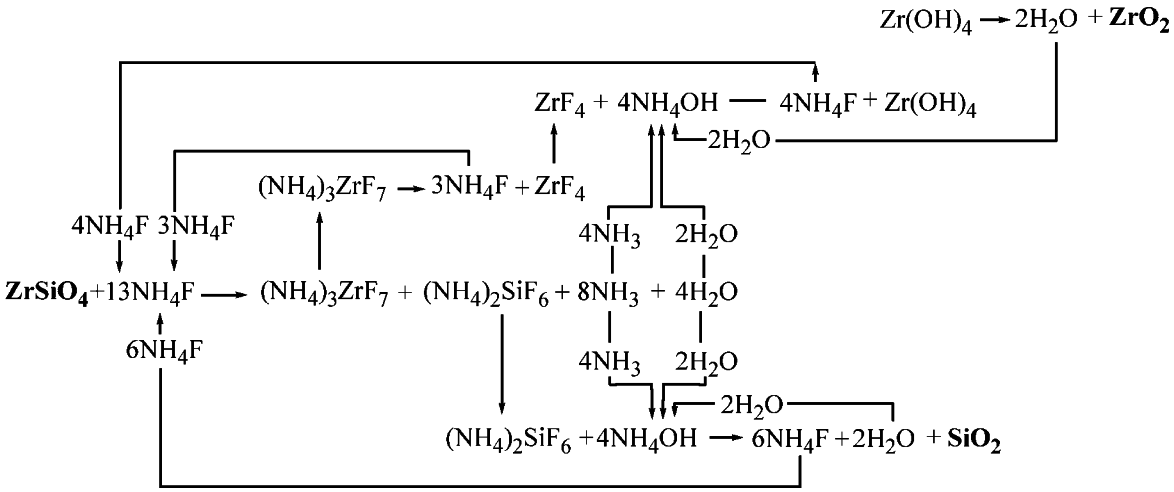
Here we report new data on the zircon breakdown with ammonium fluoride and hydrofluoride.

The essence of the method consists in the reaction of zircon with ammonium fluoride or hydrofluoride under isochoric conditions (in an autoclave), after which the reaction products are separated by sublimation to give zirconium tetrafluoride and dioxide. The advantage of ammonium fluorides over other fluorinating agents consists in their convenient physicochemical properties allowing their regeneration and recycling.

The experiments were carried out with zircon samples from Tugan deposit of Tomsk oblast.

The reactions of zircon with ammonium fluoride and hydrofluoride were studied under isochoric conditions in a 100 cm^3 stainless steel autoclave. A weighed portion of zircon with a grain size of 0.074 mm was placed in the autoclave together with a weighed portion of ammonium fluoride taken in a 20% excess in relation to the stoichiometric amount calculated for the reaction

$$ZrSiO_4 + 13NH_4F = (NH_4)_3ZrF_7 + (NH_4)_2SiF_6 + 8NH_3 + 4H_2O.$$



The autoclave was heated to 150, 200, 250, 300, 350, and 400°C and kept at these temperatures for 0.5, 1, 2, and 4 h.

After opening the autoclave, its content was transferred into a crucible and calcined for 30 min at 400°C to remove by sublimation unchanged NH_4F and formed $(NH_4)_2SiF_6$. The residue in the crucible was a mixture of unchanged $ZrSiO_4$ and NH_4ZrF_5, to which 5 ml of concentrated sulfuric acid was added, and the mixture was kept until H_2SO_4 vapor disappeared. Zirconium in the form of $ZrOSO_4$ solution was leached with water from the formed cake, converted to zirconium dioxide, and weighed to determine the degree of conversion.

The same procedure was used to study the reaction of ammonium hydrofluoride with zircon

$$2ZrSiO_4 + 13NH_4F\cdot HF = 2(NH_4)_3ZrF_7 + 2(NH_4)_2SiF_6 + 3NH_3 + 8H_2O.$$

Scheme 1.

The data on the kinetics of zircon breakdown with ammonium fluoride are given in Fig. 1, which contains two series of curves: the first corresponds to temperatures below ammonium fluoride boiling point and the second, to elevated temperatures.

The standard mathematical treatment of the kinetic data showed that the curves for 150, 200, and 250°C are described with an adequate accuracy by Gray–Weddington's, and the curves for 300, 350 and 400°C, by Crank–Ginstling–Brounshtein's equation.

The rate equation for the range 150–250°C is

$$\alpha = 1 - [1 - 10^{-3}\exp(-17\,000/RT)\,t]^3.$$

The activation energy E_A is 17 kJ mol^{-1}, which corresponds to the diffusion control, the preexponential factor $k_0 = 10^{-3}$ s^{-1}, and the gas constant R = 8.31.

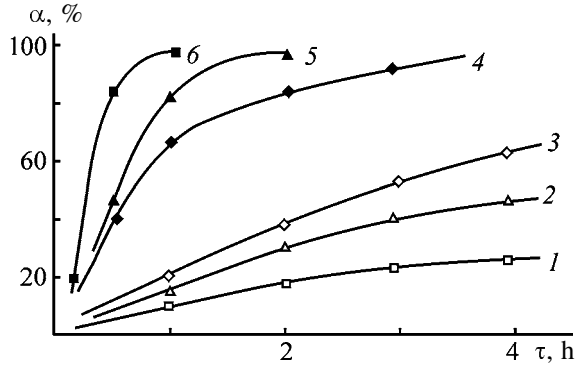


Fig. 1. Kinetic curves for the reaction of ammonium fluoride with zircon under isochoric conditions. (α) Degree of conversion degree and (τ) time; the same for Fig. 2. Temperature, °C: (*1*) 150, (*2*) 200, (*3*) 250, (*4*) 300, (*5*) 350, and (*6*) 400.

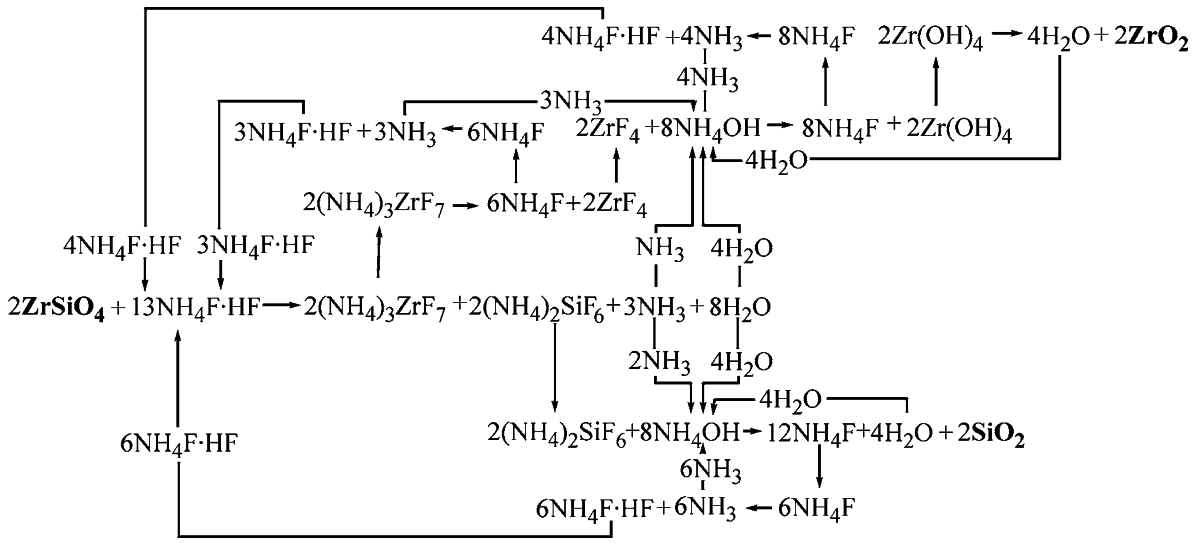
The rate equation for the range 300–400°C is

$$1 - 1/3\,\alpha(1 - \alpha)^{1/3} = \exp(-5500/RT)\,t.$$

The activation energy E_A = 55 kJ mol^{-1}, which corresponds to the kinetic control, the preexponential factor k_0 = 1 s^{-1}, and the gas constant R = 8.31. Material streams and material balance were calculated in accordance with Scheme 1.



Scheme 1 clearly illustrates the breakdown of zircon with ammonium fluoride and the formation of complexes followed by their hydrolysis and ammonium fluoride regeneration. Uniqueness of ammonium fluorides consists in the fact that their melt is the most powerful fluorinating agent reacting with zircon to form zirconium and silicon complex fluorides. Zirconium tetrafluoride and ammonium hexafluorosilicate are easy to separate by sublimation. After separation, the fluorides are subjected to hydrolysis with ammonia. Ammonium fluoride is regenerated, and oxides are precipitated from the solution. Unlike ammonium fluoride melt, its solution is inert and does not react with oxides.

The experimental dependences of the conversion α on time and temperature for the breakdown of zircon with ammonium hydrofluoride are given in Fig. 2. The kinetic curves are linearized most accurately by Yander's equation

$$\alpha = 1 - \{1 - [6.6\exp(-54\,000/RT)\,\tau]^{1/3}\}^3.$$

The preexponential factor is k_0 = 6.6 s^{-1}, and the activation energy calculated from the Arrhenius equation is E_A = 54 kJ mol^{-1}, which indicates that the process is kinetically controlled and temperature

Scheme 2.

exerts a decisive effect on its rate. Scheme 2 of material streams in the breakdown of zircon with ammonium hydrofluoride is given below.

The above-given experimental data allow us to suggest the optimal process parameters: with $NH_4F \cdot HF$, the conversion higher than 95% is reached at 300°C within 1.5 h and at 400°C, within less than 0.5 h [4].

When NH_4F was used, an elevated pressure was developed in the autoclave. The heating of ammonium fluoride is known to result in its thermal dissociation into ammonia and hydrogen fluoride, which increases the total pressure in the system [5].

The pressure of the mixture of HF and NH_4F vapors calculated by the Mendeleev–Clapeyron equation considerably exceeds the actual pressure owing to the condensation of the mixture of hydrogen fluoride and ammonia at a temperature below 240°C and also owing to considerable deviations of the behavior of this mixture from that of an ideal gas to which theoretical calculations are applicable.

To determine the real pressure which is developed under the considered conditions, we have carried out special experiments.

The temperature dependence of the vapor pressure was studied for two substances: ammonium fluoride and hydrofluoride. In a 100 cm^3 autoclave, 10 g of salt was placed, and the system was sealed and gradually heated to 350°C with continuous monitoring of the pressure with an MTP-1M manometer. The plots of the vapor pressure of ammonium fluoride and hydrofluoride are given in Fig. 3.

Apparently, the use of ammonium fluoride at high temperatures is not appropriate because high pressures arise and hence more sophisticated equipment is required; therefore, the use of ammonium hydrofluoride is the most efficient. As follows from Fig. 3, the vapor pressure of ammonium hydrofluoride at 300°C does not exceed 45 atm, which allows its use in the technology of the zircon breakdown with ammonium hydrofluoride. A considerable experience of using high-pressure devices in the industrial synthesis of ammonia and in the transportation of natural gas has been accumulated.

The temperature of 300°C is optimal for implementation of the process, as relatively low temperature will not cause strong corrosion of the instrumentation even at a long reaction time (4 h).

A distinctive feature of the zircon breakdown with ammonium hydrofluoride is the complete regeneration

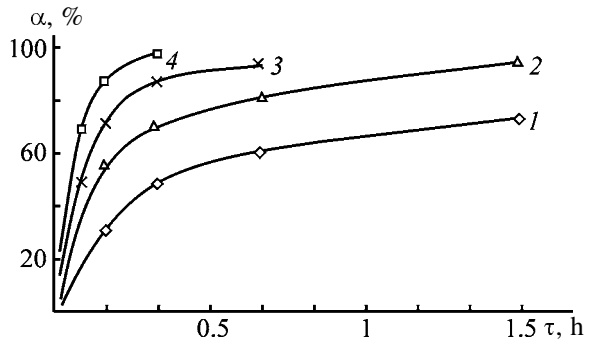


Fig. 2. Kinetic curves for the reaction of ammonium hydrofluoride with zircon. Temperature, °C: (*1*) 250, (*2*) 300, (*3*) 350, and (*4*) 400.

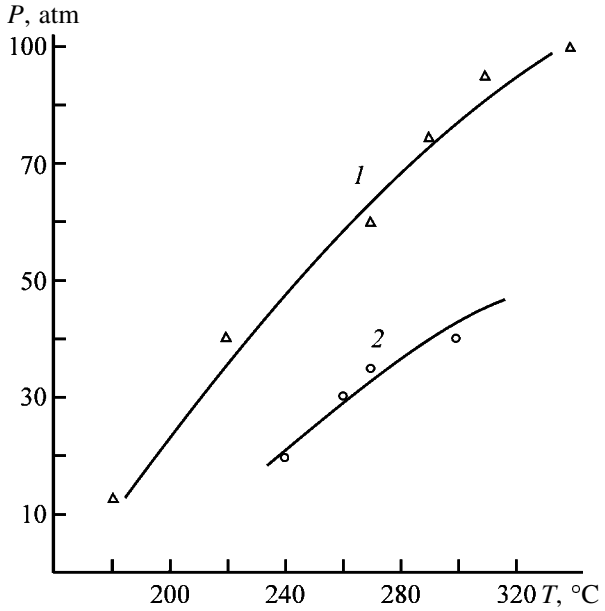

Fig. 3. Dependence of vapor pressure P of (*1*) ammonium fluoride and (*2*) ammonium hydrofluoride on temperature T under isochoric conditions in 100 cm^3 of air.

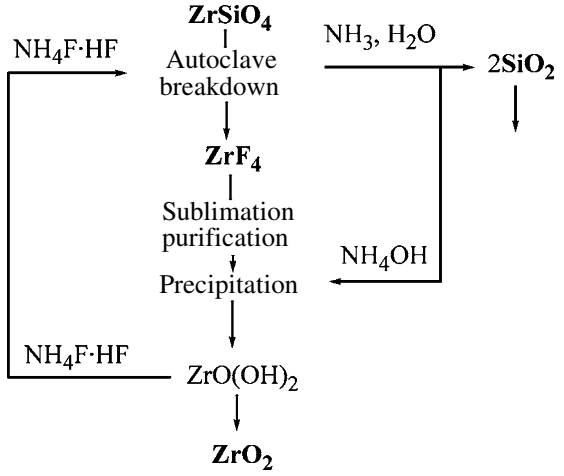

of ammonium fluoride, which makes the process economically attractive and environmentally safe.

The formed ammonium fluosilicate sublimes at temperatures above 320°C and is removed from the mixture [6].

Heating to 300°C removes unchanged ammonium fluoride from the mixture. As the temperature is increased, $(NH_4)_2ZrF_6$ decomposes to zirconium tetrafluoride, and ammonia and hydrogen fluoride are liberated.

The overall process of ammonium fluoride breakdown of zircon is shown in Scheme 3.

Scheme 3.

In the suggested scheme, the number of operations is minimized and complete recycling of the reagents is provided. Among disadvantages of the scheme is certain complexity of the instrumentation of the main process, ammonium fluoride breakdown of zircon, which is caused by the buildup of high pressure under isochoric conditions. The corrosive action of ammonium fluoride on stainless steel can be reduced by adding sodium fluoride [7]; however, the use of sodium fluoride will pose a problem of its regeneration and removal from the products.

CONCLUSIONS

(1) Optimal parameters of zircon breakdown with ammonium fluoride and hydrofluoride in an autoclave under isochoric conditions were found. In the case of ammonium hydrofluoride, the 95% decomposition at 300°C is reached within 1.5 h, and a pressure of 45 atm is developed in the system.

(2) The overall scheme of the cycle of zircon breakdown with the regeneration of ammonium fluoride and production of zirconyl hydroxide was suggested.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Sulfate-Containing Zirconium Dioxide Powders Made of Products of Baddeleyite Processing

V. N. Lebedev

Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Raw Materials, Kola Scientific Center, Russian Academy of Sciences, Apatity, Murmansk oblast, Russia

Received March 16, 2006

Abstract—Manufacture of sulfate-containing zirconium dioxide powders from basic zirconium sulfate, zirconium disulfate, and ammonium sulfatozirconate, which are sulfate-containing products of processing of baddeleyite concentrate, was studied.

DOI: 10.1134/S1070427206110048

Zirconium dioxide nanopowders are used for manufacturing specialty ceramics, catalysts, sorbents, and other materials with special properties. Such materials are commonly obtained from zirconium oxychloride or oxynitrate, with composition and properties of the products obtained dependent on both the starting salts and the method of powder preparation. Different crystalline modifications can be formed even in the stage of precipitation at prolonged boiling of hydrolysis precipitates or in an autoclave [1, 2]. The metastable cubic and tetragonal phases of zirconium dioxide are formed by the thermal dehydration below 380–400°C and transform into the stable monoclinic phase at higher temperature [3]. The temperature of the phase transitions and the properties of powders depend on the preparation conditions and on the presence of stabilizing impurities such as water, cationic, and anionic impurities [4–6].

In catalysis, ZrO_2 modified with sulfate groups came into use relatively recently. The modified ZrO_2 exhibits superacid properties, and its high specific surface area (of the order of 100 $m^2 g^{-1}$) is retained on heating [7–9]. Therefore, we consider in this study the manufacture of powders in which the content of SO_4^{2-} ions can be controlled by the starting materials. As starting materials were used products of processing of baddeleyite concentrate, i.e., basic zirconium sulfate (BZS), zirconium disulfate (ZDS), and ammonium sulfatozirconate (ASZ) [10, 11]. ZrO_2 obtained from zirconium oxychloride (ZOC) was used for comparison. The above products were separated by breakdown of baddeleyite concentrate with sulfuric acid or by sintering with calcium carbonate. The content of the impurities in BZS and ZOC was about 1×10^{-3}–1×10^{-4} wt %, and that in ZDS and ASZ, 1×10^{-1}–1×10^{-2} wt %. The basic zirconium sulfate was precipitated at the $SO_4^{2-} : ZrO_2$ molar ratios (m.r.) of 0.8, 0.6, and 0.45.

Zirconium oxides were prepared by heating hydroxides or sulfate-containing products at 380–800°C. The hydroxides were washed to remove sulfate ions to various extents, or the sulfate-containing products were heated without washing. According to data of the thermal analysis, the sulfates decompose in the range 600–800°C [12]. Zirconium hydroxides were prepared by back precipitation. To do this, a sample of zirconium-containing precipitate was introduced into a calculated amount of a 5% ammonia solution. The zirconium hydroxide precipitate thus obtained are pseudocrystalline and easy to filter [13]. The pulp was stirred for 2 h at pH 9, stored for 24 h to remove the possible products of incomplete hydrolysis, and washed to remove sulfate ions. The hydroxides were dried at 120°C for 12 h. Then, they were treated in a 0.1–1.0 M H_2SO_4 solution for 12 h to be saturated with sulfate groups.

The products obtained were subjected to X-ray phase analysis (DRON-1 diffractometer, CuK_α radiation). The specific surface area was calculated from the isotherms of low-temperature adsorption of nitrogen (BET). The content of the sulfate ions (counting on SO_3) in the samples was determined by X-ray fluorescence analysis (FRA-1 analyzer).

The monitored parameters of the samples heat-treated for 3 h are listed in Table 1.

Table 1 shows that the sintering of all samples, except for ASZ, yields zirconium dioxide powders

Table 1. Results of heat treatment of sulfate-containing zirconium products

** (n.d.) No data.

with the predominant amount of the monoclinic phase, which makes them of little use for catalysis [8]. In addition, the specific surface area of the sintered samples is low. The sulfur(VI) removal is maximal within 600–750°C. Most of sulfur(VI) ions are not removed from zirconium disulfate and ammonium sulfatozirconate after treatment at 650°C for 3 h.

The data obtained on heating the washed hydroxide samples of the different origins are presented in Table 2. Note that the hydroxides obtained by the addition into an ammonia solution of BZS, ASZ, and, to a lesser extent, of ZOC and ZDS, more readily settle and are easier to filter than those obtained by the direct neutralization of solution. The samples obtained from BZS and ASZ and dried at 120°C are powders, those obtained from ZOC, slightly sintered, and those converted from ZDS are glassy and more hydrated.

The hydroxides with sulfate history, prepared by the same method and treated at 380°C for 6 h, crystallize in different modifications. The hydroxides obtained from BZS, ASZ, and ZOC crystallize in the standard low-temperature cubic or tetragonal modification, whereas those obtained from ZDS transform into the monoclinic modification at 380°C, i.e., the phase transition temperature is abnormally low.

The surface area of the samples dried at 120°C is approximately the same (165–190 $m^2 g^{-1}$). Therefore, it is unlikely to attribute the above distinctions to the "dimensional" factor [4]. The phase transition temperature can be largely affected by the presence of impurities. In our case, however, the factor determining the phase composition is the history of samples, because the impurity concentrations in ZDS and ASZ are close.

The heat treatment accompanied by the loss of water results in the formation of crystallites. As a result, the specific surface area of the powders decreases. The surface area of the ZDS sample treated below 800°C decreases to a lesser extent, which is likely due to the constancy of the phase composition. The surface area of the sample obtained from BZS with a molar ratio of 0.45 is retained up to 600°C.

Table 3. Characteristics of heat-treated samples incompletely washed to remove sulfate ions

Precursor	SO_3, wt %	Treatment temperature, °C				
		380	600		750	
		phase	S, $m^2 g^{-1}$	m-ZrO_2, %	S, $m^2 g^{-1}$	m-ZrO_2, %
BZS (m.r. 0.45)	5.6	am + t	75	4	34	16
BZS (m.r. 0.6)	2.9	t	63	2	30	20
ASZ	10.4	am	74	2	29	10
	4.2	am + t	39	8	18	8
ZDS	11.2	am	24	60	31	85
	5.6	"	29	42	27	80

Note that the specific surface area directly correlates with the content of the monoclinic phase in samples obtained from BZS and treated at 600°C. The sample from ZOC has the largest specific surface area which, however, decreases to a greater extent on heating.

The phase composition in heat treatment and the specific surface area of the samples incompletely washed to remove sulfate ions are presented in Table 3.

The data obtained for hydroxides washed to remove sulfate ions to different extents show that the presence of sulfate ions in hydroxides shifts the zirconium dioxide crystallization to higher temperatures (Table 3). The sulfate-containing samples, except for ZDS, sintered at 600°C have the larger specific surface areas than their washed analogs. With increasing concentration of the sulfate ions, the specific surface area increased. These samples were mostly in the tetragonal modification up to 750°C, but their specific surface area, however, noticeably decreased. Thus, the effect exerted by the presence of sulfate groups in hydroxides is essentially the same as that observed in modification of the dried hydroxides with sulfuric acid.

Table 4. Characteristics of samples treated with H_2SO_4

Precursor	Characteristics of ZrO_2 powders		
	SO_3, wt %	phase	S, $m^2 g^{-1}$
BZS (m.r. 0.45)	4.5–6.0	t + 2–4% m-ZrO_2	94–108
BZS (m.r. 0.6)	5.4	t	59
BZS (m.r. 0.8)	5.6	t	16
ASZ	7.1	t	73.8
ZDS	6.2	t + 30% m-ZrO_2	45
ZOC	4.3–7.9	t	68–82

The characteristics of the zirconium dioxide samples obtained by saturating hydroxides with H_2SO_4 and sintering them at 600°C for 3 h are presented in Table 4. As seen from the table, the treatment of hydroxides with sulfuric acid results in an increase in the specific surface area of the samples and leads to stabilization of the tetragonal phase. The surface area of the powders obtained from BZS increases in the same proportion as in the samples not treated with sulfuric acid. The sample obtained from BZS at the minimal $SO_4^{2-} : ZrO_2$ molar ratio has the largest surface area. For hydroxides prepared from the BZS precursor (at the molar ratio of 0.45) and for those prepared from the ZOC precursor, the concentration of the acid in the saturated solution was varied within 0.1–1.0 M. After sintering, the concentration of sulfate groups and the specific surface area varied within the range indicated in Table 4, with rather large data scattering. In all cases, we failed to attain the characteristics presented for ZOC in [9]. In [9], hydroxides were obtained by the direct precipitation from a solution. However, in our study, the dried samples obtained by the same method were glassy and had the lower specific surface area. As in other cases, the sample obtained from ZDS stands out, as containing the monoclinic phase, though in a somewhat smaller amount.

CONCLUSIONS

(1) The characteristics of the products obtained by heat treatment of zirconium disulfate, ammonium sulfate zirconate, and basic zirconium sulfate, which are sulfate-containing products of processing of baddeleyite concentrate, were studied. Zirconium dioxide, mainly of monoclinic modification, was formed by decomposition of sulfates at 650–750°C. The specific surface area varied from 68 $m^2 g^{-1}$ with ammonium

sulfatozirconate precursor to 28 $m^2 g^{-1}$ with zirconium disulfate precursor.

(2) The presence of incompletely removed sulfate ions in hydroxides with a sulfate history increases the temperature of the onset of the zirconium dioxide crystallization, the temperature of its transformation from the tetragonal into the monoclinic phase, and the specific surface area.

(3) The sulfate-containing zirconium dioxide powders with the largest specific surface area (94–108 $m^2 g^{-1}$) were obtained from samples of basic zirconium sulfate at the molar ratio $SO_4^{2-} : ZrO_2 = 0.45$. The advantage of this method of manufacturing powders is good filterability of hydroxides and more efficient removal of chloride ions by washing in deposition of basic zirconium sulfate.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Mixed Phosphates $K_2M^{III}M^{V}(OPO_4)_2$: Heterovalence-Substituted Analogs of $KTiOPO_4$

I. V. Zatovskii, A. A. Babarik, and N. S. Slobodyanik

Shevchenko Kiev National University, Kiev, Ukraine

Received May 11, 2006

Abstract—A series of heterovalence-substituted analogs of $KTiOPO_4$ of the general composition $K_2M^{III}M^{V}(OPO_4)_2$ (M^{III} = Cr, Fe, In; M^{V} = Nb, Ta) were synthesized by crystallization from melts and by solid-phase reactions. Influence of the nature of tri- and pentavalent metals on the conditions of preparation and on the features of phase formation of substituted mixed phosphates was examined. The compounds obtained were characterized by X-ray diffraction analysis and by diffuse reflection spectroscopy.

DOI: 10.1134/S107042720611005X

Considerable interest in studying properties and preparing crystals of double phosphates with the $KTiOPO_4$ (KTP) structure does not weaken for more than 30 years. This is caused by unique nonlinear-optical and ferroelectric properties of KTP crystals [1]. Studies in this direction can be conventionally subdivided into applied and basic. The purpose of the applied studies is a search for conditions of KTP crystal growth and preparation of materials for laser technique on their basis [2]. Basic studies are aimed to reveal correlations between the composition, structure, and properties of KTP structural analogs [3, 4].

Compounds with a three-dimensional anionic sublattice of the general composition $AMOBO_4$, consisting of infinite chains of MO_6 octahedra linked in a certain mode by BO_4 tetrahedra, are usually assigned to structural analogs of KTP. In this case, a system of channels is formed, in which compensating cations of alkali or alkaline-earth metals are accommodated. Recently a considerable number of KTP analogs were synthesized by homo- and heterovalence substitution: $ATiOBO_4$ (A = Li, Na, K, Rb, Cs, Ag, Tl; B = P, As) [5–11], $AMOBO_4$ (A = Na, K, Rb, Ag, Tl; M = Sb, Nb, Ta; B = Ge, Si) [12–20]. Specific features of structures and properties of these compounds are appreciably affected by the nature of the transition metal forming their framework, by the nature of the tetrahedral anion BO_4, and by features of the charge-compensating cation.

Here we consider regular trends in formation of heterovalence-substituted KTP analogs $K_2M^{III}M^{V}(OPO_4)_2$ (M^{III} = Cr, Fe, In; M^{V} = Nb, Ta) by crystallization from melts and by solid-phase reactions. The phosphates synthesized have been characterized by X-ray phase analysis and diffuse reflection spectroscopy. Specific features of the preparation and crystallization of these compounds in relation to the nature of structure-forming metals and to the ratio of their ionic radii are discussed.

EXPERIMENTAL

Heterovalence-substituted KTP analogs were prepared by crystallization of potassium phosphate melts in the systems K_2O–P_2O_5–$M^{III}_2O_3$–$M^{V}_2O_5$ (M^{III} = Cr, Fe, In; M^{V} = Nb, Ta), and also by solid-phase reactions. As initial components we used analytically pure grade potassium phosphates KPO_3 and $K_4P_2O_7 \cdot 4H_2O$ and ultrapure and analytically pure grade oxides Nb_2O_5, Ta_2O_5, Fe_2O_3, Cr_2O_3, and In_2O_3.

When heterovalence-substituted KTP analogs were synthesized by crystallization from melts, the K/P ratio was varied from 1.10 to 1.55. The total weight content of oxides of metals in oxidation states V and III was set over a wide range (depending on their joint solubility) for M^{III}/M^{V} ratios from 0.5 to 3.0. Ground initial charges were placed in platinum crucibles and heated to 1000–1150°C. In most cases, the oxides completely dissolved within 3–8 h under isothermal conditions. The required tantalum(V) content in the systems was reached by adding K_2TaF_7 to homogeneous K_2O–P_2O_5–$M^{III}_2O_3$ melts at 900°C. The result-

Table 1. Conditions of solid-phase synthesis of heterovalence-substituted phosphates $KM^{III}_{0.5}Nb_{0.5}OPO_4$

Compound	Temperature, °C (time, h) of stepwise heat treatment
$KFe_{0.5}Nb_{0.5}OPO_4$	600 (5); 700 (3); 850 (6)
$KCr_{0.5}Nb_{0.5}OPO_4$	600 (5); 800 (5); 1000 (5); 1000 (10)
$KIn_{0.5}Nb_{0.5}OPO_4$	600 (5); 800 (5); 1000 (10)

ing melts were crystallized by cooling to 650–750°C at a rate of 10–50 deg h^{-1}. Phase formation processes were controlled by optical microscopic monitoring of samples of the melts. After the crystallization completion, fluxes were removed, and the resulting phases were washed with hot water or with solutions of inorganic acids.

To carry out solid-phase reactions in K_2O–P_2O_5–$M^{III}_2O_3$–Nb_2O_5 systems, we took stoichiometric amounts of metal oxides and potassium metaphosphate according to the equation

$$4KPO_3 + M^{III}_2O_3 + Nb_2O_5 \rightarrow 2K_2M^{III}Nb(OPO_4)_2,$$

The starting components were thoroughly ground, placed in platinum crucibles, and heated for 5 h at 600°C, after which the temperature was raised in 100°C steps to 1000–1130°C depending on the composition of the initial charge (Table 1). After each step, the charge was ground and the degree of conversion was evaluated by X-ray phase analysis.

The elemental composition of the resulting phosphates was determined by X-ray fluorexcence analysis (an Elvax Light spectrometer) and by flame photometry (an FPL-1 photometer). The X-ray diffraction patterns of products of solid-phase reactions and of powders of individual compounds were recorded on a DRON-3.0 diffractometer using CuK_α radiation (λ = 1.54178 Å). The electronic diffuse reflection spectra were taken on a UV-VIS Specord M-40 spectrophotometer in the range 11 000–40 000 cm^{-1}.

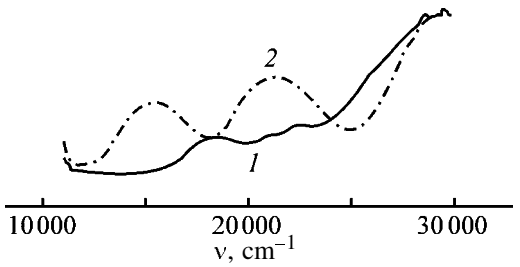
Generally, the crystallization areas of heterovalence-substituted KTP analogs $K_2M^{III}M^{V}(OPO_4)_2$ in potassium phosphate melts are limited by K/P and M^{III}/M^{V} ratios. At the same time, the regions and conditions of phase formation of pure compounds are considerably affected by the nature of a heterovalence pair of substituting metals and by the ratio of their ionic radii. Mixed phosphates $K_2M^{III}M^{V}(OPO_4)_2$ are formed of prismatic crystals with various extent of the development of base edges, which is typical for the growth of $KTiOPO_4$ crystals [21]. Conditions of the phase formation of mixed $K_2M^{III}M^{V}(OPO_4)_2$ phosphates in the course of their synthesis by spontaneous crystallization are given in Table 2.

When preparing melts in systems K_2O–P_2O_5–$M^{III}_2O_3$–Na_2O_5 (M^{III} = Cr, Fe, In), we found that the solubility of tantalum oxide in a melt considerably depends not only on the initial K/P ratio, but also on the nature of the trivalent metal present in the system. Therefore, we failed to reach homogeneity of some of the systems. Crystallization of such melts does not allow preparation of pure compounds.

The crystallization of $K_2M^{III}M^{V}(OPO_4)_2$ phosphates in iron-containing systems K_2O–P_2O_5–Fe_2O_3–$M^{V}_2O_5$ (M^{V} = Nb, Ta) is observed at the ratios K/P = 1.20–1.40 and the content of oxides in the liquid phase of 17–25 wt %. When the concentration of oxides decreases at this K/P ratio, the melts tend to vitrify. Also, the crystal phase is not formed in melts at K/P > 1.45, whereas at K/P < 1.20 the $K_2Fe_{1.5}\cdot Nb_{0.5}(PO_4)_3$ phosphate isostructural to langbeinite crystallizes [22].

The crystallization areas of phosphates with the KTP structure from the melts K_2O–P_2O_5–$M^{III}_2O_3$–$M^{V}_2O_5$ (M^{III} = Cr, In; M^{V} = Nb, Ta) are observed only in the case of the niobium-containing system. Mixed phosphate $K_2CrNb(OPO_4)_2$ is formed in melts at the ratio K/P = 1.25–1.37 in the range 860–820°C. In this case, when Cr_2O_3 is used as the initial component, preparation of a homogeneous reaction product

Table 2. Areas and conditions of crystallization of heterovalence-substituted KTP analogs from potassium phosphate melts



Compound	Ratio of components in melt	Temperature of crystal formation, °C	Color of crystals
$K_2NbFe(OPO_4)_2$	K/P = 1.2–1.4; Nb/Fe = 1; Fe/P = 0.28	860–820	Dark red
$K_2FeTa(OPO_4)_2$	K/P = 1.3; Fe/Ta = 2–3; Fe/P = 0.37	800–680	Bright red
$K_2CrNb(OPO_4)_2$	K/P = 1.25–1.37; Cr/Nb = 1; Cr/P = 0.13	860–820	Dark green
$K_2InNb(OPO_4)_2$	K/P = 1.5; In/Nb = 1; In/P = 0.13	860–780	Colorless

Table 3. Unit cell parameters of mixed phosphates, structural analogs of $KTiOPO_4$

Compound	Unit cell parameters, Å			V, Å^3
	a	b	c	
$K_2FeNb(OPO_4)_2$	10.66(5)	12.97(2)	6.46(1)	897.30(3)
$K_2FeTa(OPO_4)_2$	10.67(2)	12.96(2)	6.43(1)	890.07(2)
$K_2CrNb(OPO_4)_2$	10.67(0)	12.91(3)	6.42(9)	884.35(3)
$K_2InNb(OPO_4)_2$	10.79(5)	13.02(9)	6.58(9)	924.39(6)
$KTiOPO_4$	10.616(5)	12.814(6)	6.404(2)	871.16(64)

is considerably hampered, because of a low solubility of chromium(III) oxide in potassium phosphate melts even at 1150°C, which is caused by the formation of the double diphosphate $KCrP_2O_7$ on the surface of Cr_2O_3. The use of chromium orthophosphate $CrPO_4$ as the primary reaction product makes it possible to reach the equilibrium more quickly and to obtain $K_2CrNb(OPO_4)_2$ in the pure state. A decrease in the K/P ratio in the chromium-containing system to <1.20 leads to the crystallization of only $KCrP_2O_7$, and an increase in the K/P ratio to >1.40 in air results in partial $Cr^{3+} \rightarrow Cr^{6+}$ oxidation in the melt and, as a consequence, in the glass formation. The synthesis of $K_2InNb(OPO_4)_2$ is possible only in a very narrow range of ratios K/P = 1.47–1.52. At lower K/P ratios, joint crystallization of this compound and the mixed phosphate $K_2In_{1.5}Nb_{0.5}(PO_4)_3$ is observed [22].

Conditions of solid-phase synthesis of heterovalence-substituted phosphates $K_2M^{III}_{0.5}Nb(OPO_4)_2$ (M^{III} = Fe, Cr, In) considerably differ for various trivalent metals (Table 2). According to the IR data, the products of the primary heat treatment (600–800°C) are mixtures of phosphates always containing the double diphosphate $KM^{III}P_2O_7$. In the case of the iron-containing system, the formation of the phase $KFe_{0.5}Nb_{0.5}OPO_4$ at 850°C is complete within 6 h. Higher temperatures of 1000 and 1130°C are necessary to prepare pure $KIn_{0.5}Nb_{0.5}OPO_4$ and $KCr_{0.5}Nb_{0.5}OPO_4$, respectively. This difference in the synthesis conditions is attributable to different reactivities of double diphosphates $KM^{III}P_2O_7$ formed in the first stage of the reaction between KPO_3 and a metal(III) oxide.

Electronic diffuse reflection spectra of heterovalence-substituted KTP analogs. (ν) Frequency. (*1*) $K_2FeNb(OPO_4)_2$ and (*2*) $K_2CrNb(OPO_4)_2$.

The unit cell parameters for the KTP structural analogs obtained were calculated form the powder X-ray diffraction data. The X-ray patterns were analyzed using the least-squares iteration method applied to identity periods of structural models based on the $KTiOPO_4$ structural data [8] and also on our structural data for single crystals. All the phosphates synthesized crystallize in the orthorhombic system, and their unit cell volume increases as the ionic radius of the triple-charged metal ions increases (Table 3).

The local coordination surrounding of *d* metals in heterovalence-substituted phosphates $KFe_{0.5}Nb_{0.5}OPO_4$ and $KCr_{0.5}Nb_{0.5}OPO_4$ was studied by electronic diffuse reflection spectroscopy. The resulting spectra (see figure) suggest the octahedral oxygen surrounding of Fe^{3+} (d^5) and Cr^{3+} (d^3) ions. For the [FeO_6] chromophore, all the *d–d* transitions are spin- and Laporte-forbidden [23] and hence appear in the spectra as weak bands: $^6A_{1g} \rightarrow {}^4T_{1g}$ (ν = 26500 cm^{-1}, weak); $^6A_{1g} \rightarrow {}^4T_{2g}$ (ν = 22500 cm^{-1}, weak); $^6A_{1g} \rightarrow {}^4A_{1g}$ and $A_{1g} \rightarrow {}^4E_{1g}$ (ν = 18100 cm^{-1}, merged in a very weak common band). The charge-transfer band $Fe^{3+} \rightarrow O^{2-}$ is the strongest in the spectrum of $KFe_{0.5}Nb_{0.5}OPO_4$, which is caused by a rather strong electron-acceptor power of Fe^{3+} ions. In the diffuse reflection spectrum of $KCr_{0.5}Nb_{0.5}OPO_4$, three strong bands caused by *d–d* electronic transitions are observed: $^4A_2 \rightarrow {}^4T_2$ (ν = 25000 cm^{-1}, strong); $^4A_2 \rightarrow {}^4T_1(F)$ (ν = 18000 cm^{-1}, strong); and $^4A_2 \rightarrow {}^4T_1(P)$ (ν = 11900 cm^{-1}, strong). This pattern suggests almost regular octahedral surrounding of chromium atoms in the [CrO_6] chromophore [23].

CONCLUSIONS

(1) Features of the phase formation of heterovalence-substituted KTP analogs $K_2M^{III}M^{V}(OPO_4)_2$

(M^{III} = Cr, Fe, In; M^{V} = Nb, Ta) under conditions of the crystallization from a melt and of a solid-phase reaction were determined. The nature of M(III) ions essentially affects the conditions of formation of these compounds.

(2) The unit cell parameters of the phosphates synthesized were calculated from the powder X-ray diffraction data. These compounds crystallize in the orthorhombic system.

(3) The local coordination surrounding of *d* metals in the phosphates $KFe_{0.5}Nb_{0.5}OPO_4$ and $KCr_{0.5}Nb_{0.5}OPO_4$ was studied by electronic diffuse reflection spectroscopy.

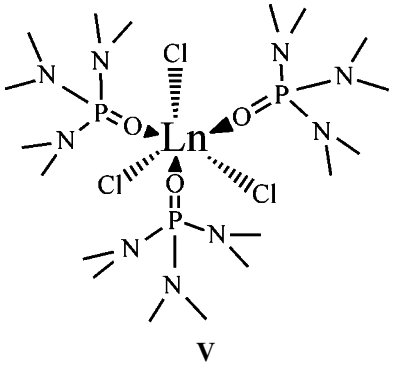
Abstract—Sol–gel process of hydrolytic polycondensation of tetramethoxysilane with trimethoxysilyl derivatives of lanthanide phosphoramide complexes was studied in order to obtain photoluminescent organic–inorganic hybrid materials.

DOI: 10.1134/S1070427206110061



Compounds of rare-earth elements (REE) are extensively used in analytical chemistry, electroplating, photooptics, and optoelectronics. The wide spectral range of emission (200 nm to 5 μm) in interaction of lanthanide derivatives with light makes them irreplaceable as nonlinear-optical and fiber-optic materials and elements of lasing media [1]. For practical use of REE derivatives in optics, they are introduced into chemically and thermally stable optically transparent coatings and materials. One of the most convenient methods for synthesis of hosts of this kind is the sol–gel process [2, 3] yielding silica matrices and, in particular, polycondensation of tetraalkoxysilanes [4]. An important disadvantage of such matrices is the high content of hydroxy groups and water molecules, which leads to strong quenching of photoluminescence (PL) from REE derivatives [5]. Therefore, introduction of lanthanides into a SiO_2 host in the form of their inorganic salts requires high-temperature treatment with special dehydrating reagents, e.g., Freons [6]. The simplest way to eliminate these labor-consuming procedures is to isolate REE from hydroxy quenching of PL via complexation with various organic ligands.

Complexes of lanthanides with various ligands have been synthesized (with 1,10-phenathroline and 2,2'-bipyridine [7], 4,4,5,5,5-pentafluoro-1-phenyl-1,3-pentanedione [8], 4,4,4-trifluoro-1-(2-thienyl)-1,3-butanedione [9], 2-pyridinecarboxaldehyde benzoylhydrazone [10], polyoxycarboxylic acids [11]). Introduction of transition elements into a silica matrix formed via hydrolytic polycondensation of tetraalkoxysilane does not present any difficulties [12–15]. Of particular interest from the standpoint of materials science are systems in which lanthanides complexes and silica are chemically bound [5, 16–19]. This improves the functional properties of the system via formation of organic–inorganic hybrids and guarantees uniform distribution of REE throughout the matrix. The formation of a chemical bond between silica and the REE complex is provided by use of ligands containing functional groups and application of special cross-linking agents [4]. As organic ligands are commonly used 5-amino-1,10-phenanthroline [16–18], 2-aminobenzoic acid [19], 2,6-pyridinedicarboxylic acid [5], etc.

In this study, organic–inorganic hybrids in the system Ln^{3+}–SiO_2 were synthesized using a derivative of hexamethylphosphoric triamide (HMPA) as a complexing agent and neodymium as REE. The choice of this ligand is not accidental. On the one hand, the synthesis and structure of complexes of salts of all REE with HMPA have been well studied [20], and on the other, use of complexes of this kind makes it possible to synthesize silica glasses in which the lanthanide ion is encapsulated in an inorganic phosphate fragment [22]. Previously unknown trimethoxysilyl derivative **II** of HMPA was synthesized as a ligand for preparing REE phosphoramide complexes chemically bound to the silica host:

The sol–gel method, hydrolytic polycondensation of tetramethoxysilane (TMOS) and complex **I**, was used to produce organic–inorganic hybrids with various concentrations of the organic component. The chemical binding of these reagents provided uniform distribution of the neodymium salt throughout the silica matrix. For comparison purposes, we synthesized composites in which the role of the organic component was played by the previously known complex of Nd^{3+} with HMPA [20, 21]:

V

Preliminary results of this study have been reported previously [23].

EXPERIMENTAL

The open porosity W_{op} and apparent density d_{app} of the composites obtained was determined by the Archimedes method for samples that did not crack in drying or measurements. The hardness of the samples was measured with a PMT-3 microhardness meter. Derivatograms were obtained with a Q-1500D derivatograph at temperatures of up to 1000°C at heating rate of 20 deg min^{-1}. The content of SiO_2 in composites **VIa**–**VIi** was found by thermal analysis. An electron-microscopic study of the gels was performed on an EM-125 instrument at an accelerating voltage of 75 kV by the method of cellulose–carbon replicas prepared on the surface of freshly cleaved samples. The pore structure of the samples was examined by studying adsorption–desorption isotherms of ethanol on a McBain spring vacuum balance [24]. ^1H and ^{13}C NMR spectra were obtained on a Bruker DPX-300 instrument at working frequencies of 300.13 and 75.5 MHz, respectively, with TMS as internal reference. UV spectra were measured on a Specord M40 instrument. Luminescence spectra were measured under sample illumination with light of argon (λ =

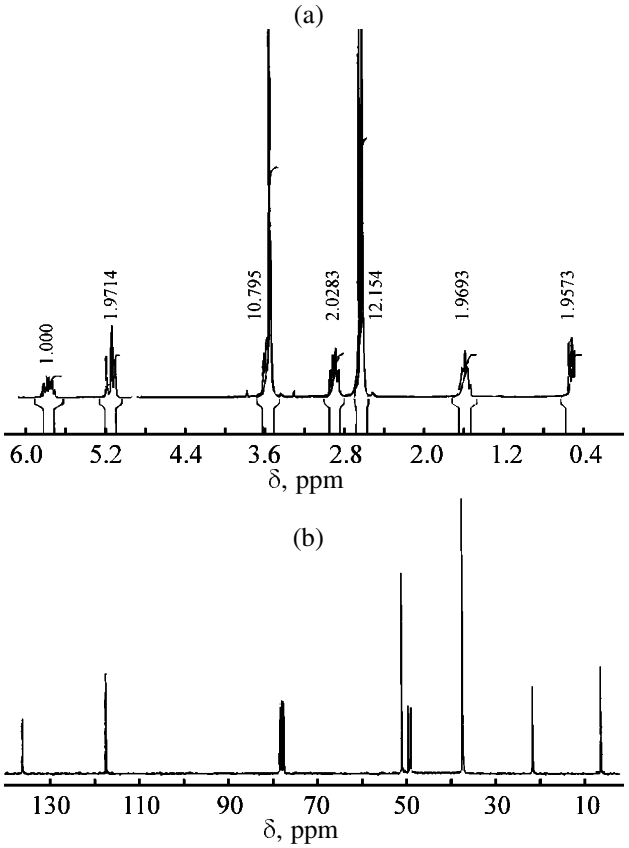


Fig. 1. (a) ^{1}H and (b) ^{13}C NMR spectra of compound **I**. (δ) Chemical shift.

337 nm) and krypton (λ = 580 nm) lasers, with detection by an optical analyzer.

Trimethoxysilylpropyl derivative **II** of phosphoric acid triamide was prepared by the reaction of tetramethylphosphorodiamidic chloride **III** [25] with 3-trimethoxysilylpropyl-*N*-allylamine **IV** [26] by the following procedure. A mixture of 3.9 g of chloride **III**, 5.0 g of amine **IV**, and 1.81 g of anhydrous pyridine in 100 ml of anhydrous petroleum ether (bp 70–110°C) was agitated for 5 days at 30°C under argon. The mixture was cooled and kept at 0°C for 24 h, after which the precipitate formed was filtered off and the filtrate was evaporated in a water-jet-pump vacuum and distilled to give 4.0 g (40%) of a colorless viscous oil [bp 128–130°C (0.01 mm Hg)]. The structure of the compound obtained was confirmed by ^{1}H and ^{13}C NMR data (Fig. 1).

In sol–gel synthesis of nanohybrids in the system Nd^{3+}–SiO_2, 4 equiv of water was added dropwise under vigorous agitation to a solution of TMOS (1 equiv) and REE complex in acetic acid (1 equiv). The resulting solutions were poured into hermetically sealed polypropylene test tubes and kept at 70°C for

Fig. 2. Electron micrograph of gel **VIc**. Magnification 60000.

2 days. Further, the hermetic stoppers of the tubes were replaced with stoppers with apertures (aperture diameter about 1 mm) and humid gels were dried for 24 h at 70°C, 24 h at 100°C, and 48 h at 120°C. The temperature was raised at a rate of 5 deg min^{-1}. Depending on the structure and content of an REE complex (1, 5, 10, 15, and 20 wt %), a number of composites were obtained (**VIa**–**VIi**, see table). The samples with a high content of the REE complex (**VIc**–**VIe**, **VIg**–**VIi**) were used in physicomechanical studies, and those with a low content of REE [0.5–1 wt % (**VIb, VId**)], in analysis of the luminescent properties of the materials obtained.

The structure of samples **VIa**–**VIi** is virtually the same (see Fig. 2). At the same time, composites **VIa**–**VId** formed via chemical binding of the components of the system are transparent (similarly to the starting SiO_2 gel, sample **VIa**); their density and

microhardness grow with an increase in the content of the organic component.

By contrast, composites **VIf**–**VIi** formed without chemical binding of the components of the sol–gel system are opaque and opalescent, and the increase in the content of the organic component has virtually no effect on the mechanical properties of the materials.

Figure 3 shows adsorption–desorption isotherms of ethanol at 18°C on composites **VIa**, **VId**, and **VIh**. These data can be used to calculate the specific surface area S and pore radius r for gel **VIa** and hybrids **VId, VIh**:

Sample	**VIa**	**VId**	**VIh**
S, $m^2\ g^{-1}$	530	10	360
r, nm	0.7	–	0.7

Apparently, the formation of a nanocomposite in which the organic and inorganic components are chemically bound is accompanied by virtually complete disappearance of porosity (i.e., pores visible in Fig. 2 for composite **VId** are not empty). In contrast to composite **VId**, in which the REE complex is uniformly distributed in the SiO_2 host because of the chemical binding to the matrix, association of REE molecules is observed for composite **VIh**. As a result, heterogeneities leading to loss of transparence by the system are formed in the composite.

Thermal analysis curves for a number of the composites synthesized (Fig. 4) allow certain conclusions about the structure of the hybrids formed. The range 100–200°C corresponds to intensive weight loss caused by evaporation of ethanol, excess acetic acid, water, methyl acetate, etc. [27]. The range 200–280°C apparently corresponds to removal of phosphoramide, primarily from composites **VIh** and **VIi**, because the intensity of the DTA effects for these composites substantially exceeds that for composites **VId** and **VIe**. The exothermic peaks of composites **VId** and **VIe** (Fig. 4, curves *2, 3*) are shifted to higher temperatures, compared with the exothermic peaks of composites **VIh** and **VIi** (curves *4, 5*). This fact suggests that hybrids whose components are not bound chemically (**VIh, VIi**) are only a mechanical mixture of the starting reagents, whereas hybrids **VId** and **VIe** exhibit a coordination Ln–O–P and Ln–N–P. Therefore, according to the weight loss curves, the organic component of the composite in hybrids **VId** and **VIe** burns-out at considerably higher temperatures.

Figure 5 shows UV spectra of a methanol solution of complex **I** (Fig. 5a) and of organic–inorganic hybrid **VId** containing 10 wt % phosphoramide com-

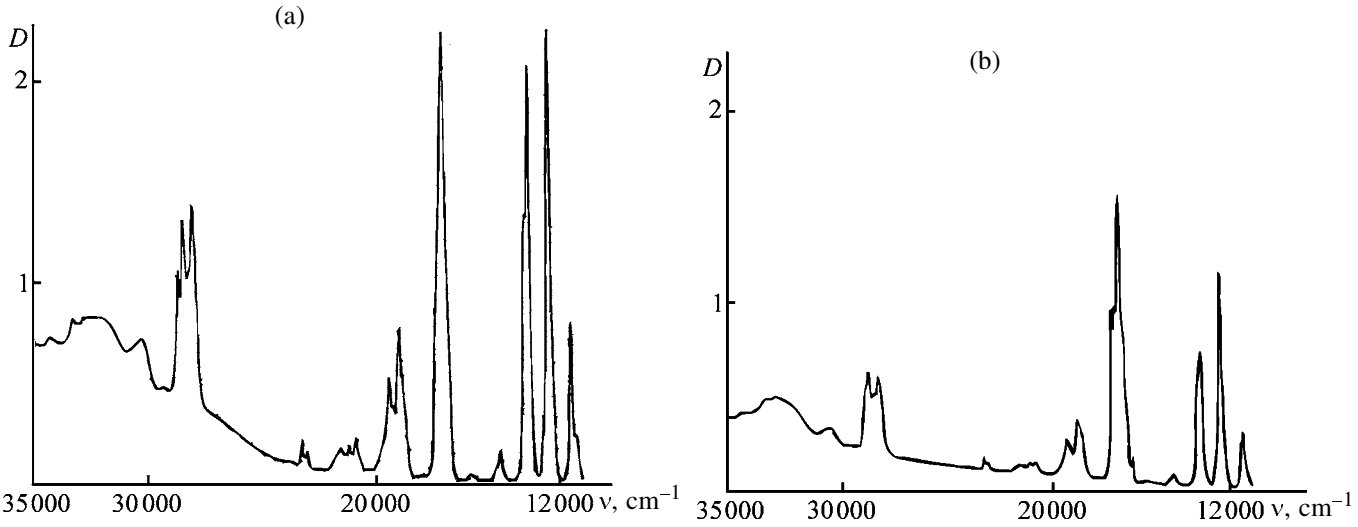

Fig. 5. UV spectra of (a) methanol solution of complex **I** and (b) organic–inorganic hybrid **VId** containing 10 wt % phosphoramide complex. (*D*) Absorption and (ν) wavenumber.

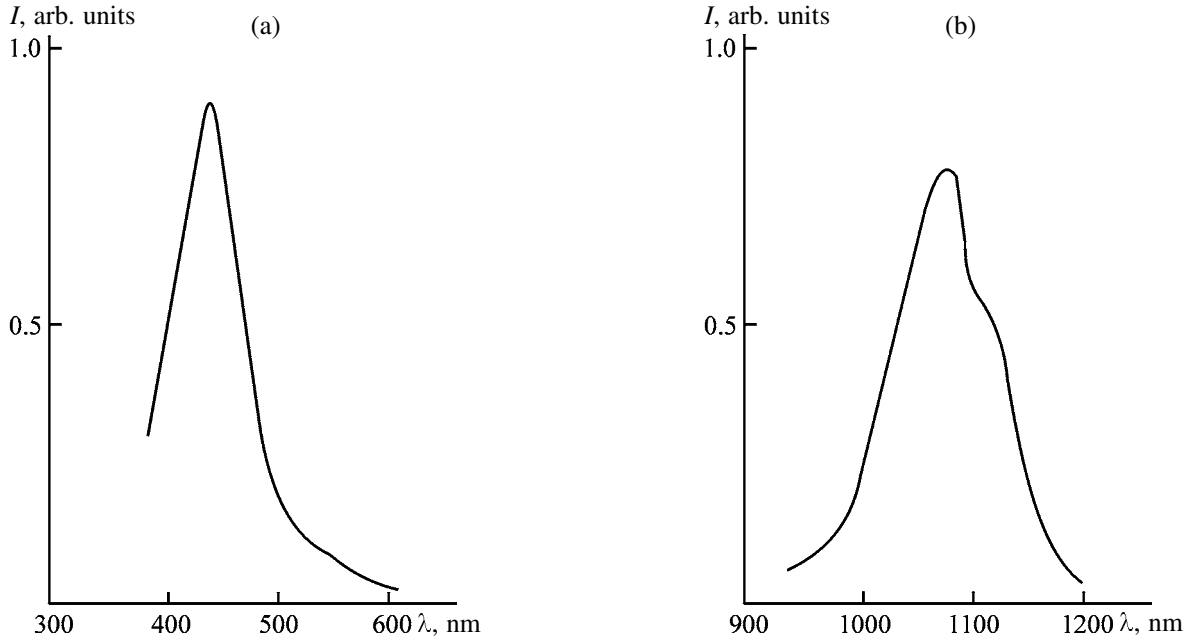

Fig. 6. PL of composite **VIb** containing complex **I** in an amount of 1 wt %. (*I*) Intensity and (λ) wavelength. The curves were obtained with sample exposure to (a) UV (λ = 337 nm) and (b) red (λ = 580 nm) light.

plex (Fig. 5b). Comparison of Figs. 5a and 5b shows good optical properties of the silica matrix synthesized. Preliminary data obtained in a study of the PL from composite **VIb** containing 1 wt % complex **I** are shown in Fig. 6. The curves in Figs. 6a and 6b were obtained with sample exposure to UV light (λ = 337 nm) and red light (λ = 580 nm), respectively.

CONCLUSIONS

(1) The hydrolytic polycondensation of tetramethoxysilane and lanthanide *N*-allyl-*N*-3-trimethoxysilylpropyl-*N*',*N*',*N*'',*N*''-tetramethylphosphoric triamide complex can be used to obtain photoluminescent materials in a system constituted by a lanthanide complex and silica.

(2) The formation of a nanohybrid via chemical binding of the components of the system provides uniform distribution of a lanthanide in the matrix.

(3) Encapsulation of the Nd^{3+} ion via complexation with a derivative of hexamethylphosphoric triamide prevents luminescence quenching under the

action of hydroxy groups of the xerogel matrix and water molecules.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

A Study of the Effect of Molecule Fragmentation Method on the Accuracy of Estimation of Phase Equilibria in Terms of the UNIFAC Model

Abstract—Application of the UNIFAC model to calculation of the liquid–vapor equilibrium in binary subsystems of the mixture of butyl alcohol, butyl Cellosolve, ethylene glycol, butyl carbitol, and diethylene glycol with different ways of molecule fragmentation into group constituents was considered. The optimal way of fragmentation was suggested.

DOI: 10.1134/S1070427206110073

In development of processes for separation of substances by distillation and extraction, it is necessary to have experimental data on liquid–vapor and liquid–liquid phase equilibria in binary and multicomponent subsystems of a mixture under study. If these data are lacking, the UNIFAC group model [1] can be used to estimate phase equilibria from the properties of pure substances.

To calculate liquid–vapor and liquid–liquid equilibria using the UNIPAC model, it is necessary to do the following: (i) fragment molecules into group constituents; (2) reduce the geometric parameters for each group constituent: volume parameter R_s and surface parameter Q_s; and (3) compose the matrix of parameters of the group interaction a_{mn}, a_{nm}.

The accuracy of estimation of a phase equilibrium is governed by the way in which molecules are fragmented into group constituents [2–4].

This study is concerned with the influence exerted by the method of molecule fragmentation on the accuracy of estimation of the phase equilibrium. A real industrial mixture formed in manufacture of butyl Cellosolve at Kazan'orgsintez Joint-Stock Company [5] was taken as a model.

The mixture includes the following components: butyl alcohol (BA), ethylene glycol (EG), butyl Cellosolve (BCe), butyl carbitol (BCa), and diethylene glycol (DEG). Among these compounds are monohydric (BA) and dihydric alcohols (EG, DEG) and ethers (BCe, BCa).

In simulation of the vapor–liquid equilibrium (VLE) using UNIFAC, it is necessary to take into account, wherever possible, specific features of each type of molecules of the mixture components and the mutual influence of their group constituents [2]. For example, formation of intermolecular hydrogen bonds is characteristic of such strongly associated molecules as alcohols. The so-called proximity effect of the ether and alcohol functional groups is observed in molecules of dihydric alcohols, e.g., diethylene glycol, and their ethers. At the same time, molecules of Cellosolves can form not only intermolecular but also intramolecular hydrogen bonds [3]. Let us consider alternative ways of fragmentation of molecules into group constituents.

Alternative 1: separation of the EG molecule into the DOH (OH–CH_2–CH_2–OH) group. For this type of fragmentation, the group interaction parameters a_{mn} and a_{nm} in [3, 4] are different. Therefore, we simulated phase equilibria using a_{mn}, a_{nm} from these references: DOH [3] and DOH [4].

Alternative 2 (for monohydric alcohols and ethers): separation of the –CH_2–CH_2–OH group [3, 4]: $n(CH_3)$–$n(CH_2)$–$n(CH_2O)$–$n(CH_2$–CH_2–OH).

Alternative 3: separation of the –OH group [3, 4]: $n(CH_3)$–$n(CH_2)$–$n(CH_2O)$–n(OH).

Alternative 4: separation of the ether group –O– [2]: $n(CH_3)$–$n(CH_2)$–n(O)–n(COH).

The values of the dimensionless geometric param-

Table 1. Geometric parameters of groups

Parameter	Group							
	$-CH_3$	$-CH_2-$	$-CH_2O$	–OH	–COH	–O–	$-CH_2OH$	–DOH
Q_s	0.85	0.54	0.78	1.20	1.12	0.24	1.66	2.25
R_s	0.90	0.67	0.92	1.00	1.20	0.24	1.88	2.41

eters R_s and Q_s coincide in all references [2–4] and are listed in Table 1 for the alternatives considered.

Alternative 5: separation of the ether group –O–, differs from alternative 4 in that the geometric parameters R_s and Q_s were found using the quasichemical group model [3].

This model rests on the Barker–Guggenheim theory [6] and represents a molecule as a sum of contact regions of different types. For example, two contact regions are distinguished in the hydroxy group, –O– and –H–, with

$$R_{OH} = R_O + R_H, \quad (1)$$

$$Q_{OH} = Q_O + Q_H. \quad (2)$$

Such a separation reflects the ability of the hydroxy group to form one hydrogen bond via the hydrogen atom and two bonds via the oxygen atom. The ether group is also separated into a contact region –O–.

However, the quasichemical Barker's model cannot be used in VLE simulation, because the group interaction parameters are not determined for all the components in terms of this model. We used the quasichemical Barker's model only in part, i.e., we used the model only to determine the geometric parameters R_s and Q_s. Published data [4] were taken for the $-CH_3$, $-CH_2-$, and –O– groups, and for the –OH group the parameters R_s and Q_s were calculated from data furnished by the quasichemical group model by formulas (1), (2). The parameters for alternative 5 are listed in Table 3.

Table 2. Geometric parameters calculated in terms of the quasichemical group model

Parameter	Group			
	$-CH_3$	$-CH_2-$	–O–	–COH(OH)
Q_s	0.68	0.43	0.19	0.90
R_s	0.72	0.54	0.20	0.96

VLE was simulated using a software package developed at Karpov Research Physicochemical Institute. The VLE was simulated using the UNIFAC model at 6–10 experimental points uniformly distributed over the entire concentration range.

The estimation accuracy was evaluated by root-mean-square discrepancies between the experimental and calculated data for the liquid–vapor equilibrium [7–9]. The resulting root-mean-square deviations of the boiling points of the mixtures, ΔT_{rms} (°C), and vapor compositions, Δy_{rms} (mol %), in binary mixtures are listed in Table 4 for all the alternatives.

As seen from Table 4, the fragmentation by alternative 1 (with the ethylene glycol molecule represented by a single subgroup) shows the largest error and can be considered unsatisfactory. Alternative 2 also exhibits gross errors.

Consequently, fragmentation of the molecules into larger subgroups containing two or more functional groups fails to give satisfactory results in VLE calculations in terms of the UNIFAC model. Finer fragmentation of the molecules (alternatives 3–5) furnishes better results.

The VLE simulation in systems that have no thermodynamic limitations on separation and are constituted by molecules of strongly different sizes yielded satisfactory and comparable accuracies of estimation of the phase equilibrium by alternatives 3–5. At the same time, the smallest root-mean-square discrepancies between the calculated and experimental boiling points and vapor compositions are obtained using alternative 5, and, therefore, this alternative is preferable.

In mixtures with molecules of components differing in size only slightly, as in the BCe–BCa system and in azeotropic mixtures such as BCe–EG (tangential azeotrope), ERG–BCa, and BCa–DEG (minimal azeotropes), alternatives 3–5 give different VLE estimations, especially at high concentrations of the low-boiling component, i.e., in the region in which separation of mixtures into individual components is difficult.

Table 5. Root-mean-square deviations of boiling points and vapor compositions in ternary systems

System	Pressure P, mm Hg	Alternative					
		3		4		5	
		ΔT_{rms}, °C	Δy_{rms}, %	ΔT_{rms}, °C	Δy_{rms}, %	ΔT_{rms}, °C	Δy_{rms}, %
BA–BCe–BCa	760	0.7	2.05	0.8	1.98	0.5	1.95
BA–EG–BCa	760	0.6	2.12	0.5	2.16	0.3	2.12
BA–BCe–EG	40	1.3	2.37	1.1	2.42	0.9	2.27
BCe–EG–BCa	40	0.9	3.14	0.7	2.98	0.6	2.85
BCe–EG–DEG	40	0.7	1.54	0.8	1.45	0.5	1.38
BCe–BCa–DEG	40	1.2	1.96	1.1	1.88	0.8	1.85
EG–BCa–DEG	40	0.9	1.28	0.8	1.15	0.7	1.08

With alternative 3, the azeotrope compositions in the EG–BCa and BCa–DEG systems are shifted by 3.5–4.3 mol %. With alternatives 4 and 5, the compositions are reproduced, with the root-mean-square errors for the boiling point and vapor composition equal to 0.8–1.4°C and 1.4–2.5 mol % for alternative 4 and to 0.6–0.8°C and 0.6–1.5 mol % for alternative 5.

To verify the reliability of the binary interaction parameters, we simulated VLE in ternary systems. The calculated and previously obtained experimental data [10] were compared, and the results obtained are listed in Table 5.

Thus, the minimum discrepancies between the calculated and experimental values were obtained with alternative 5. It may be suggested that using the geometric parameters of the quasichemical model with separation of contact regions makes it possible to reflect orientation effects and association and to take into account the formation of inter- and intramolecular bonds by alcohol and Cellosolve molecules, respectively.

CONCLUSIONS

(1) Fragmentation of molecules into large constituents containing three or more functional groups fails to provide satisfactory results in simulation of the vapor–liquid equilibrium in terms of the UNIFAC model. Finer fragmentation of molecules furnishes better results.

(2) The type of fragmentation of molecules into group constituents in systems that are composed of molecules strongly different in size and have no thermodynamic limitations on separation has virtually no effect on the accuracy of estimation of the liquid–vapor phase equilibrium in terms of the UNIFAC model.

(3) The effect of the type of fragmentation of molecules into group constituents on the accuracy of estimation of the vapor–liquid equilibrium in terms of the UNIFAC model is the most pronounced for difficultly separable (azeotropic and close-boiling) mixtures. The ether group –O– should be separated in molecules of such mixtures: [$n(CH_3)$–$n(CH_2)$–n(O)–n(COH)]. When determining the geometric parameters R_s and Q_s, it is advisable to separate the contact region –O– in the ether group and contact regions –O– and –H– in the hydroxy group.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Thermodynamic Properties of Ternary Systems: Calculation of Standard Enthalpies of Solvation of Triols, Diols, and a Series of Their Ethers in Water–Methanol Mixed Solvent

V. P. Korolev

Institute of Chemistry of Solutions, Russian Academy of Sciences, Ivanovo, Russia

Received January 11, 2006

Abstract—An equation for the standard enthalpy of solvation of a compound in a binary solvent is derived. The enthalpies of solvation in water–methanol mixtures are estimated for 1,3-propane- and 1,6-hexanediols, 1,2,4-butane- and 1,3,5-pentanetriols, 2-methoxy- and 2-propoxyethanols, and diethylene glycol. The enthalpy of solvation of 1,2-dimethoxyethane in the water–methanol mixed solvent is determined experimentally.

DOI: 10.1134/S1070427206110085

Development of empirical and semiempirical methods for calculation of physicochemical and thermodynamic characteristics of solutions is important for prediction of properties of the solution on the basis of characteristics of its components.

In this study we examined the system water–methanol as a mixed solvent, because it is widely used in various processes, as being characterized by a broad range of solvency and solvating activity. Note also that the correlation between the host–guest complexation constant and properties of the solvent was first reported just for the water–methanol mixed solvent [1].

As solutes we considered such compounds as glycerol, diols, and their ethers up to 1,2-dimethoxyethane (fragment of polyether). Mixtures containing the indicated components are currently intensively studied by various methods [2–9]. It is worth noting that polyhydric alcohols currently attract attention as protein stabilizers and cryobioprotectors.

The characteristics of the solvents (water and methanol) and solutes, required for our calculations, are summarized in Table 1. Among them the key parameter is the cohesion energy density p (kJ cm^{-3}). The compounds were selected so that two of them (glycerol and ethylene glycol) have p higher than that of methanol, two have p close in value to methanol, and two have p considerably lower than that of methanol.

Let us consider alternative calculation procedures.

A. ESTIMATION OF THERMODYNAMIC CHARACTERISTICS OF TERNARY SYSTEMS FROM DATA FOR INDIVIDUAL COMPONENTS

Following the Scatchard–Hildebrand theory, the standard enthalpy of solvation (SES) of a nonelectrolyte A in a solvent S can be estimated by Eq. (1) [12]:

$$\Delta H^0(\mathrm{S,A}) = V_\mathrm{A} p_\mathrm{S} - 2V_\mathrm{A}(p_\mathrm{A}p_\mathrm{S})^{1/2} - RT, \qquad (1)$$

where V_i is the molar volume and p_i, cohesion energy density calculated using Eq. (2)

$$p_i = (\Delta_\mathrm{vap} H_i^0 - RT)/V_i, \qquad (2)$$

where $\Delta_\mathrm{vap}H_i^0$ is the heat of vaporization; R, gas constant; and T, absolute temperature [12–16].

If S represents a binary mixture, in estimating the

Table 1. Properties of compounds at 25°C

0.75	1.05	89.6	91.3	75.9	75.4
1.0	0.87	90.1	89.6	76.2	76.4

cohesion energy density we will neglect its excess parameters, H^E_{12} and V^E_{12}:

$$p_S = p_{mix} = (x_1\Delta_{vap}H^0_1 + x_2\Delta_{vap}H^0_2 - RT)/(x_1V_1 + x_2V_2), \quad (3)$$

where x_i is the mole fraction.

Experimental [11] and theoretical [calculated by Eq. (1) on the condition that $p_S = p_{mix}$] standard enthalpies of solvation of glycerol and 1,4-butanediol in water–methanol mixtures are given in Table 2. For both compounds in methanol, the theoretical results agree well with the experiment. Therefore, SES of diols and triols in methanol can be estimated theoretically with a precision well comparable with that of the experiment. In the case of glycerol, the experimental values are well consistent with the experimental results over a wide concentration range (x_2 = 0.3–1.0). In going from glycerol to 1,4-butanediol, i.e., to the compound with a lower cohesion energy density, this range is considerably narrower. In both cases, the maximal discrepancy was observed in water as a solvent. It should be pointed out that, for 2-ethoxyethanol, having even lower cohesion energy density than glycerol or 1,4-butanediol (Table 1), the error of determination of SES by Eq. (1) is fairly high even in straight methanol (ΔH^0_{exp} = –47.2 kJ mol^{-1} [11]; ΔH^0_{calc} = –42.2 kJ mol^{-1}). Therefore, calculation by procedure A is limited by both the solvent composition and the nature of solute.

B. ESTIMATION OF THERMODYNAMIC CHARACTERISTICS OF TERNARY SYSTEMS FROM DATA FOR BINARY SYSTEMS

In this case, we should know SES values of compound A in components of the mixed solvent ΔH^0_1 and ΔH^0_2, determined experimentally or theoretically.

The enthalpy of solvation of a compound in a mixed solvent ΔH^0 can be estimated by Eq. (4) [15]:

$$\Delta H^0 = g_1\Delta H^0_1 + g_2\Delta H^0_2, \quad (4)$$

where g_i is the weight factor ($g_1 + g_2 = 1$).

Kustov et al. [15] derived an equation for the weight factor using the Scatchard–Hildebrand theory:

$$g_2 = \frac{\varphi_2(p_2 - p_1) - 2p_3^{1/2}\{[p_1 + \varphi_2(p_2 - p_1)]^{1/2} - p_1^{1/2}\}}{p_2 - p_1 - 2p_3^{1/2}(p_2 - p_1^{1/2})}, \quad (5)$$

where φ_i is the volume fraction of the ith component [$\varphi_2 = x_2V_2(x_1V_1 + x_2V_2)^{-1}$; $\varphi_1 = 1 - \varphi_2$], and subscript 3 refers to the solute.

Note that the weight factor g also reflects such a characteristic of the solute as its cohesion energy density p_3. It is easy to see that, for the hypothetical case with $p_3 = 0$, $g_2 = \varphi_2$. Actually, $p_3 \neq 0$ and $g_2 > \varphi_2$ (Table 3).

Taking our previous results [16] into account, in this study we use a new relationship for the enthalpies of solvation of nonelectrolytes in binary solvents:

$$\Delta H^0 = \varphi_1\Delta H^0_1 + \varphi_2H^0_2 + V_3p^E_{at}, \quad (6)$$

where p^E_{at} is the excess cohesion energy density of the binary solvent, estimated in the athermic approximation [16],

$$p^E_{at} = p_{at} - p_{id}, \quad (7)$$

$$p_{at} = (x_1\Delta_{vap}H^0_1 + x_2\Delta_{vap}H^0_2 - RT)/(x_1V_1 + x_2V_2 + V^E_{12}), \quad (8)$$

$$p_{id} = (x_1\Delta_{vap}H^0_1 + x_2\Delta_{vap}H^0_2 - RT)/(x_1V_1 + x_2V_2). \quad (9)$$

The cohesion energy density of an ideal mixture can be estimated also by Eq. (10) [16]:

$$p_{id} = \varphi_1p_1 + \varphi_2p_2. \quad (10)$$

The sum of the first two terms in Eq. (6) represents the additive (by φ) contribution to SES, and the third term, the deviation of SES from the additivity. Note that the first term in Eq. (1) corresponds to the heat of cavity formation in solvent S in solvation of compound A. It follows from comparison of the first term in Eq. (1) and the third term in Eq. (6) that it is the energy of cavity formation that represents the nonad-

Table 3. Experimental [11] and theoretical [calculated by Eqs. (1), (12)] standard enthalpies of solvation (kJ mol^{-1}) of compounds in water (1)–methanol (2) mixtures at 25°C [g_2 is estimated by Eq. (5)]

0.75	0.87	0.966	75.9	76.6	75.4	0.911	49.2	50.2	48.6

ditive (on the volume fraction scale) contribution to the enthalpy of solvation of the compound in the mixed solvent. Therefore, the enthalpy of interaction of the solute with the binary solvent is additive with respect to the volume fraction. Thus, Eq. (6) indirectly correlates with the theoretical equation (1).

It should be pointed out that Eqs. (4) and (6) are of particular interest in view of the fact that they include no empirical coefficients. Each of these equations includes ΔH^0_1 and ΔH^0_2, i.e., the terms reflecting the interaction of the solute with the solvent components. Equation (4) takes into account [via the weight factor (5)] the cohesion energy density of the solute p_3. Equation (6) includes the characteristics of the solute (V_3) and binary solvent [V^E_{12}, Eq. (8)].

In order to use Eq. (6), one should obtain the analytical relationship p^E_{at} vs. φ. This dependence is reproduced with a high correlation coefficient r by a symmetrical parabola:

$$p^E_{at}\ (\text{J cm}^{-3}) = (212 \pm 1)\varphi_1\varphi_2,\ r = 0.999. \qquad (11)$$

Taking Eq. (6) into account, we finally obtain:

$$\Delta H^0 = \varphi_1 \Delta H^0_1 + \varphi_2 \Delta H^0_2 + 212 V_3 \varphi_1\varphi_2. \qquad (12)$$

The experimental SES values of compounds in water–methanol mixtures are given in Table 3 in comparison with the theoretical values, and the average (for six compositions) moduli of the absolute errors $\delta H^0_{av} = \Sigma \mid \Delta H^0_{calc} - \Delta H^0_{exp} \mid /6$ (kJ mol^{-1}) are presented below.

Equation no.	(4)	(12)
Glycerol	0.6	0.4
Ethylene glycol	0.7	0.5
1,4-Butanediol	2.1	0.4
2-Ethoxyethanol	3.0	0.7

For the most hydrophilic compounds, glycerol and ethylene glycol, characterized by high cohesion energy density (Table 2), the enthalpies of solvation estimated by Eqs. (4) and (12) are well consisted with the experimental values (δH^0_{av} = 0.4–0.7 kJ mol^{-1}). The situation changes in going to the less hydrophilic compounds, 1,4-butanediol and 2-ethoxyethanol. These compounds have considerably lower cohesion energy densities as compared to glycerol or ethylene glycol. As a result, for 1,4-butanediol, the calculation error decreases by a factor of 5 in going from Eq. (4) to Eq. (12). For 2-ethoxyethanol, the calculation error decreases to nearly the same extent. Therefore, in these cases, Eq. (4) is inferior to Eq. (12) in the accuracy. However, it should be pointed out that Eq. (4) includes no characteristics of the binary mixture (Y^E_{12}).

Equation (12) reproduces the experimental values for all four solutes at nearly the same accuracy. In

1.0	71.5	71.5	85.6	85.6	94.8	94.8	99.5	99.5

the subsequent, we will analyze only Eq. (12), including predictability tests.

Equation (12) was tested for several of solutes from the diol and triol series (Table 4). There are no published data on SES of such compounds in water–methanol mixtures other than those presented in Table 3. The "experimental" solvation enthalpies of 1,3-propanediol (V = 72.5 cm^3 mol^{-1} [18]) and 1,6-hexanediol were determined by linear interpolation and extrapolation with respect to the carbon atoms of data of Table 3 for ethylene glycol and 1,4-butanediol. The molar volume of 1,6-hexanediol (mp 42°C), obtained by linear extrapolation of data for 1,3-propane- and 1,4-butanediols, is 120.8 cm^3 mol^{-1}. Note that the standard enthalpy of hydration of 1,6-hexanediol, given in monograph [19], is –94.2 kJ mol^{-1}. This quantity appears to be strongly underestimated by its absolute value. Indeed, according to [19], the difference between the enthalpies of hydration of 1,4-butanediol and 1,5-pentanediol is 6, and between 1,5-pentanediol and 1,6-hexanediol, only 1.2 kJ mol^{-1}, which is doubtful, since for higher homologs, the contribution of the CH_2 group is a constant value. Therefore, the standard enthalpy of hydration that we give in Table 4 for 1,6-hexanediol appears to be more realistic than that reported in [19].

The "experimental" SES values of 1,2,4-butane- and 1,3,5-pentanetriols were estimated on the assumption that the contribution of the CH_2 group to the enthalpy of solvation of the triols with terminal OH groups is the same as for the corresponding diols. Using this assumption, we estimated the molar volumes of 1,2,4-butanetriol (89.3 cm^3 mol^{-1}) and 1,3,5-pentanetriol (105.4 cm^3 mol^{-1}). Table 4 demonstrates reasonable agreement between the "experimental" and theoretical [calculated by Eq. (12)] standard enthalpies of solvation. The δH^0_{av} estimated for six water–methanol mixtures is 0.5 kJ mol^{-1} for 1,3-propanediol and 0.4 kJ mol^{-1} for three other compounds (Table 4). In this connection, it would be interesting to calculate SES of erythritol and, possibly, other polyhydric alcohols using Eq. (12).

Table 5. Theoretical [estimated by Eq. (12)] standard enthalpies of solvation (kJ mol^{-1}) of 2-methoxyethanol (MOE), 2-propoxyethanol (POE), and diethylene glycol (DEG) in water (1)–methanol (2) mixtures at 25°C

x_2	MOE	POE	DEG

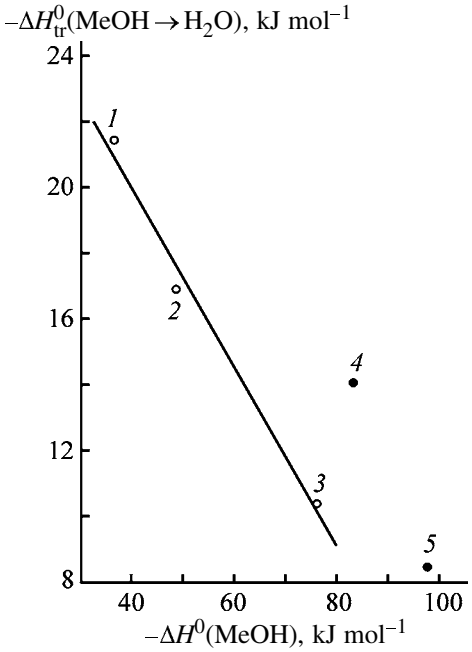
0.10	54.5	62.7	91.4
0.20	50.8	58.3	87.8
0.30	48.4	55.5	85.5
0.50	45.8	53.0	83.4
0.75	44.7	52.4	82.9
1.0	44.5	52.9	83.4

Glycols and their ethers as well are widely used in technology. Mixtures containing these components are being intensively studied. The estimated SES values of two ethylene glycol ethers in water–methanol mixtures are given in Table 5. The enthalpies of hydration of 2-methoxy- and 2-propoxyethanols were taken from [19]. The contribution of the CH_2 group to SES of alkoxyethanols in methanol was taken equal to that of 1-alkanols. The molar volume of 2-propoxyethanol (114.6 cm^3 mol^{-1}) was estimated from the published data for 2-ethoxy- and 2-butoxyethanols [10].

It is accepted that, because of their simple molecular structure, polyethylene glycols are well suited as models for studying structuring of water in solutions of macromolecules [4]. The strong hydration of poly-

ethylene glycols is caused primarily by their topology [4]. The available set of experimental data allows estimation of SES of diethylene glycol in water–methanol mixtures. This compound has a relatively high cohesion energy density (p = 0.848 kJ cm^{-3} [20]). Taking into account the excellent quality of calculation (Table 2) of the enthalpy of solvation of 1,4-butanediol (p = 0.835 kJ cm^{-1}) in methanol, SES of diethylene glycol in methanol also was estimated by Eq. (1). The resulting SES (–83.4 kJ mol^{-1}) is only slightly lower in the absolute value than that of 1,6-hexanediol (–85.6 kJ mol^{-1}) (Table 4). However, SES of diethylene glycol in methanol is considerably less negative than that of its isomer, 1,2,4-butanetriol [–94.8 kJ mol^{-1} (Table 4)]. The standard enthalpy of hydration of diethylene glycol was estimated from its heat of solution in water (–14.1 kJ mol^{-1} [21]) using Eq. (12). The results are given in Table 5. It would be interesting to perform such a calculation for, e.g., triethylene glycol and tetraethylene glycol, but, unfortunately, the required data are not available.



Our results show that Eq. (12) reproduces well SES of ethylene glycol and its monoethyl ether (2-ethoxyethanol) in methanol. It may be suggested that the theoretical data obtained for 2-methoxyethanol are sufficiently reliable (Table 5). However, one cannot be sure that Eq. (12) provides good quality of calculation of ethylene glycol dimethyl ether (1,2-dimethoxyethane). This compound in the liquid state is an aprotic solvent having a low cohesion energy density (p = 0.325 kJ cm^{-3}), which is typical of ethers. Therefore, in this study we have measured the enthalpies of solution of 1,3-dimethoxyethane in water–methanol mixtures using the same experimental procedure as in [9]. The moisture content in methanol (chemically pure grade) was below 0.1 wt %. From the heats of solution, we estimated the enthalpies of solvation of 1,2-dimethoxyethane for various ether concentrations (Table 6). The heats of solution are not presented in Table 6, since it is easy to calculate them by summing the enthalpies of solvation with the heat of vaporization of 1,2-dimethoxyethane (Table 1). Table 6 also includes the values estimated by Eq. (12). The molar volume can be found in Table 1. In water-rich mixtures ($x_2 \le 0.3$, $\varphi_2 \le 0.5$), the theoretical results agree well with the experiment. In the methanol-rich mixtures ($\varphi_2 > 0.5$), the calculation error is noticeably higher. Generally, analysis of the results obtained (Tables 3, 4, 6) reveals that Eq. (12) provides quite reliable SES for dilute solutions of methanol in water ($x_2 \le 0.1$), i.e., in the composition range where hydrophobic interactions and related structural transformations of the solutions are clearly pronounced.

Table 6. Experimental and theoretical [Eq. (12)] standard enthalpies of solvation (kJ mol^{-1}) of 1,2-dimethoxyethane in water (1)–methanol (2) mixtures at 25°C

(m) Molality of DME.

The main goal of this study was to obtain SES theoretically. Nevertheless, I would like to draw attention of readers to a feature of the behavior of the investigated compounds in water and methanol. 1,2,4-Butanetriol and diethylene glycol, on the one hand, and 1,4-butanediol, 2-ethoxyethanol, and 1,2-dimethoxyethane, on the other hand, are structural isomers. On changing the hydroxy group for the ether oxygen, both the standard enthalpies of hydration and SES in methanol become less negative. However, in this case, the standard heats of transfer of the solutes from methanol to water become more negative, as shown in the figure. As can be seen, the less negative the SES

Standard enthalpies of solvation of compounds in methanol and of their transfer from methanol to water: (*1*) 1,2-dimethoxyethane, (*2*) 2-ethoxyethanol, (*3*) 1,4-butanediol, (*4*) diethylene glycol, and (*5*) 1,2,4-butanetriol.

of the compound in methanol, the more negative is its heat of transfer from methanol to water. We attribute this trend to the fact that, in solvation of the investigated compounds, methanol behaves as a stronger base (acceptor of the hydrogen bond), while water, as a stronger acid (donor of the hydrogen bond).

CONCLUSIONS

(1) An equation for the standard enthalpies of solvation of compounds in the water–methanol mixtures is derived.

(2) The enthalpies of solvation in water–methanol mixtures are estimated for 1,3-propane- and 1,6-hexanediols, 1,2,4-butane- and 1,3,5-pentanetriols, 2-methoxy- and 2-propoxyethanols, and diethylene glycol.

(3) The enthalpy of solvation of 1,2-dimethoxyethane in the water–methanol mixtures is determined experimentally.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Dependence of the Stability of Peroxo Solvates on Their Structural and Thermochemical Characteristics and on the Chemical Properties of the Starting Salts

Abstract—Data on the dependence of the stability of peroxo solvates on their structural and thermochemical characteristics and on the chemical properties of the starting salts, carriers of hydrogen peroxide, are summarized and correlated.

DOI: 10.1134/S1070427206110097

It is common knowledge that hydrogen peroxide in aqueous solutions and in solid compounds is prone to catalytic decomposition. Hydrogen peroxide itself, present in the associated state in concentrated solutions and in the form of associates with water in dilute solutions, is a reasonably stable substance. The existing methods of the H_2O_2 purification to remove catalytic impurities make use of any stabilizers unnecessary. Stabilizers are added only when exhaustive purification of hydrogen peroxide is economically inexpedient [1].

The stability of hydrogen peroxide coordinated to salts, i.e., of peroxo solvates, can be affected by foreign impurities. Also, unlike the stability of free H_2O_2, it can depend on their intrinsic physicochemical properties, such as the degree of structural changes in H_2O_2 molecules upon coordination, binding energy of hydrogen peroxide, and chemical properties of the solvated salt.

Here we attempt to summarize and correlate the data on effect of the above characteristics on the stability of peroxo solvates, which may be useful for further studies in this field.

Peroxo solvates, as solid forms of hydrogen peroxide, are promising oxidants, oxygen sources in portable respiration apparatus, and whiteners. The high decontaminating activity found recently for some compounds of this class made it possible to develop on their basis environmentally friendly disinfectants with broad-spectrum antimicrobial action [2].

EXPERIMENTAL

Peroxo solvates were synthesized by the reaction of the starting anhydrous or hydrated salts with a 30–35% solution of hydrogen peroxide taken in different excess over the stoichiometry [3]. Water and the excess H_2O_2 were removed at 20°C in a vacuum or with a flow of heated air over the solution [2]. The solvates were analyzed for the content of hydrogen peroxide by permanganatometric titration. The thermograms were recorded on an HTP-64 device and a Q-1500D derivatograph (Pt–Pt/Rh thermocouple, Al_2O_3 reference). The heating rate was 5 deg min^{-1}. The degree of dissociation was determined for the peroxo solvate samples kept at a prescribed temperature for 2 h in a vacuum. The evolved hydrogen peroxide was frozen in a trap cooled with liquid nitrogen and then analyzed. The thermochemical data were obtained by the dissolution method. The enthalpies of solution were measured in rocking calorimeters equipped with an isothermal shell [4, 5]. The devices were calibrated before and after the dissolution of the sample. The accuracy of the determination was checked by the enthalpies of solution of KCl and $KClO_4$. The samples of the substances under study were placed into preliminarily weighed thin-walled ampules with ground-glass joints. The ampules were filled with a substance in a dry box. The ampules were evacuated, resealed, and weighed again on a Bunge balance with an accuracy of 2×10^{-6} g. To initiate dissolution, the ampules were broken.

Table 1. Crystallographic parameters of peroxo solvates

Solvate	Bond length, Å			Angle, deg		References
	O–O	O–H	F(O)···H–O	OOH	dihedral	
$Na_2CO_3 \cdot 1.5H_2O_2$	1.43–1.49	0.95	2.52–2.66	100	125, 170	[9, 10]
$KF \cdot H_2O_2$	1.44–1.54	0.84–1.07	2.45–2.60	62–133	≤110	[6]
$KF \cdot 2H_2O_2$	1.469–1.473	0.797–0.970	2.57–2.84	95.2–101.3	88.0, 95.3	[11]
$RbF \cdot H_2O_2$	1.488	0.68–0.71	2.51–2.54	92–106	94.5	[12]
$M_2C_2O_4 \cdot 2H_2O_2$, M = Li, Na	144–149	–	2.56–2.80	95–108	93–180	[13, 14]
H_2O_2	1.453	0.988	–	102.7	90.2	[15]

The structure of $KF \cdot H_2O_2$ was determined by the method described in detail in [6]. The kinetic parameters of the peroxo solvate decomposition were determined from the decomposition curves taken under the isothermal conditions and calculated using the Kolmogorov–Erofeev equation [7, 8]. The degree of decomposition in one year at 25°C was found by extrapolating the degrees of decomposition obtained from the kinetic curves to low temperatures using the $\log \eta$ vs. $1/T$ curve. The peroxo solvate samples were stored for a long time at 20 ± 2°C in closed polymeric vessels. The other methods and procedures, not presented here, are described in [3].

Effect of structural changes in H_2O_2 molecules, occurring upon coordination to anions, on the peroxo solvate stability. In most of the peroxo solvates studied, the crystal lattice is formed by layers of ions and H_2O_2 molecules. In the peroxo solvate $Na_2CO_3 \cdot 1.5H_2O_2$, Na^+ and CO_3^{2-} ions are present as separate layers. Each H_2O_2 molecule forms H bonds with oxygen atoms of two different CO_3^{2-} ions. The CO_3^{2-} anion is thus involved in three hydrogen bonds. The peroxo solvate contains two different types of H_2O_2 molecules. These are bent (dihedral angle 125°) and nearly planar molecules (dihedral angle 170°). In a bent molecule, each oxygen atom interacts with two Na^+ cations, and in a planar molecule, with one cation. The H_2O_2 molecules in the $Na_2CO_3 \cdot 1.5H_2O_2$ lattice, unlike ionic components, do not occupy definite positions. Both planar and bent molecules occupy different positions with the same probability, forming bonds with two or one Na^+ cation [9, 10].

The structure of $KF \cdot H_2O_2$ is also layered. Three layers differing in the compositions are formed in $KF \cdot H_2O_2$: a homoatomic layer of K^+ cations, a heteroatomic layer of K^+ and F^- ions, and a heteroatomic layer of H_2O_2 molecules and F^- anions. The homo- and heteroatomic layers form an alternating sequence (K^+, F^-)–(H_2O_2, F^-)–(K^+)–(H_2O_2, F^-)–(K^+, F^-)–(H_2O_2, F^-)–(K^+)–(H_2O_2, F^-)... along the *a*-axis, and the heteroatomic layers form a sequence (K^+, F^-)–(H_2O_2, F^-)–(K^+, F^-)–(H_2O_2, F^-) along the *b*-axis [6].

The structure of $KF \cdot 2H_2O_2$ consists of (K^+) and (H_2O_2, F^-) layers [11]. The tetragonal structure of $Rb \cdot H_2O_2$ is formed by layers that have the same composition along the *a*- and *b*-axes and are arranged in the same sequence, coinciding with the sequence of layers along the *a*-axis in $KF \cdot 2H_2O_2$ [12]. Each F^- ion in the structure of fluoride peroxo solvates forms two ($KF \cdot H_2O_2$, $Rb \cdot H_2O_2$) or three ($KF \cdot 2H_2O_2$) hydrogen bonds.

The crystallographic parameters of the peroxo solvates are presented in Table 1. As seen, the lengths of the O–O and O–H bonds and the O–O–H bond angles in free hydrogen peroxide change only slightly after the coordination to salts. The same is true for the hydrogen bond parameters (distance O(F)···H–O lies within 2.51–2.84 Å). The dihedral angles change to a considerably greater extent. The largest angles are observed in $Na_2CO_3 \cdot 1.5H_2O_2$. Of 12 hydrogen peroxide molecules constituting the unit cell, eight molecules have a dihedral angle of 125°, whereas in the remaining four molecules this angle is 170°.

It may be suggested that the bonds between H_2O_2 and CO_3^{2-} in $Na_2CO_3 \cdot 1.5H_2O_2$ are somewhat stronger owing to larger opening of hydrogen peroxide dihedral angles. Sarin et al. [11] inferred that the dihedral angle is the most sensitive parameter to the surrounding of H_2O_2 molecules, because it is connected with the change in the potential energy of hydrogen peroxide molecules at rotation of hydroxy groups with respect to each other. The enthalpy of formation of $Na_2CO_3 \cdot 1.5H_2O_2$ from the components is considerably higher in the absolute value than for other peroxo solvates (–93.8 kJ mol^{-1}) [16–18]. The loss of H_2O_2 by the solvate at 25°C in 1 year, estimated from the degrees of decomposition determined from the kinetic curves

Table 2. Thermochemical data for peroxo solvates [3] and some hydrates [19]

Reaction	$-\Delta H$ of reaction, kJ mol^{-1}	$-\Delta H$ of binding 1 mol H_2O_2(g), kJ
$Na_2CO_3(s) + 1.5H_2O_2(g) = Na_2CO_3 \cdot 1.5H_2O_2(s)$	140.70	93.80
$KF(s) + H_2O_2(g) = KF \cdot H_2O_2(s)$	85.53	85.53
$KF(s) + 2H_2O_2(g) = 2KF \cdot H_2O_2(s)$	156.23	78.13
$KF(s) + 3H_2O_2(g) = 3KF \cdot H_2O_2(s)$	221.39	73.80
$NH_4F(s) + H_2O_2(g) = NH_4F \cdot H_2O_2(s)$	72.20	72.20
$Na_2HPO_4(s) + 2H_2O_2(g) = Na_2HPO_4 \cdot 2H_2O_2(s)$	155.89	77.90
$Na_4P_2O_7(s) + 3H_2O_2(g) = Na_4P_2O_7 \cdot 3H_2O_2(s)$	235.10	78.40
$KF \cdot H_2O_2(s) + H_2O_2(g) = KF \cdot 2H_2O_2(s)$	70.88	70.88
$KF \cdot 2H_2O_2(s) + H_2O_2(g) = KF \cdot 3H_2O_2(s)$	65.03	65.03
$Na_2CO_3(s) + H_2O(g) = Na_2CO_3 \cdot H_2O(s)$	58.60	58.60
$KF(s) + H_2O(g) = KF \cdot H_2O(s)$	53.5	53.5

in the interval 100–125°C by extrapolation to lower temperatures, is $7 \cdot 10^{-4}$%. The crystal structure of $KF \cdot H_2O_2$ has also a characteristic feature. In the majority of solvate H_2O_2 molecules, except for one molecule, H(29)–O(29)–O(30)–H(30) [6], hydrogen atoms form an acute angle with respect to the O–O bond. Such configuration suggests the existence of O···H–O intramolecular bonds. Thus, in $KF \cdot H_2O_2$ crystals the majority of H_2O_2 molecules form not only intermolecular bonds O–H···F, but also intramolecular bonds O–H···O. This makes the $KF \cdot H_2O_2$ crystal structure fundamentally different from the structures of other peroxo solvates and may be responsible for its stability. The enthalpy of formation of $KF \cdot H_2O_2$ from H_2O_2(g) and KF is lower in the absolute value (–85.5 kJ mol^{-1}) than of that of $Na_2CO_3 \cdot 1.5H_2O_2$. For this reason, the H_2O_2 loss in 1 year is correspondingly larger (4×10^{-2}%). The examples of $Na_2CO_3 \cdot 1.5H_2O_2$ and $KF \cdot H_2O_2$ show that the solvate structure exerts a certain effect on their stability. However, this effect may be partially or completely leveled off by the effect of the chemical properties of the starting salts.

Dependence of the stability of peroxo solvates on their thermochemical characteristics. The enthalpies of reactions of salts with hydrogen peroxide and the energies of binding of 1 mol of H_2O_2(g) with the corresponding salt are given in Table 2. As seen, the enthalpies of coordination of H_2O_2 are fairly high in the absolute value, varying from –93.8 for $Na_2CO_3 \cdot 1.5H_2O_2$ to –65.0 kJ mol^{-1} for the addition of 1 mol of H_2O_2 to $KF \cdot 2H_2O_2$.

For certain salts, the enthalpy of solvation is higher than the enthalpy of hydration. For example, the enthalpy of hydration of Na_2CO_3 by 1 mol of H_2O(g) is –58.6 kJ mol^{-1} and that of KF, –53.5 kJ mol^{-1}, which is by a factor of 1.5 lower than the enthalpy in solvation of these salts with H_2O_2(g).

Apparently, stability of peroxo solvates toward dissociation is largely determined by the H_2O_2 binding energy. The decomposition pathway through dissociation may be insignificant or predominant. The dissociation can occur simultaneously with the irreversible decomposition of H_2O_2 or may be the only stage of the solvate decomposition. In the latter case, the H_2O_2 decomposition will occur in the gas phase as a typical heterogeneous gas-phase reaction catalyzed by the reactor surface. The degrees of dissociation in the overall process of the peroxo solvate decomposition in a vacuum at different temperatures are given in Table 3.

The direct dependence of the degree of dissociation α_{dis} on the H_2O_2 binding energy ΔH_{bind} is observed for peroxo solvates of potassium and ammonium fluorides at 60°C and for the other solvates ($Na_2HPO_4 \cdot 2H_2O_2$, $Na_2CO_3 \cdot 1.5H_2O_2$, $KF \cdot H_2O_2$), at 100°C (see figure). The solvate $Na_4P_2O_7 \cdot 3H_2O_2$, with a considerably lower degree of dissociation at 100°C, drops out of the latter series.

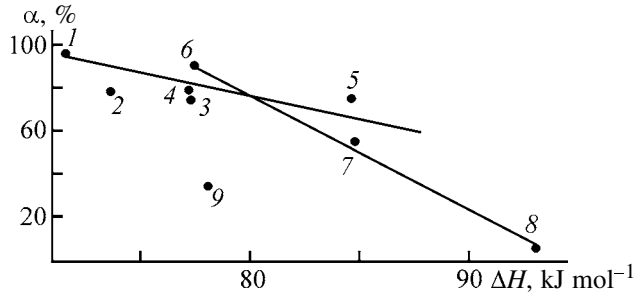

Table 4 shows how the H_2O_2 binding energy correlates with the kinetic parameters of the peroxo solvate decomposition. As seen, sodium carbonate peroxo solvate having the highest H_2O_2 binding energy is the fourth in the decomposition rate constant. In actual practice of storage, the nonstabilized solvate $Na_2CO_3 \cdot 1.5H_2O_2$ is unstable. Coarse, well-edged $Na_2CO_3 \cdot 1.5H_2O_2$ crystals stored for 15 days in closed reservoirs do not loss available oxygen [3], whereas samples obtained under conventional laboratory conditions decompose within a rather short time of storage (loss of H_2O_2 after 1 year is 60%) [19].

Table 3. Dissociation of peroxo solvates in a vacuum ($p = 10^{-3}$ mm Hg, $\tau = 2$ h)

Solvate	T, °C	Overall degree of decomposition η, %	Decomposition through dissociation	Irreversible decomposition
			% of η	
$Na_2CO_3 \cdot 1.5H_2O_2$	100	90	5	95
$KF \cdot H_2O_2$	60	4	77	23
	80	18	75	25
	100	59	55	45
$KF \cdot 2H_2O_2$	40	45	90	10
	60	58	75	25
	80	83	72	28

Table 4. Kinetic parameters of thermal decomposition of peroxo solvates

Solvate	Decomposition temperature, °C	Initial stage, η	$K \times 10^3$, min^{-1}, at 115°C		Calculated loss of H_2O_2, %/year	ΔH of binding H_2O_2(g), kJ mol^{-1}
			K_1	K_2		
$Na_2CO_3 \cdot 1.5H_2O_2$	100–125	0.07–0.80	8.2	9.8	7.0×10^{-4}	93.8
$KF \cdot H_2O_2$	90–125	0.01–0.12	1.2	0.8	4.0×10^{-2}	85.5
$NH_4F \cdot H_2O_2$	70–90	0.04–0.40	–	–	–	72.2
			4.2 (90°C)	1.45 (90°C)		
$Na_2HPO_4 \cdot 2H_2O_2$	100–120	0.10–0.50	12.0	8.3	5.1×10^{-4}	77.9
$Na_4P_2O_7 \cdot 3H_2O_2$	115–135	0.04–0.06	4.0	1.1	2.0×10^{-4}	78.4

Degree of dissociation α of peroxosolvates vs. H_2O_2 binding energy ΔH: (*1*) $NH_4F \cdot H_2O_2$, (*2*) $KF \cdot 3H_2O_2$, (*3, 6*) $Na_2HPO_4 \cdot 2H_2O_2$, (*4*) $KF \cdot H_2O_2$, (*5, 7*) $KF \cdot H_2O_2$, (*8*) $Na_2CO_3 \cdot 1.5H_2O_2$, and (*9*) $Na_4P_2O_7 \cdot 3H_2O_2$.

$KF \cdot H_2O_2$ is the second in the H_2O_2 binding energy, but it surpasses well $Na_2CO_3 \cdot 1.5H_2O_2$ in the decomposition rate constant under isothermal conditions and belongs to the most stable compounds among the peroxo solvates studied. The loss of H_2O_2 in 1 year is 1.5%.

Ammonium fluoride peroxo solvate markedly differs from $KF \cdot H_2O_2$ in the stability and character of decomposition. The low H_2O_2 binding energy in the solvate (72.2 kJ mol^{-1}) causes it to decompose under the isothermal conditions within 70–90°C. At the same time, the solvate is fairly stable in storage (less than 4% H_2O_2 is lost in 1 year). The degree of its dis-

sociation in a vacuum reaches 95% even at 60°C. Evidently, the solvate decomposes virtually completely owing to the dissociation.

Assuming that the decomposition rate constant in the longest portion of the kinetic curve at the same temperature (115°C) is the most adequate criterion for comparing the peroxo solvate stability (Table 4), we obtain that the order in which the stability of peroxo solvates decreases (see below) differs from the order in which the H_2O_2 binding energy decreases: $KF \cdot H_2O_2$, $K_2 = 0.8$; $Na_4P_2O_7 \cdot 3H_2O_2$, $K_2 = 1.1$; $Na_2CO_3 \cdot 5H_2O_2$, $K_1 = 8.2$; $Na_2HPO_4 \cdot 2H_2O_2$ $K_1 = 12.0$.

The effect of the H_2O_2 binding energy on the peroxo solvate stability should be considered in more detail. Naturally, the small value of the energy means that the solvate stability is low. In this case, however, its decomposition through dissociation followed by decomposition of hydrogen peroxide outside the solid phase prevents the formation of a catalytically active film of a solution on the surface of crystals and makes the solvate fairly stable, as shown by the example of ammonium fluoride peroxo solvate.

At a high H_2O_2 binding energy, a part of hydrogen peroxide should irreversibly decompose in the solid phase concurrently with the dissociation, and the solvate stability will be largely determined by the properties of the solution film being formed. For example, in the case of $KF \cdot H_2O_2$, the irreversible decomposition of the solvate in the solid phase yields a neutral film of the solution.

Sodium carbonate peroxo solvate characterized by the highest H_2O_2 binding energy decomposes through dissociation at relatively high temperatures only slightly, and the major pathway is the catalytic decomposition of H_2O_2 in a highly alkaline medium formed by a film of the solution on the surface of the solid phase.

Thus, the solvate stability depends to a considerably greater extent on the chemical properties of the salt, hydrogen peroxide carrier, than on any other parameters.

Effect of chemical properties of salts coordinating hydrogen peroxide on the peroxo solvate stability. In the peroxo solvates studied, the starting salts, hydrogen peroxide carriers, are not oxidized upon solvation. Although products of carbonate oxidation, so-called true percarbonates, exist, they are formed by electrolysis of concentrated carbonate solutions or by other reactions that do not involve CO_3^{2-} anion [20]. Since salts are solvated by hydrogen peroxide owing to the formation of hydrogen bonds between H_2O_2 and the anions, it may be suggested that the water of hydration coordinated to cations can be retained in the peroxo solvates. However, even in salts hydrated with a large amount of water, $KF \cdot 2H_2O$, $NaHPO_4 \cdot 12H_2O$, $Na_4P_2O_7 \cdot 10H_2O$, and $Na_2SO_4 \cdot 10H_2O$, the water of hydration is not retained after the hydrogen peroxide coordination. Exceptions are hydrated oxalate peroxo solvates $[C(NH_2)_3]_2C_2O_4 \cdot 2H_2O \cdot H_2O_2$ and $[C(NH_2)_3]_2C_2O_4 \cdot 0.5H_2O \cdot 0.5H_2O_2$ [21], for which crystallographic data were obtained. The existence of hydrated peroxo solvate of sodium sulfate, $Na_2SO_4 \cdot 0.5H_2O_2 \cdot H_2O$, found as the bottom phase in the Na_2SO_4–H_2O_2–H_2O system at –20°C in [22] and at 20 and 35°C in [23], was not confirmed by the structural data. Thus, the effect exerted by the chemical properties of salts on the peroxo solvate stability must be considered assuming that the peroxo solvates do not contain water of hydration and any derivatives of the salts.

All peroxo solvates are hygroscopic. They absorb water from air to form a microscopic film of the solvate solution on the surface of crystals. The more concentrated the solution, the higher the solubility of the solvate in water. The comparison of the solubilities in water for Na_2CO_3 and $Na_2CO_3 \cdot 1.5H_2O_2$, and for KF and $KF \cdot H_2O_2$ shows that the hydrogen peroxide coordination to salt affects the solubility only slightly (Table 5). Thus, a film of a relatively concentrated solution will be always formed upon absorption of water vapor by the peroxo solvate. In such solution, the H_2O_2 stability, responsible for the stability of the peroxo solvate itself, depends on two factors acting in the opposite directions. The first refers to the acid properties of a solution film, and the second, to the stabilizing property of the solvated salt, its ability to transform microimpurities present in the salts, mainly transition metals or other compounds, into the catalytically inactive state with respect to H_2O_2. It should be noted, however, that various mechanisms responsible for the stabilization of hydrogen peroxide by a particular substance were suggested, but no satisfactory explanation has been found for this effect [1]. The only true conclusion consists in that peroxo solvate stabilization involves purification of both the starting substances and solutions from which a solvate is crystallized, and also their protection from microimpurities. In some cases as, e.g., with sodium percarbonate, the ready solid solvate is protected against moisture to prevent formation of an alkaline film of solution.

Data on the solubility of the starting salts and peroxo solvates are presented in Table 5, along with the pH values of their solutions. As seen, the pH values for the solutions of the starting salt and its solvate

Table 5. Solubility and pH of solutions of salts and their peroxo solvates

Compound	Solubility, wt % (T, °C) [reference]	pH (c, wt %), 20°C [reference]	Stabilizing effect
Na_2CO_3	6.86 (0) [24] 44.5 (100)	11.5 (1.1) [25]	–
$Na_2CO_3 \cdot 1.5H_2O_2$	10.5 (0) [28] 12.8 (26)	10.4 (10) [3, 21] 10.5 (10)	–
KF	92.3 (18) [24] 150.0 (80)	7.1 (1.0) [27]	–
$KF \cdot H_2O_2$	51.1 (0) [26] 60.7 (20)	6.8 (1.0) [27]	–
NH_4F	74.1 (10) [25] 62.8 (20)	6.3 (1.0) (experimental)	–
$NH_4F \cdot H_2O_2$	–	6.1 (1.0) (experimental)	–
Na_2HPO_4	Soluble (0) [24] 104.1 (100)	9.2 (1.4) [25, 28] 8.9 (1.0)	+
$Na_2HPO_4 \cdot 2H_2O_2$	–	9.2 (5) (experimental)	+
Na_3PO_4	10.5 (15) [24] 77.0 (100)	12.0 (1.6) [25, 28] 12.1 (1)	+
$Na_3PO_4 \cdot 3H_2O_2$	–	11.7 (1.5) (experimental)	+
$Na_4P_2O_7$	[24]	10.2 (1.0) [28]	+
$Na_4P_2O_7 \cdot 3H_2O_2$	–	9.9 (1.0) [28]	+

differ slightly (for example, 7.1 and 6.8 for 1% solutions of KF and $KF \cdot H_2O_2$, respectively). With growing concentration, the pH of the KF solution increases considerably (pH 8.0 for a 10% solution), whereas for $KF \cdot H_2O_2$ solution the increase is slight (pH 7.0 for a 10% solution) [26]. Evidently, the effect in coordination of a weakly acidic component, H_2O_2, to highly alkaline salts will be even less significant, especially at high and medium concentrations.

All the peroxo solvates studied can be subdivided into three groups with respect to the extent to which their stability is affected by the chemical properties of the starting salt. The first group includes solvates of salts that form essentially neutal solutions. The second group includes peroxo solvates of salts forming alkaline solutions and exhibiting no stabilizing properties. Peroxo solvates derived from salts that form alkaline salts but, at the same time, exhibit pronounced stabilizing properties with respect to hydrogen peroxide constitute the third group. The first group includes peroxo solvates of potassium and ammonium fluorides, and, probably, of rubidium and cesium fluorides. The pH of solutions of these salts and solvates ranges from 7.8 (65% $KF \cdot H_2O_2$ solution) to 6.1 (1% $NH_4F \cdot H_2O_2$ solution) [27, 28].

Peroxo solvates of potassium and ammonium fluorides, as all peroxo solvates, are hygroscopic. They absorb water from the air without loss of H_2O_2, which made it possible to determine their hygroscopic points [3]. Solutions of solvates are also stable. A saturated solution of $KF \cdot H_2O_2$ decomposes at 20°C at an average rate of $0.1\% \cdot day^{-1}$ (observation time 5 days). The moistened samples are also stable: $KF \cdot H_2O_2$ after taking up 10 wt % water does not loss available oxygen for 75 days. Thus, we can state that the main parameter determining the stability of these compounds is the neutral character of their solutions. A microscopic film formed by a solution on the solvate surface does not exert a catalytic effect on the boundary layer of the solid solvate. Therefore, the solvate $KF \cdot H_2O_2$ with a high H_2O_2 binding energy and presence of an intramolecular hydrogen bond shows extremely high stability, even in the absence of intrinsic stabilizing activity. The solvate does not noticeably lose hydrogen peroxide after 5 years of storage. Its annual loss does not exceed 0.1%. The developed $KF \cdot H_2O_2$ disinfectants containing some additives lose no more than 8% of H_2O_2 after 10 years of storage [2].

The second group includes peroxo solvates of carbonates. The solvates in the solid state are unstable. Highly alkaline solutions of $Na_2CO_3 \cdot 1.5H_2O_2$ are also unstable, because pH of their 10% solution is 10.4 (pH of 1% solution of the carbonate itself is 11.5). A 10 wt % $Na_2CO_3 \cdot 1.5H_2O_2$ solution after 1 day of storage at 20°C loses 12.2% of H_2O_2 [3]. Alkaline solutions of carbonate peroxo solvates on the surface of solid crystals not only promote the hy-

drogen peroxide decomposition but also convert impurities of transition metal compounds into the hydroxides, which have extremely high catalytic activity. It was found [3] that fresh $Fe(OH)_3$ added to $K_2CO_3 \cdot 3H_2O_2$ in an amount of 5×10^{-5}% increases the rate constant of the solvate decomposition to the same extent as does the addition of Fe_2O_3 in an amount of 4×10^{-2}%, higher by three orders of magnitude. Thus, carbonate peroxo solvates, unlike phosphate peroxo solvates, do not have intrinsic stabilizing properties. Therefore, carbonate peroxo solvates moistened with the formation of a highly alkaline film of solution are examples of how the low stabilizing properties of the structure and the high H_2O_2 binding energy are leveled off virtually completely by the chemical properties of the starting salt, a hydrogen peroxide carrier.

Unlike carbonate peroxo solvates, phosphate peroxo solvates of the third group, despite highly alkaline properties, exert a stabilizing effect on aqueous solutions of hydrogen peroxide [1] and on its solid forms, including sodium percarbonate. More than 200 patents are published concerning $Na_2CO_3 \cdot 1.5H_2O_2$ stabilization, with a majority of them using sodium pyrophosphate, its derivatives, and mixtures with other compounds [3]. Although $Na_2CO_3 \cdot 1.5H_2O_2$ is unstable in the pure form, addition of appropriate stabilizers enhances its stability to the level allowing its use as bleaching agent in multicomponent detergents [20]. According to [1], phosphates as a class of compounds are the best stabilizers and the only substances that can be recommended for H_2O_2 stabilization. We found no data about the difference in the stabilizing abilities of sodium pyrophosphate and phosphates of different degrees of substitution. At the same time, it is known that the $P_2O_7^{4-}$ ion in an aqueous solution even at 20°C is hydrolyzed to HPO_4^{2-} [28]. This fact suggests that disubstituted and, apparently, fully substituted phosphates do possess, though to a lesser extent than pyrophosphates, the stabilizing properties with respect to H_2O_2.

Among the phosphate peroxo solvates studied, the most alkaline is a solution of $Na_3PO_4 \cdot 5H_2O_2$ (pH of 1.5% solution is 11.7; pH of 1% phosphate solution 12.1). Apparently, the high alkalinity of the peroxo solvate solution at its low stabilizing activity is the main reason for the low stability of $Na_3PO_4 \cdot 5H_2O_2$.

Disubstituted sodium phosphate, like its peroxo solvate, is less alkaline. In the decomposition rate constant, $Na_2HPO_4 \cdot 2H_2O_2$ is the closest to $Na_2CO_3 \cdot 1.5H_2O_2$. It should be noted that the lower alkalinity of its solutions in comparison with $Na_2CO_3 \cdot 1.5H_2O_2$ solutions and the lower H_2O_2 binding energy lead to the fact that $Na_2HPO_4 \cdot 2H_2O_2$ in the degree of dissociation in a vacuum surpasses well sodium carbonate peroxo solvate (91% against 5% at 100°C).

Sodium pyrophosphate peroxo solvate is less alkaline than $Na_2HPO_4 \cdot 2H_2O_2$ (pH of 1% $Na_4P_2O_7$ solution is 10.8 and pH of the solvate solution of the same concentration, 9.6). At the same time, $Na_4P_2O_7 \cdot 3H_2O_2$ in the decomposition rate constant is close to the most stable solvate $KF \cdot H_2O_2$. This is certainly due to the stabilizing effect of the $P_2O_7^{4-}$ anion. However, $Na_4P_2O_7 \cdot 3H_2O_2$, stable under ambient conditions, irreversibly decomposes in a vacuum, with the degree of decomposition larger compared to $Na_2HPO_4 \cdot 2H_2O_2$ and $KF \cdot H_2O_2$. The degree of decomposition at 100°C is as follows (%): 65 for $Na_4P_2O_7 \cdot 3H_2O_2$, 45 for $KF \cdot H_2O_2$, and 9 for $Na_2HPO_4 \cdot 2H_2O_2$. This fact suggests that the solution on the surface of crystals of pyrophosphate peroxo solvate, because of the growth of its concentration in the course of evacuation, becomes more alkaline; as a result, the degree of the irreversible decomposition of H_2O_2 increases.

CONCLUSIONS

(1) The stability of peroxo solvates largely depends on the chemical properties of salts, H_2O_2 carriers. First of all, it depends on their acidity and on the ability of the solvated salt to neutralize or bind catalytically active foreign impurities.

(2) For neutral salts (KF, NH_4F) the binding energy is the major factor determining the degree of decomposition of their peroxo solvates through dissociation.

SORPTION AND ION-EXCHANGE PROCESSES

Composition of Ion-Exchange Materials Based on Titanium Phosphate

Abstract—Composition and structure of synthetic ion-exchange materials based on titanium phosphate were studied. The materials were synthesized from titanium(IV), phosphorus(V), and silicon(IV) reagents taken in various concentrations, using various modes of the synthesis and treatment of the precursors. The dependence of the ion-exchange properties of the final products on the composition of the precursors was examined.

DOI: 10.1134/S1070427206110103

High sorption characteristics of ion-exchange materials based on elements of Groups III–IV of the periodic table attract attention of chemists and ecologists. Insoluble iron, aluminum, titanium, and zirconium oxyhydroxides, phosphate compounds of transition elements, and compositions based on them belong to this class of ion exchangers. They exhibit high resistance to chemical agents, heat, and radiation, and also selectivity with respect to a number of ions. The selectivity is determined by the structure of an ion exchanger matrix and by the nature of functional groups capable of ion exchange.

Titanyl phosphates $TiOHPO_4 \cdot xH_2O$ are also highly selective materials. Methods for preparing this sorbent and its properties have been described in detail [1–4]. Most frequently, a titanyl phosphate intermediate product (precursor) is synthesied by precipitation from solutions of titanium(IV) salts with orthophosphoric acid. Another procedure is based on the treatment of freshly precipitated titanium(IV) oxyhydroxide with orthophosphoric acid [5]. More rarely, the synthesis is carried out from dilute solutions of reagents (sol–gel method) [6, 7]. The subsequent treatment of precursors involves transformation of a sorption material into a state convenient for the efficient use. There are data on the preparation of precursors with a mixed composition, e.g., of hydrated titanium phosphates containing silicon compounds. Such products can be readily granulated with the formation of porous sorbent matrices, which makes it possible to accelerate the exchange processes and enhance the selectivity to multiply charged ions. It is possible to vary sorption properties during the preparation of the compositions by varying the precursor composition and the mode of its synthesis [8].

Here we report new data on the composition of sorbents based on titanyl phosphate. As a raw material for their production we used concentrates, products of integrated processing of apatite–nepheline ores, in particular, a concentrate containing titanite (calcium titanosilicate $CaTiSiO_5$), and also nepheline and apatite concentrates. The principal flowsheet of production of the sorbents and the process features have been published in several works and patented [9–12].

EXPERIMENTAL

Finely dispersed titanite concentrate was mixed with a sulfuric acid solution (H_2SO_4 concentration 550 g l^{-1}, weight ratio s : l = 1 : 1.65), and the reaction mixture was heated with stirring for 7 h at 105–110°C [13]. Under these conditions, titanium(IV) is leached from the mineral and passes into the sulfuric acid liquid phase (a titanium solution). The synthesis of a composite titanyl phosphate precursor and its subsequent treatment were carried out by the known technique [14]. A phosphoric acid silicate solution obtained by the reaction of nepheline with 15% phosphoric acid and containing 60 g l^{-1} of SiO_2 was added to a titanium solution heated to 70–80°C. Then phosphoric acid was added in an amount corresponding to

Synthesis conditions, composition, and main characteristics of the synthesized ion-exchange materials

Sample	Synthesis conditions*	Composition	Characteristic of structure	S_{sp}, $m^2\ g^{-1}$
I	H_3PO_4 30%	$TiO_2 \cdot 0.5P_2O_5 \cdot 3.0H_2O$	X-ray amorphous	60.5
II	H_3PO_4 60%	$TiO_2 \cdot 0.75P_2O_5 \cdot 3.0H_2O$	Finely crystalline	95.5
III	H_3PO_4 30%, $TiO_2 : SiO_2 = 1 : 0.25$ (mol)	$TiO_2 \cdot 0.5P_2O_5 \cdot 0.16SiO_2 \cdot 2.5H_2O$	X-ray amorphous	85.9
IV	H_3PO_4 60% $TiO_2 : SiO_2 = 1 : 0.25$ (mol)	$TiO_2 \cdot 0.75P_2O_5 \cdot 0.16SiO_2 \cdot 2.75H_2O$	Finely crystalline	122.3

* For all the samples $TiO_2 : P_2O_5 = 1 : 1$ (mol).

the molar ratios of the components given in the table. The resulting suspension was kept for 12 h, after which the precipitate was filtered off and washed with 5% phosphoric acid and distilled water to pH 4.5. The product washed to remove the residual mother liquor was dried at 60°C.

The specific surface areas of the sorbent samples were determined by the BET method on a Flowsorb II 2300 electronic analyzer; the samples were degassed for 2 h at 140°C. The thermogravimetric analysis of the samples placed in quartz test tubes was performed in the range 20–980°C with heating at a rate of 9 deg min^{-1}. The X-ray phase analysis of the samples was carried out on a DRON-2 diffractometer (CuK_α radiation). The IR spectra of the samples were recorded on a UR 20 IR spectrometer in the range 400–4000 cm^{-1}. The pH-metric titration was carried out with an I-120.2 ionomer; the initial and equilibrium concentrations of metal ions in solution were determined by standard techniques on a Perkin–Elmer FT-IR 200 spectrometer.

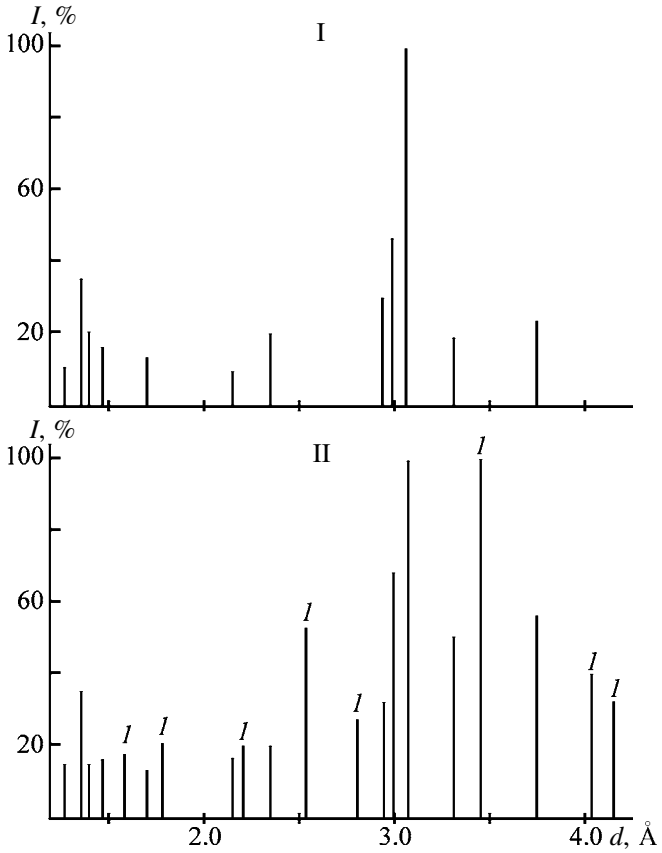

Fig. 1. X-ray diffraction patterns of products I and II dehydrated at 280°C. (*I*) Intensity and (*d*) interplanar spacing. (*1*) Phase corresponding to the composition $TiO(H_2PO_4)_2$.

According to the X-ray data, air-dry precursors have an X-ray amorphous or finely crystalline structure depending on the synthesis conditions (see table). Products I and III dehydrated at 280°C have the composition $TiOHPO_4$, and products II and IV are mixtures containing $TiOHPO_4$ and $TiO(H_2PO_4)_2$ (Fig. 1). The phosphoric acid concentration does not affect the rate of the solid phase formation. However, an increase in its concentration leads to increasing crystallinity of the precipitate. Judging from the specific surface areas, particles of crystalline precipitates show weaker tendency to sticking during heat treatment than particles of amorphous precipitates. Two endothermic effects at 165–170 and 312–326°C accompanied by a weight loss were detected in the DTA curves (Fig. 2). The presence of two effects indicates that the dehydration is stepwise. However, as the TG curve shows, samples containing no silicon component have a higher content of both water of crystallization and water released from the condensation of acid phosphate groups. Two exothermic effects without weight loss refer to the formation of titanium pyrophosphate (TiP_2O_7). The shift of the effects of the titanium pyrophosphate formation toward lower temperatures for the silicon-containing precipitate is presumably associated with the formation of solid solutions of titanium pyrophosphate with SiO_2.

The IR spectra of the precipitates under study (Fig. 3) are practically identical and contain strong broad bands in the range 3600–3100 cm^{-1} belonging

to stretching vibrations of water and OH groups, and also less strong bands belonging to bending vibrations of OH^- groups (1630 cm^{-1}). Strong bands in the region of 1000 cm^{-1} correspond to asymmetric vibrations of P–OH bonds, and bands in the region of 650–750 cm^{-1}, to vibrations of titanium polyhedra [15]. It is known that the Si–O–Ti bond is manifested in the region of 960 cm^{-1} [16] and can overlap with the vibrations of P–OH groups.

To determine the nature of bonding between titanium and silicon in the precursors under study, we used the known technique based on the determination of active and passive OH^- groups [17]. According to this technique, two processes occur successively when a suspension sample reacts with potassium fluoride: fast substitution of fluoride ions for terminal OH^- groups bonded to titanium and silicon and slow cleavage of the bridging bonds. We found the number of OH^- groups graphically from the intersection with the ordinate axis of the tangent to the flat portion of the curve corresponding to the range 0–30 min for active OH^- groups and 1–5 h for passive OH^- groups. The experimental data obtained were interpreted from this point of view.

Both terminal and bridging OH^- groups are absent from samples I and II. As such products were synthesized without silicate component, we can conclude that titanium(IV) species do not polymerize to form –Ti–O–Ti– chains, and the precursor matrix is formed by multiple repetition of the events of bonding between titanyl ions and phosphate groups. Both active and passive OH^- groups are determined in silicon-containing samples III and IV (Fig. 4). As we found that titanium(IV) in the synthesized products does not contain terminal OH^- groups, the formation of –Si–O–Ti– bonds seems improbable. The OH^- groups found in the composite sorbents can be assigned only to silanol groups (Si–OH). The number of terminal OH groups for samples III and IV is the same, 0.05 mol of OH^- per mole of SiO_2. Bridging –Si–O–Si– bonds are formed by cross-linking of silicon hydroxo complexes by OH^- groups with the formation of species with a friable structure, as seen from the specific surface area. The use of dilute phosphoric acid for the synthesis of products leads to the formation of silica particles hydrated to a greater extent; hence, the number of passive OH^- groups in such products is considerably larger.

The results obtained allow us to state that sorbents I and II represent hydrated titanyl hydrophospates free from hydroxy groups. Composite sorbents III and IV consist of two phases. Particles of hydrated silicon

oxide (HSO) are rather evenly distributed in a titanyl phosphate matrix exceeding them in weight.

In the curve of pH-metric titration of sample II (Fig. 5), there are two clear pH jumps, which, apparently, correspond to the first and second steps of the dissociation of phosphate groups. The curve of pH-metric titration of sample I is a monotonically ascending curve suggesting continuous dissociation of all the possible functional groups.

The total ion-exchange capacity of the synthesized materials varies within narrow limits, 3.12–3.22 mg-equiv g^{-1}. In addition to HPO_4 groups, the sorbents obtained using 60% phosphoric acid also contain strongly acidic ion-exchange groups making a 15–20% contribution to the total ion-exchange capacity.

The influence of the structure on the ion-exchange properties was found when studying the sorption activity of the materials (Fig. 6). For this purpose, the precursors were dried at 60°C and then treated for 24 h with a 100 g l^{-1} Na_2CO_3 solution. To maintain constant pH 6, the sorption was carried out in the presence of an acetate buffer solution.

The sorption activity of the materials under study decreases in the following order: for titanyl phosphate, Cs(I) > Cu(II) > Fe(III) > Co(II) > Ni(II) > Zn(II) > Cr(III); for the composite sorbent, Cs(I) > Cu(II) > Fe(III) = Ni(II) > Co(II) = Zn(II) = Cr(III).

We found that both types of the synthesized ion-exchange materials exhibit a high selectivity to cesium cations.

The above series of selectivity to transition metals do not correlate with the sequence of crystal-chemical radii of the ions. It is known that an ion exchanger has the strongest affinity for a metal ion when active groups of the ion exchanger form stable complexes with counterions. Therefore, iron(III) cations having the smallest ionic radius and, hence, the largest hydration shell should have the lowest sorption ability. However, due to the formation of a strong coordination bond of a sorbed ion with oxygen in the sorbent structure (Ti=O), sorption of iron(III) ions increases. Chromium(III) ions with a developed hydration shell have the lowest ability to penetrate into sorbent pores, and the ion exchange proceeds basically due to the active groups concentrated on the sorbent surface.

Different sorption behavior of cobalt(II) and nickel(II) ions is of interest, as there is a problem of the separation of these elements in the case of liquid radioactive waste treatment. The Ni^{2+} ion has a smaller ionic radius (0.69 Å) than Co^{2+} (0.74 Å); hence, it is more strongly hydrated and more difficultly penetrates into a sorbent. This dependence is observed when the elements are sorbed on titanyl phosphate. In the case of a composite sorbent, the series undergoes partial inversion. We believe that this is possible only if active sites of the HSO surface make a certain contribution.

As found previously, the composite sorbent is a mixture of two phases, titanyl phosphate and HSO, evenly distributed throughout the sorbent volume. In aqueous solutions, SiO_2 has active sites with a variable charge, appearing as a result of protonation or deprotonation of surface hydroxy groups. The degree of the protonation of the surface sites depends on pH of a medium and is a surface characteristic of an oxide. It is known that, in the region of neutral pH, silanol groups of silicon oxide are charged negatively [18], and the deprotonation reaction on surface sites can be presented as $\equiv SiOH \rightleftarrows \equiv SiO^- + H^+$. Surface $[\equiv SiOH]^0$ and $[\equiv SiO]^-$ groups are potential ligands, i.e., they can form surface complexes with an ion of the adsorbed metal as an acceptor; $[\equiv SiO]^-$ is a more

active ligand than $[\equiv SiOH]^0$ [19]. In view of the aforesaid, we can assume that the deprotonated active sites of silanol groups play a noticeable role in sorption processes due to specific adsorption of metal ions. When studying the adsorption of cations of polyvalent metals on quartz, Tikhomolova and Urakova [20] found that Ni(II) is adsorbed more actively than Co(II), which agrees with our data. Nickel(II) ions are adsorbed by the donor–acceptor mechanism, and the bond in such complex is rather strong [21]. Complexes of Co(II) with monodentate ligands having an oxygen atom as a donor center, as a rule, are labile [22].

The data of our studies were confirmed by the results of semicommercial trials on the treatment of highly saline radioactive solutions from the Leningrad Atomic Power Plant and of liquid wastes from the Plant of Art Paints of St. Petersburg.

CONCLUSIONS

(1) The study of how the conditions of the synthesis of titanyl phosphate precursors of ion-exchange materials affect their phase composition and structure showed that an increase in the phosphoric acid concentration promotes the formation of a titanyl phosphate solid phase with a crystalline matrix, which is formed by multiple repetition of the events of bond formation between titanyl ions and phosphate groups.

(2) Species in the titanyl phosphate precursor containing hydrated silicon oxide are additionally bound together by the formation of –Si–O–Si– bridging bonds, which promotes the formation of a solid phase with a friable structure. The higher the phosphoric acid concentration, the larger the specific surface area of the precipitate particles.

(3) The silicate component in the composite sorbents makes a certain contribution to sorption processes due to specific adsorption of metal cations on active centers of hydrated silicon oxide.

(4) The synthesized ion-exchange materials have relatively high exchange capacity for Cs^+, Cu^{2+}, Fe^{3+}, Co^{2+}, and Ni^{2+} ions and, as the trials showed, can be used for the treatment of industrial sewage and liquid radioactive solutions.

Abstract—γ-Keto sulfide concentrates were prepared by alkylthiomethylation of propanone, butanone, and acetophenone with technical-grade *tert*-dodecyl mercaptan and other sufur-containing substances, and their extractive power with respect to palladium(II) and gold(III) from hydrochloric acid solutions (chloroform as diluent) was studied.

DOI: 10.1134/S1070427206110115

Polyfunctional sulfides and petroleum sulfides and sulfoxides are promising extractants for recovery and separation of a number of radioactive, rare, trace, and nonferrous metals [1]. γ-Keto sulfides [2] prepared by alkylthiomethylation (ATM) of ketones with mercaptans [3] are accessible extractants., A method for the synthesis of γ-keto sulfide concentrates based on natural mercaptan mixtures with prevalent content of C_1–C_6 carbon chains was developed recently [4]. To obtain high-molecular-weight keto sulfides by ATM of propanone, technical-grade *tert*-dodecyl mercaptan was used as a sulfur-containing component [5] (Salavatnefteorgsintez Open Joint-Stock Company).

In this study, γ-keto sulfide (hereinafter γ is omitted for brevity) concentrates were prepared by ATM of propanone, butanone, and acetophenone with a technical mixture of C_{12}–C_{18} mercaptans (TM), and the extractive power of these concentrates with respect to palladium(II) and gold(III) recovered from hydrochloric acid solutions was examined.

Industrial mixtures of isomeric C_{12}–C_{18} mercaptans were used as sulfur-containing reagents. TM-1 (M = 190) is a mixture of $C_{12}H_{25}SH$ tertiary isomers (96–97%) and $C_{12}H_{24}$ *tert*-isoolephins (3–4%). TM-2 (M = 330), along with $C_{12}H_{25}SH$ tertiary isomers (8%) and $C_{12}H_{24}$ *tert*-isoolephins (8%), contains high-molecular-weight mercaptans, sulfides, and disulfides (25.0, 26.3, and 8.6%, respectively) and unidentified compounds (about 24%) [6].

Keto sulfide concentrate I was prepared by alkylthiomethylation of propanone with a mixture of formaldehyde and TM-1. TM-2 was used to prepare keto sulfide concentrates II, III, and IV by alkylthiomethylation of propanone, butanone, and acetophenone, respectively.

Synthesis procedure. Aqueous formaldehyde and appropriate ketone were added dropwise to TM-1 or TM-2 with vigorous stirring. The formaldehyde : ketone : sodium hydroxide (15% aqueous solution) molar ratio per mole of mercaptan sulfur was 1.2 : 1.2 : 1.2. Sodium hydroxide solution was diluted with ethyl alcohol in 1 : 1 volume ratio. The mixture was stirred for 3 h at 50°C, washed with 10% HCl, and then extracted with chloroform (3 × 25 ml). Extracts were washed with water (1 : 1 by volume), dried with $MgSO_4$, and chloroform was distilled off. In the concentrates I–IV, we determined total, sulfide, and mercaptan sulfur [7, 8]. The mercaptan conversion was monitored by determination of mercaptan and sulfide sulfur by potentiometric titration [8]. Formation of keto sulfides was confirmed by ν(C=O) bands at 1716–1720 cm^{-1} in the IR spectra of the products. The data of the chemical analysis of products are listed in the table. The maximal content of total (12.8 wt %) and sulfide (12.2 wt %) sulfur was found in concentrate I, which corresponds to 94% content of sulfides. In concentrates II, III, and IV, the content of sulfide sulfur amounts to 89.9, 76.7, and 87.6% of total sulfur, respectively (see table). The concentrates obtained are mixtures of keto sulfides. Concentrates I–IV contain mono- (67, 18, 47, and 26%, respective-

Chemical analysis of ketosulfide concentrates based on TM-1 and TM-2 prepared by alkylthiomethylation of ketones

Ketosulfide concentrate (ketone)	Content, wt %						*M*
	C	H	S				
			total	mercaptan	sulfide	disulfide	
TM-1	71.80	13.00	14.2	13.4	Absent	Absent	90

ly) and bis(alkylthiomethyl)-substituted (27, 29, 0, and 21%, respectively) ketones and initial compounds (hydrocarbons and organosulfur compounds) [6].

The extractive power of keto sulfide concetrates I–IV was compared with that of petroleum sulfides V and concentrates of C_6–C_{10} keto sulfides VI in which the extractive powers of different components are averaged. Petroleum sulfides V [9] are mixtures of monocyclothiaalkanes (50%), di-, tri-, and tetracyclothiaalkanes (18%), thiophenes (25%), thiaindans, thiaalkanes, and cycloalkyl sufides (6%). Keto sulfide concentrate VI is a mixture of aliphatic keto and diketo sulfides C_6–C_{10} [10].

Palladium(II) and gold(III) were extracted from 0.5 M hydrochloric acid solutions. The palladium concentration was varied within the 0–0.008 M range, and that of gold, within the 0–0.005 M range. All the extractant solutions had equal contents of sulfide sulfur. The solutions of keto sulfide concentrates in chloroform with sulfide sulfur content of 0.005 and 0.0025 M were used for palladium and gold, respectively. The extraction was performed in temperature-controlled separating funnels at 25°C and 1 : 1 volume ratio of aqueous to organic phase . The extraction equilibrium is reached within 20 min for palladium(II) and 7 min for gold(III).

Backwashing of gold(III) and palladium(II) from the organic phase was performed with 5% aqueous solutions of sodium sulfite and thiourea, respectively, for 3 min. After washing with 0.5 M hydrochloric acid, the extractants are suitable for the further use. The initial concentration of metal ions was determined spectrophotometrically with a Specord M40 spectrophotometer; palladium(II) with tin(II) chloride [11], and gold(III) as $AuCl_4^-$ ion at 313 nm with a calibrating plot [12]. The equilibrium concentrations of metal ions in raffinates were determined by atomic absorption spectrophotometry on a Hitachi 508 spectrometer. Aqueous solutions of Pd(II) and Au(III) were burned in an acetylene–air flame. Lamps with a hollow cathode made of metals to be determined served as monochromatic light sources with analytical wavelengths of 247.6 and 242.8 nm for Pd and Au, respectively. The error of the metal concentration determination was 5–10 rel %.

The steep slopes of the initial parts of the extraction isotherms (Figs. 1, 2) show that the keto sulfide

Extractant: (*1*) *tert*-C_{12}; (*2–4*) sum of *tert*-C_{12}, C_{15}, and C_{18}; (*5*) petroleum sulfides; (*6*) C_6–C_{10} mixture; the same for Fig. 2.

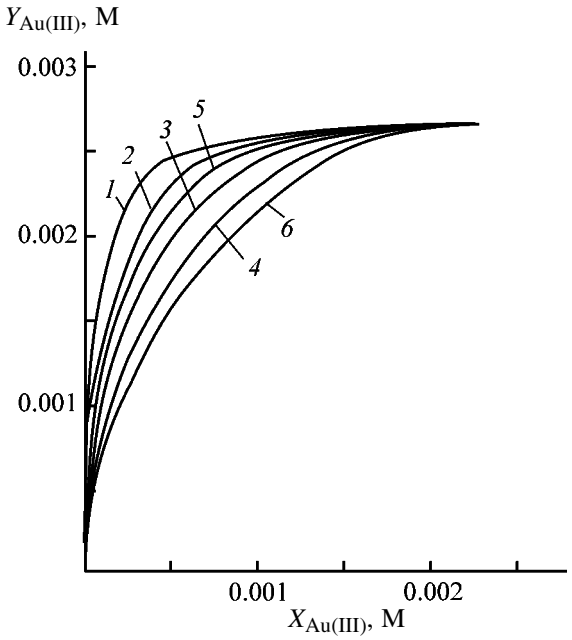

Fig. 2. Isotherms of palladium(II) extraction from 0.5 M HCl solutions with 0.0025 M solutions of keto sulfide concentrates in chloroform at 25°C.

concentrates studied efficiently recover metal ions from moderately acidic aqueous solutions. Concentrates of keto sulfides I and II based on TM-1, TM-2, and propanone are better extractants than III and IV. Product I based on TM-1 is a better extractant than II, which may be associated with the higher molecular weight of keto sulfide in the latter case. The extractive power in the series of concentrates II, IV, and III based on TM-2 and propanone, acetophenone, and butanone, respectively, decreases. A decrease in the extractive power of III and IV as compared to II may be due to elevated content of disulfide sulfur in III and IV (see table). The ratio of mono- and disubstituted ketones probably also affects the extractive power. In the saturation region, the extraction isotherms of palladium(II) with I and II differ from the isotherms with V and VI insignificantly; however, extraction with low-boiling keto sulfides is more efficient than extraction with high-boiling keto sulfides I–IV. The extractive power of petroleum sulfides V with respect to palladium(II) is lower than that of keto sulfides VI and higher than that of keto sulfides based on C_{12}–C_{18}.

For I–VI, the solvate number found by the saturation method is equal to 2 for palladium(II), and hence extraction is accompanied by formation of coordination compounds $PdCl_2L_2$ in the organic phase. At the same time, the slopes of the extraction isotherms show that palladium(II) recovery increases in the order III < IV < II < I < V < VI. Higher extractive power of IV as compared to III is probably caused by the effect of the phenyl substituent in the keto sulfide molecule.

It follows from the gold(III) extraction isotherms (Fig. 2) that its solvate number with I–VI is equal to 1. No reduction of Au(III) during extraction was observed. The extractive power increases in the order VI < IV < III < V < II < I. The extractive power of petroleum sulfides with respect to gold(III) is lower then that of keto sulfides I–IV and VI.

Taking into account the stability and accessibility of the technical-grade TMs for obtaining keto sulfides with high extractive power with respect to palladium(II) and gold(III), we can recommend to use keto sulfide concentrates I and VI in the analytical and hydrometallurgical practice.

CONCLUSIONS

(1) Concentrate of keto sulfides I based on TM-1 (yield 94%) with a high content of keto sulfides (12.2 wt % sulfide sulfur) and no impurities is the most efficient extractant of palladium(II) and gold(III).

(2) The use of low-boiling C_6–C_{10} keto sulfides is preferable for palladium(II) recovery.

Abstract—Extraction of Th(IV), La(III), and Y(III) from aqueous solutions containing 0–4 M sodium nitrate with a composite solid extractant based on a polymeric support impregnated with trialkylmethylammonium nitrate (Aliquat-336) was studied. The extraction isotherms were analyzed assuming that lanthanides and thorium are extracted with the solid extractant in the form of complexes $(R_4N)_2[Ln(NO_3)_5]$ and $(R_4N)_2[Th(NO_3)_6]$, respectively. The extraction constants were calculated. The joint extraction of Th(IV) and La(III) [Y(III)] with the solid extractant from aqueous salt solutions was studied.

DOI: 10.1134/S1070427206110127

Russian loparite, orthite, and monazite, along with rare-earth metals, usually contain also thorium and uranium as natural radioactive impurity metals. Therefore, the separation of thorium and uranium from rare-earth metals is an urgent technological problem. This problem is usually solved by solvent extraction [1]. Another approach to solution of this problem is the use of composite solid extractants based on a porous support impregnated with a liquid extractant. This technique eliminates certain drawbacks characteristic of common solvent extraction procedures.

The extraction of rare-earth metals(III) [REM(III)] from aqueous solutions containing sodium nitrate (1–5 M) with a composite solid extractant (SE) based on a polymeric support impregnated with trialkylmethylammmonium nitrate (Aliquat-336) was studied in [2]. The extraction isotherms were processed assuming formation of the extractable complex $(R_4N)_2 \cdot [Ln(NO_3)_5]$ in the solid extractant.

No data have been reported on extraction of Th(IV), La(III) and Y(III) nitrates from aqueous solutions containing sodium nitrate with the composite solid extractant based on a polymeric support impregnated with neat trialkylmethylammonium nitrate. Since extraction of these metals with solid extractants is important from both scientific and practical viewpoints, in this study we tried to fill this gap.

The granulated composite solid extractant Purolite D4384 MD 1/5 based on super-cross-linked poly(styrene–divinylbenzene) matrix impregnated with Aliquat-336 [general formula $(C_8H_{17}–C_{10}H_{21})_3CH_3NNO_3$] was used. Its specific volume was 1.93 ± 0.02 dm^3 kg^{-1}. The Aliquat-336 content in the composite solid extractant was 2.33 ± 0.02 mol dm^{-3}. The REM(III) and Th(IV) content in the solid extractant and aqueous phase was determined by the technique similar to that reported in [2–5]. The metal nitrate content in SE (mol kg^{-1}) was recalculated to mol dm^{-3} taking into account the density of the composite solid extractant.

The relative errors in determining REM(III) [Th(IV)] concentration in the aqueous and SE phases were $\pm$(1–3) and $\pm$(1–5) rel. %, respectively. As a rule, each final result was the average from the results of no less than three experiments. The errors in parameter determination are given as the standard deviations.

Figure 1a shows the extraction isotherm of thorium(IV) nitrate from aqueous solutions containing $NaNO_3$ (0–4 M) with SE at pH 1 and 298.15 K. With increasing $NaNO_3$ concentration in the aqueous phase, the thorium content in SE increases and becomes close to $c_s/2$, where c_s is the Aliquat-336 concentration in SE (2.33 ± 0.02 mol/dm^{-3}). This fact suggests

that, in saturation of SE (Aliquat-336) with thorium nitrate, the compound $(R_4N)_2[Th(NO_3)_6]$ is formed.

The extraction of Th(IV) nitrate with TAA nitrate can be described by the equation of the following heterogeneous reaction:

$$Th^{4+}(aq) + 4NO_3^-(aq) + 2R_4NNO_3(o) \rightleftarrows (R_4N)_2[Th(NO_3)_6](o), \quad (1)$$

where (aq) and (o) refer to the aqueous phase and SE, respectively.

The effective extraction constants of Th with Aliquat-336 can be calculated by the equation

$$K_{ex}^{2,0} = \frac{c_{(R_4N)_2[Th(NO_3)_6](o)}}{c_{Th^{4+}(aq)} c_{NO_3^-(aq)}^4 \gamma_\pm^5 c_{R_4NNO_3(o)}^2}, \quad (2)$$

where $c_{i(o)}$ *and* $c_{i(aq)}$ are the equilibrium concentration of components in SE and aqueous phase, respectively, and $\gamma_\pm$ is the mean ionic molar activity coefficient of Th(IV) nitrate in the aqueous phase.

The equilibrium Th concentrations in SE, calculated assuming the occurrence of reaction (1), are listed in the table. The $\gamma_\pm$ values used in these calculations were taken from [3]. The table shows that the calculated Th(IV) concentrations in the solid extractant reasonably agree (within 1–4%) with the experiment. Thus, our model adequately describes the extraction of thorium(IV) nitrate from aqueous solutions with the solid extractant in the systems widely differing in the $Th(NO_3)_4$ concentration in both aqueous and solid extractant phases, with $\log K_{ex}^{2,0} = 2.95 \pm 0.05$.

The influence of the ionic strength of the aqueous phase ($I^\Sigma = 0.5\Sigma c_i Z_i$) on the concentration extraction constants K_{ex}^2 can be estimated by the equation [2]

$$\log K_{ex}^2(I^\Sigma) = \log K_{ex}^{2,0} + \Delta Z^2 F(I^\Sigma) + 10\theta_1 c_{Th^{4+}(aq)} + \theta_2 c_{NaNO_3(aq)}, \quad (3)$$

where ΔZ^2 is the algebraic sum of the charge numbers squared of the ionic species participating in the extraction equilibrium. For the extraction of Th(IV), $\Delta Z^2 = -20$; $F(I^\Sigma)$ is a function of the ionic strength of aqueous solution, e.g., $F(I^\Sigma) = -a(I^\Sigma)^{1/3}$; θ_1 and θ_2 are empirical parameters; $c_{Th^{4+}}$ and c_{NaNO_3} are the equilibrium concentrations of Th(IV) and sodium nitrates in the aqueous phase.

The mathematical treatment of the extraction isotherms was carried out with an algorithm reported in

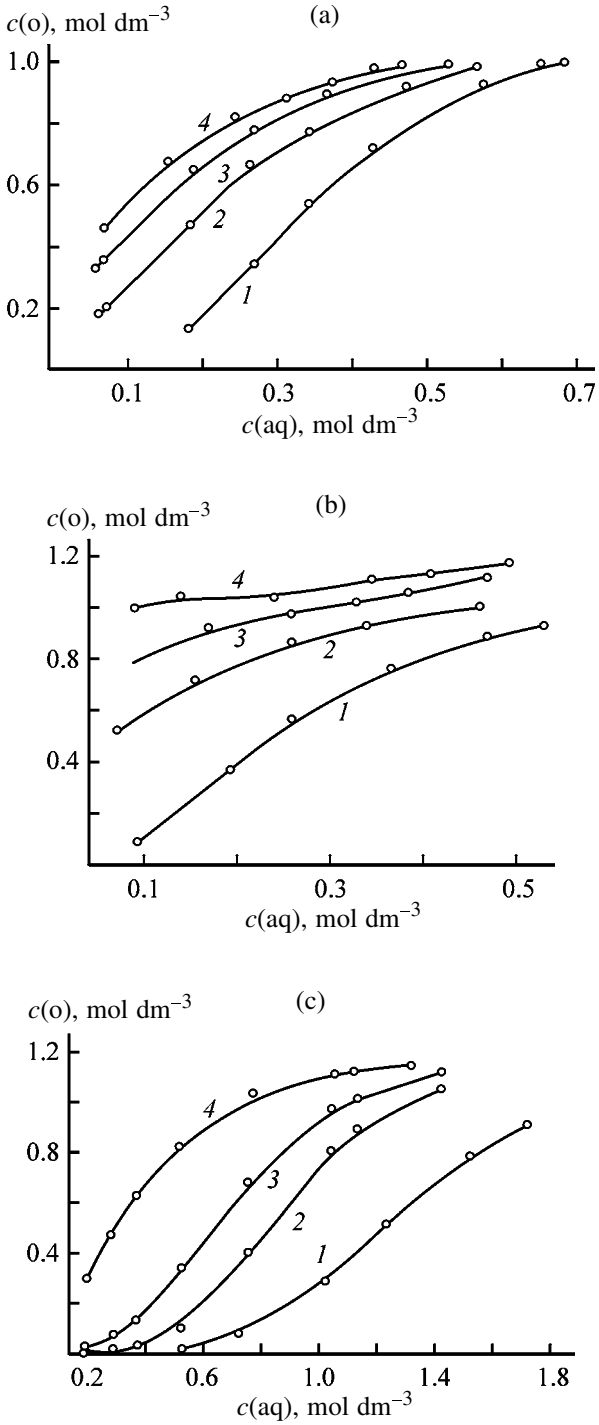

Fig. 1. Extraction isotherms of (a) thorium(IV), (b) lanthanum(III), and (c) yttrium(III) nitrates from aqueous solutions in the absence and in the presence of sodium nitrate with SE (Aliquat-336). [c(aq)] Th(IV), Ln(III), and Y(III) nitrate concentration in the aqueous phase; [c(o)] Th(IV), Ln(III), and Y(III) nitrate concentration in solid extractant; the same for Figs. 2 and 3. Sodium nitrate concentration, mol dm^{-3}: (*1*) 0, (*2*) 1.0, (*3*) 2.0, and (*4*) 4.0.

Results of mathematical processing of data on the extraction of thorium(IV), lanthanum(III), and yttrium(III) nitrates from aqueous solutions with SE(Aliquat-336) at T = 298.15 K

Note: c(aq) is the equilibrium concentration of thorium(IV), lanthanum(III), or yttrium(III) nitrate in the aqueous phase; c(o), equilibrium concentration of thorium(IV), lanthanum(III), or yttrium(III) nitrate in the organic phase; c(o) (calc), calculated equilibrium concentration of thorium(IV), lanthanum(III), or yttrium(III) nitrate in the SE phase; deviation means the deviation of the calculated values from the experimental data; $[R_4NNO_3](o)$, equilibrium extractant concentration; D_{ex}, distribution ratio; and $\gamma_{\pm}$, mean ionic molar activity coefficient of thorium(IV), lantanum(III), or yttrium(III) nitrate in the aqueous phase.

[1], taking into account the material balance equations. The prameter a in function $F(I^{\Sigma})$ is equal to 0.155 ± 0.005 at $c_{Th}^{4+} < 0.7$ mol dm^{-3} and 0.139 ± 0.005 at $c_{Th}^{4+} > 0.7$ mol dm^{-3}. Within these thorium concentration ranges θ_1 is 0.345 ± 0.005 and 0.258 ± 0.006, respectively; $\theta_2 = 0 \pm 0.005$.

Figures 1b and 1c show the extraction isotherms of La(III) and Y(III) nitrates from aqueous solutions containing $NaNO_3$ (0–4 M) with SE at pH 2. It is seen that, with increasing $NaNO_3$ concentration in the aqueous phase, the REM content in the SE increases and becomes close to $c_s/2$. This fact suggests that, in saturation of SE(Aliquat-336) with REM nitrate, the compound $(R_4N)_2[Ln(NO_3)_5]$ is formed. The efficiency of extraction of La(III) nitrate is higher than that of Y(III) nitrate. The extraction of Y(III) with SE in the absence of sodium nitrate occurs only at the equilibrium concentration of Y(III) nitrate in the aqueous phase higher than 0.5 mol dm^{-3} (Fig. 1c).

The extraction of REM nitrate with Aliquat-336 can be described by the equation of the following heterogeneous reaction:

$$Ln^{3+}(aq) + 3NO_3^-(aq) + 2R_4NNO_3(o) \rightleftarrows (R_4N)_2[Ln(NO_3)_5](o). \quad (4)$$

The extraction constants of Ln(III) nitrate with Aliquat-336 can be calculated by the equation

$$K_{ex}^{2,0} = \frac{c_{(R_4N)_2[Ln(NO_3)_5](o)}}{c_{Ln^{3+}(aq)} c_{NO_3^-(aq)}^3 \gamma_{\pm}^4 c_{R_4NNO_3(o)}^2}. \quad (5)$$

The equilibrium concentrations of La(III) and Y(III) in the solid extractant, calculated by Eqs. (4) and (5) using $\gamma_\pm$ taken from [2, 3], are listed in the table. The calculated values fairly well agree with the experiment, i.e., our model adequately describes the extraction of REM nitrates from aqueous solutions with the solid extractant; $\log K_{ex}^{2,0}$ is equal to 3.00 ± 0.05 for La and 0.40 ± 0.05 for Y. The extraction constant of La(III) and Th(IV) are close but considerably exceed the extraction constant of Y(III).

The effect of the ionic strength of the aqueous phase on the concentration extraction constants K_{ex}^2 of La(III) and Y(III) nitrates can be expressed by the equation

$$\log K_{ex}^2(I^\Sigma) = \log K_{ex}^{2,0} + \Delta Z^2 F(I^\Sigma) + 6\theta_1 c_{Ln^{3+}(aq)} + \theta_2 c_{NaNO_3(aq)}, \quad (6)$$

where $\Delta Z^2 = -12$, $a = 0.238\pm0.005$, $\theta_1 = 0.451\pm0.005$ for La and 0.579 ± 0.006 for Y; $\theta_2 = 0.400\pm0.005$ for La and 0.602 ± 0.005 for Y.

The joint extraction of Th(IV) and Y(III) nitrates from aqueous salt solutions with SE was also studied. Figure 2 shows the extraction isotherms of Th(IV) nitrate from aqueous solutions containing varied amounts of yttrium nitrate. We found that Y(III) nitrate is not noticeably extracted in the presence of Th(IV) nitrate [Y(III) concentration in the SE phase is less than 0.005 mol dm^{-3}]. With increasing yttrium nitrate concentration in the aqueous phase, the Th(IV) nitrate content in SE becomes close to $c_s/2$ as in the case of extraction of Th(IV) nitrate from $NaNO_3$ containing no Y(III) (Fig. 1a).

The effect of the ionic strength of aqueous solution on the extraction constant K_{ex}^2 of Th(IV) nitrates from its aqueous solutions containing yttrium nitrate is described by the equation

$$\log K_{ex}^2(I^\Sigma) = \log K_{ex}^{2,0} + \Delta Z^2 F(I^\Sigma) + 10\theta_1 c_{Th^{4+}(aq)} + 6\theta_2 c_{Y^{3+}(aq)}, \quad (7)$$

where $\Delta Z^2 = -20$, $a = 0.139\pm0.005$, $\theta_1 = 0.420\pm0.005$, and $\theta_2 = 0.315\pm0.005$.

The joint extraction of Th(IV) and La(III) nitrate from aqueous salt solutions with SE was studied in relation to the Th(IV) nitrate equilibrium content in the aqueous phase at different La(III) nitrate concentrations in the initial solution (Fig. 3).

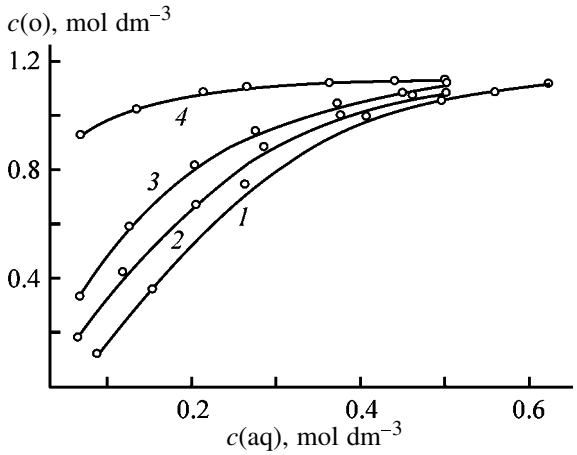

Fig. 2. Th(IV) concentration in the SE vs. its equilibrium concentration in aqueous solutions containing yttrium nitrate. Yttrium nitrate content in the initial aqueous solution (mol dm^{-3}): (*1*) 0.1, (*2*) 0.2, (*3*) 0.3, and (*4*) 1.0.

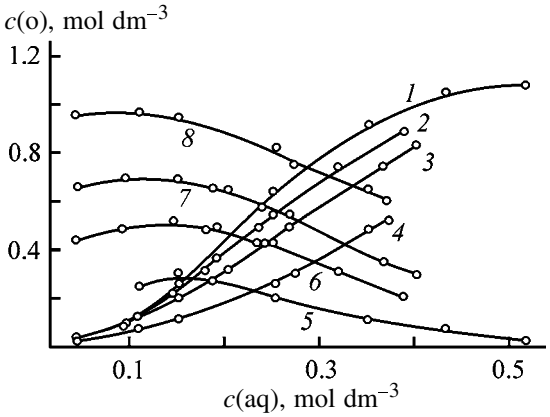

Fig. 3. Extraction of (*1–4*) thorium and (*5–8*) lanthanum nitrate with SE based on Aliquat-336 vs. the equilibrium thorium nitrate concentration in the aqueous phase. Lanthanum nitrate concentration in the initial aqueous solution, mol dm^{-3}: (*1, 5*) 0.1, (*2, 6*) 0.2, (*3, 7*) 0.3, and (*4, 8*) 0.5.

As seen from Fig. 3, in this system both metals are extracted with SE. At thorium(IV) nitrate concentration in the aqueous phase below 0.3 mol dm^{-3}, the extraction of lanthanum(III) nitrate prevails and the La(III) nitrate concentration in the SE increases with an increase in its concentration in the aqueous phase. At the Th(IV) nitrate concentration in the aqueous phase exceeding 0.3 mol dm^{-3}, its extraction predominates and the Th(IV) nitrate content in the SE decreases with increasing La(III) nitrate content in the initial solution (Fig. 3).

The effect of the ionic strength of the aqueous phase on the concentration constant of extraction K_{ex}^2 of Th(IV) nitrate from aqueous solution containing

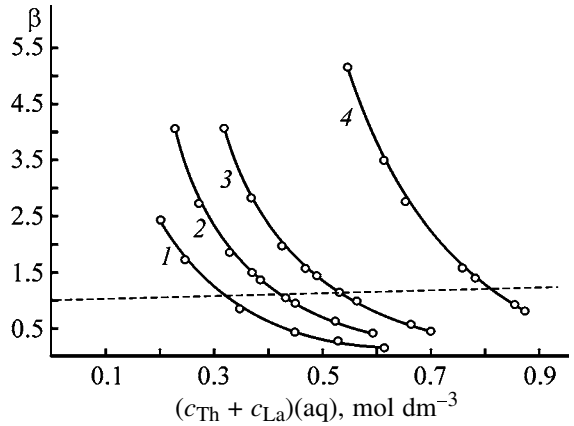

Fig. 4. La/Th separation factor β vs. the total equilibrium concentration of La + Th nitrates in the aqueous phase $(c_{Th} + c_{La})$(aq). La(III) nitrate concentration in the initial solution, mol dm^{-3}: (*1*) 0.1, (*2*) 0.2, (*3*) 0.3, and (*4*) 0.5.

thorium and lanthanum nitrates is expressed by the equation

$$\log K_{ex}^{2}(I^{\Sigma}) = \log K_{ex}^{2,0} + \Delta Z^2 F(I^{\Sigma}) + 10\theta_1 c_{Th^{4+}(aq)} + 6\theta_2 c_{La^{3+}(aq)}, \quad (8)$$

where $\Delta Z^2 = -20$, $a = 0.139 \pm 0.005$, $\theta_1 = 0.690 \pm 0.005$, $\theta_2 = 0.300 \pm 0.005$ at $I^{\Sigma} < 7$ and $\theta_1 = 0.400 \pm 0.005$, $\theta_2 = 0.265 \pm 0.005$ at $I^{\Sigma} > 7$, $\log K_{ex}^{2,0} = 2.95 \pm 0.06$.

The concentration constant of extraction of La(III) from aqueous solutions containing Th(IV) and La(III) nitrate can be calculated by Eq. (8). In this case, $\Delta Z^2 = -12$, $a = 0.238 \pm 0.005$, $\theta_1 = 0.500 \pm 0.005$, $\theta_2 = 0.500 \pm 0.05$; $\log K_{ex}^{2,0} = 3.00 \pm 0.06$.

Figure 4 shows dependence of the separation factor of lanthanum from thorium on the total equilibrium concentration of Th(IV) and La(III) nitrates in the initial aqueous solution containing variable amounts of La(III) nitrate. It is seen that the La/Th separation factor β significantly depends on both the total content of these metals in solution and their ratio. The highest La/Th separation factor (β = 5) is attained at low thorium nitrate and high lanthanum nitrate concentrations in the aqueous phase. For certain systems, β becomes equal to unity, i.e., the separation of La from Th disappears (see the boundary line of inversion of the separation factor in Fig. 4). At low equilibrium lanthanum nitrate concentration and high thorium nitrate concentration in the aqueous phase, the Th/La separation factor becomes equal to approximately five. The expression for the La/Th separation factor can be obtained by combination of Eq. (2) and Eq. (5):

$$\beta_{La/Th} = \frac{K_{ex,La}^{2,0} \gamma_{La\pm}^{4}}{K_{ex,Th}^{2,0} c_{NO_3^-(aq)}^{5} \gamma_{Th\pm}^{5}}. \quad (9)$$

This equation shows that, at small difference between the extraction constants of La and Th nitrates, the La/Th separation factor is controlled by the concentration of nitrate anion in the aqueous phase and the ratio of the mean ionic molar activity coefficients of La^{3+} and Th^{4+} risen to the corresponding power.

The composite solid extractant based on a polymeric support impregnated with neat trialkylmethylammonium nitrate can be used for purification of concentrated solution of La(III) nitrate to remove Th(IV) impurities, and, vice versa, for purification of concentrated solutions of Th(IV) nitrate to remove La(III) impurities. This solid extractant is also suitable for purification of Y(III) nitrate to remove Th(IV) nitrate impurities.

CONCLUSIONS

(1) The extraction isotherms of REM(III) and Th(IV) nitrate with a composite solid extractant based on a polymeric support impregnated with trialkylmethylammonium nitrate can be analyzed assuming that lanthanides and thorium nitrates are extracted in the form of complexes $(R_4N)_2[Ln(NO_3)_5]$ and $(R_4N)_2[Th(NO_3)_6]$, respectively. The extraction constants were calculated.

(2) In joint extraction of Th(IV) and Y(III) nitrates from aqueous salt solutions with a solid extractant, Y(III) nitrate is not noticeably extracted in the presence of Th(IV) nitrate. With increasing Y(III) nitrate concentration in the aqueous phase, the extraction of Th(IV) nitrate with the solid extractant increases.

(3) In joint extraction of Th(IV) and La(III) nitrates from aqueous salt solutions containing different amounts of Th(IV) and La(III), both metals are recovered with the solid phase, and the La/Th separation factor significantly depends on the Th(IV) and La(III) concentration and the Th(IV) : La (III) ratio in the aqueous phase.

(4) The composite solid extractant based on the polymeric support impregnated with neat trialkylmethylammonium nitrate can be used for purification of concentrated solution of La(III) nitrate to remove Th(IV) impurities, and, vice versa, for purification of concentrated solutions of Th(IV) nitrate to remove La(III) impurities. This extractant is also suitable for

purification of Y(III) nitrate to remove Th(IV) nitrate impurities.

Abstract—Lanthanide tris(β-diketonates) were used as ionophores for plasticized polymer membranes of ion-selective electrodes. Electrochemical properties of the membranes were characterized, and the possibility of their use as components of chloride ion-selective electrodes was studied.

DOI: 10.1134/S1070427206110140

Surface waters and wastewaters are analyzed using various chemical, physical, and physicochemical methods. Currently used analytical methods and devices for monitoring the composition of surface waters and wastewaters are either too expensive or insufficiently prompt. There is a great need in developing sensors for prompt analysis of the ionic composition of aqueous solutions, including chemical sensors such as electrodes with ion-selective plasticized membranes. The use of ion-selective membrane electrodes is confined by the complexity of synthesis of sufficiently selective and sensitive ionophores as their basic components. Among the most efficient ionophores used in ion-selective electrodes are quaternary ammonium salts [1–3], vitamin B_{12} derivatives [4], metal porphyrins [5–7], and fluorinated polyethers [8].

Because of their high selectivity, ionophores based on lanthanide tris(β-diketonates) are of particular interest [9]. However, there is only limited information on the dependences of the selectivity and other electrode characteristics of these compounds on the composition and properties of aqueous solutions.

In this study we used lanthanide tris(β-diketonates) as ionophores for plasticized polymer membranes of ion-selective electrodes for prompt analysis of various aqueous systems for chloride.

EXPERIMENTAL

Lanthanide tris(β-diketonates) were synthesized from the corresponding lanthanide chlorides and β-diketones (Aldrich). For preparation of the membranes, we used THF after purification.

Tris(1,1,1-trifluoro-2,4-pentanedionato)europium (TPE). An aqueous-alcoholic solution containing 9 ml of H_2O and 9 ml of 95% EtOH was heated to 50°C. $EuCl_3 \cdot 6H_2O$ (0.122 g, 0.33 mmol) was added with stirring to obtain a clear solution. To the resulting solution, 1,1,1-trifluoro-2,4-pentanedione (0.154 g, 1 mmol) was added, and pH was adjusted to 6.5 by adding ammonia dropwise. White crystals were filtered off and vacuum-dried over P_2O_5. Yield 0.147 g (68%); mp 142–146°C.

Found, %: C 28.58, H 2.19, O 19.78, F 26.99, Eu 24.19.

$C_{15}H_{14}O_7F_9Eu$.

Calculated, %: C 28.63, H 2.24, O 17.79, F 27.17, Eu 24.15.

IR (ν, cm^{-1}): 1620 (C=O), 1280 (C–F), and 410 (Eu–O).

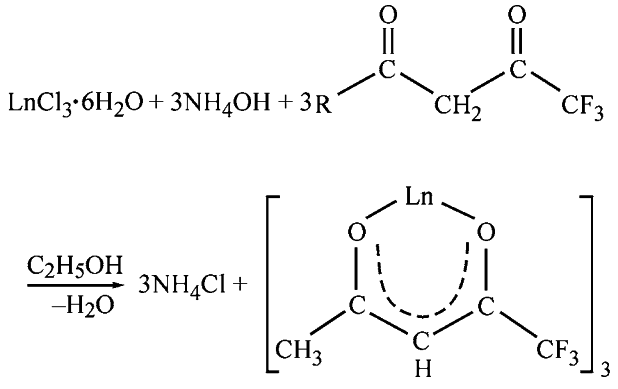
Tris(4,4,4-trifluoro-1-phenyl-1,3-butanedionato)-europium (PBE) was prepared by adding dropwise $EuCl_3 \cdot 6H_2O$ (0.216 g, 1 mmol) to a hot alcoholic solution containing 4,4,4-trifluoro-1-phenyl-1,3-butanedione (0.122 g, 0.33 mmol) with stirring. Then aqueous ammonia was added to adjust pH to 6.5. The precipitated white solid was filtered off, washed with alcohol, and vacuum-dried over P_2O_5. Yield 0.493 g (59.18%); mp 130–134°C.

Found, %: C 45.11, H 2.57, O 12.08, F 21.41, Eu 19.03.

$C_{30}H_{18}O_6F_9Eu$.

Calculated, %: C 45.17, H 2.59, O 12.04, F 21.44, Eu 19.06.

IR (ν, cm^{-1}): 1660 (C_6H_5), 1622 (C=O), 1282 (C–F), and 414 (Eu–O).



The IR spectra were recorded on a Perkin–Elmer 16 PC FTIR spectrometer using the KBr technique.

The ion-selective membranes were prepared as follows: PVC powder (0.01923 g, 31 wt %), ionophore (0.002 g, 3.3 wt %), sodium tetraphenylborate as a lipophilic ionic additive (0.0002 g, 0.3 wt %), and dioctyl phthalate as a plasticizer (0.03917 g, 64.7 wt %) were dissolved in THF in a 20-ml weighing bottle. The components were weighed on a VLR-20 balance to within 5×10^{-5} g. The resulting solution was cast into a glass mold 1 cm in diameter and allowed to stand for 24 h until complete removal of THF. As a result, an elastic transparent membrane 0.3–0.5 mm thick was obtained.

From the membrane, a circle 6–7 mm in diameter was cut off and then glued to the face of a PVC tube 50 mm long and 5 mm in diameter using a solution of PVC in THF as an adhesive. 0.01 M NaCl was used as an inner electrolyte. The inner electrode (AgCl/Ag) was fixed inside the PVC tube using silicone paste. Three membrane electrodes were prepared for each ionophore.

The potentiometric measurements were carried out with a pH-150 pH–millivoltmeter.

Using the procedure described in [10], we synthesized four complexes with the general formula LnL_3 (Ln = Dy, Eu; L = 1,1,1-trifluoro-2,4-pentanedionate, 4,4,4-trifluoro-1-phenyl-1,3-butanedionate). The route to the tris(β-diketonates) is shown in the scheme below.

The complexes were synthesized in aqueous–alcoholic solutions. The solution with the precipitated solid was stirred for 15 min and then the precipitate was filtered off. All the complexes are white, except for dysprosium tris(1,1,1-trifluoro-2,4-pentanedionate) which is pale-orange.

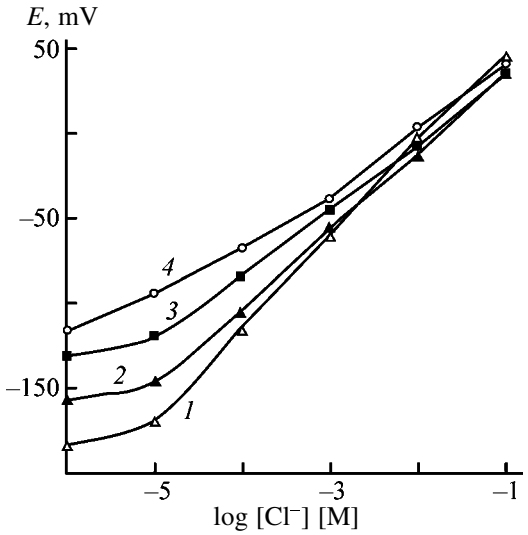


Fig. 1. emf E as a function of the chloride concentration. Ionophore: (*1*) PBE, (*2*) TPE, (*3*) PBD, and (*4*) TPD.

The structure of the complexes was derived from the elemental composition and IR spectra.

The ionophore-based membranes were prepared according to the procedure described in [9].

The emf vs. log[Cl] curves for the investigated electrodes are presented in Fig. 1. The highest slope of the electrode function was obtained for the PBE-based membrane (54 mV/decade). The detection limit of this electrode with respect to the chloride ion was found to be 10^{-5} M. The slopes of the electrode function of the other electrodes are as follows (mV/decade): 34 dysprosium tris(1,1,1-trifluoro-2,4-pentanedionate) (TPD), 34 dysprosium tris(4,4,4-trifluoro-1-phenyl-1,3-butanedionate) (PBD), and 46 TPE.

To characterize the selectivity of the membranes, we performed potentiometric measurements in NaCl solutions containing foreign anions such as I^-, Br^-, ClO_4^-, CH_3COO^-, NO_3^-, CO_3^{2-}, and SO_4^{2-}. The results obtained for the PBE-based electrode are given in Fig. 2.

The PBE-based electrode demonstrates the highest selectivity among the electrodes studied. For all the electrodes, the most interfering anion was bromide ($\log K_{A/B} = -1.6$).

The selectivity coefficients of the PBE-based electrode were determined at constant concentration of interfering anions (10^{-2} M) and variable concentration of chloride. In the table, the selectivity coefficients of our PBE-based electrode are compared with published data for electrodes based on various ionophores [8, 9,

Selectivity coefficients $K_{A/B}$ for membranes with various ionophores

Interfering ion B	$\log K_{A/B}$ for indicated ionophore				
	(5,10,15,20-tetraphenylporphyrinato)Mn(III) chloride [11]	trisdodecylmethylammonium chloride [12]	MC [8]	europium tris(2,2-dimethyl-6,6,7,7,8,8,8-heptafluorooctane-3,5-dionate) [9]	PBE
I^-	+2.4	+2.8	+2.3	–2.71	–2.0
Br^-	+0.9	+0.6	+1.0	–1.19	–1.6
ClO_4^-	–3.6	+4.6	–2.8	–2.94	–3.0
NO_3^-	+1.2	–	–2.7	–3.34	–3.0
CO_3^{2-}	–	–	–	–3.97	–2.9
SO_4^{2-}	–	–	–	–4.02	–3.2

11, 12]. As seen, the PBE-based electrode demonstrates higher selectivity with respect to the chloride ion.

Since pH of natural waters and, particularly, process solutions can vary over a wide range, we studied the pH effect on the electrode function of the PBE-based electrode (Fig. 3). As seen, the pH effect is insignificant over the pH range from 5 to 9, allowing the use of this electrode for environmental monitoring.

We also studied the stability of the potential of the PBE-based electrode in time. It was demonstrated that the electrode potential in 0.01 M NaCl is stable for 2 months.

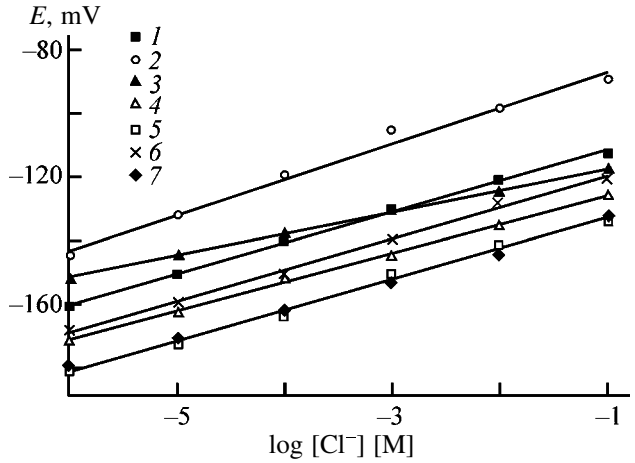

Fig. 2. emf E as a function of the chloride concentration for the PBE-based electrode in solutions containing interfering anions: (*1*) I^-, (*2*) Br^-, (*3*) ClO_4^-, (*4*) CH_3COO^-, (*5*) NO_3^-, (*6*) CO_3^{2-}, and (*7*) SO_4^{2-}.

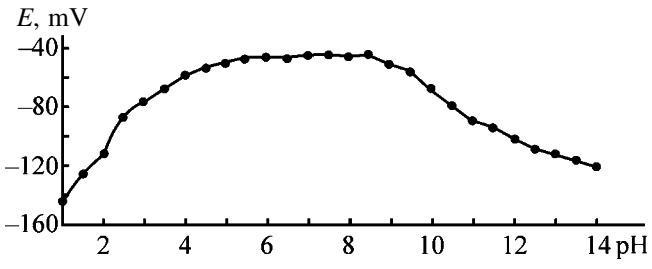

Fig. 3. emf of PBE electrode E as a function of pH.

CONCLUSION

The investigated lanthanide tris(β-diketonates) can be used as ionophores for membranes of ion-selective electrodes. All the ionophores studied demonstrate high selectivity and sensitivity over a wide concentration range and low detection limit with respect to the chloride ions. The best electrode characteristics were obtained with europium tris(4,4,4-trifluoro-1-phenyl-1,3-butanedionate). Electrode with this ionophore can be used a chloride-sensitive sensor for analysis of various aqueous systems.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Calculation of the Most Uniform Electroplated Coating with Account of Changes in the Concentration of Electrolyte Components

V. I. Karavaev, I. L. Korobova, and Yu. V. Litovka

Tambov State Technical University, Tambov, Russia

Received May 6, 2006

Abstract—The problem of optimization of the electroplating process by the nonuniformity criterion with account of the effect of changes in the concentration of electrolyte components on the polarization is formulated and solved.

DOI: 10.1134/S1070427206110152

One of the most important quality parameters of an electroplated coating is the uniformity of metal distribution over the article surface. The uniformity depends on the configuration of an electrolytic cell (shape, size, and relative position of electrodes) and on the electrochemical component (polarization phenomena). The effect of these factors on the coating uniformity has been extensively studied [1, 2]. However, the influence of the concentration of electrolyte components on the polarization and, consequently, on the uniformity of electroplated coatings has been insufficiently studied. At the same time, the concentration of electrolyte components varies with time because of the carry-over of the electrolyte with processed articles, consumption of these components by electrochemical and chemical reactions, and electrolyte evaporation.

In many cases, the polarization strongly depends on the concentration of the electrolyte components. It was shown in [3] that the concentration of ammonium ions affects the run of the overall polarization curves in electrodeposition of a nickel–molybdenum alloy. In [4], polarization curves obtained at various concentrations of lead ions in the cyanide electrolyte in electrodeposition of gold were reported. It was demonstrated in [5–8] that polarization curves depend on the concentration of various electrolyte components in zinc-, cadmium-, tin-, rhodium-, nickel-, and silver-plating. In all of these examples, the overvoltage changes by 10–20% when the concentration of electrolyte components varies.

In this study, the influence exerted by the concentration of electrolyte components on the coating uniformity is examined and electrical parameters of the electroplating bath that provide the highest coating uniformity at varied electrolyte concentration are sought for.

The coating nonuniformity factor R is defined by the formula

$$S_c = \frac{1}{S_c}\int_{S_c}\frac{\delta(x, y, z) - \delta^{min}}{\delta^{min}}dS_c, \qquad (1)$$

where S_c is the cathode surface area; $\delta(x, y, z)$, coating thickness at a certain point of the cathode, with the coordinates (x, y, z); and δ^{min}, minimum coating thickness on the cathode.

The optimization problem is formulated as follows.

Let the concentration of a component that affects the polarization be c at a certain instant of time (the concentration can be measured or calculated in terms of a mathematical model [9]). It is necessary to find the voltage U applied to the bath, at which the coating nonuniformity (1) is at a minimum.

To relate the criterion R to the concentration c, we use a set of equations of the mathematical model, which will have the following form.

The coating thickness at a certain point (x, y, z) on the cathode surface S_c is calculated by the formula derived from the Faraday law:

$$\delta(x, y, z) = \frac{E\, i(x, y, z)\, \eta\, \tau}{\rho}, \qquad (2)$$

where E is the electrochemical equivalent of the substance; τ, process duration; ρ, substance density; $i(x, y, z)$, current density at a point (x, y, z) of the article; and η, cathode current efficiency.

The current density at the electrodes is calculated by Ohm's law in the differential form:

$$i(x, y, z) = -\chi \frac{\partial \varphi(x, y, z)}{\partial n} \Big| S_c, \quad (3)$$

where χ is the electrical conductivity of the electrolyte; φ, potential of the electric field; n, normal to the surface S_c of the cathode at a point (x, y, z); $\partial\varphi(x, y, z)/\partial n$, vector of the field of potentials in the normal direction.

The potential distribution over the volume of the electrolytic cell satisfies the Laplace equation

$$\partial^2\varphi(x, y, z)/\partial x^2 + \partial^2\varphi(x, y, z)/\partial y^2 + \partial^2\varphi(x, y, z)/\partial z^2 = 0. \quad (4)$$

The boundary conditions for Eq. (4) have the form:

(1) at the electrolyte–insulator interface:

$$\partial^2\varphi(x, y, z)/\partial n \,|\, S_b = 0, \quad (5)$$

where S_b is the insulator surface.

This equation means that no current flows through the insulator, i.e., there is no potential difference across the interface with the insulator.

(2) at the electrolyte–anode interface:

$$\varphi(x, y, z) + F_a[i(x, y, z)] \,|\, S_a = U, \quad (6)$$

where $F_a[i(x, y, z)]$ is a function of the anodic polarization; S_a, anode surface; and U, voltage across the anode and cathode.

(3) at the electrolyte–cathode interface:

$$\varphi(x, y, z) - F_c[i(x, y, z), c] \,|\, S_c = U, \quad (7)$$

where $F_c[i(x, y, z), c]$ is a function of the cathodic polarization.

The coating thickness is subject to the following limitation:

$$\delta(x, y, z) \geq \delta^{min}. \quad (8)$$

The basic equation for calculation of the electric field in the electrolyte is the Laplace equation. To obtain the distributions of the potentials and coating thickness, we use a combination of the methods of upper relaxation [10] and simple iterations [11] to provide that the boundary conditions (6) and (7) are satisfied.

We are going to search for the optimal solution by the method of internal penalty functions [12].

Let us consider as an example of implementation of the procedure suggested the problem of calculation of the most uniform coating for zinc plating in an alkaline electrolyte.

The experimental plots of cathodic polarization curves $F_c^{exp}(i, c)$ obtained at various zinc concentrations c in an alkaline electrolyte used in the experiments were reported in [5]. In calculations, it is more convenient to have an approximating analytical expression. Let us seek the approximating function in the form of a polynomial of two variables $F_c^{calc}(c, i) = a_1 + a_2c + a_3ci + a_4ci^2 + a_5c^2 + a_6c^2i + a_7i + \ldots$. The coefficients a_c of the polynomial are found by minimizing the error function ε (%):

$$\varepsilon = \{n^{-1}\sum_{j=1}^{n}[F_c^{exc}(j) - F_c^{calc}(j)]^2/[F_c^{exc}(j)]^2\}^{1/2} \times 100,$$

where j is the number of a point on a plot; n, number of points; $F_c^{exp}(j)$ and $F_c^{calc}(j)$, experimental and calculated values of the function.

Raising the number of terms in the polynomial and its order, we obtain an error ε smaller than 10% (10% is the accuracy of the MIP-10 nondestructive testing device for measuring the coating thickness, used to verify the adequacy of the mathematical model).

The result of the approximation is a follows:

$$F_c^{calc}(c, i) = -1.29 + 0.795c - 0.016ci - 0.00996ci^2 - 1.642c^2 + 1.6c^2i - 0.288i, \quad (9)$$

with $\varepsilon = 3.75\%$.

The plot of the approximating function obtained is shown in Fig. 1.

To confirm the adequacy of the analytical mathematical model we constructed, we compared the results of calculation of the coating thickness on cathodes-articles with the experimental data we obtained.

The relative root-mean-square error Δ (%) was calculated by the formula

$$\varepsilon = \{n^{-1}\sum_{j=1}^{n}[\delta^{exc}(i) - \delta^{calc}(i)]/\delta^{exc}(i)\}^{1/2} \times 100, \quad (10)$$

where i is the point number; n, number of points; δ^{exp}

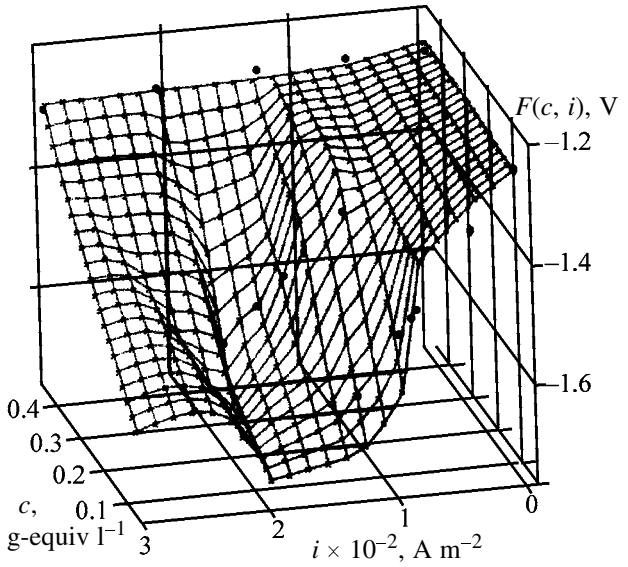

Fig. 1. Plot of the approximating function $F(c, i)$ obtained. (i) Current density and (c) Zn(II) concentration.

and δ^{calc}, experimental and calculated coating thicknesses at ith point.

In the first experiment, a zinc coating was deposited in an industrial electroplating bath. The electrolytic cell had dimensions of 750 × 1100 × 1300 mm; electrolyte level 1120 mm; four rectangular 250 × 500-mm anodes, with a 250 × 370-mm part submerged in the electrolyte; cathode, planar rectangular 270 × 140-mm plate (Fig. 2a); temperature 17°C; current strength 25 A; voltage 1.25 V; coating deposition time 20 min; electrolyte composition (g l^{-1}): ZnO 8–10, NaOH 140–150, Ekomet Ts1 3–4, and Na_2CO_3 35–40. The coating thickness was measured with an MIP-10 nondestructive testing device.

The following values were used in the calculation: current efficiency 100%, zinc density 7133 kg m^{-3}, electrical conductivity 0.118 Ω^{-1} cm^{-1} (found experimentally), electrochemical equivalent 3.39×10^{-7} kg (A s)$^{-1}$, ZnO concentration taken to be 9 g l^{-1} (0.221 g-equiv l^{-1}).

The conditions of the second experiment were as follows: 750 × 1100 × 1300-mm electrolytic cell, electrolyte level 1120 mm; two rectangular 230 × 500-mm anodes and two rectangular 270 × 500-mm anodes (the latter two extend beyond the electrolyte level and, therefore, their height is regarded to be 370 mm); cathode 1 in the form of a 90 × 140-mm angle and cathode 2, as a 50 × 190-mm angle (Fig. 2b); temperature 17°C; current strength 25 A; voltage 3 V; coating deposition time 30 min; electrolyte composition

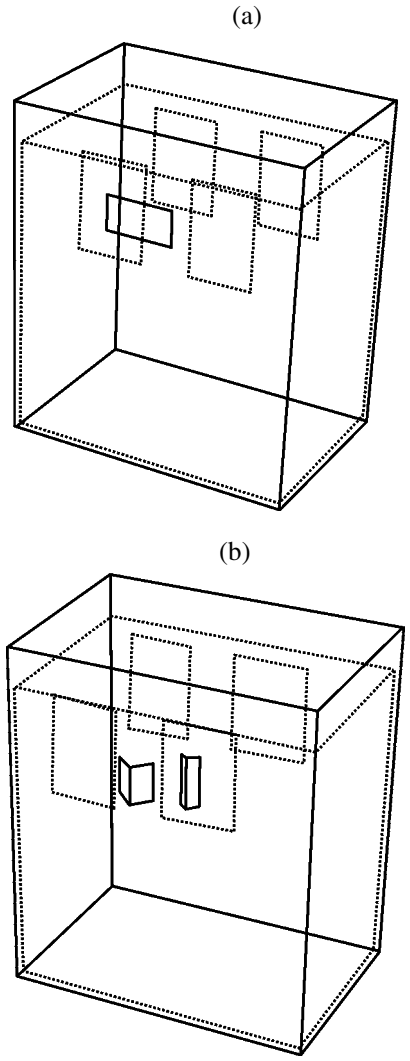

Fig. 2. Schematic of the electroplating bath. Experiment: (a) first and (b) second.

(g l^{-1}): ZnO 10–11, NaOH 170–180, Na_2CO_3 43–44. The coating thickness on the first article (90 × 140-mm angle) was measured. This article is constituted by two identical plates mounted at an angle of 90°. The coating thickness was measured with an MIP-10 nondestructive testing device.

The following values were used in the calculation: current efficiency 100%, zinc density 7133 kg m^{-3}, electrical conductivity 0.118 Ω^{-1} cm^{-1} (found experimentally), electrochemical equivalent 3.39×10^{-7} kg (A s)$^{-1}$, ZnO concentration taken to be 10.5 g l^{-1} (0.258 g-equiv l^{-1}).

In the calculations, the anodic polarization function $F_a[i(x, y, z)] = 0$, i.e., the anodic overvoltage was taken to be zero.

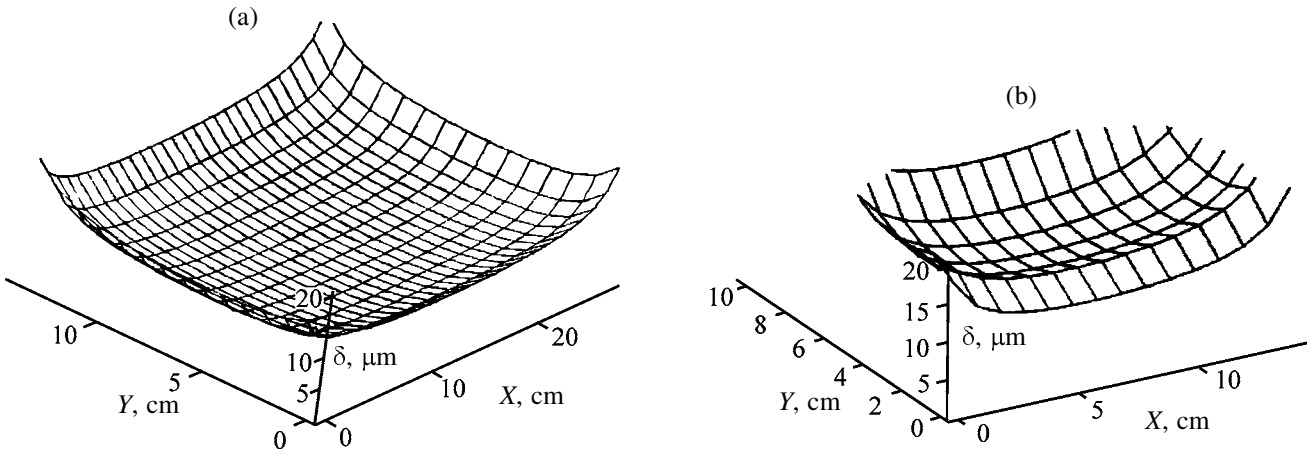

Fig. 3. Calculated coating thickness distribution $\delta(X, Y)$ (a) in the first experiment and (b) in the second experiment (first plate of the 90 × 140-mm angle).

Figures 3a and 3b show the coating thickness distribution over the cathode surface, calculated in terms of the mathematical model for the first and second experiments, respectively. The experimental and calculated coating thickness distributions over the cathode surface for a section with a plane parallel to $x0\delta$ are shown in Figs. 4a and 4b. Comparison of the calculated and experimental coating thicknesses at different points of the articles being coated shows their good agreement. The error calculated by formula (10) was 12.808% for the first experiment and 12.161% for the second, which indicates that mathematical model has a practically acceptable accuracy and is adequate.

It should be noted that the current density i is the current density at a cathode point (x, y, z), rather than the average current density. In the first experiment, for example, the current density $i^{min} = 0.7$ A dm^{-2} for a point with the minimum coating thickness $\delta^{min} = 4$ μm and $i^{max} = 3$ A dm^{-2} for the point with the maximum coating thickness $\delta^{max} = 17$ μm.

On confirming the validity of the model, we found the optimal voltage to be applied to the bath.

The problem was solved using the geometric parameters taken from the first experiment at various concentrations c_{ZnO}. The minimum coating thickness was taken to be 9 μm [8], and the time of coating deposition was 20 min. We obtained the following optimal voltages and the corresponding nonuniformity factors:

ZnO concentration, g l^{-1}	U, V	δ^{min}, μm	R_{min}
17.5	1.83	9.871	0.58038
9.0	2.03	9.911	0.5802962
6.0	2.21	9.952	0.580176

Thus, the voltage that provides the minimum nonuniformity varies rather strongly with the concentration (within 10–20%).

The effect of a change in the concentration can be illustrated as follows. If, for example, we use $U = 1.83$ V, calculated for $c_{ZnO} = 17.5$ g l^{-1}, then the minimum coating thickness and nonuniformity factor will be $\delta^{min} = 8.281$ μm and $R_{min} = 0.5806289$ at $c_{ZnO} = 9$ g l^{-1}, and $\delta^{min} = 7.968$ μm and $R_{min} = 0.5806933$ at $c_{ZnO} = 6$ g l^{-1}.

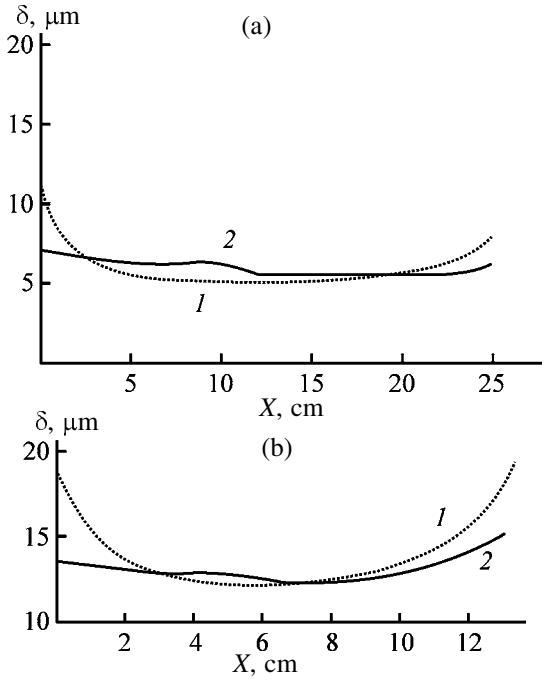

Fig. 4. Coating thickness δ along the X axis at (a) $Y = 6$ cm in the first experiment and (b) $Y = 4$ cm in the second experiment (first plate of the 90 × 140-mm angle). (*1*) Calculation and (*2*) experiment.

CONCLUSIONS

(1) The adequacy of the mathematical model developed is confirmed.

(2) Disregarding the influence exerted by changes in concentration on the polarization may lead to essentially negative results, such as deterioration of the coating uniformity and failure to satisfy the limitation on the minimum coating thickness.

Abstract—Procedures allowing the use of cadmium electrodes from worked-out nickel–cadmium batteries as a secondary raw material in manufacture of the active paste for negative electrodes were developed and tested under industrial conditions at AIT Plant.

DOI: 10.1134/S1070427206110164

The presently wide use and predictable high demand for alkaline nickel–cadmium batteries (NCBs) for industrial and household applications necessitate a search for economically efficient and environmentally safe methods for their utilization. Practical experience shows that one of ways to tackle this problem is to process the components of the active paste of alkaline NCBs to enable their repeated use [1]. The economic expediency of processing of the nickel oxide electrode is beyond any doubt, whereas the possible expenditure for storage, utilization, or processing of cadmium electrodes diminishes the commercial attraction of projects of this kind.

As a starting component of the active paste for the cadmium electrode serves CdO obtained by sublimation and oxidation of metallic Cd (Cd_{met}) in a cadmium-burning furnace at 700–800°C [2, 3]. On mixing CdO with activating additives, the content of Cd(II) in the active paste of cadmium electrodes varies from 40 to 70%, depending on the formula used in fabrication of active pastes [2, 3]. Metallic cadmium used to obtain CdO should conform to the requirements of GOST (State Standard) 1467–93, imposed on cadmium of Kd0 brand. The cost of Cd_{met} is determined by that of the cadmium-containing raw material and by the method used to produce Cd_{met} from this raw material. The high percentage content of Cd(II) in the active paste of cadmium electrodes suggests that their processing after the end of the service life of alkaline NCB is economically expedient. Simultaneously, this diminishes the probability of environment contamination by toxic cadmium compounds, which makes apparent the positive environmental aspect of this procedure.

Methods for processing of worked-out NCB electrodes are known; however, they do not allow repeated use of the raw material containing nickel and cadmium for production of components of active pastes [4, 5]. For example, worked-out electrodes of alkaline nickel–iron (cadmium) batteries are fused at 1450–1575°C to give nickel in the form of an alloy with iron [6]. A disadvantage of this method is that cadmium and nickel cannot be separated because Cd(II) is partly reduced at these temperatures, passes into the gaseous state, and is oxidized and carried away by discharge gases into the atmosphere, thereby contaminating the environment.

The aim of this study was to develop an economically efficient and environmentally safe technique for production of CdO from the active paste of cadmium electrodes of worked-out alkaline NCB by improving the efficiency of Cd_{met} recovery from the electrodes, diminishing the discharge of hazardous materials into the environment, and lowering the laboriousness and energy capacity of the process.

EXPERIMENTAL

To solve the problem formulated above, a laboratory installation for distillation of Cd_{met} was fabricated. It is shown schematically in Fig. 1. The installation operates on the pyrometallurgical principle, which consists in that cadmium waste is mixed with a reducing agent, with the subsequent heating of the mixture (stock) in an electric furnace without access of air [6].

Experiments were carried out with a stock containing 71.2% Cd(II). The component composition of the

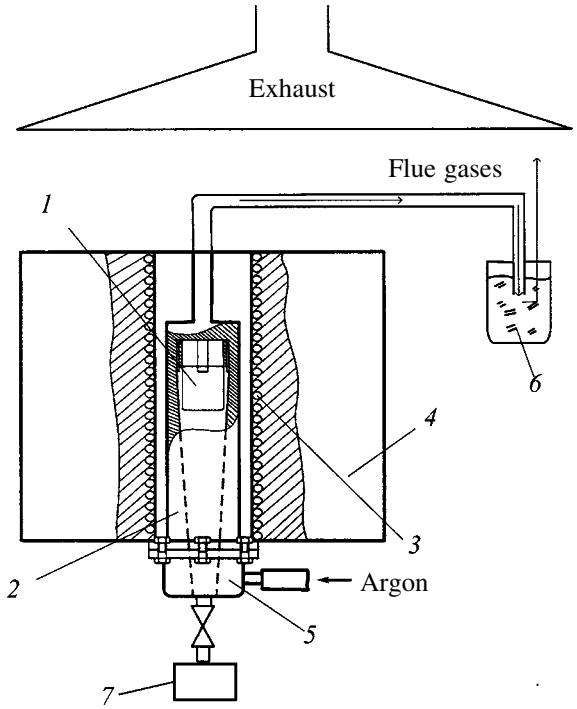

Fig. 1. Schematic of the installation for reduction of waste Cd(II): (*1*) reactor vessel, (*2*) solution, (*3*) heater, (*4*) furnace, (*5*) Cd_{met} collector, (*6*) water seal, and (*7*) dispenser vessel.

stock and the optimal conditions of the distillation process were found experimentally. As a criterion of quality of the process served such parameters as the reduction rate and recovery of Cd_{met}. It was found that these parameters strongly depend on the amount of stock present in the reaction zone. As can be seen in Fig. 2a, the reduction rate increases with the amount of stock in the working zone, whereas the recovery of Cd_{met} shows an opposite behavior (Fig. 2b).

The results of a chemical analysis of the stock after

Chemical composition of the stock with waste Cd(II) after distillation

Distillation	Content, %		
	Cd_{tot}	Ni_{tot}	Fe_{tot}
Primary	25	5.2	0.4
Secondary	0.06	58.4	0.3

primary and secondary distillation are listed in the table. The high residual content of Cd(II) in the stock after the primary distillation points to its incomplete recovery. However, repetition of the process enables virtually total reduction and recovery of Cd_{met} from the stock. The active pastes subjected to distillation contain nickel, and, therefore, the stock is enriched with this component in the course of thermal treatment.

Further, an industrial water-cooled groove furnace for processing of waste cadmium(II) was designed with account of the results obtained in the study and fabricated (Fig. 3).

The furnace includes a charging chamber *1*, into which trays with the stock containing waste cadmium(II) are introduced. For convenience of charging, guiding rollers are mounted in the chamber. The door opening is sealed in the closed state with a rubber cord laid in a groove on the chamber door. An inspection window and an air cylinder *2* are situated on the edge surface of the charging chamber. The cylinder is intended for pushing the trays into the preliminary condensation chamber *3*. The preliminary condensation chamber is separated from the charging chamber with a shutter attached to the shaft of an air cylinder *4*, which is opened immediately before pushing in the trays. When closed, the shutter prevents discharge of hot flue gases into the shop at the instant when a tray

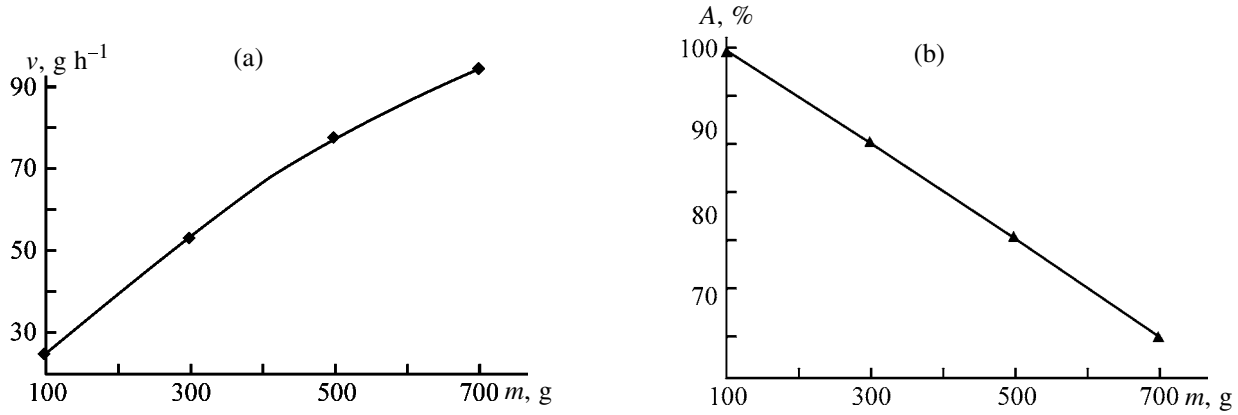

Fig. 2. (a) Cd_{met} recovery rate v and (b) recovery A of metallic cadmium vs. the amount m of stock in the reaction zone.

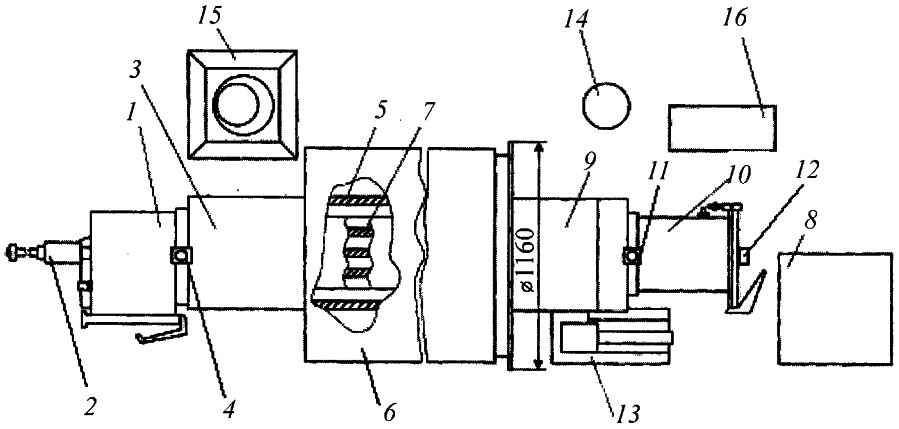

Fig. 3. Industrial water-cooled groove furnace for processing of waste cadmium(II). For explanations, see text.

with a stock is introduced into the charging chamber. The chamber walls are cooled by a water jacket.

A tray is moved from the preliminary condensation chamber into the muffle *5* of the heating chamber *6*. The muffle lying on the base frame is welded from 8-mm-thick sheets of 12Cr18Ni10Ti stainless steel. The heat insulation of the muffle is made of lightweight refractory bricks and kaolin wool. At joints with the charging chamber the muffle is rigidly attached to the frame. The opposite end of the muffle is mounted on a movable support and can shift via thermal elongation. To make molten Cd_{met} or its vapors move in a certain direction, the muffle is inclined at an angle of 2° by the frame, with rotation by 5° about the muffle axis. Thermocouples are fixed in the central part of the upper and lower surfaces of the muffle. A heater *7* is mounted in a metallic case within the muffle. The furnace is heated by electric current passed through a heater in the form of a Nichrome wire coil on a ceramic tube. For insulation from the case, each of the coils of the three-phase heater is placed in a large-diameter ceramic tube. The tubes are mounted in sections of a hermetically sealed metallic box, which prevents Cd_{met} vapor from coming in contact with the heater. To monitor the reaction course and provide the prescribed reaction conditions, two more thermocouples are fixed on the inner surface of the upper plate of the heater. The analog signal from temperature sensors is converted on the real-time basis by a personal computer on the control stand *8* into the digital form, analyzed, and further used to operate thyristor controllers in order to maintain a prescribed temperature.

At the exit from the heating chamber, the muffle is jointed with the Cd_{met} vapor condensation chamber *9* and unloading chamber *10*. Two air cylinders are mounted in the unloading chamber, one *11* serves to move the carriage with a tray to be unloaded, and the other *12* controls the shutter hermetically separating the unloading and condensation chambers. Cd_{met} reduced by carbon arrives in the form of a vapor to the condensation chamber, to be cooled there and to be delivered into a discharge chamber equipped with its own ribbon heater and thermocouple. From the discharge chamber, liquid cadmium runs down into water in the collector tank *13*, to form droplike particles.

The charging and unloading chambers are blown-through with argon from cylinder *14* in automatic mode. Because the working atmosphere in the heating chamber is reductive in the steady state, the whole heating chamber is blown-through with argon only at the beginning or end of furnace operation via charging and unloading chambers. The furnace is equipped with argon supply system. The operation of the gas pipes is monitored with three rotameters mounted on the gas panel. Flue gases are discharged through a water seal *15*. By changing the water level in the water seal, a necessary excess pressure can be created in the chambers. To maintain a certain air pressure in the system of control over air cylinders, the furnace is equipped with an autonomous compressor *16*.

The heating chamber and the charging and unloading chambers with condensation chambers are mounted on three separate frames welded from rectangular tubes. The power unit, gas distribution unit, air preparation unit, and water collector are mounted on the inner side of the frame and closed with decorative panels on their faces.

To distill off Cd_{met} according to the procedure developed, cadmium(II)-containing waste is screened,

separated from the metallic component, and mixed with P324 carbon (GOST 7885–86) [0.020 – 0.200 kg of carbon per 1 kg of Cd(I) contained in the active paste]. The resulting mixture is charged in batches in the continuous mode into the heating chamber of the furnace and kept at 650 –1100°C without access of oxygen, with the charging interval determined for each batch with account of the time of its keeping at a prescribed temperature for 5–15 h. The output capacity of the furnace is, on the average, about 95 kg of Cd_{met} per 24 h and varies, depending on the type of waste being processed, in the range 70 –120 kg in 24 h. In this case, the electric energy actually consumed by the furnace does not exceed values of about 7 kW h. The Cd_{met} obtained fully conforms in the content of impurities to the requirements of GOST 1467–93, imposed on cadmium of Kd0 brand:

Impurity	Content, %
Fe	0.0004
Pb	0.001
Cu	0.001
Ni	<0.001
Zn	0.001
Tl	<0.002
Mn	–

Gaseous reaction products, a mixture or carbon monoxide and carbon dioxide, pass through the water seal and are discharged into the environment without additional purification. Further, Cd_{met} is sublimed in a cadmium-burning furnace and oxidized with atmospheric oxygen to CdO. The resulting CdO is mixed with activating additives and used to fabricate cadmium electrodes for NCBs. The residual carbon containing cadmium compounds in an amount of 25 to 0.06% is accumulated and used to prepare subsequent portions of a mixture of carbon with the active paste of cadmium electrodes of worked-out NCBs.

The technique suggested allows use of cadmium electrodes of worked-out alkaline NCB as a secondary raw material for production of CdO without use of toxic reagents; no industrial wastewater or environmentally hazardous gas discharges are formed.

CONCLUSIONS

(1) The technique suggested for utilization of cadmium electrodes of worked-out nickel–cadmium batteries provides a high efficiency of recovery of the expensive Cd_{met} for repeated use with any impact on the environment.

(2) Presently, the technique can only be used to process the industrial cadmium(II) waste from the battery industry in order to prevent its accumulation and to diminish the production cost of articles.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Allylacetylenes and Their Derivatives as Inhibitors of Steel Corrosion in Sulfuric Acid

M. G. Veliev, N. M. Agaev, M. I. Shatirova, A. Z. Chalabieva, G. D. Geidarova, and S. S. Alieva

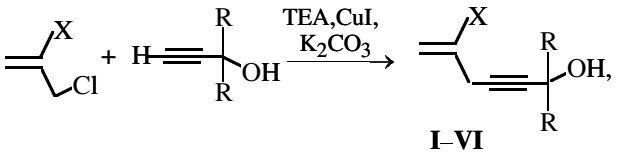
Received August 3, 2005; in final form, March 2006



Abstract—New functionalized derivatives of allylacetylenes were prepared, and their ability to inhibit corrosion of St.3 low-carbon steel in 5 N sulfuric acid was studied. The effectiveness of inhibition of steel corrosion was studied in relation to the structure of acetylene derivatives, their concentration, and temperature of acidic medium.

DOI: 10.1134/S1070427206110176

Functionalized unsaturated compounds are efficient inhibitors of the steel acid corrosion [1–4]. Acetylene derivatives strongly decelerate corrosion of steel in hydrochloric acid [5–9]. The multiple bonds with mobile π electrons determine high adsorption and protective properties of acetylene compounds. It was found that inhibition of the acid corrosion of steel with allylacetylenes only slightly depends on the nature of functional groups and substituents at unsaturated bonds; the decisive effect is exerted by acetylene and ethylene bonds.

Proceeding with studies of high-performance acid inhibitors, in this work we prepared new allylacetylenes and their derivatives and studied their inhibition properties in 5 M sulfuric acid in relation to the structure (nature of substituents).

Previously [10, 11] we studied the reaction of alkenyl halides with monosubstituted primary and tertiary acetylenic alcohols in the presence of EtMgBr/CuCl and NH_4Cl/CuCl, which are not universal reagents for preparing the corresponding allylacetylenic alcohols in a high yield. In this study, allylacetylenic alcohols **I**–**VI** were prepared by reaction of alkenyl halides with the corresponding monosubstituted acetylenylcarbinols in dimethylformamide (DMF) in the presence of copper iodide, triethylamine (TEA), and potassium carbonate:

I–VI

where X = R = H (**I**); X = H, R = CH_3 (**II**); X = CH_3, R = H (**III**); X = R = CH_3 (**IV**); X = Cl, R = H (**V**); X = Cl, R = CH_3 (**VI**).

The other functionalized allylacetylene derivatives **VII**–**XXII** were prepared from appropriate alcohols **I**–**VI** in accordance with procedures given in [10–12] (Scheme 1), where X = R = H (**VII**), X = CH_3, R = H (**VIII, XI, XIV, XVII, XIX; X**) = Cl, R = H (**IX**); X = Cl, R = CH_3 (**X**); X = R = CH_3 (**XII, XV, XVIII, XX, XXI**); X = H, R = CH_3 (**XIII, XVI**, and **XXII**).

The physicochemical properties of compounds **I**–**XXII** are listed in Table 1. The structure and composition of the resulting compounds were studied by thin-layer (TLC) and gas–liquid (GLC) chromatography and by IR and ^1H NMR spectroscopy (Table 2) [10, 11, 13].

As seen from Scheme 1, the resulting allylacetylenes can be divided in two groups: (a) primary and tertiary alcohols of allylacetylene series and (b) ethers and esters of allylacetylene compounds, also containing functional groups.

When choosing the inhibitor structure, we took into account the fact that multiple (double and especially triple) bonds and functional groups [OH, $OCOCH_3$, $OCH(OC_2H_5)CH_3$] provide efficient adsorption of the compounds on the steel surface with the formation of a protective film decelerating the corrosion.

EXPERIMENTAL

The IR spectra were recorded on a UR-20 spectrophotometer in the 4000–400 cm^{-1} range (thin

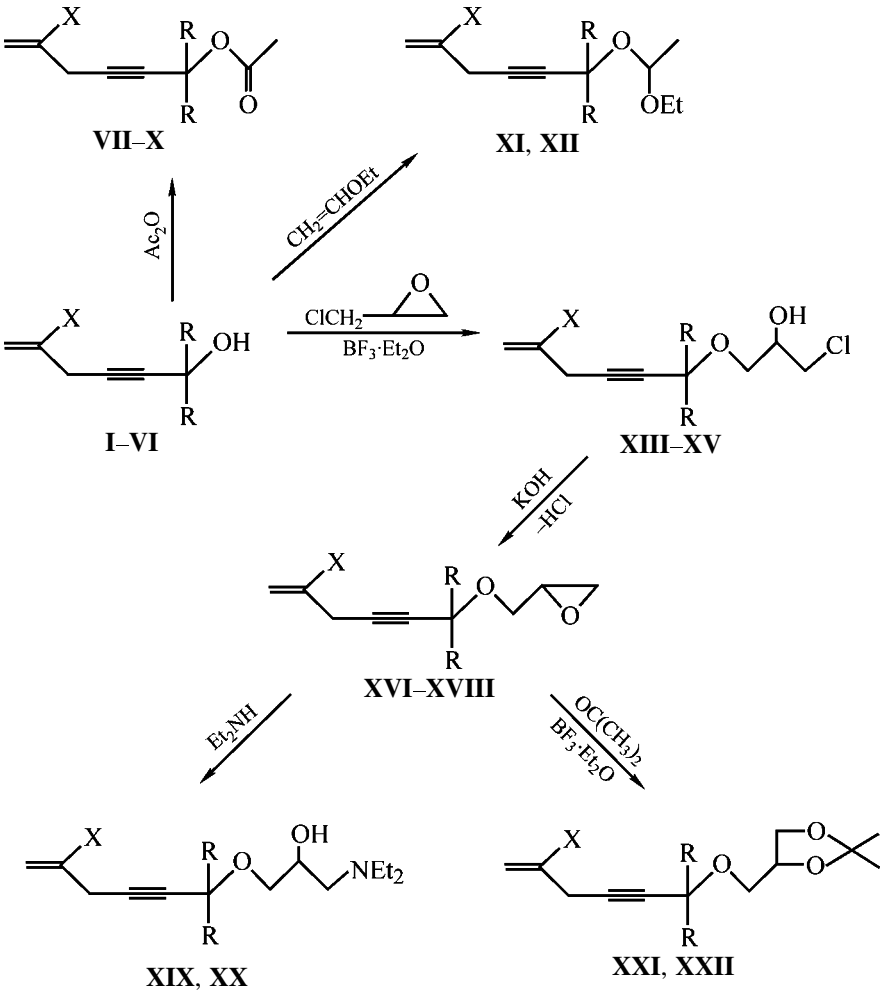
Note: The data for compounds **I**–**IV**, which are not included in the table, are given in [10].



layer). The ^{1}H NMR spectra were recorded on a Tesla BS-487 B spectrometer (80 MHz) in carbon tetrachloride solutions using HMDS internal reference. The purity of the resulting compounds was controlled by thin-layer chromatography using Silufol UV-254 plates in various solvent mixtures and by gas–liquid chromatography on an LKhM-8 MD-5 device.

The physicochemical properties and spectra of compounds **I**–**XXII** are listed in Tables 1 and 2.

To prepare primary and tertiary allylacetylenic alcohols **I**–**VI**, dimethylformamide (100 ml), K_2CO_3 (1.5 g), CuI (9.5 g), and triethylamine (0.5 ml) were placed in a three-necked flask and stirred for 15–20 min in a nitrogen flow at 50°C. Appropriate acetylene compound (propargyl alcohol or dimethylethynylcarbinol) (0.05 mol) was added, the reaction mixture was stirred for 2 h, and then appropriate alkenyl halide (allyl chloride, 2,3-dichloropropene, methallyl chloride) (0.1 mol) was added dropwise. The resulting mixture was stirred for an additional 8 h at 50–55°C. After cooling, the mixture was washed with water and extracted with ether. The ether layer was separated, dried with $MgSO_4$, and evaporated in a vacuum. The yield of products **I**–**VI** was 65–80%. The physicochemical properties of the resulting compounds were close to those of the compounds prepared by the published procedure [10].

1-Acetoxy-5-hexen-2-yne VII. Acetic anhydride (4.1 g, 0.04 mol) was added with stirring to a mixture of allylacetylenic alcohol **I** (2 g, 0.02 mol) and concentrated sulfuric acid (0.1 ml) at 6–9°C, and the reaction mixture was left overnight. Then, the mixture was stirred for 1.5 h on heating to 65–70°C. After cooling, the reaction mixture was diluted with water, neutralized with K_2CO_3, and extracted with ether. The ether layer was dried ($MgSO_4$) and evaporated in a vacuum to yield compound **VII**.

Scheme 1.

Compounds **VIII**–**X** were prepared by similar procedures using alcohols **III, V**, and **VI**.

2-Methyl-7-oxa-8-ethoxy-1-nonen-4-yne XI. Hydrochloric acid (33%, 0.3 ml) was added with stirring at 11°C to a mixture of allylacetylenic alcohol **III** (0.06 mol) and vinyl ethyl ether (0.06 mol). The flask was intermittently shaken; in so doing, the temperature of the reaction mixture increased to 42°C. The reaction mixture was left overnight. Then, the reaction mixture was neutralized and extracted with ether. The ether layer was dried (K_2CO_3), the solvent was evaporated in a vacuum, and compound **XI** was isolated by vacuum sublimation.

Acetal **XII** was prepared by a similar procedure using alcohol **IV**.

3-Chloro-1-(1,1-dimethyl-5-hexen-2-ynyloxy)-propan-2-ol XIII. Epichlorohydrin (4 g, 0.043 mol) was added with stirring at 0–5°C to allylacetylenic alcohol **II** (12.4 g, 0.1 mol) containing boron trifluoride etherate (0.1 ml). The reaction mixture was stirred for 4 h at 25°C, and compound **XIII** was isolated by vacuum distillation.

Chlorohydrins **XIV** and **XV** were prepared by similar procedures from alcohols **III** and **IV**.

1-(1,1-Dimethyl-5-hexen-2-ynyloxy)-2,3-epoxypropane XVI. Powdered KOH (8.4 g, 0.15 mol) was added with stirring at 8–10°C to a solution of chlorohydrin **XIII** (10.8 g, 0.05 mol) in ether (60 ml). The reaction mixture was stirred for 3 h at 12–14°C. After common work-up and removal of the solvent, compound **XVI** was isolated by vacuum distillation.

Epoxides **XVII, XVIII** were prepared similarly from chlorohydrins **XIV** and **XV**.

1-(5-Methyl-5-hexen-2-ynyloxy)-3-diethylamino-propan-2-ol XIX. A mixture containing epoxide **XVII** (3 g, 0.018 mol) and diethylamine (6.5 g, 0.5 mol) was stirred in the presence of water (2 ml)

for 8 h at 50°C, then dioxane (about 10 ml) was added to obtain the homogeneous mixture; in so doing, the temperature of the reaction mixture increased. The mixture was heated at 40°C for 3 h. Then it was extracted with ether and the ether layer was dried (K_2CO_3). The solvent was removed in a vacuum and compound **XIX** was isolated by vacuum distillation.

Amino alcohol **XX** was prepared similarly from epoxide **XVIII**.

2,2-Dimetyl-4-(3,3,7-trimethyl-2-oxo-7-octen-4-ynyl)-1,3-dioxolane XXI. Epoxide **XVI** (1.8 g, 0.01 mol) was added to a mixture of acetone (8,1 g, 0.14 mol) containing boron trifluoride etherate (1.8 g, 0.01 mol); in so doing, the temperature of the reaction mixture increased. After storage for 24 h, the reaction mixture was treated with a saturated aqueous solution of K_2CO_3, and the organic layer was separated and dried ($MgSO_4$). The solvent was removed in a vacuum and 1,3-dioxolane **XXI** was isolated by vacuum distillation.

1,3-Dioxolane **XXII** was prepared similarly from epoxide **XVIII**.

Among all the allyl derivatives prepared, ten compounds (namely, **I, III, V, VII, VIII, XI, XII, XIX–XXI**) were studied as inhibitors of the acid corrosion of steel in 5 N H_2SO_4.

The inhibition effect of compounds was studied by gravimetric procedure simulating the conditions of acidic etching of steel and rolled metal. Before experiments, the specimens ($30 \times 20 \times 3$ mm) were cleaned on a polishing device with rubber discs, degreased with acetone, and stored for 1 day in a desiccator. The inhibitor concentration was 0.5–1.0 g l^{-1}; the required temperature of the acid medium of 40, 60, or 80°C was maintained with a thermostat. The experimental results listed in Table 3 show that all the above compounds are highly effective inhibitors of steel corrosion in sulfuric acid.

Along with studying the protective properties of compounds, we also tried to evaluate the correlation between the structure of organic compounds and their inhibiting performance and to determine the role of various functional groups in the total protection effect.

As seen, all the allylacetylenes studied exhibit pronounced activity in inhibition of the acid corrosion of steel. The degree of steel corrosion protection Z is 84–99%.

The compounds with normal structure with a terminal alcohol group **I, III**, and **V** are highly effective inhibitors. Substitution of the hydrogen atoms with chlorine atom and methyl groups slightly decreases the inhibiting performance of compounds **V** and **III** as

compared to **I**. Allylacetylenes **VII** and **VIII** with a terminal acetoxy group are also effective inhibitors. Addition of the methylene group at the double bond enhances the inhibition properties at 40 and 60°C, but *Z* remains almost unchanged at 80°C.

Substitution of two hydrogen atoms with methyl groups (acetals **XI, XII**) slightly decreases the inhibiting performance of allylacetylenes. The protective effectiveness of amino alcohols **XIX** and **XX** is ambiguous.

On the whole, our experimental results suggest that functionalized allylacetylenes are highly effective inhibitors of the acid corrosion of steel; with increasing concentration of inhibitors their protection effect increases.

The performance of inhibitors increases with increasing temperature of the corrosion medium (especially at 80°C), which is probably due to the activation of chemisorption of the particles and molecular fragments on the metal surface. On substitution of methyl groups for hydrogen atoms, the structure of inhibitors becomes more branched, which hinders their adsorption on the metal surface and thus ordering in the resulting protective film. We assumed that the protection effect of allylacetylenes as inhibitors of the acid corrosion of steel is due to the π-electron interaction of the double and triple bonds with metal, resulting in the formation of chemisorption bonds at elevated temperatures. The contribution of the other fragments to corrosion inhibition is not decisive, because the overall inhibition effect is extremely high.

CONCLUSIONS

(1) Methods were developed for preparing primary and tertiary allylacetylenic alcohols in high yields by the reaction of alkenyl halides with the corresponding monosubstituted acetylenic alcohols in the presence of copper(I) iodide, triethylamine, and potassium carbonate in dimethylformamide.

(2) A series of functionalized allylacetylenes prepared are highly effective inhibitors of steel corrosion in 5 N sulfuric acid. The inhibition effect is primarily determined by the presence of double and triple bonds and is virtually independent of the nature of functional groups.

(3) With increasing temperature of the reaction mixture and concentration of the inhibitor, the protection effect increases.

Received April 21, 2006

Abstract—The structure and durometric and anticorrosive properties of gas-thermal coatings deposited by sputtering of steel wires, with subsequent modification by boronizing, were studied.

DOI: 10.1134/S1070427206110188

The problem of reliability and durability of machine and mechanism elements can be successfully solved by creating new highly efficient processes and composite materials. The most versatile method for production of composite materials is deposition of coatings. This technique is of primary importance in reclamation of worn articles and units and can bring the article size to required values. Using materials with required properties for coating deposition, it is possible to prolong the service life of a reclaimed article as compared to a new one. A particular place among the wide variety of techniques for regeneration of worn working surfaces of machine units is the method of gas thermal spraying (GTS) [1, 2]. The advantages of GTS consist in the simplicity and relatively low cost of the process and in the possibility of deposition of coatings with prescribed protective properties [3].

A possible efficient way to improve the performance of GTS coatings is to form high-strength surface layers with gradient structure, using economical methods of chemical-thermal treatment, which is of indubitable scientific and practical interest. This study is concerned with the influence exerted by boronizing of GTS coatings composed of Sv 08 low-carbon steel on their structural state, microhardness, and corrosion resistance.

EXPERIMENTAL

The study was carried out on $30 \times 30 \times 5$-mm samples made of sheet steel 10. Prior to deposition of a gas-thermal coating, the samples were subjected to abrasive-blast treatment to activate the surface layer and to impart a certain roughness to this layer.

Coatings of Sv 08 low-carbon steel taken in the form of a wire of diameter d = 2 mm were deposited by electric-arc metallization and flame spraying on TERKO installations (manufactured by INDMASh NANB). The wire feed velocity was 0.4 m min^{-1}, air flow rate, 60 m^3 h^{-1}, and gas expenditure (propane–butane), 0.011 kg h^{-1}. Upon deposition, the coatings had thicknesses of 0.6–0.7 mm, which were brought by grinding to 0.5 mm.

Thermal-diffusion saturation was performed by boronizing in powder media of compositions listed in Table 1. The time and temperature of saturation were 1073–1173 K and 1–6 h. The samples were cooled after the thermal-diffusion hardening to room temperature together with the container.

Metallographic studies were carried out with a Unimet optical microscope; a Micromet II microhardness meter was used in durometric measurements (load 0.49 N). The phase and structural transformations in modified coating layers were examined by X-ray diffraction analysis on a DRON 3.0 diffractometer in monochromated CoK_α radiation. The standard PDF file was used in phase analysis.

A corrosion-electrochemical study was carried out on a PI 50.1.1 potentiostat with an LKD 4-002 *XY* recorder in a 3% NaCl solution. A silver chloride electrode served as reference, and a platinum electrode, as auxiliary electrode. Also, forward and back sweep curves were measured at a potential sweep rate of 2 mV s^{-1}. The study was performed using the procedure described in [4].

The boronizing of an Sv 08 steel coating is accompanied by formation of deep diffusion layers with a thickness of up to 300–320 μm, which have a relatively high microhardness. The distribution of the

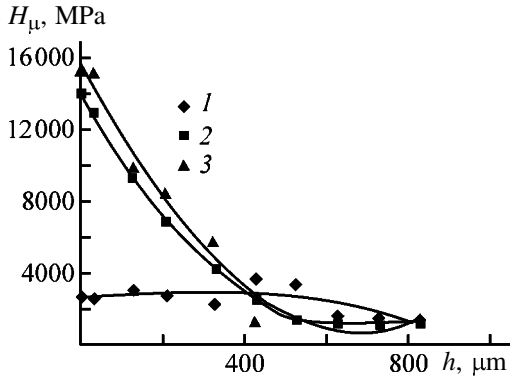

Fig. 1. Distribution of the microhardness H_μ of coatings across the layer thickness h. (*1*) Sv 08, initial state; boronizing: (*2*) single-phase and (*3*) two-phase.

microhardness across the boronized layer is shown in Fig. 1.

Boron-modified coatings have a multilayer structure including two boride zones and a diffusion-porosity zone. The results of an X-ray phase analysis indicate that mostly iron borides FeB are formed in the 30–50-μm-thick surface layer having a microhardness of 14500–16000 MPa (Fig. 2).

Figures 3 and 4 show how the thickness h of the diffusion layers on boronized GTS Sv 08 steel coatings and the thickness of the boronized layer obtained on monolithic steel depend on the time t and temperature T of boronizing.

The time necessary for Fe_2B nucleation is determined by the activity of a saturating medium. For

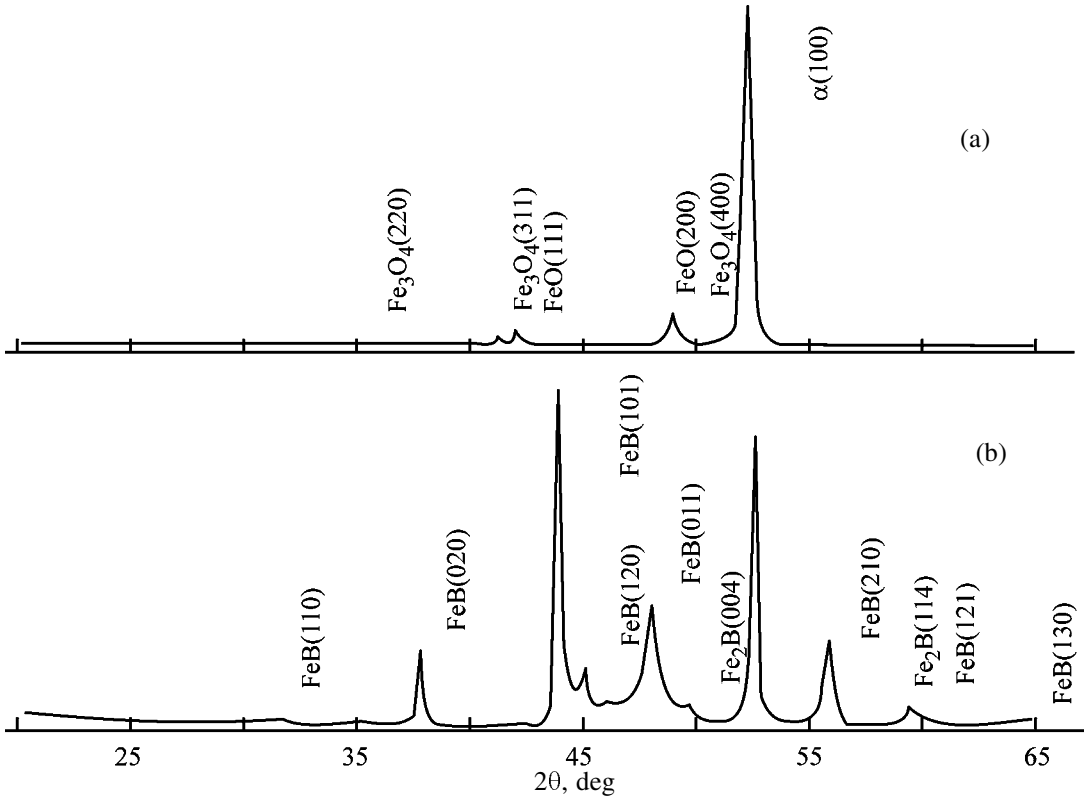

Fig. 2. X-ray diffraction pattern illustrating the phase composition of Sv 08 steel coatings. (2θ) Bragg angle. (a) Initial state (flame spraying) and (b) that upon boronizing.

example, this time does not exceed several minutes in boronizing in a melt of borax with 40 wt % B_4C. This time is sufficient for a developed zone of a solid solution of boron to be formed in the support.

The saturation of the samples was studied at temperatures of 1073, 1123, and 1173 K. During the first hour, the kinetic curves (Fig. 4) show high rates of formation of the boride layer and a nearly linear time dependence of the thickness. As the thickness of the saturated layer increases, the curves gradually pass into a parabola. The boride layer formed in the initial stages of the process is presumably composed of FeB.

An X-ray phase analysis of samples boronized to varied extent indicated that the phase composition of the boride layers is determined by the chemical composition of the saturating powder mixtures (Fig. 2). The true rate of saturation of the samples with boron was found by graphical analysis of the curve describing the dependence of the thickness of the boride layer on time t. For this purpose, tangents were drawn at several points of the curve. Further, their slopes were used to find the true saturation rate v ($\mu m\ h^{-1}$):

$$v_s = \tan\varphi.$$

The activation energy Q_a was calculated from the slope of the $\log k$–$1/T$ dependence by the formula

$$Q_a = 2.3R\tan\alpha,$$

where R is the gas constant, and α is the tangent slope.

The kinetic and energetic parameters of the saturation of the samples with boron are listed in Table 2.

The main task in the structural study of the sprayed coatings was to examine the kinetics of formation of diffusion layers on the surface of gas-thermal coatings, which affect the protective properties of the coatings. The structure of a coating composed of Sv 08 steel not subjected to any additional hardening treatment has the form of flattened particles with oxide films and separate poorly coated regions on the periphery. The transition zone has no region of interaction between the sprayed particles and the base metal. The coating has small characteristic closed pores.

The multilayer structure of a sprayed coating subjected to single-phase thermal-diffusion boronizing is shown in Fig. 5b. The outer unetchable layer of the coating, with a thickness of about 120–140 μm, has a needle-like structure characteristic of the boronizing process. At a larger depth lies a layer having no distinct boundaries between the sprayed particles. This layer is formed via reduction of oxide films in the

course of thermal-diffusion saturation. The deepest is the 180–250-μm-thick unreacted layer of the coating. Pores in the upper and lower layers of the main coating differ in size and shape, which points to a certain mechanism of diffusion in thermal treatment of the sprayed coating in a powder saturating medium.

The sprayed coating hardened by two-phase boronizing (Fig. 5c) has a denser structure, compared to the untreated coating. A specific feature of this coat-

ing is the presence of comparatively coarse pores and a deep transition zone (about 80–90 μm).

The protective properties of hardened GTS coatings were examined. An analysis of the time dependence of the corrosion potential demonstrated that the potentials of the samples shift in the course of time into the negative region. At the same time, the surface potentials of the coating material become more positive, which indicates that the passivation properties of the samples studied are improved.

The saturation of the sprayed low-carbon steel coatings with boron leads to a decrease in the corrosion current density and, accordingly, in the corrosion rate of the samples (Table 3). Upon the boronizing, the corrosion current density reaches values of 0.0047–0.0049 A m^{-2}.

Thus, thermal-diffusion saturation by boronizing makes it possible to improve the critical parameters to such an extent that the coating can spontaneously pass into the passive state under the passivating action of those oxidizing components which are present in a corrosive medium under natural conditions.

CONCLUSIONS

(1) A study of the mechanism by which a boride layer is formed revealed that thermal-diffusion saturation of sprayed coatings in powder media results in that the defectiveness of phase boundaries, leading to an increase in the actual contact area and activating the chemical interaction between the contacting materials, decreases dramatically. The true saturation rate is about 12–40 μm h^{-1}, and the value of the apparent activation energy of the saturation process (69.5–95.6 kJ mol^{-1}) indicates that the saturation is diffusion-controlled.

(2) It was found that sprayed coatings modified with boron have a multilayer structure constituted by two boride zones of total thickness 300–320 μm and a diffusion-porosity zone. Iron boride FeB is formed in the 30–50-μm-thick surface layer. FeB has a microhardness of 14 500–16 000 MPa and simultaneously can serve as a corrosion-protective layer.

CATALYSIS

Relationship between the Selectivity of the Fischer–Tropsch Process and Type of Pore Structure of Cobalt Catalysts

A. P. Savost'yanov and V. G. Bakun

Southern-Russia State Technical University (Novocherkassk Polytechnic Institute), Novocherkassk, Rostov oblast, Russia

Received April 13, 2006

Abstract—The dependence of the selectivity and output capacity of the Fischer–Tropsch process with respect to liquid and solid hydrocarbons on pore structure parameters of a catalyst was determined for the example of a cobalt catalyst produced by impregnation of a preformed aluminosilicate support. The results obtained are analyzed in terms of the diffusion–kinetic theory.

DOI: 10.1134/S107042720611019X

In synthesis of hydrocarbons from CO and H_2 by the Fischer–Tropsch method, a three-phase system constituted by a gas (reactants and reaction products), liquid (C_{11+} reaction products), and solid (catalyst) is formed in the reaction zone. Accumulation of condensed hydrocarbons in catalyst pores may lead to a decrease in the rate of delivery of the reactants (CO and H_2) to the active centers of the catalyst or that of removal of synthesis products to the outer surface of the catalyst and into the flow core.

There is contradictory published evidence concerning the relationship between the diffusion and kinetic factors of the process. The activation energies are 30–125 kJ mol^{-1} [1–6]. E_a = 65–75 kJ mol^{-1} for coarse grains (1–3 mm) and 125 kJ mol^{-1} for fine grains (0.11–0.18 mm) [2, 3]. According to the results obtained in the differential reactor of a flow-through circulation installation [5], E_a = 30–69 kJ mol^{-1} for 0.25–1.0-mm metallic (Ni, Ru, Rh, Co) catalysts on γ-Al_2O_3 supports. For example, a conclusion has been made that the key factors responsible for the selectivity of a catalyst in the Fischer–Tropsch process are its porosity and particle size, which control the relative rates of mass-transfer of the reactants, readsorption of α-olefin, and chemical interaction [2, 3].

It has been shown [7, 8] that synthesis of various hydrocarbon fractions at a pressure of 0.9 MPa on a catalyst with a grain size of 3–4 mm is governed by the occurrence of different diffusion stages of the process: outer-diffusion for C_5–C_{60} hydrocarbons and inner-diffusion for ceresine (C_{60+}). The possibility of controlling the selectivity with respect to liquid and solid hydrocarbons by varying the pore structure parameters of a catalyst has been revealed for the example of coprecipitated cobalt catalysts [9, 10]. However, the pore structure of catalysts of this type is governed both by the support and by the secondary pore structure whose nature largely depends on a number of additional factors (support size, coprecipitation conditions, etc.).

Of interest is a study of model catalysts, for which the effect of only a single factor, predominant pore radius, on the conversion efficiency for various groups of hydrocarbons could be traced. Catalysts produced by impregnation of preformed supports of the same chemical composition are convenient in this regard.

EXPERIMENTAL

AS-37 amorphous aluminosilicate was used as a support. The pore structure was transformed by hydrothermal treatment at a pressure of 1–1.2 MPa for 72 and 164 h (designated as ASM.72 and ASM.164, respectively) and at 8 MPa for 4 h (ASM.R8) in a 5 dm^3 autoclave. The catalysts were prepared by impregnation of a support dried at 250°C with a 55% cobalt nitrate solution at 70°C to complete saturation (impregnation time 30 min). The catalyst was dried and calcined in air to a final temperature of 300°C. A catalyst with a grain size of 2–3 mm was used in the study. The catalyst was reduced with hydrogen at 380–400°C and space velocity of hydrogen equal to 3000 h^{-1} for 30–40 min until 50–55% of cobalt was reduced. The degree of cobalt reduction was determined by volumometry. The specific surface area of

the reduced catalyst was measured chromatographically from thermal desorption of argon. The pore structure of the unreduced catalyst was analyzed by mercury porosimetry, i.e., the size and volume of pores with diameters of 2 nm and more were determined.

Hydrocarbons were synthesized from CO and H_2 in a 30 cm^3 flow-through reactor under atmospheric pressure from an industrial synthesis gas with an H_2 : CO ratio of 2.1. The content of impurities in the feed was as follows (vol %): CO_2 8, CH_4 2, and N_2 2. The gaseous reaction products were analyzed by chromatography on two columns: C_1–C_5 were separated using Chromosorb with *n*-heptadecane as active phase; N_2, CO_2, CO, and CH_4 were separated on NaX zeolite. The composition of liquid products was determined by gas–liquid chromatography on a column with Apiezon L on Chromosorb P (flame-ionization detector, carrier gas helium).

The duration of uninterrupted tests of the catalyst in a single mode was as long as 24–48 h. No significant changes in the catalyst activity were observed in the process.

The catalysts have about the same content of cobalt, 18.3–19.7% (Table 1). The pore diameter of the catalysts varies from 4 to 80 nm. Support modification with steam leads to an insignificant increase in the surface area of the catalyst, which can be attributed, despite that the pores become larger, to an increase in the pore size. Experimental data on the catalytic properties of Co/AS systems are listed in Table 2.

An increase in the diameter of catalyst pores to 8 nm is sufficient for an increase in the C_{5+} yield by 10 $g\ m^{-3}$ at 170–210°C, but fails to improve significantly the conversion of the starting substances into reaction products. Upon an increase in the catalyst pore diameter to 12 nm, the specific surface area is about the same (72 and 85 $m^2\ g^{-1}$), but the efficiency of synthesis grows because of the increase in contraction, and synthesis can be performed purposefully, with high selectivity with respect to C_5–C_{20} hydrocarbons. In the presence of this catalyst, the highest yield of C_{5+} hydrocarbons is obtained (82–96 $g\ m^{-3}$) and the maximum conversion of the reaction gas mixture (48–64%) is reached at 200–230°C. Structural differences between the catalysts are reflected in the composition of the hydrocarbons synthesized (Table 3).

The products obtained on the Co/ASM catalysts have an increased content of branched olefins and paraffins C_8–C_{14} and lower content of paraffins C_{15}–C_{18}.

Figures 1 and 2 show the calculated performances of the catalysts in conversion of CO and synthesis of C_{5+}. It can be seen that the performance of the catalyst in CO conversion steadily increases with temperature, whereas that in synthesis of liquid hydrocarbons passes through a maximum in the temperature range 190–210°C.

The activation energy of CO hydrogenation (Fig. 3) on catalysts with a predominant pore diameter of 4–12 nm is virtually constant and equal to 55 $kJ\ mol^{-1}$. An increase in the average pore diameter to 80 nm makes it possible to diminish the diffusion limitations and to bring the process closer to the kinetic control (E = 84 $kJ\ mol^{-1}$). In this case, the selectivity with respect to C_{5+} substantially decreases, as it was noted above. As the pore size grows from 4 to 12 nm, the

Table 3. Composition of hydrocarbons

		C_5–C_7	C_8–C_{10}	C_{11}–C_{14}	C_{15}–C_{18}	C_{19+}	C_5–C_7	C_8–C_{10}	C_{11}–C_{14}	C_{15}–C_{18}	C_{19+}
Co/AS	7	1	27	34	22	3	1	23	35	20	3
Co/ASM.72	15	3	21	41	16	4	2	11	26	14	4
Co/ASM.164	18	3	21	38	17	3	5	12	32	15	2

activation energy of C_{5+} synthesis in the temperature range 170–200°C increases from 23 to 58 kJ mol^{-1} (Fig. 4).

Thus, it was found that the hydrogenation of CO and selectivity with respect to C_{5+} are strongly affected by diffusion factors. However, their influence is ambiguous. The acceleration of reactant transport with an increase in pore diameter hinders readsorption of olefins and diminishes the performance with respect to high-molecular-weight products. The latter is confirmed by the increased content of olefins in products synthesized on catalysts with a high degree of transformation of the pore structure and, accordingly, with large pore diameter (Table 3). The content of olefins is 7% on the Co/AS catalyst and 15 and 18% on catalysts with pore diameters of 8 and 12 nm, respectively.

All the catalysts had virtually the same composition and the study was carried out in a comparatively narrow temperature range. Therefore, it can be suggested that the formation mechanism of primary intermediates remains the same and the gross differences in the process selectivity are due solely to the features of the pore structure of the catalysts. In this context, it is advisable to verify the applicability of concepts of the kinetic–diffusion model of the process, suggested in [3].

The diffusion and kinetic factors are related to structural characteristics of a catalyst by the Thiele modulus. The second factor χ depends only on the

structural characteristics of the catalyst:

$$\chi = R_0^2 \varphi \theta_m / r_p, \quad (1)$$

where R_0 is the grain radius; φ, relative porosity; θ_m, density of Co distribution (g-at. Co/m^2); and r_p, pore radius (m).

The results obtained by processing the experimental data for temperatures of 190, 200, and 210°C in terms of Eq. (1) are shown in Fig. 5. These data are close to the recommended values of the structural factor [3].

Catalysts on the untreated (pore diameter 4 nm) and modified (pore diameter 8 nm) aluminosilicate were tested in synthesis of hydrocarbons under elevated pressure (Table 4).

Differences in the nature of the pore structure of the catalysts are manifested in the amount and composition of synthesis products. A considerably smaller amount of C_{5+} hydrocarbons was obtained on the catalyst with a predominant pore radius of 8 nm.

When predicting the way of development of theoretical concepts concerning formation of cobalt catalysts with controllable selectivity with respect to liquid and solid hydrocarbons, it can be assumed that these concepts may be based on determining the extent of utilization of the active surface of the catalysts. The Thiele modulus makes it possible to take into account both the kinetic and structural factors affecting the extent of surface utilization. The first, kinetic factor is largely determined, as regards the Fischer–Tropsch process, by the state of cobalt on the surface and primarily by its dispersity and by the electronic interaction in the Co–Co_xO_y–support system [11].

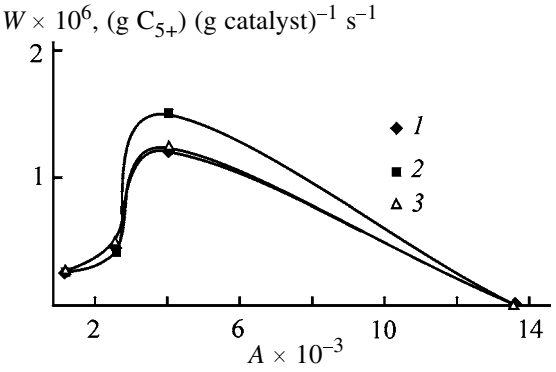

Fig. 5. Effect of the structural factor A on the performance W of the catalysts in C_{5+} synthesis at different temperatures. Temperature (°C): (*1*) 190, (*2*) 200, and (*3*) 210.

The second, structural factor, which combines the grain size and porosity, relates the time necessary for readsorption of primary α-olefins to their mass-transfer within the catalyst grain and, in the end, to the process selectivity with respect to separate groups of hydrocarbons.

When considering the concept suggested, it is necessary to analyze the arising contradictions. In particular, the chemical nature of a support cannot, at first sight, affect the process selectivity in this case. However, numerous data point to the opposite [12].

In our opinion, the contradiction is eliminated if we take into account the following. First, the chemical nature of the support affects the interaction in, and properties of, the $CoCo_xO_y$–support system in accordance with the two-center model of the active center [11]. Second, the structural factor of the Thiele modulus contains as parameter the Co distribution density, i.e., a quantity close in physical meaning to the dispersity of the active component.

CONCLUSIONS

(1) The activation energy of CO hydrogenation on catalysts with a pore diameter of 4–12 nm is virtually the same (55 kJ mol^{-1}). An increase in the average pore diameter to 80 nm diminishes the diffusion limitations and brings the process closer to kinetic control (E = 84 kJ mol^{-1}), with the selectivity with respect to C_{5+} decreasing dramatically. The activation energy of synthesis of condensed hydrocarbons (C_{5+}) grows from 23 to 58 kJ mol^{-1} as the pore size increases from 4 to 12 nm. The products synthesized on catalysts with a high degree of transformation of the pore structure contain a 2.5 times larger amount of olefins.

(2) With the conditions governing the dispersed

state of cobalt, its electronic interaction in the Co–Co_xO_y–support system, and the structural factor (χ in the Thiele modulus) determined, it is possible to control the activity and selectivity of cobalt catalysts for synthesis of hydrocarbons from CO and H_2.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Synthesis of Antiagglomeration Agent Based on Calcium Stearate for Synthetic Rubbers in Tubular Apparatus

V. P. Zakharov

Received November 25, 2005; in final form, April 2006

Abstract—Formation of an antiagglomeration agent for synthetic rubbers, based on an aqueous suspension of calcium stearate, by the reaction a highly concentrated solution of calcium chloride (up to 40 wt %) and a dilute solution of potassium stearate (up to 5 wt %) in a small tubular apparatus of diffuser–confuser design was studied.

DOI: 10.1134/S1070427206110206

An integral stage in large-tonnage manufacture of synthetic rubbers by polymerization in solution is isolation of the polymer [1, 2]. To remove residual amounts of the solvent and unchanged monomer, the reaction mixture is treated, on reaching the required conversion and decomposing the catalyst, with live steam in the stage of aqueous degassing. To prevent coalescence of the polymer crumb in the deaerator and to reduce the viscosity of process flows in the degassing stage, an antiagglomeration agent is introduced into the reaction mixture in the form of a dilute suspension [1, 2]. Because of the formation of a loose precipitate, low-soluble calcium carboxylates and, in particular, calcium stearate are most frequently used as antiagglomeration agents. Particles of the antiagglomeration agent prevent agglomeration of the polymer crumb and enable its transportation to the drying stage by forming a structural-mechanical barrier [3] at the interface between the aqueous phase and the polymer. Apparently, the antiagglomeration capacity of the aqueous suspension of calcium stearate and, in the end, its expenditure and residual content in the finished product (at an expenditure of 7.5 kg of stearic acid and 1.5–2.5 kg of calcium chloride per ton of the polymer, the content of the antiagglomeration agent in the polymer should not exceed 1.1 wt %) are largely determined by the granulometric composition of particles of the active substance.

Under industrial conditions, calcium stearate is obtained just before introduction into a polymer solution (freshly prepared antiagglomeration agent) by the two-stage scheme (St = $C_{17}H_{35}COO$) [1, 2]:

$$HSt + KOH \longrightarrow KSt + H_2O,$$

$$2KSt + CaCl_2 \xrightarrow{Fast} CaSt_2\downarrow + 2KCl.$$

In the second stage, an irreversible reaction of ion exchange occurs at a high rate to give the solid phase (condensation method for synthesis of disperse systems) [3]. As a consequence, the granulometric composition of the suspension of the antiagglomeration agent can be affected by varying the conditions under which the reaction of potassium stearate and calcium chloride is performed.

Under industrial conditions, the antiagglomeration agent based on calcium stearate is obtained directly in the pipeline for circulating water. The content of stearic acid in the solution is 4.3–5.3 wt %, at an average flow rate of 3 $m^3 h^{-1}$ and temperatures of up to 75°C. The content of $CaCl_2$ in the aqueous solution is 2–3 wt %, at an average flow rate of 1.8 $m^3 h^{-1}$ and temperatures of 20–25°C. The content of calcium stearate in the resulting solution does not exceed 5 wt %. The low motion velocities of the starting solutions in their mixing in the pipeline (not exceeding 0.1 m s^{-1} at a total flow rate of 1.2 to 8 $m^3 h^{-1}$) predetermine the poor efficiency of reagent mixing and lead to formation of rather coarsely dispersed particles (diameter about 100–500 μm [4]).

The aim of the present study was to examine the fundamental aspects of variation of the granulometric composition of particles of the calcium stearate suspension with the conditions under which aqueous solutions of potassium stearate are reacted with $CaCl_2$.

The high rate of the reaction under consideration and the formation of the solid phase necessitate vigor-

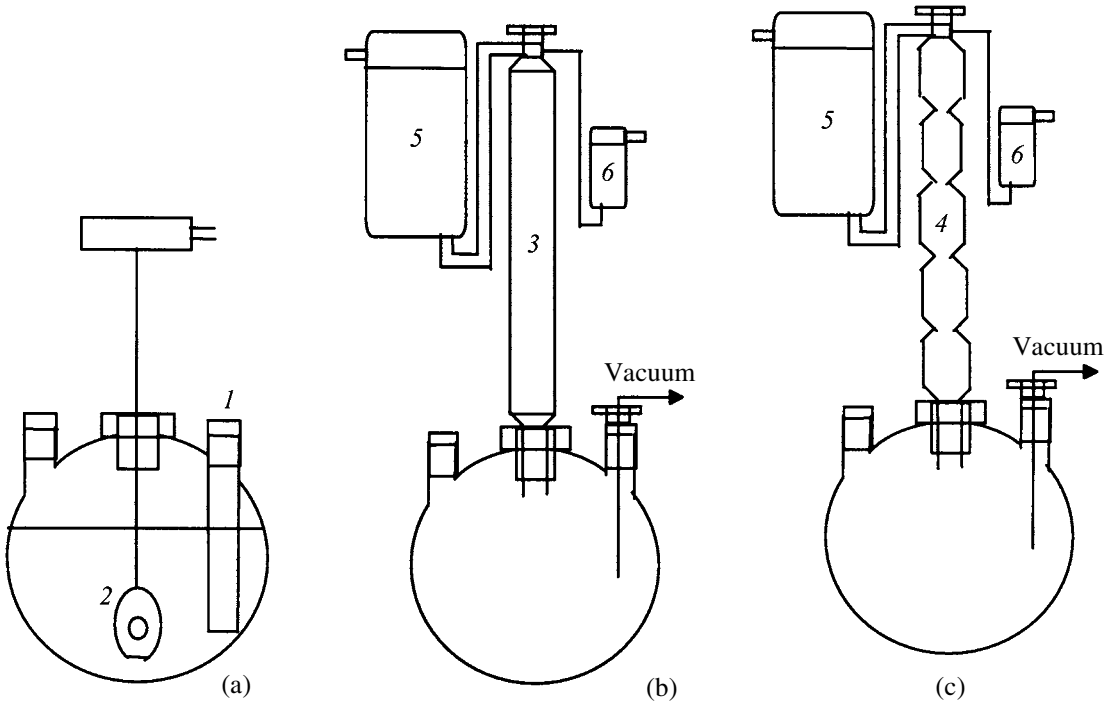

Fig. 1. Schematic of the experimental installation for synthesis of the antiagglomeration agent based on calcium stearate: (*1*) reflecting partition and (*2*) mechanical stirrer; tubular turbulent apparatus: (*3*) cylindrical and (*4*) of diffuser–confuser design; vessel: (*5*) for KSt and (*6*) for $CaCl_2$.

ous agitation of the reaction mixture directly in the reaction zone, which is significantly smaller in size. For this purpose, calcium stearate was synthesized in tubular turbulent apparatus of cylindrical and diffuser–confuser design [5, 6]. Potassium stearate was reacted with $CaCl_2$ in various reaction devices. The first is a volume apparatus (vessel) with a mechanical stirrer (~2000 rpm, method 1), with an additional turbulizing device (reflecting partition) mounted in the bulk of the reaction mixture to create intense turbulent agitation in the vertical direction (Fig. 1a). The second and third are tubular turbulent apparatus of cylindrical (Fig. 1b, method 2) and diffuser–confuser (Fig. 1c, method 3) designs [7]. The tubular apparatus for synthesis of calcium stearate had the following dimensions: diameter of the wide part (diffuser) 24 mm, that of the narrow part (confuser) 10 mm, length of the diffuser–confuser section 48 mm, overall reactor length ~480 mm, and diffuser opening angle $45° \pm 5°$.

To reduce the viscosity of the aqueous solution of potassium stearate, it was preliminarily heated to 75°C. The granulometric composition of the suspension was analyzed by the microscopic method, with a differential particle-size distribution curve plotted and then the average integral diameter and polydispersity factor calculated [7].

Of particular importance in the condensation method for synthesis of a disperse system are local concentration supersaturations of a poorly soluble reaction product, which serve as nucleation centers of the solid phase. Therefore, we primarily studied the effect of the concentration of reactants and reaction products on the granulometric composition of the suspension of the antiagglomeration agent. Raising the concentration of $CaCl_2$ at a fixed content of potassium stearate in the aqueous solution leads to a decrease in the particle size (Fig. 2). In this case, a significant change in the diameter occurs at the content of $CaCl_2$ in water of up to 2–3 wt %. In addition, the suspension particle size steadily decreases on passing from method 1 to method 2, and further to method 3, which correlates with the increase in the intensity of turbulent agitation [5, 6]. A similar influence is exerted on the granulometric composition of the antiagglomeration agent by changes in the concentration of the aqueous solution of potassium stearate (Fig. 3). However, the dependences are in this case smoother, without any pronounced breaks, and the particle diameter steadily decreases as the concentration of the starting reagent becomes higher. This is apparently due to the increased viscosity of the potassium stearate solution, which is also the reason for the fact that

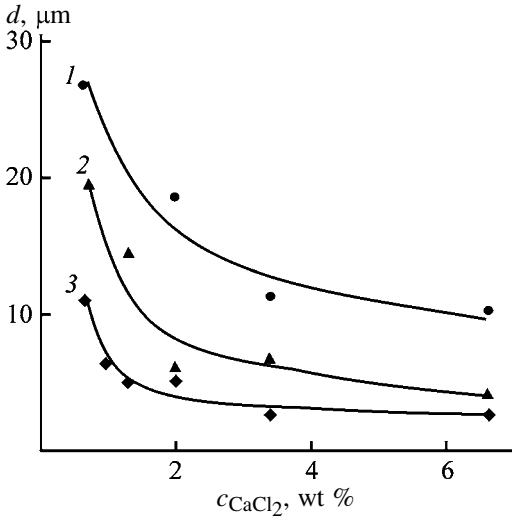

Fig. 2. Suspension particle diameter d vs. the $CaCl_2$ content c_{CaCl_2}. (*1*) Volume apparatus; tubular turbulent apparatus: (*2*) cylindrical and (*3*) of diffuser–confuser design; the same for Fig. 4. c_{KSt} = 5 wt %.

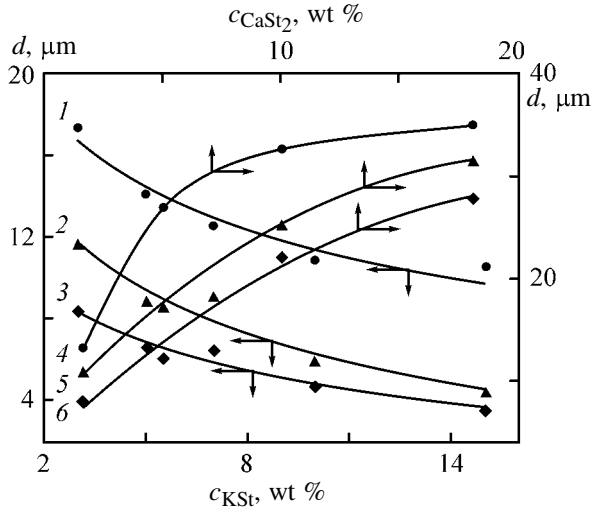

Fig. 3. Suspension particle diameter d vs. (*1–3*) KSt content c_{KSt} (c_{CaCl_2} = 2 wt %) and (*4–6*) $CaSt_2$ content. (*1, 4*) Volume apparatus; tubular turbulent apparatus: (*2, 5*) cylindrical and (*3, 6*) of diffuser–confuser design.

the limiting content of the reagent does not exceed 15 wt %. At a fixed ratio of the reactant concentrations, an increase in the content of the solid phase in the resulting calcium stearate suspension results in that the particle size grows (Fig. 3). In all cases, particles with the minimum, under certain experimental conditions, diameter are obtained when the reaction is carried out in the tubular turbulent apparatus of the diffuser–confuser design.

The dependences obtained can be attributed to variation of the ratio between the rates of nucleation and crystal growth. An increase in the concentration of one of the reactants at fixed low content of the other leads to a rise in the rate of solid phase nucleation because zones of local supersaturation, which are the driving force of formation of a new phase, appear in the reaction mixture. A decrease in the concentration of the second reactant provides a low rate of particle growth because of the diffusion limitations on motion of molecules from the bulk of the aqueous phase to the crystal surface, which, in the end, leads to a decrease in the particle size of the suspension. Apparently, it is advisable to use in manufacture of synthetic rubbers solutions of potassium stearate with its content not exceeding 5 wt % and a concentrated $CaCl_2$ solution. In view of the fact that the solubility of $CaCl_2$ in water is about 50 wt % (at 30°C), it is advisable to work with solutions containing up to 40 wt % $CaCl_2$ to obtain a finely dispersed suspension of the antiagglomeration agent and preclude premature crystallization of $CaCl_2$ on walls of the process equipment. Use of a small tubular turbulent apparatus of the diffuser–confuser design leads to an increase in the nucleation rate via intensive micromixing in the reaction zone, with the crystal growth rate growing to a lesser extent, which leads to a significant change in the granulometric composition of the suspension formed.

It should be noted that the formation of a structural-mechanical barrier via adsorption of calcium stearate particles in stabilization of the polymer crumb in the degassing stage depends to a greater extent on the particle size, and to a lesser extent on the particle size distribution. Data on changes in the polydispersity factor are not presented here, because the changes revealed in [7] for the case of synthesis of barium sulfate are similar to those for systems based on calcium stearate. Homogeneous systems with the minimum possible, under the experimental conditions, polydispersity factor are synthesized in tubular turbulent apparatus of diffuser–confuser design.

It is well known [3] that all disperse systems show poor aggregation stability because of the developed phase boundary surface and uncompensated surface energy. In addition, calcium stearate passes under industrial conditions, before being directly introduced into a polymer solution in the degassing stage, through a number of process units (pipeline, buffer vessel, etc.). This is accompanied by partial settling and inevitable agglomeration of particles. Therefore, it seemed appropriate to estimate the probability of agglomeration of freshly prepared calcium stearate upon keeping for varied time without agitation. For this purpose, we modeled under laboratory conditions the

processes that occur in real systems when a freshly prepared suspension is kept and partial settling of the reaction mixture is caused by gravity forces.

In keeping a suspension produced by methods 1–3, particles of the solid phase become coarser despite the low content of KSt and $CaCl_2$ (≤ 5 wt %) in the disperse systems obtained (Fig. 4). For particles formed in the volume mixing apparatus by method 1, the increase in size is about 30% after 40 min of keeping without agitation. Virtually no further changes occurred in the granulometric composition of calcium stearate. Because of the small initial size of suspension particles obtained in tubular turbulent apparatus of cylindrical and diffuser–confuser designs, they become virtually 4 times larger in 60 min. However, the final particle size of suspensions preliminarily produced in a tubular turbulent apparatus of diffuser–confuser design (method 3) and kept in the absence of agitation remains smaller than that for methods 1 and 2. Thus, agglomeration of solid phase particles is possible in motion of a suspension of a freshly prepared antiagglomeration agent through units of the process equipment before the degassing stage. The decrease in the antiagglomeration capacity of a more coarsely disperse suspension of calcium stearate may lead to an inadmissible increase in the content of the antiagglomeration agent in the finished product. The experimental data obtained (Fig. 4) indicate that additional fragmentation of particles of the antiagglomeration agent based on calcium stearate is necessary prior to using the suspension for stabilization of polymer crumb in the deaerator.

A hydrodynamic treatment of a suspension preliminarily produced and kept for a certain time in a volume apparatus with an additional turbulizing device leads to an only slight decrease in the particle size of the disperse phase (Fig. 5). A decrease in the particle size is observed upon a hydrodynamic treatment in cylindrical tubular apparatus. The thus treated suspension has a particle size of the active substance comparable with that obtained in the case of in situ synthesis (freshly prepared without preliminary keeping) in a volume apparatus with an additionally installed turbulizing device (Fig. 5, curve *5*). Motion of a preliminarily kept suspension in a tubular turbulent apparatus of diffuser–confuser design leads, because of strong shear deformations caused by the continuous phase, to formation of particles not exceeding in size those produced in situ in a volume apparatus (Fig. 5, curve *3*).

It should be noted that treatment by methods 1–3 of a suspension kept for varied time leads to the same

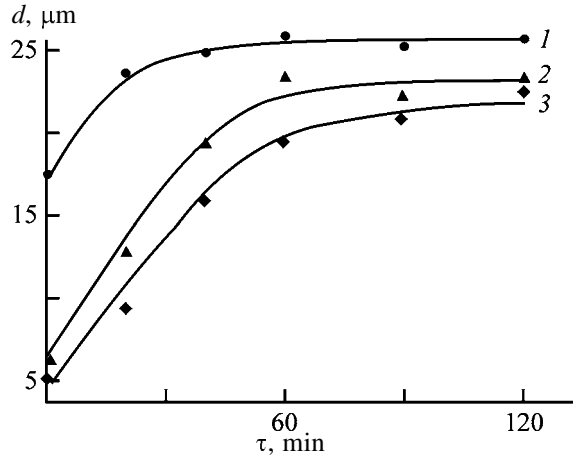

Fig. 4. Suspension particle diameter d vs. time τ of keeping without agitation. c_{KSt} = 5 wt %, c_{CaCl_2} = 2 wt %.

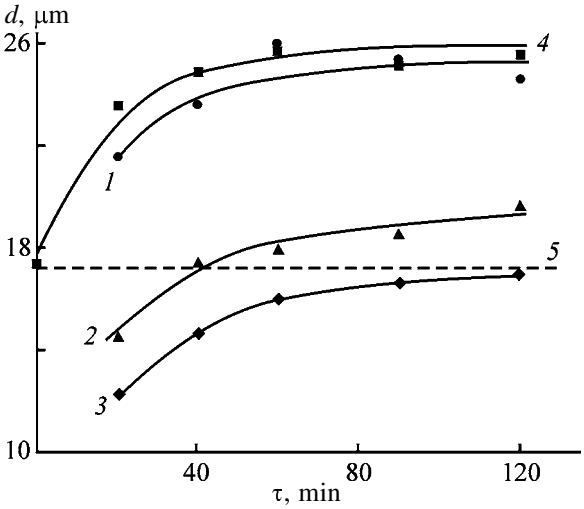

Fig. 5. (*4*) Diameter d of particles obtained in the volume apparatus vs. the time τ of keeping the suspension without agitation. Treatment of preliminarily obtained particles in (*1*) volume apparatus, (*2, 3*) tubular turbulent apparatus of (*2*) cylindrical and (*3*) diffuser–confuser design; (*5*) in situ synthesis.

decrease in particle size. This is manifested in a parallel shift of the plots describing the dependence of the particle size of calcium stearate on the keeping time for various synthesis conditions (Fig. 5, curves *1–3*) with respect to that for "aging" of the antiagglomeration agent (Fig. 5, curve *4*). This indicates that the shear deformations caused by the continuous phase govern the fragmentation of preliminarily obtained and kept suspension particles, with the intensity of the hydrodynamic action being the highest, among the reaction devices considered, for the tubular apparatus of diffuser–confuser design.

It should be noted that satisfying the industrial conditions in synthesis of the antiagglomeration agent

based on calcium stearate in tubular turbulent apparatus makes it possible to obtain an aqueous suspension with pH 10.5–12. Analysis of published data [1] shows that this pH value of the solution is the optimal both for stabilization of the polymer crumb and for recovery of the unreacted monomer and solvent from the reaction mixture in the degassing stage.

Thus, optimization of the reactant concentration in synthesis of calcium stearate based antiagglomeration agent for synthetic rubbers enables effective control over the granulometric composition of the active substance. All other conditions being the same, a suspension with the minimum possible, under the experimental conditions, particle size of the solid phase can be obtained in a small tubular turbulent apparatus of diffuser–confuser design. Variation of the reactant concentrations, combined with improvement of the type and design of the reaction device, make it possible to achieve the maximum ratio of the nucleation and crystal growth rates and, as a result, to obtain calcium stearate particles with high antiagglomeration capacity. The possibility of obtaining a high-quality product and the absence of mechanical agitating devices and mobile elements confirm that tubular turbulent apparatus of diffuser–confuser design are advantageous for production of an antiagglomeration agent based on calcium stearate for synthetic rubbers.

Performing the reaction of aqueous solutions of potassium stearate with calcium chloride in tubular turbulent apparatus provides a stoichiometric reaction course and shorter residence time of the reaction mixture in the apparatus. The latter factor precludes deposition of particles on walls of the process equipment and, as a result, leads to longer overhaul period, lower metal intensity of the process in the smaller reactor, lower energy consumption by the process because of the removal of mechanical stirrers from the process scheme, and higher dispersity of the antiagglomeration agent suspension obtained.

CONCLUSIONS

(1) The reaction of a concentrated solution of calcium chloride (up to 40 wt %) with a dilute solution of potassium stearate (up to 5 wt %) gives a calcium chloride based antiagglomeration agent for synthetic rubbers, which has a developed specific surface area of the phase boundary and high antiagglomeration capacity.

(2) An antiagglomeration agent with the minimum particle size of the solid phase is formed in a tubular turbulent apparatus of diffuser–confuser design both at the instant of synthesis and under a hydrodynamic treatment of a preliminarily obtained and aged aqueous suspension.

Abstract—Liquid-phase oxidation of bromovinyl compounds with the aim to obtain the corresponding α-bromo acids was studied.

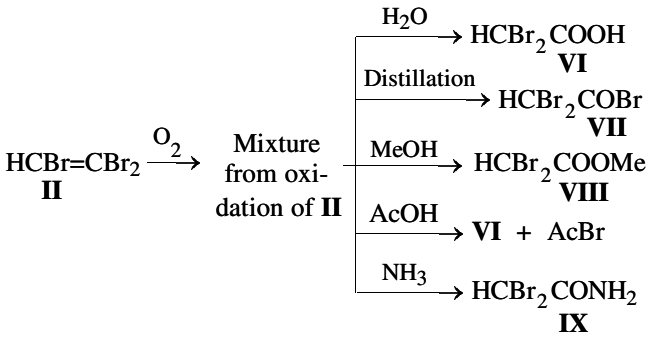
DOI: 10.1134/S1070427206110218

α-Bromo acids and their derivatives are of interest as intermediates in the synthesis of drugs, insecticides, fungicides, plasticizers, and stabilizes of polymers and α-amino acids against thermal oxidative degradation [1–5].

Data on liquid-phase oxidation of bromovinyl compounds are scarce [6–10]. Demole [6, 7] reported only qualitative data on the liquid-phase oxidation of bromovinyl compounds; Pericas and Serratosa [8] studied the stereochemistry of liquid-phase oxidation with molecular oxygen of certain 1-bromo-1,2-diisopropoxyethenes and showed that these compounds are very sensitive to oxygen. In particular, bubbling of oxygen through a dilute solution of 1-bromo-1,2-diisopropoxyethene in pentane results in an exothermic reaction; the oxidation is complete in 1.5 h. The reaction product, isopropyl isopropoxybromoacetate, was isolated in 87% yield by distillation after removing the solvent. Oxidation of 1,2-dibromo-3,3-diphenylmethylene-1,2-cyclobutene with molecular oxygen in benzene [9] occurs at the endocyclic double bond, with the migration of a bromine atom. The kinetics of autooxidation of tribromoethene in chlorobenzene at 303 and 313 K was studied by monitoring the oxygen uptake rate [10]. The reaction was shown to occur by the branched radical-chain mechanism; its major final stable products were bromooxirane and dibromoacetic anhydride. A probable mechanism of the autooxidation of tribromoethene was suggested.

Previously we studied the oxidation with molecular oxygen of a series of 1,1-dichloro- and 1,1-dibromochlorovinyl compounds and found that the reactions were highly selective and gave α-haloacyl chlorides in high yields [11–22]. It seemed interesting to study oxidation with molecular oxygen of bromovinyl compounds, with the aim to compare the results and discuss the general mechanism of oxidation of halovinyl compounds.

Proceeding with studies on oxidation of halovinyl compounds, we examined the oxidation of 1,2-dibromoethene **I** (1 : 4 *cis/trans* isomer mixture), tribromoethene **II**, tetrabromoethene **III**, β,β-dibromostyrene **IV**, and α,β,β-tribromostyrene **V**.



Experiments were performed on a laboratory installation in the temperature range 20–100°C at an oxygen feeding rate of 2–5 $1\,h^{-1}$.

The experiments revealed formation of bromooxiranes in the early oxidation steps; their content reaches 45–60% (determined iodometrically) at 70–80% conversion. Upon distillation, they transform into α-bromoacyl bromides. The only product of oxidation of **I** is dibromoacetic acid **VI**. A more detailed study of the oxidation of **II** with oxygen showed that pentabromoethane was also formed (15–20%) along with dibromoacetyl bromide **VII**. The amount of pentabromoethane depended on the oxidation conditions. For example, its formation was suppressed by increasing reaction temperature and oxygen feeding rate. This result can be attributed to partial removal of the released free bromine from the reaction mixture. However, the formation of free bromine does not appreciably affect the yield of **VII** (80–90% at 100% conversion).

Free bromine can be formed in the system by the reaction of HBr with peroxides accumulating in the

mixture, or by photochemical decomposition of **II** and its oxidation products.

Whereas direct distillation of the reaction mixture from the oxidation of **II** yielded acid bromide **VII**, treatment of the same mixture with water, acetic acid, alcohols, and ammonia yielded the corresponding products **VI**, **VIII**, and **IX**:

Oxidation of tetrabromoethene **III** gave tribromoacetyl bromide in high yield.

Under the similar conditions, the oxidation of **IV** and **V** gave bromo- and dibromophenylacetyl bromides, respectively, in 70–80% yields; as compared to **II**, these compounds are oxidized very slowly, i.e., the oxidation rate is strongly affected by the aromatic substituent.

The structure and purity of the compounds were checked by comparison of their physicochemical constants with the published data, and also by GLC.

The most interesting feature of liquid-phase oxidation of bromovinyl compounds with oxygen is high selectivity of the reaction at temperatures below 70°C, with the formation of α-bromoacyl bromides. With an increase in the temperature, the oxidation rate increases insignificantly, but the selectivity is lost, and other products, including polymers, are formed along with acyl bromides.

EXPERIMENTAL

The starting bromovinyl compounds **IV** and **V** were prepared according to [23], and **I**–**III**, by modified procedures from [24]; their physicochemical constants agree with the published data.

The starting compounds and final products were analyzed with a Tsvet-800 chromatograph equipped with a thermal conductivity detector; 3000 × 3-mm glass column, stationary phase E-301 + polyethylene glycol adipate (5% each) on Inerton Super (0.16–0.20 mm), column temperature 50–250°C, carrier gas He (40–60 ml min^{-1}).

***cis,trans*-1,2-Dibromoethene I.** A 250-ml flask equipped with a reflux condenser and a thermometer was charged with 172.9 g of 1,1,2,2-tetrabromoethane and 36.5 g of dimethylformamide, after which 14 g of iron powder was gradually added. The reaction was exothermic, and the reaction mixture, if necessary, was cooled with water. After the reaction completion, the mixture was distilled to give 86.7 g (93%) of a mixture of *cis*- and *trans*-dibromoethenes **I** in a 1 : 4 ratio (GLC data); bp 102–105°C (680 mm Hg), D_4^{20} = 2.2754, n_D^{20} = 1.5458 [25].

Tribromoethene II. A mixture of 16 g of NaOH, 20 ml of water, 2 g of a 50% aqueous solution of Katamin AB, and 148.3 g of 1,1,2,2-tetrabromoethane was stirred for 2 h at 25–30°C. The organic layer was separated and dried over $CaCl_2$; distillation gave 95.3 g (90%) of tribromoethene **III**, bp 53–55°C (10 mm Hg), D_4^{20} = 2.7080, n_D^{20} = 1.6040 [26]. The product purity (GLC data) was 99.2%.

Tetrabromoethene III was prepared similarly to **II** from 169.8 g of pentabromoethane; yield 126.8 g (92%), bp 100–102°C (16 mm Hg), crystallizes during distillation, mp 55–56°C (from ethanol) [27]. The product purity (GLC data) was 98.6%.

α-Bromoacyl bromides. A glass reactor 35 mm in diameter and 1 m high, equipped with a porous bubbler, an efficient reflux condenser, and a sampler was charged with dibromovinyl compounds freshly distilled from P_2O_5 (0.01 mol %); the vessel was placed in a thermostat. The temperature of 70°C was maintained, and technical-grade oxygen was fed at a rate of 2–4 l h^{-1}. Before entering the vessel, oxygen was purified by passing through two U-shaped tubes, one of which was packed with $CaCl_2$, and the other, with KOH, through a Tishchenko bottle with P_2O_5, and through a trap. All the parts of the system were connected with rubber tubes. The reaction completion was judged from the disappearance of the peak of the starting bromovinyl compound in the GLC pattern.

Oxidation of 1,2-dibromoethene I. A mixture of *cis*- and *trans*-dibromoethenes **I** (18.6 g) was oxidized with oxygen (3 l h^{-1}) at 30°C for 20 h. Vacuum distillation of 10 g of the oxidation products gave 7.4 g (74%) of dibromoacetic acid, bp 68–69°C (2 mm Hg). This compound gradually crystallizes on storage at 20°C; mp 48°C [28].

Oxidation of tribromoethene II. The reactor was charged with 3.5 kg of tribromoethene **II** and heated to 70°C; at this temperature, oxygen was fed (15–20 l h^{-1}) for 250 h. We obtained 3.69 kg of oxidation products. Vacuum distillation of their 300-g portion

gave 205.9 g (80%) of dibromoacetic anhydride **VII**, bp 77–80°C (10 mm Hg), D_4^{20} = 1.8236, n_D^{20} = 1.5480 [29].

Dibromoacetic acid VI. Water (1.5 l) was slowly added with cooling and stirring to 2100 g of the oxidation products of **II**. The mixture was allowed to stand at 20°C for 12 h, after which the insoluble fraction (287.5 g, tetrabromoethene : pentabromoethane = 95.8 : 4.2) was separated from the aqueous layer. Acetic acid (200 ml) was added to the aqueous layer, and the mixture was distilled under reduced pressure (water-jet-pump vacuum); the residue was distilled in a vacuum. Acid **VI** was obtained; yield 1219.2 g (88% based on converted **II**), bp 128–130°C (16 mm Hg), crystallizes in the course of distillation, mp 46°C [28].

Methyl dibromoacetate VIII. A three-necked flask equipped with a dropping funnel, a thermometer, and a reflux condenser was charged with 150 g of oxidation products of **II**, and 30 ml of absolute methanol was slowly added with cooling and stirring from a dropping funnel. After completion of the exothermic reaction and release of HBr, excess methanol was removed, and the residue was distilled. Ester **VIII** was obtained; yield 108.2 g (87%), bp 178–180°C (680 mm Hg), D_4^{20} = 1.8711, n_D^{20} = 1.9137 [29].

Oxidation of tetrabromoethene III. The reactor was charged with 68.9 g of **III** and heated to 90°C; at this temperature, oxygen was fed (2.5–3 $l\,h^{-1}$) for 90 h. We obtained 71.8 g of oxidation products. Vacuum distillation of their 16.8-g portion gave 13.2 g (79%) of tribromoacetic anhydride, bp 90–92°C (12 mm Hg), D_4^{20} = 2.6510, n_D^{20} = 1.8518 [30].

Tribromoacetic acid X. Water (15 ml) was slowly added with cooling to 20 g of oxidation products of **III**; the mixture was allowed to stand at 20°C for 12 h, and excess water was removed in a water-jet-pump vacuum. The residue was recrystallized from ethanol; yield of **X** 13.8 g (84%), mp 129–131°C [30].

Ethyl tribromoacetate XI. Absolute ethanol (15 ml) was slowly added from a dropping funnel with cooling (water–ice) to 20 g of oxidation products of **III**. After completion of the exothermic reaction, excess ethanol was distilled at reduced pressure, and the residue was distilled; yield of **XI** 15.9 g (88%), bp 148–150°C (70 mm Hg), D_4^{20} = 2.1105, n_D^{20} = 1.5349 [29].

Tribromoacetamide XII. Gaseous ammonia was passed through a solution of 8 g of oxidation products of **III** in 20 ml of absolute toluene until the ammonia uptake ceased. The precipitate was filtered off, washed with water, and air-dried. Yield of **XII** 5.2 g (78%), mp 119–120°C (from ethanol) [31].

Oxidation of β,β-dibromostyrene IV. The reactor was charged with 26.2 g of dibromostyrene **IV** and heated to 70°C. At this temperature, oxygen was fed (5 $l\,h^{-1}$) for 180 h. Distillation of 10 g of the oxidation products gave 7.4 g (74%) of phenylbromoacetic anhydride **XIII**, bp 140–143°C (20 mm Hg), D_4^{20} = 1.8557, n_D^{20} = 1.6000 [32].

Phenylbromoacetic acid XIV. A mixture of 10 g of oxidation products of **IV** and 10 ml of water was allowed to stand at 20°C for 12 h. Low-boiling products were evaporated in a water-jet-pump vacuum, and the residue was vacuum-distilled. Yield of acid **XIV** 5.9 g (77%), mp 84°C (from ethanol) [23].

Ethyl phenylbromoacetate XV: bp 141–143°C (8 mm Hg), D_4^{20} = 1.4165, n_D^{20} = 1.5415 [32].

Phenylbromoacetamide XVI: mp 146°C (from water) [32].

Oxidation of α,β,β-tribromostyrene V. Similarly to the oxidation of **IV**, 24 g of **V** was oxidized with oxygen for 250 h. Water (20 ml) was added to 20 g of the oxidation products, and the mixture was allowed to stand at 20°C for 12 h. After evaporation of water and recrystallization of the residue from petroleum ether, 10.9 g (72%) of phenyldibromoacetic acid **XVII** was obtained; mp 102–104°C (from CCl_4 : petroleum ether = 1 : 1) [23].

CONCLUSIONS

(1) Liquid-phase oxidation of bromovinyl compounds with oxygen in the range 20–100°C was studied, and conditions for selective preparation of α-bromoacyl bromides were found. The primary oxidation products are bromooxiranes; their maximal content in the oxidation products reaches 60%. In the course of distillation, hydrolysis, alcoholysis, aminolysis, and acidolysis, bromooxiranes quantitatively transform into the corresponding α-bromo carboxylic acid derivatives.

(2) Oxidation of some bromovinyl compounds with molecular oxygen yields, along with α-bromoacyl bromides, also the product of addition of bromine to the double bond. Aromatic substituents at the double bond considerably decrease the rate of oxidation of bromovinyl compounds.

(3) Liquid-phase oxidation of bromovinyl compounds occurs exclusively at the double bonds. The bromooxiranes formed in the process are insufficiently

reactive to induce side reactions (cleavage of the double bond or allyl oxidation).

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Polyethylene Glycol Monomethyl Ethers as the Main Component of Brake Fluid

Abstract—The main physicochemical properties of polyethylene glycol monomethyl ethers in a wide temperature range were determined. The effect exerted on the main quality indices of brake fluids by the introduction of polyethylene glycol monomethyl ethers borates was studied. The use of these ethers as the main component of DOT-5.1 brake fluids was analyzed.

DOI: 10.1134/S107042720611022X

Brake fluids (BFs) are used to transfer energy to the actuating mechanism in the hydraulic drive of the brake assembly of a car and to remove heat from the brake disks. The modern requirements to BFs are determined by FMVSS 116 (DOT) American federal motor vehicle safety standards [1].

According to this standard, BFs are subdivided into three classes: DOT-3, DOT-4, and DOT-5.1. The main requirements to these BFs are high operation temperatures, good low-temperature and viscosity–temperature properties, physical and chemical stability, protection of metals from corrosion, inactivity with respect to mechanical rubber articles, and lubricating effect. Some requirements of FMVSS 116 (DOT) are summarized in Table 1.

The boiling point is the main parameter determining the maximal operation temperature of a hydraulic drive of a brake assembly. Boiling point of most of brake fluids decreases in the course of their operation owing to high hygroscopicity of the fluids. In practice, the advantages of high-boiling BFs are actually useful when the fluids are frequently replaced.

Thus, a high boiling point of BF does not ensure its efficiency under hard operation conditions. Hence, not only "dry" equilibrium reflux boiling point (ERBP) of BF but also wet equilibrium reflux boiling point (WERBP) of BF containing 3.5% water [1] is determined. The WERBP corresponds to the temperature at which the liquid will boil after its operation in a hydraulic drive of a brake assembly of a vehicle for 1.5–3 years.

The viscosity–temperature properties of brake fluids should provide their efficiency in a wide temperature range. At low temperatures the fluid should be movable. To ensure reliable operation of a hydraulic drive of the brakes in summer time or in the South, the saturated vapor pressure of the fluid should be low and its boiling point should be sufficiently high [2].

Analysis of the available literature [3–5] revealed growing use of glycols or their derivatives, in particular, di-, tri-, and tetraethylene glycol monoalkyl ethers [3–8], in the last decade as the main components of BFs. To increase the boiling point of both wet and dry liquid, tris(methyl glycol) borates are introduced in BF [9, 10]. At the present time, Russian analogs of DOT-3 and DOT-4 brake fluids are widely used in Russia. Since the motor vehicle safety standards become tougher, the requirements to brake fluids become more stringent. Therefore, preparation of a BF of DOT-5.1 grade meeting these requirements is an urgent problem. However, no detailed data are available in the literature on physicochemical properties of tris(methyl glycol) borates of both pure polyethylene

Table 1. Some requirements of FMVSS 116 (DOT)

glycol monomethyl ethers and their mixtures with tris(methyl glycol) borates, as well as on the influence of the degree of boration of the initial compounds on the boiling point and viscosity of BF.

The aim of this study was to determine how additions of borates affects the boiling point and low-temperature viscosity of brake fluids.

EXPERIMENTAL

Diethylene glycol monomethyl ether (MeDEG), triethylene glycol monomethyl ether (MeTEG), and tetraethylene glycol monomethyl ether (MeTetraEG) were isolated from polyoxide-101 in accordance with TU (Technical Specifications) 2422-027-56649936–01 and were purified by repeated vacuum distillation on a bench unit at a residual pressure of 2–5 mm Hg. The purity (99%) was determined by comparison of their main physicochemical properties with the published data and by chromatographic analysis. The results are presented in Table 2.

Chromatographic analysis was performed on a Tsvet-500 chromatograph. We used a 2-m steel column 3 mm in diameter packed with PEG-20M on a Chromaton and a flame ionization detector with a sensitivity of 1×10^{-7}. The flow rate of hydrogen, carrier gas (nitrogen), and air was 30, 30, and 300 ml min^{-1}, respectively. The temperature of the vaporizer and junction chamber of the detector was 170 and 180°C, respectively. The temperature in the course of the analysis was automatically changed from 110 to 200°C at a rate of 10 deg min^{-1}. The temperature was controlled by a BU-125 control unit of the chromatograph with an accuracy of ±0.1°C.

The density was determined pycnometrically according to GOST (State Standard) 3900–85. The kinematic viscosity measured on a VPZh-3 viscometer (GOST 33–82) was converted into the dynamic viscosity. The substances were controlled thermostatically in a UT2/77 thermostat with an accuracy of ±0.05°C. The densities and dynamic viscosities of the pure ethers are summarized in Table 2.

The boiling points were measured in accordance with the MFVSS 116 standard [1]. The results are presented in Table 2 and in the figure.

The borates were prepared by conventional esterification on a vacuum bench unit consisting of a round-bottom flask used for distillation of the polymerization products, adapter with a reflux condenser, and a receiver for liberating water. The initial compounds were boric acid (GOST 9656–75) and MeTEG. These substances taken in a required ratio were placed in the reaction flask. The flask was evacuated to a residual pressure of 10–20 mm Hg. The reaction mixture

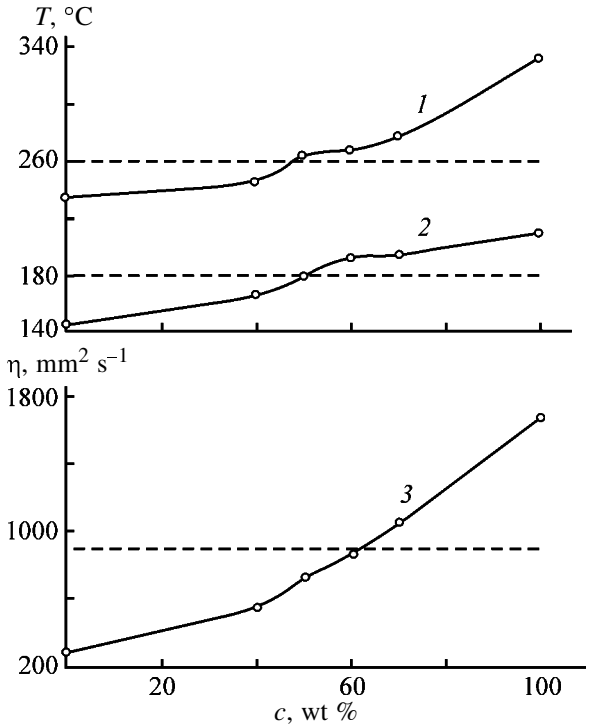

Fig. 1. (*1*) ERBP and (*2*) WERBP (*T*, °C) and (*3*) kinematic viscosity η at –40°C as functions of the concentration of tris(methoxyethoxyethoxyethyl)borate in MeTEG *c*.

was continuously stirred by a nitrogen flow fed through a capillary. The flask was gradually (over a period of 1.5–2.0 h) heated to 120°C, and the liberated water was distilled off.

As seen from Table 2, the temperature dependence of the density and viscosity of pure ethers monotonically decreases in the series MeDEG–MeTEG–MeTetraEG. The density and viscosity increase, probably due to densification of the structure (an increase in the degree of association) and increase in the number of intermolecular hydrogen bonds. The ERBP of MeTetraEG meets the requirements for DOT-5.1 BF. However, this ether freezes at –40°C. MeTEG, in turn, has good low-temperature viscosity but unsatisfactory boiling point. Oxyethylated additives have a negative effect on the properties of BF: the low-molecular-weight additives decrease the boiling point and the additives with higher molecular weight increase the low-temperature viscosity. Thus, MeTEG has good ERBP and low-temperature properties and can be used as the main component of BF.

To eliminate the negative effect of water and to increase the boiling point, borate esters of alkylene glycol monoethers were added to BF [9, 12]. The borate additive is readily hydrolyzed by water present in BF, binding this water and thus increasing the boiling point of a wet fluid [6]. However, since the viscosity of borate esters is high, introduction of large amounts of these compounds is undesirable. The main advantage of brake fluids containing borate esters is insignificant change of their physical properties in the presence of moisture. Esters of boric acid not only bind water but also have good lubricating and corrosion-preventing properties.

As noted above, an increase in the fraction of borate esters of methoxypolyethylene glycols in a brake fluid increases its boiling point. We studied the influence of methoxyethylene glycol borates on boiling points of their mixtures with individual polyethylene glycol monomethyl ethers. The content of tris(methoxyethoxyethoxyethyl) borate (BEMeTEG) ranged from 0 to 100%.

As seen from the figure, the kinematic viscosity of the mixtures monotonically increases with increasing borate content. The maximal permissible kinematic viscosity in accordance with FMVSS 116 (900 $mm^2 s^{-1}$) is reached at the borate content of about 60 wt %. The ERBP and WERBP of brake fluids containing this amount of borate are 260 and 180°C, respectively, which meets the FMVSS 116 (DOT) requirements.

CONCLUSIONS

(1) A mixture of triethylene glycol monomethyl ether with its full borate ester can be used as the main component of DOT-5.1 brake fluid. The ERBP, WERBP, and low-temperature viscosity of this BF meet the FMVSS requirements.

(2) To meet the FMVSS requirements to boiling points and low-temperature properties, the content of tris(methoxyethoxyethoxyethyl)borate in its mixture with triethylene glycol monomethyl ether should be in the range 55–60 wt %.

Abstract—Specific features of modification of some alicyclic polyimides with polyamido acids derived from aromatic tetracarboxylic acid dianhydrides were studied. The possibility of preparing new polymer systems with improved characteristics was demonstrated.

DOI: 10.1134/S1070427206110255

Recently there has been a considerable progress in modification of polymers with various additives and fillers. A promising approach to the development of new polymeric materials with high physicomechanical characteristics and good processability, including materials based on polyimides, is blending of polymers belonging to the same or different classes [1–4].

Published papers mainly concern aromatic polyimides. At the same time, alicyclic polymers are also of interest for various branches of engineering. In particular, they are promising materials for multilayer dielectrics in stacks of multiintegrated circuits, for production of enameled wires, film insulators, etc. [5–8]. However, these polymers, as compared to the aromatic analogs, exhibit insufficiently high physicomechanical characteristics. These characteristics can be improved by modification with various polymers.

The main goal of this study was to examine specific features of modification of polyimides containing tricyclodecene fragments in the backbone with polyamido acids derived from aromatic tetracarboxylic acid dianhydrides.

EXPERIMENTAL

The starting compounds and solvents were purified by standard procedures. The IR spectra were recorded on an IR-25 spectrometer. Polymer samples were prepared as 3–5-μm films.

The reduced viscosities of 0.5% solutions of the polyimides were measured with an Ubbelohde viscometer at 25°C in dimethylformamide (DMF). Thermogravimetric analysis of the polymers was performed with a TGA SDTA Mettler Toledo device at a heating rate of 8 deg min^{-1}. The temperatures of the onset of the polymer decomposition ($T_{o.d}$) were calculated from the TGA curves.

The physicomechanical (tensile strength, relative elongation) and dielectric (dielectric loss tangent, permittivity) characteristics were studied under standard conditions by known procedures [9, 10].

Dianhydrides were prepared by the Diels–Alder reaction upon UV irradiation of saturated solutions of maleic anhydride in appropriate hydrocarbons in the presence of acetophenone as sensitizer. Tricyclo-[4.2.2.$0^{2,5}$]dec-7-ene-3,4,9,10-tetracarboxylic acid dianhydride (photoadduct of benzene and maleic anhydride, AB) was prepared in a temperature-controlled quartz glass vessel by irradiation of a solution of 196.00 g (2.0 mol) of maleic anhydride in 1000 ml of benzene containing 24.12 g (0.2 mol) of acetophenone with a PRK-2M mercury quartz lamp for 15 h. In the course of irradiation, a white crystalline precipitate formed; it was filtered off, recrystallized from propionic anhydride, washed with dry diethyl ether, and vacuum-dried at 80–90°C to constant weight. Yield 80% based on maleic anhydride.

9-Oxotricyclo[4.2.$1^{1,6}0^{2,5}$]nonane-3,4,7,8-tetracarboxylic acid dianhydride (photoadduct of furan and maleic anhydride, AF) was prepared by irradiation of the monoanhydride prepared beforehand from furan and 193.24 g (2.0 mol) of maleic anhydride, performed for 10 h in 1000 ml of dioxane containing 24.12 g (0.2 mol) of acetophenone. Yield of AF 84.5%.

Melting points, °C: AB 350–352 and AF 408–410.

The composition and structure of the dianhydrides were determined by elemental analysis and IR spectra.

AB. Found, %: C 61.40; H 3.70; esterification number (EN) 137.03.
$C_{14}H_{10}O_6$. Calculated, %: C 61.33; H 3.65; EN 137.07.

AF. Found, %: C 54.60; H 3.12; EN 131.80.
$C_{12}H_8O_7$. Calculated, %: C 54.56; H 3.03; EN 132.01.

IR spectra, cm^{-1}: 1500 (benzene ring), 1775–1780, 1835–1840 (anhydride groups [11]).

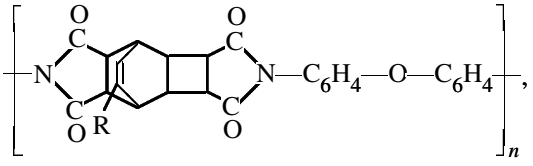
The dianhydrides derived from fluoro- and chlorobenzene and maleic anhydride (AFB, ACB) were prepared by the procedures described in [7, 12].

The solvent, *N*-methyl-2-pyrrolidone (MP), was dried over 4A molecular sieves.

Unmodified polyimides were prepared in the presence of catalytic amounts of triethylamine. The polyimide derived from AB and 4,4'-diaminodiphenyl ether (DADPE) was prepared as follows: A three-necked flask equipped with a stirrer and an inlet tube for an inert gas was charged with 13.70 g (0.05 mol) of the dianhydride, 10.00 g (0.05 mol) of DADPE, and 3.55 g (15 wt % of the sum of the monomers) of triethylamine, after which 71.1 ml of MP was added. The flask with the reaction solution was placed on an oil bath (T = 50°C). The mixture was stirred for 15 min, after which the temperature was raised to 160°C over a period of 20 min, and the mixture was stirred for an additional 4.5 h. After cooling to room temperature, films were cast from the solution, or the polymer was precipitated into acetone (chemically pure grade); the resulting precipitate was washed with two portions of acetone and dried in a vacuum oven at 80–90°C to constant weight. The polyimides derived from AFB and ACB were prepared similarly.

The elemental analysis of the precipitated polymers gave consistent results. Polyimide films were prepared by casting 25% MP solutions of the precipitated polyimides onto glass surfaces; to remove the solvent, the films were first predried by heating in a vacuum oven to 80°C for 0.3 h and then additionally heat-treated in the temperature range 80–300°C in air for 1.0 h.

Syntheses of polyimides in the presence of catalytic amounts of polyamido acids derived from pyromellitic and benzophenonetetracarboxylic acid dianhydrides were performed similarly.



Polyamido acids (PAAs) derived from AB and AF (25 wt % solutions in dimethylacetamide) were prepared at equimolar ratio of the components at 25°C in 1.5 h. Heat treatment of the films prepared from blends of homopolyamido acids was performed at 80–300°C in a vacuum (2×10^{-2} hPa) for 2.0 h.

The prepolymers derived from pyromellitic and benzophenonetetracarboxylic acid dianhydrides were prepared by well-known procedures; polymer yield 98.5–99.0%.

Polymer blends of the polyimide derived from AB and DADPE with polyamido acids were prepared as follows: 10–25% solutions of the prepolymers, taken in an amount corresponding to the required PI–PAA ratio, were added at room temperature to a solution of the polyimide. The mixture was stirred for 1.5 h at room temperature, after which films were cast. The films were dried in the temperature range 80–300°C in air for 1.5 h. The degree of imidization was evaluated from the IR spectra.

Published data show that the choice of one or another modification procedure is governed by the nature and purpose of the polymer, and also by other factors. The widely used route to new polymers and polymer systems is chemical modification; it allows purposeful control of the formation of the material structure. A primising approach to the development of new polymers and polymer systems involves the use of various macromolecular compounds [1–4, 13, 14].

In particular, properties of polymer blends can be improved and their stability enhanced by performing the synthesis of one of the polymers in the presence of the other polymer as a matrix; at its definite content, this matrix can affect the formation rate, structure, and molecular weight of the target product. In is study, we used other approaches: mechanically blending polymers of different nature or performing the synthesis of alicyclic polyimides of the general formula

where R = H, F, Cl, in the presence of catalytic amounts of the second polymeric component (P2).

As a first step in examining the possibility of modification of polyimides with tricyclodecene fragments in the backbone, we considered the effect of polyamido acids derived from aromatic and alicyclic tetracarboxylic acid dianhydrides. These substances were added to a solution of a ready polyimide with ~100% degree of imidization. We found that different prepolymers exert different effects on the properties

Table 1. Properties of the polyimide derived from AB and DADPE and modified with various polyamido acids

Property	PAA			No PAA added
	AB	PMDA	BZP

Elastic modulus, MPa	4100	3500	–	4400
Dielectric loss tangent (1 KHz)	0.001	0.001	0.001	0.001
Volume resistivity, Ω m	1.6×10^{15}	5.1×10^{15}	3.2×10^{15}	2.2×10^{15}
Dielectric permittivity	2.2–2.6	2.7–2.9	3.0–3.3	2.2–2.6
Softening point, °C:				
of prepolymer	150	100	110	155
of polyimide	300	310	300	No softening
$T_{o.d}$ in air, °C	370	375	370	370
Intrinsic viscosity, dl g^{-1}, in DMF	1.52	1.92	1.71	1.21

of the polyimide being modified; in the process, the concentration of the second component (P2) should also be controlled. Monitoring of the intrinsic viscosity [η] of the polyimide derived from AB and DADPE (PI_{AB}) in the presence of various polyamido acids showed that higher viscosities are attained when the PAA derived from 4,4'-diaminodiphenyl ether and pyromellitic dianhydride (PAA_{PMDA}) is added to the polyimide solution, and somewhat lower viscosity is attained with the PAA derived from benzophenonetetracarboxylic acid dianhydride (PAA_{BZP}); the optimal concentration of the second component is 10 wt %. With a further increase in the P2 content in the reaction mixture, the solution becomes turbid, and at 12–15 wt % content of P2 the phase segregation and coagulation of the polymer occur, i.e., the polymers are thermodynamically compatible up to a certain limit.

Some properties of the polyimide prepared by heat treatment of a blend containing 10 wt % PAA are given in Table 1. Introduction of polyamido acids into a polyimide solution yields a new polymer system with the intrinsic viscosity of 1.52 to 1.92 dl g^{-1}; whereas in the case of the polyamido acid derived from the same components (PAA from AB and DADPE) the elemental composition remains unchanged, with the PAA derived from pyromellitic or benzophenonetetracarboxylic acid dianhydride the resulting polymers differ in the composition and properties from the starting polymers and presumably have the structure of interpenetrating polyimide networks.

The completion of the transformation of the amido acid fragments into imide rings was judged from the IR spectra. The spectrum of the final polyimide did not contain bands characteristic of amido acid units (about 3280, 1670, 1540 cm^{-1}) but contained characteristic bands of imide rings [1780 (doublet with 1720), 1380, 730 cm^{-1}] [11].

For PIs derived from AFB and ACN with DADPE, the intrinsic viscosity reached, respectively, 2.10 and 1.75 dl g^{-1} with addition of PAA_{PMDA}, and 1.84 and 1.55 dl g^{-1} with addition of PAA_{BZP}; the tensile strength and elongation increased by 20–30%, and the dielectric characteristics changed insignificantly.

It should be noted that it is hardly possible to judge the interactions between the polymeric components from the IR spectra, because the major bands in the spectra of the alicyclic and aromatic polyimides are essentially the same (the only distinction is the band of the C=C bond at about 1620 cm^{-1} in the spectra of polyimides derived from tricyclodecenetetracarboxylic acid dianhydride). As noted above, in this case we took advantage of the elemental analysis.

As noted above, higher values of the viscosity, tensile strength, and elongation are attained for polyimide films containing PI_{PMDA}. The intrinsic viscosity of the new polymer system prepared in the presence of PAA_{BZP} is somewhat lower. It should be noted that introduction into a ready polyimide of the prepolymer of the similar structure also leads to a certain increase in the viscosity and other characteristics. Similar effects were also observed with the PIs derived from AFB and ACB.

One more procedure for modification of polyimides is based on the use of blends of polyamido acids [5, 15]. In this study, with the aim to enhance the heat resistance of alicyclic polyimides, we used mechanical blending of PAA_{AB} with the PAA derived from

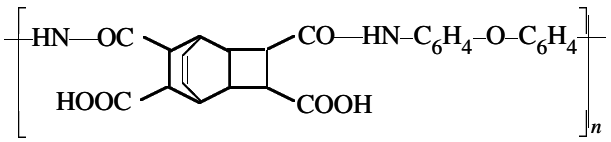

Table 2. Properties of polyimides prepared from AB–DADPE and AF–DADPE polyamido acids

Polymer	Initial blend composition, wt %		[η], dl g^{-1} (DMF, 25°C)	$T_{o.d}$ in air, °C	Tensile strength, MPa	Elongation, %

DADPE and AF. The furan structure of AF ensures higher thermal characteristics of the polymers [16, 17]. The properties of polyimides prepared by heat treatment of blends with various contents of polyamido acids of the general formulas

PAA_{AB}

PAA_{AF}

are listed in Table 2. it is seen that the intrinsic viscosity increases monotonically; the temperature parameters also gradually change. In going from the polymer prepared from the blend containing 20 wt % PAA_{AF} to the polymer with a higher content of this component, the decomposition onset temperature increases; for example, for the PI prepared with 80% PAA_{AF} (PI-5), $T_{o.d}$ is 405°C, whereas for PI-2 (20 wt % PAA_{AF}) it is 375°C.

Similar measurements were performed with the polyimides prepared from blends of PAAs derived from AB and PMDA. The properties of the polymers prepared by mechanical blending of alicyclic and aromatic polyamido acids are given in Table 3.

Data for PI-2 in Table 2 deserve particular attention. The physicomechanical characteristics of this polymer are considerably improved relative to PI-1: Introduction of only 5 wt % PMDA increases the tensile strength of a 40–45-μm film by 50 MPa and the elongation, by a factor of 2. With a further increase in the PAA_{PMDA} content in the starting blend, the properties of the polyimides change monotonically and more gradually.

Polyamido acids derived from alicyclic and aromatic tetracarboxylic acid dianhydrides can also be used as catalysts of the polycondensation in polar aprotic solvents of the amide type. We showed previously that MP is a suitable solvent for preparing by one-step polycondensation polyimides derived from tricyclo-

Table 4. Conditions for the synthesis of the polyimide derived from AB and DADPE in the presence of PAA

PAA	C_{mon}, wt %/C_{cat}, wt %	T, °C	Time, h	[η], dl g^{-1} (DMF, 25°C)
PMDA	40/1.5	170	4.0	1.73
BZP	40/1.5	180	5.0	1.51
AB	40/2.0	180	5.0	1.40

decenetetracarboxylic acid dianhydrides and various diamines, because the higher boiling point of this solvent is favorable for the process. The optimal conditions for the synthesis of PIs derived from AB in the presence of various prepolymers are listed in Table 4.

For the chlorinated and fluorinated polyimides prepared under the similar conditions, [η] was 1.58–1.92 dl g^{-1}.

Table 4 shows that, when an alicyclic polyimide is prepared in the presence of catalytic amounts of aromatic polyamido acids, [η] is somewhat lower compared to the procedure involving introduction of PAA into ready polyimide solutions (Table 1). However, in this case the viscosities of the PIs are also fairly high, i.e., the second polymer plays the role of not only a catalyst but also a polymeric matrix on which a polymer with improved properties is formed. The tensile strength of the polyimide films is 136–140 MPa, and the breaking elongation, 25–30%.

Certain dielectric characteristics of the new polymer systems deserve particular discussion. It is known that polyimides containing alicyclic fragments have lower dielectric permittivity compared to their aromatic analogs [6]. This is also true for the polyimides derived from tricyclodecenetetracarboxylic acid dianhydrides that we developed [7, 12]. For example, the dielectric permittivity ε of polyimide films prepared from the alicyclic polyimide derived from AB and DADPE is intermediate between that of the homopolymers: $\varepsilon(PI_{PMDA}) = 3–3.5$, $\varepsilon(PI_{AB}) = 2.2–2.6$, ε of the polyimide prepared with 10% PAA_{PMDA} is 2.7–2.9, and ε of the polyimide prepared with 2–3% PAA_{PMDA} is 2.5–2.7. At catalytic preparation of the alicyclic polyimide in the presence of polypyromellitic acid, ε is 2.4–2.7. The dielectric permittivity of the fluorinated PI is somewhat lower, and that of the chlorinated polyimide, higher than that of PI_{AB}: 1.8–2.1 and 1.9–2.2, respectively [8, 18]. The other characteristics (dielectric loss tangent, volume resistivity, electrical strength) are similar to those of aromatic polyimides.

To conclude, the best characteristics of the polymers are attained at their modification with polyamido acids introduced into PI solutions. The observed improvement of the properties of the alicyclic polyimide in the presence of polyamido acids may be due to the following factors: on the one hand, an increase in the size of the macromolecular globule and "loosening" of the structure; on the other hand, apparently, more complete reaction of the functional groups with each other.

Thus, modification with other polymers allows improvement of properties of alicyclic polyimides.

CONCLUSIONS

(1) Experiments on modification of polyimides derived from tricyclodecenetetracarboxylic acid dianhydrides with aromatic and alicyclic polyamido acids showed that higher viscosity and better physicomechanical characteristics are attained by modification of alicyclic polyimides with the polyamido acid derived from pyromellitic dianhydride.

(2) In one-step preparation of polyimides in the presence of prepolymes, the prepolymers exert a catalytic and plasticizing effect.

Abstract—Optimal conditions for the synthesis of phytoactive polymers from mono- and bispiperidols and maleic anhydride copolymers were found. The growth-stimulating activity of these polymers was tested on arid cultures.

DOI: 10.1134/S1070427206110267

To improve the germinating capacity of seeds and enhance the resistance of plants to natural stress factors, synthetic biologically active substances (BASs) improving the formation of the root system and accelerating the growth and development of plants are used along with phytohormones. It is apparently preferable to use polymeric growth regulators exhibiting prolonged effect, high biological efficiency at small dosages, and single action in the vegetation period.

In this study, with the aim to obtain phytoactive polymers stimulating the growth of plants, including arid cultures, we examined the immobilization of 1,4-bis[*N*-(2-ethoxyethyl)-4-hydroxypiperid-4-yl]buta-1,3-diyne (Kaz-4) and 1,2,5-trimethyl-4-dimethoxyphosphorylpiperid-4-ol (Fospinol, ASA) with 1,4-bis-(1,2,5-trimethyl-4-hydroxypiperid-4-yl)buta-1,3-diyne (Akpinol, AE) on maleic anhydride copolymers. It is known that Fospinol affects to a greater extent the growth of tops, whereas Akpinol stimulates the root formation; therefore, the development of a polymeric plant growth regulator containing both these piperidols is of interest from both scientific and practical viewpoint.

Biologically active polymers were prepared by polymer-analogous transformations in a dimethyl sulfoxide solution. As starting polymers we used copolymers of maleic anhydride with styrene (Styromal, StMA) and with acrylic acid (AAMA). These copolymers, which are mainly alternating [1], allow immobilization of a BAS uniformly along the macromolecular chain. This feature allows prediction of the properties of phytoactive polymers being synthesized and facilitates further standardization and certification of agricultural agents based on them.

EXPERIMENTAL

To prepare a mixed polymeric monoester of Akpinol, Fospinol, and Styromal, a 1.212-g portion of StMA (0.006 mol) was charged into a two-necked flask equipped with a stirrer and was dissolved in 9.5 ml of DMSO at 60°C within 5–10 min. After the StMA dissolved completely, the temperature was raised to 90°C, and 0.7532 g (0.003 mol) of Fospinol and 0.4 ml (0.003 mol) of triethylamine (TEA) were added. Two hours later, 0.996 g (0.003 mol) of Akpinol, 9.1 ml of DMSO, and 0.4 ml (0.003 mol) of TEA were added. The reaction mixture concentration was 15 wt %, and total reaction time, 4.5 h. After the lapse of the prescribed time, the synthesis was stopped, and the polymer solution was slowly poured while hot into a precipitant mixture (150 ml of acetone, 30 ml of isopropyl alcohol, and 20 ml of 8% KOH solution in isopropyl alcohol). The mixture was allowed to stand for 15 min, after which the precipitate was filtered off at reduced pressure, washed on the filter with isopropyl alcohol, and filtered once more. The precipitate was transferred into a Petri dish and dried first at room temperature and then in a vacuum oven at 35°C

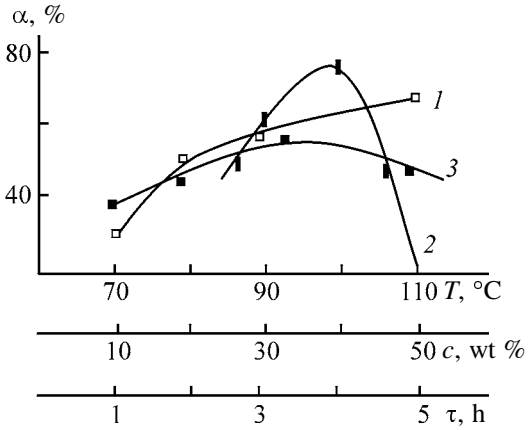

Fig. 1. Degree of immobilization α of a BAS on the copolymer as a function of the (*1*) reactant concentration *c*, (*2*) temperature *T*, and (*3*) reaction time τ.

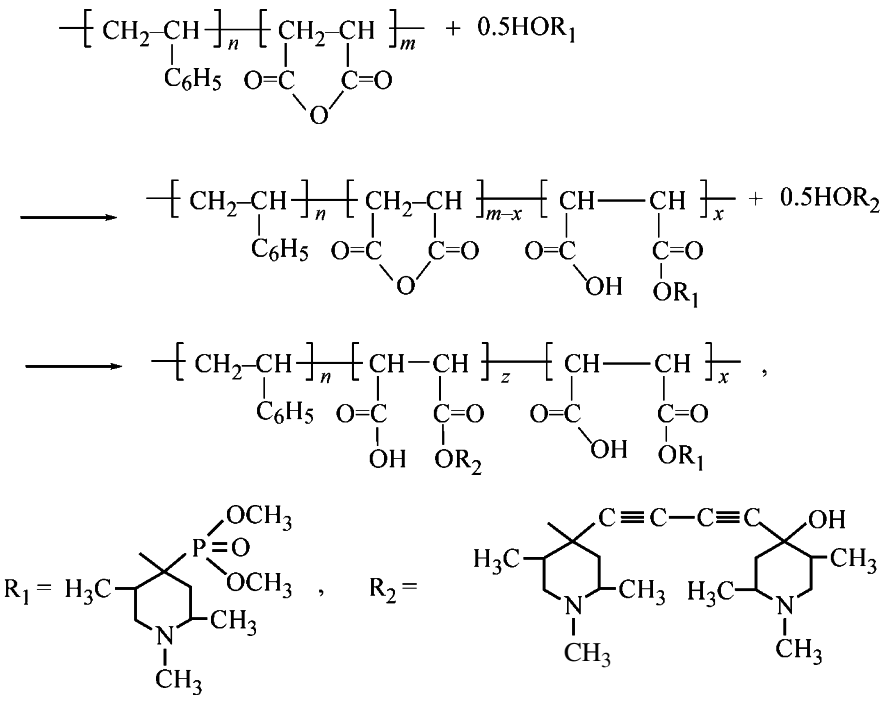
to constant weight. Yield 2.701 g. The degree of immobilization determined by potentiomeric titration was 75 mol %. The IR spectrum contained a new band at 1710 cm^{-1} (ester groups).



The biologically active polymers derived from Kaz-4 and Akpinol were prepared similarly.

The styrene–maleic anhydride copolymer (Kaustik Research and Production Association, molecular weight 40 000) was purified to remove residual monomer by reprecipitation from cyclohexane into petroleum ether and then was subjected to additional anhydridization in a vacuum at 200°C. The IR spectrum contained bands at 1770–1850 and 1080–1220 cm^{-1} (anhydride ring). The content of anhydride groups was 39 mol %.

Akpinol and Fospinol (submitted by the Laboratory of Chemistry of Physiologically Active Compounds, Bekturov Institute of Chemical Sciences, Ministry of Education and Science of Kazakhstan Republic) were used without additional purification. The physical constants agreed with the published data [2].

The amount of anhydride groups and degree of immobilization were determined by procedures described in [3].

The IR spectra of the starting and synthesized compounds were recorded on a Jasco IR-810 spectrometer (Japan) in KBr pellets against pure KBr pellet in the range 4000–400 cm^{-1}. The reactions of StMA with Fospinol and Akpinol followed the scheme

The reactant ratio was calculated per mole of elementary unit containing anhydride ring: copolymer : ASA : AE = 1.0 : 0.5 : 0.5. The IR spectrum confirmed the formation of an ester bond, and elemental analysis confirmed the presence of P and N.

To determine the optimal synthesis conditions, we examined the effect of various factors on the degree of immobilization of BAS on the copolymer.

Figure 1 shows how the degree of immobilization

of ASA and AE on StMA depends on the temperature, reaction time, and concentration of the reactants. With an increase in the concentration of the reaction solution to 30 wt %, the BAS content increases to 67.4 mol % (curve *1*). However, at this concentration the mixture becomes viscous, which prevents complete removal of the unchanged reactants. Therefore, it is not appropriate to use higher concentrations. The temperature dependence (curve *2*) passes through a maximum, and this point is shifted toward higher temperatures compared to experiments on immobilization of each BAS taken separately [2]. The highest degree of immobilization, 77.1 mol %, is attained at 100°C. An increase in the reaction time (Fig. 1, curve *3*) leads to a gradual increase in the BAS content. The maximal degree of immobilization is attained in the 4-h reaction.

The influence exerted on the degree of immobilization of phytoactive substances by the reaction time in the presence and in the absence of a catalyst and at different temperatures was examined in more detail; the results are shown in Fig. 2. The molar ratio of the reactants, copolymer : BAS : catalyst, was 1 : 1 : 1; the concentration, 15 wt %; and the temperature, 75 and 90°C.

At 75°C (Fig. 2, curve *1*), the maximal degree of immobilization (35.6%) is attained in 4 h. As the temperature is raised to 90°C (curve *2*), the degree of immobilization increases to 51.3%, and the effective time of BAS binding decreases to 3 h. Addition of TEA as catalyst (curve *3*) increases the degree of BAS immobilization to 57.3 mol %. The difference between the BAS amounts in the absence and in the presence of TEA is minor, which confirms the previously revealed capability of piperidols (in particular, ASA) for autocatalysis [2]. Figures 1 and 2 show that the temperature dependence of the degree of BAS immobilization passes through a maximum. A decrease in the content of immobilized BAS with an increase in the temperature above the optimal level is caused by the fact that esterification is an equilibrium process, and on reaching the maximal conversion the reverse process starts to prevail.

We determined the degree of immobilization of each piperidol separately. The results are given in the table. It is seen that addition of TEA increases the binding of the first component: ASA reacts almost completely within 4 h, and the degree of immobilization is 48.3 mol %, whereas the AE content is as low as 9.0%. In the absence of TEA, as seen from the table, the maximal content of ASA in the polymer decreased to 31.5%, but the degree of AE immobilization increased to 19.8 mol %. At 75 and 90°C, in the absence of the catalyst, the trend was similar; in the initial period (1–2 h), the content of both BASs was comparable, but in the subsequent period the amount of bound ASA increased and that of bound AE decreased. Thus, by varying the reaction conditions, it is possible to control the BAS ratio in the bioactive polymer.

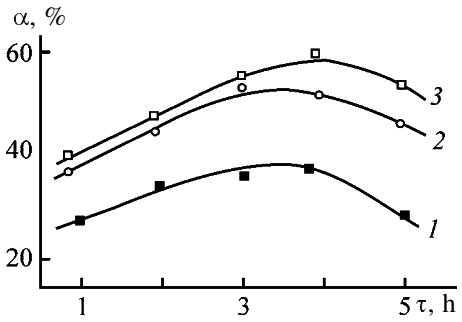


Fig. 2. Degree of immobilization α as a function of the reaction time τ at (*1*) 75 and (*2*, *3*) 90°C (*1*, *2*) in the absence and (*3*) in the presence of the catalyst.

The immobilization of Kaz-4 on StMA was studied similarly. The optimal conditions appeared to be as follows: copolymer : BAS ratio 1 : 1, 85–90°C, 3.5 h, concentration of the reactants 15–20 wt %. Under these conditions, the degree of immobilization determined by potentiometric titration was 35.4%. Addition of 1 mol of TEA per anhydride group increased this parameter to 54.0 mol %.

The use of AAMA as polymeric carrier allowed

Influence of the reaction temperature and time on the degree of BAS immobilization

T, °C	τ, h	Degree of immobilization, mol %		
		Fospinol	Akpinol	total
75	1	13.8	27.6	41.4
	2	19.1	33.3	52.4
	3	20.7	34.6	55.3

	4	28.9	47.9	76.8
	5	22.2	40.0	62.2
90 (in the presence of TEA)	1	38.4	39.3	77.7
	2	43.8	42.3	86.1
	3	48.5	48.6	97.1
	4	56.0	49.3	105.3

preparation of a water-soluble Kaz-4 polyester. We found that binding of Kaz-4 with AAMA occurs under milder conditions: concentration of the reactants 15–20 wt %, 75°C, 2.5 h; the maximal BAS content was 80.6 wt %, which is 1.5 times higher compared to the immobilization on StMA.

We also examined the influence of the TEA content on the degree of immobilization of Akpinol on AAMA. We found that, in the absence of a catalyst, the amount of the active substance did not exceed 46.0%. With introduction of the catalyst into the reaction mixture, the degree of BAS binding increased and reached 98.0% on adding 1 mol of TEA per mole of anhydride groups. At larger amounts of the catalyst, the degree of immobilization calculated from the nitrogen content exceeds 100%, which can be due only to binding of the catalyst with the carboxy group of the copolymer. Therefore, in the next step of our study we examined how the copolymer : BAS ratio affects the degree of binding of Akpinol which also contains tertiary nitrogen. We found that maximal immobilization of Akpinol (58.5 mol %) was attained at the AAMA : Akpinol ratio of 1 : 2.5. Then we examined how the amount of the immobilized substance depends on the reaction mixture concentration, temperature, and time. We found that the biopolymer with the maximal degree of binding of Akpinol with AAMA is obtained at 90–100°C in 3 h at the reaction mixture concentration of 30 wt %.

The IR spectrum of this polymer suggests the formation between the piperidol and copolymer of an ester bond (1717 cm^{-1}) and an ionic bond (absorption bands of the carboxylate ion at 1573 cm^{-1} and of the quaternary nitrogen moiety at 2528 cm^{-1}).

The character of BAS bonding with the polymer matrix suggests that, when this preparation will be used as aqueous solutions, the active agent will be released in time. The process will start with fast hydrolysis of the ionic bond (since the initial acid and base are relatively weak), which will be followed by slow hydrolysis of the ester bond. Furthermore, in contrast to Styromal-based polymeric BASs, the AAMA-based substances are soluble in water, apparently due to carboxy groups present in the copolymer. This fact makes it unnecessary to convert the polymeric BASs into potassium salts (this procedure is done with polymeric biostimulants based on maleic anhydride copolymers, in particular StMA, to make them water-soluble).

The biopolymers prepared were tested for the germination energy and germinating capacity of corns. The polymeric growth regulators showed higher, compared to the monomeric analogs, biological activity; the highest germination capacity was attained upon treatment with a 0.001% solution of polymeric Akpinol (87.3%).

The field tests showed that the biopolymer containing two growth regulators is more active than polymeric Akpinol. The polymeric growth regulators developed can be used for presowing treatment of seeds in cultivation of arid cultures (crops, saxaul) under semidesert conditions on alluvial sandy soils.

CONCLUSIONS

(1) Phytoactive polymers derived from 1,4-bis[*N*-(2-ethoxyethyl)-4-hydroxypiperid-4-yl]buta-1,3-diyne and 1,2,5-trimethyl-4-dimethoxyphosphorylpiperid-4-ol (Fospinol) with 1,4-bis(1,2,5-trimethyl-4-hydroxypiperid-4-yl)buta-1,3-diyne (Akpinol) were prepared. The optimal conditions for immobilization of these compounds on copolymers of maleic anhydride with styrene and methacrylic acid were found: copolymer : BAS : catalyst ratio 1 : 1 : 1, reation time 2.5–4 h, concentration of the reactants 15–30 wt %, temperature 90–100°C depending on the nature of the starting compounds.

(2) Tests of the polymers synthesized showed that the biopolymer prepared by immobilization of Akpinol with Fospinol on maleic anhydride–styrene copolymer is the most active.

Received March 24, 2006

Abstract—The influence of high-temperature treatment on the properties of a styrene-containing polymer prepared from by-products of polybutadiene production was studied. The use of the products in production of emulsion rubbers and for protecting treatment of wood materials was examined.

DOI: 10.1134/S1070427206110279

Polymers prepared by emulsion (co)polymerization occupy a prominent place in world industry [1–4]. Emulsion polymerization does not require hazardous, inflammable, and explosive organic solvents and yields polymers with good physicomechanical properties. Studies are continued to improve the process for production of polymers by emulsion (co)polymerization and to extend the assortment of these polymers.

Polymers can be prepared in a high yield by (co)polymerization of wastes and by-products of petrochemical industry with styrene in a solution or in the bulk in the presence of both ionic and radical initiators [5, 6]. Hence, preparation of artificial aqueous dispersions of these polymers is promising. This procedure is based on fine mechanical dispersion of a polymer in an aqueous phase containing surfactants as stabilizers. Then the solvent is distilled off and the resulting dispersion is introduced into a latex. The possibility of such modification was demonstrated in [7, 8].

The substantial disadvantage of the process developed in our previous study [7, 8] is the use of a 50–70% hydrocarbon solution of the low-molecular weight polymer for preparing dispersions. In this case, an additional step, distillation of the hydrocarbon solvent from the aqueous polymer dispersion, is required. Since the polymers prepared from petrochemical wastes are solid under the ordinary conditions, a hydrocarbon solvent is required to prepare the aqueous polymer dispersion. Hydrocarbon solvents such as toluene, xylene, Nefras (commercial solvent based on butylbenzene), etc. are used to dissolve these polymers. This additional step complicates the process and decreases its efficiency. In addition, the problem of recovery and processing of these solvents arises. To eliminate the use of a hydrocarbon solvent or to decrease its content in an aqueous polymer dispersion, the molecular weight of the polymers should be decreased and solid polymers should be converted into an oil. For this purpose, the polymers prepared from wastes and by-products of petrochemical industry are subjected to thermal oxidative treatment.

It this study we examined the influence of thermal oxidative treatment in the presence of pinane hydroperoxide on the properties of a low-molecular-weight styrene-containing polymer prepared from polybutadiene production wastes. We also studied the possibility of using the product as an additive to emulsion rubber and for protecting treatment of wood materials.

EXPERIMENTAL

First we determined the molecular weight of styrene-containing low-molecular weight polymer (SLMWP) treated at 100±2°C in the presence of pinane hydroperoxide (PH). The thermal oxidative treatment was performed by the following procedure.

A reactor equipped with a stirrer was charged with 100 g of a toluene solution of SLMWP containing 70–75 wt % of bound styrene. PH in amount of 0, 1.0, 2.0, and 3.0 wt % of the initial SLMWP was added to the solution with continuous stirring. The reaction mixture was heated to 100±2°C. The total time of the process was 30 h. Samples of the reaction mixture were taken at regular intervals, their molecular weight $\overline{M}_v$ was measured viscometrically, and the acid number was determined analytically. After treatment completion, the solvent and other low-boiling fractions were distilled off from the product.

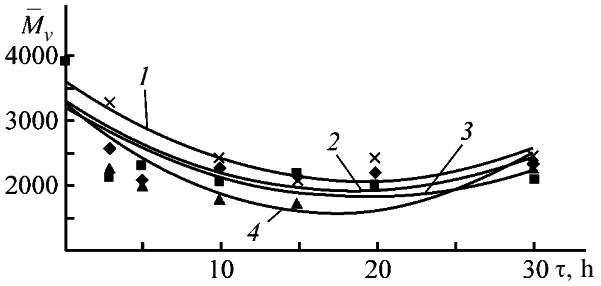

Fig. 1. Molecular weight $\overline{M}_v$ of SLMWP as a function of the time of thermal oxidative treatment τ. (*1*) Without PH and with (*2*) 1.0, (*3*) 2.0, and (*4*) 3.0 wt % of PH; the same for Fig. 2.

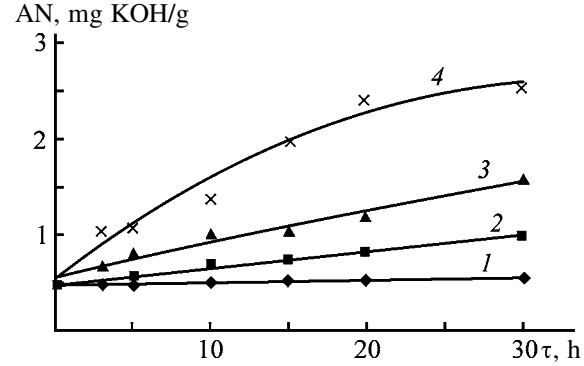

Fig. 2. Acid number AN as a function of the time of thermal oxidative treatment τ.

The molecular weight of the polymer decreases after the high-temperature (100°C) treatment of SLMWP in the presence of PH within the first 15–18 h (Fig. 1). This fact suggests that the thermal treatment involves mainly oxidative degradation to form products with oxygen-containing functional groups.

Degradation of SLMWP macromolecules can be considered as oxidative degradation of the units containing double bonds with preservation of styrene blocks [9, 10].

An increase in the acid number from 0.4–0.6 to 2.3–3.0 mg KOH/g in the whole temperature range (Fig. 2) confirms this assumption. The minimal viscosity and molecular weight are attained in 15–18 h. Then the viscosity and molecular weight of the system gradually increase, which can be due to prevalence of the cross-linking over degradation.

Low-molecular-weight polymers can cross-link to form oxygen-containing bridges.

Introduction of an additional amount of pinane hydroperoxide has a positive effect on the SLMWP modification: the molecular weight decreases to a greater extent (intensification of degradation) and the acid number increases.

Thus, our experimental data show that the properties of the products of thermal oxidative degradation can be controlled by the amount of PH added and the treatment duration. Polymers with minimal molecular weight can be prepared by treatment in the presence of 3.0 wt % PH for 15–18 h. To obtain polymers with an increased content of oxygen-containing groups (increased polarity) and a higher molecular weight, longer treatment (30 h) is required.

The molecular-weight characteristics of the initial and modified SLMWP are presented in Table 1.

Table 1. Molecular weight and content of SLMWP fractions before and after thermal oxidativer treatment*

$\overline{M}_w \times 10^{-3}$	Content of fractions, %	
	initial SLMWP	modified SLMWP
>300	0.11	–
200–300	0.19	–
100–200	0.64	–
50–100	1.57	–
20–50	4.33	–
10–20	4.92	–
5–10	4.18	0.08
3–5	13.00	1.17
1–3	31.33	20.08
0.5–1	28.96	59.26
<0.5	7.77	19.41

* According to the results of gel-permeation chromatography, SLMWP has the following molecular-weight parameters: initial, $\overline{M}_n$ = 1200, $\overline{M}_w$ = 6830, $\overline{M}_v$ = 4420, $\overline{M}_z$ = 84 173, $\overline{M}_w/\overline{M}_n$ = 5.68, $\overline{M}_z/\overline{M}_w$ = 12.33; modified, $\overline{M}_n$ = 720, $\overline{M}_w$ = 890, $\overline{M}_v$ = 850, $\overline{M}_z$ = 1260, $\overline{M}_w/\overline{M}_n$ = 1.24, $\overline{M}_z/\overline{M}_w$ = 1.42.

As seen from Table 1, the content of high-molecular-weight fraction sharply decreases, the content of the low-molecular-weight fraction increases, and the polydispersity ($\overline{M}_w/\overline{M}_n$) decreases.

As shown above, polymers prepared from petrochemical wastes can be used as fillers of emulsion polymerization rubbers, in tire and industrial rubber production, and as agents increasing the hydrophobicity and strength of wood and wood-containing articles. We tested for these applicxation SLMWP treated at high temperature in the presence of PH. We also examined the influence of the modified SLMWP on the properties of rubber, rubber stocks, vulcanizates, and wood fiberboards (WFB).

First we prepared an aqueous oligomer–antioxidant emulsion (AOAE) of modified SLMWP. A stable emulsion was obtained in the presence of emulsifiers on a unit equipped with a high-speed stirrer. An antioxidant was added to a toluene solution of modified

SLMWP and PN-6 oil (petroleum oil containing up to 14 wt % paraffin–naphthene hydrocarbons and up to 19 wt % light and up to 65 wt % medium aromatic hydrocarbons; this oil is widely used in production of extended rubbers). The mixture was stirred at 50–60°C for 0.5–2.0 h. Our preliminary results showed that no stable aqueous emulsion was formed in the presence of PN-6 oil and unmodified SLMWP without a solvent. Since these products are highly viscous, special equipment should be used for dispersing them. To prepare a stable emulsion, 20% of a solvent (toluene) was added to unmodified SLMWP and NP-6 oil.

An aqueous dispersion of SLMWP modified with PH can be prepared without introduction of a hydrocarbon solvent, since the products are oily liquids whose molecules have hydrophilic oxygen-containing functional groups.

Since the oxidative treatment of SLMWP with PH is performed in toluene, antioxidants used in production of emulsion rubber should be dissolved in an oxidized SLMWP solution prior to distillation of the solvent and low-molecular-weight products. As a result, the antioxidant will be uniformly distributed an SLMWP. Then, the solution of oxidized SLMWP and an antioxidant was emulsified and the low-molecular fraction was distilled off.

We found that the fairly uniform emulsion satisfactorily stable to phase separation can be prepared at the emulsifier content (rosin soap) of approximately 6.0 wt % and Leukanol content of 0.5 wt % relative to the dispersed phase. The content of the dispersed phase after distillation of the low-boiling fraction was 35–40 wt %.

The stable AOAE was mixed with SKS-30 ARK rubber latex and the resulting mixture was coagulated by the conventional procedure using a sodium chloride solution as a coagulating agent and a sulfuric acid solution as an acidifier [11]. The polymer content in the rubber matrix was 2.0, 3.0, 4.0, 5.0, and 6.0 wt % of the rubber and the antioxidant content was 1.2 wt % of the rubber.

Our results showed that introduction of AOAE increases the productivity of the process and results in uniform distribution of the filler in the bulk of the rubber matrix.

We prepared rubber stocks containing SLMWP samples and studied their physicomechanical properties. The optimal content of modified SLMWP in the matrix of SKS-30 ARK rubber is approximately 3.0 wt %. The strength of the vulcanizates decreases by 20–30% at the content of modified SLMWP in the rubber matrix increased to 5.0 wt %. The use of this rubber in critical articles is undesirable. However, rubber stocks with high SLMWP content can be used for preparing less critical articles such as rugs etc.

Modified SLMWP is an oily liquid whose properties are close to those of common widely used industrial oils. We performed a comparative study of the influence of SLMWP, SLMWP subjected to thermal oxidative degradation, and PN-6 oil on the properties of the rubber stocks and vulcanizates (Table 2).

Our tests of rubber stocks and vulcanizates prepared from SKS-30 ARK butadiene–styrene rubber showed that the properties of the samples containing initial and oxidized SLMWP were better than those of the samples containing PN-6 oil.

Among the positive properties of the composites are deceleration of a decrease in their strength with time, which is due to more uniform distribution of the antioxidant in the rubber matrix. In addition, the thermal resistance of the composite is enhanced.

An increase in the thermal aging coefficient is probably caused by encapsulation of the antioxidant in the areas on microheterogeneous concentration of the modified polymer. This is due to the fact that the solubility of amine and phenolic antioxidants in low-molecular-weight and more polar oxidized SLMWP is higher than that in the matrix of high-molecular-weight and low-polarity butadiene–styrene rubber. As a result, sites with high antioxidant concentrations appear in the bulk of the rubber. The concentration of the antioxidant in these sites decreases during their migration to the sample surface. Thus, this procedure for introducing antioxidants enhances the resistance of rubber articles to thermal oxidative aging and is an example of the efficient use of expensive antioxidants [12].

The next step of this study was to impregnate wood fiberboards (WFBs) with oxidized SLMWP.

The use of SLMWP treated with PH for this purpose is based on the assumption than the functional groups formed in the course of oxidation can react with the functional groups of wood components (cellulose, hemicellulose, and lignin) to form both chemical and hydrogen bonds. Formation of these bonds decreases the washout of a coating from an article in the course of its operation. The possibility of this interaction was demonstrated in our previous study [13] where a low-molecular-weight copolymer of the bottoms from styrene distillation and maleic anhydride was used for impregnation.

High-temperature treatment with PH of styrene-containing SLMWP prepared from polybutadiene production wastes sharply decreases the content of high-molecular-weight fractions and increases the content of low-molecular-weight fractions (Table 1). It should be noted that SLMWP penetrates in conductive elements of wood and gets bound with them in the course of the treatment of wood-containing materials.

The treatment was performed as follows. The WFB samples were weighed, immersed in an impregnation bath containing SLMWP subjected to thermal oxidative treatment in the presence of ~10% dryer, and kept for 1 min. Impregnation was performed at 60°C with subsequent heating at 160°C for 3 h. We chose these conditions on the basis of the known procedure for protecting treatment of wood materials by polymers prepared from petrochemical by-products [13, 14]. For impregnation we used SLMWP heated at 100°C for 17–20 h in the presence of 3.0 wt % PH.

Introduction of dryer accelerates both formation and decomposition of hydroperoxides. Intense reactions with atmospheric oxygen occur in the surface layers. In the depth of the composite, the contribution of the oxidation processes decreases owing to restricted oxygen access, and the contribution of high-temperature polymerization increases. These reactions are activated by various radicals present in the system.

Formation of films is inevitably accompanied by oxidative degradation to form compounds with carbonyl, carboxy, and hydroxy groups. The number of functional groups capable of interacting with reactive groups of lignin and cellulose increases. The probability of these processes is particularly high in the surface layers under conditions of film formation on exposure to air.

Our experimental results show that the treatment enhanced the stability of the WFB shape, its resistance to water and high humidity, and the mechanical properties (Table 3). Visual inspection of WFB sections showed a uniform distribution of oxidized SLMWP in the bulk of the board and filling of manufacturing

Table 3. Experimental properties of WFB samples treated with oxidized SLMWP

defects and of micro- and macropores. The polymer framework formed from three-dimensionally cross-linked styrene-containing SLMWP and the products of its reaction with wood components decreases the formaldehyde release from the articles prepared using phenol– or urea–formaldehyde resins as the binder.

Protective treatment of wood materials with SLMWP prepared from by-products and wastes from petrochemical industry not only improves their properties but also solves environmental problems.

CONCLUSION

High-temperature treatment of low-molecular-weight styrene-containing copolymer prepared from by-products of polybutadiene production decreases the molecular weight of the polymer and increases the content of oxygen-containing functional groups. The modified polymer can be used in production of extended rubbers and for protective treatment of wood materials.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Influence of Zone Stretching on the Properties of Semicrystalline Thermoplastic Polyimide

Abstract—The effect exerted on the crystallizability of semicrystalline polyimide by zone stretching at a temperature above the glass transition point was studied.

DOI: 10.1134/S1070427206110280

Polyimides (PIs) whose macromolecules contain "hinge" heteroatoms in the diamine and dianhydride components (PI classification group 4 [1]), having an even number of benzene rings in the diamine component of the elementary unit, can occur in amorphous or semicrystalline state, depending on the conditions of synthesis of the corresponding prepolymers, polyamido acids (PAAs), and conditions of their thermal cyclization [1, 2]. A characteristic feature of the crystalline state of the most of PIs is its irreversibility: After heating above the melting point, the sample becomes amorphous, and the crystallinity is not regained after the subsequent heat treatment. A distinctive feature of the thermoplastic polyimide ROdPO of the structure

which was the subject of this study, is the ability for recrystallization after melting. This makes it suitable as a semicrystalline matrix of composite materials with carbon fibers as filler [3, 4].

Previously [3, 4] we examined the crystallizability and recrystallizability of these PIs as influenced by the molecular weight of the PAA, introduction into PI of oligoamides of identical chemical structure, and temperature modes of imidization, melting of the crystalline phase, and recrystallization.

To analyze how the characteristics of the crystalline structure of semicrystalline PIs are influenced by the above-mentioned factors, it is necessary to prepare highly oriented polymer films with oriented crystalline phase. However, highly crystalline films of this polymer are characterized by very low breaking elongations, which substantially restricts the possibilities of their orientation stretching.

As known, many carbochain polymers, both amorphous and semicrystalline with low degrees of crystallinity, are able of crystallization in the course of the orientation stretching [5]. This allows preparation of materials with oriented crystalline phase directly during such stretching.

In this study we examined the ability of ROdPO for crystallization under uniaxial stretching conditions at temperatures above the glass transition point.

EXPERIMENTAL

The PAAs were synthesized by polycondensation of a mixture of 1,3-bis(3',4- dicarboxyphenoxy)benzene dianhydride and 4,4'-bis(4'-aminophenoxy)biphenyl in a polar solvent, *N*-methyl-2-pyrrolidone, at 25°C. Our experiments were performed with PI film samples prepared from two types of PAA:

PAA-1 with $M_w \approx 150000$, prepared at the equimolar ratio of the reactants, and PAA-2 characterized by a decreased molecular weight $M_w \approx 23500$ [6]. The latter parameter was achieved at a nonstoichiometric dianhydride : diamine ratio of 0.97 : 1.00 with addition of 0.06 mol of phthalic anhydride to block excess terminal amino groups.

The PI films were prepared by casting the PAA solutions onto glass substrates and drying at 60°C for 5 h. Thermal cyclization of the films was carried out in two modes. Mode 1 involved stepwise temperature rise from 50 to 300°C (step of 50°C, keeping time at each step 15 min, heating rate between steps 3 deg min^{-1}). Cyclization mode 2 followed the above-described procedure to 110°C, whereupon the temperature was jumpwise raised to 280°C (crystallization point of ROdPO), and then slowly (over a period of 2 h) raised to 300°C. According to [1], both these modes allow complete conversion of the prepolymer to PI.

The molecular orientation of the samples was carried out by uniaxial stretching on a setup with an Utyuzhok contact heater. The hot-zone temperature was varied from the glass transition point to the crystallization point of the PI, namely, from 215 to 280°C. The optimal temperature affording the maximal degree of stretching is 250°C. The sample passed the heated zone at a velocity of 3.5 cm min^{-1}. The stretching was performed by a multistep procedure. Each step increased the degree of stretching by 50%.

The mechanical properties of the initial and oriented samples were examined using dynamic methods and tests in the uniaxial stretching mode. The temperature dependences of the dynamic Young modulus and the mechanical loss of the samples were determined on a setup described in [7] at a frequency of 660 Hz. The main characteristic reflecting the changes in the structural parameters of the samples, prepared under different conditions, was the dynamic Young modulus measured at room temperature. The reason was that an increase in the modulus, caused by the stretching, is governed by the degree of uniaxial molecular orientation or crystallinity [8]. The deformation and strength properties were determined in the uniaxial stretching mode for samples shaped as stripes with a 1×20 mm working segment. The tests were carried out on a UTS 10 (UTStestsysteme, Germany) tensile-testing machine. During tests, the sample stretching diagram was recorded; the results of the tests allowed determination of the strength σ_t and breaking elongation ε_b. The stress relaxation at isometric heating of the oriented films was determined on a UMIV-3 setup.

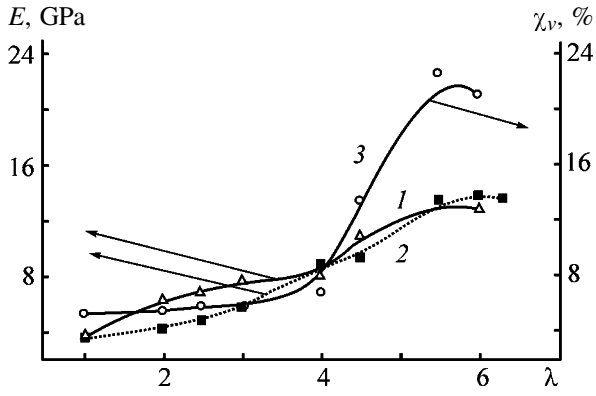

Fig. 1. (*1, 2*) Dynamic Young modulus E of the ROdPO films prepared from PAA-1 and (*3*) degree of crystallinity χ_v of the PI films prepared from PAA-1 as functions of the degree of stretching λ. Stretching temperature, °C: (*1*) 215 and (*2, 3*) 250.

The density of the samples was determined by the flotation method in a toluene–carbon tetrachloride mixture at 20°C. The experimental densities of the samples examined and densities of the amorphous phase (density after melting) of ROdPO, determined by this method, were used for estimating the degree of crystallinity of the samples by the formula [1]

$$\chi_v = \frac{\rho - \rho_a}{0.11\rho_a},$$

where χ_v is the volume degree of crystallinity; ρ, density of the sample; and ρ_a, density of the amorphisized sample.

Differential scanning calorimetric (DSC) examination of the initial and oriented samples was carried out on a DSM-2M (Specialized Designing Bureau, Pushchino) differential scanning calorimeter at a heating rate of 8 deg min^{-1}. The enthalpy of the transitions was calibrated with $KClO_4$ as reference.

The degree of crystallinity and characteristics of the transition to the oriented state for the initial film and the sample with the maximal degree of stretching were examined by X-ray diffraction analysis using a VIP-50–60 high-voltage power source, a PRF-1 X-ray accessory, and a URK-3 X-ray chamber, as well as on a DRON-3 diffractometer. We utilized Ni-filtered CuK_α radiation.

by mode 2. Our previous studies [3] showed that a high molecular weight of PAA-1 decreases the crystallizability of the polymer in the isotropic state. Indeed, the initial (not subjected to orientation) films prepared by mode 2 are distinguished by very low degrees of crystallinity (see table), although it was shown previously [2, 3] that specifically this mode is favorable for crystallization. However, subsequent stretching of such films by a factor of 4 and over is accompanied by a significant increase in the strength, a decrease in the breaking elongation, and increases in the dynamic modulus and density (see table). This suggests enhanced molecular orientation and degree of crystallinity. It should be noted that the dependences of the modulus on the degree of stretching change very little with the stretching temperature.

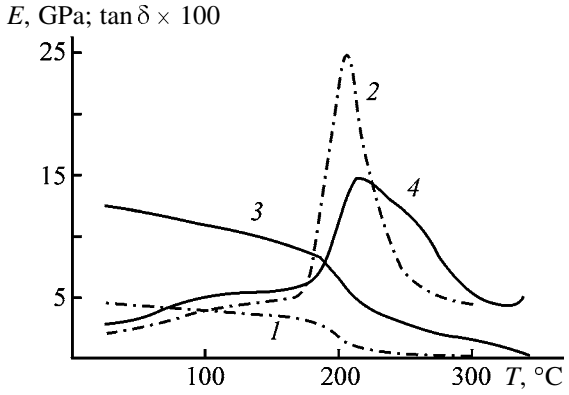

Fig. 2. Temperature dependences of (*1, 3*) the dynamic modulus E and (*2, 4*) mechanical loss tangent tan δ of the samples prepared from PAA-1, cyclized by mode 2. Sample: (*1, 2*) initial and (*3, 4*) stretched by a factor of 6.3 at 250°C.

The DSC curves showed that stretching by a factor of 6.3 of the PI sample prepared by mode 2 causes the enthalpy of melting to increase by a factor of 2.4 (see table). This can be due to an increase in the degree of crystallinity in the course of the orientation stretching.

Figure 2 presents the temperature dependences of the dynamic Young modulus and the mechanical loss tangent of the initial PI film prepared by mode 2 and the same film subjected to orientation stretching by a factor of 6.3 at 250°C. At temperatures above T_g, the modulus of the initial sample approaches that of the amorphous sample in a softened state, and that of the oriented sample is preserved up to the melting point at a significantly higher level. The mechanical loss tangent of the initial sample exhibits a narrow maximum near the softening points; the loss tangent maximum of the oriented sample is much broader, it is shifted by 10°C to higher temperatures and is asymmetric, with a shoulder near the melting points. It should be noted that such a pattern of variation of these parameters was observed for the orientation crystallization of polyethylene terephthalate [9].

Figure 3 presents the stress relaxation curve for the oriented sample at isometric stretching. It is

typical for oriented systems: With approaching the glass transition point of the polymer, the stresses in the sample significantly increase due to disorientation of the macromolecules. However, after the transition to the devitrified state, the stresses in the sample do not exhibit such a sharp decrease: The high-temperature branch of the relaxation curve contains a prominent shoulder; the stresses continue to decrease up to the melting point of RODPO. This run of the relaxation curve suggests that significant concentrations of the crystalline phase occur in the sample after the orientation stretching.

To increase the degree of crystallinity, the sample with the maximal degree of stretching was annealed for 2 h in the free state at the crystallization temperature, 280°C, which was accompanied by shrinkage of the sample and a decrease in the Young modulus (see table). At the same time, such heat treatment caused the enthalpy of melting and the degree of crystallinity (estimated from the density of the sample) to increase. The degree of crystallinity of this sample was estimated by X-ray diffraction analysis at 30%.

The PI films prepared from PAA-2 exhibit a noticeable dependence of the degree of crystallinity on the temperature and time mode of cyclization. A jumpwise mode of imidization (mode 2) allows preparation of films with a high degree of crystallinity (see table), but these samples were brittle and could not be subjected to orientation stretching. Upon heating to temperatures no higher than 320°C, these samples preserve the ability for recrystallization, but after heating to higher temperatures this ability in the isotropic state disappears [3]. To prepare oriented PI films cyclized from PAA-2 in the jumpwise mode, the initial samples with a high degree of crystallinity were amorphisized at 380°C, whereupon they were subjected to orientation stretching at 215 and 250°C.

Cyclization of PAA-2 in the jumpwise mode (mode 1) yielded films with high breaking elongations (see table) and a low degree of crystallinity. For these films, orientation stretching was achieved even in the initial state at different temperatures.

Figure 4 presents the dynamic moduli as functions of the degree of stretching at 215 and 250°C for RODPO films of two types prepared from PAA-2: imidized by mode 1 and by mode 2 with subsequent amorphization. The samples stretched at softening points (215°C) are characterized by significantly higher moduli than those stretched at 250°C. The dependences obtained for the initial samples prepared by mode 1 and those amorphisized after imidization by mode 2 and stretched at identical temperatures are close. The DSC data and the densities of these samples suggest close enthalpies of melting and crystallinities of the samples stretched at 215 and 250°C (see table, Fig. 5). Therefore, high moduli of the samples stretched at 215°C reflect, above all, a higher degree of molecular orientation, rather than a higher crystallinity compared to the films oriented at 250°C. This

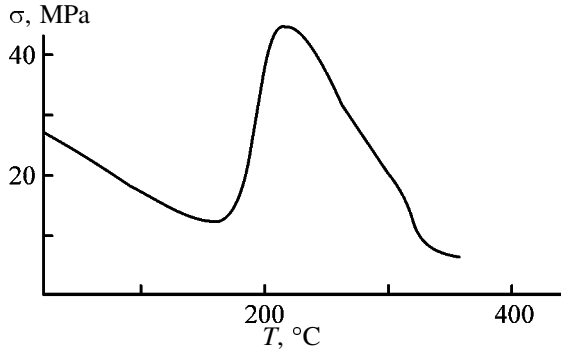

Fig. 3. Stress relaxation σ for isometric heating of the RODPO film from PAA-1, preliminarily stretched at 250°C by a factor of 6.3.

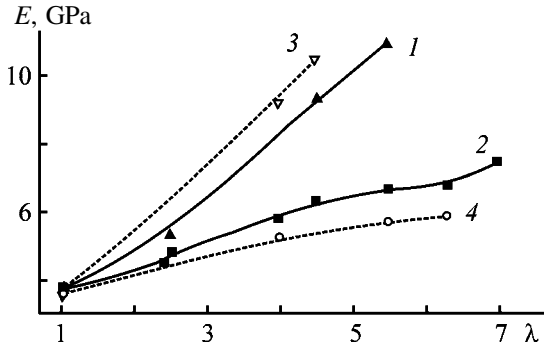

Fig. 4. Dynamic moduli *E* of the (*1, 2*) initial and (*3, 4*) amorphisized at 380°C RODPO films from PAA-2 as functions of the degree of stretching λ at (*1, 3*) 215 and (*2, 4*) 250°C.

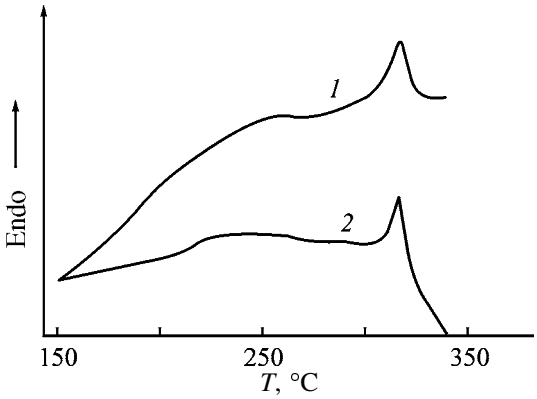

Fig. 5. DSC thermograms of the RODPO films from PAA-2, amorphisized at 380°C and subsequently stretched (*1*) by a factor of at 4.5 at 215°C and (*2*) by a factor of 5.5 at 250°C. (*T*) Temperature.

fact is confirmed by measurements of the enthalpy of disorientation of the amorphisized samples stretched at different temperatures (Fig. 5). The DCS thermograms clearly suggest thermoinduced disorientation of the preliminarily stretched samples. For samples stretched at 215°C by a factor of 4.5, this process is observed at 180–280°C and is characterized by the disorientation enthalpy of 92 J g^{-1}. For the film stretched by a factor of 5.5 at 250°C (the same process is realized at 200–280°C) we revealed a substantially lower enthalpy of disorientation, 32.5 J g^{-1}.

The influence of zone stretching on orientation of the amorphous phase was estimated from the results of the relaxation tests, as well as from measuring the shrinkages of the preliminarily oriented films as a result of heating at a temperature exceeding the stretching temperature by 5°C (see table). As known, stretching of a polymer film at temperatures above the glass transition point is realized via two kinds of strain: reversible hyperelastic and irreversible plastic strain. The former strain is realized via stretching of the macromolecules, orientation of their segments along the direction of the applied stress, and the latter, by mutual slipping of the macromolecules. Thus, the degree of molecular orientation, achieved during such stretching, is proportional specifically to the hyperelastic strain of the polymer. The plastic component of the strain should increase with increasing stretching temperature and decreasing molecular weight.

The fraction of the hyperelastic component of the strain can be estimated from the shrinkage of preliminarily stretched samples, arising from their subsequent heating at a temperature above the stretching temperature. We took specifically this approach. The shrinkage was estimated as the ratio of the length of the oriented samples before annealing L_0 to that after annealing L_1. The remainder of the strain of the sample during stretching is accounted for by plastic strain. The tabulated shrinkages of the samples stretched under different conditions to identical degrees suggest an increase in the fraction of plastic strain for the samples prepared from low-molecular-weight PAA (PAA-2) with rising stretching temperature. This agrees well with the Young moduli of the samples stretched at different temperatures. Our data confirm the fact that stretching of the samples prepared from PAA-2 at 215°C affords a higher molecular orientation than stretching to the same degrees at 250°C.

The shrinkages and elasticity moduli of the samples prepared from PAA-1 and stretched to identical degrees at 215 and 250°C are close. Hence, the hyperelastic strains in stretching at both temperatures are also close. It should be noted that, at high-temperature stretching of these samples, the hyperelastic strains are higher than those of the samples prepared from low-molecular-weight PAA-2 (see table).

The strength characteristics of the films prepared from PAA-1 and PAA-2 in the initial state are very close. However, upon stretching at 250°C by a factor of 4.5, these films substantially differ in the strengths (see table). Higher strengths of the stretched ROdPO samples prepared from PAA-1 suggest a higher degree of their molecular orientation.

Our results show that the orientation stretching substantially affects the crystallizability of the ROdPO polyimide samples. Such treatment of the films causes the degree of crystallinity of the PI to increase at temperatures below the crystallization point. This afforded a high degree of crystallinity for the samples prepared from high-molecular-weight PAA-1, whose crystallizabilty in the isotropic state is very low. The tabulated data suggest that stretching of these samples affords a higher degree of crystallinity than for the samples of PAA-2 stretched under identical conditions.

Further increase (above 250°C) in the temperature of stretching did not enhance the degrees of stretching, molecular orientation, and crystallinity of ROdPO. The table presents the parameters of the sample stretched to the prefailure state at the crystallization temperature (280°C). The enthalpy of melting, the Young modulus, and the degree of crystallinity of this sample proved to be lower than those of the samples stretched to the same degree at 250°C. This effect is due to the fact that, at so high temperatures, intensive relaxation processes occur in the sample directly during stretching.

Our studies showed that, taking into account all the competing processes occurring in the course of zone stretching, such as molecular orientation, crystallization, and relaxation, a multistep stretching at 250°C at the above-mentioned rate is the optimal mode for preparation of samples with the maximal degree of crystallinity.

The samples prepared by stretching in this mode were examined by wide-angle X-ray diffraction analysis. Figure 6 presents the X-ray diffraction patterns of the initial film prepared from PAA-2, imidized by mode 2 and crystallized in the isotropic state (Fig. 6a), as well as of the film prepared from PAA-1, imidized by the same mode and crystallized in the course of a sixfold stretching at 250°C (Fig. b).

Figure 6a shows that the initial film prepared by

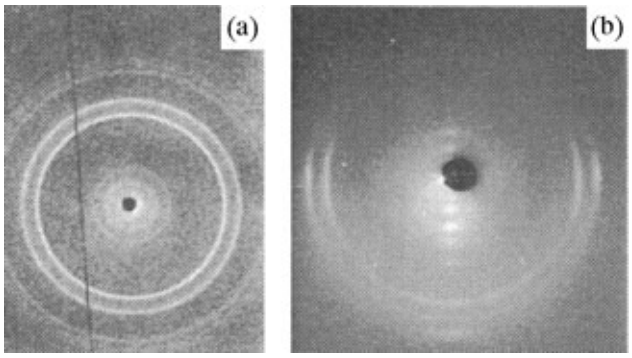

Fig. 6. X-ray diffraction patterns of the sample crystallized (a) in isotropic state and (b) during stretching by a factor of 6.3 at 250°C.

the above-described procedure is a nonoriented film and occurs in a semicrystalline state. The film subjected to a sixfold stretching is also semicrystalline. The degree of orientation of the crystallites is fairly low. Against the background of continuous rings, areas of increased intensity are prominent at the X-ray diffraction pattern equator within 30°. The orientation stretching of the weakly crystallized initial film causes the degree of crystallinity to increase, but the orientation of the crystalline phase proper is insignificant.

It can be assumed that the molecular orientation in the PI examined proceeds by orientation of the segments of the macromolecules in the amorphous phase, and a weak orientation of the crystallites is due to a low anisotropy of the shape of the crystalline domains.

CONCLUSIONS

(1) Orientation stretching at temperatures above the glass transition point to degrees of stretching above 4 noticeably increases the degree of crystallinity of the films of thermoplastic semicrystalline RODPO polyimide. This effect is observed both for the samples prepared from low-molecular-weight polyamido acids, whose degree of crystallinity in the isotropic state can be widely varied by varying the temperature–time mode of cyclization, and for the samples prepared from high-molecular-weight polyamido acids.

(2) This procedure is suitable for crystallization of samples preliminarily amorphisized at a high temperature, which do not crystallize in the isotropic state.

(3) Zone stretching does not afford significant orientation of the crystallites.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Specific Features of Separate and Joint Mastication of Natural and 1,4-*cis*-Butadiene Rubbers in the Presence of Dibenzoylaminodiphenyl Disulfide

Abstract—Variation of the molecular structure characteristics and properties of natural and 1,4-*cis*-polybutadiene rubbers (gel content, molecular weight, degree of branching of macromolecules, viscosity) in the course of their separate and joint mastication in the presence of dibenzoylaminodiphenyl sulfide as mastication accelerator or without it was studied.

DOI: 10.1134/S1070427206110292

Natural rubber (NR) and its blends with other rubbers (e.g., *cis*-butadiene rubber, SKD) are widely used in rubber industry, in particular, for production of treads and sidewalls of R-type tyres. Industrial processing of NR is more labor- and power-consuming than that of synthetic rubbers, because it requires preliminary mastication with the aim to decrease the molecular weight and viscosity to the level suitable for processing into rubber stocks and semifinished products on the existing equipment. With polymer blends, the viscosity of compounds can be significantly decreased owing not only to a decrease in the molecular weight of rubber macromolecules, but also to formation of a specific structure. The causes of such a decrease in the viscosity of blends consisting of different rubbers are described in detail [1]. The most pronounced decrease in the viscosity of NR–SKD blends, measured at shear rates less than 100 s^{-1}, is observed at their ratios in the range from 80/20 to 50/50 [2]. However, in view of the free-radical nature of mechanochemical reactions, we should take into account the possibility of recombination of free radicals [3], which can lead to an increase in the molecular weight and decrease in the mastication effect.

It is well known that the molecular weight of rubbers can be decreased by introducing special additives, so-called chemical mastication accelerators [3, 4]. In this connection, it is appropriate to study specific features of joint mastication of NR and SKD in the presence of a commercially used additive, dibenzoylaminodiphenyl disulfide (DBADD), and without it.

DBADD

The commercial name of the accelerator is Pepton-22. It is a light yellow crystalline powder melting at 136–143°C [5].

EXPERIMENTAL

Experiments were performed with RSS-1 NR (Indonesia), SKD [GOST (State Standard) 14924–73], and an NR–SKD blend (1 : 1). The mastication of NR, SKD, and their blends was performed on Lb 320 160/160 laboratory rollers with addition of DBADD (0.3 wt % relative to rubber) or without it. The clearance between the rollers was 2.3 mm at a friction of 1 : 1.14. The mastication was performed for 5, 10, and 15 min. DBADD mastication accelerator was added in all the cases on the second minute after the rubbers adhere to the roller at the initial rubber temperature of 35°C. In the course of mastication, the rubber temperature increased to 75–80°C.

To evaluate changes in the rubber structure, we determined viscometrically at 25°C the intrinsic vis-

cosity [η] of the sol fraction soluble in toluene. From the slope of the linear concentration dependence of the reduced viscosity, we determined the branching coefficient from which we calculated the Huggins constant K_H characterizing the degree of macromolecule banching [6].

The content of the gel (insoluble fraction) was determined by two methods: from the weight of the residue on the filter and from the difference in the solution concentrations before and after filtration. From these data, we determined the constant of mechanical degradation K_σ and the degree of degradation φ [3]. The degradation constant was calculated by the equation

$$(\eta_t - \eta_\infty)/(\eta_0 - \eta_\infty) = \exp(-K_\sigma t), \quad (1)$$

where η_0, η_t, and η_∞ are the intrinsic viscosities of the rubber before rolling, after the treatment for time t, and after the 60-min treatment (limiting degradation).

The degree of degradation was calculated as

$$\varphi = (\eta_0 - \eta_t)/(\eta_0 - \eta_\infty). \quad (2)$$

The viscosity of rubbers and their blends was determined on a Mooney shear disk viscometer and evaluated in Mooney units (1 Mooney unit = 0.0846 N m) [7].

Table 1 shows how the rolling time τ and DBADD content affect the properties and molecular characteristics of NR, SKD, and their blends, and Table 2 shows how these factors affect the constant of mechanical degradation and degree of degradation of these materials.

An increase in the time of NR mastication without chemical accelerator is accompanied by a monotonic decrease in the gel content, intrinsic viscosity, and Mooney viscosity. The degree of degradation grows monotonically, but there is no definite trend in variation of the degree of branching: In the case of NR, it first decreases upon mastication for 5 min and then gradually increases. This may be due to the development of nonlinear degradation [3]. On the whole, the changes observed are consistent with the well-known views [8] that the viscosity of polymers in the condensed state of macromolecules decreases with a decrease in the gel content and in the molecular weight and with an increase in the degree of branching.

Table 2. Influence of the rolling time and DBADD content on the constant of mechanochemical degradation K_α and degree of degradation φ of NR and SKD

Sample	τ, min	K_σ, min	φ
NR:

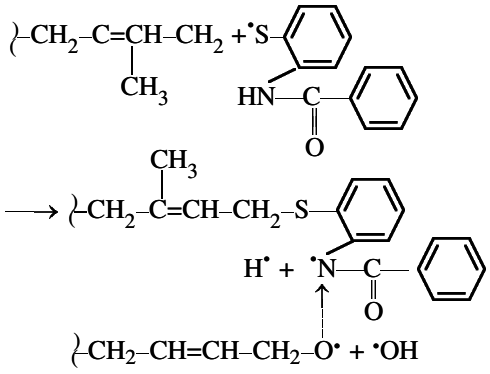
without DBADD	5	0.008	0.039
	10		0.078
	15		0.095
with DBADD	5	0.013	0.256
	10		0.191
	15		0.182

Addition of DBADD mastication accelerator noticeably increases the rate and degree of degradation of NR and SKD macromolecules. At the same time, more pronounced decrease in molecular weight (MW) at a mastication time of 5 and 10 min results in increased branching of macromolecules in the sol fraction and higher gel content in the masticated rubber. For example, after mastication of NR for 5 min, the branching of the macromolecules is characterized by the Huggins constant of 0.57 $(\text{dl g}^{-1})^{-2}$ and gel content in the masticated rubber of 4.43%; after rolling for 10 min, these parameters become 0.96 $(\text{dl g}^{-1})^{-2}$ and 3.45%, respectively. Longer rolling (15 min) results in a certain increase, rather than decrease, in the molecular weight; in the process, the degree of branching and gel content sharply decrease: from 0.96 to 0.33 $(\text{dl g}^{-1})^{-2}$ and from 3.45 to 1.55%, respectively. The Mooney viscosity monotonically decreases. Larger branching of macromolecules observed in the initial period of mastication in the presence of mastication accelerator indicates that the major pathways of deactivation of polymeric radicals in the initial period of the process are their recombination and reaction with nondegraded macromolecules, rather than addition of the sulfide radical of DBADD. Longer mastication results in more uniform distribution of the mastication accelerator and hence in higher probability of the reaction of polymeric radicals with DBADD. The high melting point of DBADD also plays a certain role, impeding its dispersion at the mastication temperature of 75–80°C.

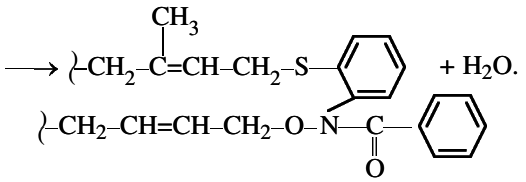
Thus, mastication of NR for 15 min without mastication accelerator results in the formation of a rubber structure with decreased MW and increased branching of macromolecules. In the presence of DBADD, a decrease in the molecular weight is accompanied by a decrease in the polymer chain branching.

An increase in the time of SKD mastication without accelerator to 15 min results in monotonic but slight decrease in the molecular weight, with the Huggins constant increasing (from 0.14 to 0.33). The gel content in the initial period of the mastication decreases, but after the treatment for 15 min somewhat increases. The observed changes in the structure do not lead to noticeable changes in the Mooney viscosity. Addition of the mastication accelerator leads to a more noticeable decrease in the molecular weight of SKD rubber, with a considerable increase in the Huggins constant (to 0.67). An increase in the mastication time to 10 and 15 min results in a certain increase, rather than decrease, in the molecular weight. At the same time, the degree of branching of the macromolecules decreases to 0.39, and the gel content in the masticated rubber somewhat increases. The trends in the kinetics of degradation and branching of SKD and NR show certain analogy determined, as noted above, by decelerated dispersion of the mastication accelerator in the rubber matrix due to high melting point of its crystals.

Joint mastication of NR and SKD without mastication accelerator leads to a decrease in the intrinsic viscosity of the rubber blend, indicative of a decrease in the MW of the elastomeric components. The intrinsic viscosity of the rubber blend is close to the additive value. At the same time, macromolecules in the ash are characterized by increased degree of branching relative to the sum of the contributions of the components at the separate mastication. The masticated rubbers are characterized by the increased gel content, which imparts to them higher Mooney viscosity. Apparently, higher branching of macromolecules in the sol fractions is due to recmobination of chain radicals of NR and SKD, and also to the presence of fragments of the three-dimensional structure of the initial gel, which is broken down during mastication. Somewhat lower degree of the gel degradation may be caused by the lower shear stress in the initial period of the mastication, due to a decrease in the initial viscosity of the combined system [1].



The effect of DBADD on the elastomer blend is similar to its effect in mastication of each rubber taken separately. More pronounced decrease in the MW in the initial period of the process (the intrinsic viscosity decreases from 3.27 in rolling without accelerator to



2.97 in the presence of DBADD) is accompanied by its increase with an increase in the mastication time. Initially high values of the Huggins constant decrease in the course of the mastication. At the same time, the gel content in the masticated rubber increases.

In joint mastication of NR and SKD both in the presence of DBADD and without it, the degree of branching of macromolecules and the gel content in the masticated rubber are higher than in mastication of the rubbers taken separately. This fact indicates that the role of the recombination of polymeric radicals and their reaction with macromolecules in rubber blends is more significant. It was interesting to additionally estimate the probability of the reaction of chain radicals belonging to different elastomers. To this end, the sol fraction of 1 : 1 NR + SKD blends masticated in the presence of DBADD and without it (rolling time 15 min) was dried and subjected to quantitative analysis by pyrolytic gas chromatography (Biokhrom-1 chromatograph):

Masticated rubber	NR/SKD rubber content in sol fraction, %
Without DBADD	50/50
With DBADD	55/45

These data show that, in the mastication without DBADD, the ratio of the rubbers in the sol fraction and hence in the gel is equal to their initial ratio. This fact suggests (though tentatively) formation of a chemical bond NR–SKD, which also follows from the stronger branching of the blended masticated rubber. In the joint mastication of NR and SKD with DBADD, a part of the macromolecules becomes incorporated in the gel structure. This fact also suggests that the joint mastication of NR and SKD is accompanied by chemical reaction of the chain radicals of different elastomers. The following scheme of formation of a chemical bond between polyisoprene and polybutadiene radicals in the presence of DBADD can be suggested:

The primary or peroxy radical of polyisoprene reacts with *o*-benzoylaminophenylthio radical to form macromolecules incorporating an amine-type antioxidant. Hydroperoxides of butadiene rubber, forming successively or simultaneously, readily decompose into products to form low-molecular-weight and chain radicals [3, 4]. These radical chemically bind the amine radical which is already bound chemically to a polyisoprene macromolecule. Repeated degradation of the linked chains can lead to an increase in their molecular weight, branching, and gel formation. The sequence of the reactions of polyisoprene or polybutadiene radicals with DBADD is apparently random. Thus, on the one hand, DBADD accelerates the mastication of *cis*-1,4-polyisoprene and *cis*-1,4-polybutadiene whose addition favors a decrease in MW; on the other hand, DBADD is an antioxidant and acts oppositely, promoting formation of interpolymers and enhancing the interactions at phase boundaries of different rubbers. It should also be noted that this accelerator is the most effective at treatment temperatures in the range 80–140°C [9]. This is apparently associated with its high melting point. In the course of mastication in closed rubber mixers and preparation of rubber stocks, rubbers are subject to simultaneous action of the mechanical and thermal energy. The temperature of extended rubber stocks in their preparation in closed rubber mixers increases to 160°C and more [5], which should lead to prevalence of processes leading to a decrease in the molecular weight.

In this study we examined the possibility of preparing rubber stocks with NR and performing the mastication directly in the step of stock preparation. Under industrial conditions, we prepared tread rubber stocks from nonmasticated NR in combination with SKD (85/15), with addition of 0.3 wt % DBADD in the first step of compounding. The properties of the experimental rubber stocks and vulcanized products were compared with those of the commercial product of the same composition in which NR was taken as P-3 masticated rubber prepared in a rubber mixer without mastication accelerator. The experimental and commercial rubber stocks were prepared under the same conditions. Their technological properties appeared to be the same. At the same time, vulcanized

Table 3. Physicomechanical parameters of vulcanized rubber stocks prepared by joint mastication of NR with SKD in the presence of DBADD

Parameter	Reference	Experimental value
Nominal tensile strength, MPa	171	187
Rebound elasticity, 20°C/100°C, %	38/50	41/56
Endurance at repeated 150% extension, thousands of cycles	35.1	53.7
Coefficient of resistance to thermal aging* at 100°C, 48 h, with respect to:		
nominal strength	0.73	0.84
relative elongation	0.58	0.69
tear resistance	0.70	0.97
De Matthias head buildup, T, °C:		
before aging	123	111
after aging at 100°C, 48 h	142	128
Mir-1 abradability, $m^3\ TJ^{-1}$:		
before aging	80	62.2
after aging at 100°C, 48 h	133.9	110.5
Schopper abradability, mm^3	64	58

* The coefficient of resistance to thermal aging is defined as the ratio of the indicated parameter before aging to that after aging.

products from experimental rubber stocks exhibit higher values of certain parameters (Table 3), in particular, higher elasticity, higher endurance at repeated extension, and lower heat buildup, which is attributable to weaker branching of NR macromolecules, at a considerably higher content of NR compared to SKD. Experimental rubbers have also a higher coefficient of resistance to thermal aging and wear. In this case, DBADD behaves as an aging inhibitor. According to [10], stabilizers incorporated in the polymer chain decrease the abradability of rubbers. Also possible is a positive effect of stronger bonding between the phases, due to formation of interpolymers of types NR–SKD and NR–DBADD–SKD.

CONCLUSIONS

(1) In separate mastication of natural and 1,4-*cis*-butadiene rubbers without using dibenzoylaminodiphenyl disulfide as mastication accelerator, the molecular weight monotonically decreases and the degree of branching of the macromolecules increases. In the presence of this mastication accelerator, the pattern is different.

(2) In joint mastication of natural and 1,4-*cis*-butadiene rubbers in the presence of dibenzoylaminodiphenyl disulfide and without it, the degree of branching of the macromolecules, gel content, and Mooney viscosity of the masticated rubbers are higher than the sum of the contributions of the components, determined at their separate mastication.

(3) Joint mastication of natural and 1,4-*cis*-butadiene rubbers can be combined in one step with the preparation of extended rubber stocks in closed rubber mixers in the presence of dibenzoylaminodiphenyl disulfide. The resulting stocks exhibit the required processing characteristics, and the physicomechanical properties of the resulting vulcanizates are improved owing to weaker branching of natural rubber macromolecules, incorporation of an *o*-benzoylaminophenylthio fragment, behaving as amine-type antioxidant, in the macromolecules, and stronger bonding between the polymer phases owing to formation of interpolymers.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Combination of Oxidative and Hydrolytic Functions of Nitric Acid in Production of Enterosorbents Based on Carboxylated Microcrystalline Cellulose

Abstract—A single-stage procedure was developed for preparing carboxylated microcrystalline cellulose from native cellulose in 45–55% nitric acid acting as a deposited form of catalyst of cellulose oxidation, nitrogen(IV) oxide, and as a selective reagent partially hydrolyzing cellulose.

DOI: 10.1134/S1070427206110309

According to the results of clinical trials in gastroenterology and detoxication therapy [1–3], carboxylated microcrystalline cellulose (CMCC) in the form of gels of its salt species [4] is an efficient enterosorbent with clearly pronounced coating and antiulcerogenic effects. The necessity of developing this type of enterosorbents stems from the following reasons. Widespread carbon enterosorbents cannot substitute in full measure enterosorbents of polysaccharide nature, food fibers adapted to human digestive system in the overall course of evolution. Traditional use of natural polyuronides in enterosorption is complicated by the possibility of accumulation of toxic substances from the biosphere in the vegetation period [5]. As regards high degree of chemical purity, among polysaccharides not digested in a human body, microcrystalline cellulose (MCC) deserves particular attention. In its production, foreign impurities accumulated predominantly in the structurally disordered component of the fiber precursor are removed together with this component in the course of hydrolytic cleavage of the fiber to so-called limited degree of polymerization (DP) [6].

Microcrystalline cellulose is widely used as a filler in production of many drugs, as a dietetic additive decreasing the caloric value of the food ration, and also as a remedy for removal of a dross from gastrointestinal tract. The possibility of using MCC in pharmaceutical and food industry is significantly widened by its unique ability to form stable thixotropic gels under the action of high shearing dynamic stresses on 5–20% aqueous dispersions [6]. However, the efficiency of MCC as enterosorbent is limited by the absence of ion-exchange groups that are contained in pectins and polysaccharides of seaweed (laminarin, carraginan).

Previously [1] CMCC was prepared by oxidation of cellulose with nitrogen(IV) oxide at room temperature in the gas phase followed by hydrolysis of the oxidized fiber to the microcrystalline state with a mixture of boiling dilute nitric and nitrous acids formed upon addition of the calculated amount of water into the oxidizing system. Implementation of this two-stage procedure allowing production of CMCC of high quality (increased stability, whiteness, and gel-forming ability) involves technical and environmenyal problems caused by direct use of a highly volatile (bp 21.2°C), toxic, and deleterious nitrogen(IV) oxide catalyzing the oxidation. First of all, consideration must be given to the problems of transportation and storage of nitrogen(IV) oxide. These problems can be largely solved using a "deposited" form of nitrogen(IV) oxide, in particular, nitric acid capable of generating the oxidation catalyst in situ under certain conditions of the reaction with cellulose. The aim of this study was testing of this approach to synthesis of CMCC and also comparison of the physicochemical characteristics of the resulting products.

EXPERIMENTAL

As in the previous study [1], the initial material for the synthesis of CMCC was bleached coniferous sulfite cellulose of the SS type (Bratsk Pulp and Paper

Plant) in the form of pulp which was cut into fragments 1×1 cm in size before charging into the reactor. The initial concentration of nitric acid of pure grade produced by the Azot Production Association (Grodno) was 59%.

The experiments were performed in a temperature-controlled glass reactor equipped with a reflux condenser, a thermometer, and a stirrer. The reaction products were repeatedly squeezed and washed to completely remove nitrate ions (test with diphenylamine). For analysis, a part of the resulting CMCC was dried at 60°C, milled in a mortar, and fractions passing through a sieve with a cell size of 100 μm were taken. For preparing hydrogels, we used the moist form of CMCC (washed and squeezed). The content of carboxy groups in CMCC was determined by the barium acetate method [7]. The content of "bound" nitrogen in the form of nitrate ester groups was determined by the Kjeldahl method [8]. The IR spectra of the samples pressed in KBr pellets were recorded on a Specord 75 IR spectrophotometer.

The X-ray patterns of the samples were recorded on an HZG-4a diffractometer (CuK_α radiation, Ni filter) at a scanning rate of the scintillation quantum counter of 1 deg min^{-1}. The samples for recording were prepared in the form of plane discs of the same weight by pressing.

The morphology of particles of dispersed phase of hydrogels was studied with an EM-125K transmission electron microscope. A drop of 10% hydrogel was diluted to a slightly opalescent suspension, which was irradiated with ultrasound (a UZDN-2T unit), applied to the surface of freshly split mica, and dried. The samples for examination were prepared by the method of palladium–carbon replicas.

The sorption of Methylene Blue with CMCC hydrogels (recalculated to dry substance) was determined from the residual concentration of the dye in the solution with a KFK-2UKhL 4.2 photoelectric colorimeter (λ = 450 nm, green filter). A calibration curve of the dependence of the solution optical density on the dye concentration was plotted preliminarily. The weight of the dry sorbent in all cases was approximately 0.3 g, the volume of the dye solution of the given concentration was 50 ml, and solution pH was 6.5–7.0.

The synthesis of oxidized powder-like cellulose using only HNO_3 without auxiliary additives (e.g., $NaNO_2$) stimulating formation of the oxidation catalyst, nitrogen dioxide, was described in Heuser's monograph [9]. In that monograph, with the reference to an earlier publication (*Berichte*, 1899, vol. 32, p. 2592), it was suggested that under heating of cotton with 49% HNO_3 nitrogen oxides are vigorously released and cellulose is oxidized with simultaneous conversion of the fiber into a powder-like substance.

These data were used previously for production of uniformly oxidized structurally disordered powder cellulose with a fairly high content of carboxy groups (12.3–18.3 wt %)[1] [10]. For this purpose, cellulose was preactivated with 68.5% HNO_3 to form a Knecht adduct which was oxidized with the same acid diluted to 55% concentration. Incorporation of HNO_3 molecules into the cellulose crystal lattice in the activation stage provided a high rate and uniformity of oxidation and, correspondingly, decrystallization of the initial material.

The aim of this work was to design a single-stage procedure of synthesis of a material combining ion-exchange properties with the characteristics of MCC, first of all, gel-forming ability. It is evident that solving this problem is possible only under conditions of intercrystalline reaction of cellulose with HNO_3 in which oxidation of crystalline grains is limited with their surface. This predetermines fairly low degree of cellulose oxidation excluding transformation of the reaction into intracrystalline reaction. Decrystallization of the initial material under conditions of intracrystalline reactions adversely affects the yield and morphology of the final product [1, 10]. The content of carboxy groups in previously synthesized CMCC preparations that showed high efficiency in enterosorption [1–4] did not exceed 4.8 wt %, which is comparable with the content of free carboxy groups in pectins.

Considering published data [9, 10], we tested the conditions of the reaction of cellulose with HNO_3 that seemed to be appropriate for our case. The curve describing accumulation of carboxy groups in the reaction of cellulose with 55% HNO_3 at 70°C is shown in Fig. 1. As seen, the course of oxidation is typical for heterogeneous transformations of cellulose, whose degree is limited by low accessibility of the crystalline "component" of the fiber. The results of our experiments are presented in the table; they show that increases in the HNO_3 concentration, temperature, and the reaction duration promote two parallel processes: cellulose oxidation and its hydrolytic cleavage. Accumulation of carboxy groups in cellulose is accompanied by a decrease in the yield of the final product. This can be explained by the fact that high rate and degree of hydrolytic cleavage of cellulose stimu-

[1] Theoretically, at oxidation of the sixth carbon atom of all anhydroglucose units of cellulose, the content of COOH groups is 25.57 wt %.

50	3	70	4.8	80
50	5	70	5.5	76
50	5	60	3.6	82
55	3	70	5.8	75
55	3	60	3.5	83

late oxidation, since the hydrolysis products act as reducing agents additionally (along with temperature) promoting formation of nitrogen dioxide in the system [11]. The activation energy of heterogeneous acid hydrolysis of cellulose is fairly high (approximately 150 kJ [12]); therefore, its rate strongly depends on temperature. A decrease in the reaction temperature from 70°C to 60°C noticeably increases the yield of the final product and, correspondingly, weakens factors stimulating the oxidation (see table). The reaction of cellulose with fairly strong HNO_3 under the conditions presented in the table gives the oxidized product in a high yield (75–83%) comparable to the adequate yield of the ordinary MCC from wood cellulose by the classic scheme of recovery with dilute boiling mineral acids [6]. This fact indirectly suggests formation of the microcrystalline form of oxidized cellulose, although, according to published data [6], the hydrolytic selectivity with respect to structurally disordered areas of cellulose fiber is typical for dilute (2–3 N) boiling mineral acids, first of all HCl.

In the IR spectra of the resulting products (Fig. 2), there is an absorption band at 1730 cm^{-1} belonging to the C=O stretching modes of carboxy groups and typical for monocarboxy cellulose. Its intensity regularly increases with increasing content of COOH groups determined by the barium acetate method. Extremely low intensity or practical absence of absorption bands at 1650, 1280, 850, and 750 cm^{-1} in the spectra are indicative of trace content of nitrate ester groups in the samples. Analysis by the Kjeldahl method showed that the sample prepared under the most severe reaction conditions (55% HNO_3, 70°C, 3 h) contains approximately 0.3% bound nitrogen, which is in the limits of the determination error. It is likely that nitrate ester groups are removed from the final products in the course of partial hydrolysis of cellulose. In the spectra of the samples of oxidized cellulose, the absorption

bands in the range 1315–1375 cm^{-1} and in the low-frequency range 400–700 cm^{-1}, interpreted as the "crystallinity" bands [13, 14], are more pronounced in comparison with the spectrum of the initial cellulose. Thus, the synthesized monocarboxy cellulose surpasses the initial cellulose in the degree of crystallinity, which, considering the weight loss of 17–25% in the reaction with HNO_3 (see table), can be due only to the formation of a microcrystalline structure.

The conclusions based on the IR data are confirmed by data of the X-ray phase analysis (Fig. 3). The reflections in the X-ray pattern of the acidic form (H-CMCC) are stronger and more discrete than those in the X-ray pattern of the initial cellulose, which is quite natural for the transition from cellulose to its microcrystalline modification free of the structurally disordered component. An additional cause of increasing crystallinity of the reaction products of cellulose with HNO_3 can be cellulose refining due to its hydrolytic cleavage in oxidizing medium. These hydrolysis conditions should, in particular, promote additional oxidation of carbonyl groups. The cellulose refining is visually manifested in a noticeable increase in the whiteness of the final products in comparison with the initial cellulose. An increase in the crystallinity of cellulose upon introduction of carboxy groups (disturbing the regularity in the structure of macromolecules) is a strong evidence of localization of these groups at the crystallite grain surface.

The hydrogel state is the most efficient form of CMCC allowing realization of its sorption and, in particular, cation-exchange potential in full measure [1]. In addition, it is convenient for production of CMCC compositions with vitamins, minerals, biologically active fatty components, microorganism strains, drugs, and thus for design of new drug forms, including those with a prolonged effect (ointments, microcapsules) [2–4].

The acidic form of the reaction products of cellulose with HNO_3 (H-CMCC) is able to form stable hydrogels under conditions of using special high-speed (approximately 20000 rpm) mixers of the cutting type. Only applying a high shearing dynamic load provides disaggregation of microcrystals required for formation of a stable cohesive dispersion system. As regards gel formation, the behavior of H-CMCC differs only slightly from that of the ordinary MCC. A well-known procedure facilitating gel formation of MCC is addition of 8–10 wt % of water-soluble Na-carboxymethyl cellulose in the final stage of the synthesis [6]. This additive coats microcrystals, playing a role of peculiar "barrier" substance preventing

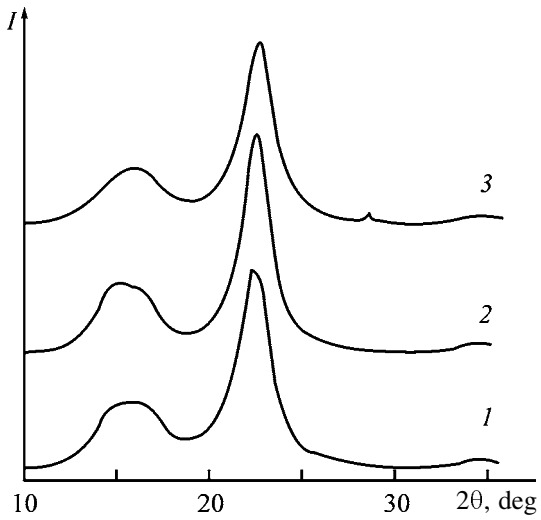

Fig. 3. X-ray patterns. Sample: (*1*) initial cellulose; (*2, 3*) H- and Na-CMCC, respectively, with 5.8% content of carboxy groups. (*I*) Relative intensity and (2θ) Bragg angle.

formation of stable associates in synthesis of dry MCC and promoting disaggregation of microcrystals when dispersing their associates in an aqueous medium.

Hydrogels are formed extremely readily in conversion of H-CMCC into salt forms, sodium or lithium salts. High-speed mixers are not required, ordinary domestic mixers are quite sufficient. The hydrogels were prepared in neutralization of moist (washed and squeezed) H-CMCC with a solution of alkali metal hydroxide under stirring. The amount of hydroxide required for neutralization was determined based on the content of carboxy groups in H-CMCC. The completeness of salt formation follows from a comparison of the IR spectra of dry samples of H-CMCC and Na-CMCC (Fig. 2). The strong absorption band at 1730 cm^{-1} in the spectrum of H-CMCC, caused by the C=O stretching modes of carboxy groups, practically completely disappears. Instead, a strong band at 1610 cm^{-1} corresponding to stretching modes of carboxylate groups [15] appears in the spectrum of Na-CMCC. Conversion of H-CMCC into NaCMCC is accompanied by significant weakening of the above-mentioned bands of cellulose "crystallinity." Under the experimental conditions with low-speed mixers we obtained creamy hydrogels containing 10 ± 0.5 wt % CMCC salt with pH 6.5–7.0.

The Na-CMCC hydrogels prepared do not show any signs of settling in storage for many months at a temperature of approximately 5°C. They have clearly pronounced thixotropy: they are structured with time, losing fluidity, but become fluid after shaking.

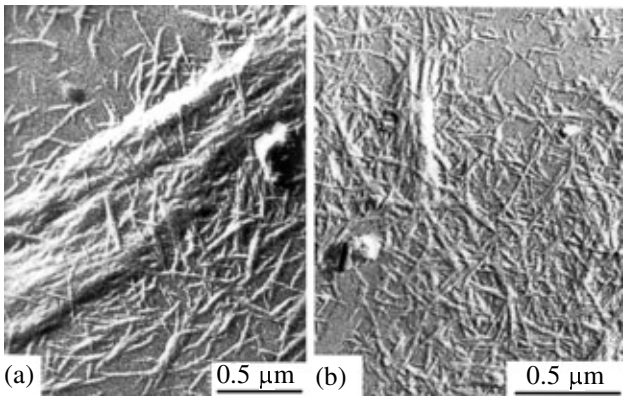

Fig. 4. Electron micrographs of particles of dispersed phase of (a) H-CMCC and (b) Na-CMCC hydrogels with 5.8% content of carboxy groups.

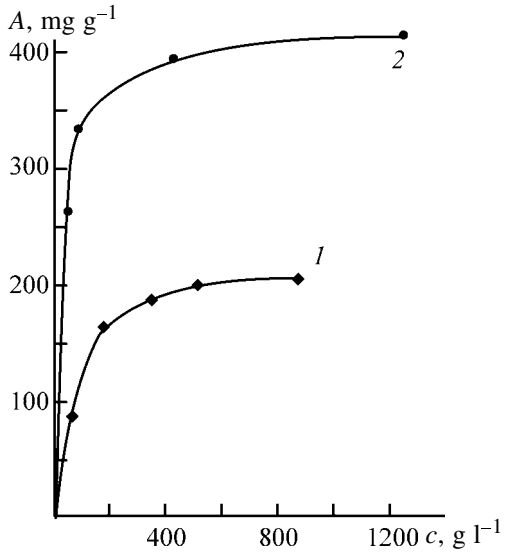

Fig. 5. Sorption isotherms of MB with 10% (*1*) H-CMCC and (*2*) Na-CMCC hydrogels with 5.8% content of carboxy groups. (*A*) Sorption and (*c*) equilibrium concentration.

In drying of thin layers of Na-CMCC hydrogels, dull films readily subjected to powdering are formed. The consistence of hydrogels formed by the salt forms of CMCC depends not only on the polymer concentration in the system but also on the disintegration conditions (intensity and duration). For example, substitution of a high-speed Warring blender (20000 rpm) for low-speed blender even at short disintegration results in obtaining a uniform cream-like nonfluid mass. This fact allows stable gel-like consistence to be attained in a wide range of concentrations of CMCC salt in the system (higher than 1 wt %).

Conversion of the acidic form of CMCC into a Na salt results in noticeable weakening and broadening of the reflections in the X-ray pattern of cellulose (Fig. 3), which is in good agreement with diffusion of the "crystallinity bands" in the IR spectra of Na-CMCC (Fig. 2). Broadening of interference peaks is caused by a decrease in the crystallite size and an increase in the lattice defectivity. This concerns first of all the least interrelated (101) reflection planes in the three-dimensional lattice of cellulose ($2\theta \approx 15°$), to which predominant penetration of reactants is most probable [16]. The decrease in the size and increase in the concentration of defects of H-CMCC crystallites is accompanied by strong hydrophilization of their surface due to salt formation and formation of a water-soluble sol-like fraction from a part of oxidized macromolecules of the surface layer. From the experimental estimation, approximately 10 wt % of water-soluble material is present in the Na-CMCC hydrogel containing 5.8% carboxy groups. This fraction plays the role of a "barrier" between microcrystals and facilitates their disaggregation in dispersion of aqueous Na-CMCC suspension to the hydrogel state.

The electron-microscopic examination of particles of the dispersed phase of H- and Na-CMCC hydrogels undoubtedly confirms their microcrystalline morphology (Fig. 4). Disintegration of an aggregate of H-CMCC microcrystals, holding microfibril shape, to separate elements is illustrated in Fig. 4a. The stability of MCC hydrogels is reached even upon release of approximately 30% of individual microcrystals from their aggregates [6]. The Na-CMCC samples (Fig. 4b) are characterized by more convincing crystalline morphology than the H-CMCC samples, since the degree of disintegration and homogeneity of the dispersed phase of their hydrogels is significantly higher. The above data on the yield and structure of the reaction products of cellulose with 45–55% HNO_3 strongly suggest that not only dilute boiling mineral acids but also fairly strong acids at low temperature show hydrolytic selectivity with respect to structurally disordered cellulose fiber.

The sorption activity of CMCC was estimated with respect to a bulky organic cation, Methylene Blue (MB), under the conditions described in [1].

Under the same conditions, the maximum sorption of MB with powdered H-CMCC sample containing 3% carboxy groups is approximately 30 times higher than the sorption with powdered MCC sample [1]. MB is mostly absorbed by the cation-exchange mechanism. Hydrogels have the highest sorption power recalculated to dry substance, which is due to the maximum accessibility of their active centers. The sorption isotherms of MB with 10% H- and Na-CMCC hydrogels with 5.8% content of carboxy groups are shown in Fig. 5. As expected, the sorption

isotherms are described by the Langmuir equation. The salt forms of CMCC apparently surpass acidic forms in the sorption power. This logically follows from the high degree of their ionization. Account must be taken of the fact that NaCl is formed in the reaction of Na-CMCC macroions with MB in the form of hydrochloride. The product of the reaction of H-CMCC with MB · HCl is HCl, a strong acid shifting the ion-exchange equilibrium toward the initial substances. The maximum sorption of MB with Na-CMCC hydrogel with 5.8% content of carboxy groups is 420 mg g^{-1}, which corresponds to 101% of the total exchange capacity. This result is in good agreement with published data [1], where the maximum sorption of MB with Na-CMCC hydrogel with 4.8% content of carboxy groups was 390 mg g^{-1}. For the above reasons, the sorption power of H-CMCC is more than 2 times lower than that of Na-CMCC hydrogel (Fig. 5). The degree of utilization of its exchange capacity is 48%.

Thus, as judged from the chemical composition, phase and morphologic states, and gel-forming and cation-exchange power of the materials studied, with respect to the most important physicochemical characteristics they are identical to those synthesized previously using gaseous nitrogen(IV) oxide [1].

CONCLUSIONS

(1) The conditions of using 45–55% nitric acid as a "deposited form" of nitrogen(IV) oxide for selective oxidation of cellulose at the sixth carbon atom of the anhydroglucose ring with simultaneous selective hydrolytic cleavage of structurally disordered areas of the fiber were determined.

(2) Examination by IR spectroscopy, X-ray phase analysis, and transmission electron microscopy shows that the resulting materials are microcrystals of cellulose modified with carboxy groups localized at the surface.

(3) Conversion of the acidic form of the samples into the salt forms (sodium or lithium) is accompanied by strong hydrophilization of microcrystals and formation of a water-soluble fraction from a part of oxidized macromolecules of the surface layer, which facilitates preparation of stable thixotropic gels.

Abstract—A matrix of microcrystalline cellulose was used as a nanoreactor for the reduction of Ni(II) ions with hydrazine dihydrochloride.

DOI: 10.1134/S1070427206110310

Numerous polymeric nanocomposites with preset physicochemical properties [1], containing stabilized metal (Ag, Cu, Ni, Pt, Pd, etc.) nanoparticles [2–7], have been prepared by now. Nanoparticles of some metals, e.g., Ni, impart fo polymeric nanocomposites magnetic and catalytic properties [8]; however, the preparation of Ni(0) nanoparticles is complicated because Ni metal is readily oxidized [9].

Recently the interest in preparation of metal nanoparticles in ordered solid matrices (nanoreactors) increased, because in these matrices, in contrast to polymer solutions, significant aggregation of nanoparticles can be avoided [1]. Among promising nanoreactors is cellulose, a natural polymer characterized by a highly porous system of conjugated fibers. It has a large specific surface area and is successfully used as a solid matrix for intercalation of transition metal (Ag, Pt, Pd, Cu) nanoparticles [10–12]. Papers on the intercalation of Ni nanoparticles into natural polymers (in particular, cellulose) are few [13, 14]. Ishiyama et al. [13] reported on the preparation of 5–21-nm particles of Ni and its oxide in a gel membrane of cellulose acetate by thermal decomposition of the membrane after the intercalation of Ni^{2+} ions.

This paper continues our studies of the use of a cellulose matrix as a nanoreactor for intercalation of nanoparticles of zero-valent metals (in particular, Ni) and their oxides [15]. Nanocomposites based on cellulose and nickel can be used in catalysis and also as magnetic and conducting materials.

EXPERIMENTAL

Cellulose samples containing nanoparticles of Ni(0) or its oxides were prepared by diffusion of Ni^{2+} ions into a cellulose matrix from a solution of nickel nitrate $Ni(NO_3)_2 \cdot 6H_2O$, followed by reduction of Ni^{2+}. As a matrix we used microcrystalline cellulose (MCC) prepared by acid hydrolysis according to [10]; it was a powder with the particle size less than 0.06 mm and moisture content not exceeding 1 wt %. As a reductant for Ni^{2+} we used hydrazine dihydrochloride $N_2H_4 \cdot 2HCl$ (Reaktiv Joint-Stock Company, St. Petersburg). It is known that nickel ions are reduced with $N_2H_4 \cdot 2HCl$ only in alkaline solutions containing complexing anions at a large excess of the reductant and elevated temperatures [16].

A 1-g sample of MCC was vigorously stirred with 20 ml of a 0.05 or 0.1 M citrate solution of nickel nitrate for 1 h; the diffusion temperature was varied from 20 to 95°C. The $C_m(C_6H_5O_7^{3-})/C_m(Ni^{2+})$ ratio was 1 : 1. Citrate ions served as ligands for Ni^{2+} ions, preventing the precipitation of nickel hydroxide in a strongly alkaline medium; also, being sorbed on the forming metal particles and imparting to them a negative charge, they prevented the particle aggregation.

Nickel content in the bulk and on the surface of MCC-Ni samples and crystallite size of Ni and MCC

Sample no.	Temperature of Ni^{2+} diffusion, °C	Ni content, wt %		Crystallite size (XPA), nm	
		in the bulk (elemental analysis)	on the surface (XPES)	MCC	Ni(0)
1	20	6.9	31.5	7.5 ± 0.3	10.8 ± 1.0
2	70	7.4	17.4	7.5 ± 0.3	12.3 ± 1.0
3	95	10.0	18.7	7.4 ± 0.3	13.5 ± 1.0

To a suspension obtained after the diffusion of Ni^{2+}, we added with vigorous stirring a solution prepared by dissolving a weighed portion of $N_2H_4 \cdot 2HCl$ in 20 ml of 3 M NaOH. The $N_2H_4 \cdot 2HCl$ concentration in this solution was varied from 0.5 to 4 M, so that the molar ratio $C_m(N_2H_4 \cdot 2HCl)/(C_m(Ni^{2+})$ (MR) was varied from 5 to 40. The reduction was performed at 95°C for 0.5–2 h.

After the reduction, the precipitate was separated on a glass frit and washed with water and ethanol. The washing completeness was judged from the neutral reaction of the wash waters and negative reaction for the Ni^{2+} ions with dimethylglyoxime [17]. The samples after vacuum drying at 40°C were powders of the color varying from light green to black. All the chemicals used in the synthesis were of pure or analytically pure grade. The nickel-containing cellulose materials obtained by this procedure are hereinafter designated as MCC-Ni.

The nickel concentration in the bulk of MCC-Ni samples was determined by elemental analysis, and that on the sample surface, by X-ray photoelectron spectroscopy (XPES). The oxidation state of Ni on the fiber surface was also determined by XPES. The sample structure, nickel oxidation state in the bulk of cellulose, and changes in the chemical composition were studied by X-ray phase analysis (wide-angle X-ray scattering, XPA) and IR Fourier spectroscopy. The procedures for sample preparation and calculations are described elsewhere [10]. The morphology of MCC-Ni samples and the nickel particle size and particle-size distribution were studied by scanning electron microscopy (SEM) [15].

The experimental conditions strongly affect both the amount of Ni intercalated into the MCC matrix and its oxidation state in MCC-Ni samples. For example, as the temperature of Ni^{2+} diffusion into the MCC matrix in the first step of the process was increased from 20 to 95°C, the amount of the intercalated nickel after the subsequent reduction appreciably increased (from 6.9 to 10.0 wt %) at any $C_m(N_2H_4 \cdot 2HCl)/C_m(Ni^{2+})$. A similar trend was observed when $NaBH_4$ and KH_2PO_2 were used as reductants [15].

Another factor strongly affecting the Ni content in the final products is the reductant concentration. As the MR was increased from 5 to 40, the Ni content in the bulk of MCC increased until the maximal value of 10.0 wt % was attained. An increase in the reductant concentration also favors the reduction of Ni^{2+} to Ni(0). It is known that the color of the samples obtained characterizes the oxidation state of Ni in the samples [18]. An increase in the MR from 5 to 40 led to a change in the sample color from light green or greenish-brown, caused by the presence of $Ni(OH)_2$, to light gray (at MR = 15) and then dark gray (at MR = 20 and over), characteristic of finely dispersed Ni(0). Thus, the reduction of Ni^{2+} to Ni(0) is possible only at a high concentration of the reductant, hydrazine dihydrochloride (MR ≥ 15–40). The maximal amount of nickel introduced into the cellulose matrix (10.0 wt %) corresponds to 0.289 mol of Ni per mole of MCC units. With $NaBH_4$ and KH_2PO_2 used as reductants, the maximal Ni content (molar ratio to MCC units) was 0.315 and 0.358 (11.1 and 12.8 wt %), respectively [15]. All these values are close, i.e.,

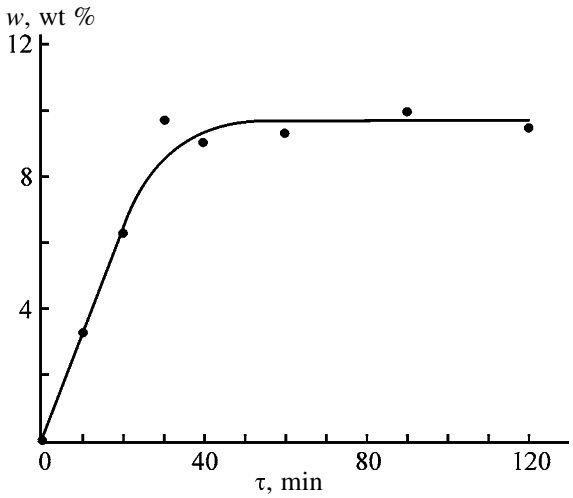

Fig. 1. Kinetic curve of Ni^{2+} reduction with $N_2H_4 \cdot 2HCl$. $C_m(Ni^{2+})$ 0.1 M, MR = 30, diffusion and reduction temperature 95°C. (*w*) Ni content and (τ) time.

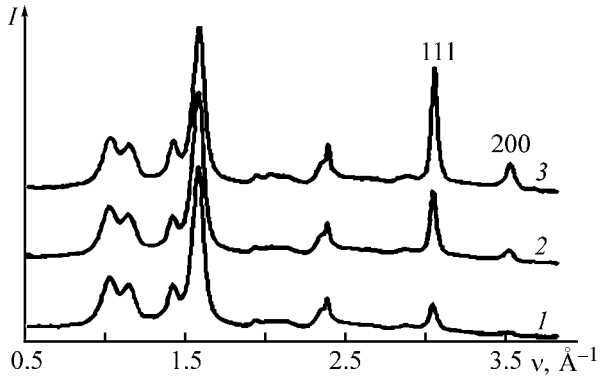

Fig. 2. Diffraction patterns of MCC-Ni sample nos. 1–3 prepared at MR = 30; reduction temperature 95°C. (*I*) X-ray scattering intensity and (ν) scattering angle. (*1–3*) Sample nos. 1–3 (see table), respectively; the same for Fig. 3.

about 1 mol of Ni was intercalated per 3 cellulose units with all the three reductants.

One of the major factors affecting the nickel content in the final products is the reduction time. The dependence of the nickel content in MCC-Ni samples on the reduction time (Fig. 1) shows that the equilibrium content of Ni in the MCC matrix is attained in 0.5 h and does not further change in the subsequent 1.5 h. The apparent rate constant of the pseudo-first-order reaction under these experimental conditions (the reaction was performed at MR = 30), calculated from the semilog plot, was $k = 2.7 \times 10^{-2}$ min^{-1}. The lower the MR, the slower the reduction. At MR = 20, the reaction rate decreases by a factor of approximately 3. It should be noted that the rate of the Ni^{2+} reduction with $N_2H_4 \cdot 2HCl$ exceeded by an order of magnitude the rate of its reduction with KH_2PO_2 reported in [15].

As shown above, an increase in the reductant concentration leads to a proportional increase in the Ni content in the bulk and to the reduction of Ni^{2+} to Ni(0). This was confirmed by XPA. The scattering curves of samples prepared at MR = 20 contained strong reflections of nickel oxide in the region of 2θ 36.8° and 42.9° and weak reflections of Ni(0) in the region of 2θ 44.3° and 51.2° ([111] and [200], respectively). With an increase in the MR to 30, the X-ray scattering curves of MCC-Ni samples differing only in the temperature of diffusion of Ni^{2+} into the MCC matrix (Fig. 2) contained Ni(0) reflections, and their intensity was proportional to the nickel content in the sample. This fact indicates that Ni(0) was the major nickel form in the bulk of these samples. The mean size of the crystallites, determined from the [111] reflections, was 10.8–13.5 nm (see table). Thus, XPA

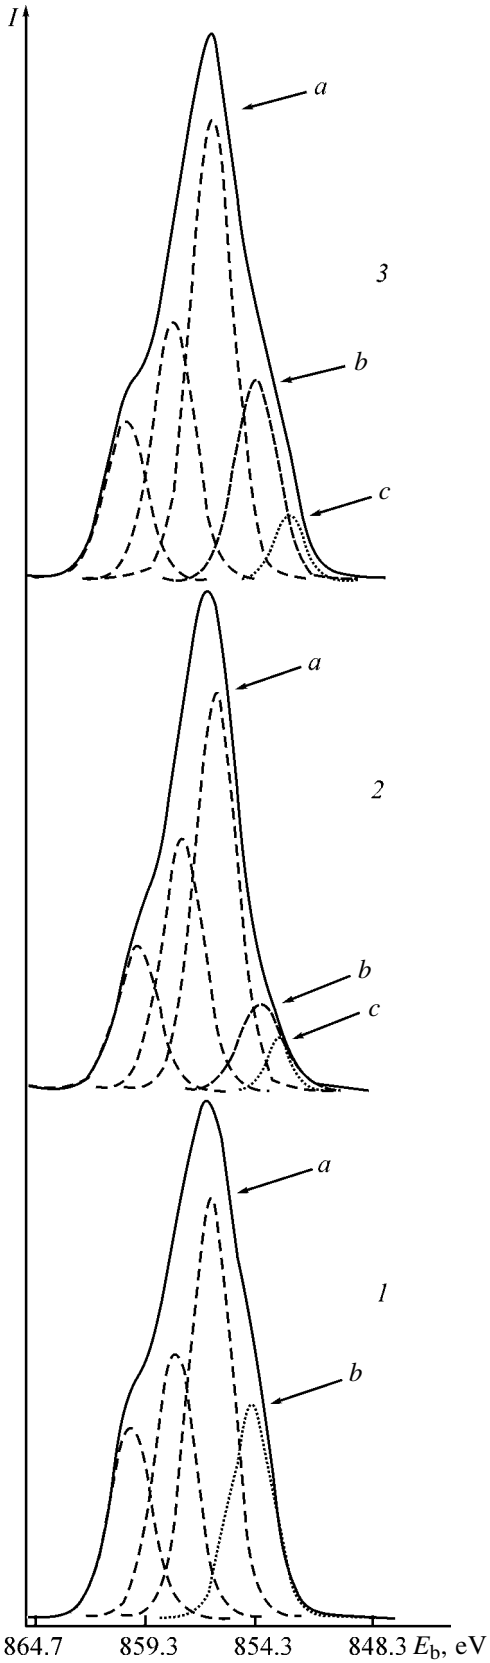

Fig. 3. XPE spectra of MCC-Ni sample nos. 1–3: (*I*) Intensity and (E_b) binding energy.

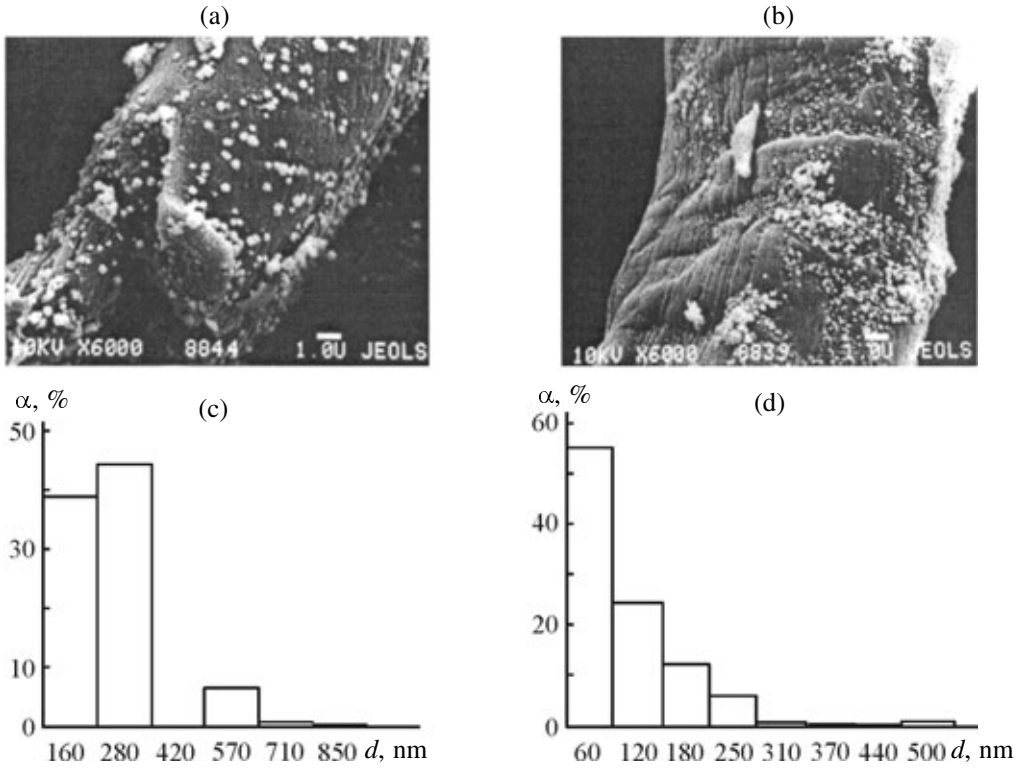

Fig. 4. Electron micrographs of MCC-Ni sample nos. (a) 1 and (b) 2; histograms of the distribution of Ni nanoparticles on the surface of sample nos. (c) 1 and (d) 2 with respect to the particle diameter. (α) Fraction of particles and (*d*) particle diameter.

confirmed the presence of the nanodispersed crystalline phase of Ni(0) in the bulk of the samples.

As in the case of reduction of Ni^{2+} with $NaBH_4$ and KH_2PO_2, the formation of nickel nanoparticles in the cellulose matrix did not affect the MCC crystal structure. The structural morphology of cellulose I, characteristic of MCC, was preserved, and the size (width) of MCC crystallites in MCC-Ni samples was close to that in the initial MCC (7.4 ± 0.1 nm, see table).

Thus, by intercalation of nickel in an MCC matrix we prepared MCC-Ni nanocomposites containing in the bulk mainly Ni(0) nanoparticles; the Ni oxidation state and crystallite size depended on the experimental conditions and primarily on the reductant concentration.

A comparison of the IR Fourier spectra of the MCC-Ni (at the maximal Ni content in the bulk) samples with that of the initial MCC revealed a minor decrease in the intensity of the absorption band at 3000–3600 cm^{-1} belonging to the stretching virbations of OH groups participating in inter- and intramolecular hydrogen bonds. Apparently, intercalation of Ni into a cellulose matrix is accompanied by cleavage of a small amount of hydrogen bonds on the surface of cellulose fibrils, followed by their redistribution.

The nickel concentration on the surface of fibers, determined by XPES, exceeds by a factor of 1.8–4.6 the nickel content in the bulk (see table). The ratio of redox forms on nickel on the surface is also different. Figure 3 shows the XPE spectra of the Ni $2p_{3/2}$ line and the resolution of spectral lines into four or five major components in MCC-Ni sample nos. 1–3. The components correspond to the Ni $2p_{3/2}$ binding energy in Ni_2O_3 (E_b = 856.7 eV, components *a*), NiO (E_b = 854.8 eV, components *b*), and Ni(0) (E_b = 853.4 eV, components *c*) [19]. The Ni(0) content on the fiber surface in sample nos. 2 and 3 (2.8 and 4.1 wt %, respectively) is considerably lower than that of nickel oxides. The high content of nickel oxides on the sample surface is due to the high susceptibility of Ni(0) nanoparticles to oxidation with atmospheric oxygen [9]. Thus, the samples obtained are not uniform in the chemical composition of nickel on the surface. It should be noted that the spectra of all the samples have also components with higher binding energies (858.0 and 860.4 eV, about 10%) which cannot be assigned to the above-noted nickel compounds. These may be electronic satellites [19]. Thus, an XPES study shows that the MCC-Ni nanocomposites prepared by reduction of Ni^{2+} ions in a cellulose matrix have a

variable content of nanoparticles of Ni(0) and nickel oxides on the surface of MCC fibes.

The distribution of nanoparticles of Ni(0) and nickel oxides on the surface of MCC-Ni samples is shown in the electron micrographs of MCC-Ni sample nos. 1 and 2 (Figs. 4a, 4b) and in the histograms of the nickel particle-size distribution (Figs. 4c, 4d). In most cases, nanoparticles of Ni(0) and its oxides have a globular shape and are nonuniformly distributed on the surface. In some cases, nanoparticles form giant agglomerates (however, few in number). The majority of nanoparticles in sample no. 1 (>55%) have a size within 160–280 nm (Fig. 4c). Contrary to sample no. 1, the majority (about 80%) of nanoparticles in sample no. 2 have a size of about 60 nm (Fig. 4d). Sample nos. 1 and 2 were prepared at the same MR, but the diffusion of Ni^{2+} into the MCC matrix was performed at 20 and 70°C, respectively. These results show that an increase in the diffusion temperature (see table) favors formation of smaller nanoparticles of Ni and its oxides on the surface. As a rule, the size and size distribution of nanoparticles are the decisive factors governing the applicability of materials containing nanoparticles. The results of reduction of Ni^{2+} in a cellulose matrix with $N_2H_4 \cdot 2HCl$ show that nanoparticles of Ni(0) and its oxides on the surface have a smaller size than those obtained by reduction with other solvents, in particular, KH_2PO_2 [15], whereas the size of Ni(0) crystallites in the bulk does not depend essentially on the kind of reductant used (cf. data from [13, 14]).

Thus, by reduction of Ni^{2+} in an MCC matrix with $N_2H_4 \cdot 2HCl$ we found that the temperature of the Ni^{2+} diffusion into the matrix and the reductant concentration are the major factors affecting the formation of nanoparticles of Ni(0) and its oxides of widely varied size in the bulk and on the surface of MCC fibers.

CONCLUSIONS

(1) Powdered cellulose materials with the maximal content of intercalated nickel of 10.0 wt % were prepared by reduction of Ni^{2+} ions in a cellulose matrix with hydrazine dihydrochloride.

(2) The presence of nanoparticles of Ni(0) and its oxides in the bulk of the cellulose matrix was confirmed by XPA.

(3) The distribution of nanoparticles of Ni(0) and its oxides on the surface of microcrystalline cellulose fibers was studied by SEM, and the qualitative composition and oxidation state of nickel on the surface, by XPES.

Abstract—The possibility of improving the quality of polyester fiber-glass products prepared by environmentally safe low-pressure procedures by modification of the polymeric matrix with moderate amounts of polycaproamide powder in combination with small amounts of epoxy resin was studied.

DOI: 10.1134/S1070427206110322

Owing to high strength, small specific density, and low cost, polyester fiber-glass materials reinforced with glass fabrics are excellent and widely used structural materials [1]. To increase the area of special-purpose applications, the quality of fiber-glass products (in particular, dimensional accuracy and dimensional stability) should be improved with preservation of their low cost. For this purpose, various procedures of chemical and physicochemical modification can be used [2, 3]. These methods can provide required results and can be realized without significant investments and material expenses.

In this work we studied the possibility of improving the direct low-pressure procedures for molding fiber-glass articles with a relatively small content (30–35%) of glass fibers. These procedures include the resin transfer molding (RTM), membrane procedures, cold pressing, etc. These environmentally safe procedures seem very promising. However, products prepared using these procedures have certain drawbacks such as high shrinkage and deformability.

To eliminate these drawbacks, moderate amounts of polycaproamide powder in combination with small amounts of epoxy resin (ER) are often added to unsaturated polyester resins.

EXPERIMENTAL

In this work we used Viapal UP 4627E/61 brand unsaturated polyester resin (UPER) (Vianova company, Austria); methyl ethyl ketone peroxide initiator (MEKPO) (Peroximon 41 brand, ATO company, France); 50% phthalate solution; cobalt octoate $Co(Ot)_2$ (Accelerator NZ 495, AKZO company, Holland); 6% phthalate solution containing Co(II) ions (1%); glass fabric (GF) (R12-500 9631 brand, Ahlstrom company, Finland) with a surface density of 500 g cm^{-2} woven of glass fibers of E glass (tex 1200) brand with orientation of 55.5 and 44.5% along the warp and weft, respectively; polyamide powder (PAP) (Vidakhim company, Bulgaria) with a particle size of 0.5–10 μm (after additional milling); epoxy resin (ER) (Epoks 1 brand) without plasticizer (Lakprom company, Bulgaria) with content of epoxy groups of 14%; and 2,4,6-dimethylaminotribenzylphenol (DMATBP) accelerator (Araldit Y060 brand, Ciba–Geigy company, Switzerland).

Powdered polyamide 6 was prepared by precipitation from solutions [4–7]; the precipitate consist of agglomerated particles of 60–200 μm size. Before studies, it was additionally powdered on a high-speed cutter-type mill. The size of finely dispersed PAP varied from 0.5 to 10.0 μm with the predominant fraction of 3–5 μm size.

The resin compositions were prepared from UPER, appropriate amount of PAP, ER (10% with respect to PAP), and DMATBP (10% with respect to ER). After thorough dispersion of the filler, a 1% solution of $CoOt_2$ and a 3% solution of MEKPO were added successively with vigorous stirring. The resin composite was quickly poured over the surface of glass-fabric reinforcement designed as a stack of four GF pieces

placed in the matrix cavity. The mold was closed with a punch and pressed for 35 min at 0.3 MPa. Using this procedure of cold pressing, we prepared the fiber-glass plates (250 × 25 × 4 mm) reinforced with orthogonally oriented glass fabrics with 35% content of the glass fibers. The density of the fiber-glass composite was 1405 kg m^{-3}. After removal from the mold, the plates were heated at 120°C for 24 h. Then, using a diamond saw, we prepared the specimens of the required sizes for each test procedure. The ends of the specimens, which were clamped with the dynamometer clips, were thickened with the plates of the same material glued at both sides of the sample.

To determine the degree of shrinkage, the size of the thermally treated plates was compared with the mold size. Deformations and strains of the plate surface were evaluated visually.

The tensile and bending strengths of the samples were studied on a TT-DM/INSTRON 85 dynamometer in accordance with ISO-527 and ISO-178. The impact resilience was measured on an CEACT 645/000 unit according to ISO-179 (after Charpy without notches).

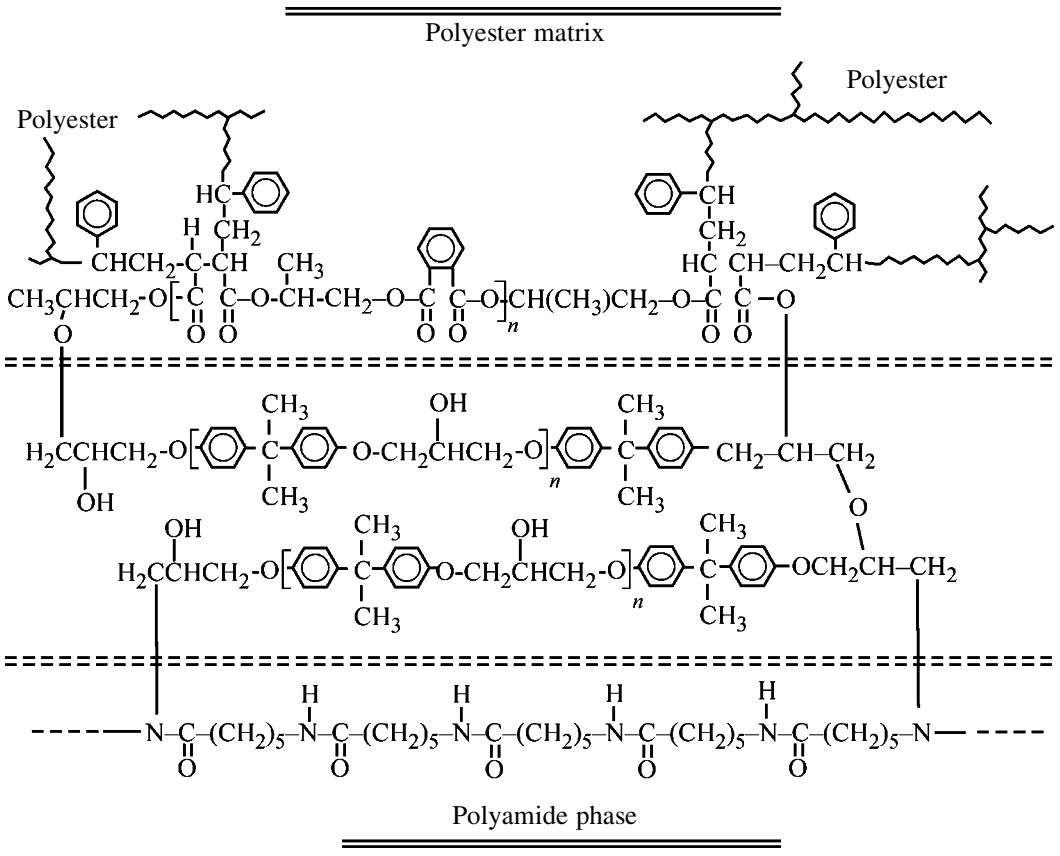
In the course of curing, the volume of UPER decreases by 8%. Shrinkage of the polyester materials is due to the complex of interrelated chemical, rheological, and physicochemical processes. The shrinkage of the composites decreases with increasing filler content.

UPER composite is cured owing to free-radical polymerization, which occurs in several stages under various thermodynamic, rheological, and concentration conditions, which is reflected in the heterogeneity of the three-dimensional polymer network. This gives rise to internal stresses in the fiber-glass products and their elevated shrinkage and deformations.

The fiber-glass objects of stable shapes with elevated size accuracy and small internal stress are commercially produced using liquid or powdered polymer additives. For example, some of them are thermoplastic powders chemically inert to UPER, whereas the others are liquid rubbers, which, copolymerizing with UPER, form elastic blocks in the three-dimensional network [1].

The mechanism of the effect of these modifying agents is different. For example, polyvinyl, polyacrylate, and other thermoplastic powders are well wetted by liquid resins; in this case some of them partially swell under the effect of styrene contained in the resin. Modifying agents provide both quantitative and qualitative changes in the fiber-glass plastic shrinkage: the content of the twisting agent decreases and surface interaction occurs between UPER and the solid phase of the modifying agent in the course of polymerization. In the process, the effect of adsorption structuring is observed, which promotes formation of the three-dimensional network closer to the equilibrium steric structure. This procedure is associated with the adhesion contact between two phases in the polymer matrix. It is believed that the modifying agent grains, limited by the boundary polymeric layers, become the centers of relaxation microareas which partially compensate internal stresses in the cured composite and stresses appearing during operation of the fiber-glass plastic articles.

The other mechanism is associated with the copolymerization of UPER and liquid rubber. The rubber fragments are incorporated in the three-dimensional polymer network as elastic blocks, which at various stages of polyester cross-linking relieve the internal stresses and the shrinkage and deformation caused by them.



Using these concepts of the mechanism of the shrinkproofing agents, we developed a new approach [8, 9] based on formation of soft (low-elastic-modulus) microparticles in the polymeric matrix. In accordance with this approach, such microparticles enhance adhesion between the polymeric binder and reinforcing fibers in the stage of composite formation. In the course of operation, these soft particles act as structural nodes relieving stresses that appear under the effect of external forces.

The aim of this study was to design aggregate microcenters in the polymeric matrix of fiber-glass composites. In accordance with the Gibbs law, in all stages of the composite formation epoxy resin is deposited on the surface of polyacrylamide particles forming a shell around them. It acts as an intermediate layer between polyamide and polyester phases in the polymer matrix. It is known that the epoxy rings are able to participate in the addition polymerization with active hydrogen of amide groups [10]. Under the conditions of the exothermic stage of UPER curing and thermal treatment of the composite articles, the epoxy shell is grafted to the polyamide surface. At the same time, the epoxy groups of the external layer react with a multitude of carboxy groups contained in UPER. The internal layers of the epoxy resin are also partially linked owing to the hydroxy groups present in the polymer and formed upon grafting of the external layers to polyamide and polyester. Since the interactions of the epoxy and hydroxy groups are relatively weak, the resulting network is friable and hyperelastic.

Based on the above considerations, we assumed

that the epoxy shell of the polyamide particle consists of three layers: (1) grafted to polyamide surface, (2) internal weakly linked, and (3) chemically grafted to polyester surface (see scheme).

Fragment of the chemical structure of a three-component aggregate of epoxy shell of polyamide particles

Owing to their structure, the heterogeneous microareas of the aggregate grains of the modifying agent act as efficient relaxation centers relieving internal stresses and dissipating certain fraction of energy of the external forces.

The effect of the above modification is confirmed by the data on mechanical properties, shrinkage, and deformation of fiber-glass plastic articles (Fig. 1). For the convenience, the modifying agent concentration in Figs. 1 and 2 is expressed through the concentration of PAP. It is assumed that it corresponds to the content of ER taken in 1 : 10 ratio with respect to PAP.

As seen from Fig. 1, with increasing content of the modifying agent the shrinkage of the fiber-glass plastic plates decreases nonlinearly. At small concentrations, the effect is more pronounced. For example, at the PAP content of 3–4 wt % the "Low shrink" accuracy grade is attained. The effect becomes less pronounced with increasing PAP concentration to

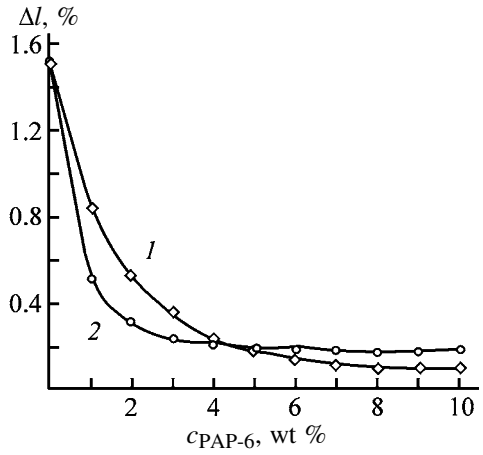


Fig. 1. Linear shrinkage Δl of fiber-glass plastic plates along the (*1*) warp and (*2*) weft of the reinforcing fabric as a function of the modifying agent concentration c_{PAP-6} in the UPER.

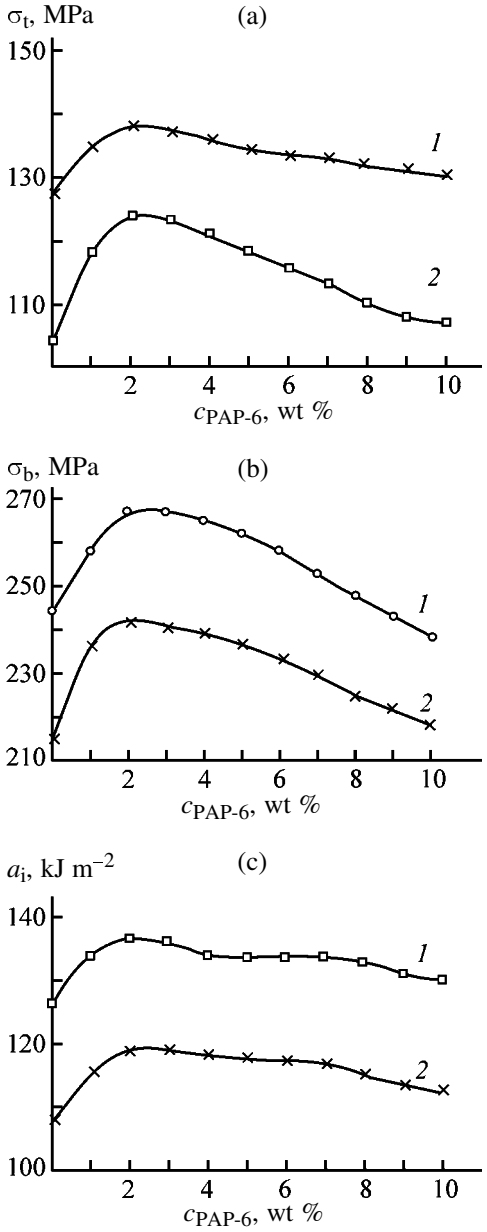

Fig. 2. (a) Tensile strength σ_t, (b) bending strength σ_b, and (c) impact resilience a_i of the fiber-glass plastic plates along the (*1*) warp and (*2*) weft of the reinforcing fabric as functions of the modifying agent concentration $c_{PAP\text{-}6}$ in the UPER.

≥5 wt %, and to prepare the objects with "Low profile" accuracy grade the content of PAP in UPER should be increased to 6–8 wt %. Moreover, along with decreasing shrinkage, no deformation and cracking of the resulting fiber-glass plastic plates was observed.

The data on the effect of modification on the mechanical properties of fiber-glass plastics are of particular importance from both the theoretical and practical viewpoints.

As seen from Fig. 2a, the tensile strength at small concentrations of the modifying agent increases by 10 and 15% along the warp and weft, respectively. With increasing content of the modifying agent in the matrix, its strength decreases but remains still higher as compared to the unmodified composites.

At small concentrations of the modifying agent (1–4 wt % PAP-6), the increase in the strength of fiber-glass composites is more pronounced. With increasing content of ER and PAP, their strength gradually decreases and at maximal degree of filling (10 wt % PAP) it is comparable with that of unmodified fiber-glass plastic materials (Fig. 2b).

The dependence of the impact resilience of the fiber-glass plastic on the concentration of the modifying agent is similar (Fig. 2c). Our experimental data showed that in all the cases the strength of the resulting materials along the warp is higher than that along the weft. This fact may be due to the decisive effect of the content of the glass fibers on the strength of the reinforced plastics as compared to the effect of other strengthening factors.

Our experimental data showed that, with increasing content of PAP modifying agent to 10 wt % and ER to 1 wt %, the scatter in the mechanical properties of the specimens cut out from plates of similar compositions decreases by a factor of 2.

CONCLUSIONS

(1) Fiber-glass plastic articles with decreased shrinkage were prepared. At 3 wt % content of the polyamide powder, the shrinkage of the resulting composite is 0.2–0.25%, which corresponds to the "Low shrink" accuracy grade. With increasing content of the modifying agent to 6–8 wt %, the shrinkage of the fiber-glass composite decreases to 0.10–0.15%, which corresponds to the "Low profile" accuracy degree.

(2) The articles of the modified composite do not deform irrespective of their shape and thickness.

(3) The tensile and bending strengths and impact resilience of the modified materials increases with increasing concentration of the modifying agents, and small amounts of the modifying agents are more efficient.

(4) The mechanism of modification, based on the

hybridization of the polymer matrix, is proposed. In accordance with this approach, microheterogeneities in the form of aggregate micronodes are formed in the network of the polymer matrix, which act as the relaxation centers compensating internal stresses in the fiber-glass plastic and dissipating certain fraction of the mechanical stresses caused by external forces.

INFORMATION

The 3rd International Conference on Times of Polymers

DOI: 10.1134/S1070427206110334

The 3nd International Conference on Times of Polymers (TOP) was held in Italy from June 18 to 22, 2006.

About 150 scientists from 22 countries (Algeria, Argentina, Bahrein, Brazil, Canada, Chile, China, France, Georgia, Greece, Iran, Israel, Italy, Kuwait, Mexico, Portugal, Russia, Slovak Republic, Switzerland, Taiwan, the United States, and Venezuela) participated in the Conference. They represented 65 research centers.

The Conference provided a forum for scientists and engineers throughout the world interested in the timescales of polymer and composite processing, structure, and properties. The Conference's motto was "Research, Development, Production."

As time is the driving concept in the polymer science community, the Conference included sessions on various topics and provided opportunities for exchanging ideas and opinions on both fundamental science and industry-relevant subjects such as viscoelasticity, thin films, nanocomposites, organic electronics (OLED, OTFT), polymer-based sensors, industrial rheology, durability/degradation, processing, biomaterials, cultural heritage, and fracture and yielding.

The Conference Program included a plenary lecture, 11 invited presentations, 50 oral contributions from participants, and the same number of poster presentations.

The plenary lecture entitled Nanomechanical Measurements of Polymers in the Vicinity of the Glass Transition: Question about T_g and Enhanced Surface Dynamics was presented by G.B. McKenna (the United States).

The eleven invited lectures were as follows: (1) Timescales of Mechanically Stimulated Glassy Polymers [A. D'Amore (Italy)]; (2) Dynamics of Nanoparticles for Biomedical Applications [J. Mijovic (the United States)]; (3) Control of the Macromolecular Architecture during Reactive Processing [F. Ciardelli (Italy)]; (4) Computer Simulations of Radical Polymerization at Unusual Conditions [A.R. Khoklov (Russia)]; (5) Reinvestigating Polymer Oxidation Processes by New Tools [G. Montaudo (Italy)]; (6) Comparison of the Viscoelastic Bulk and Shear Moduli [S.L. Simon (the United States)]; (7) Modelling and Experimental Characterization of Hydrothermoelastic Stress in Polymer Matrix Composites [A. Vautrin (France)]; (8) Water Diffusion in Glassy Polymers and Their Silica Hybrids: an Analysis of State of Water Molecules and of the Effect of Tensile Stress [G. Mensitieri (Italy)]; (9) Large Area Processing of All Organic Electronic Systems Combining Nanoscale Imprinting and Inkjet Printing Technologies [F. Zenhausern (the United States)]; (10) Chain Entanglement in Thin Free-Standing Polymer Films [K. Dalnoki-Veress (Canada)]; and (11) The Effect of Solvents (Plasticizers) on PVC Degradation [G.E. Zaikov (Russia)].

Oral and poster presentations covered such topical problems as development of conducting polymeric and composite materials as well as materials having semiconductor properties; biopolymers and their medical applications; new methods for polymer characterization (including chemiluminescence); relaxation phenomena in polymers and composites; liquid-crystalline polymers (preparation and characterization); and reactions in solid polymers under pressure and shear stress (reactions in extruders).

Several presentations were devoted to filled polymers (preparation and characterization), inorganic and organic polymers and their blends, dyeing of polymers and the contribution of chemical additives in the behavior of polymeric materials, degradation and stabilization of polymers, flame retardation in polymers, novel environmentally friendly fire retardants, "smart" polymers and their properties, polymeric hydrogels and their applications in medicine and farming, structure and properties of various polymers, diffusion of multicomponent systems (electrolytes) in a solid polymer, nanopolymers (preparation and characterization), mechanical properties of composite materials, prediction of the service and storage life of polymeric and composite materials, and biochemical synthesis as a novel approach to preparation of polymers.

The Conference revealed that synthesis, properties, and applications of polymers, polymer blends, polymer composites, and filled polymers continue to be topical basic and applied problems.

Proceedings of the Conference will be published as a special issue of the European Polymer Journal.

The next Conference Times of Polymers-IV will be held in July, 2006 at the same place.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Development of a Rational Technology for Synthesis of High-Quality Detonation Nanodiamonds

V. Yu. Dolmatov

Tekhnolog FGUP SKTB, St. Petersburg, Russia

Received February 9, 2005; in final form, June 2006

Abstract—Concepts concerning the structure of detonation nanodiamonds were generalized on the basis of data reported in previous publications. The pH value of the nanodiamonds in an aqueous suspension was determined. The mechanism of the longest stage, washing of nanodiamonds with water to remove excess acidity, was considered. A novel method for substantially improving the quality of nanodiamonds and the stability of aqueous suspensions of nanodiamonds was suggested.

DOI: 10.1134/S1070427206120019

The task of achieving a high purity of detonation nanodiamonds and preparing stable nanosize suspensions is a key issue for successful application of nanodiamonds in various areas of science and technology. However, due attention has not been given to this question because of the complexity of these problems. This study is devoted to generalization of concepts about the structure of nanodiamonds and to practical solution of the above problems.

Detonation nanodiamonds (average size 4–6 nm) are exceedingly complex objects having, at least, a three-layer structure [1–3]. Each particle (cluster) contained in aggregates is a set of constituent elements.

(1) A core composed of carbon atoms (sp^3 hybridized) bound into a cubic crystal structure characteristic of diamond includes 70–90% of carbon atoms and has, according to X-ray data, a size of 40–60 Å; the core contains 2.5–2.8 wt % nitrogen as substitution atoms [4].

(2) An intermediate carbon sheath of thickness 4–10 Å, which envelops the core, is composed of X-ray-amorphous carbon structures, and may contain 10–30% of carbon atoms of the cluster [5]. The sheath composed of sp^2-hybridized carbon is inhomogeneous. It is believed [2] that the inner layer of this sheath, immediately adjacent to the diamond core, is composed of continuous layers of onion-like carbon. Above the inner layer are situated, within the same sheath, fragmented graphite-like monolayers. This amorphous carbon sheath has a porous structure, contains numerous defects and discontinuous regions of structural carbon formations, and may include a minor amount of heteroatoms incorporated into the sheath in the course of detonation synthesis and chemical purification.

(3) Surface layer containing, in addition to carbon atoms, also other heteroatoms forming a broad spectrum of widely diverse functional groups. The amount of heteroatoms may be as large as 10% relative to the total mass of a particle, and oxygen may constitute their larger part [6]. Hydrogen contained in functional groups and nitrogen rather uniformly distributed over all layers of nanodiamonds are revealed in minor amounts. The major place is occupied by oxygen-containing groups (hydroxy, carboxyl, ketone, lactone, etc.).

In view of the fact that the core and its intermediate sheath are nearly wholly composed of carbon, all the heteroatoms (except nitrogen) are concentrated in the surface layer and their content in the surface layer is about 50%, i.e. [7], nanodiamond particles are not a purely carbon material. Moreover, carbon itself is present in the product simultaneously in several modifications, and only one of these corresponds to the structure of diamond.

The structure and quantitative characteristics of the core and intermediate carbon sheath of nanodiamonds are formed in the course of detonation synthesis [3, 7]. The outer sheath determines the relationship between the nanodiamond cluster and the environment. It is this sheath that forms the interface and

is involved in the interaction with the ambience. Its structure and composition may strongly depend on how nanodiamonds are recovered, purified, and stored. The ultrasmall size of particles results in that the role of surface interphase interactions becomes exceedingly important. It is these interactions that largely predetermine macroscopic characteristics of nanodiamonds and their consumer properties. The presence of highly polar and reactive groups concentrated in a small volume at the surface predetermines the strong impact of nanodiamond particles on the environment.

The existing methods for production of nanodiamonds, which are based on detonation synthesis, can actually yield only a raw carbon material, diamond stock, in which nanodiamonds are contained [1, 8]. The diamond stock also includes graphite-like structures and amorphous destructured chains of carbon atoms bearing numerous functional groups. It also contains technological impurities (metals and metal derivatives: carbides, oxides). The chemical methods used to recover nanodiamonds from the raw carbon material and purify them actually newly form the surface sheath [9].

From the standpoint of modeling, it is more appropriate to represent nanodiamond particles as a cross-linked rigidly structured polymer, whose internal skeleton is formed by saturated carbon bonds and the surface is saturated with highly polar groups, rather than as a small nanodiamond crystal with defective surface. The 3*D* skeleton provides concentration of a large amount of organic products within a very small volume. As a result, a strong field of impact on the environment can be created and the structuring action of nanodiamond particles is manifested. Nanodiamonds are a unique material owing to their intermediate position between inorganic and organic products. It is this circumstance that determines their particular place among ultradisperse materials and those related to nanocarbon (fullerenes, nanotubes, carbyne).

The most efficient and high-output-capacity technique for chemical purification of detonation nanodiamonds (ultradisperse diamonds, UDD) consists in treating the detonation diamond stock with dilute nitric acid under pressure (up to 100 atm) at high temperatures (240–260°C) [10]. With this method, it is possible to achieve a UDD purity of 99% and more at a residence time of diamond stock in the high-pressure and high-temperature zone as short as 30–40 min. This technology has been successfully implemented in Russia, China, and Belarus. However, despite the high quality of nanodiamonds and high output capacity of the reactor unit, the rate-determining stage is the seemingly simple last operation, washing of nanodiamonds to remove the acid and soluble impurities. This process takes as long as four to five days, which strongly affects the output capacity of the stage of chemical purification as a whole.

EXPERIMENTAL

Nanodiamonds were produced at Tekhnolog FGUP SKTB by detonation decomposition of a trinitrotoluene–hexogen alloy containing 40 wt % TNT (TNT/hexogen 40/60) in a nonoxidizing gas medium, with the explosive charge (0.6 kg) placed in a water envelope. The water : explosive ratio was 6 : 1. The diamond-containing stock obtained upon an explosion was subjected to nitric acid purification [10]. The product formed upon the nitric acid purification was subjected to ammonia thermolysis. The nanodiamonds obtained were of the UDD-TAN brand. According to TU (Technical Specification) 05 121 441-275–95, UDD-TAN should contain (wt %): main substance (nanodiamonds) ≥96.5, oxidizable carbon ≤2.5, and incombustible impurities ≤1.0; with the pH of the aqueous suspension in the range 5–8.

The pH of the aqueous suspension or of the clarified water layer (containing no nanodiamonds) was measured with a pH-121 pH-meter (ESL 43-07 glass electrode and EVL-1 M 3.1 silver chloride reference electrode).

The sedimentation rate of the solid phase (nanodiamonds) was determined in a 1-l glass cylinder by examining the motion of the interface between clarified water and thickened suspension in the course of time.

The thermolysis (treatment of weakly acidic nanodiamond suspensions having pH ~2.5 with ammonia, followed by heating) was carried out in a 10-l titanium autoclave equipped with a stirrer. The autoclave should sustain temperatures of up to 280°C and pressures of up to 500 atm. Aqueous ammonia was added to a nanodiamond suspension and the pH of the suspension was brought to 10.5–12.0. Then the weakly alkaline suspension was charged into the autoclave (charge 60–80% of the total volume), heated to 230°C, and kept for 2–3 h. After the keeping the suspension was cooled and the excess pressure was relieved. The pH value of the resulting nanodiamond suspension was 7–8.

The content of the main substance in the nanodiamond suspension was determined by taking an aliquot of the suspension (10–20 ml) and evaporating it to dryness. Then the percentage content of nanodiamonds was calculated.

When considering issues associated with washing of nanodiamonds to remove water-soluble impurities, control over the washing efficiency, and aggregation conditions, it is necessary to take into account that nanodiamonds have their own noticeable acidity determined by the presence of carboxyl groups on their surface.

A suspension of pure nanodiamonds in water cannot be neutral and should be acidic (Fig. 1). Two layers are formed in sedimentation of a nanodiamond suspension: lower thickened and upper clarified (nanodiamond-free water). A distinction should be drawn between the suspension acidities in these layers. The acidity of the lower thickened layer is determined by the overall effect of acid groups of nanodiamonds and acid agents dissolved in water, and that of the clarified layer, only by dissolved products.

Measurements of the pH value and titration in decantation of the upper clarified layer of the suspension make it possible to judge the content of acid impurities, and the difference in acid content between the thickened and clarified layers can be used to evaluate the contribution of nanodiamonds to the total acidity of the medium. At an acid content of the upper layer exceeding 0.5% (pH ~ 1), there is virtually no difference in acidity between the upper and lower layers. However, with further washing (pH > 3), the difference between the total acidities grows fast to become as large as orders of magnitude (Fig. 2). Nanodiamond particles should behave in water as a poorly soluble weak organic acid, which is the case in actual practice. Consequently, it is impossible to obtain a neutral nanodiamond suspension without use of neutralizing alkaline agents.

The acid properties are primarily manifested in the aggregative and sedimentation stability of aqueous suspensions. This circumstance is of fundamental importance for the technology of nanodiamond purification, because all the known variants include treatment with strong acids.

Commonly, acids are removed by washing with water. Free settling of a nanodiamond suspension in the course of its washing to remove acids or ammonia water (in the case of neutralization of acids) yields suspensions thickened to 5–7% in terms of nanodiamonds. After that, further settling virtually terminates (at least that observed visually) in the absence of considerable concentrations of salt-forming impurities. The sedimentation rate in dilute suspensions corresponds to a settling velocity of particles about 1 μm in size. The time sufficient for sedimentation of

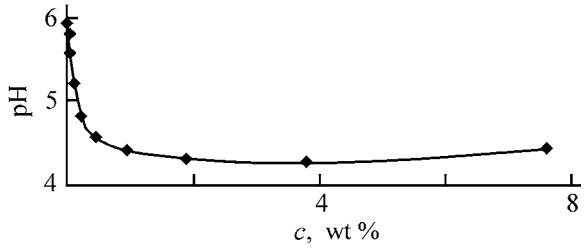

Fig. 1. pH of a washed nanodiamond suspension vs. content *c* of nanodiamonds.

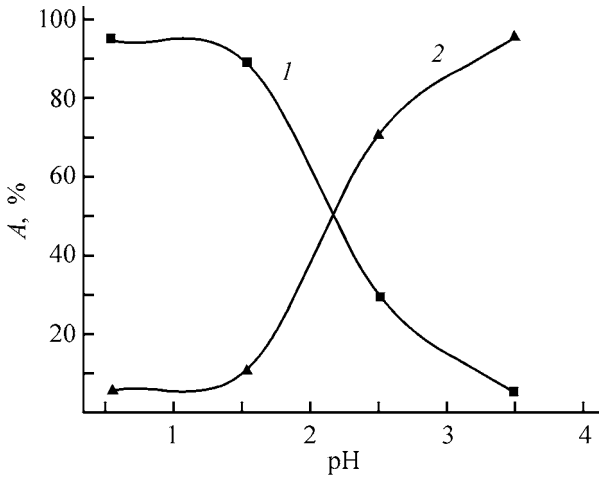

Fig. 2. Distribution of the overall acidity *A* of the nanodiamond suspension among nanodiamonds and the aqueous phase at different pH values of the medium. Fraction of the overall acidity: (*1*) in the aqueous phase and (*2*) on nanodiamonds.

the main part of nanodiamond particles to form a thickened aqueous suspension at pH < 2 is 12–24 h. The content of nanodiamond particles at the maximum thickening (5–7 wt %) is well reproducible. The interface between the thickened and clarified layers remains distinct. Presumably, the value of 5–7 wt % should be considered a characteristic value.

Physically, this can be interpreted as follows. At the given concentration, water in a thickened suspension is in the zone of structuring action of nanodiamond particles. As a result, water forms solvation shells that tightly envelop nanodiamond particles or aggregates of particles and are retained in the near field of these particles. The key role in the transfer of the structuring action is presumably played by ionic mechanisms and hydrogen bonds. It is known that, in the absence of foreign impurities, the surface of nanodiamond particles in aqueous suspensions is negatively charged, which is determined by the large number of oxygen-containing polar groups, and primarily hydroxy and carboxyl groups. However, in solutions

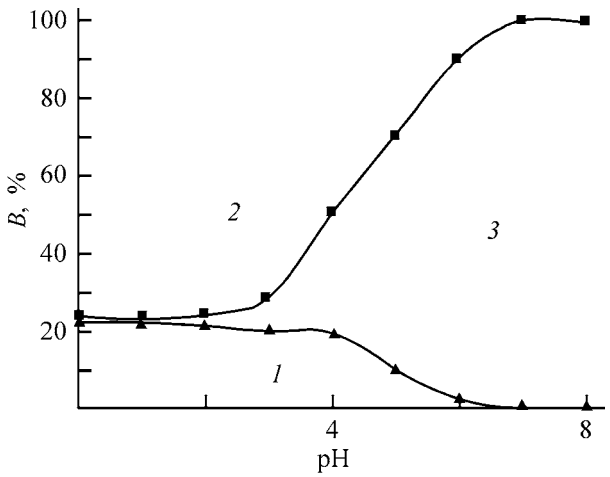

Fig. 3. Stratification of the nanodiamond suspension in settling in relation to the pH of the medium. Settling time 24 h, initial concentration of the nanodiamond suspension 1%. (*B*) Fraction of thickened suspension in the whole volume. (*1*) Thickened layer, (*2*) clarified layer, and (*3*) unsettling UDD suspension.

of strong acids (e.g., nitric acid), the surface of nanodiamonds should take on a positive charge because of the chemisorption and physical sorption of hydroxonium ions. As the concentration of nitric acid in the aqueous medium decreases in the course of washing, which is well monitored by pH values, the concentration of the thickened layer decreases and the interface between the clarified and thickened layers is smeared (Fig. 3). The interface smearing is due to a decrease in the amount of the electrolyte (acid) in the aqueous suspension in the course of nanodiamond washing. As a result, coarse aggregates partly disintegrate, with the remaining ions predominantly concentrated in the hydrospheres of nanodiamonds. Visually, this is observed as a decrease in the degree of thickening and boundary smearing (Fig. 3) ("hanging" effect).

Centrifugation accelerates the process of UDD concentration in the thickened layer (to 12–14% at pH < 2), but this is only effective for strongly acidic media. At pH values close to 7, the centrifugation efficiency falls dramatically and the "hung-up" suspension is not clarified completely.

It was shown that, after a fourth washing of acid nanodiamonds with water (with the ratio between the thickened layer of nanodiamonds and pure water maintained constant at 1 : 4), the content of HNO_3 in the suspension is 0.18–0.25 wt % (pH 1.8–2.0), and that after a fifth washing, 0.07–0.10 wt % (pH 2.2–3.0). Further washing to remove such an insignificant amount of HNO_3 is inadvisable because the suspension starts to "hang" and the waiting time increases dramatically. To prevent hang-up on reaching a pH value of 1.5–2.5, it is advisable to neutralize the acid remaining in solution and acid groups on the surface of nanodiamond particles with ammonia water, with the pH value of the medium changed abruptly from acidic (content of nitric acid in the suspension 0.1–0.3 wt %) to weakly alkaline (pH 9–10). In this case, the excess of ammonia water in the suspension is only 0.025 wt % even at pH 10.

The advantages of treatment of a nanodiamond suspension with ammonia water are as follows: (i) ammonium salts of nitric and nitrous acids are well soluble in water and are readily removed (in one or two washings), together with the clarified layer from the thickened nanodiamond suspension; (ii) excess of ammonia water is easily evaporated in the form of ammonia; and (iii) NH_4^+ ion, which has the smallest ionic radius among alkaline agents, readily penetrates into meso- and micropores of nanodiamond aggregates and neutralizes trace amounts of mineral acids, present there.

The weakly alkaline reaction of the suspension in the presence of an excess amount of ammonia water and the presence of ammonium salts (electrolyte) provide a sufficiently fast stratification (in two or three washings) and thickening of nanodiamonds in the lower layer to approximately 8 wt %, and, in some cases, even to 12 wt %.

However, no chemical purification, or even treatment of sufficiently well washed nanodiamonds with ammonia water under common conditions can significantly change the situation as regards the amount of nitrogen oxides contained in meso- and micropores of nanodiamond aggregates; these oxides are difficult to remove even under strong heating.

This problem can be solved, with the nanodiamond aggregates simultaneously made smaller, by heating a weakly acidic nanodiamond suspension neutralized with ammonia water at 200–240°C for 30 min. The following processes occur in the given medium at high temperature (and pressure).

(1) The salts formed on the surface, and primarily NH_4NO_3 and NH_4NO_2, readily diffuse into the aqueous solution.

(2) Most part of NH_4NO_3 and NH_4NO_2 starts to vigorously decompose at 200–240°C to give gaseous products and water by reactions (1) and (2); nitrogen(I) oxide formed by reaction (1) further decomposes to nitrogen by reaction (3), and nitrogen oxides

brought in contact with the excess ammonia water are converted to nitrogen and water:

$$NH_4NO_3 \rightarrow N_2O + 2H_2O, \quad (1)$$

$$NH_4NO_2 \rightarrow N_2 + 2H_2O, \quad (2)$$

$$N_2O \rightarrow N_2 + 0.5O_2, \quad (3)$$

$$N_2O_3 + 2NH_3 \rightarrow 2N_2 + 3H_2O. \quad (4)$$

(3) Vigorous gas evolution results in that nanodiamond aggregates 350–500 nm in size disintegrate to 10–100-nm aggregates, with harmless products, such as nitrogen and water, released.

(4) There also occurs a rather full desorption of nitrogen oxides from the surface of nanodiamonds (especially from internal pores) to give an excess amount of ammonia water in hydrolysis in water of ammonium nitrate and nitrite.

(5) Cooling of the nanodiamond suspension and its washing (two or three times) to remove residual amounts of ammonium salts and ammonia water yield a colloid-stable highly concentrated (10–12 wt %) aqueous nanodiamond suspension with low viscosity and high fluidity, which makes it highly technologically convenient for further use.

(6) The enhanced desorption of inorganic and organic impurities from the surface of nanodiamond particles in the presence of ammonia water at high temperatures and pressures and the subsequent washings result in that the purity of nanodiamonds is as high as 99.5 wt % in some cases.

The purity of nanodiamonds was determined by the conventional method (indirectly) from the difference between 100% and the total content of impurities (incombustibles and readily oxidizable carbon) in nanodiamonds.

For example, the total content of incombustibles in a well-washed (seven washings with water) batch of nanodiamonds of the UDD-STV brand (TU 05 121 441-275–95) is 0.95 wt % (see table), whereas the same batch of nanodiamonds, neutralized with ammonia water to pH 7.3, subjected to thermolysis at 230°C and then twice washed with water (UDD-TAN brand) contains only 0.4 wt % incombustibles.

After the thermolysis, the nanodiamond suspension contains an excess amount of ammonia water (pH ≥ 7) and a certain amount of ammonium salts, and, therefore, it is sedimentation-unstable. This circumstance facilitates its 2–3-fold washing with water.

Content of incombustibles in samples of an aqueous nanodiamond suspension (according to atomic-absorption spectroscopy)

* Manufactured by Tekhnolog FGUP SKTB.

** Manufactured by RFYaTs–VNIITF. Analysis of nanodiamonds made by S.I. Chukhaeva (RFYaTs–VNIITF, Snezhinsk).

The resulting suspension can be stored for years, but the pH of the medium gradually decreases to 4.5, which corresponds to the pH value of pure nanodiamonds. In storage, the size of nanodiamond aggregates increases from 10–100 to 150–300 nm.

CONCLUSIONS

(1) The basic properties of nanodiamonds, which characterize this product as a new formation combining all the possible forms of carbon atoms with various hybridizations into a single ensemble, are described. Nanodiamonds can be regarded as a material intermediate between inorganic and organic products.

(2) Washing of nanodiamonds to remove acids is a complicated task. At pH > 3, the acidity of the suspension is determined by the intrinsic acidity of sur-

face oxygen-containing groups on nanodiamonds. The pH of aqueous media containing well-washed nanodiamonds (1–10 wt %) is 4.4–4.5.

(3) The maximum content of gravitationally thickened nanodiamond suspensions in a daily (conventional) technological cycle of washing is as high as 5–7 wt %.

(4) A novel method is suggested for conditioning of nanodiamonds, which consists in that a weakly acidic aqueous nanodiamond suspension (pH 2–2.5) is treated with ammonia water and then heated to 200–240°C for 30 min.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Thermodynamic Characterization of the Amphoterism of Solid Oxides MO in Aqueous Media

E. V. Shkol'nikov

St. Petersburg State Forestry Academy, St. Petersburg, Russia

Received October 2, 2006

Abstract—Thermodynamic method was used to calculate, with account of the formation of hydroxo complexes, the molar solubilities of crystalline and amphoteric oxides MO as functions of the pH value of an aqueous-alkaline nonoxidizing medium at 25°C and constants of heterogeneous equilibria in water and alkaline and acid media for amphoteric metal MO, where M is Be, Mn–Zn, Cd, Hg, Sn, or Pb.

DOI: 10.1134/S1070427206120020

Previously, the thermodynamic method has been used to calculate the effect of the pH value on the molar solubility of solid hydroxides $M(OH)_2$ and their amphoterism in aqueous media has been characterized. Of interest is a thermodynamic calculation of the solubility of solid oxides MO, where M is Be, Sn, Pb, Cd, and 3*d*-elements from Mn to Zn, in an aqueous alkaline medium.

Crystalline and amorphous oxides are widely used in manufacture of ceramics and glasses, mineral paints and enamels, oxide electrodes and catalysts, in metallurgy, semiconductor electronics, and medicine [3–6]. As products of real dehydration of hydroxides, solid oxides can be obtained by heating of hydroxides in an inert medium. Anhydrous oxides are produced by burning of metals in oxygen or by pyrolysis of carbonates, oxalates, and nitrates [4–6].

Ionic-covalent oxides MO are frequently formed with defective crystal structure and, depending on the preparation method and conditions, have noticeable homogeneity regions and show differences in coloration and chemical activity [5, 6].

The amphoteric nature of the oxides MO is poorly understood, and quantitative data on their solubility in aqueous media are rather scarce and frequently contradictory [3–7]. For example, according to the reference book [7], the metal oxides under consideration are poorly soluble (PbO, HgO) or virtually insoluble in water, all react with acids, and only BeO (in fusion), ZnO, and PbO react with alkalis. According to [4], a white precipitate of $Sn(OH)_2$, soluble in acids and alkalis, is readily transformed to dark amphoteric oxide SnO upon heating. Dehydration of the white precipitate of $Pb(OH)_2$ yields red α-PbO at 100°C and yellow oxide β-PbO at lower temperatures. Both modifications are dissolved in acids and concentrated alkalis [4]. According to [5], the BeO oxide reacts under heating with acids and alkalis, CoO is amphoteric with predominance of basic properties, and MnO reacts with alkalis under strong prolonged heating. According to [6], black oxide α-SnO and red α-PbO with a tetragonal structure are amphoteric with predominance of basic properties. Brown cubic modification of CdO, black monoclinic CuO, and gray-green cubic modification α-CoO form, when fused with alkalis, cadmate, cuprates, and cobaltites(II). Black iron(II) oxide reacts with acids and alkaline solutions, but upon calcination, its chemical and pyrophoric activity decreases. Uncalcined hexagonal oxide α-BeO is hygroscopic, and that calcined below 500°C readily reacts with acids, and more difficultly, with alkali solutions [6].

The procedure described in [1] was used to perform a thermodynamic calculation of the solubility of crystalline and amorphous oxides MO in pure water and aqueous alkaline medium (with addition of NaOH) at pH 7–15 and 25°C. The standard Gibbs energies of formation of ions in aqueous solutions, ΔG_f^0, necessary for calculation of thermodynamic solubility constants K_s^0 (SP = $a_{M^{2+}} a_{OH^-}^2$) were taken from [8], and the Gibbs energies of formation of solid oxides at 298 K, from reference books [7, 9, 10]. The molar solubility of MO in pure water and aqueous solutions

Table 1. Thermodynamic parameters of dissolution of amorphous and crystalline oxides in water and alkali at 25°C

Composition	pK_s^0		H_2O			NaOH		s, M, in 1 M NaOH
	calculation	[13]	pH^0	s^0, M	$[M(OH)_2]$, M	pH_{opt}	ps_{min}

* Amorphous powder.

of NaOH was calculated, taking into account the ionic strength of the solution and the formation of mononuclear hydroxo complexes, from reference data [11], and that for iron(II), cobalt(II), and copper(II), from the data of [12] by the generalized equation

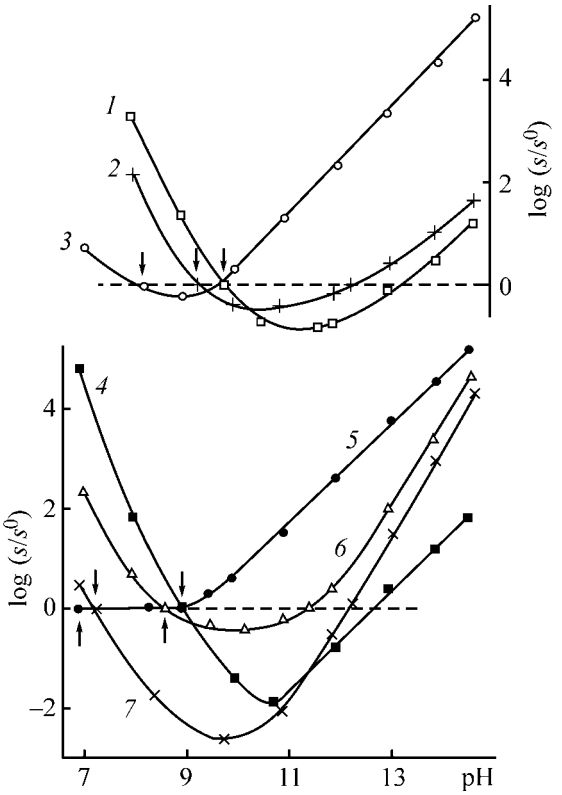
$$s = c_M = \frac{K_s^0}{f_{M^{2+}} f_{OH^-}^2} \sum_{i=0}^{n} \beta_i [OH^-]^{i-2}.$$

Here, the constant K_s^0 characterizes the heterogeneous chemical equilibrium (2); $f_{M^{2+}}$, f_{OH^-}, molar activity coefficients of M^{2+} and OH^- ions; and $\beta_0 = 1$, β_1, β_2, β_3, β_4, general stability constants of the hydroxo complexes MOH^+, $M(OH)_2$, $M(OH)_3^-$, and $M(OH)_4^{2-}$ [average values $\beta_1 = 2.4 \times 10^6$, $\beta_2 = 4.2 \times 10^{10}$, and $\beta_3 = 7.9 \times 10^{13}$ were taken for lead(II)]. The molar solubility of MO in a 1 M solution of NaOH was calculated using a simplified formula, $s = 1.06 K_s^0 \Sigma \beta_i$.

The equilibrium concentration of free OH^- anions and the pH^0 value of saturated solutions of oxides in pure water (indicated by arrows in the figure) were found by solving a system of, as a rule, three equations [1], using Cardano's method for a reduced cubic equation. For the oxides SnO, PbO, and CuO, a system of four equations was solved with account of the formation of, respectively, the $Sn(OH)_3^-$, $Pb(OH)_3^-$ [11], and $Cu_2(OH)_2^{2+}$ complexes [12].

The heterogeneous reaction MO(s) + H_2O(l) = $M(OH)_2$(s) does not proceed to any noticeable extent in standard conditions [3–6] for the MO oxides under consideration (ΔG_{298}^0 varies from –18 kJ mol^{-1} for MnO to +10 kJ mol^{-1} for CuO, in contrast to the ionic oxides CaO, SrO, and BaO, for which ΔG_{298}^0 of the reaction mentioned above is in the range from –58 to –64 kJ mol^{-1}). For this reason, formation of solid hydroxides $M(OH)_2$ was disregarded in the calculations. The contribution from neutral $M(OH)_2$ complexes to the molar solubility in pure water ranges from 0.2% for FeO to 99% for HgO.

The results of the calculations are listed in Table 1, in which $pK_s^0 = -\log K_s^0$; s^0, total molar solubility of solid oxides in water; and $[M(OH)_2]$, equilibrium molarity of neutral complexes in aqueous solutions of oxides at 25°C.



It can be seen from Table 1 that there is a satisfactory agreement between the pK_s^0 values calculated in this study and taken from [13]. For a number of oxides, K_s^0 was calculated for the first time. The solubility of amorphous oxides, as well as that of amorphous hydroxides [1, 2], is higher than that of crystal-

line modifications. The solubility (Table 1) and chemical activity of finely dispersed yellow α-modification of HgO markedly exceeds that of the red crystalline modification β-HgO having a more ordered rhombic structure [4–6]. The experimental values of the solubility in pure water at 25°C are as follows: 2.4×10^{-4} and 2.3×10^{-4} M for α-HgO and β-HgO, respectively [7]; $\sim 3 \times 10^{-5}$ and $\sim 6 \times 10^{-5}$ M for α-PbO and β-PbO [4]; and 4×10^{-5} M for CoO [6].

Calculation of the average ligand number $\bar{n}$ in hydroxo complexes (Bjørrum function) at pH 15 gives values in the range 2.5–4 for all the oxides in Table 1, which indicates that the amphoterism condition $\bar{n} > 2$ is satisfied for these oxides, in contrast to basic oxides MgO, CaO, SrO, and BaO ($\bar{n} < 2$). The minimum solubility of oxides MO is observed at the optimal concentration of OH^- ions, for which the mole fraction of neutral complexes $M(OH)_2$ in the alkaline solution is the highest. This condition was used to find, as it was done in [1], pH_{opt} and then s_{min}. The values of $ps_{min} = -\log s_{min}$ at 25°C are listed in Table 1. The figure shows a strong (85- and 500-fold) negative effect of common OH^- ions on the solubility of, respectively, FeO and CuO oxides in the alkali (curves *4* and *7*). For SnO, similarly to HgO [1] and $Sn(OH)_2$ [2], the effect of common OH^- ions is virtually zero (see figure, curve *5*). The figure shows on the logarithmic scale dependences of the ratio of molar solubilities of a number of oxides in an alkaline medium and pure water on the pH value of the medium at 25°C.

A comparative evaluation of the amphoterism of the oxides was based on the ratio ($A > 1$) of their molar solubilities in an alkaline medium with pH 14.7 (5 M NaOH solution) and in pure water. As follows from the data in Table 2, the amphoterism parameter A of stable crystalline oxides MO decreases as the element M replaced in the order Be → Sn → Zn → Cu → Pb → Ni → Mn → Fe ≈ Co → Cd → Hg. This series mainly differs from that established for hydroxides $M(OH)_2$ [2] in the position of Be and Pb, which is due to the low value of s^0 for the polymeric oxide BeO, compared with s^0 for PbO (Table 1). The amphoterism parameter A of amorphous oxides ZnO (4.5×10^4), CuO (3.9×10^4), and CdO (77) markedly exceeds that for crystalline modifications (Table 2). The amphoterism parameter and molar solubility of stable oxides MO (except ZnO, α-SnO, and CuO) markedly exceed the corresponding values for stable hydroxides $M(OH)_2$ [1, 2].

The molar solubility of stable crystalline oxides in a 5 M NaOH solution at 25°C decreases in the order

Ratio of molar solubilities in an aqueous-alkaline medium (s) and in pure water (s^0) vs. the pH value of the medium at 25°C. Oxide: (*1*) CdO, (*2*) α-CoO, (*3*) α-BeO, (*4*) FeO, (*5*) α-SnO, (*6*) ZnO, and (*7*) CuO.

α-BeO → MnO → α-SnO → ZnO → α-PbO → CuO → α-NiO–CdO → α-CoO → FeO ≈ β-HgO from 0.51 M for α-BeO to 3×10^{-4} M for FeO and β-HgO. The solubility of the oxides, beginning with CuO,

Table 2. Amphoterism parameters of stable crystalline oxides in aqueous media at 25°C

Oxide	A	pH_b	B	C_b	C_a
α-BeO	2.2×10^5	9.6	1.5	1.1	0.65
α-SnO	1.47×10^5	7.5	0.5	1.0	0.45
ZnO	4×10^4	11.5	2.8	1.4	1.5
CuO	1.5×10^4	12.3	5.0	1.6	1.1
α-PbO	3.4×10^3	10.8	1.3	0.9	1.2

CdO	9.09	12.99	17.43	–	5.37	3.44	–	–4.89	–14.98
β-HgO	14.96	25.55	18.53	–	3.74	4.54	–	0.97	–2.43

under the conditions specified does not exceed 0.12 g l^{-1}. Raising the solubility requires heating in more concentrated alkaline solutions and, in the case of the readily oxidized oxides, FeO, MnO, and CoO, also the presence of a reducing atmosphere [5, 6]. Despite the high value of the basic amphoterism parameter A, the solubility of the oxides CuO and α-NiO in a 5 M NaOH solution is low (1.5×10^{-3} M) because of the low values of s^0 and s_{min} (Table 1) and influence of other parameters (Table 2) supplementing the characterization of the amphoterism of the oxides. Table 2 lists, in addition to the amphoterism parameter A, also the pH_b values at which the negative effect of common OH^- ions is completely compensated for upon addition of NaOH by the positive contribution of hydroxo complexes to the solubility of oxides ($s_b = s^0$). The lower the pH_b value, the smaller the amounts of the alkali added and its concentrations necessary for the solubility of an oxide to increase, compared with that in pure water. The lowest pH_b values were observed for the amphoteric oxides α-SnO and α-BeO, which also have the highest values of parameter A, and the highest pH_b values, for CdO and HgO with weak manifestation of amphoterism (Table 2). Parameter B, equal to ($pH_b - pH^0$) determines the range of pH values in which $s < s^0$ is the lowest for α-SnO and the highest for CuO and HgO (see figure and Table 2). Parameters C_b and C_a, equal to $|\Delta ps_b/\Delta pH|$ and $\Delta ps_a/\Delta pH$, respectively, characterize the rate at which the solubility increases as the pH value is varied upon addition of NaOH ($pH > pH_b$) or $HClO_4$ ($pH < pH^0$). The amphoteric oxides SnO, ZnO, PbO, and BeO, which have increased values of parameter C_b and low pH_b, dissolve to a noticeable extent even in 1–2 M NaOH [3, 5]. By contrast, the oxides NiO, FeO, CoO, and CdO, which have high values of parameter C_a, readily dissolve in acids [3–5], but very difficultly and in small amounts in highly concentrated alkalis [3, 5, 6].

Similarly to hydroxides [2], amphoteric oxides with chemical bonds close in ionicity [1] to the O–H bond can shift the equilibrium of water ionization and add hydroxide ions or protons in aqueous media to give the corresponding ions. Therefore, the comparative characterization of the acid-base properties of the stable crystalline oxides was supplemented with a calculation of thermodynamic parameters, ΔG^0_{298} and pK_{298} (K equilibrium constant), for heterogeneous reactions in a saturated aqueous solution:

$$MO(c) + H_2O(l) \rightleftarrows MOH^+(s) + OH^-(s), \quad (1)$$

$$MO(c) + H_2O(l) \rightleftarrows M^{2+}(s) + 2OH^-(s), \quad (2)$$

$$MO(c) + H_2O(l) \rightleftarrows H^+(s) + HMO_2^-(s), \quad (3)$$

$$MO(c) + H_2O(l) \rightleftarrows 2H^+(s) + MO_2^{2-}(s), \quad (4)$$

$$MO(c) + H_2O(l) \rightleftarrows M(OH)_2(s). \quad (5)$$

The results obtained in calculation of pK_{298}, based on the data of [7–12], are listed in Table 3, whence follows that, with the exception of α-SnO [the constant of equilibrium (3) exceeds that of equilibrium (1)], the basic properties of the amphoteric oxides MO dominate over the acid properties. The same

conclusion follows from a calculation of pK_{298} for chemical equilibria in alkaline and acid media:

$$MO(c) + OH^-(s) \rightleftarrows HMO_2^-(s), \quad (6)$$

$$MO(c) + 2OH^-(s) \rightleftarrows MO_2^{2-}(s) + H_2O(l), \quad (7)$$

$$MO(c) + H^+(s) \rightleftarrows MOH^+(s), \quad (8)$$

$$MO(c) + 2H^+(s) \rightleftarrows M^{2+}(s) + H_2O(l). \quad (9)$$

It can be seen from Table 3 that SnO, PbO, BeO, and ZnO are best soluble in alkalis, and MnO, CdO, PbO, and CoO, in acids. According to equilibrium (5), formation of neutral complexes $M(OH)_2$ in dissolution of solid oxides in water is the most probable for HgO and the least so for CuO, FeO, and NiO.

CONCLUSIONS

(1) The thermodynamic method was used to calculate, taking into account the formation of hydroxo complexes, the effect of the pH value of the aqueous-alkaline nonoxidizing medium on the molar solubility at 25°C of solid oxides MO, where M is Be, Sn, Pb, Cd, Hg, and 3*d* elements Mn–Zn.

(2) It was found that the amphoterism condition (average ligand number in hydroxo complexes $\bar{n} > 2$ at pH 14–15) is satisfied for the oxides studied and their amphoterism is evaluated (parameter *A* increases from 1.6 for HgO to 2.2×10^5 for BeO).

(3) It was shown that the solubility in aqueous media and the amphoterism parameter *A* of the oxides decreases on passing from an amorphous to a stable crystalline modification. The molar solubility and amphoterism parameter of stable oxides MO, except ZnO, α-SnO, and CuO, substantially exceed those of stables hydroxides $M(OH)_2$.

(4) A calculation of the thermodynamic constant of heterogeneous acid-base equilibria in aqueous media for stable crystalline oxides MO demonstrated that the basic properties predominate and are the most pronounced in MnO, CdO, and FeO and the weakest in HgO. Only in SnO, similarly to $Sn(OH)_2$ [2], weak acid properties predominate over weak basic properties.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Capillary Moisture Content of a Number of Powders of Varied Nature

Abstract—The moisture content of a number of powders of varied nature, kept in a medium with 100% humidity, was studied. The volume of capillary fluid "bridges" between particles of powdered materials was evaluated.

DOI: 10.1134/S1070427206120032

Storage and processing of a powder under real conditions are accompanied by its moistening via adsorption of water vapor from the ambience onto the surface of particles and its capillary condensation in pores of the material. These processes lead to formation of fluid "bridges" between powder particles and give rise to capillary forces between the particles [1–5], which strongly affect the properties of powders and dispersed formulations based on these powders. The amount of moisture absorbed by a powder depends on various parameters of the material and ambience, size and shape of particles, their wettability, "free volume" of the powdered material, ambient temperature and humidity, etc.

The aim of this study was to evaluate the amount of moisture absorbed by powders of varied nature as a manifestation of their capillary properties and, in particular, capillary condensation of water vapor from the humid ambience in pores of the material and the contribution to the water content from the volume of fluid bridges between particles of powdered materials. In solving the problem formulated above, we used a previously developed calculation model for determining the capillary forces between powder particles [6–8], which also makes it possible to find the amount of capillary moisture in fluid bridges between the particles.

It is known that capillary forces occur in any powder in its storage in a humid medium [1–4]. These forces are generated under the action of capillary condensation of water vapor in the spaces between particles, described by the Kelvin equation. The fluid condensed between the particles takes the form of a bridge with a meniscus (Fig. 1) curved by the interaction between fluid molecules with one another and with dispersed particles, with an additional pressure ΔP created in the fluid. According to the Laplace equation, this pressure is given by

$$\Delta P = \sigma(1/r_1 + 1/r_2), \quad (1)$$

where σ is the surface energy (tension) of the fluid at the phase boundary; r_1 and r_2, curvature radii of the principal mutually perpendicular sections of the fluid surface.

The dependences obtained for calculating the capillary forces and its components in the general form are as follows

$$F_c = F_{c1} + F_{c2} = f(D_p, \theta, \sigma, h, \alpha, C, \Phi_p), \quad (2)$$

where F_c, F_{c1}, F_{c2} are the capillary force and its components, caused by the surface tension of the fluid

MPh	20–40	"	61	0.6	0.47	6
ASD-4 aluminum	1–10	"	65	0.72	0.54	5
TiO_2	0.2–1	Grainy	55	0.79	0.67	4
ZnO	0.5–2	"	48	0.94	0.77	3
MgO	0.2–0.5	"	39	0.94	0.78	3

* For the free volume of a densified powder.

and the Laplace pressure; D_p, particle size; θ, angle of contact between the fluid and particle surface; h, distance between particles; α_f, angle characterizing the fluid volume V_f in a bridge; C, coordination number; and Φ_p, particle shape.

The results of our microscopic studies make it possible to approximate the meniscus of the fluid bridge by a circular arc of radius r [8]. With account of this circumstance, the fluid volume enclosed between particles is defined as a volume of a figure produced in revolution of a circular arc of radius r, minus the volume of particles immersed in the fluid:

$$V_f = 2\pi \int_{y_1}^{y_2} [f(y)]^2 dy - V_c, \quad (3)$$

where $f(y)$ is the equation describing the curve forming the surface of revolution; y_1 and y_2, integration limits defined as the ordinates of the lower and upper points of the perimeters of particle wetting by the fluid; and V_c, volume of particles submerged in the fluid.

If there is no mass exchange of fluid between the medium and the "bridge," then, in accordance with the Kelvin equation, we obtain

$$\Delta P = \frac{\ln(p_1/p_2)\rho_f R_g T}{2M}, \quad (4)$$

where p_1 and p_2 are the saturated vapor pressures of the fluid over curved and planar surfaces, respectively; ρ_f, fluid density; R_g, universal gas constant; T, temperature; and M, molecular weight of the fluid.

Solving Eqs. (1)–(4) by numerical methods, we obtain the capillary pressure, capillary forces, and volume of the fluid bridge with account of various particle parameters. The calculations demonstrated that the region in which the model we suggested is valid is restricted to a certain limiting volume of the fluid ($V_{f.\,max}$ or $\alpha_{f.\,max}$) [6], on exceeding which the neighboring bridges between contacting particles merge.

EXPERIMENTAL

The experimental amount of moisture absorbed was determined for powders differing in the nature of the solid phase and in the particle size and shape. We also examined the following materials: aerosil of A-380 brand; finely dispersed oxides of titanium (anatase), zinc, and magnesium (light magnesia); aluminum of ASD-4 brand; and hollow glass (MG) and phenol-formaldehyde (MPh) microspheres. The values of the parameters characterizing the powdered materials under study are listed in Table 1.

Preliminarily dried powder samples were placed in desiccators with a certain humidity set with saturated aqueous solutions of various salts and were kept there until an equilibrium state was attained. The gain in the mass of the powdered materials depended not only on the adsorption of moisture on the samples and its capillary condensation, but also on the possible chemical interaction of the material of particles with moisture and gaseous components of the ambience. Therefore, we also evaluated the contribution of the capillary component to the overall increase in the powder mass. The study was performed at the following relative air humidities: 31, 84, 98, and 100%.

According to the experimental data, the powder mass increases to the greatest extent at high, nearly

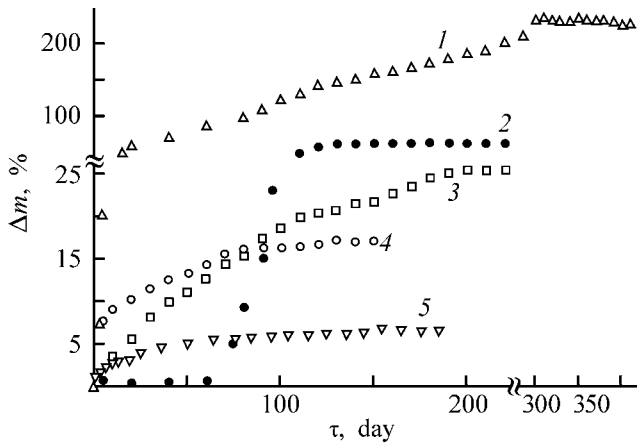

Fig. 2. Mass gain Δm by various powdered materials vs. the time τ of their residence in a humid medium (relative humidity 100%). (*1*) A-380 aerosil, (*2*) ASD-4 aluminum, (*3*, *4*) glass and phenol-formaldehyde microspheres, and (*5*) titanium oxide.

100%, relative humidities of the medium. This is in a qualitative agreement with the results of calculations by the previously obtained dependences and by Eqs. (1)–(4) for determining the volume of the fluid bridge between powder particles. In accordance with these results, further studies of the moisture content of the powders, including the capillary content, were carried out for the maximum relative humidity of the medium, 100%. The dynamics of mass gain by the materials under study is illustrated by Fig. 2.

It can be seen that the equilibrium values of the mass gain by the powders, as also the time in which these values are reached, strongly vary with the material of powder particles. According to the data obtained, the highest rate of mass gain by the majority of powdered materials is observed in the initial stage, whose duration does not exceed several days. The equilibrium state is reached by the powder mass during a significantly longer time.

The distinctive run of the curve describing the moistening of the ASD-4 aluminum powder is probably due to the influence of the oxide film on the particle surface. In this case, the initial stage of moistening is governed by the large contact angle between the oxide film and water and corresponds to a low moistening of the material, and further stages are determined by the gradual disintegration of the oxide film, which leads to a steep rise in the powder mass because of the chemical interaction between aluminum and water. Figure 2 does not show data for powders of zinc and magnesium oxides, for which the chemical interaction of the particle material with moisture and gaseous components of the ambience is, according the data of [9, 10] and results of thermogravimetric measurements, the key factor in the mass gain by the powders. Nevertheless, it is beyond any doubt that these powders also contain a certain amount of capillary-bound water, which depends on the relation between rates of adsorption and capillary condensation of moisture, on the one hand, and those of chemical reactions, on the other.

It can be seen from Fig. 2 that the highest absorption capacity (229%) is observed for A-380 aerosil, which is mainly determined by the large adsorption surface area of the material (380 $m^2 g^{-1}$). In addition, the nearly spherical shape of the contacting particles favors formation of small pores between the particles, and, according the Kelvin equation, a greater amount of capillary condensation of moisture vapor is observed in these pores. This assumption is confirmed by the results obtained by Ur'ev [11], who, in particular, studied the effect of the particle size on the structuring of dispersed materials. The rather large amount of moisture absorbed by microspheres (MG and MPh) is due to the low density of hollow particles (300 kg m^{-3}). The absolute amounts of moisture absorbed by microspheres and titanium oxide can be considered rather close if we take into account their relative densities (300 and 3700 kg m^{-3}) and insignificantly differing contact angles.

Moisture adsorbed by a powder is initially concentrated in spaces between contacting particles and forms fluid bridges. Here, we mean by the contact between particles not only direct contact of their surfaces, but also their arrangement at a certain distance from one another, which, however, does not lead to disintegration of the fluid bridge [6]. As small bridges between particles are formed, the fluid starts to fill coarser pores and voids in the powder, the volume of the fluid (or α_f) starts to exceed $V_{f.\,max}$ ($\alpha_{f.\,max}$), and this process may occur during a long time. The large amounts of moisture absorbed by these powders can be only understood if we take into account the decisive contribution of the capillary condensation of water vapor in spaces between particles and within pores of the material to its overall moisture content. To verify this assumption, we carried out thermogravimetric and differential-thermal studies of powders and, in particular, determined the relationship between the temperature *T*, changes in mass (thermogravimetry, TG), rate of changes in mass (differential thermogravimetry, DTG), and differential-thermal changes (differential-thermal analysis, DTA) in the samples on an MOM Q-1500D derivatograph (Hungary). The TG and DTA

curves of humid powders composed of A-380 aerosil and glass microspheres are shown in Fig. 3.

These curves were obtained in the dynamic mode at a low sample heating rate of 2.5 deg min^{-1}. The TG and DTA curves for phenol-formaldehyde spheres are qualitatively similar to those for glass microspheres and are not shown for this reason. To compare the amounts of moisture sorbed and desorbed by the powders, the values of these parameters were determined relative to the mass of dry materials. The experimental data in Table 2 characterize the mass gain (loss) by the powders as a result of absorption (desorption) of not only moisture as the main component responsible for changes in the mass of most of the samples studied, but also, as a rule, of minor amounts of other components contained in the humid ambience. It was found that aerosil loses 98% of moisture it absorbed, on being heated to 150°C, and 99% at 300°C. For glass microspheres, the loss of moisture at these temperatures is 78 and 90%, respectively. The loss of capillary moisture by phenol-formaldehyde microspheres is somewhat lower, 70% at 150°C. On further heating, a loss of mass is also observed, which starts to be determined by thermal destruction of the material of the particles as 255°C is reached (Fig. 4). An indication of the moisture loss by the samples is the endothermic peak at temperatures close to 100°C, well-pronounced in the DTA curves.

Most of the other samples studied also show a characteristic strong decrease in mass on reaching temperatures of 100°C and more (Fig. 4). It can be seen that the TG curves of the samples represented in the figure are more intricate than those in Fig. 3. To refine the run of the dependences and the manner in which

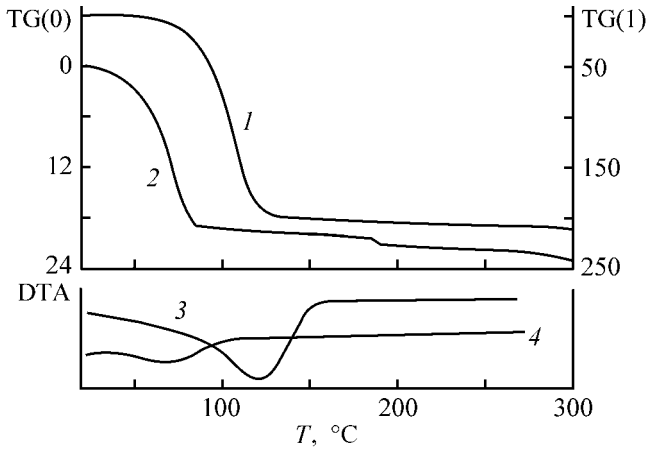

Fig. 3. TG and DTA curves for humid powders. (TG) Change in powder mass and (T) temperature; the same for Fig. 4. Powder: (*1*, *3*) A-380 aerosil and (*2*, *4*) glass microspheres.

the sample mass changes, we carried out additional TG experiments under quasi-isothermal conditions, which provide a higher selectivity of the reactions accompanied by changes in sample mass. The data obtained confirmed the type of the TG curves for all the samples represented in Figs. 3, 4.

The multiple-step run of the TG curves in Fig. 4 has different explanations for different samples. For example, the mass loss of 17% relative to the amount of moisture absorbed by the ASD-4 aluminum powder at temperatures below 150°C (Table 2) is mostly due to loss by the sample of physically adsorbed moisture and capillary moisture. The portions of mass loss at higher temperatures are associated with the loss of water molecules by aluminum hydroxides and, further, with the formation of aluminum oxide, which is confirmed by the data of [10, 11].

For humid MgO and ZnO powders, the multiple-step run of the TG curves is accounted for not only by the processes listed above, but also by transformations under the action of high temperatures of other chemical compounds: hydroxides and carbonates formed in these materials when they are kept in a humid medium [10–12].

The run of the TG curve of powdered titanium oxide, which is chemically inert toward the components of a natural humid ambience, is affected by another factor. Although a greater amount of moisture absorbed by the powder is evaporated or desorbed below 130°C (Fig. 4, Table 2), the remaining amount of water in the powder is still rather significant (40%). This is possibly due to the fact that a titanium oxide pigment was chosen for the study as a nontoxic material widely used in various industries, which, however, contains various, including water-soluble, impurities. These impurities, which find their way into the product from raw materials, are formed as by-products in synthesis, and are specially introduced into the material in manufacture to impart to it necessary properties [12–17], affect its adsorption-desorption properties. This assumption is also applicable, to a certain approximation, to other powders under study: zinc and magnesium oxides. However, revealing the composition of frequently insignificant admixtures in the powders under consideration and determining the properties of these admixtures, their effect, and mechanisms of formation and decomposition of the supposed compounds is beyond the scope of our study and cannot affect its main conclusions.

According to the experimental data in Table 2 and Figs. 3 and 4, the fraction of the capillary-bound water exceeds, for most of the samples, 50% of the amount of moisture and other components of the humid ambience, absorbed by the samples. We estimated by calculation the amount of moisture capillary-condensed in fluid bridges between particles (Table 2). The calculation was based on the data from Table 1 and on theoretical relations [6–8] and Eqs. (1)–(4) for determining the volume of a fluid bridge. It can be seen that, for all the samples, the calculated amounts of the capillary moisture contained in the bridges are lower than the corresponding experimental values. This discrepancy can be explained in several ways. The most important of these is that moisture is condensed in a powdered material not only in narrow spaces between contacting particles to form fluid bridges, which is accounted for by the calculational model we developed ($V_f \le V_{f.\,max}$), but also in the free volume of the powder, which includes coarser pores and voids and may reach considerable values. A substantial amount of moisture is also accumulated within agglomerates formed in a moisture-containing powder. This assumption is in an agreement with the results of [18–22]. It was also shown in [21, 22] that larger agglomerates have a higher porosity, compared with smaller agglomerates. Consequently, powders with higher porosity contain a greater amount of large particle agglomerates and, accordingly, a greater amount of moisture bound within these agglomerates.

We also estimated the amount of moisture necessary for complete filling of pores in a powder. The calculated ranges of variation of the moisture content with the experimentally determined free volume of the powder (Table 1) changing from a densified to a bulk powder are listed in Table 2. It can be seen that the amount of adsorbed and capillary-bound moisture in the powders is considerably smaller than our calculated values, which are, to be sure, rather specific and approximate parameters for the moisture forms in the powders, analyzed here. If, however, we only qualitatively explain the essence of the phenomena we observed, these data can characterize, to a certain approximation, the adsorption and capillary properties of the powders under study.

A next, though less significant explanation of the discrepancy between the calculated and experimental values is that the moisture adsorbed by the powder is originally concentrated on the particle surface to form polymolecular layers of the fluid [18, 19, 23]. The amount of this moisture is commonly small, compared with that of the capillary condensate. However, it can substantially increase at a higher dispersity of powder particles (e.g., for nanoparticles) and the accordingly larger specific surface area of the material.

The fraction of the forms of bound moisture under consideration, of adsorbed and capillary types, is the greater, the larger the free volume of the material, the higher the air humidity and particle dispersity, and the better their wettability. The effect of these factors on the powder properties is the most clearly manifested for A-38 aerosil.

Our study revealed that the method we suggested for calculating the amount of capillary fluid in a powdered material cannot be used to find the absolute amount of the capillary moisture in the powder because it is difficult to determine the shape and size of pores in the material and the type of contact between its particles. To solve this problem, it is necessary to carry out additional studies with a comprehensive account of the relationship between various parameters of powdered materials and of the ambient medium. The calculation method can qualitatively estimate the effect of certain parameters of particles and the ambience, such as dispersity of particles and their contact angle, humidity of the ambience, and free volume of the powder, on its capillary moisture content.

CONCLUSIONS

It was shown that the amount of moisture adsorbed by the powders under study from the ambience at its high humidity and capillary-bound in fluid bridges between contacting particles is considerably smaller than the amount of capillary moisture contained in pores of the material.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

A Calorimetric Study of the Enthalpy of Enzymatic Hydrolysis of Components of a Product from Vegetable Raw Materials for Enteral Feeding

Abstract—The enthalpy of hydrolysis of potato starch and some starch-containing components of Lider-1 nutrition product for enteral (tube) feeding in the presence of α-amylase enzyme was studied on a DAK-1-1 differential microcalorimeter.

DOI: 10.1134/S1070427206120044

Full-value, balanced, and ecologically pure nutrition is a powerful factor in improving the peoples' health and enhancing the protective function of an organism. An important role in these processes is played by biologically active additives. This particularly refers to food products for enteral feeding, in which case a patient cannot feed on his (her) own, e.g., because of a cranial or maxillary injury. The action of such biologically active additives largely depends on the degree of assimilation by a human organism of valuable substances contained in these additives. In this context, development of an instrumental technique for evaluating the completeness of food digestion in a human organism is a topical task. In recent years, thermodynamic methods have been finding increasing use in solution of biochemical and biological problems. For example, attempts have been made to characterize enzymatic reactions and processes involving various proteins, cells, and cell communities by changes in the basic thermodynamic functions, entropy, enthalpy, and Gibbs function [1–5]. However, studies of this kind are few in number.

A calorimetric technique has been used to determine the enthalpy in our studies of the reaction of enzymatic hydrolysis of some polysaccharides, which models the process that occurs in the gastrointestinal tract of a human in food digestion [6–9]. In addition, we measured the specific heat of potato starch and its constituents, amylase and amylopectin, in the range 6–230 K and calculated their thermodynamic characteristics (enthalpy, entropy, and Gibbs energy) [10].

In the present study, we determined the enthalpy of hydrolysis of potato starch and some starch-containing components of Lider-1 nutrition product for enteral (tube) feeding[1] in the presence of the α-amylase enzyme.

EXPERIMENTAL

We studied potato starch of Ekstra brand [GOST (State Standard) 7699–78] with 13.6 wt % H_2O in the air-dry state. It contained 33.5 wt % amylase and 66.5 wt % amylopectin [10].

Lider-1 preparation includes the following starch-containing components (wt %): germinated wheat 7.76, potato 15.52, apple 23.72, and carrot 3.10 [TU (Technical Specification) 9160-002-39232318–97, TU 9164-001-39232318–01, TU 9197-018-39232318–01). They were prepared using a unique technique of cryogenic grinding, developed at Biofit ZAO (Nizhni Novgorod) [12–14]. The air-dry samples of vegetable products contained 4–6 wt % water.

α-Amylase (α-1,4-glucose-4-glucanohydrolase, KFZ 2.1.1), also named dextrinogenamylase or gly-

[1] The formulation of the product has been developed at Fitograd ZAO (Nizhni Novgorod) [11].

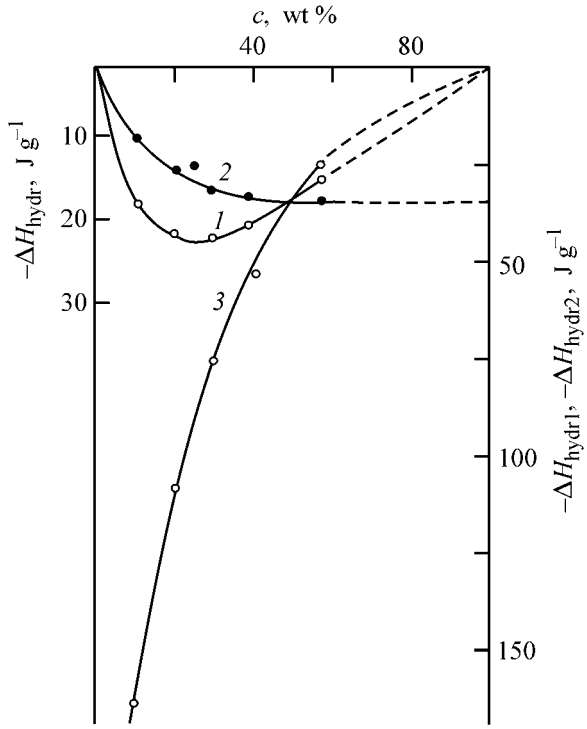
cogenase, belongs to enzymes that are involved in catabolic reactions.

It is an endoamylase, which favors rupture of intramolecular α-1,4-glucoside bonds of amylase and amylopectin and leaves intact the α-1,6-glucoside bonds of the latter. Therefore, starch is mostly hydrolyzed in the presence of α-amylase to low-molecular weight dextrins and a certain amount of maltose.

The enzyme was extracted from a cattle pancreas and had the form of a white powder produced by sublimation drying.[2]

According to [15], the optimal medium for amylase is an alkaline medium (e.g., in the small intestine), whose pH is controlled by sodium hydrocarbonate contained in the human intestinal juice. Therefore we adjusted the pH value to 8.3 with $NaHCO_3$. The optimal temperature of enzymatic process is in the range 303–313 K [16]. Therefore, we carried out experiments at a temperature of 310 K, close to the normal temperature of the human body. The amylolytic activity of α-amylase was determined colorimetrically (λ = 590 nm), as recommended in [17], using the Lachema biotest (AMS-50), and the specific activity of the enzyme was found to be 2260 E ml^{-1}.

The energy-related effects accompanying the hydrolysis of starch and starch-containing vegetable products in the presence of α-amylase were measured with a DAK-1-1 differential microcalorimeter (of the Thiane–Calve type [3]). This device can continuously record release and absorption of very small amounts of heat at some temperature in the range 298–373 K during a long period of time [18]. The control-and-calibration unit of the microcalorimeter can give 11, varied in steps, values of power in the range 8×10^{-5}–4×10^{-3} W in heaters of any of the cells, provide a prescribed temperature mode of operation in the temperature range specified, and ensure isothermal experimental conditions. The minimum and maximum measurable power was 1×10^{-6} and 3×10^{-1} W, respectively.



A sample of a vegetable product (0.1–0.25 g) was sealed in a thin-walled glass ampule and a liquid modeling the stomach medium, the optimal for the action of α-amylase, was poured in a preliminarily sterilized metallic ampule of the calorimetric cell. As noted above, the solution had a pH value of 8.3, which was maintained with $NaHCO_3$. A 0.02–0.1-g portion of α-amylase was dissolved in 4 ml of this solution. The metallic ampules were closed with Teflon stoppers. After a thermal equilibrium was attained between the cells of the calorimeter (at 310 K), the reagents were mixed by breaking the glass ampule with a pin and agitating the mixture. The energy obtained was corrected for heat effects accompanying the ampule breaking, reagent agitation, and solvent evaporation. These values were found in preliminary experiments to be 0.02–0.05 J (ampule breaking) and 0.005–0.03 J (agitation). The calorimeter was calibrated with electric current [13, 18]. An electric current of certain power was passed through the heater of a calorimetric cell, the amount of heat released in the heater was found from the Joule–Lenz formula, and the corresponding peak was recorded on the chart strip of the self-recorder. The time was measured with a stopwatch with an accuracy of 0.1 s.

To evaluate the measurement error and check the experimental procedure for absence of systematic errors, we determined the integral enthalpy of solution of chemically pure KCl in twice-distilled water. The concentration of KCl solutions in water was varied from 0.003 to 0.1 mol per 1000 g. To pass from the KCl solutions under study to a solution with a molality of 0.278, we used a value of the enthalpy of dilution (concentration) equal to 360 J mol^{-1} [19]. The experiments were performed under the same conditions as the experiments aimed to determine the enthalpy of the reaction of enzymatic hydrolysis under study. It was found that the error of separate measurements of the enthalpy of KCl solution in water is 4%, and the error in determining the average value does not exceed 2% at a confidence probability of 95%. Our results coincided with reliable published data for 310 K (160.20 ± 0.30 kJ mol^{-1}) to within these values [19].

Differential curves of heat release or heat absorption provide information about the rate of energy release or absorption and the area delimited by the curve and the time axis corresponds to the amount of energy accompanying the process under study. Using the calibration curve for the given experiment, we found the change in enthalpy in the process studied by the weighing method [3]. The process was considered to be complete when the differential curve reached the zero level.

The enthalpy of hydrolysis, ΔH_{hydr}, was found for starch and cryopowders in the air-dry state and recalculated per gram of the dry (anhydrous) process. In addition, we compared the values we obtained for the enthalpy of their hydrolysis with the enthalpy of enzymatic hydrolysis of the same components, but

[2] The enzyme was delivered by the Research Institute of Antibiotics and Enzymes (St. Petersburg).

Enthalpy of enzymatic hydrolysis of air-dry starch. (*c*) Amylase content. For explanation, see text.

subjected to thermal drying and mechanical crushing. This made it possible to evaluate the degree of digestion of the products preserved by different methods. The values obtained were compared with the enthalpy of mixing of the products with an aqueous solution of $NaHCO_3$ (pH 8.3) that contained no enzyme, ΔH_{mix}.

Published data were available only for the enthalpy of mixing of starch and water [20], and, therefore, we measured the enthalpy of its mixing with the aqueous solution of $NaHCO_3$ (pH 8.3). This process is accompanied by an exothermic effect. The contribution to the negative enthalpy of mixing of starch and an aqueous solution of $NaHCO_3$ comes not only from the enthalpy of hydration of starch macromolecules by molecules of water, but also from the negative enthalpy of transformation of starch from the glassy state to the hyperelastic state upon its mixing with water. This is the so-called excess enthalpy of the glassy state [21–24]. In our experiments, the fraction of starch in the final solution varied from 2 to 5 wt %. The value found for ΔH_{mix} of the process of starch mixing with an aqueous solution of $NaHCO_3$ in this concentration range was –88…103.5 J g^{-1} starch. This value coincides within the experimental error with the published value of the enthalpy of mixing of starch and water [20]. The enthalpy of mixing of α-amylase (0.6 wt %) and an aqueous solution of $NaHCO_3$ (pH 8.3) was found to be 12.3 J g^{-1} amylase.

The values obtained for the enthalpy of hydrolysis of air-dry starch (13.6 wt % H_2O) in the presence of α-amylase, ΔH_{hydr}, calculated per gram of the mixture are shown in the figure (curve *1*). The same figure presents the values of ΔH_{hydr} recalculated per gram of starch (ΔH_{hydr1}, curve *2*) and per gram of amylase (ΔH_{hydr2}, curve *3*). A correction for water contained in the air-dry starch (13.6 wt %) was made and the values obtained were recalculated to anhydrous starch. The results obtained are listed in Table 1. As can be seen in the figure and Table 1, this process is exothermic and the value of ΔH_{hydr} is three times smaller than the enthalpy of mixing of starch and water [20]. The resultant value of ΔH_{hydr} includes the exothermic enthalpy of mixing of starch and water, endothermic enthalpy of rupture of glucoside bonds in macromolecules of amylase and amylopectin, enthalpy of formation of hydroxy groups in the products, and exothermic enthalpy of hydration of the products formed.

Tables 2 and 3 list the enthalpies of hydrolysis of vegetable products with an aqueous solution of $NaHCO_3$ (pH 8.3) in the presence of α-amylase and the enthalpies of mixing of some of these products with the aqueous solution of $NaHCO_3$ in the absence of α-amylase.

It can be seen from these tables that the enthalpies in question are negative. At the same time, ΔH_{hydr} exceeds ΔH_{mix} in absolute value. The difference exceeds the error in determining the enthalpies. The fact that a tendency opposite to that for starch is observed in this case indicates that more complex processes accompany the enzymatic hydrolysis of starch in real vegetable products. According to [25], α-amylase attacks the starch grain in a vegetable process and loosens its surface to form channels and grooves, i.e., leads to a kind of grain disintegration into parts. In our opinion, this makes it possible to evaluate by the enthalpy of hydrolysis the accessibility of starch in a vegetable product in relation to the type of its treatment. As can be seen from the data in Tables 2, 3, the values of ΔH_{hydr} and ΔH_{mix} are close for a sample of crushed germinated wheat, i.e., starch in the crushed sample is inaccessible to the enzyme.

It is important that the enthalpy of hydrolysis of cryopowders is more negative (by a factor of 1.2–1.5), compared with thermally dried and mechanically crushed samples. This indicates that starch in cryopowders is more accessible to the enzyme, compared with mechanically crushed vegetable products. Thus, it may be assumed that both the cryopowders and Lider-1 preparation, in which they are contained, will be better digested and assimilated by a human organism. ΔH_{hydr} of Lider-1 preparation was calculated from the additive contributions of the enthalpies of hydrolysis of the cryopowders it contains, with account of their content in the preparation. It was found to be –14.6 J g^{-1} dry product. This value is close to that found experimentally: ΔH_{hydr} = –13.8 J g^{-1} dry product (Table 2).

CONCLUSIONS

(1) It was shown that the enthalpy of hydrolysis of products prepared using the cryogenic grinding method and of thermally dried and mechanically ground samples is negative. The enthalpy of hydrolysis of cryopowders is more negative (by a factor of 1.2–1.5) than that of thermally dried and mechanically ground samples. Thus, starch in cryopowders is more accessible to the enzyme, compared with the mechanically ground vegetable products.

(2) The enthalpy of enzymatic hydrolysis of Lider-1 preparation was calculated from the additive contributions of the enthalpies of hydrolysis of the constituent cryopowders, with account of their contents in the preparation. It was demonstrated that the assimilability of products for enteral feeding can be evaluated by the additive contributions of the enthalpies of enzymatic hydrolysis of the components of these products. This provides objective criteria for assessing the quality of food additives and enables

deliberate selection of those better digested and assimilated by a human organism.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Coagulation in Lipid- and Protein-containing Systems

T. Yu. Gumerov, A. F. Dobrynina, R. A. Yusupov, and V. P. Barabanov

Kazan State Technological University, Kazan, Tatarstan, Russia

Received March 16, 2006

Abstract—The behavior of real disperse systems with organic impurities was examined under conditions of destabilization by inorganic coagulants. A number of physicochemical methods of analysis and a simulation method were used to identify the character and type of the complexes formed and to calculate their stability constants.

DOI: 10.1134/S1070427206120056

Real colloid systems in wastewater from industrial enterprises are complex multcomponent systems. The data on the stability of lipid- and protein-containing systems [1, 2] need adequate systematization.

In this study, we optimized the conditions of removal of lipid- and protein-containing impurities from wastewater with inorganic coagulants.

EXPERIMENTAL

We examined disperse systems in wastewater from meat processing enterprises.[1] The main characteristics of the disperse systems are listed in Table 1. It is seen that all of them exceed the levels prescribed by the existing standards by an order of magnitude.

As coagulants served aluminum sulfate [GOST (State Standard) 12966–85], aluminum chloride [TU (Technical Specifications) 102612–88], and iron(III) chloride (GOST 4147–74).

We used the Soxhlet [3], Kjeldahl [4], and IR Fourier spectroscopic methods [5] for physicochemical analysis. The optimal concentrations of the coagulants were determined on the basis of the sedimentation analysis data in combination with measurements of the optical density of the solutions. The composition of the compounds in the system and the constants of equilibria involving them were determined by potentiometric titration and simulation [6]. An IR Fourier spectroscopic study showed that the samples of both disperse systems (KMC, SMC) contain nearly identical sets of absorption bands (Fig. 1). The absorption band intensities were estimated from the optical densities, using the band at 1600 cm^{-1} as internal reference.

The IR Fourier spectra contain a broad absorption band at 3300–3348 cm^{-1} corresponding to stretching vibrations of the NH groups. A group of bands at 3000–2850 cm^{-1} is associated with the absorption of

Table 1. Main characteristics of the disperse systems

methylene (CH_2) and methyl (CH_3) groups in the paraffin and naphthene moieties. The absorption at 1742 cm^{-1} corresponds to carbonyl groups (C=O) in esters, and that at 1710 cm^{-1}, to the same groups in acids.

The IR spectra of both the systems suggest a close similarity between their structural and group compositions (Fig. 1).

To select the optimal concentrations, samples of both the systems were subjected to sedimentation analysis and optical density measurements [7]. Figure 2

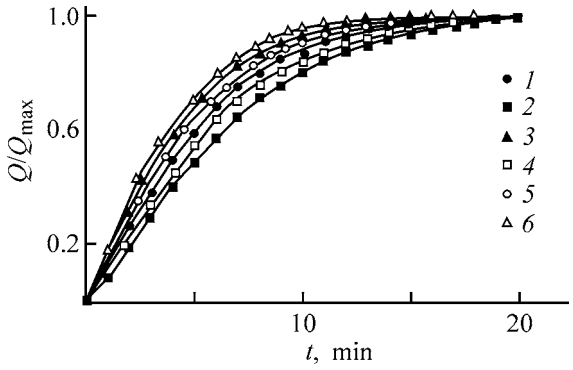

Fig. 2. Sedimentation curves of the samples of water from the overall discharge, plotted in the Q/Q_{max}-vs.-t coordinates. (Q, Q_{max}). shows the optimal concentrations of the coagulants, derived from the sedimentation analysis data. It is seen that the iron(III) and aluminum salts differ in the coagulating power. Upon introduction of iron(III), the chloride sedimentation proceeds at a higher rate than that in the case of the aluminum salts. The coagulating powers of the aluminum salts with respect to disperse phases having close structural and group compositions are virtually identical. Minor differences in the performance of the coagulants based on Al(III) may be due to complexation during hydrolysis in the dispersion medium and to quantitative differences in the chemical composition of the initial blends. At low doses of the coagulants introduced, iron(III) chloride surpasses in performance the coagulants based on Al(III) [$FeCl_3 > Al_2(SO_4)_3 \approx AlCl_3$].

To explain the influence exerted by the dispersion medium on the coagulating power of the coagulants, we converted the potentiometric titration curves obtained to the plots of the formation function: $n_L = (c_{NaOH}V_{NaOH})/(c_{salt}V_{salt})$ vs. pH of solution [8]. The curves in Fig. 2 were obtained at the optimal concentrations of the coagulants, derived from the sedimentation analysis data. In contrast to the curves obtained at lower concentrations of the coagulants, the converted potentiometric titration curves obtained under these conditions (Fig. 3) exhibit characteristic ascending sections due to the formation of compounds containing OH^- ions. Treatment of the potentiometric titration curves using the simulation method [9] al-

* Order of indexing of complexes: (1) K is the step stability constant of the complex; (2) X, addition sign (the plus or minus sign cannot be used because of the incompatibility in programming); 3) B, the most stable series of a complex, termed the basis series of the complex (in this study, hydroxo complexes); the digit to the right of symbol B denotes the compound no. in these series [e.g., B0 corresponds to Al^{3+}, B1, to $AlOH^{2+}$, B2, to $Al(OH)_2^+$, etc.]; the digit to the left of symbol B, the number of the particles added; and C, the accompanying series of the complex compound; (4) P, polynuclear compounds; and (5) S, sediments.

lows determination of the type, amount, and distribution pattern for the Al(III) and Fe(III) complexes formed. Table 2 shows that complexing during hydrolysis of the aluminum and iron(III) salts involves formation of a series of polynuclear compounds.

The higher coagulation activity of $FeCl_3$ compared to $Al_2(SO_4)_3$ and $AlCl_3$, can be due to formation of complexes with higher stability constants. For example, compounds of Fe(III) include complexes ML, ML2, ML3, and ML4 from the basis series with higher stability constants as compared to similar complexes of Al(III) (Table 2). Polynuclear compounds of Fe(III) and Al(III) differ in both stability and composition. Polynuclear compounds of Fe(III) form an M2L complex similar to that of Al(III), with higher stability constants [log β 3.8 for Fe(III) against 2.3 for Al(III)] and a series of new complexes, differing from those of Al(III) in composition: M32L64, M32L70, and M40L100. The stability constants of these complexes (from 146 to 186) suggest possible formation of stable polymeric Fe(III) compounds. In the scheme of formation of the main complexes in the Al(III)–H_2O–OH^-–Cl^- and Fe(III)–H_2O–OH^-–Cl^- systems, protein

Formation of main complexes in the Al(III)–H_2O–OH^-–Cl^- and Fe(III)–H_2O–OH^-–Cl^- systems.

and lipid impurities are removed from the wastewater at pH 6.2–7.1. Under these conditions, the coagulants occur in solutions as stable complexes M6L12 and M6L12S for aluminum salts and M32L64 and M32L70 for iron(III) chloride with a higher degree of polymerization at the formation function $n_L = 2$.

CONCLUSIONS

(1) The behavior of disperse systems containing protein and lipid impurities under the action of coagulants, Al(III) and Fe(III) salts was studied. The optimal concentrations of the coagulants were determined by sedimentation analysis.

(2) It was shown that, for disperse systems containing protein and lipid impurities with comparable structural and group compositions, the coagulating power of the Fe(III) and Al(III) salts varies as $FeCl_3 > Al_2(SO_4)_3 \approx AlCl_3$.

(3) It was demonstrated that the presence of polynuclear compounds with close quantitative characteristics for coagulants based on Al(III) and of polynuclear compounds with higher stability constants for Fe(III) can be among the factors determining the effect of coagulants on disperse systems.

Abstract—The adsorption capacity of ultradispersed diamonds for synthetic dyes and medicinal preparations was studied.

DOI: 10.1134/S1070427206120068

Recently, the interest has substantially increased in the field of special-purpose adsorption materials that possess improved properties and are intended for analytical separation of substances, synthesis of ultrapure materials and preparations, fast removal of impurities from liquids and gases, and operation under severe conditions, e.g., at high temperatures and large mechanical loads and in aggressive media.

Particularly stringent requirements are imposed on adsorbents and ion exchangers on their base that are developed for medical purposes. There exists a large demand for hemo- and enterosorbents and application sorbents that can adsorb toxins and carry ions, medicinals, and enzymes necessary for an organism. Carbon sorbents are most widely used in medicine. At present, carbon therapeutic methods constitute a broad and rapidly developing discipline, whose impact on the practice and results of curing may be rather important.

Previous studies have shown that the adsorption properties of detonation-produced ultradispersed diamonds (UDD) compare well with the adsorption properties of numerous carbon sorbents [1], and, moreover, UDD have a number of advantages: they posses a large specific surface area, have a plentiful of electrons on the diamond surface (multiple radical-donor), show nanometer dimensions, bear a large number of oxygen-containing functional groups, have chemically inert grains and hydrophilic surface and do not show any carcinogenic, mutagenic, or toxic properties [2].

The present study is concerned with the possibility of using as medical adsorbents the UDD produced by separation of ultradispersed diamonds by acid treatment of a detonation-produced carbon-containing stock under mild conditions in the presence of metal salts. UDD of this kind are distinguished by a high degree of purification and stable particle size scatter (3–4 nm) and are not subject to graphitization upon prolonged storage or use [3, 4].

It has been found previously that high-temperature treatment of UDD in a flow of hydrogen or argon leads to virtually complete removal of protonogenic surface groups and to an increase in the sorption capacity because of the active diamond skeleton [1]. Thus, UDD can be used both as carrier of medicinals, which does not cause their destruction, and as a means of removal of toxins from a human organism, e.g., in hemoperfusion.

EXPERIMENTAL

Information about the applicability of a sorbent to detoxication of an organism is provided by analysis of its adsorption capacity in aqueous solutions. As test substances are used synthetic dyes, whose molecules have dimensions close to those of biological substances serving as objects of medical studies, but are more stable and convenient in handling [5]. The adsorption capacity of UDD was evaluated by studying the adsorption of the following dyes: Methylene Blue (M = 344), Bromocresol Purple (M = 540), and Indigo Carmine (M = 466). The choice of dyes as test substances is based on the similarity in size and structure between their molecules and molecules of such preparations as antitumor medicinals of alkylating nature and soporifics belonging to the group of barbiturates.

Table 1. Amount of dye adsorption for various forms of ultradispersed diamonds

Dye	Molecular weight	Amount of adsorption, mg g^{-1}, at indicated modification temperature, °C						
		Starting UDD	argon			hydrogen		
			400	600	800	400	600	800
Methylene Blue	344	1.72	17	24	103	58	103	137
Bromocresol Purple	540	14	16	19	18	19	19	19
Indigo Carmine	460	4	6	9	89	9	9	

The dye concentrations were determined by photocolorimetry on a FEK-56N device. The amount of adsorption was evaluated for Luminal (Phenobarbital) preparation, whose removal from a human organism is an important detoxication problem.

This study is concerned with the ability of UDD to adsorb on their surface medicinals of the most important groups used for therapeutic purposes: (1) ampicillin, an antibiotic of the penicillin series with a broad action spectrum, quantitatively determined by acid–base titration [6]; (2) euphyllin (salt of theophylline with ethylenediamine), an alkaloid of the purine series, whose application in medicine is based on its stimulating effect of the nerve system, quantitatively determined in terms of ethylenediamine by acid–base titration [7]; (3) papaverine hydrochloride, an alkaloid of the isoquinoline series, exhibiting a high spasmolytic activity, quantitatively determined by acid–base titration in nonaqueous media [7]; (4) norsulfazol, a sulfanilamide preparation widely used in curing of inflammatory processes, quantitatively determined by nitritometry [8]; and (5) Phenobarbital (Luminal), a barbiturate exhibiting, together with a soporific effect, an antispasmodic action, quantitatively determined by acid–base titration in nonaqueous media [6].

An UDD, whose purification and preparation has been described by the authors previously [3, 4], was used in the study.

The amount of adsorption was determined under static conditions at room temperature [5, 9]. A dry UDD powder (0.5 g) was placed in 50 ml of a solution of a substance under study. The following solvents were used: distilled water for all the dyes, ampicillin, euphyllin, and norsulfazol; 50% ethanol for papaverine hydrochloride; and 95% ethanol for Phenobarbital. The choice of solvents was governed by the analytical procedure used to determine a substance [6–8]. After a sorbent–solution system reached equilibrium, the residual concentration of the sorbate was determined.

The adsorption capacities of unmodified UDD and UDD calcined in a flow of argon at 400, 600, and 800°C and in a flow of hydrogen at the same temperatures (modified UDD) were studied.

It was found experimentally that the maximum amount of adsorption corresponds to the following dye concentrations (mg ml^{-1}): Methylene Blue 1.9×10^{-2}, Bromocresol Purple 0.92, and Indigo Carmine 9.0×10^{-2}. The data obtained in determining the amount of dye adsorption for various kinds of modified UDD are listed in Table 1.

The experiments performed demonstrate that high-temperature modification of UDD improves their adsorption capacity. A significant increase in the amount of adsorption is observed for Methylene Blue. It should be noted that the adsorption capacity of unmodified UDD for Bromocresol Purple exceeds that for the other dyes; however, it is virtually unaffected by modification. The effect of thermal treatment of UDD on the sorption of Bromocresol Purple is also insignificant. Thus, it may be assumed that presence of acid groups on the surface of UDD does not noticeably affect the adsorption process and the adsorption capacity increases upon modification because of the coarsening of pores in UDD aggregates.

The results obtained in determining the adsorption of Methylene Blue demonstrate that UDD is a more effective adsorbent than carbon hemosorbents studied previously. For example, the maximum amount of adsorption is 137 mg g^{-1} for UDD and only 31 mg g^{-1} for AR-3 industrial carbon [10].

The amounts of adsorption of the medicinal substances were determined using pelletized pharmaceutical preparations. The content of the substances under study was monitored by pharmacopoeial techniques

Table 2. Adsorption of medicinal preparations

Medicinal preparation	Molecular weight	c_{in}, mg ml^{-1}	Adsorption, mg g^{-1}, for indicated modification temperature, °C					
			argon			hydrogen		
			400	600	800	400	600	800
Ampicillin	349	1.8	42	52	741	54	88	
Euphyllin (in terms of ethylenediamine)	60	1.6	25	44	50	19	48	82
Papaverine hydrochloride	376	2.6	41	51	74	60	70	86
Norsulfazol	255	1.3	10	32	46	6	32	52
Phenobarbital	232	9.2	–	22	15	–	33	21

[6–8]. The amounts of adsorption of the medicinal preparations are listed in Table 2.

It can be seen from Table 2 that, as in the case of dyes, the specific adsorption of the medicinal preparations strongly varies with UDD modification conditions and reaches the highest values, except for Phenobarbital, when there are virtually no surface groups on the UDD surface (thermal treatment at 800°C). UDD samples modified at 400°C in a flow of argon have a higher adsorption capacity than those calcined at the same temperature in a flow of hydrogen. As the treatment temperature is raised, the situation changes: the best adsorption properties are observed for UDD samples modified at 600 and 800°C in a flow of hydrogen. Presumably, the presence of protonogenic surface groups hinders the adsorption process, because these groups are most completely removed in modification in a flow of hydrogen at higher temperatures. A considerable increase in adsorption is observed for norsulfazol.

The results obtained in determining the adsorption capacity of UDD for the medicinal preparations show that UDD is a more effective sorbent that AR-3 industrial carbon. The maximum adsorption capacity for Phenobarbital is 33 mg g^{-1} for UDD and only 12 mg g^{-1} for AR-3 industrial carbon [10].

It should be noted that both for medicinal preparations and for dyes there is no unambiguous dependence of the amount of adsorption on the molecular weight of a substance.

CONCLUSIONS

(1) Ultradispersed diamonds possess a sufficient adsorption capacity for some medicinal preparations and show promise for use in medicine.

(2) Thermal treatment of ultradispersed diamonds in a flow of argon or hydrogen improves their adsorption capacity.

(3) Thermal treatment of ultradispersed diamonds at 800°C in a flow of hydrogen is the most effective method for raising their adsorption capacity.

SORPTION AND ION-EXCHANGE PROCESSES

Reactivation of a Solid Carbon-Containing Adsorbent, Graton, in a Microwave Electromagnetic Field

Abstract—Results of experimental studies of reactivation of a graphite packing, Graton, in a microwave electromagnetic field are presented.

DOI: 10.1134/S107042720612007X

Adsorbents are widely employed in purification of gases and liquids to remove impurities [1]. Their use requires periodic regeneration, removal of adsorbed substances from adsorbent pores [1]. For example, electrochemical decomposition of a sodium amalgam on a carbon-containing packing with a developed surface area (Graton or graphilite) is used at organochlorine plants[1]. The packing serves as an anode, and sodium amalgam, as a cathode. The sodium amalgam is produced in the reaction of sodium with mercury: sodium is recovered from brine in discharge of Na^+ ions at the mercury cathode of a chlorine electrolyzer:

$$Na^+ + e + nHg \rightarrow NaHg_n.$$

Decomposition of the sodium amalgam with water is the second stage in manufacture of sodium hydroxide. In the process, NaOH and H_2 are formed, and mercury is regenerated and returned into the electrolyzer:

$$NaHg_n + H_2O \rightarrow NaOH + 1/2H_2 + nHg.$$

In electrochemical decomposition of the amalgam, reduction and oxidation processes occur separately and involve the current-conducting surface, which accepts electrons from the reducing agent, $NaHg_n$, and transfers them to the oxidizing agent, H_2O:

$$NaHg_n \rightarrow Na^+ + e + nHg,$$

$$H_2O + e \rightarrow OH^- = 1/2H_2.$$

The process of amalgam decomposition can be made tens of times faster if it is directed by the electrochemical pathway. For this purpose, it is necessary to diminish the hydrogen overvoltage. The most pronounced effect is achieved when hydrogen evolution occurs on a material with a lower overvoltage, brought in electric contact with mercury, rather than on mercury itself.

The amalgam is decomposed in vertical cylindrical apparatus (VCA) filled with a graphite packing (Fig. 1).

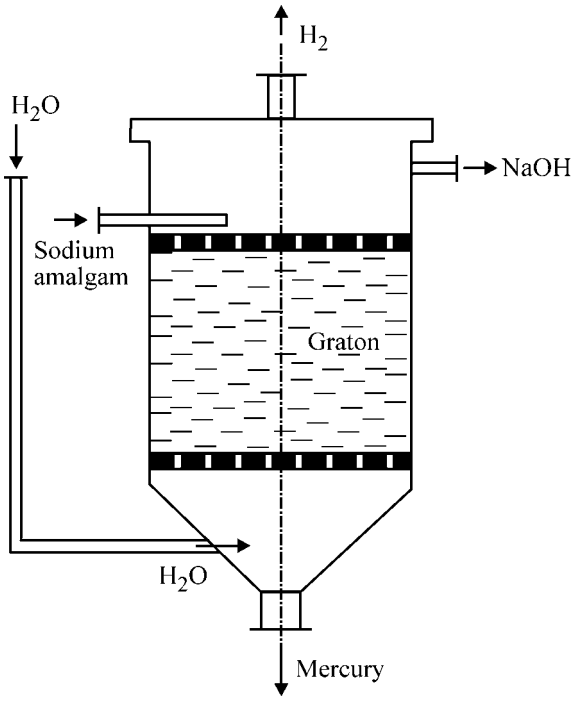

Fig. 1. Schematic of a VCA for decomposition of a sodium amalgam.

[1] Kaustik ZAO, Sterlitamak.

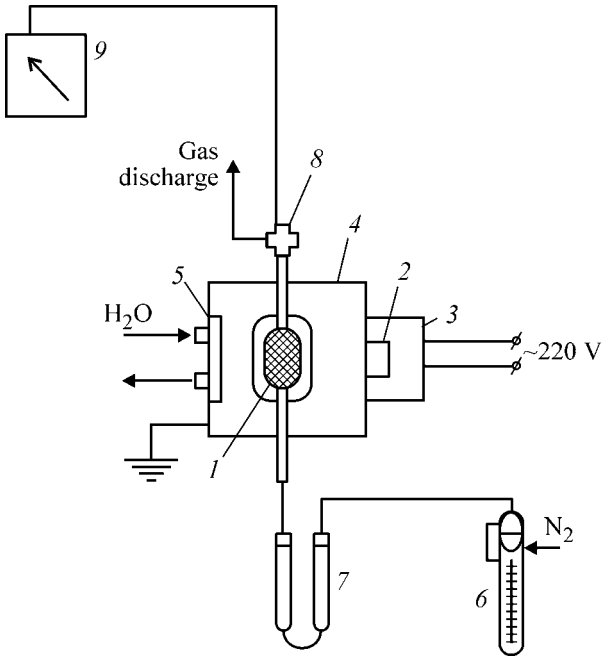

Fig. 2. Schematic of a laboratory microwave installation. (*1*) Reactor (150 cm^3), (*2*) magnetron, (*3*) power unit, (*4*) resonator, (*5*) load, (*6*) rheometer, (*7*) dehumidifier, (*8*) thermocouple, and (*9*) potentiometer.

Vigorous hydrogen evolution occurs on its surface. Such a system, constituted by a packing, a sodium amalgam, and water, operates as a short-circuited cell in which the packing serves as a cathode, and the amalgam, as an anode.

The content of sodium in the amalgam is 0.5×10^{-2} to 0.5 wt % (weak amalgam at the VCA outlet, ≤0.005–0.05 wt % sodium; and strong amalgam at the VCA inlet, ≤0.5 wt %).

At present, Graton packing (pellets 15–20 mm in diameter and 10–15 mm high) are used to fill VCA. Graton is a graphite packing with titanium carbide (up to 30%), which is added to make lower the hydrogen overvoltage.

A deposit of magnesium, calcium, and iron hydroxides, carbonates and sulfates is formed on the Graton surface. The exchange current decreases because a part of the surface is eliminated from the process of electrochemical decomposition of the amalgam. Therefore, the packing is periodically regenerated. At present, this is done under industrial conditions by washing with an HCl solution (5 wt %). This procedure is labor-consuming, has a low efficiency, and is ecologically unsafe.

The degree of filling of the packing material with adsorbed final and intermediate products of the electrochemical reaction depends on the state of the electrically conducting surface. For the sodium amalgam to be decomposed efficiently, a developed adsorbing surface of the packing is necessary. The exchange current decreases because adsorbed molecules of surface deposits screen a part of the packing surface. The catalytically active surface may constitute only a minor fraction of the whole adsorbing surface, and even a small amount of catalytic poisons may suppress the surface activity, with the adsorption capacity reduced only slightly.

Thus, to provide the electrocatalytic activity of palletized graphite packings (Graton, graphilite), it is necessary to preserve and maintain their porosity by regenerations at regular intervals of time, with blocking of active centers precluded.

To reactivate such a catalyst-adsorbent as Graton, it is necessary to desorb reaction products from pores. This is presently done for the most part by thermal methods. For example, thermal reactivation of AG-5 activated carbon saturated with elementary sulfur in oxidation of hydrogen sulfide by sulfur dioxide on a catalyst, activated carbon, has been reported [1]. According to [1], only 35% of sulfur contained in the carbon is extracted in 2 h at 200°C, and about 90% of sulfur is removed during the same time at 300°C. The thermal reactivation is carried out as follows. Spent carbon heated to 150°C is charged into a regenerator and is suspended there by overheated steam delivered into the regenerator from below. Before being fed into the regenerator, the steam is heated to 500°C in a superheater [1]. This treatment results in that reaction products and impurities are removed from pores of the spent carbon.

This method has a number of disadvantages: inefficient delivery of energy by steam via convective heat exchange; high energy expenditure for heating of steam to 500°C; formation of waste gases (toxic products of fuel combustion in the steam superheater) and wastewater (condensed steam), contaminated with desorbed reaction products.

The authors suggest to improve the efficiency and ecological safety of the reactivation of the adsorbent and the duration of its work between regenerations and to raise its activity by microwave (ν = 2450 MHz) heating of the adsorbent in a flow of an inert gas (nitrogen).

Figure 2 schematically shows a laboratory microwave installation for adsorbent reactivation. Graton containing up to 80 wt % carbon and about 20 wt % TiC was used in the experiments.

The graphite packing (Graton) was calcined, without any preliminary washing, at 400–450°C for 1–1.5 h in a bed of graphite particles in a laboratory reactor having a working volume of 150 cm^3 (Fig. 2). After a thermal treatment cycle was complete, the furnace was switched off and the packing cooled down in the inert gas. After the temperature of the packing decreased to 30–40°C, Graton was discharged from the reactor into a dry hermetical vessel.

The process occurred in reactor *1* (Fig. 2) under the action of a microwave electromagnetic field produced by microwave generator (magnetron) *2*, fed by high voltage from power unit *3*. To absorb the microwave radiation reflected from the walls of resonator *4*, a matching load *5* was installed within the working chamber (resonator). The load had the form of a horizontal cylindrical glass (quartz) vessel with flowing-through water. The air-cooling of the magnetron was provided by a ventilator built in the case of the microwave furnace. The power unit was energized from a two-phase three-line ac supply (220 V, 50 Hz).

Figure 3 shows how the volume of evolved hydrogen depends on the duration of sodium amalgam decomposition.

Introduction into the Graton bed (particle size 10 mm) of finer particles of a solid substance, filler, with particle size not exceeding 3 mm, e.g., of the same adsorbent, Graton, leads to an increase in the bulk density of the adsorbent and to a higher degree of conversion of the electromagnetic power into heat. After an experiment is complete, the filler is separated from Graton by sieving (5 mm mesh). The effect of the bulk density of a sample on its heating (temperature) at a fixed power (750 W, 2450 MHz) is illustrated below:

Change in bulk density, g cm^{-3}	Rise in sample temperature, °C
0.5	8.5
0.10	22
0.15	27
0.2	30

As can be seen from these data, an increase in the bulk density by 0.2 g cm^{-3} (from 1.03 to 1.23 g cm^{-3}) leads to a rise in the Graton temperature by 30°C (from 420 to 450°C). An increase in the amount of the substance by a certain amount in a unit volume favors transformation of a greater amount of microwave power into heat in the Graton bed. However,

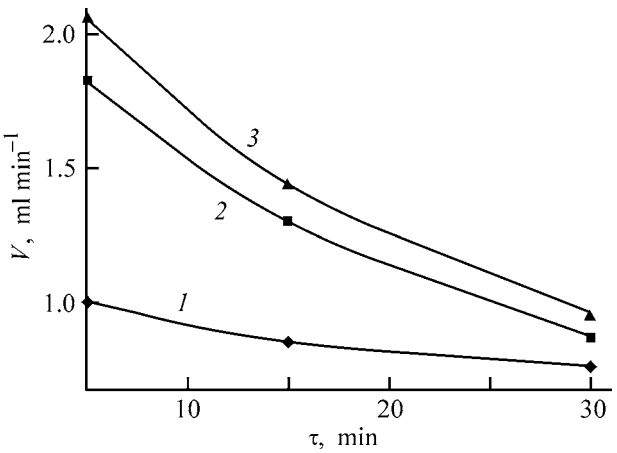

Fig. 3. Volume *V* of evolved hydrogen vs. the duration τ of decomposition of the sodium amalgam. Graton packing: (*1*) fresh, (*2*) reactivated by the conventional method, and (*3*) reactivated in a microwave field.

the temperature stabilizes at a certain mass of the substance and starts to decrease as the mass grows further.

The results obtained in studying the reactivation of the Graton graphite packing in a microwave field are presented in Fig. 3. It can be seen that, upon calcination of a spent packing in a microwave field (curve *3*), the rate of hydrogen evolution increases, compared with the case of a packing reactivated by the conventional method (curve *2*) and even with that of afresh (unused) packing (curve *1*).

The reactivation of the packing occurs as follows. In thermal regeneration without access of air, salts and bases adsorbed on the packing surface are decomposed and desorbed. Being evaporated, the desorbed substances raise the porosity of the graphite packing, i.e., make its active surface area larger. In the case of a highly intense evaporation of desorbed substances, observed under the action of microwave radiation on the adsorbent, the porosity of the graphite packing and, consequently, the active surface area increase to a greater extent.

Introduction of a solid substance that effectively converts the microwave power into heat, e.g., graphite with finer grains, into the packing (Graton) bed will enable these particles to act not only as an insulating material that provides accumulation of heat in the regeneration zone, but also as an absorber of desorbed substances, because the highest sorption capacity is observed just for powdered substances. As graphite particles of this kind can serve, in particular, particles of crushed Graton (with a size of up to 3 mm).

Application of the reactivation technique developed in this study improves the activity of the Graton graph-

ite packing by 14.3% [2]. This, in turn, makes longer the service life of the adsorbent between regenerations, raises its absorption capacity, and improves the efficiency of the process using the thus reactivated adsorbent.

CONCLUSIONS

It was shown that the reactivation technique developed raises the activity of the Graton graphite packing by 14.3%. This, in turn, improves the efficiency of the process employing the adsorbent reactivated in this way.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Combined Standardless Electrochemical Method for Determination of Lead(II), Copper(II), and Cadmium(II) in Aqueous Solutions

A. A. Sheremet and S. S. Ermakov

St. Petersburg State University, St. Petersburg, Russia

Received August 1, 2006

Abstract—A combined standardless method (no calibration of the device against standard solutions or use of the method of additives is required) for determination of lead, copper, and cadmium in aqueous solutions is suggested. The method operates on principles of inversion voltammetry and potentiostatic coulometry. It is convenient for automated analysis of technological solutions and wastewater from electroplating and hydrometallurgical shops.

DOI: 10.1134/S1070427206120081

The inversion voltammetry (IVA) is one of the most sensitive analytical techniques. The high sensitivity of IVA is primarily due to the fact that the scheme of analysis includes a stage of pre-electrolysis, i.e., electrolytic concentration of a substance on the electrode. The stage of electrolysis is also included by another analytical technique, controlled-potential coulometry (CPC). The sensitivity of the latter method is lower, but it does not require calibration of the devices, i.e., it is not necessary to construct calibration plots or to use the method of additives. A condition for correct application of IVA is that the concentration c^0 of a substance being determined should remain unchanged in the bulk of the solution. Commonly, this is achieved by using a sufficiently large volume of a solution being analyzed and a small area of the working electrode. The latter circumstance predetermines a low pre-electrolysis current, which virtually does not change the analyte concentration in the solution bulk in the stage of its electrolytic concentration.

By contrast, the potentiostatic coulometry is based on measurements in which the analyte concentration varies with time. This occurs because the substance being determined is transformed under the action of electric current in electrolysis of a solution. Therefore, large-area electrodes are used in coulometry, and attempts are made to minimize the volume of a solution being analyzed.

The experimental conditions of IVA and CPC can be represented as follows.

For the IVA method:

$$\left.\begin{aligned} c(t) &= c^0 = \text{const}, \\ i_\text{d}^0 &= Kc, \\ i_\text{d} &= i_\text{d}^0 = \text{const}, \end{aligned}\right\} \quad (1)$$

$$V/S \to \infty, \quad (2)$$

For the CPC method:

$$\left.\begin{aligned} c(t) &= c^0 e^{-kT}, \\ i_\text{d}(t) &= Kc(t), \\ i_\text{d}(t) &= i_\text{d}^0 e^{-kT}, \end{aligned}\right\} \quad (3)$$

$$V/S \to 0, \quad (4)$$

Here, c^0 is the concentration of a substance being determined in solution; t_d^0, limiting diffusion current corresponding to the volume concentration c^0; $i_\text{d}(t)$, limiting diffusion current at an instant of time t; t, electrolysis duration; V, solution volume; and S, electrode area.

The advantage of IVA and CPC is the simplicity of measurements by these techniques, which is especially convenient under industrial conditions. However, IVA requires that the measuring device should be preliminarily calibrated or the method of additives should be used. The CPC technique is free of this disadvantage, which makes automated measurements less complicated.

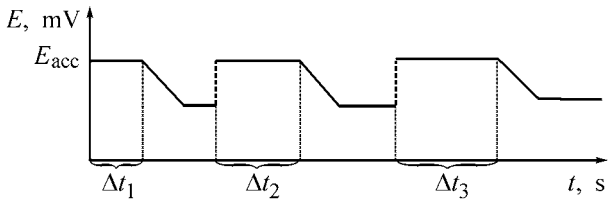

Fig. 1. Time diagram of variation of the potential in the combined electrochemical method. (E) Electrolysis potential and (t) electrolysis duration.

To improve the sensitivity of analysis by the CPC method and make it faster, it has been suggested to use thin-layer cells [1] or porous electrodes [2–4] in order to diminish the ratio between the volume of a solution being analyzed and the electrode area. In these studies, solution electrolysis was performed to complete, as postulated by the authors, recovery of the substance and, further, its amount was calculated by the Faraday law.

Several variants of inversion methods, which allow standardless electrochemical determination of analytes in solution, have been suggested [5–10]. The authors of [5, 6] used the potentiometric analytical procedure: they created by pre-electrolysis an amalgam of a metal being determined of a known concentration and then used the quasi-equilibrium potential of the $M(Hg)/M^{n+}$ system to calculate the concentration of the analyte in solution.

An inversion-chronopotentiometric variant of the standardless electrochemical method of analysis has been suggested [7]. This method is based on a multiple-cycle dissolution of a metal from an amalgam obtained in the pre-electrolysis stage and subsequent finding of a charge Q_∞ corresponding to complete recovery of the substance from solution. Further, the amount of the analyte in solution is found from the Faraday law.

A similar technique, named "dynamic coulometry" by the authors, was suggested in [8, 9]. This method can take into account the charging current of the electric double layer.

A combined electrochemical method based on fundamental aspects of inversion voltammetry was developed in [10]. The general principle of this technique is that it combines the advantages of IVA and potentiostatic coulometry. The latter is used to supplement the high sensitivity of IVA with an opportunity to make an analysis without standards.

The scheme of an electrochemical experiment, suggested in [10], includes three successive stages of IVA measurements (Fig. 1). The stage of electrolytic accumulation is performed three times during three different intervals of time: Δt_1, Δt_2, and Δt_3. The time is chosen in such a way that $(\Delta t_2 - \Delta t_1) = (\Delta t_3 - \Delta t_2)$. Further, the quantities of electricity, Q_1, Q_2, and Q_3, that correspond to the times of pre-electrolysis (Δt_1, Δt_2, and Δt_3) are found by integrating the current of metal ionization from the amalgam over time. This measurement procedure makes it possible to find the quantity of electricity Q_∞ that is necessary for complete electrodeposition on the electrode of the substance being determined, by using the Meites formula

$$Q_\infty = \frac{Q_2^2 - Q_1 Q_3}{2Q_2 - (Q_1 + Q_3)}. \quad (5)$$

Further, it is rather simple to calculate the amount of the substance in solution by the Faraday law, and, with the solution volume known, to find the concentration of the analyte.

The present study is concerned with the possibility of simultaneous determination of ions of lead, copper, and cadmium, which are metals most frequently used in electrolytic metallurgy, by the combined standardless electrochemical method.

The inversion-voltammetric measurements were performed on a PU-1 polarograph (ZIP, Moscow) with an AKV-07 transducer (Akvilon NPKF, Moscow) and on an AKV-07MK voltammetric analyzer with Polar-4.0 software (Akvilon NPKF, Moscow) in the dc and ac modes. Solutions with various concentrations of copper and cadmium ions were prepared from solutions of 10- and 1-g l^{-1} state standard samples (GSO 7255 and GSO 6690, respectively), using reagents of chemically pure and analytically pure grades and twice-distilled water. The measurements were carried out on a mercury-graphite film electrode rotated at a speed of 1000 rpm in the accumulation stage. A solution of composition (M): 1×10^{-4} $Hg(NO_3)_2$ + 5×10^{-2} HCl + 1×10^{-4} HNO_3, was used as a supporting electrolyte. The pre-electrolysis in IVA measurements was performed at a potential of –1.3 V, with a silver chloride reference electrode. To produce an electrochemical cell with a variable volume, a polyethylene terephthalate cylinder 20 mm in diameter and 20 mm high was glued with a sealing compound into the central part of a standard cell, glassy carbon crucible of volume 50 ml. The volume was further controlled by introduction of glassy-carbon inserts. Thus, the working volume of the cell could be varied from 5 to 1 cm^3. Measurements in larger volumes (20 ml) were carried out in the standard cell. The area of the working electrodes was

0.071 and 0.385 cm^2, which corresponded to diameters of the working surface of the electrodes equal to 3 and 7 mm, respectively. To satisfy the condition of a complete dissolution of the metal from the amalgam, slow (2–5 mV s^{-1}) potential sweep rates were used [10].

The first part of our study was aimed to verify whether or not principles of potentiostatic coulometry are satisfied in the method we suggested for the example of copper and cadmium and to find the coulometric constant k, which is a most important quantity characterizing the measurement conditions because it is related to the solution volume, electrode area, and hydrodynamic conditions of electrolysis [12]:

$$k = DS/V\delta, \quad (6)$$

where δ is the thickness of the diffusion layer.

For this purpose, we studied how the concentrations of these ions vary with the electrolysis duration and solution volume.

The dependence of the concentration variation rate on the electrolysis duration was studied as follows. The electrolysis was performed in a solution of a supporting electrolyte containing 5×10^{-8} M Cd^{2+} in the course of 2 min. The dissolution was carried out in a background solution containing no Cd^{2+} ions. Then a copper-containing solution was again subjected to electrolysis and then copper was dissolved in a background solution. The successive electrolyses led to variation of the concentration of metal ions in the solution. The height of the ionization peak of cadmium was used to determine its concentration in the solution. A similar experiment was carried out for a solution containing copper ions. The dependence of the volume concentration of cadmium(II) and copper(II) on the electrolysis duration is shown in Fig. 2, and the dependence of the fraction η of the substance being recovered on the electrolysis duration, in Fig. 3. The fraction of the substance being recovered was calculated by the formula

$$\eta = (c_i - c_{i+1})/c^0.$$

If we plot the data of Fig. 2 in the coordinates $\log(c/c^0)$–t, we obtain a linear dependence described by the equation $\log(c/c^0) = -kt$ (Fig. 4), which corresponds to condition (3). For comparison, the same figure shows a similar dependence for lead, plotted using the data of [10]. The dependences in Fig. 4 were used to find the coulometric constants for cadmium and copper: $k_{Cd} = 5.8 \times 10^{-3}$ s^{-1} and $k_{Cu} = 5.4 \times 10^{-3}$ s^{-1}. Because the coulometric constant depends on the solution volume, its value was reduced to a volume of 1 ml. The constant for lead under the same conditions, $k_{Pb} = 5.5 \times 10^{-3}$ s^{-1}, was found in [10]. The close values of the constants found for different ions point to a good reproducibility of the measurement results, because, as follows from Eq. (6), the values

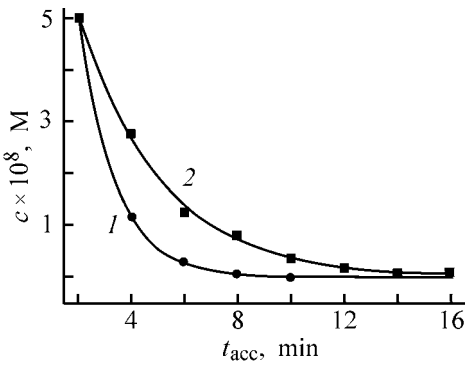

Fig. 2. Volume concentration c of (*1*) copper(II) and (*2*) cadmium(II) vs. the electrolysis duration t_{acc}. $c^0_{Cu} = c^0_{Cd} = 5 \times 10^{-8}$ M, $V = 5$ ml; the same for Fig. 3.

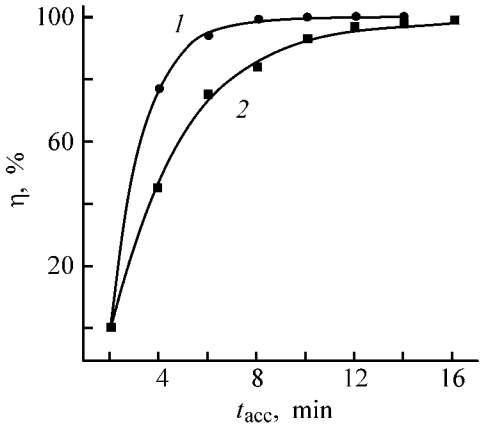

Fig. 3. Fraction of substance recovered, η, vs. the electrolysis duration t_{acc}. (*1*) Cu(II) and (*2*) Cd(II).

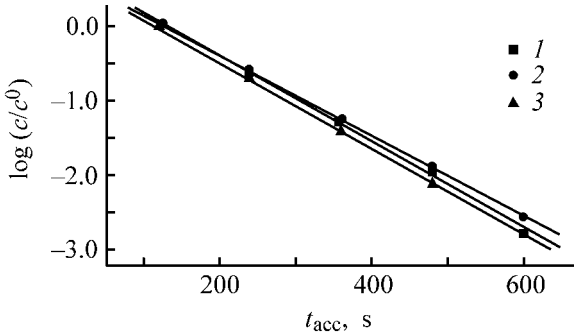

Fig. 4. Dependence of the logarithm of the normalized concentration, $\log(c/c^0)$, on the accumulation time t_{acc}, plotted using the data of Fig. 3. (*1*) Cd(II), (*2*) Cu(II), and (*3*) Pb(II) [10]; the same for Fig. 5.

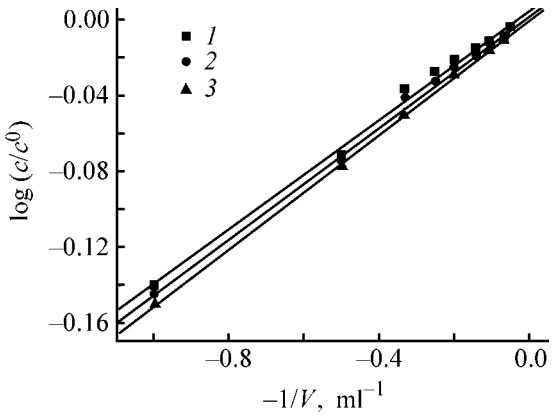

Fig. 5. Logarithm of the normalized concentration, $\log(c/c^0)$ on the volume V of the solution being analyzed. Accumulation time t_{acc} = 5 min, $c^0_{Cu} = c^0_{Cd} = c^0_{Pb} = 5 \times 10^{-8}$ M.

of the constants will differ at the same experimental conditions (solution volume, electrode area, and agitation conditions) in line with the diffusion coefficients.

It follows from condition (3) and Eq. (6) that, in electrolysis of a solution, the concentration will depend on the solution volume at a certain t, and this dependence is linearized in the coordinates $\log(c/c^0)$–$1/V$. Figure 5 shows the dependences of the concentration of copper and cadmium in solution on the volume of the solution being analyzed, which are linear in the coordinates $\log(c/c^0)$–$1/V$. The accumulation time was the same in all the measurements, and the volume was varied from 1 to 20 ml. For comparison, Fig. 5 also shows the same dependence for lead, plotted using the data of [10].

The experimental data we presented above indicate that the basic principles of potentiostatic coulometry are satisfied under the chosen measurement conditions. Therefore, we tested in the next stage of our study the applicability of the combined electrochemical method to determination of copper and cadmium, and also of copper, lead, and cadmium simultaneously present in a solution.

Cadmium was determined in a supporting electrolyte solution into which a known amount of Cd(II) ions was introduced in the concentration range 1×10^{-8}–1×10^{-7} M. Then measurements were made in accordance with the scheme in Fig. 1, the corresponding quantities of electricity (Q_1, Q_2, Q_3) were calculated, and Q_∞ was found using formula (5). The accumulation times (Δt_1, Δt_2, Δt_3) were 4, 6,

and 8 min, respectively, in all measurements. Knowing the quantity of electricity, necessary for a complete recovery of a substance, we calculated the content of cadmium and its concentration in the solution by the Faraday law. The measurement results are listed in Table 1.

Similar measurements were made for solutions containing ions of copper(II) (Table 1), copper(II) and cadmium(II) simultaneously (Table 2), and copper(II), cadmium(II), and lead(II) simultaneously (Table 3).

CONCLUSION

The results presented indicate that standardless determination of copper(II) and cadmium(II) is possible both in the case of their individual or joint presence in solution and in the case when lead(II) is also present.

Abstract—The possibility of replacing the electrolyte based on imported ethylene carbonate with a domestic SO_2-containing electrolyte based on propylene carbonate was considered for the example of operation of the negative electrode of a lithium–ion battery.

DOI: 10.1134/S1070427206120093

The standard electrolyte for lithium–ion batteries commonly contains ethylene carbonate (EC), which is not presently produced in Russia. At the same time, it has been shown in the development of primary lithium power sources that SO_2-containing electrolytes based on propylene carbonate (PC) can form on carbon electrodes surface layers similar in properties to those produced by EC-containing electrolytes [1]. However, the existence and stability of intercalation/deintercalation of lithium ions into/from the carbon matrix with a surface layer formed by SO_2 has not been studied.

To actualize the possibility of using a SO_2-containing electrolyte, it was necessary to complete studies of the electrochemical behavior of carbon materials in SO_2-containing electrolytes and to demonstrate the stability of operation of not only negative, but also positive electrodes and of the cell as a whole.

This study is concerned with the behavior of the carbon electrode in a PC-based electrolyte containing SO_2. It was established that the main characteristics determining the working capacity of a negative carbon electrode in a lithium ion battery are the expenditure of electricity for the formation of surface layer during the first charging, preservation of the surface layer on the charged and discharged electrode and on that subjected to cycling, stability of charging-discharge characteristics, and charge preservation in storage (self-discharge).

EXPERIMENTAL

We used as active material a powdered spectrally pure graphite (SPG) with grain size $d \le 40$ μm. The carbon of this type was used for two reasons. First, it is the standard material [TU (Technical Specification) 16-538-240–74] produced in Russia. Second, this material contains, by virtue of its main application, no impurities of spectrally active elements, which makes impossible a number of reactions leading to an irreversible immobilization of lithium ions. The electrode paste had the standard composition (%): SPG 85, acetylene black 5, and binder 10. As binder was used FP-42D or F2-ME. The electrodes fabricated contained about 2 mg cm^{-2} SPG. A 1 M solution of $LiClO_4$ in PC, with an SO_2 content of 13–20, served as the electrolyte. The electrolyte volume in the cell was 2.5 ml. The humidity of the electrolyte, as determined by the Fischer titration method, was 100 ppm. A plate of metallic lithium served as the counter electrode, so that the cell of composition C/Li was, in fact, subjected to electrolysis. The electrolysis was performed at $i = 0.06 - 0.127$ mA cm^{-2} of the apparent surface area (35.3–75.0 mA g^{-1} of carbon).

In the first charging, a surface layer responsible for the working capacity of an electrode in a battery is formed on the electrode surface. It should be noted that the first-cycle charging curve of the SPG electrode in the SO_2-containing electrolyte is well reproducible. The charging curves obtained by continuous electrolysis and by the method of static coulometric titration [2] in similar electrolytes (PC, 1 M $LiClO_4$, 13% SO_2 and PC : DME = 7 : 3, 0.6 M $LiClO_4$, 17% SO_2) are presented in Fig. 1. It can be seen that the curves largely coincide, especially in the region corresponding to reduction of sulfur dioxide.

The first-cycle charging curve plotted in the coordinates $(E_0 - E)$–$\ln[Q_0/(Q_0 - Q)]$ and E–$\log[(\tau^{1/2} - t^{1/2})/t^{1/2}]$, which correspond to SO_2 reduction and intercalation of lithium ions into the electrode matrix, is analyzed in Figs. 2, 3. The upper part of the curve at potentials of 2.5–1.5 V well correlates with SO_2 reduction. The inflection at a potential of 1.5 V corresponds to a change of the mechanism, and, according to the data of Fig. 3, this change characterizes a transition of the process to intercalation of lithium ions. This process is mainly complete by a potential of 0.2 V. Thus, the quantity of electricity corresponding to the inflection in the charging curve is spent for formation of a surface layer. It constitutes about 200 mA h g^{-1}

The studies performed demonstrated that, in the first-cycle charging, the content of water in the electrolyte decreases. The quantity of electricity spent for the electrochemical reduction of water was calculated from the difference of the water content of the electrolyte before the beginning and at the end of the first cycle of charging to be 3×10^{-10} mA h. It was found from this value of the capacity and from the corresponding electrode mass and its specific surface area that the products of water reduction will cover less than 0.01% of the electrode surface. Thus, we can state that the presence of the initial amount of water would not affect the shape and extent of the charging curve.

The preservation of surface layer on a charged and discharged electrode in the course of time and on an electrode subjected to cycling is an important property responsible for the working capacity of a lithium ion battery. It can be defined as the stability of the surface passivity reactions of electrochemical reduction. As an important indication that the passivity is disturbed can serve expenditure of electricity for reduction of the surface layer in a charging cycle that follows the discharge cycle, i.e., the case when the inequality $Q_{ch} > Q_{dis}$ (irreversible loss of capacity) holds. This loss is the most clearly pronounced in charging/discharge of an electrode stored after discharge in a zero-current state. Table 1 lists the irreversible loss in relation to the storage time of a discharged electrode before the following charging.

As can be seen from Table 1, the properties of the surface layer are fully preserved during 24 h of storage. The loss of the irreversible capacity appears upon a more prolonged storage. In this case, the process develops linearly with time and constitutes about 1% per day of the total capacity spent for the formation of the surface layer during the first charging.

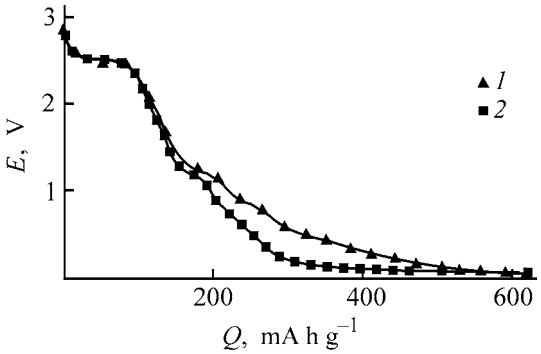

Fig. 1. First-cycle charging curves in various electrolytes. (E) Potential, (Q) capacity; the same for Figs. 2, 4; Electrolyte: (*1*) PC : DME = 7 : 3, 0,6 M $LiClO_4$, and 17% SO_2; (*2*) PC, 1 M $LiClO_4$, and 13% SO_2.

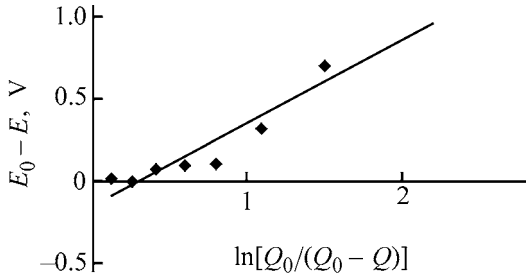

Fig. 2. $(E_0 - E)$–$\ln[Q_0/(Q_0 - Q)]$ dependence. SPG, 0.6 M $LiClO_4$, PC : DME = 7 : 3, 17% SO_2; the same for Fig. 3.

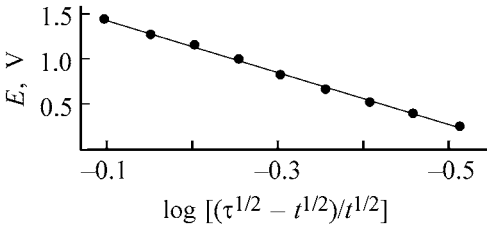

Fig. 3. E–$\log[(\tau^{1/2} - t^{1/2})/t^{1/2}]$ dependence.

A possible reason for the appearance of an irreversible loss is dissolution of the main surface layer component, lithium dithionite [1]. Another reason may be decomposition of the dithionite to give a thiosulfate. On

the assumption that the dissolution of the surface layer components is the main reason for the expenditure of electricity for additional charging in operation of a negative electrode, it would be expected that this phenomenon should be diminished at a smaller electrolyte volume.

The stability of the charging–discharge characteristics was determined by cycling an experimental C/Li cell during more than 100 cycles. Figure 4 shows the successively obtained charging–discharge curves for the 12th and 54th cycles, along with the curves measured at different current densities.

As can be seen from Fig. 4, the results are well reproducible at current densities of 35–50 mA g^{-1}. The stable discharge capacity obtained under the indicated electrolysis conditions (200–210 mA h g^{-1}) was retained during the entire period of cycling. The SPG cannot be classed by these values with high-capacity carbons. However, it is well suitable for studies concerned with the fundamental aspects of the behavior of a carbon electrode in SO_2-containing electrolytes.

The charge preservation in storage (self-discharge) is an important electrode characteristic predetermining the retention of a charge imparted to the electrode in the course of time in a stored battery. The dependence of the discharge capacity on the time of storage of a charged electrode is shown in Fig. 5. It can be seen that there is a clearly manifested correlation between the capacity retained by the electrode and the time of its storage in a charged state. Beginning with 20 h of storage this decrease is satisfactorily described by the equation $Q_{day}(\%) = -0.5T + 90$, which corresponds to a daily loss of capacity by about 10%.

To elucidate the reasons for the electrode self-discharge, we superimposed on the plot of self-discharge in Fig. 5 the plot reflecting the disintegration of the surface layer, expressed in the fraction of accumulated irreversible capacity (percent relative to the capacity after the first cycle of charging). Comparison of these curves shows that there is no correlation between the amount of self-discharge and the extent of disintegration of the surface layer. Moreover, the whole self-discharge process occurs within the region in which there is virtually no disintegration of the surface layer. In this context, the self-discharge mechanism requires an independent analysis.

Comparison of the SPG characteristics with the properties of carbons used in commercial products, such as the carbon of the FGC brand (Repsol), shows that a 1 M solution of $LiClO_4$ PC in PC/SO_2 can be used as electrolyte instead of a 1 M solution of $LiPF_6$ in EC/DEC. Also of interest are some other properties of the SPG electrode, observed in a study of the C/Li cell.

The processes occurring in intercalation-deintercalation of lithium ions in the carbon matrix can be judged from the ranges of potentials in which the charging and discharge capacities are formed. As can be seen from Fig. 6, a major part of the charging

capacity is imparted in a narrow range of potentials (0.2–0.4 V). This shows that, as expected in selecting the SPG as the active material, there is no irreversible binding of lithium ions to active centers of impurities in the carbon matrix. The fact that the first charging curve has a significantly different shape reflects the formation of a surface layer.

At the same time, there is no characteristic occurrence range for the discharge capacities. A common feature of all the discharge curves is that the discharge starts at potentials exceeding 0.2 V. The reason is that the potential of the charging curve includes the sum of the potential drops associated with the ohmic and polarization resistances. On switching the circuit to charging, the potential is shifted by 0.2–0.25 V and discharge begins just after this shift.

Information about the influence exerted by the charging–discharge current density on the specific capacity of the electrode makes it possible to optimize the conditions of these processes both by a reasonable choice of the load and by use of the best suitable operation modes of the charging device.

To obtain these data, the charging (and discharge) was performed in separate cycles of the experiment at three current densities: 0.06, 0.1, and 0.127 mA cm^{-2} (35.3; 58.8, and 75.0 mA g^{-1}). Comparison of the portions in which the current density is changed with those of increased Q_i values does not show any noticeable correlation. Thus, it can be stated that the charging–discharge current density has no effect on fluctuations of the irreversible expenditure of electricity in cycling.

The results of an analysis of the charging–dischage curves obtained at various current densities (Fig. 4) are listed in Table 2 as the specific discharge capacity in relation to the discharge current density.

As can be seen from the data presented, the efficiency of the charging–discharge process strongly decreases as the current density increases. Two characteristic features should be noted. At lower current densities the charging capacity is higher, but the efficiency is less than 100%. At higher current densities, the capacity is lower, but the efficiency is 100%.

Comparison of the charging and irreversible capacities shows that the observed decrease in the reversible capacity is a combined effect of the decrease in the charging capacity and the increase in the irreversible capacity (decrease in efficiency). It may be assumed that, as the current density becomes higher, the gradient of concentration in the electrode matrix, from the surface layer into the electrode bulk, gradually increases. In other words, the diffusion flow has not enough time to distribute the intercalated lithium ions throughout the volume of particles constituting the electrode. As a result, the saturation of the surface layer occurs earlier at higher charging current densities and the charging capacity decreases. Accordingly, the whole amount of lithium ions has not enough time to deintercalate and remains in the electrode bulk, which is manifested as an increase in the irreversible capacity.

Table 2. Specific characteristics in relation to current density

I		Q_{ch}	Q_{dis}	Efficiency %	Charge/discharge ratio X
mA g^{-1}	mA cm^{-2}	mA h g^{-1}			
35	0.06	264	206	80	0.7/0.55
50	0.10	264	206	80	0.7/0.55
75	0.127	176	176	100	0.5/0.5
90	0.20	118	118	100	0.3/0.3

The charging current is determined by the design of the charging device. Apparently, its parameters should be determined on the basis of the consumer requirements. Let us consider these requirements for the example of a mobile phone battery. There are two conflicting parameters: weight-size and recharging frequency. If we choose a low charging current density, we should use an excess amount of the cathode material in the battery, which makes it heavier and larger. Choosing a high current density, we force a consumer to charge the power source more frequently. It is a developer's choice.

CONCLUSIONS

(1) A propylene carbonate electrolyte containing SO_2 can be prepared from domestic materials, and its cost will be considerably lower than that of imported electrolytes based on ethylene carbonate. The surface layer formed in the first cycle of charging as a product of SO_2 reduction is similar in properties to the layer formed in electrolytes containing ethylene carbonate.

(2) The expenditure of electricity for loss in the form of irreversible capacity in prolonged cycling of the electrode is zero or insignificant.

(3) The solubility of the components of the surface layer in storage of a discharged electrode is low and, to a first approximation, the self-discharge of a charged electrode is admissible.

(4) The specific capacity of the electrode strongly depends on the charging and discharge current densities. The optimal modes of electrode operation are suggested.

(5) The reproducible operation of a carbon electrode in the electrolyte under consideration is confirmed by its cycling for more than 100 cycles.

(6) Analysis of the charging–discharge characteristics of a carbon electrode in propylene carbonate electrolyte containing SO_2 shows that this electrolyte can be used for development of a long-lived electrode for a lithium ion battery.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrochemical Procedure for Express Evaluation of the Corrosion Effect of Aqueous Glycol Solutions on Metals

Abstract—Electrochemical procedure for express evaluation of the corrosion effect of aqueous glycol solutions on the metallic construction materials for cooling systems was studied. This procedure was used to develop new coolant formulations.

DOI: 10.1134/S107042720612010X

Efficient corrosion protection of metals is one of decisive factors determining prolonged and safe operation of various apparatus, installations, and industrial equipment. To select the most appropriate procedures for corrosion protection, preliminarily tests are necessary with the aim to develop measures for prevention or restriction of metal corrosion under the action of an aggressive medium.

At present, the data on the corrosion effect of antifreezing aqueous glycol solutions on the metallic construction materials of various heat-exchange apparatus (in particular, cooling systems of the internal-combustion engines) are of particular importance. Obviously, control over the state of polymetallic construction materials under the action of aggressive media, development of new coolant compositions on water–glycol basis, and prompt quality control of commercial products require an express and reliable evaluation of the corrosion effect of liquids on various structural materials. Such data can be obtained in preliminarily tests on corrosion effect of liquids using an appropriate express procedure.

However, an analysis of published data showed that any appropriate procedure of these preliminarily tests is lacking. At present, the corrosion effect of liquids is often evaluated using procedures of gravimetric and electrochemical analyses.

The tests with electrochemical control are performed both without external polarization [1] and using external polarization of electrodes [2, 3]. Well-developed series of electrochemical procedures for evaluation of the metal corrosion also involves the method of polarization resistance and coulostatic procedure [4, 5]. The data on electrochemical impedance allow detailed analysis of the corrosion mechanism [6], and the procedure of impedance spectroscopy is the most widely used for studying the corrosion behavior of metals [7]. Computer techniques for recording and processing of experimental results promote development of various pulse procedures to study corrosion phenomenon and, in particular, the pulse galvanostatic method [8, 9].

Among all the above electrochemical procedures, only the Evans method of corrosion diagrams [10] allows study of the direct contact corrosion in polymetallic systems. This rather complex procedure involves recording of curves of anodic and cathodic polarization for each metal of the multielectrode system, their combined processing, and plotting of the resulting corrosion diagram, from which the maximum possible current strength is determined. Then, using the known surface areas of the metal electrodes and neglecting the ohmic loss, the corrosion rate is calculated. It is assumed that the cathode remains unchanged and the rate of the anode corrosion is proportional to the strength of the local current.

However, a study of the contact corrosion by the above procedure has significant drawbacks, because it disregards the self-dissolution of the anode

and cathode, which strongly affects the corrosion processes in many cases. Moreover, certain contradiction is inherent in the Evans diagram, because, in the case of a completely polarized system, the difference of potentials of the anode and cathode is zero, whereas the strength of the local current in the absence of electromotive force reaches a maximum value.

Experimental data obtained using gravimetric methods seem to be more reliable for studying the corrosion behavior of metals at their prolonged storage in aggressive media, especially in the course of the corrosion processes changing with time.

A series of international [11, 12] and Russian [13, 14] gravimetric procedures can be used to evaluate the corrosion effect of antifreezing and process liquids. The procedure with gravimetric control [GOST (State Standard) 28 084 – 89] is the most reliable and widely used domestic laboratory method for evaluation of the corrosion effect of aqueous glycol solutions on metals. However, owing to the prolonged analysis time (336 h) and significant measurement errors (up to 28–50%, depending on the metal nature), this procedure is unacceptable for express evaluation of the metal corrosion.

Thus, the aim of this study was to develop a proximate laboratory method combining a certain promptness of electrochemical methods with the simplicity and reliability of gravimetric analysis and to study the corrosion effect of the aqueous glycol solutions on polymetallic construction materials for cooling systems of internalcombustion engines.

EXPERIMENTAL

Plates (50 × 25 × 3 mm) of St. 3 steel (GOST 380), GH-190 cast iron (normal VAZ 52 205), AK6M2 aluminum alloy (GOST 1583), M-1 copper (GOST 859), POS-35 solder [TU (Technical Specifications) 48-13-10], and L-63 brass (GOST 931) were polished and degreased, and their electrochemical behavior was studied in a 50% solution of monoethylene glycol (MEG) in water containing anhydrous sodium sulfate (148 mg l^{-1}), sodium chloride (165 mg l^{-1}), and sodium hydrocarbonate (138 mg l^{-1}) at 20 ± 2°C.

The tests were carried out in a specially designed electrochemical cell in the form of a 150-ml cylindrical vessel with a plastic lid equipped with electrode holders (one at the center for a cathode and three for anodes at equal distances from each other and from the center, with the anode holders short-circuited). Standard metal plates with a working surface area of 10 cm^2 were used as anodes, and a carbon rod (18 mm in diameter), as a cathode.

The current of the electrochemical couple was measured with an M 198/2 microammeter. Simultaneously, we measured, using a digital high-resistance voltmeter Shch 1413, changes in the electrode potentials of metals with time both in the absence of electrical contacts between them and in couples short-circuited through an external low-resistance conductor. We used a silver chloride reference electrode.

In accordance with a gravimetric procedure (GOST 28 084–89), to simulate the galvanic couples operating under the real conditions, three metallic plates are connected with each other (e.g., copper–brass–solder and steel–cast iron–aluminum) and kept in a corrosive medium studied for 336 h, and then the corrosion effect is determined from the changes in the sample weights. In our approach to the development of the express evaluation, the same set of metal samples were placed in the solution for galvanostatic treatment for a certain time in which the metals were subjected to anodic dissolution. This should strongly decrease the time of corrosion tests. The corrosion effect of the liquid in question was determined from the changes in the sample weights; in this case, the nature of corrosion (e.g., selective, intercrystallite pitting, etc.) was disregarded. We selected the mode of galvanostatic dissolution of the metals because the electrochemical methods with external potentiostatic polarization, which are frequently used in laboratory practice to study the corrosion processes, are rather convenient but require a sophisticated laboratory equipment.

To substantiate this approach, we first studied the anodic polarization of the metal samples in question in the aqueous glycol solution in the potentiostatic mode and found that the current in the electrolytic cell varied insignificantly (by no more than ±10%) with time in a fairly wide range of potentials (0.5–10.0 V). This result indicates that corrosion tests can be performed in the galvanostatic mode.

For further substantiation, it is also necessary to simulate anodic dissolution of the materials studied in the aqueous glycol solutions containing corrosion inhibitors in such a mode that would give results comparable with the gravimetric data according to GOST 28 084 – 89. For this purpose, we studied the dependence of the weight loss by individual standard metal samples in aqueous MEG solution at given current densities. We found that this dependence is linear

Table 1. Metal corrosion loss in aqueous glycol solutions at different current densities

Current density, mA cm^{-1}	Corrosion loss, mg

* Experimental and calculated data are given in the numerator and denominator, respectively.

in a fairly wide range of current densities (Fig. 1), and, except the aluminum sample, reasonably agreed with the calculated data listed in Table 1.

The above data unambiguously suggest that only anodic dissolution of metals acting as working electrodes is observed, and the weight loss by the metal samples corresponds to the corrosion rate.

The certain discrepancy between the experimental and calculated data for aluminum in a wide range of current densities is probably due to the formation of a compact oxide films on the metal surface, which prevents aluminum dissolution. Actually, the experimental results and calculated values of the weight loss of the aluminum samples coincide at low current densities (i = 0.25 mA cm^{-2}) within the measurement error. However, with increasing current density ($i \geq$ 1.0 mA cm^{-2}), the deviation between the experimental and calculated values grows. The weight loss becomes independent of the current densities and, beginning with $i \geq 3.0$ mA cm^{-2}, an "cut-off" of the aluminum anode is observed (Fig. 2).

Table 3. Corrosion loss by aluminum, steel, and cast iron samples at their anodic polarization in the CC–water mixture

i, mA cm^{-2}	τ, min	Weigh loss, mg		
		aluminum	steel	cast iron
2.0	60	0.0	0.0	0.0
3.0	60	0.0	0.0	0.0
7.0	120	0.0	6.1	10.0

This behavior of aluminum can be accounted for by the fact that, in the course of anodic polarization, aluminum oxidation proceeds simultaneously with the metal ionization on the electrode. With increasing polarization, the degree of the surface oxidation increases and at a certain current density (or potential) an oxide film completely covers the electrode surface. The diffusion of aluminum ions into solution through the oxide film becomes hindered, and the rate of anodic dissolution decreases. As a result of these two opposite factors, the rate of aluminum anodic dissolution remains nearly constant, being almost independent of the current density.

In view of the above data, we performed two series of experiments. In the first series, copper, brass, and solder were connected in parallel as anodes, and an inert material (graphite) was used as a cathode. The electrolyte was a Procor 3000 coolant concentrate (CC) (PEUGEOT, France) diluted with water to a 1 : 1 volume ratio, whose corrosion effect on the metal materials was reliably determined using standard gravimetric methods (GOST 28 084 – 89). As optimal, we used the electrolysis mode providing a corrosion weight loss by the metal samples that was comparable with the loss in gravimetric tests; the results are listed in Table 2.

As can be seen from Table 2, a decrease in the sample weight in the course of anodic dissolution strongly depends on the current density, i.e., on the anode potential. At low current densities (and, accordingly, at low potentials) the solder dissolution is mainly observed, which is probably due to the lower standard potential of tin. High currents densities ($i \geq 3.0$ mA cm^{-2}) allow simulation of the gravimetric data (test nos. 1, 4). To minimize changes in the surface state and, thus, in the surface area upon dissolution of the sample, we chose the following optimal conditions of the corrosion tests: 3.0 mA cm^{-1} current density and 30 min test time.

Electrochemical simulation of corrosion using the other three metals (steel–cast iron–copper) as anodes appeared to be difficult. Tests on the anodic dissolution in the CC–water mixture (as in the above case of anodic dissolution of aluminum in the aqueous glycol solution) of a separate aluminum plate, as well as of the aluminum plate connected in parallel with iron and steel plates, showed that no dissolution of aluminum occurred even at high current densities (Table 3). At the same time, the gravimetric data showed that the loss of aluminum in given system was about 2.5 mg.

It has been found previously [15–19] that the effective dissolution rate of various metals in aqueous solutions cannot be fitted by the exponential dependence of the current density on the potential, which is untypical of electrochemical processes. The current densities were higher than the expected values, which suggests that another process of metal dissolution occurs concurrently with electrochemical process. It was experimentally observed in the range of cathodic polarization as a deviation of the anodic partial current density from the Tafel dependence toward high current densities. The rate of partial anodic dissolution at a stronger cathodic polarization was almost independent of the potential. These experimental facts suggest that this process, occurring simultaneously with the electrochemical reaction, is chemical dissolution. In the case of cathodic polarization it becomes predominant, because the anodic partial current density exponentially decreases with increasing negative potential. A similar abnormal dissolution has been observed for several other metals, including aluminum [20]. The tendency of metals to dissolve in this way is associated with their electronic structure, and the chemical dissolution is due to direct reaction between the metal and water.

Indeed the metal actively dissolves with vigorous hydrogen evolution on the electrode surface in cath-

odic polarization of the aluminum sample in both aqueous and aqueous glycol solutions. The dependence of the corrosion weight loss by aluminum on the current density is shown in Fig. 3.

Significant difference between the types of behavior of aluminum in its cathodic dissolution in water and an aqueous glycol solution is probably due to the changes in the structure of the electric double layer upon adsorption of ethylene glycol, whose molecules can form compact shielding film owing to the planar arrangement on the electrode surface [21, 22]. Moreover, ethylene glycol (similarly to other polyatomic alcohols) strongly increases the viscosity of solutions and hinders the diffusion stages of the cathodic reactions [23].

Thus, cathodic polarization of aluminum in aqueous glycol solutions causes dissolution of the oxide film on the surface of the metal and is accompanied by its chemical corrosion. Based on the above data, the model of the corrosion behavior of the steel–cast iron–aluminum in aqueous glycol solutions can be described as that of a three-electrode system in which the aluminum plate acts as cathode, and steel and cast iron plates, as anodes.

Corrosion currents in the aluminum–steel and aluminum–cast iron couples were observed when studying the corrosion behavior in the short-circuited steel–cast iron–aluminum system in an aqueous glycol solution without external polarization (Fig. 4, curves *5*, *6*). Our experimental results showed that, after keeping the given electrochemical system in the aqueous glycol solution for 12–15 h, the aluminum sample becomes a cathode with respect to both steel and cast iron samples. This suggests that the use of aluminum cathode to determine the corrosion effect of aqueous glycol solutions on metals is quite reasonable. To determine the possibility of simulation of the gravimetric tests, we performed the electrolysis of the CC–water mixture, using an aluminum cathode and an anode consisting of the steel and cast iron plates connected in parallel; the results are listed in Table 4.

As can be seen from Table 4, at a current density i = 7.0 mA cm^{-2} the corrosion metal loss is high, and the results are insufficiently reproducible, whereas at i = 5.0 mA cm^{-2}, our experimental results well agree with the gravimetric data. Thus, the operation conditions for electrochemical simulation of the aluminum corrosion were as follows: current density 5.0 mA cm^{-2} and time 60 min.

For the electrochemical procedure, the relative total error of our experimental results at a confidence level P = 0.95 for all the metals studied does not exceed

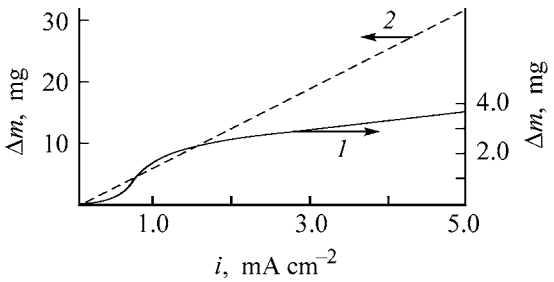

Fig. 3. Aluminum corrosion loss Δm vs. the current density i in the course of cathodic polarization. Polarization: in (*1*) MEG : water (1 : 1) solution and (*2*) water.

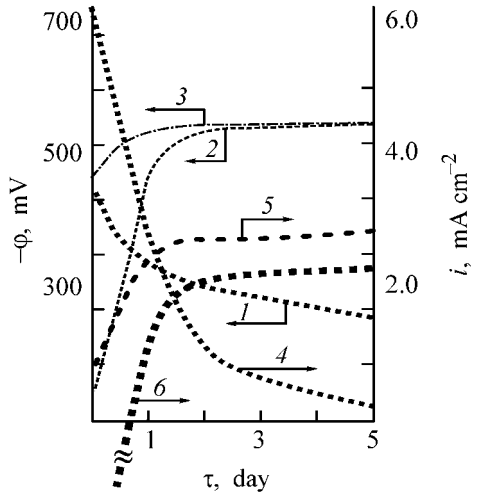

Fig. 4. Electrode potentials φ and current density i in the short-circuited aluminum–cast iron–steel system vs. time τ. Potential of: (*1*) aluminum, (*2*) steel, and (*3*) cast iron; current density in the contact couple: (*4*) steel–cast iron, (*5*) aluminum–cast iron, and (*6*) aluminum–steel.

± 15%, whereas for the gravimetric method, it is greater in accordance with GOST 28 084 – 89: ± 28% for copper, brass, aluminum, cast iron, and steel and ± 50% for solder.

Gravimetric	4.5	7.0	4.0	5.1	1.9	2.3

Table 6. Effect of inhibitors on the corrosion loss by metals in 50% aqueous MEG solutions

Solution component	Weight loss, mg					
	solder	copper	brass	aluminum	steel	cast iron
Without additives	17.4	3.2	3.4	4.3	22.1	34.6
$Na_2HPO_4 \cdot 12H_2O$	1.4	3.7	3.9	2.5	0.3	2.6
$Na_2B_4O_7 \cdot 10H_2O$	27.4	5.1	3.1	0.7	11.0	6.8
$Na_2B_4O_7 \cdot 10H_2O$, $Na_2HPO_4 \cdot 12H_2O$	25.9	3.2	3.0	1.3	1.3	1.7
Sodium benzoate	7.8	3.9	4.1	3.4	5.1	6.6
Sodium benzoate, sodium tetraborate	4.4	3.5	2.9	3.3	3.3	2.0

Thus, our experimental data allow us to suggest a procedure for express analysis of corrosion processes, involving galvanostatic dissolution of metals in the medium under study in the course of 30–60 min and gravimetric control of the corrosion weight loss.

The suitability of this express procedure for studying the corrosion effect of various coolants was tested using industrial TOSOL–TORSA concentrate (TU 6-15-2007–98, Bulgar-Sintez Joint-Stock Company, Kazan, Russia) and widely used TOSOL-AM concentrate (TU 6-02-751–86). The metal samples were tested in 50% aqueous solutions of coolants, which were prepared from their concentrates by direct dilution with water. The results obtained using our express method were compared (Table 5) with the averaged data furnished by the gravimetric method (GOST 28084–89).[1]

[1] Experimental data were obtained at the State Research Institute no. 25, Laboratory and Test Department, AVTOVAZ Joint-Stock Company (Togliatti, Russia) and Center of Laboratory Installations, Kazan'orgsintez Joint-Stock Company (Kazan, Tatarstan, Russia).

As can be seen from Table 5, the corrosion losses in both liquid systems determined by two methods well agree with each other. This fact shows that our method is suitable for express evaluation of the corrosion effect of glycol aqueous solutions on construction materials for cooling systems of internal-combustion engines.

Our method was used to evaluate the performance of the corrosion inhibitors with the aim to develop new coolant formulations. For example, a significant drawback of the TOSOL–TORSA coolant concentrate, whose main components are disodium hydrogen phosphate and sodium tetraborate, is the relatively high corrosion activity with respect to solder. At the same time, TOSOL-AM concentrate containing sodium benzoate and tetraborate (corrosion inhibitors) exhibits no corrosion activity toward the solder (Table 6). It was suggested that addition of sodium benzoate to the TOSOL–TORSA coolant would improve its anticorrosive properties toward solder.

Table 6 illustrates the effect of corrosion inhibitors used in the coolant concentrates in similar concentrations on the corrosion behavior of metals in aqueous

Table 7. Effect of sodium benzoate on the corrosion weight losses by metals in 50% aqueous solution of TOSOL–TORSA concentrate

Sodium benzoate, wt %	Weight loss, mg					
	solder	copper	brass	aluminum	steel	cast iron
0.00	16.8	3.1	4.4	2.5	2.3	2.6
0.10	3.9	3.0	3.8	2.6	2.9	2.7
0.20	2.9	3.1	3.5	2.8	2.5	2.1
0.20*	2.6	2.7	3.2	0.8	3.4	2.5

* Measurements were performed in accordance with GOST 28084–89.

glycol solutions. As can be seen from Table 7, the corrosion loss of solder strongly decreases with addition of sodium benzoate (≥0.1 wt%) to 50% aqueous solution of commercial TOSOL-TORSA concentrate.

CONCLUSIONS

(1) An electrochemical procedure based on galvanostatic dissolution of metals was developed for preliminarily express evaluation of the corrosion effect of aqueous glycol solutions on metallic construction materials for cooling systems.

(2) This method can be used to evaluate the performance of corrosion inhibitors.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Catalytic Electroreduction of Oxygen on Products of Pyrolysis of Heterobimetallic Complexes of Zinc

Abstract—Electrocatalysts for reduction of oxygen were synthesized from AG-3 activated carbon promoted with pyrolized heterobimetallic complexes $[CoLCl_2]$ $[ZnDMFACl_3]$ and $[ML][ZnCl_4]$ (M = Cu^{2+}, Ni^{2+}; L = 4,6,6-trimethyl-1,9-diamino-3,7-diaza-nona-3-ene). The optimal conditions of synthesis of the catalysts, which affect the efficiency of oxygen electroreduction, were found and the activity series of the catalyst in relation to the nature of the second metal was determined.

DOI: 10.1134/S1070427206120111

Use of binuclear or heteropolynuclear complexes as precursors in synthesis of reduction electrocatalysts provides better and more stable characteristics in fuel cells and chemical power cells, compared with mononuclear complex compounds [1–3]. The interest in catalysts based on polynuclear complexes is exhibited by scientists in many countries of the world [4]. Catalysts based on mononuclear complexes [5] of phthalocyanine, porphyrin, and some other chelate complexes with *d*-elements are well known, the most active catalysts have been obtained on the basis of cobalt complexes.

Catalysts are commonly synthesized by adsorption of a complex on the support surface, with its subsequent thermal treatment in an inert atmosphere. Pyrolysis in an inert atmosphere of complexes that incorporate ligands coordinated to central atoms via oxygen atoms yields electrocatalysts having active centers in the form of nonstoichiometric metal oxides on the surface of the carbon support [1]. In contrast to spinels, these oxides are more active because they form nanostructures on the support surface, whereas spinels are crystals with poor electrical conductivity [6]. Complexes with ligands coordinated to the central atom via nitrogen atoms enable imitation of pyropolymers produced on the basis of N_4-complexes [7]. They approach in electrical activity the known complexes, but are less expensive in manufacture than porphyrin and phthalocyanine complexes of *d*-elements. Use of heterobimetallic complexes combining different *d*-metals and ligands will make it possible to obtain new high-efficiency electrocatalysts for oxygen reduction and replace some expensive or noble metals. As shown in [3], heteropolynuclear complexes with copper and zinc are good precursors for high-efficiency catalysts, and, therefore, the following heterobimetallic complexes produced by direct template synthesis [8] were used to obtain electrocatalysts for oxygen reduction:

where $[CoLCl_2]$ $[ZnDMFACl_3]$ (**I**) and $[ML][ZnCl_4]$ [M = Ni^{2+} (**II**), Cu^{2+} (**III**); L = 4,6,6-trimethyl-1,9-diamino-3,7-diaza-nona-3-ene].

The aim of this study was to examine the influence exerted by the nature of the second metal in heterobimetallic complexes of zinc (Zn^{2+}–M, where M = Cu^{2+}, Ni^{2+}, Co^{2+}) in the reaction of oxygen reduction on

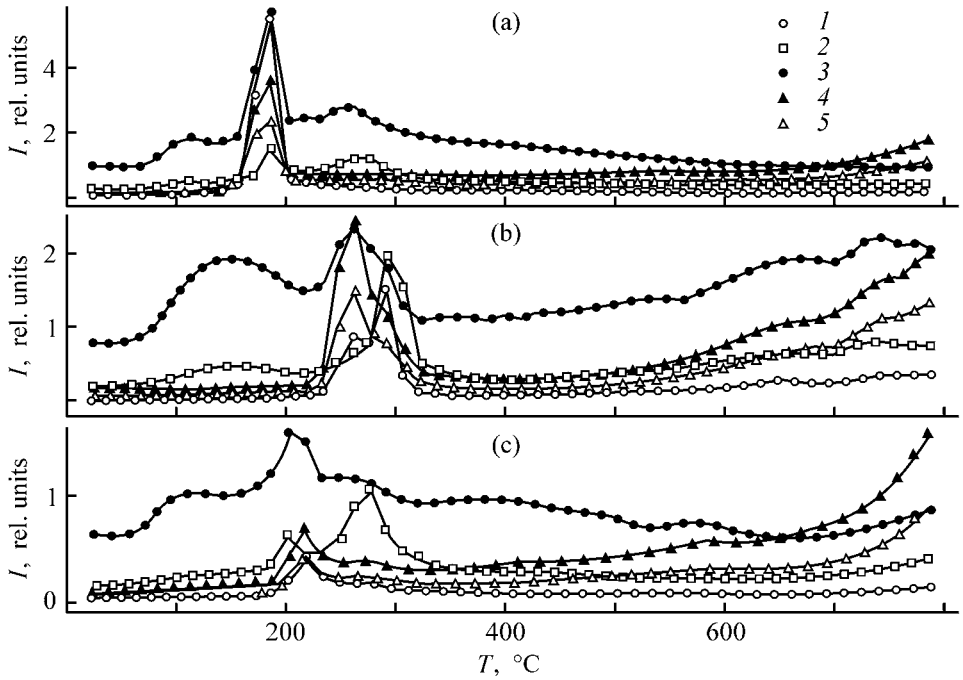

Fig. 1. Thermodesorption mass spectra of the complexes (a) [CoL] [$ZnDMFACl_3$], (b) [NiL][$ZnCl_4$], and (c) [CuL][$ZnCl_4$] in a vacuum at a residual pressure of 10^{-6} Pa and heating rate of 10 deg min^{-1}. the electrocatalytic properties of catalysts produced by the thermal method.

EXPERIMENTAL

To obtain electrocatalysts, heterobimetallic complexes of zinc, **I**–**III**, were synthesized by direct template synthesis [8]. The complexes were dissolved in dimethylformamide and adsorbed on AG-3 high-porosity carbon with a dispersity of less than 50 μm and specific surface area of 850 $m^2 g^{-1}$ (measured by BET). Then, the carbon materials with deposited complex compounds were thermally treated at various temperatures (in the range 200–800°C) in the atmosphere of argon. For this purpose, a 100-mg portion of AG-3 carbon with an adsorbed complex was placed in a tubular quartz furnace through which argon was permanently passed and was gradually heated to a prescribed temperature and kept under these conditions for 1 h. The samples were thermally treated at temperatures of 200, 400, 600, and 800°C and then their catalytic activity in the reaction of oxygen electroreduction was studied.

To determine the composition of products formed in pyrolysis of complexes on the surface of the carbon support, thermal analysis of complexes **I**–**III** was made on a Q-1500D derivatograph (MOM, Hungary). The analysis was performed under the following conditions: weighed portion 500 mg, TG galvanometer sensitivity 500, phase transformations fixed in the range 10–800°C at a heating rate of 5 deg min^{-1} in the atmosphere of argon. Freshly calcined Al_2O_3 served as reference. In a thermal analysis with a large amount of a complex at 180–220°C, the contents of the platinum crucible were ejected because of the pronounced exothermic effect with destruction of the ligand 4,6,6-trimethyl-1,9, diamino-3,7-diaza-nona-3-ene. Therefore, thermal analysis was performed for all the samples in the presence of Al_2O_3 taken in the proportion Al_2O_3 : complex = 0.04 g : 0.16 g. The final products of pyrolysis were analyzed for the content of hydrogen, nitrogen, and carbon, with the result of analysis of the starting complexes taken into account.

The starting complexes were examined by the method of thermal desorption with mass-spectrometric analysis of the species being desorbed on an MX-1302 mass spectrometer under the following conditions: heating temperature 20–800°C, heating rate 10 deg min^{-1} residual pressure 10^{-6} Pa, weighed portion of a complex 1 mg.

The thermal destruction of complex **I** begins with decomposition of dimethylformamide at 50–180°C, which corresponds to loss of 15.1% of the total mass of the complex. In this temperature range, the mass spectrometer records products of pyrolysis, such as NH_4^+, NH_3, CH_3^+. The thermodesorption mass spectra of complex **I** are shown in Fig. 1a. Because the spec-

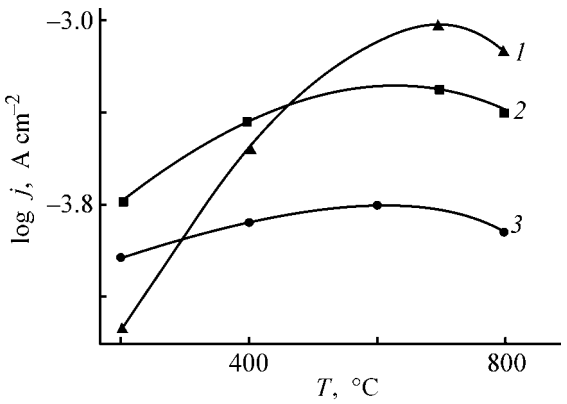

Fig. 2. Rate of oxygen electroreduction on catalysts formed by pyrolysis of heterobimetallic complexes on AG-3 in a 1 M KOH solution at 20°C vs. the pyrolysis temperature *T*. (*j*) Current density. Potential $E = -0.1$ V relative to Ag/AgCl reference electrode. Complex: (*1*) [CuL][$ZnCl_4$], (*2*) [NiL][$ZnCl_4$], and (*3*) [CoL][$ZnDMFACl_3$].

tra are rather intricate, Fig. 1 shows for all the complexes only selected data for species with *m*/*z* less than 29. The mass-spectra clearly show the temperature ranges in which the intensity of pyrolysis of the complexes under study is the highest. At 180–220°C occurs partial decomposition of the ligand (4,6,6-trimethyl-1,9-diamino-3,7-diaza-nona-3-ene) and the thermogravimetric curve demonstrates a considerable loss of mass (12.2%). The mass spectra reveal splitting-off of the following species: NH_4^+, NH_3, CH_3^+, $CH–NH_2^+$, $CH–NH^+$, $CH_2–CH_2^+$, etc. Some of the species desorbed add a Cl^- ion to form species with *m*/*z* exceeding 36. Molecular Cl_2 formed in pyrolysis may be present in decomposition products in minor amounts, with *m*/*z* of 69, 70, 71. In the following stage of pyrolysis (220–280°C) continues decomposition of the ligand and zinc oxide starts to be formed. In the range 280–620°C occurs full decomposition of the organic ligand to give the final product in the form of a mixture $CoCl_2$ + ZnO, which is confirmed by the results of elemental and thermal analyses.

The thermolysis of complex (**III**) begins with decomposition of 4,6,6-trimethyl-1,9-diamino-3,7-diaza-nona-3-ene. In the temperature range 100–240°C, the mass spectrometer records (Fig. 1c) such desorption products as NH_4^+, NH_3, CH_3^+, $CH–NH_2^+$, $CH–NH^+$, $CH_2–CH_2^+$ and chlorine-containing species with heavier mass (loss of mass was 15.1% of the total mass of the complex). At 240–550°C, the decomposition of the organic ligand is complete (37.6%) to give pyrolysis products containing $ZnCl_2$ and fragments of a compound of copper and nitrogen.

Complex (**I**) is more thermally stable. Its destruction also begins with decomposition of the ligand L in the range 130–320°C (15.1%). The decomposition products are similar for complexes **I**–**III** (Fig. 1b). In the range 320–710°C, the decomposition of the ligand L is complete (43.1%) to give pyrolysis products in the form of a mixture Ni + $ZnCl_2$.

The substances obtained were analyzed in the reaction of electrochemical reduction of oxygen in a three-electrode electrochemical cell (with 1 M KOH solution and separated cathode and anode spaces) by the method of the "floating" gas-diffusion electrode [9] at 20°C. The floating gas-diffusion electrode had the form of a pellet of hydrophobized acetylene black containing 30 wt % polytetrafluoroethylene, with a mass of 300 mg, density of 0.95 g cm^{-3}, diameter of 10 mm, and thickness of 2 mm, compacted under a pressure of 5–7 MPa. A nickel-wire current lead was embedded in the pellet. A layer of an electrocatalyst under study, with a particle size of less than 20 μm, was deposited in an amount of 1 mg cm^{-2} onto the electrode surface and compacted under a pressure of 5–6 MPa. This amount of the catalyst provided a kinetic mode of the electrochemical reaction [10]. The catalyst was retained on the surface of the support by adhesion forces. Polarization curves were measured in the potentiostatic mode on a PI-50-1.1 potentiostat with a step of 10 mV. The current was recorded with an M 2020 milliammeter.

The activity was evaluated by the current of oxygen reduction, observed at a potential of –0.10 V, and by the slope of the polarization curve, $\partial E/\partial \log j$ (b_1; b_2). The kinetic characteristics of oxygen electroreduction on the catalyst, obtained in the study, are listed in the table. Dependences of the rate of oxygen electroreduction at a constant potential $E = -0.1$ V on the temperature at which the electrocatalysts based on heterobimetallic complexes were synthesized are shown in Fig. 2. It can be seen from Fig. 2 and the table that the highest current of oxygen reduction is observed for the catalysts obtained from heterobimetallic complexes of copper and zinc at 700°C. It is known that electrocatalysts produced from porphyrin and phthalocyanine complexes [5, 11, 12] at $T \le 800$°C form active centers in which the MN_4 structure is preserved, and its chemical bonding with the carbon support is assumed.

Thus, 700–800°C is the optimal temperature range for production of active catalysts from complexes based on copper–zinc heterobimetallic complexes, which decompose in an inert atmosphere on the carbon surface and, probably, also form metal-and-nitrogen-

containing pyrolysis products bound to the carbon surface. In this case, the most active electrocatalysts for oxygen reduction are formed from Cu–Zn complexes. For catalytic compositions Zn–Co, catalytically active centers are formed at 600°C, as also in the case of oxygen-containing complexes [1–2], which give pyrolysis products in the form of nonstoichiometric oxides. The presence of oxygen in complex **I** contained in dimethylformamide favors formation of various oxide structures on the surface of the carbon support, which provides the electrocatalytic effect of oxygen reduction.

In the case of complex **II**, Ni and $ZnCl_2$, which show weak activity in the reaction of oxygen reduction, are formed in pyrolysis products. The highest current of oxygen reduction at –0.10 V is observed for catalysts synthesized at 700°C from a bimetallic Zn–Cu complex: 1.72 mA cm^{-2} (b_1 = 60 mV, b_2 = 100 mV). Next in activity are the compositions Zn–Co (1.68 mA cm^{-2}, b_1 = 55 mV, b_2 = 115 mV) and Zn–Ni (0.91 mA cm^{-2}, b_1 = 50 mV, b_2 = 110 mV) obtained at 600°C.

The steady-state polarization curves of oxygen reduction on catalysts synthesized at 600°C in the atmosphere of argon are shown in Fig. 3. It can be seen that the change in the steady-state potentials of the catalysts relative to the substrate is approximately 0.10 V. The positive shift of the steady-state polarization curves relative to AG-3 is 0.12 V for catalysts with Zn–Cu, 0.10 V for Zn–Co, and 0.08 V for Zn–Ni; the slopes $\partial E/\partial \log j$ for the catalysts formed on the basis of heterobimetallic complexes are close to those for AG-3 activated carbon. This indicates that the mechanisms of oxygen electroreduction are similar in these cases. The slopes suggest that the electroreduction of oxygen occurs by the single-electron mechanism with slowed-down addition of a first electron and via the stage of formation of hydrogen peroxide, which is characteristic of activated carbons [13]. The kinetic parameters of oxygen electroreduction on catalysts produced from heterobimetallic complexes (see table) show that the highest exchange

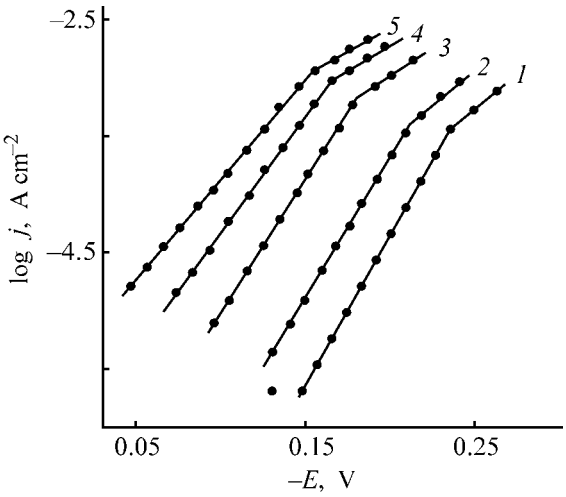

Fig. 3. Potentiostatic polarization curves of oxygen electroreduction, measured on a substrate of hydrophobized carbon black in a 1 M KOH solution at 20°C on catalysts formed by pyrolysis of heterobimetallic complexes on AG-3 at 600°C. (*j*) Current density and (*E*) electrode potential. (*1*) Hydrophobized carbon black, (*2*) AG-3 carbon, (*3*) Ni–Zn(AG-3), (*4*) Co–Zn(AG-3), and (*5*) Cu–Zn(AG-3).

currents are observed for the electrocatalyst obtained from the Zn–Cu complex (**III**) at 700°C. Thus, the electrocatalysts prepared from complex (**III**) are more electrically active than (**I**)–(**III**) complexes because their active centers contain a metal and nitrogen bound to surface carbon atoms, as also in the case of pyropolymers [5]. The slopes of the steady-state polarization curves lie within the ranges: b_1 = 0.04–0.06 V, b_2 = 0.10–0.12 V.

The electrocatalysts obtained can be used in metal-air chemical power cells, fuel cells, and sensors.

CONCLUSIONS

(1) The highest activity is characteristic of catalysts synthesized in thermal destruction of heterobimetallic complexes in the temperature range 500–700°C in the atmosphere of argon.

(2) The catalytic activity of the catalysts for oxygen reduction, prepared on the basis of heterobimetallic complexes of zinc, decreases in the order Zn–Cu > Zn–Co > Zn–Ni.

ACKNOWLEDGMENTS

The study was performed in the framework of the INTAS program (project no. 03-51-4532) and was financially supported by the State Foundation for Basic Research of the Ministry of Education and Science of Ukraine.

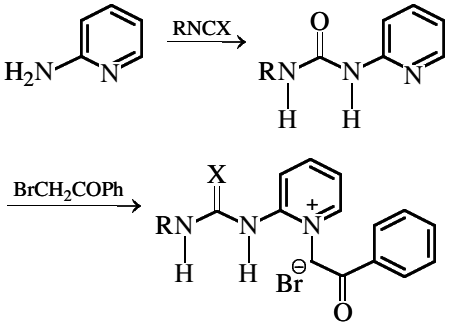
Abstract—Inhibiting effect of 1-phenacylmethylpyridinium bromides containing urea or thiourea substituents in the pyridinium ring on steel and zinc corrosion in sulfuric acid solutions was studied.

DOI: 10.1134/S1070427206120123

We found in [1, 2] that 1-phenacylmethylpyridinium bromides (**I**) are inhibitors of steel acid corrosion:

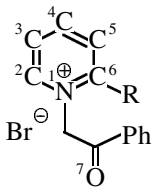


I

Introduction into the second position of the pyridinium ring in **Ia** (R = H) of an amino group (compound **Ib**, R = NH_2) enhances the inhibiting effect, whereas transformation of **Ib** into 1-phenacylmethyl-2-benzamidopyridinium bromide (**Ic**) substantially weakens it because of a decrease in the electron density on the nitrogen atom of the amino group. A different behavior is shown by amides [**I**; R = R_1CONH] in which substituents R_1 contain groups that can be independently involved in adsorption on the metal surface. Introduction of MeO group into the *p*-position of the phenyl ring of the benzamide group of compound **Ic**, or replacement of the latter with a heterylamide group (R = $HetCONH_2$) enhances the inhibiting effect as compared to **Ic**.

In this study, we considered, in order to further examine of the correlation between the structure and inhibiting effect of pyridinium salts, 1-phenacylmethyl-2-arylcarbamidopyridinium bromides (**II**) and -2-arylthiocarbamidopyridinium bromides (**III**). As known [3], many urea and thiourea derivatives are efficient inhibitors of acid corrosion of iron and steels. In addition, taking into account that arylurea and arylthiourea fragments of these compounds, similarly to phenacyl and pyridinium fragments, can be involved in adsorption, we may expect that compounds **II** and **III** should have a strong inhibiting effect on the steel acid corrosion.

The compounds studied were prepared by the reaction between 2-aminopyridine with the corresponding arylisocyanates or arylisothiocyanates, followed by alkylation of the compounds obtained with ω-bromoacetophenone:



where X = O, R = (**a**) C_6H_5, (**b**) 4-$CH_3C_6H_4$, (**c**) 4-ClC_6H_4 (**II**); X = S, R = (**a**) C_6H_5 and (**b**) 4-$CH_3OC_6H_4$ (**III**).

The structures of compounds synthesized were confirmed by IR and NMR spectra.

phenylethyl)-2-[3-phenylthiocarbamido]pyridinium bromide (**IIIa**), and 1-(2-oxo-2-phenylethyl)- 2-[3-(4-methoxyphenyl)thiocarbamido]pyridinium bromide (**IIIb**). A mixture of 2-aminopyridine (0.02 M), appropriate isocyanate or thiocyanate, and dioxane (15 ml) was refluxed for 2 h. The reaction mixture was treated with a small amount of water, left overnight, and then the precipitate was separated. Then, a mixture containing equimolar amounts (0.0015 mol) of one of the compounds obtained, ω-bromacetophenone, and 15 ml of ethyl acetate was refluxed for 3 h, and the precipitate formed was separated. Yields (%) and boiling points (°C): **IIa**, 81, 205–207; **IIb**, 85, 242–244; **IIc**, 87, 253–255; **IIIa**, 80, 227–229; and **IIIb**, 80, 220–222, respectively.

The corrosion tests were performed by a commom procedure [1] with 08 KP steel and Ts0 zinc with a working surface area of 14×10^{-4} and 5.76×10^{-4} m^2, respectively. The steel samples were kept in 3 M H_2SO_4 at 20°C for 24 h, at 40 and 60°C for 2 h, and at 80°C for 1 h, and the zinc samples, in 0.5 M H_2SO_4 at 20°C for 0.5 h. The efficiency of metal protection was evaluated by the inhibition coefficient $\gamma = K_M/K'_M$ and degree of protection $Z = [(K_M - K'_M)/K_M] \times 100\%$, where K_M and K'_M (g m^{-2} h^{-1}) are the gravimetric corrosion indices in pure and inhibited acid solutions, respectively. Voltammetric measurements with steel and zinc were performed in the potentiodynamic mode after stabilization of the free corrosion potential E_c at a scanning rate of 2 mV s^{-1}.

Quantum-chemical calculations performed by the procedure from [4, 5] showed that the effective charges on the nitrogen atom of the amino group directly bonded to the pyridine ring in ureas **II**, thioureas **III**, and compound **Ic** (Table 1) differ only

slightly and are substantially lower than those in **Ib**. These results suggest that the inhibiting effect of the 1-phenacylmethylpyridinium bromides studied should be close to the effect of **Ic** and substantially lower than that of **Ib**.

The results of the corrosion test showed that compounds **II** and **III** are efficient inhibitors of steel acid corrosion (Table 2). The efficiency of the protection effect substantially increases as temperature is elevated to 60°C. This is in agreement with the hypothesis of specific adsorption of 1-phenacylmethylpyridinium bromides on the surface of steel, developed in [1, 2, 6]. Ureas (**II**) and thioureas (**III**) are characterized by the stronger anticorrosion effect as compared not only to compound **Ic**, but also to **Ib**. For instance, in the presence of **IIa** and **IIIa**, γ for steel is higher by a factor of 1.2 at 20°C and by a factor of 2.6 and 3.2, respectively, at 60°C than that in the presence of **Ib**. Electron-donor groups CH_3 and CH_3O introduced in the *p*-position of the phenyl ring of **IIa** and **IIIa** enhance the protective properties of these compounds, whereas the chlorine atom decreases them. An increase in the temperature to 80°C is accompanied, as for the other compounds of this type, by a small decrease in the inhibiting effect, probably caused by desorption of the inhibitor from the metal surface due to the elevated rate of its dissolution. The above results show that our compounds are, indeed, efficient inhibitors of the steel corrosion, whose corrosion-protective activity is mainly caused by the presence of arylurea and arylthiourea groups responsible for adsorption and inhibition.

Being efficient inhibitors of steel acid corrosion, compounds **II** and **III** only slightly inhibit the corrosion of zinc in 0.5 M H_2O_4, and compound **IIIa** at its low concentrations even stimulates the corrosion (Table 3). The decrease in the protective properties of **Ia**, **IIa**, and **IIIa** for zinc, compared to steel, is probably caused by involvement of these compounds in catalytic evolution of hydrogen due to discharge of their protonated forms.

In accordance with modern views [7], the catalytic evolution of hydrogen in acid media in the presence of nitrogen-containing organic compounds capable of protonation can proceed by the scheme

$$B + H^+ = BH^+,$$

$$BH_s^+ + e = BHs,$$

$$BH_s = B_s + 1/2H_2,$$

$$B_s + H_s^+ = BH_s^+,$$

where B and B_s are molecular forms and BH^+ and BH_s^+, protonated forms in the solution bulk and on the metal surface, respectively. Depending on a particular metal and on the structure and concentration of the inhibitor, the above reactions can either accelerate (due to easier hydrogen elimination) or decelerate the corrosion (due to inhibiting effect of protonated and molecular forms of compounds).

It is known that the discharge of hydroxonium ions on the zinc surface is characterized by high activation energy, whereas regeneration of BH_s^+ cations proceeds fairly rapidly due to the presence of activated hydrogen ions (H_s^+) in the electric double layer. Therefore, during zinc corrosion in the acid medium, the above processes usually decrease the hydrogen overvoltage and the inhibiting effect of the nitrogen-containing compounds [7]. On the steel surface, these processes are complicated, because the activation energy of the hydroxonium ion discharge on the surface of *d* metals is relatively low and regeneration of BH_s^+ is slow due to the ability of nitrogen atoms to interact with unoccupied *d* orbitals of iron [7]. This fact accounts for the high inhibiting effect of the compounds studied in the steel corrosion in sulfuric acid solution and for its substantial decrease in the case of zinc. For instance, at 20°C in the presence of **IIa** or **IIIa** (1×10^{-2} M), the rate of steel corrosion decreases by a factor of 28 and 29, respectively, whereas that of zinc corrosion, by only a factor of 2.3 (Tables 1, 3). In the presence of **Ib** (1×10^{-2} M) containing amino group at 20°C, the steel corrosion is inhibited by a factor of 24, and zinc corrosion, by a factor of 3, whereas unsubstituted 1-phenacylmethylpyridinium bromide (**Ia**) containing no protonation centers in the pyridinium ring virtually equally inhibits the corrosion of steel [1] and zinc (Table 4).

Quantum-chemical calculations showed that the negative charges on oxygen and sulfur atoms in

the arylurea and arylthiourea groups that can be directly involved in the protonation amounts to –0.15229, –0.16143 and –0.62322, –0.62615, respectively. Therefore, in going from urea (**IIa**) to thiourea (**IIIa**) derivatives, the bond strength in the protonated arylthiourea group can decrease, which should facilitate catalytic evolution of hydrogen on zinc and hence decrease the protective effect of this group. This assumption is confirmed by the fact that at a concentration of 1.6×10^{-3} M compound **IIa** increases the overvoltage of the hydrogen evolution on zinc, whereas **IIIa** decreases it (Fig. 1a); compound **IIa** slightly inhibits zinc corrosion in 0.5 M H_2SO_4, whereas **IIIa** stimulates it (Table 3).

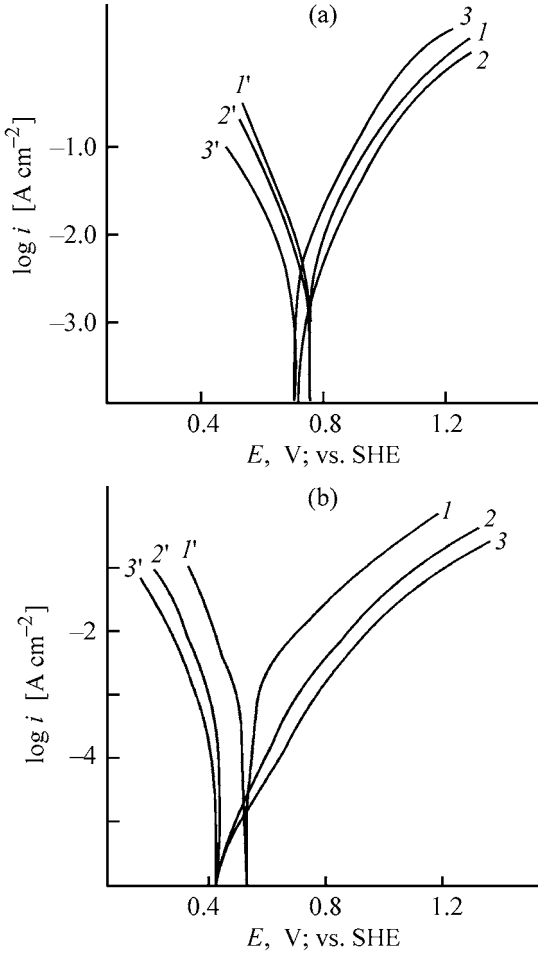

Fig. 1. (*1*–*3*) Catodic and (*1'*–*3'*) anodic polarization curves recorded (a) on Ts0 zinc in 0.5 M H_2SO_4 and (b) on 08 KP steel in 3 M H_2SO_4 at 20°C in the presence of 1.6×10^{-1} M of compounds **IIa** or **IIIa**. (*i*) Current density and (*E*) potential. (*1*, *1'*) none, (*2*, *2'*) **IIa**, and (*3*, *3'*) **IIIa**.

At the same time, the bulk and surface concentration of the molecular species of compounds capable of chemisorption on steel can increase from ureas (**II**) to thioureas (**III**) due to interaction with the metal surface of their arylurea and arylthiourea groups. This should inhibit catalytic evolution of hydrogen on steel and noticeably enhance its protection. This suggestion is in good agreement with the fact that compound **IIIa** increases the overvoltage of hydrogen evolution (Fig. 1b) and, correspondingly, is more efficient inhibitor of steel corrosion than the related urea **IIa** (Table 2).

CONCLUSIONS

(1) Arylurea and arylthiourea groups in the pyridinium ring of 1-phenacylmethylpyridinium bromides are responsible for the high level of their corrosion-protective effect in steel corrosion in 3 M sulfuric acid solution at 20–80°C.

(2) The compounds studied are ineffective as inhibitors of zinc acid corrosion, which is caused by catalytic evolution of hydrogen due to discharge of their protonated species.

Abstract—Principles of construction of a mathematical model of a reaction-rectification column for ethylene glycol synthesis are considered. Some specific features of the operation of the reaction-rectification column are analyzed. The correctness of the assumptions and limitations of the model is substantiated and the adequacy of the model is assessed.

DOI: 10.1134/S1070427206120135

Recently, interest has increased in development of reaction-rectification apparatus [1] combining a chemical process with separation of the reaction products, which markedly simplifies the technological scheme and diminishes the capital expenditure for construction of installations and optimization of the process as a whole [2–6]. Reaction-rectification columns can be used in such processes as etherification, hydrolysis, oxidation, alkylation, and isomerization, in which the chemical stage occurs in the range of boiling points of components of the reaction mixture on several contact mass-exchange devices of the column [1]. As an example of a process of this kind can serve production of ethylene glycol via direct hydration of ethylene oxide

$$C_2H_4O + H_2O \rightarrow HO–C_2H_4–OH. \quad (1)$$

Simultaneously with the target reaction occur side reactions of glycols with ethylene oxide to give diethylene glycol

$$C_2H_4O + HO–C_2H_4–OH \rightarrow HO–C_2H_4–O–C_2H_4–OH, \quad (2)$$

triethylene glycol

$$C_2H_4O + HO–C_2H_4–O–C_2H_4–OH \rightarrow HO–C_2H_4–O–C_2H_4–O–C_2H_4–OH \quad (3)$$

and tetraethylene glycol

$$C_2H_4O + HO–C_2H_4–O–C_2H_4–O–C_2H_4–OH \rightarrow HO–C_2H_4–O–C_2H_4–O–C_2H_4–O–C_2H_4–OH \quad (4)$$

To suppress the side reactions, ethylene glycol is synthesized in the liquid phase at elevated temperatures (about 200°C) and pressures (1.5–2 MPa) in the presence of water.

The technological scheme of the process is rather cumbersome and includes, in addition to the reactor, three evaporation installations for removal of excess water from the reaction mixture and a unit of rectification columns for removal of admixtures of di-, tri-, and tetraethylene glycol from the commercial ethylene glycol. All the components of the reaction mixture are successively evaporated and condensed, and only tetraethylene glycol is obtained from the bottom of the last rectification column in the liquid phase. This intricate technological scheme can be, in principle, replaced with a single apparatus, a reaction-rectification column [7, 8].

A specific feature of the operation of a reaction-rectification column in synthesis of ethylene glycol is the possibility of circulating the excess water within the column at a virtually total conversion of ethylene oxide and the resulting operation of the upper part of the column in the virtually total reflux mode (Fig. 1), which improves the fractionation efficiency [9].

Simulation of the operation of a reaction-rectification column is complicated by the fact that the reaction and rectification processes are commonly calculated by different methods. The rectification process is, as a rule, calculated by predetermined statics models based on the concept of a theoretical plate, which provide attainment of equilibrium between the contacting vapor and liquid during a conditionally infi-

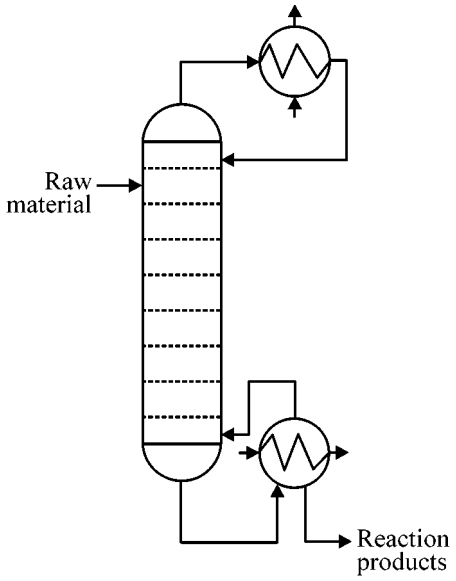

Fig. 1. Schematic of a reaction-rectification column.

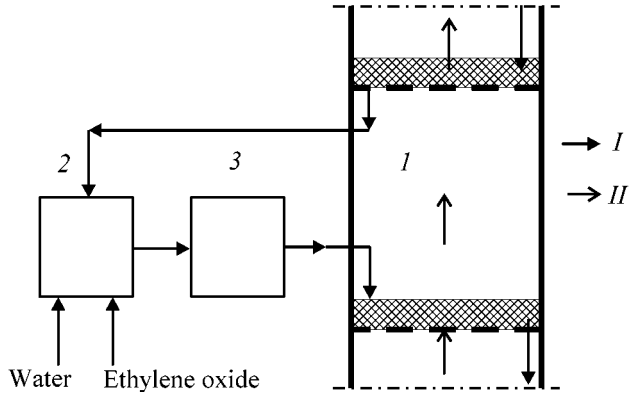

Fig. 2. Flow chart in calculation of the reaction zone of a reaction-rectification column. (*1*) Fractionating part, (*2*) mixing of flows of the raw material and recirculating water, and (*3*) reaction part. (*I*) Liquid flows and (*II*) vapor flows.

nite contact time. This makes unnecessary use of such difficultly determined characteristics as the phase boundary area, mass-transfer coefficient, and hydrodynamic structure of flows in a real contact device, which can only be obtained in full-scale experimental studies of the process. At the same time, simulation of a chemical process requires that its kinetics should be taken into account. The two approaches to solution of the problem can be united in a single combined static-kinetic model of operation of the reaction-rectification column.

The combined static-kinetic model is based on the rectification process in a complex composite column equivalent to any system of simple columns [10]. In the construction of this model, it was assumed that the raw material is introduced into each theoretical plate and the vapor and liquid phases are partly or totally removed from the plate after the mass exchange is complete; these phases are removed as final products or introduced as raw materials into other theoretical plates of the composite column. Such a construction of the model made it possible to simultaneously calculate the whole system of columns of the installation, which enabled optimization of the system as a whole. This model of the theoretical plate, as applied to the problem of calculation of the reaction-rectification column, considered here, was supplemented with units of mixing of the raw-material and circulating flows, and the chemical transformation on the theoretical plate simultaneously serving as the reaction device (Fig. 2) was calculated. In this case, it is possible to remove the reflux (mainly containing the circulating water) from a higher-lying plate and mix it with raw-material flows of ethylene oxide ($F0_{J,1}$) and water ($F0_{J,2}$), with the subsequent chemical reaction and separation of the reaction products both on the *J*th (reaction) plate and on other fractionating plates of the column. In this context, two calculation techniques are combined when calculating the column: statics of fractionation on the theoretical plate, which provides determination of the quality of the products of separation in the vapor–liquid system via mass exchange, and kinetics of the chemical process on the reaction plate, which makes it possible to determine the composition of the reaction products in the reaction mixture and the time necessary for achieving the acceptable degree of conversion of the raw material.

The reaction-rectification column can be effectively used only if the following two limitations are overcome: (i) the reaction duration should not exceed the residence time of the flows in the reaction zone of the column (necessary limitation); and (ii) the composition of the reaction mixture obtained in the reaction zone should provide the acceptable purity of the target product discharged from the column bottom (sufficient limitation).

The following assumptions were made in the development of the mathematical model of the reaction-rectification column: hydrodynamics of the contact device is described by the plug-flow model; relative volatility of the components of the mixture being separated, relative to the reference component, is taken to be constant along the column height; as the reference component is taken ethylene glycol, the boundary component of a mixture being fractionated: water with a minor admixture of organic substances goes to the top part of the column, and ethylene glycol

with admixture of water and higher glycols, products of side reactions, to the bottom part of the column.

The mathematical model of the reaction-rectification process on a contact device comprises three units: mixing unit, unit of the chemical reaction kinetics, and rectification statics unit.

The model of the unit of mixing of a balance amount of the raw material with the circulating water (reflux) coming from a higher-lying plate and containing a minor admixture of all the components of the reaction mixture, in which the initial amount $GR_{J,I}$ of each of the six components (ethylene dioxide, water, ethylene glycol, diethylene glycol, triethylene glycol, tetraethylene glycol) delivered into the reaction unit is determined, is constructed in the form of material-balance equations of the unit

$$GR_{J,I} = B_{J-1}x_{J-1,I} + FO_{J,I}, \quad (5)$$

Here, B_{J-1} and $x_{J-1,\,I}$ are the amount and composition of the reflux removed from the higher-lying plate.

The model of the reaction unit comprises a system of differential equations that account for the influence exerted by the hydrodynamic situation on the kinetics of the chemical process for all the components of the reaction mixture:

$$\left.\begin{aligned}
\frac{dx_{1,R}}{d\tau} &= -K_1x_{1,R}x_{2,R} - K_2x_{1,R}x_{3,R} - K_3x_{1,R}x_{4,R} - K_4x_{1,R}x_{5,R} - W\frac{dx_{1,R}}{dl},\\
\frac{dx_{2,R}}{d\tau} &= -K_1x_{1,R}x_{2,R} - W\frac{dx_{2,R}}{dl},\\
\frac{dx_{3,R}}{d\tau} &= -K_1x_{1,R}x_{2,R} - K_2x_{1,R}x_{3,R} - W\frac{dx_{3,R}}{dl},\\
\frac{dx_{4,R}}{d\tau} &= -K_2x_{1,R}x_{3,R} - K_3x_{1,R}x_{4,R} - W\frac{dx_{4,R}}{dl},\\
\frac{dx_{5,R}}{d\tau} &= -K_3x_{1,R}x_{4,R} - K_4x_{1,R}x_{5,R} - W\frac{dx_{5,R}}{dl},\\
\frac{dx_{6,R}}{d\tau} &= -K_4x_{1,R}x_{5,R} - W\frac{dx_{6,R}}{dl},
\end{aligned}\right\} \quad (6)$$

Here, $x_{1,R}$, ..., $x_{6,R}$ are the concentrations of ethylene dioxide, water, ethylene glycol, diethylene glycol, triethylene glycol, tetraethylene glycol, respectively (mole fractions); τ, reaction duration (s); W, motion velocity of the reaction mixture (m s^{-1}); l, path of the reaction mixture in the reaction zone (m); K_1–K_4, rate constants of reactions (1)–(4).

The reaction rate constants were calculated by the Arrhenius reaction

$$K_M = K_{M,0}\exp(-E_M/RT), \quad M = 1, 2, 3, 4, \quad (7)$$

where $K_{M,0}$ and E_M are the pre-exponential factor and activation energy for Mth reaction; T, process temperature; and R, universal gas constant.

The values of $K_{M,0}$ and E_M for reactions (1)–(4) were taken from [11]. In the calculation of the reaction unit, the amount E_J of the reaction products arriving to Jth plate were determined. The model of the rectification statics yielded the composition $Z_{J,I}$ of the mixture formed on a plate after mixing of the raw material introduced (reaction mixture) with flows of vapor and liquid coming from the lower- and higher-lying plates:

$$Z_{J,I} = \frac{L_{J-1}x_{J-1,I} + V_{J+1}y_{J+1,I} + F_Jx_{J,I}}{L_{J-1} + V_{J+1} + F_J}. \quad (8)$$

Further, the fraction of E_J of the vapor removed from the starting mixture was calculated

$$E_J = \frac{P_J}{F_J + L_{J-1} + V_{J+1}} \quad (9)$$

and the phase equilibrium constant $K_{E,J}$ of the reference component at which the prescribed fraction is achieved was found from the condition

$$\sum_{I=1}^{6} x_{J,1} = \sum_{I=1}^{6} \frac{Z_{J,I}}{1 + E_J(A_I K_{E,J} - 1)} = 1. \quad (10)$$

This made it possible to calculate, from the com-

position $x_{J,I}$ of the liquid phase, the composition $y_{J,I}$, of the vapor phase:

$$y_{J,I} = A_I K_{E,J} x_{J,I}, \quad (11)$$

where A_I are the volatilities of the mixture components, related to the reference component.

The phase equilibrium constant of the reference component was used to calculate the temperature T_J of the product on the theoretical plate:

$$T_J = [B_E/\log(P_c K_{E,J}) - A_E] + C_E. \quad (12)$$

where P_c is the pressure in the column; A_E, B_E, and C_E, constants of the Antoine equation for calculation of the saturated vapor pressure for the reference component.

The chemical stage of the process was calculated by the first-order Runge–Kutta method, with kinetic curves obtained for all the components of the reaction mixture and the time determined in which the maximum yield of ethylene glycol is reached.

The rectification stage was calculated by the relaxation method, with the column filled with pure water as the initial condition in solving the problem. The input data used in the calculation include setting the number of theoretical plates, mole vapor fluxes P_J ascending from each plate, positions at which raw materials are charged into the column, and the amount and composition of the raw material. The solution algorithm of the problem exhibits fast convergence (duration of computer calculation of a variant of the column operation is 1–2 h) at a high accuracy of the calculation (the integration step in calculating the chemical stage of the process is 0.0001 min at a reaction duration of 1.5–0.5 min; the equilibrium constant of the reference component is determined in calculating the rectification statics with an accuracy of 0.00001). The calculation of the problem is complete at discrepancies of $\leq 10^{-8}$ mole fraction between the compositions of the vapor ($x_{J,I}$) and liquid ($y_{J,I}$), obtained in two neighboring iterations on all plates of the column.

In mathematical calculation of the synthesis of ethylene glycol in the reaction-rectification column, the possibility was considered of overcoming the abovementioned limitations and the adequacy of the assumptions made both in the stage of chemical transformation of the raw material used to produce ethylene glycol on the reaction plate of the rectification column and in further fractionation of the reflux.

The process of synthesis of ethylene glycol was analyzed taking into account the formation of the byproducts, di-, tri-, and tetraethylene glycol, in a wide range of process temperatures and water : ethylene oxide ratios, because detailed published data are only available for a limited range (from zero to two parts of water per one part of ethylene oxide). Under industrial conditions, this ratio is about 6 : 1 [11].

A calculation of the reaction mixture compositions for obtaining ethylene glycol in maximum yield at a water : ethylene oxide ratio of 6 : 1, characteristic of industrial conditions, demonstrated that the yield of the product is virtually independent of the hydration temperature, 12.5–12.7 mol %. An increase in temperature in the range 373–493 K leads to a decrease in the concentration of unreacted ethylene oxide by nearly three orders of magnitude, with an insignificant acceleration of side reactions, because the rate constants of the side reactions and the target reaction are mutually proportional [11]. A calculation of the composition of the residue formed in the rectification column in full separation of unreacted water from the glycols formed demonstrated that high-purity ethylene glycol cannot be obtained at a water : ethylene dioxide ratio of 6 : 1 in the starting raw material (Table 1). It is necessary to introduce, in addition to the reaction-rectification column, a unit for fractionation of glycols, as it is commonly done in the industry. In this case, an increase in the temperature at which the chemical process is performed has virtually no effect on the quality of residue formed in the rectification column, but leads to a significant decrease in the reaction duration: from 182 min at 373 K to 0.9 min at 493 K.

Raising the water : ethylene oxide ratio within the range 2–100 leads to a considerable increase in the concentration of ethylene glycol (from 68 to 99 mol %) in the residue obtained at the column bot-

Table 2. Effect of the water : ethylene oxide ratio on the calculated composition of the residue from the column bottom at the maximum yield of ethylene glycol and temperature of 473 K

tom (Table 2). Thus, the limitation on the purity of ethylene glycol obtained in the rectification column can be overcome by proper choice of the water : ethylene oxide ratio in the starting raw material.

A simulation of the synthesis of ethylene glycol also demonstrated that an increase in temperature can make markedly shorter the synthesis duration, with the high purity of the final product preserved, if the starting raw material (water : ethylene oxide = 1 : 1) is mixed with the reflux removed from the upper-lying plate and circulated in the column.

The water : ethylene oxide ratio recommended on the basis of the results of simulation is (30 – 40) : 1, because further increase in the content of water fails to give any noticeable positive effect and only leads to a higher energy expenditure for the process (Fig. 3).

The possibility of providing the necessary residence time of the reaction mixture in the reaction zone on the rectification plate of the column was assessed by calculating the synthesis kinetics of ethylene glycol. The calculations demonstrated that, at a temperature of 493 K and a water : ethylene oxide ratio at the onset of the reaction equal to 29.3 : 1 (initial C_2H_4O concentration in the reaction mixture 0.033 mole fraction), ethylene oxide is virtually completely consumed to a level of 0.0746×10^{-3} mole fraction in 0.5 min, with concentrations of 0.0167×10^{-5} and 0.04×10^{-8} mole fraction reached in 1 and 1.5 min, respectively. The virtually total absence of ethylene oxide in the reaction mixture suppresses side reactions. The real residence time of the reflux flow in the reaction zone was calculated by the Souders–Brown method [12] by determining the column diameter *D* and the admissible vapor flux on a real plate of the column in the reaction zone, G_g (kg m^{-2} h^{-1}):

$$G_g = 0.305C\sqrt{\rho_V(\rho_L - \rho_V)}, \qquad (13)$$

where ρ_V and ρ_L are the densities of the vapor and liquid flows in the column, respectively, and *C* is a coefficient.

The residence time of the reaction mixture on a real fractionating plate of the reaction-rectification column was calculated for a throughput of 6.2 ton h^{-1} for ethylene glycol in a wide range of reflux : ethylene oxide ratios and column pressures (Table 3). The cal-

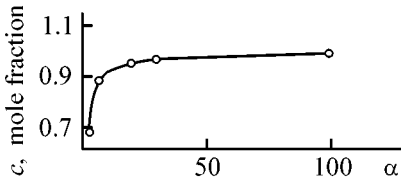

Fig. 3. Maximum concentration *c* of ethylene glycol in the potential residue of the column vs. the water : ethylene oxide ratio α in the starting raw material at a temperature of 493 K in the reaction zone.

culations demonstrated that the residence time of the reaction mixture on a real plate is independent of the reflux : ethylene oxide ratio and decreases as the column diameter becomes smaller. A comparison of the residence time of the reaction mixture on a series of real plates with the necessary reaction duration demonstrated (Fig. 4) that it is the most appropriate to perform the process at a sufficiently high temperature and pressure in the reaction zone. At temperatures of 475–493 K, one to three real plates are sufficient for the reaction, i.e., the reaction virtually completely occurs on a single theoretical plate. The reaction requires 3–5 real plates at 450–475 K, up to 20 real plates at 425–450 K, and 30–40 real plates at 400–425 K. Thus, the limitation concerning the correspondence of the residence times of flows in the reaction zone of the column to the reaction duration in the reaction-rectification column can be overcome by proper choice of the temperature and pressure in the reaction zone.

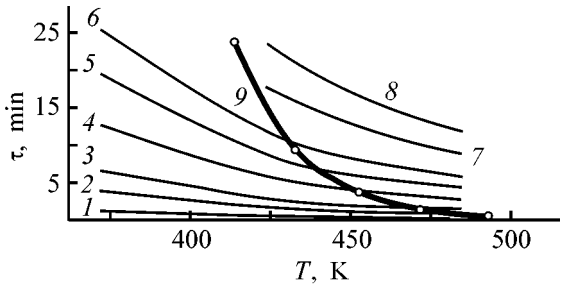

Fig. 4. Effect of temperature T and number of real plates in the reaction zone on the residence time τ of the reaction mixture in the column. Number of plates: (*1*) 1, (*2*) 3, (*3*) 5, (*4*) 10, (*5*) 15, (*6*) 20, (*7*) 30, and (*8*) 40; (*9*) effect of temperature on the reaction duration.

At a column diameter larger than 2 m, the hydrodynamics of the real rectification plate can be described by the plug-flow hydrodynamic model at a number of mixing members (e.g., tray caps) in the vapor–liquid system exceeding ten [13]. Thus, the description of the hydrodynamics in the reaction zone in terms of the plug-flow model taken into account by the system of equations (6) is quite adequate. The formal duration of the reaction in which ethylene glycol is synthesized, calculated in terms of the kinetic model, will be also valid for the process performed on a real contact device. This is so because, in this case, the model of the kinetics of the chemical reaction coincides in form with the mathematical model of the reaction plate, which takes into account both the kinetics and hydrodynamics of the stationary process.

An analysis of the assumption that the relative volatilities of the components are constant along the column height demonstrated that, in view of the significant difference between the saturated vapor pressures of the components of the system, the conventional procedure taking into account the average relative volatility A_I as

$$A_I = \sqrt{A_{I,b}A_{I,t}} \qquad (14)$$

[$A_{I,b}$ and $A_{I,t}$ are the relative volatilities at temperatures of the bottom and top parts of the column, respectively (Table 4)] leads to a gross error in calculat-

Table 5. Profile of temperature distribution over plates of the reaction-rectification column at a pressure of 0.1 MPa

Plate no.	Temperature at column plates, K		
	in calculation of relative volatilities A by (14)	with A taken to be separately constant in the upper and lower halves of the column	according to [9]
Top temperature 373 K (in discharge of pure water: actually, 0.9999 mole fraction of water the reflux)			
1	384.12	372.24	372.2
2	384.41	372.48	373.5
3	384.41	372.48	373.5
4	384.50	373.16	374.1
5	386.79	405.89	391.2
6	414.78	440.63	448.1
7	461.63	465.99	468.7
Bottom temperature 470 K (in discharge of pure ethylene glycol: actually, 0.9765 mole fraction of ethylene glycol in the residue)			

Table 6. Composition of nonequilibrium counter flows of vapor and liquid on neighboring plates of the reaction-rectification column (column pressure 0.5 MPa, reflux : ethylene oxide ratio at the inlet of 3rd theoretical plate 50 : 1)

Component	Composition of counter flows			
	between 1st and 2nd plates		between 7th and 8th plates	
	liquid	vapor	liquid	vapor
Ethylene oxide	2.529448×10^{-6}	2.528886×10^{-6}	1.46414×10^{-11}	1.4921×10^{-11}
Water	0.9999515	0.99990670	0.13059	0.132864
Ethylene glycol	3.599192×10^{-5}	3.599089×10^{-5}	0.8649360	0.8629011
Diethylene glycol	1.264544×10^{-8}	1.264509×10^{-8}	4.45336×10^{-3}	4.21003×10^{-3}
Triethylene glycol	1.35198×10^{-11}	1.35195×10^{-11}	2.058291×10^{-5}	1.72148×10^{-5}
Tetraethylene glycol	1.38167×10^{-15}	1.38194×10^{-15}	6.695805×10^{-8}	4.02859×10^{-8}

ing the temperature profile along the column height. In this case, the calculated product temperature on top plates of the column is overestimated, and that on bottom plates, underestimated with respect to the real values. For example, in a column operating at a pressure of 0.1 MPa and water content of the vapor upflowing from the top plate equal to 0.9999 mole fraction, the calculated top temperature of the top part of the column was 384.1 K, instead of the real value of 373 K. Therefore, the relative volatilities were taken, in simulating the operation of the reaction-rectification column, to be constant throughout the upper and lower halves of the column, but determined by the temperatures of the top and bottom parts of the column, respectively. This made it possible to obtain a more precise temperature profile along the column height (Table 5). Thus, the assumption that relative volatilities are constant along the column height is sufficiently correct in the modification accepted.

A simulation of the operation of a reaction-rectification column demonstrated that the compositions of the nonequilibrium counter flows of vapor and liquid are rather close for neighboring plates (Table 6). This corresponds to operation of the apparatus in the total reflux mode. A specific feature of the operation of the column is that the quality of the residue obtained is virtually independent of the number of theoretical plates, beginning with five or six. This is so because an increase in the number of plates between the input of raw materials and discharge of the residue leads to formation of a kind of a constant-concentration zone on a number of theoretical plates, and the tem-

Table 7. Effect of the number of theoretical plates on the variation of temperature T and the concentrations of water (x_2) and ethylene glycol (x_3) in the liquid phase downflowing from plates of the reaction-rectification column (column pressure 0.1 MPa, reflux : ethylene oxide ratio at the inlet of 3rd plate 90 : 1)

perature and composition of vapor and liquid flows in this zone are virtually constant (Table 7). This situation additionally confirms that the reaction can be performed on several plates without any significant effect of the reaction on the fractionation in this zone.

To assess the adequacy of the model developed, the operation of a reaction-rectification column for synthesis of ethylene glycol was calculated and the flow rates of the raw material, vapor, and liquid on the plates were obtained, which virtually coincided with the data reported in [9]. The calculated profiles of temperatures and concentrations of the boundary components of the system (water and ethylene glycol), being separated, along the column height in a wide range of

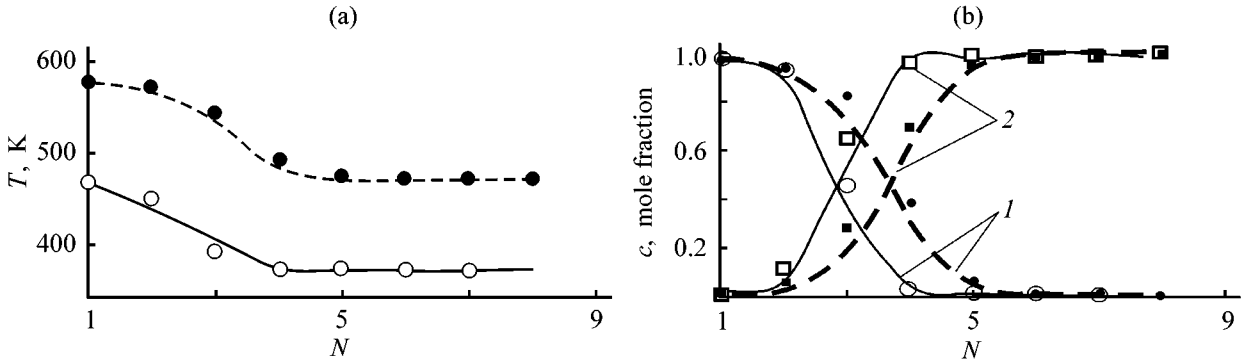

Fig. 5. Variation of (a) temperature T and (b) concentration c of (*1*) ethylene glycol and (*2*) water over plates of the reaction-rectification column. (N) Plate number. *Solid lines*, calculation in terms of the model at a pressure of 0.1 MPa; *dashed lines*, calculation by the model at a pressure of 1.5 MPa; *points*, data of [9].

pressures (Fig. 5) demonstrated an acceptable coincidence with the data of [9]. This circumstance can serve as a correct qualitative substantiation of the adequacy of the combined static-kinetic model of the reaction-rectification column, developed in this study.

CONCLUSIONS

(1) The principles of formation of a combined static-kinetic mathematical model of a reaction-rectification column were considered for the example of ethylene glycol synthesis.

(2) The possibility of obtaining high-purity ethylene glycol in a reaction-rectification column was substantiated.

(3) Ways for overcoming the limitations on synthesis of ethylene glycol in a reaction-rectification column were described.

(4) The correctness of the assumptions made in developing the mathematical model of the apparatus was substantiated.

(5) The adequacy of the combined static-kinetic model of the reaction-rectification column was confirmed.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis of Esters of *D*,*L*-, *D*(+)-, and *L*(–)-Camphor Oximes: Structure–Odor Correlation

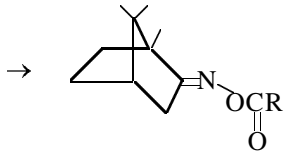
Abstract—Esters of *D*,*L*-, *D*(+)-, and *L*(–)-camphor oximes were synthesized, and the correlation between their structure and odor was examined.



DOI: 10.1134/S1070427206120147

Examination of the correlation between the tints and scents of fragrance compounds and odorants, on the one hand, and structures of fragments of natural compounds used in the synthesis of these substances, on the other hand, is a topical problem of fragrance chemistry [1–3].

In this study we developed a convenient procedure for preparing esters of *D*,*L*-, *D*(+)-, and *L*(–)-camphor oximes and examined the correlation between their odor and structure:

I, **II**, **III** **IV**, **V**, **VI**

VIIa–**VIIv**, **VIIIa**–**VIIId**, **IXa**–**IXd**

I, **IV**, **VII**: *D*,*L*-camphor and its oxime and esters, respectively; **II**, **V**, **VIII**: *D*(+)-camphor and its oxime and esters, respectively; **III**, **VI**, **IX**: **L**(–)-camphor and its oxime and esters, respectively; **VII**, **VIII**, **IX**: R = Me (**a**), Et (**b**), Pr (**c**), $CHMe_2$ (**d**), Bu (**e**), CH_2CHMe_2 (**f**), $(CH_2)_4Me$ (**g**), $(CH_2)_5Me$ (**h**), $(CH_2)_6Me$ (**i**), $(CH_2)_7Me$ (**j**), $(CH_2)_8Me$ (**k**), $(CH_2)_{11}Me$ (**l**), $(CH_2)_{16}Me$ (**m**), $CHBrCCl{=}CCl_2$ (**n**), $(CH_2)_2C(O)OMe$ (**o**), C_6H_{11}-cyclo (**p**), C_6H_5 (**q**), C_6H_4Cl-2 (**r**), $C_6H_3Cl_2$-2,4 (**s**), $CH_2OC_6H_3Cl_2$-2,4 (**t**), $C_6H_4NO_2$-3 (**u**), $C_6H_4NO_2$-4 (**v**), $C_6H_3(NO_2)_2$-3,5 (**w**).

Camphor oxime esters **VIIa**–**VIIv**, **VIIIa**–**VIIId**, and **IXa**–**IXd** were prepared by the reactions of **IV**–**VI** with appropriate alkane- or arenecarboxylic acid anhydrides or chlorides in absolute hexane or benzene. The reactions with carboxylic acid chlorides were performed in the presence of pyridine. The reactant ratio was stoichiometric (1 : 1 or 1 : 1 : 1). By these reactions, the starting oximes **IV**–**VI** were converted to the corresponding esters **VIIa**–**VIIw**, **VIIIa**–**VIIId**, and **IXa**–**IXd** in yields of 88–92%.

Camphor oxime esters **VIIa**–**VIIw**, **VIIIa**–**VIIId**, and **IXa**–**IXd** are colorless liquids or crystalline substances (crystallizing from hexane) (Table 1). The esters do not require additional purification, contain no admixtures of the starting compounds, benzene, and pyridine, and are suitable for direct use in fragrance and food industry [4]. The purity of the compounds was 97–98% according to the ^{1}H NMR spectra.

The structure and properties of camphor oxime esters **VIIa**–**VIIv**, **VIIIa**–**VIIId**, and **IXa**–**IXd** were confirmed by elemental analysis, cryoscopic determination of the molecular weight (Table 1), and ^{1}H NMR, IR, and UV spectroscopy.

The IR spectra of **VIIa**–**VIIv**, **VIIIa**–**VIIId**, and **IXa**–**IXd** contain the following characteristic absorption bands (ν, cm^{-1}): 3020–2800 (CH_{Alk}), 1780–1750 (C=O), 1670–1660 (C=N), 1100–1220 (C–O), and 910–1000 (N–O).

The UV spectra of **VIIa**–**VIIv**, **VIIIa**–**VIIId**, and **IXa**–**IXd** show an absorption peak at 208 nm (ε 4000) assigned to the C=N–O fragment.

In the ^{1}H NMR spectra of **VIIa**–**VIIv**, **VIIIa**–**VIIId**, and **IXa**–**IXd**, the methyl groups of the bicyclic core

give three characteristic singlets at 0.78–1.20 ppm, and the CH proton, a singlet at 2.20–2.30 ppm.

The IR, UV, and ^{1}H NMR spectra of **VIIa**–**VIIv**, **VIIIa**–**VIIId**, and **IXa**–**IXd** contain characteristic absorption bands and signals confirming the expected structure of the ester fragments [5].

A number of the compounds prepared have a pleasant odor[1] with various strong tints (Table 2). Of particular interest are compounds **VIIc**–**VIIi** having fruit–berry scents with various notes. With an increase in the size of the alkyl radical, the scent becomes more intense, changing from berry to fruit. Further increase in the size of the alkyl radical in the series **VIIj**–**VIIq** leads to disappearance of the fruit–berry scent and appearance of a wood scent with camphor notes and various tints; in this series, the odor intensity decreases. Particularly attractive among these derivatives are **VIIk** and **VIIo**, having popular odors of ozone and sweet leather. Esters **VIIn** and **VIIr**–**VIIw** have no odor because of low volatility. A very interesting fact for perfumery is the pronounced musk note in *D*-cam-

[1] Organoleptic evaluation of scents of **IV**–**VI**, **VIIa**–**VIIv**, **VIIIa**–**VIIId**, and **IXa**–**IXd** was performed by the Tasting Council at the Accredited Analytical Laboratory of the Tereza Inter Limited Liability Company (Moscow).

Table 2. Specific rotation and odor of camphor oximes IV–VI and their esters **VIIa–VIIm**, **VIIo–VIIq**, **VIIIa–VIIId**, and **IXa–IXd**

Compound	$[\alpha]_D^{20}$, deg	Odor

IXc	+26.9	Green and sour fruit with musk note
IXd	+27.2	Fruit–wood with peach peel note

phor esters **IXa–IXd**, in contrast to wood–camphor notes in the related *L*-camphor esters **VIIIa–VIIId** or berry–fruit notes in *D,L*-camphor esters **VIIa–VIId**. It should be noted that the presence of sweetish notes in the scents of *D* enantiomers of esters **IXa–IXd** and their absence in the scentes of *L* enantiomers **VIIIa–VIIId** well correlate with the presence and absence of these notes in the odors of the starting oximes **VI** and **V**, respectively.

EXPERIMENTAL

The IR spectra were recorded on a Protege-460 IR Fourier spectrometer (Nicolet) in a thin film or in KBr, and the UV spectra, on a Specord UV-Vis spectrometer from 1×10^{-4} M solutions in methanol. The ^{1}H NMR spectra were measured on a Tesla BS-587A spectrometer (100 MHz) from 5% solutions in $CDCl_3$; the chemical shifts were determined relative to internal TMS. The specific rotation was measured with an SM-2 device (3.5% solutions in 96% ethanol). The molecular weights were determined cryoscopically in benzene.

As starting compounds we used 96% *D,L*-camphor (mp 175–177°C; $[\alpha]_D^{20} = 0°$, $c = 10$, EtOH) (**I**), 98% *D*(+)-camphor (mp 179–181°C; $[\alpha]_D^{20} = +44.1°$, $c = 10$, EtOH) (**II**), 99% *L*(–)-camphor (mp 178–180°C; $[\alpha]_D^{20} = -43.0°$, $c = 10$, EtOH) (**III**). *D,L*-, *D*(+)-, and *L*(–)-camphor oximes **IV–VI** (pure *E* isomers) were prepared by the reaction of *D,L*-, *D*(+)-, and *L*(–)-camphor **I–III** with a threefold excess of hydroxylamine in ethanol [6, 7].

Carboxylic acid chlorides were prepared by refluxing the corresponding carboxylic acids with a 1.5-fold excess of $SOCl_2$ in benzene. We used freshly distilled carboxylic acid chlorides and absolute hexane, benzene, and pyridine.

Camphor oxime alkanoates VIIa–VIId, VIIIa–VIIId, and IXa–IXd. A 0.01-mol portion of *D,L*-, *D*(+)-, or *L*(–)-camphor oxime was mixed with

0.01 mol of an appropriate acyl chloride. The mixture was hermetically sealed and allowed to stand for 24–48 h at 20–23°C with intermittent careful shaking. Then the mixture was dissolved in 50 ml of hexane, transferred into a separating funnel, thoroughly washed with water and 20% NaCl to suppress formation of an emulsion, and washed with two or three portions of 5% $NaHCO_3$. The organic layer was separated and filtered through a paper filter. The hexane was removed in a vacuum at a bath temperature not exceeding 30°C.

Camphor oxime carboxylates VIIe–VIIw. A solution of 0.01 mol of pyridine in 10 ml of benzene was added to a solution of 0.01 mol of *D*,*L*-camphor oxime **IV** and 0.01 mol of an appropriate alkanoyl or aroyl chloride in 50 ml of benzene; in the process, the mixture was agitated by shaking the reaction flask. The mixture was hermetically sealed and allowed to stand for 10–12 h at 20–23 h with intermittent careful shaking. Then the mixture was transferred into a separating funnel, thoroughly washed with water and 20% NaCl solution to suppress formation of an emulsion, and washed with two or three portions of 5% $NaHCO_3$. The organic layer was separated and filtered through a paper filter. Benzene was removed in a vacuum at a bath temperature not exceeding 30°C. Compounds **VIIm**, **VIIn**, **VIIq–VIIs**, and **VIIu–VIIw** were crystallized from hexane.

CONCLUSIONS

(1) A convenient procedure was developed for preparing *D*,*L*-, *D*(+), and *L*(–)-camphor oxime esters in 88–92% yields.

(2) Some of the compounds prepared can be of interest as components for fragrance industry and available fragrance compounds.

Abstract—The effect of electrolytes on the surface activity of aqueous anionic (1,1-dimethyl-1-alkylhydrazinium chloride homologues with the C_{10}–C_{18} alkyl radical) and nonionic (Neonol AF 9-12) surfactants in aqueous solutions was studied.

DOI: 10.1134/S1070427206120159

1,1-Dimethyl-1-alkylhydrazinium chloride homologues with C_{10}–C_{18} (DMAHCs) alkyl radicals belong to the quaternary hydrazinium salts (QHS). These compounds are efficient surfactants strongly decreasing the surface tension at the water-air interface [1]. Along with the surface activity, DMAHCs also exhibit other kinds of chemical and biochemical activity. For example, these compounds are antiseptics, corrosion inhibitors, and biocides [3, 4]. 1,1-Dimethyl-1-alkylhydrazinium chloride with the alkyl C_{12} and C_{14} radicals (commercial brand ChGS-1214) is applied as an effective collector in flotation of an insoluble residue of silicate and carbonate minerals in leaching of KCl from potassium-containing ores [5]. The consumption of ChGS-1214 in flotation of the insoluble mineral residue is two times less than that of commonly used collectors [6]; DGS-1214 is also less toxic. Owing to the higher selectivity in separation of the mineral residue, ChGS-1214 can be used without frothing [4]. However, to elucidate whether or not ChGS-1214 can be used for flotation of minerals from their suspensions in concentrated aqueous KCl, its surface activity in relation to ionic strength of aqueous solutions should be examined. Such data are lacking. In this study, we attempted to fill this gap.

EXPERIMENTAL

1,1-Dimethyl-1-alkylhydrazinium chloride homologues of the general formula $[R(CH_3)_2NNH_2]Cl$ (R = C_nH_{2n+1}, n = 10, 12, 14, 16, 18, and n = 12 + n = 14 mixture) were prepared by quaternization of 1,1-dimethylhydrazinium with primary chloroalkanes [7]. The main substance content determined by a modified method reported in [8] was no less than 96%. For comparison, nonionic surfactant Neonol AF 9-12 was also studied.

The surface tension at the interface between an aqueous DMAHC solution and air was determined stalagmometrically [9], and calculated by the formula

$$\sigma_x = (\sigma_0 m_x n_0)/(m_0 n_x), \quad (1)$$

where σ_x and σ_0 are the surface tensions of the solution tested and water, respectively (mN m^{-1}); m_x and m_0 are the weights of aqueous DMAHC and water that flowed out from the stalagmometer (g); n_x and n_0 are the number of drops of aqueous DMAHC and water that flowed out from the stalagmometer.

The surface tension of the model solutions containing KCl (1.34 M), NaCl (3.73 M), and varied DMAHC concentration was also measured stalagmometrically. The electrolyte content of these solutions was close to that in the saturated process solutions used to recover KCl by flotation [6].

The values of the surface tension at the water–air interface were taken from [10]. All the data reported hare were obtained by averaging the results of three

Effect of strong electrolytes on the solubility and CMC of solutions of cationic DMAHC {$[R(CH_3)_2NNH_2]Cl$} and neutral (AF 9-12) surfactants

or four replicate measurements. The experiments were carried out at 20°C.

We found that addition of a strong electrolyte (1.34 M KCl or 3.73 M NaCl) to an aqueous surfactant solution significantly decreases its surface tension at the interface between the aqueous electrolyte and air as compared to a surfactant solution without electrolytes. For aqueous DMAHC with R = C_{10} and C_{12} containing NaCl + KCl, σ_{min} was 25 and 23 mN m^{-1}, respectively, whereas in the absence of these electrolytes the surface tension was 35 mN m^{-1} [1] (see table).

Figure 1 shows that, in going from a solution of DMAHC in distilled water to an electrolyte-containing aqueous DMAHC solution, the slope of the initial portion of the surface tension isotherm significantly increases. We believe that one of the reasons for this effect is partial dehydration of the polar groups of the surface-active cations in the presence of the electrolyte, which salts-out the surfactant and decreases its solubility. For example, the solubility of DMAHC with R = C_{10} and C_{12} decreases in the presence of an electrolyte from 300 to 20 g l^{-1}. The other DMAHC homologues added to water even in minor amounts form a separate phase. Therefore, the surface tension isotherms of the salt solutions were not studied for these surfactants. The solubilities of DMAHCs in both distilled water and the model electrolyte solutions, and also the critical micelle concentrations (CMC) are listed in the table. The CMC values were calculated from the plot of the logarithm of the surface tension vs. the electrolyte concentration. In this plot, the CMC is manifested as a point at which the curved portion of the plot transforms into a straight line parallel to the abscissa axis [11].

We found that addition of a strong electrolyte to the aqueous surfactant decreases both CMC_1 and CMC_2. This means that, in the presence of a strong electrolyte, the micellization power of the surfactant increases. A similar pattern has been observed on adding a strong electrolyte to aqueous sodium dodecyl sulfate [12]. Serdyuk and Chervontseva [12] believe that this phenomenon is due to the fact that, in the course of micellization, the surfactant dissociation and the micell charge decrease, and micelles tend to aggregate and form supramicellar structures. As a result, the viscosity of the aqueous surfactant increases at surfactant concentrations exceeding CMC_2.

Neonol AF 9-12 and ChGS-1214 used as collectors in flotation treatment of potassium-containing ores

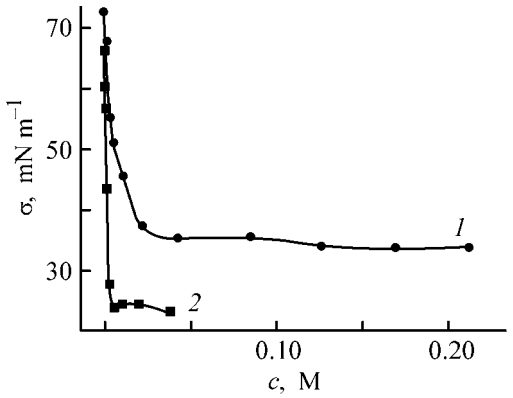

Fig. 1. Surface tension isotherms of solutions of DMAHCs (R = $C_{12}H_{25}$) in (*1*) distilled water and (*2*) model electrolyte solution. (σ) Surface tension and (*c*) electrolyte concentration.

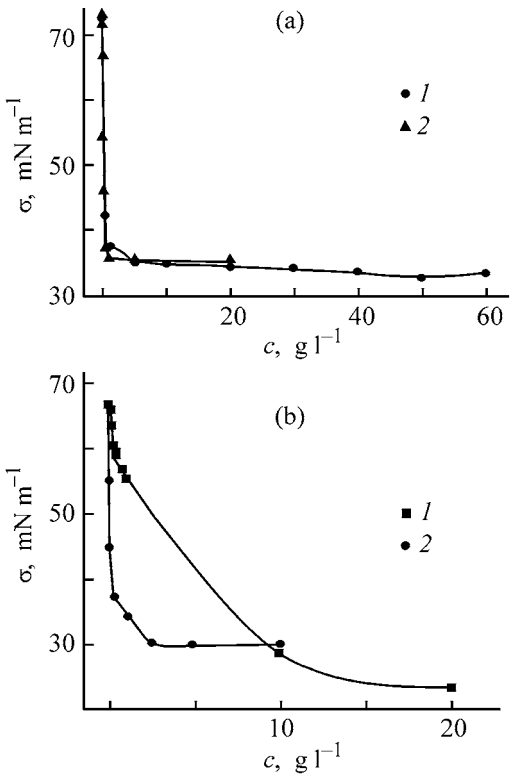

Fig. 2. Surface tension isotherms of (*1*) ChGS-1214 and (*2*) Neonol AF 9-12 in (a) distilled water and (b) model KCl + NaCl solution. (σ) Surface tension and (*c*) surfactant concentration.

exhibit virtually identical surface activities. Their surface tension isotherms in distilled water virtually coincide and σ_{min} is approximately 35 mN m^{-1} for both surfactants (Fig. 2a). On adding an electrolyte to both aqueous surfactants, the minimal surface tension decreases (Fig. 2b), but for Neonol AF 9-12 this effect is weaker (σ_{min} ~ 30 mN m^{-1}) than for ChGS-1214 (σ_{min} ~ 23 mN m^{-1}). The CMC values of both Neonol AF 9-12 and ChGS-1214 in the model electrolyte-containing solution and distilled water are virtually equal. These features are typical of this kind of surfactants.

If the surfactant counterion is identical to one of the ions of the electrolyte added, the effect of the counterion concentration c_i on CMC is determined by the equation [13]

$$\ln \mathrm{CMC} = \mathrm{const} - K_g \ln c_i, \qquad (2)$$

where K_g is a dimensionless constant. Its physical sense is explained below.

In association of ionic surfactant molecules into a micelle, they overcome the repulsion between similarly charged ions. When long-chain micelle-forming ions is accomodated on the micelle surface, the integral work against the electrostatic repulsion is $e\varphi_0$. However, in the presence of counterion, the electric charge of the micelle-forming ion becomes smaller than elementary charge. Therefore, the effective electrostatic work of association of a long-chain micelle-forming molecule with a micelle is $K_g\varphi_0 e$, where $K_g < 1$. Thus, K_g characterizes the effect of a counterion on the electrostatic energy of micelle formation [13].

The addition of electrolyte suppresses the factors hindering the micelle formation. This effect is manifested as a decrease in CMC_1 and CMC_2 for both the individual surfactants and their mixtures (see table).

In aqueous solutions of neutral nonionic surfactants, the micelle formation occurs without electrostatic interactions. Therefore, introduction of electrolytes weakly influences the CMC of Neonol AF 9-12.

Figure 2b shows that, at surfactant concentration exceeding 10 g l^{-1}, ChGS-1214 is a stronger surfactant than Neonol AF 9-12. This is manifested as a higher surface tension and lower CMC.

CONCLUSIONS

(1) On adding electrolytes to aqueous solutions containing 1,1-dimethyl-1-alkyl hydrazinium chloride homologues, their minimal surface tension decreases by a factor of two as compared to the initial aqueous solutions; the solubility of the surfactant and the critical micellization concentration sharply decrease due to a decrease in the degree of surfactant dissociation. At the same time, the electrolytes virtually do not affect the related characteristics of Neonol AF 9-12 nonionic surfactant.

(2) In the series of 1,1-dimethyl-1-alkyl hydrazinium chloride homologues, ChGS-1214 exhibits higher surface activity in concentrated aqueous NaCl + KCl than the nonionic surfactant Neonol AF 9-12.

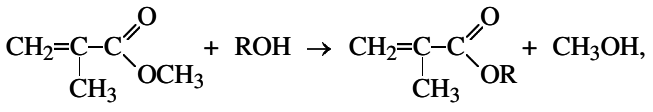
Abstract—Optimal conditions were found for preparing higher alkyl methacrylates by ester interchange of methyl methacrylate with fractions of higher alcohols.

DOI: 10.1134/S1070427206120160

Higher esters of unsaturated carboxylic acids find wide application [1, 2]. The particular interest in these monomers is due to their easy conversion into macromolecular compounds used as viscosity and depression additives to mineral oils and fuels [3–6], components of adhesive formulations [7], agents for treating textile and paper [8], plasticizers [8], lubricants [9], and components of paint-and-varnish coatings [10].



It is well known that synthesis of higher alkyl methacrylates by esterification of methacrylic acid in the presence of acid catalysts [11] is accompanied by substantial tarring of both the starting reagents and the reaction products, which requires additional expenses for purification and isolation of the target products. Furthermore, washing of higher alkyl methacrylates with alkaline solutions in the course of their isolation results in that stable, difficultly settling emulsions are formed, which results in major loss of the desired esters and yields a large amount of concentrated wastewater.

To eliminate the problems that arise in the synthesis and isolation of higher alkyl methacrylates by esterification, it seems appropriate to examine the possibility of preparing these compounds by ester interchange of methyl methacrylate with higher aliphatic alcohols in the presence of base catalysts, allowing the reaction to be performed virtually without formation of tar and by-products.

This paper deals with the preparation of higher alkyl methacrylates by ester interchange, choice of effective catalytic systems, and optimization of the reactant ratio with the aim to obtain high-purity products in high yields.

EXPERIMENTAL

Methyl methacrylate (MMA) met GOST (State Standard) 20370–74, and fractions of synthetic fatty alcohols, TU (Technical Specifications) 38.107119–85. As catalysts we tested potassium carbonate (GOST 4421–76, pure grade), sodium carbonate (GOST 83–79, pure grade), dibutyltin dicaprylate (TU 6-09-1150–76), sodium methylate (prepared in the laboratory), sodium borohydride (TU 1-92-162–90), and sodium phosphate (GOST 9337–79). The inhibiting system consisted of *p*-methoxyphenol (*p*-MOP) (TU 6-09-1248–78) and Ionol (TU 3810 1459–75). The ester interchange follows the scheme

I–IV **V–VIII**

where R = C_8H_{17}–$C_{10}H_{21}$ (**I**, **V**), $C_{12}H_{25}$–$C_{14}H_{29}$ (**II**, **VI**), $C_{12}H_{25}$–$C_{18}H_{37}$ (**III**, **VII**), and $C_{16}H_{33}$–$C_{20}H_{41}$ (**IV**, **VIII**).

A chromatographic analysis was performed with a Tsvet-500 chromatograph equipped with a flame-ionization detector and a 2-m packed glass column; stationary phase polyethylene glycol adipate, column temperature 150±5°C, vaporizer temperature 290°C, carrier gas N_2, flow rate 30 ml min^{-1}.

The IR spectra were recorded on a Specord M80 spectrophotometer in the range 4000–400 cm^{-1} from thin films of the substances pressed between KBr plates.

The ester interchange of MMA with alcohols **I**–**IV** was performed in a four-necked vessel equipped with a power-driven stirrer thermometer, bubbler for feeding dry air, and heated distillation column with a total condenser and a receiver for taking off the MMA–methanol azeotrope formed in the course of the synthesis.

The reaction mixture was heated to 110°C and kept for 1 h, after which the mixture was brought to boiling (120°C), the distillation column heater was switched on, and the MMA–methanol azeotrope distilling at 65–78°C was taken off. After the distillation of the azeotrope ceased, the reaction was stopped, the vessel was cooled, the catalyst was separated, and the excess MMA was removed.

The conversion of the starting alcohol was evaluated by gas–liquid chromatography and acetylation [12].

To choose an effective catalytic system for ester interchange of MMA with fractions of synthetic higher alcohols **I**–**IV**, we tested a series of ester interchange catalysts differing in catalytic activity [8, 13] and reactivity toward the starting compounds.

To avoid undesirable polymerization in the course of the synthesis and isolation of the desired product, we added a system of inhibitors *p*-MOP + Ionol (0.1 and 0.03 wt % relative to the sum of the reactants, respectively) and performed the reaction with continuous air bubbling through the reaction mixture.

We found (Fig. 1a) that sodium methylate and sodium borohydride are effective catalytic systems and provide the highest yield of alkyl methacrylate **V** (96% in 8 h). However, use of these catalysts requires thorough drying of MMA, and it is difficult to separate the suspended catalyst from the reaction mixture. To remove trace amounts of the catalyst completely, twofold washing with water followed by drying is required. A similar pattern (necessary washing with water) is observed with dibutyltin dicaprylate, although the yield (96%) and the rate of formation of alkyl methacrylate with this catalyst are also acceptable.

Of particular interest in this context are heterogeneous base catalysts which are insoluble in the reaction mixture and can be readily separated after the reaction completion. Among the three catalysts meeting these requirements, potassium carbonate appeared to be the most active: Alcohol **I** was completely exhausted in 15 h, and the ester yield was 97%. The desired product was readily separated from potassium carbonate by filtration. One more advantage of potassium carbonate over sodium phosphate and sodium carbonate was that it did not appreciably lose its activity in repeated runs (Fig. 1b), whereas the other two catalysts, when reused, did not provide the required conversion. Potassium carbonate was reused without additional washing or heat treatment.

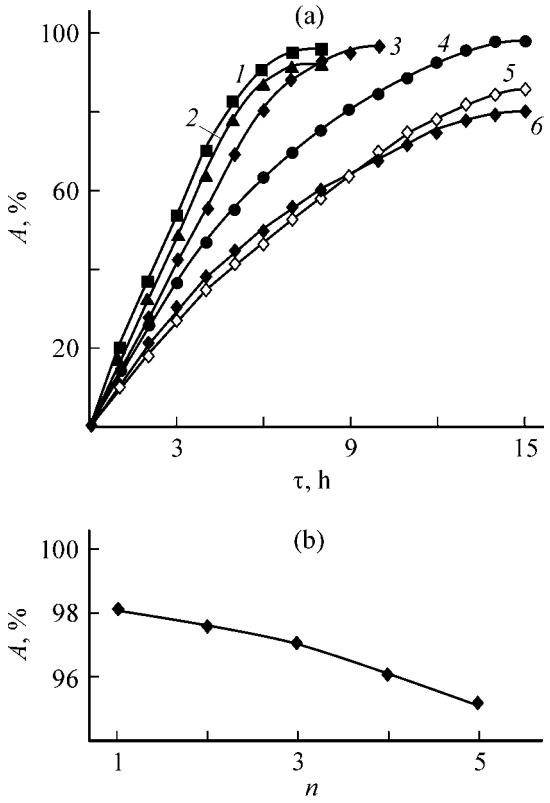


Fig. 1. Yield of alkyl methacrylate **V** *A* (a) vs. time τ with various catalysts and (b) vs. the number *n* of runs performed with potassium carbonate. Molar ratio MMA : alcohol **I** = 2 : 1, catalyst concentration 1%. (a) Catalyst: (*1*) sodium methylate, (*2*) sodium borohydride, (*3*) dibutyltin dicaprylate, (*4*) potassium carbonate, (*5*) sodium carbonate, and (*6*) sodium phosphate.

In ester interchange of MMA with longer-chain fractions of alcohols **II**–**IV**, the catalytic activity of potassium carbonate is of particular importance, because specifically in this case there are problems with separation of the desired esters from the high-boiling starting alcohols.

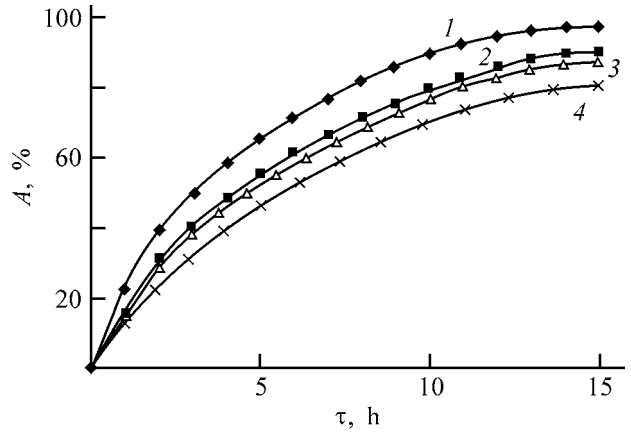

Fig. 2. Yield *A* of alkyl methacrylates **V**–**VIII** vs. time τ. Ratio MMA : alcohol **I**–**IV** = 2 : 1, catalyst (potassium carbonate) concentration 1%. Monomer: (*1*) **V**, (*2*) **VI**, (*3*) **VII**, and (*4*) **VIII**.

Experiments on the ester interchange of MMA with alcohols of fractions **II**–**IV** showed (Fig. 2) that, at the initial molar ratio MMA : alcohol = 2 : 1, and presence of 1% catalyst, the reaction decelerated with an increase in the length of alkyl chains in alcohols, and the yield of monomer **VIII** was as low as 80% (cf. 97% for **V**).

To raise the conversion of long-chain alcohols **II**–**IV**, we performed the ester interchange in the presence of 3 and 5% potassium carbonate; however, increased amounts of the catalyst did not provide increased yield of the long-chain alkyl methacrylates.

To attain the maximal exhaustion of higher alcohols, we studied how the yield of esters **VI**–**VIII** is influenced by the ratio of the starting components, MMA : alcohol (Table 1).

We found that, at the component ratio increased to 3 : 1 and 5 : 1, long-chain alkyl methacrylates **VI**–**VIII** can be prepared in acceptable yields, 91–95%.

It should be noted that, after the completion of ester interchange, excess MMA was removed at 50°C and a pressure of 30 mm Hg. The distilled MMA was reused in the synthesis of alkyl methacrylates, which ensured a virtually quantitative exhaustion of MMA.

The refining of the synthesized alkyl methacrylates to remove unchanged alcohols or traces of MMA was performed on a rotary-film evaporator at a jacket temperature of 135–150°C and residual pressure of 20 mm Hg. The properties of the higher alkyl methacrylates obtained are listed in Table 2.

Monomers **V**–**VII** are weakly colored or colorless transparent liquids with a characteristic ester odor. Alkyl methacrylate **VIII** is a wide solid waxy substance without odor.

The structures of the higher alkyl methacrylates synthesized were confirmed by the IR spectra. The spectra are similar and are characterized by the following absorption bands (cm^{-1}): ~1726 (C=O); 1150–

Table 1. Yield of alkyl methacrylates **VI**–**VIII** at various MMA : alcohol ratios (synthesis time 15 h)

Ester	Starting substance, mol		Ester yield, %	Ester	Starting substance, mol		Ester yield, %	Ester	Starting substance, mol		Ester yield, %

Table 2. Properties of alkyl methacrylates obtained

Ester	Monomer	Main substance content, %	Kinematic viscosity at 20°C, cSt	d_4^{20}	n_D^{20}
V	Alkyl(C_8H_{17}–$C_{10}H_{21}$) methacrylate	98.3	4.7	0.8783	1.4410
VI	Alkyl($C_{12}H_{25}$–$C_{14}H_{29}$) methacrylate	98.0	5.1	0.8771	1.4458
VII	Alkyl($C_{12}H_{25}$–$C_{18}H_{37}$) methacrylate	97.4	6.5	0.8796	1.4475
VIII	Alkyl($C_{16}H_{33}$–$C_{20}H_{41}$) methacrylate	95.0	Melting point 32°C		

1350 (C–O in the C–O–C fragment of methacrylates); ~1644 (C=C); 724 [rocking vibrations of $(CH_2)_n$ fragments, where $n \geq 4$].

The higher alkyl methacrylates **V**–**VIII** synthesized were used in free-radical polymerization without additional purification.

CONCLUSION

A procedure was developed for preparing higher alkyl methacrylates by ester interchange of methyl methacrylate with fractions of higher fatty alcohols in the presence of a catalyst, potassium carbonate. The ester interchange rate decreases with an increase in the length of the alkyl radical.

Abstract—Chromatographic behavior and separation conditions of pyrimidine derivatives were studied by high-performance liquid chromatography using a reversed-phase column and a multiwave UV detector.

DOI: 10.1134/S1070427206120172

Pyrimidine derivatives are of both scientific and practical interest. Functionalized pyrimidines exhibit chelating, photochromic, and biologically active properties. These compounds are used in preparation of heat-resistant polymers. They are contained in many biologically significant compounds and in antitumor and antiviral drugs [1].

Reversed-phase high-performance liquid chromatography (RF HPLC) is widely used for analysis of pyrimidines and their derivatives. Since these compounds are weak organic bases, they are analyzed and separated on alkyl silica gel columns, using organic buffer solutions as eluents [2, 3].

Most of published studies concern development of the sorbents and mobile phases for analysis of specific pyrimidine derivatives used in medicine, biology, and food industry [4–10].

In this study, to develop a procedure for identifying pyrimidine derivatives with different substituents in positions **2**, **4**, and **6**, we examined chromatographic separation of these compounds by RFHPLC with a multiwave UV detector.

EXPERIMNETAL

We studied the following compounds: 2,4-bis(*p*-aminophenyl)pyrimidine, 2-amino-4-(*p*-nitrophenyl)py-

Table 1. Parameters* of chromatographic separation of pyrimidine derivatives

Compound no.	Pyrimidine	*N*, TP	*t*, min (±0.003)	*k*', (± 0.001)	α, (± 0.001)	R_s

rimidine, 2-trichloromethyl-4,6-dimethylpyrimidine, 2,4-bis(*p*-aminophenyl)-6-phenylpyrimidine, 2-methyl-4-phenylpyrimido[4,5-β]indole, and 2,4-bis-(*p*-bromophenyl)pyrimidine. The structures of these compounds are listed in Table 1. Compounds **1**, **4**, and **6** (Table 1) were used as monomers for preparing high-strength heat-resistant polymers [11–13]. Derivatives of pyrido[4,5]indole (Table 1, compound **5**) exhibit various kinds of biological activity [14, 15].

The pyrimidine derivatives were separated on a Milikhrom A-02 chromatograph (EkaNova Institute of Chromatography, Novosibirsk) equipped with a multiwave UV detector and a 2 × 75-mm steel column packed with Prontosil 120-5-C18 AQ reversed-phase sorbent (Bischoff Chromatography, Germany).

The elution was performed in the gradient mode by changing the acetonitrile or methanol content from 30 to 100% within 7 and 8 min and in the isocratic mode using 100% organic solvent. The eluent flow rate v was 100 μl min^{-1}; sample volume V = 4.0 μl; pyrimidine concentration 1 mg ml^{-1}; column temperature T = 35°C; maximal pressure 5.0 MPa; λ = 210 nm.

The results of a chromatographic separation of a mixture of six pyrimidines using different elution systems (Table 3) including published systems are presented in Table 2. The mixture was successfully separated using a half of the solvent systems examined

Table 4. Spectral ratios

Pyrimidine derivative no.	Ratio of absorption of pyrimidine derivative at indicated wavelength to absorption at 210 nm					
	240	250	270	300	320	330
1	0.469 ± 0.002	0.199 ± 0.001	0.364 ± 0.001	1.306 ± 0.003	1.641 ± 0.005	1.621 ± 0.005
2	0.485 ± 0.001	0.552 ± 0.002	0.698 ± 0.001	0.464 ± 0.002	0.424 ± 0.004	0.435 ± 0.002
3	0.524 ± 0.002	0.516 ± 0.002	0.054 ± 0.002	0.004 ± 0.001	0.004 ± 0.001	0.003 ± 0.002
4	0.615 ± 0.003	0.586 ± 0.003	0.604 ± 0.006	1.021 ± 0.010	1.224 ± 0.010	1.134 ± 0.009
5	0.605 ± 0.001	0.746 ± 0.017	0.428 ± 0.008	0.333 ± 0.004	0.236 ± 0.002	0.146 ± 0.001
6	0.334 ± 0.004	0.647 ± 0.017	1.438 ± 0.046	0.428 ± 0.010	0.074 ± 0.003	0.014 ± 0.004

Table 5. Detection limit of pyrimidines (sample volume, 5 μl)

Pyrimidine derivative no.	λ_{max}, nm	Detection limit, μg	Pyrimidine derivative no.	λ_{max}, nm	Detection limit, μg
1	210	0.010	**4**	210	0.020
2	210	0.016	**5**	250	0.010
3	210	0.020	**6**	270	0.030

(B, E, F, I, K, and N). With the other systems, the separation was incomplete within the optimal period of time. To separate a mixture of pyrimidine derivatives with the multiwave detection and the gradient elution mode, we used an efficient and simple gradient elution system N (methanol–water), which has not been applied previously to pyrimidine derivatives.

Pyrimidines were detected at 210, 240, 250, 270, 300, 320, and 330 nm. Multiwave detection of the chromatograms allows calculation of the so-called "spectral ratios," i.e., ratios of the optical density at a wavelength examined to that at a reference wavelength (210 nm in our case). This parameter is independent of the sample concentration, is well reproducible, and allows identification of compounds in mixtures without references (Table 4). The UV spectra of the components recorded in a wide spectrum range at stopped eluent flow (Fig. 1) can also be used to identify these compounds in mixtures in the absence of references.

The chromatographic parameters are more conveniently calculated using the chromatogram plotted as total absorption of the component at all the wavelengths examined vs. time (Fig. 2). To optimize

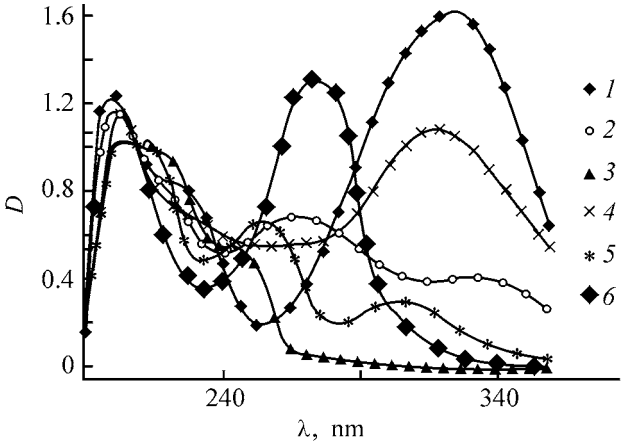

Fig. 1. UV spectra of substituted pyrimidines. (*D*) Optical density and (λ) wavelength. *Numbers at the curves* correspond to the pyrimidine derivative numbers in Table 1; the same for Fig. 2.

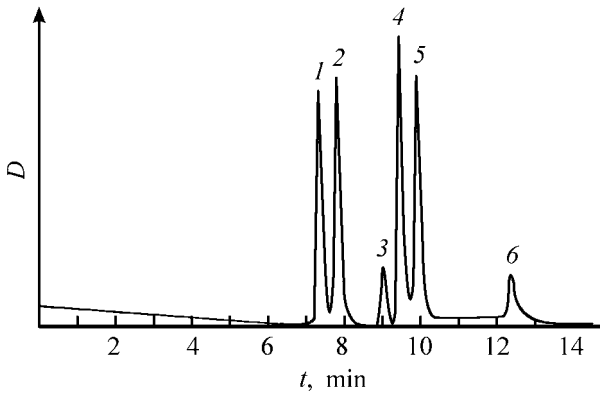

Fig. 2. Chromatrogram of a pyrimidine mixture (system N). Gradient of methanol in water is 30–100% in 7 min; isocratic conditions: 100 % methanol for 8 min; sample volume 4 μl; temperature 35°C (*D*) Total optical density of the component at all wavelengths and (*t*) time.

the separation conditions, we calculated the reduced capacity factor k', and the selectivity of separation α and resolution R_s of the adjacent peaks of the components (Table 1).

We determined the minimal detectable concentrations of the pyrimidines (Table 5). The detection limit of the pyrimidines at the indicated wavelength under the optimal conditions is 0.01–0.03 mg ml^{-1}.

CONCLUSIONS

(1) The chromatographic parameters [reduced capacity factor (k'), selectivity of separation (α), and resolution R_s of adjacent peaks of the components] of the pyrimidine derivatives were determined.

(2) The detection limits of the components at 210, 250, and 270 nm are 0.01–0.03 mg ml^{-1}.

ACKNOWLEDGMENTS

The authors are grateful to V.P. Borovikov for placing the pyrimidine derivatives at our disposal.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Inverse Gas Chromatographic Study of Supramolecular Organization in Microheterogeneous Systems for the Example of Polyblock Copolymers

A. V. Kalinin and A. P. Voznyakovskii

Abstract—The potentialities of inverse gas chromatography for studying microheterogeneous polymer systems are analyzed. For the first time this method is applied to examination of the microstructure of multiblock copolymers obtained by condensation. A procedure for evaluation of the partial contribution of the dissolution to the total retention volume is suggested.

DOI: 10.1134/S1070427206120184

The steadily increasing environmental pollution hazard and the necessity for green technologies stimulate polymeric materials science to develop new generations of materials with considerably enhanced performance characteristics. The limited spectrum of available monomers and the low possibility of emergence of novel ones make it clear that new generations of polymeric materials are to be based on development of new 3*D* structures and composites. By a polymeric composite material is meant that consisting of at least two phases with a distinctly pronounced interface. In fact, a composite material is a polymeric matrix with incorporated particles of inorganic or organic filler. The occurrence of a filler in the bulk of a polymer results in the formation of interfacial layers, making the supramolecular structure remarkably more complex. In turn, the supramolecular structure of polymeric materials controls to considerable extent their physicochemical and mechanical properties.

The development of novel materials requires relatively simple methods for characterization of a small amount of a material with respect to its supramolecular organization.

In recent decades, the X-ray diffraction, dielectric, mass spectrometric, and, in particular, sorption methods used for characterization of the polymer structure have been considerably improved. Among the advantages of the sorption method are sufficiently high informativeness and the simplicity of the hardware implementation. At the same time, the establishment of an equilibrium in most of polymer–solvent systems takes a long time. In this respect, the dynamic version of the sorption method, i.e., inverse gas chromatography (IGC) is rather convenient and also allows examination of fine aspects of the supramolecular organization in polymers.

The use of IGC for characterization of homopolymers is well known and does not present any significant problems. In studying di- and triblock polymers, the contribution of the dissolution can be roughly estimated from data on the sorption characteristics of the homopolymer constituting the flexible block of the macromolecule. However, in microheterogeneous systems, the resultant sorption is a superposition of partial contributions of various (generally different) mechanisms of sorption of the molecular sample on each of the existing phases, interfacial layers, and on the dispersion medium [1]. In this case, it should be taken into account that the covalent bonds between the blocks prevent complete phase separation, so that the dispersion medium does not fully correspond to the individual phase of the flexible block.

Brown and Guillet have demonstrated [2] for a polymer of complex structure that the total retained volume can be correctly estimated using additive equation (1):

$$V_g = V_{g1} + V_{g2} + \ldots + V_{gn}, \quad (1)$$

where V_{g1}, V_{g2}, …, V_{gn} are the retention volumes of each of the phases of the polymer.

The simplest case is the presence of two phases in the bulk of the polymer. If both phases are in the viscoelastic state, the retention mechanism in each of them will involve the dissolution of the mobile phase in the polymer mass. If one of the phases occurs below its glass transition or crystallization temperature, the corresponding retention mechanism is associated with surface sorption. Then, for a block copolymer of the AB or ABA type, consisting of two phases, one of these (A) is in the viscoelastic state, and the other (B), in the glassy or crystalline state, the retention volume can be written as:

$$V_g = k_{S(A)}\omega_A + k_{D(B)}A_B, \quad (2)$$

where $k_{S(A)}$ is the volume sorption coefficient of phase A; ω_A, weight of phase A; $k_{D(B)}$, surface adsorption coefficient of phase B; and A_B, surface area of the domains formed by phase B.

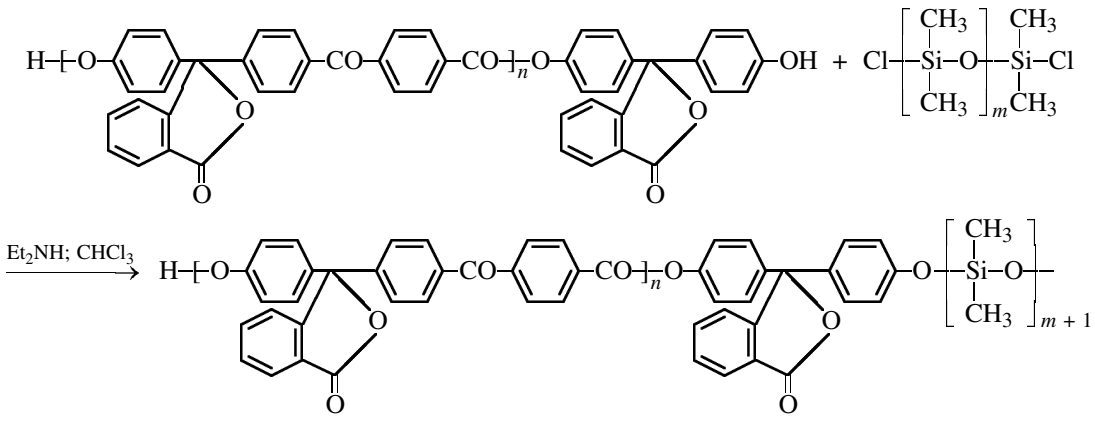
It follows from Eq. (2) that the adsorption retention volume is influenced not by the weight fraction of the dispersed phase, but only by the surface area of its particles. Therefore, if a blend of homopolymers A and B were used instead of the block copolymer with the same A/B ratio, the second term whould become negligible, since the dispersed particles are too large in size [3]. Brown and Guillet have demonstrated [2] that, for polymers in which both the above-mentioned retention mechanisms act simultaneously, the concepts of the volume and adsorption retention volumes can be introduced:

$$\ln V_{gA} = \ln \omega_A + \ln k_{S(A),0} - (\Delta H_{solv}/RT), \quad (3)$$

$$\ln V_{gB} = \ln A_B + \ln k_{D(B),0} - (\Delta H_{ads}/RT), \quad (4)$$

where ΔH_{solv} and ΔH_{ads} are the enthalpies of solvation and adsorption, respectively.

It has been demonstrated [2, 4] that the simultaneous action of two retention mechanisms in a polymer is reflected in that the retention diagram is no longer linear, which makes it impossible to calculate the thermodynamic parameters of the sorption in terms of the commonly accepted model. For the first time this phenomenon was described for homopolymers over an extremely narrow temperature range (3–5°C) corresponding to glass transition or crystallization [2]. In the subsequent years, it was reported that this phenomenon is widely spread among di- and triblock copolymers [5–7]. A similar effect on the shape of the retention curve has also been observed when the aggregates of an inorganic filler were sufficiently small ($<5 \times 10^{-6}$ m) [8–11].



Schlick and Levy [12] were the first who demonstrated that properties of copolymers can be strongly affected not only by the chemical structure of the blocks, but also by their size and number in the macromolecule [this was shown for the example of isoprene/styrene copolymers of fixes molecular weight, but with different numbers of blocks (from two to nine) and, accordingly, with their different lengths]. From the modern standpoint, this phenomenon can be attributed to a decrease in the size of the rigid block nanodomains and also to the fact that the supramolecular structure of the polymer becomes more complex on passing from diblock to polyblock copolymers. It follows from Eqs. (2)–(4) that a change of the macrochain structure in this direction should generally result in a more intricate shape of the retention curve (as superposition of several linear functions). However, we have found no published IGC studies of the supramolecular structure of polyblock copolymers.

Therefore, we examined in this study the potentialities of IGC for studying the supramolecular structure of polymers on the basis of such parameters of sorption of low-molecular-weight substances as the excess partial molar enthalpy and entropy.

To determine the thermodynamic parameters of sorption, it is necessary to estimate separately the contribution from dissolution of the sorbate in the dispersion medium. It has been demonstrated previously [13] that, for polymers of a complex supramolecular structure, the contribution of absorption of low-molecular-weight substances by the polymers increases with temperature, while the contribution of adsorption tends to zero. Therefore, it may be suggested that, at high temperatures, the adsorption term is negligible, and the tangent to the retention curve is, in fact, the plot of $\ln V_{gA}$ vs. $1/T$. Then, using the iteration procedure described in [14, 15], we can accurately estimate the partial contributions of dissolution and adsorption to the total retention.

EXPERIMENTAL

In the experiments, we used poly(dimethylsiloxane) (PDMS) as a reference sample and three specially synthesized samples of copolymers of PDMS and poly(phenolphthalein terephthalate) (PPT) with rigid to flexible block ratios of 1 : 4.5 (sample no. 1), 1 : 10.5 (sample no. 2), and 1 : 21.5 (sample no. 3). Block copolymers of PPT and PDMS were synthesized by condensation of oligomeric phenolphthalein terephthalate with bis(ethylamine)-substituted siloxane oligomers:

Generally, we used the procedure described in [16], which was slightly modified with allowance for available chemicals.

The molecular weight of all the three samples was determined by gel filtration chromatography to be about 150000, and that of the PDMS sample, at least 200000.

The chromatographic experiments were carried out on the installation designed on the basis of an LKhM-8MD chromatograph (Fig. 1). The carrier gas (He),

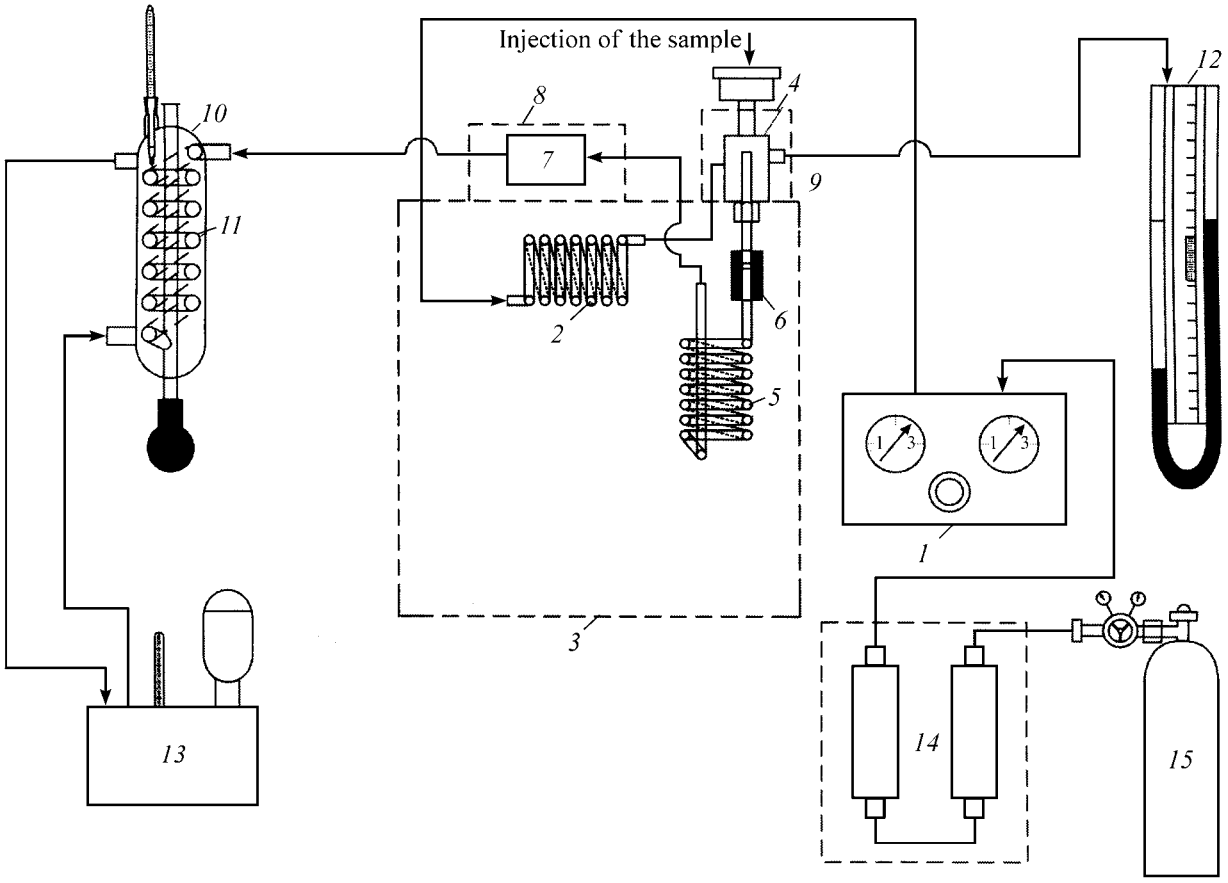


Fig. 1. Schematic of the experimental setup: (*1*) gas preparation unit, (*2*) heat exchanger, (*3*) chromatographic oven, (*4*) sample injection block, (*5*) chromatographic column, (*6*) connector, (*7*) thermal conductivity detector, (*8*) detector oven, (*9*) injection block oven, (*10*) foam flow meter, (*11*) heat exchanger of the foam flow meter, (*12*) mercury gage, (*13*) liquid thermostat, (*14*) gas dewatering unit, and (*15*) high-pressure cylinder with the carrier gas.

purified by passing through a set of NaX zeolite filters, was fed into the gas preparation unit (*1*), which allowed control over the carrier gas flow to within 0.5%. This unit was a PPR-1 unit from the set of components for a Tsvet-100 chromatograph. Then the carrier gas was heated to the working temperature of the column, using the spiral copper heat exchanger *2* arranged inside the chromatographic oven *3*, and was fed into the sample injection block *4*, to heat it to the working temperature. In the experiments, we used spiral glass columns 1.5 m long with an inner diameter of 4 mm (diameter of the spiral was 65 mm). The oven was temperature-controlled to within 0.05% using a Pt resistance sensor mounted directly in the column zone.

The gas flow rate at the column outlet was measured with a temperature-controlled foam flow meter. Before measurement, the carrier gas was heated to the standard temperature of 30°C in the spiral heat exchanger mounted in the same temperature-controlled space. The pressure of the carrier gas at the column inlet was measured by a mercury gage to within 0.5 mm Hg. The samples (vapor mixtures with air, collected from over the surface of the corresponding liquid) were injected into the column using a microsyringe.

Aa a support for the stationary phase served Chromaton N-AW-DMCS with a particle size of 0.315–0.400 mm. The support was dried to remove water adsorbed on the particle surface by heating to 300°C at 1–2 mm Hg in a long-necked round-bottom flask connected to a vacuum pump through a trap placed in a Dewar bottle with liquid nitrogen. The process was stopped when the ice formation ceased.

Double-reprecipitated polymer, pretreated to remove volatiles, was applied onto the solid support. A packing for the columns was prepared by removal of the solvent from a coarse suspension of the solid support in the polymer solution with continuous gentle stirring.

The specific retention volumes were estimated by Eq. (5) [17]:

$$V_g^0 = (t_R F/g) J_3^2 (P_{input}/P_{output}), \quad (5)$$

where t_R is the corrected retention time $t_R = t - t_0$; t, retention time corresponding to the peak maximum; t_0, dead point; and F, flow rate;

$$F = \{[F_T(P_f - P_W)]/P_0\}(273.2/T_f), \quad (6)$$

where F_t is the flow rate at the flow-meter temperature T_f; P_f, pressure in the flow meter; P_W, saturated vapor pressure of water at the flow-meter temperature; P_0, atmospheric pressure; g, amount of the polymer in the column; and J_3^2, carrier gas compressibility factor:

$$J_3^2 = (3/2)\{[(P_{input}/P_{output})^2 - 1] \times [(P_{input}/P_{output})^3 - 1]\}, \quad (7)$$

where P_{input} and P_{output} are the carrier-gas pressure at the column inlet and outlet, respectively.

The t_R value necessary to calculate V_g^0 by Eq. (5) was calculated as the average of 5–6 replicate measurements. The error of determination of V_g^0, determined by the standard procedure [11], was within 1%.

To analyze data obtained for the investigated set of polymers, it is necessary to have a possibility to calculate V_g^0 at fixed temperatures (it is convenient to select temperatures divisible by 10°C). This task can be solved most reliably by deriving an equation for V_g^0 as a function of temperature. For this purpose, we performed statistical processing of the V_g^0 dataset obtained over the range 20–120°C. An approximating equation was selected taking into account that, in general case, the retention curve is fitted by Eq. (8):

$$\partial \ln V_g^0/\partial\, 1/T = -\Delta H_{cond}/R - \Delta \bar{H}_1^{E\infty}/R + [\partial \ln f_1^{\infty}/\partial\, 1/T)], \quad (8)$$

where ΔH_{cond} is the standard enthalpy of condensation of a mole of the pure sorbate from the state of ideal gas into the liquid state at the temperature T; $\Delta H_1^{E\infty}$, excess enthalpy of mixing in the sorbate–polymer system; and f_1^{∞}, fugacity coefficient of the sorbate at infinite dilution in the carrier gas.

Taking into account that all the three terms on the right-hand side of Eq. (8) are temperature-dependent, the retention curve plotted in the coordinates $\ln V_g^0$–$1/T$ will be strictly linear (particularly, over a wide temperature range) only in the case of mutual compensation of the temperature dependences of these terms [18]. It is clear that, generally, the retention diagrams can deviate from linearity to a greater or lesser extent. Therefore, as a fitting equation we used the relation we suggested in [19]:

$$\ln V_g^0 = A \ln T + B \ln T + C(1/T) + D. \quad (9)$$

This equation allows minimization of the approximation error in calculating V_g^0. The dataset obtained for each sorbate included 30–35 points, which, taking into account the number of replicate runs for each

point, gives at least 150 degrees of freedom, allowing reduction of the error of determination of V_g^0 to below 0.5%.

Based on Eq. (5), we can writte the expression for the relative error of V_g^0 as

$$\Delta V_g^0/V_g^0 = \Delta t/t + \Delta F/F + f(P)\Delta P/P + \Delta g/g. \quad (10)$$

Since the column temperature can be measured to within 0.1°C, and the flow rate, to within 0.5°C, the total error of the first three terms in Eq. (11) does not exceed 1%. The main contribution to the error of determination of V_g^0 is provided by the uncertainty of determination of the amount of the polymer in the column [9]. In this study we used an ADV-200 analytical balance (weighing error ±1 mg). Since the weight of the solid support in the column ranged from 2 to 10 g, and the weight of the supported polymer was 5–15% relative to the support, the error of determination can be accepted to be below 1%.

The corrected retention time was determined from t_0 and t, which were measured using a modified ITs-26 integrator to within 0.05 cm.

A weighed portion of the packing was triply washed with large volumes of the solvent, placed in a muffle, and heated at 800°C for several hours. The amount of the polymer removed was estimated taking into account the weight loss in calcination by the initial inert support, and then was recalculated to 1 g of packing.

For the investigated polyblock copolymers of PPT and PDMS, we examined the factors influencing the retention volume: gas flow rate, thickness of the polymeric film, and sample weight. It was demonstrated that, on changing the flow rate from 15 to 90 ml min^{-1} and the amount of the polymer in the column from 5 to 15 wt % relative to the weight of the solid support, the retention volume remained unchanged to within the experimental error, suggesting that the equilibrium chromatography condition was met in our experiments and also that the contribution of adsorption at the gas–polymer and polymer–support interfaces can be neglected.

To characterize the activity coefficients of polymers, the mass activity coefficient $\Omega_1^\infty = a_1/w_1$ is used [20]. We estimated Ω_1^∞ as

$$\ln \Omega_1^\infty = \frac{273.15R}{V_g^0 P_1 M_1} - \frac{P_1^0}{RT}(B_{11} - V_1), \quad (11)$$

where V_g^0 is the specific retention volume of the sorbate; P_1, V_1, and M_1 are the saturated vapor pressure, molar volume, and molecular weight of the sorbate, respectively; B_{11} is the second virial coefficient of the sorbate; and R, gas constant.

The excess thermodynamic functions related to Ω_1^∞ by the well-known expression:

$$\Delta\bar{H}_1^{E\infty} = RT^2\partial(\ln\Omega_1^\infty)/\partial(T), \quad (12)$$

$$\Delta\bar{S}_1^{E\infty} = (R/T)\,\partial(\ln\Omega_1^\infty)/\partial(T) - R\ln\Omega_1^\infty, \quad (13)$$

where $\Delta\bar{H}_1^{E\infty}$ and $\Delta\bar{S}_1^{E\infty}$ are excess partial molar enthalpy and entropy, respectively.

The enthalpy of solution of a low-molecular-weight substance in a polymer can be estimated from the temperature dependence of the retention volume:

$$-\Delta H_s/RT^2 = \partial(\ln V_g^0)/\partial T. \quad (14)$$

We believe that the choice of the approximating equations for calculation of thermodynamic functions of mixing (12) and (13) requires some comments. In estimating $\Delta\bar{H}_1^{E\infty}$, its independence from temperature is generally assumed ($\Delta C_{s\,1}^{E\infty} = 0$). In this case, $\Delta\bar{H}_1^{E\infty}$ is determined from the slope of the linear dependence $\ln\Omega_1^\infty$–$1/T$. Note that, in this case, the temperature interval should not exceed 30–50°C [21]. In most cases, the least-squares method provides a high accuracy in calculating the slope. However, it should be taken into account that, in the system polymer–"good" solvent, the slope of the dependence $\ln\Omega_1^\infty$–$1/T$ frequently only slightly differs from zero, which can lead to a considerable (100% and more) error in determination of the slope [22], and, accordingly, to a considerable error of determination of $\Delta\bar{H}_1^{E\infty}$. Therefore, linear approximation of the dependence $\ln\Omega_1^\infty$–$1/T$ is of little use for precise estimation of $\Delta\bar{H}_1^{E\infty}$ even if the condition $\Delta C_{s\,1}^{E\infty} = 0$ is sutisfied.

In a more rigorous approach, it is assumed that $\Delta C_{s\,1}^{E\infty} = \text{const}$ (const ≠ 0). In this case, the temperature dependence of $\Delta\bar{H}_1^{E\infty}$ should be taken into account, but this dependence can be extrapolated by a linear function. Previously it has been demonstrated [23, 24] that, in calculating the activity coefficients in the above approximation, the best suited extrapolating function is as follows:

$$\ln\Omega_1 = C\ln T + D/T + E, \quad (15)$$

where C, D, and E are constants.

According to Eqs. (13) and (14), the corresponding relationships for $\Delta\bar{H}_1^{E\infty}$ and $\Delta\bar{S}_1^{E\infty}$ are written as

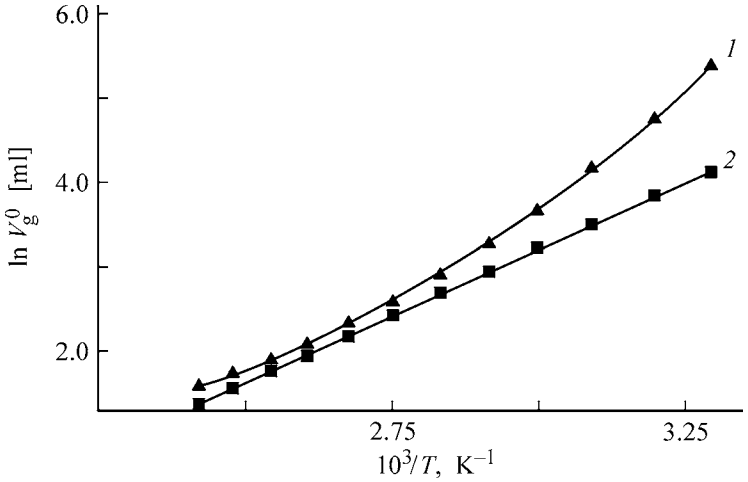

Fig. 2. Retention curves of *n*-pentane on (*1*) PDMS/PPT copolymer and (*2*) homo-PDMS. (V_g^0) Retention volume and (T) temperature.

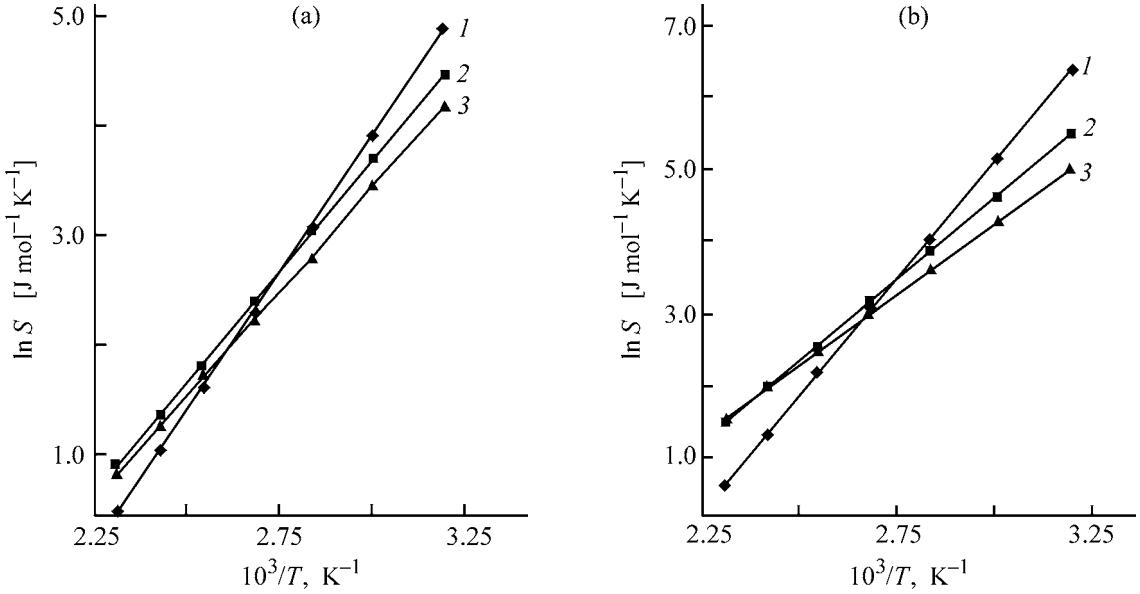

Fig. 3. ln$S$ vs. 1/T for (a) *n*-pentane and (b) *n*-hexane on three block copolymers: (*1*) PPTDMS-1, (*2*) PPTDMS-2, and (*3*) PPTDMS-3.

$$\Delta\bar{H}_1^{E\infty} = RD - RTC, \quad (16)$$

$$\Delta\bar{S}_1^{\infty} = -R(C + E) - RC\ln T. \quad (17)$$

Coefficients C, D, and E can be derived from Eq. (15) using the statistical methods. With at least 30 points in the dataset, the error of determination of the coefficients was generally within 0.5%. In this case, $\Delta\bar{H}_1^{E\infty}$ can be estimated to within 10%. It should be pointed out also that calculation by Eqs. (16) and (17) provides closer insight into the relationship between the excess thermodynamic functions and the polymer structure. In this case, the excess functions can be estimated at a fixed (standard) temperature, whereas in the linear approximation, the calculated $\Delta\bar{H}_1^{E\infty}$ depends on the selected temperature range, thus considerably impairing the validity of the comparative analysis.

As expected, the retention diagrams of various sorbates on the stationary phase composed of PDMS/PPT copolymer are nonlinear (Fig. 2), in contrast to those on homopolymeric supports. The contribution of the dissolution S, extracted using the method of successive approximations, is a linear function of the reciprocal temperature (Figs. 3a, 3b). It should be pointed out that, among the three investigated samples, the slope of the plot of ln S vs. 1/T is maximal for

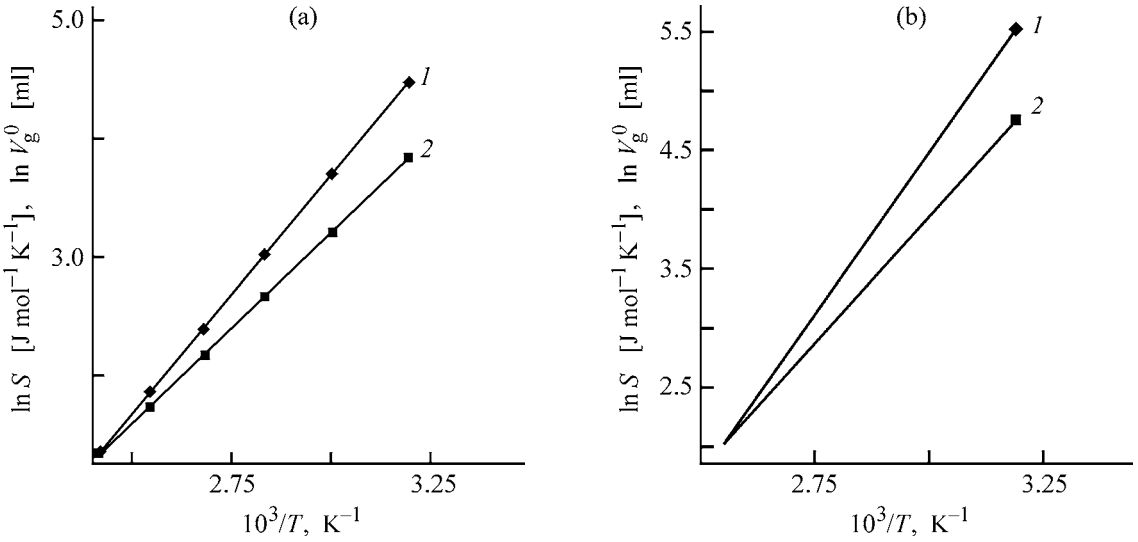

Fig. 4. ln S vs. $1/T$ for (a) *n*-pentane and (b) *n*-hexane on PPTDMS-2 (*1*) and ln V_g^0 vs. $1/T$ on PDMS as the pure flexible-block phase (*2*).

the polymer with the highest fraction of rigid blocks, and the most gently sloping plot is observed for the polymer with the lowest fraction of the terephthalate blocks, suggesting that, in polyblock copolymers, complete phase separation does not occur, in contrast to di- and triblock copolymers. Not all the rigid-chain parts of the molecules can be incorporated into nanodomains, and a considerable fraction of them remains in the bulk of the dispersion medium, having a significant effect on its properties. It is the presence of a large amount of such rigid-chain fragments "loosening" the dispersion medium that provides the emergence of free-volume elements, which, in turn, may remarkably change its sorption characteristics. To test this hypothesis, we compared lnS of a sorbate on the copolymers investigated with the retention diagram of the same sorbate on straight PDMS (Figs. 4a, 4b). If the dispersion medium of the block copolymer consisted of pure PDMS, these two plots would be coincident. However, as can be clearly seen from Fig. 4, this is not the case. For both the examples, the slope of the plot of ln S vs. $1/T$ is considerably higher than that of ln V_g^0 vs. $1/T$, and the values of ln S obtained for the copolymer over the temperature range 30–140°C are higher than those for PDMS.

We used the calculated S values to calculated by the above algorithm, the mass activity coefficient, an important characteristic parameter of the system polymer–low-molecular-weight solvent, and then excess partial molar enthalpy and entropy.

Previously, we have demonstrated [25] that the excess partial molar enthalpy is a resultant of all the intermolecular interactions in the system polymer–low-molecular-weight substance at a nearly infinite dilution. It can be written as the following sum:

$$\Delta H_1^{E\infty} + \Delta H_{BREAK} + \Delta H_{HOLE} + \Delta H_{DISP} + \Delta H_{SP}, \quad (18)$$

where ΔH_{BREAK} is the enthalpy of rupture of the bond between the solute molecules; ΔH_{HOLE}, enthalpy of cavity formation in pure solvent, i.e., in the polymer in our case; ΔH_{DISP}, enthalpy of nonspecific interaction; and ΔH_{SP}, enthalpy of specific interaction.

To calculate the excess functions of mixing in the system polymer–low-molecular-weight substance, we derived the equations for the temperature dependences of Ω_1^∞. The mass activity coefficients calculated for the temperature range 30–120°C at a step of 10°C are given in Table 1, and the estimated $\Delta\bar{H}_1^{E\infty}$, in Table 2.

The $\Delta\bar{H}_1^{E\infty}$ values obtained for the solutions of PDMS/PPT block copolymers appeared to be fairly high in the absolute value and negative in sign. This is quite expectable, knowing that *n*-alkanes are good solvents for PDMS forming a continuous phase of this block copolymer. In the case of the polymer with a rigid-to-flexible block ratio of 1 : 4.5, the dependence of the enthalpy of solution on the number of carbon atoms in the sorbate demonstrates a maximum for hexane. It may be suggested that, in such a microstructure of the polymer chain, a considerable amount of nanoscopic intraassociate cavities occur, whose size is close to that of the hexane molecule. In this case, the partial characteristic ΔH_{HOLE} is reduced, which

gives rise to a minimum in the dependence of $\Delta\bar{H}_1^{E\infty}$ on the number of carbon atoms in the sorbate molecule.

In the Flory–Hugging thermodynamics, the partial molar entropy of alkanes is written as

$$\Delta\bar{S}_1^{E\infty} = R[\ln m - (m - 1)/m], \qquad (19)$$

where m is the ratio of the rigid-core volumes of a polymer and a low-molecular-weight component [26].

The limitations of Eq. (19) are the lack of intermolecular interactions and the constancy of the free volume in the course of mixing. Under these conditions, Eq. (19) predicts the decrease in $\Delta\bar{S}_1^{E\infty}$ with increasing molar volume of *n*-alkane.

The dependence of $\Delta\bar{S}_1^{E\infty}$, calculated by Eq. (19), on the number of carbon atoms in the sorbate molecule has a maximum at $N = 6$ (hexane).

It should be pointed out here that, for elastomers, Eq. (19) is not generally valid [27]. Conversely, they are characterized by the independence of $\Delta\bar{S}_1^{E\infty}$ from the molar volume of alkane. The occurrence of the minimum in $\Delta\bar{S}_1^{E\infty}$ in the case of hexane can be attributed to the sorption mechanism involving the insertion of the hexane molecules into intraassociate cavities (free-volume elements) of the elastomer, like that in sorption on associated liquids [27, 28].

CONCLUSIONS

(1) Inverse gas chromatography shows promise as a method for studying fine (nanoscopic) organization of block copolymers.

(2) An algorithm is suggested for calculating the partial contribution of dissolution for the cases of the dual mechanism of retention on polyblock copolymers.

(3) The partial molar enthalpy and entropy are calculated for three different compositions of the copolymers built by the phenolphthalein terephthalate and poly(dimethylsiloxane) blocks.

(4) The abnormally high $\Delta\overline{H}_1^{E\infty}$ obtained for the copolymers, compared to poly(dimethylsiloxane) (flexible-block phase), and small differences in $\Delta\overline{S}_1^{E\infty}$ suggest the presence of a considerable amount of free-volume elements in the supramolecular structure of the polymers investigated, which makes them promising materials for, e.g., selective gas-permeable membranes.

Abstract—Rheological properties of dilute and moderately concentrated aqueous solutions of methyl cellulose–polyvinyl alcohol blends, as well as the conditions of gelation in these solutions were studied. The compatibility of the polymers was examined by the solvent vapor sorption method; the range of the compositions corresponding to thermodynamic compatibility of methyl cellulose and polyvinyl alcohol was identified.

DOI: 10.1134/S1070427206120196

Recently there has been increased interest in self-associated polymer systems based on environmentally safe and biodegradable natural polymers. As is known, a number of cellulose compounds form physically thermoreversible gels in aqueous solutions. These compounds include methyl cellulose (MC), hydroxypropyl cellulose (HPC), hydroxypropyl methyl cellulose (HPMC), and methyl ethyl cellulose (MEC). These cellulose ethers are widely used as gel-forming agents, thickeners, stabilizers, and emulsifiers in food industry [1]. Among the cellulose compounds mentioned, the most widely used is MC.

The gelation temperature of aqueous solutions of MC is affected by many factors: polymer concentration and degree of substitution and uniformity of distribution of the substituents in anhydroglucoside units and along the macrochain [2–5]. Substituents of a different nature, introduced into the MC macromolecule, affect the solubility of mixed cellulose ethers, the rheological properties of solutions, their associative structural organization, and the gelation and phase segregation conditions in these solutions [6–11]. The rheological properties of MC solutions and conditions of gelation in them, as well as the physicomechanical properties of the film obtained from solutions, can be also varied by introducing another water-soluble polymer into solutions [12–14].

Aqueous solutions of MC (systems with lower critical solution temperature, LCST) form physically thermoreversible gels under heating [15–18], whereas solutions of polyvinyl alcohol (PVA) (systems with upper critical solution temperature, UCST) form gels under cooling [19–22]. Examination of blends of these two kinds of polymers in a common solvent is of both scientific and practical interest.

In this study, we examined the rheological properties of dilute and moderately concentrated solutions of MC–PVA blends and the conditions of gelation in them, as well as the thermodynamic compatibility of the polymers in the solid state, depending on the polymer blend composition.

EXPERIMENTAL

As initial materials served MC-100 commercial cellulose with the degree of substitution of 1.62, M_η = 147 000, and two PVA samples, PVAI with M_η = 17 500 and degree of hydrolysis of 98% and PVAII with M_η = 58 000 and degree of hydrolysis of 98%. Distilled water served as the solvent.

The 3% aqueous MC and PVA solutions, prepared in advance, were mixed in the necessary proportions. Dilution of the 3% solutions yielded 0.15–0.20% solutions, which were examined viscometrically.

An aqueous solution of MC was prepared by polymer swelling in hot water at 80–90°C, followed by dissolution under cooling to 5–10°C with stirring for 6 h. The PVA solutions were prepared at 80°C, stirred for 3 h, and then cooled to room temperature. The resulting solutions were filtered under pressure and then deaerated for 1 h. The solutions of the two polymers were mixed in the necessary proportions and stirred for 4 h.

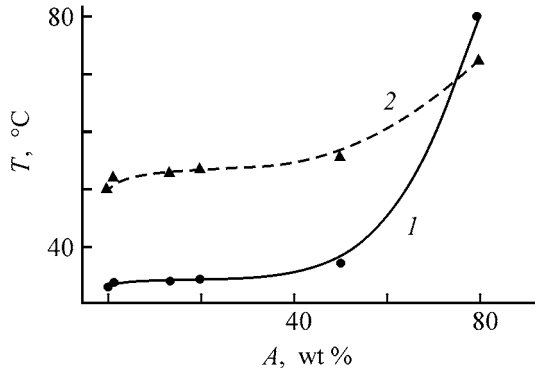

Fig. 2. (*1*) T_{gel} and (*2*) T_{cloud} (9 s) in relation to the composition of the 3% solutions of the blends.

Films were prepared from the aqueous solutions of the polymer blends by casting the solution through a laboratory draw plate with controlled slit onto Teflon plates at 20°C, followed by drying at 30°C. The films were detached from the support after 1 day.

The gelation conditions in the solutions were monitored by variation of the viscosity of the solutions and also photometrically. The gelation onset temperature T_{gel} in the 3% solutions, depending on the composition, was determined with a Hoeppler viscometer according to the procedure from [6]. The phase segregation (cloud) point T_{cloud} in the 0.2% solutions was determined with a KFK-2 photocolorimeter in a temperature-controlled cell (at λ = 670 nm) at a light transmission of 50% by the procedure from [3, 6, 9].

The viscosity characteristics of the dilute (0.15 and 0.20%) solutions were measured on an Ubbelohde capillary viscometer at 20°C. The rheological properties of the concentrated solutions were examined on a Rheotest 2.1 rotary viscometer with a cylinder–cylinder working unit in the shear stress range 3–600 Pa at 20–40°C.

As is known, cellulose and its compounds are in most cases only partially compatible with other polymers in blends [23]. To elucidate the compatibility of MC with PVA in the moderately concentrated solutions, we examined the optical properties of these blends (Fig. 1). We measured the optical density of the solutions of the MC–PVAI blends. It is seen that, upon addition of the PVAI solution to the MC solution at 20°C, the optical density of the blends increases. The maximal optical density is observed for solutions of the polymer blends at 50 wt % PVAI. On the whole, the optical densities of the solutions of the blends substantially exceeds those of the MC and PVAI solutions at the polyvinyl alcohol content in the blend from 20 to 80%. The higher optical densities of the solutions of the blends in this range of the PVAI concentrations suggest phase segregation in the systems. Upon heating an aqueous solution of MC to 60°C, gelation occurs; as a result, the solution becomes turbid, and the optical density of the solution sharply increases [4, 5, 15, 16]. A decrease in the optical density of the solutions of the blends at 60°C with increasing PVA proportion may be due to a decrease in the proportion of the polymer, responsible for formation of the gel under heating, i.e., of MC.

It would be expected that a change in the MC concentration in the solutions of the blends, phase segregation in solutions, and interaction between the macromolecules of the different kinds of polymers should modify the gelation conditions in the systems of interest. Therefore, we determined T_{gel} and T_{cloud} in the solutions examined (Fig. 2). It is believed that, if interactions between the MC and PVA macromolecules dominate over the MC–MC and PVA–PVA interactions, the heat resistance of the MC macrochains in water is enhanced because of an increase in the solubility of PVA in water with temperature. It should be noted that a decrease in the MC concentration in solutions always causes T_{gel} and T_{cloud} to increase [3].

It is seen that introduction of up to 50.0 wt % PVAI into the blends does not substantially modify the gelation conditions in the solutions, which indirectly confirms the interaction between the macromolecules of the different kinds of the polymers. Substantial increases in T_{gel} and T_{cloud} are observed for blends with over 50.0 wt % PVAI. Such a change in the gelation conditions can be due to a decrease in the propor-

tion of the gelating polymer, MC. At the PCA content above 80.0 wt %, no gelation is observed in the solutions.

To evaluate the compatibility of MC and PVA, we used the solvent vapor sorption method [24]. The films prepared by the above-described procedure were vacuum-dried to constant weight. The residual content of the solvent was no greater than 0.02%. The water vapor sorption by the films was measured at 20°C in a vacuum setup with a McBain quartz spring balance (spring sensitivity 0.5–0.7 μg m^{-1}, accuracy within 0.01%) at the saturated solvent vapor pressure.

The polymer–solvent interaction parameter ζ_1 for MC, PVA, and their blends was calculated from the sorption data by the Flory–Huggins equation [25]:

$$\ln a_1 = \ln(P_1/P_1^0) = \ln(1 - \varphi_2) + \varphi_2 + \zeta_1\varphi_2^2, \quad (1)$$

where a_1 is the solvent vapor activity, and P_1/P_1^0, relative pressure of the solvent vapor. The experiments were performed at the saturated solvent vapor pressure, i.e., at $a_1 = P_1/P_1^0 = 1$, which suggests $\ln a_1 = 0$. The volume proportion of the polymer in the swollen film was calculated by expression (2):

$$\varphi_3 = \frac{1}{1 + (d_2/d_1)Q}, \quad (2)$$

where d_1 is the solvent density; d_2, polymer density; and Q, amount of the solvent sorbed (grams of solvent per gram of dry polymer). The density of the samples was determined by hydrostatic weighing in heptane.

The polymer–polymer interaction parameter was calculated from the sorption data by the Patterson relationship [26]:

$$\zeta_{23} = (\zeta_{12}\varphi_a + \zeta_{13}\varphi_b - \zeta_{1(23)})/\varphi_a\varphi_b, \quad (3)$$

where ζ_{12}, ζ_{13}, and $\zeta_{1(23)}$ are the Flory–Huggins parameters of interaction with water of individual polymers MC and PVA and their blends, respectively, and φ_a and φ_b, volume proportions of the polymers in the blend, respectively. For blends of compatible polymers, $\zeta_{23} < 0$ [27]. Therefore, any positive ζ_{23} suggests the incompatibility of polymers.

Figure 3 shows that, in the MC–PVAI blends with a PVA content of up to 15.0 wt %, the polymers are compatible, i.e., $\varphi_{23} < 0$. At a higher content of PVA, the polymers in the solid state are incompatible.

The pattern of variation of the viscosity for the dilute solutions of the polymer blends suggests possible interaction of the macromolecules of different kinds

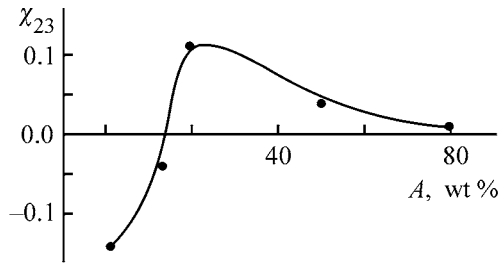

Fig. 3. Polymer–polymer interaction parameter 23 vs. the PVAI content *A*.

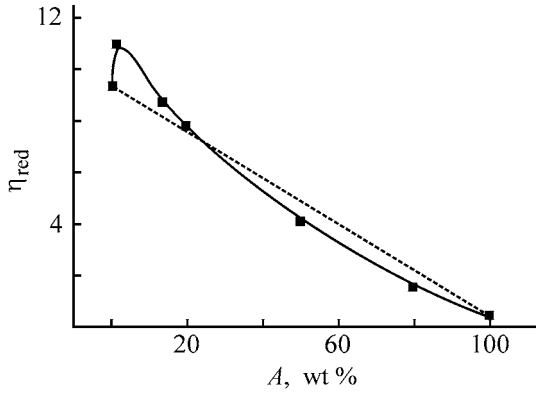

Fig. 4. Reduced viscosity $\eta_{red} = \eta_{sp}/C$ of the 0.20% solutions of the MC–PVAI blends vs. the PVAI content *A* at 20°C. *Dashed line*: calculated additive values.

of polymers in solution [7, 28, 29]. In dilute solutions (Fig. 4) with up to 30.0 wt % PVAI in the blend, the viscosity of 0.20% solutions exceeds the additive value. The viscosities of the solutions of the blends with over 30.0 wt % PVAI are lower than the additive values. The fact that the viscosities of the blends of the dilute solutions exceed the additive values suggests that intermolecular interactions between the macromolecules of different kinds of the polymers dominate in solution. This is responsible for the formation of structures whose hydrodynamic volume exceeds the weighted-average hydrodynamic volume of the two components taken separately. The fact that the reduced viscosities of the solutions of the blends (with over 30.0% PVAI) are lower than the additive value can be due both to compaction of the macromolecules of the polymers if they are incompatible and to formation of mixed complexes whose hydrodynamic volume is smaller than those of either polymer. Figure 4 shows that, in our case, a decrease in the reduced viscosity is due to incompatibility of the polymers. It should be noted that, with increasing molecular weight of PVA, the range of the composition of the blends within which MC and PVA are compatible tends to narrow. This is consistent with the published data on the thermodynamic compati-

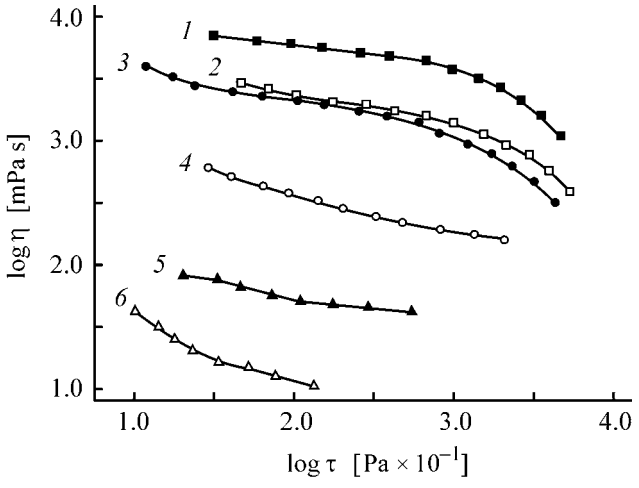

Fig. 5. Flow curves for 3% solutions of (*1*) MC, (*2–5*) MC–PVA blends containing (*2*) 1.4, (*3*) 20, (*4*) 50, and (*5*) 80% PVA, and (*6*) PVA at 20°C. (η) Viscosity and (τ) shear stress.

bility of polymers in relation to their molecular weight [25]. In the case of PVAII with a higher molecular weight, the reduced viscosity exceeds the additive value for the blends with up to 8.0 wt % PVAII only.

The intermolecular interactions in moderately concentrated solutions were analyzed by examination of the rheological properties of the 3% solutions of MC–PVAI and MC–PVAII blends at 20–40°C. The temperature of 40°C exceeds the T_{gel} of the MC solution (Fig. 2), which makes it suitable for elucidating the influence of gelation of MC on the viscosity of the solutions of polymer blends.

Figure 5 presents as an example the flow curves for the solutions of the MC–PVAII blends at 20°C. The flow curves for the solutions of MC, PVA, and their blends are partial flow curves of non-Newtonian fluids. The structural viscosity branch for the MC solution becomes prominent at shear stresses over $\log \tau = 2.8$ (630 Pa × 10^{-1}). On the flow curve of the PVAII solution, the structural viscosity branch is less prominent in the shear stress range of interest because of the substantially lower molecular weight of PVA compared to MC. Variation of the viscosity with the shear stress is typical of structured polymer systems. Similar flow curves are also observed for the MC–PVAI solutions.

Figure 6 shows the viscosity of the MC–PVAII blends in relation to the composition at 20 and 40°C. For convenience, these dependences were plotted on different scales, which prevented their overlapping.

At 20°C, the viscosity–composition dependence for moderately concentrated solutions of MC–PVA blends is opposite to that for the dilute solutions at the same temperature (Fig. 4). Such a trend is typical of the viscosity of semirigid chain polymers due to changing thermodynamic affinity of the polymer for the solvent. The worsening of the solvent quality is responsible for the contraction of the macromolecules of the cellulose compounds and reduction of the viscosity of dilute solutions. At the same time, the degree of aggregation of the solvated macromolecules in concentrated solutions increases due to enhancement of intermolecular interactions, which is responsible for an increase in viscosity [25].

The viscosity of concentrated solutions of the polymer blends is affected by many factors. In blends of polymer solutions, new hydrogen bond systems can be formed, stronger than those in solutions of MC and PVA taken separately, as can be seen from Fig. 3 (the range of the compositions in which MC and PVA are thermodynamically compatible). It should be noted that the thermodynamic quality of the solvent (water) with respect to MC can change upon addition of a different polymer, PVA, to the MC solution. Also, under phase segregation in solution, the mechanism of flow of the heterogeneous blend will differ from that of the homogeneous solution. The viscosity will be affected by the shape, number, and stability (strength) of the microparticles of the disperse phase, in a solution of a different phase, matrix. The viscosity can be both higher and lower than the additive value.

Presumably, addition of PVA to an MC solution (up to 20 wt %) at 20°C destroys the system of intermolecular hydrogen bonds between the solvated

macromolecules of the cellulose ether, which causes the viscosity of the solutions to decrease over the PVA concentration range of interest. Further increase in the PVA proportion in the blend causes the viscosity to increase due to phase segregation in solutions (the polymers are incompatible).

The temperature dependences of the viscosities of the solutions of the blends (20–35°C) were used for calculating the heat of activation of viscous flow of solutions E_a. For the MC and PVAII solutions, E_a was estimated at 28.0 and 27.0 kJ mol^{-1}, respectively. In the solutions of the blends with the PVAII content of up to 30.0 wt %, the heats of activation are lower than the additive values, while at the PVAII content in the blends over 30.0 wt %, the heat of activation of the viscous flow of the solutions reaches 40.0 kJ mol^{-1}. Such a deviation of the E_a parameters from the additive values, depending on the PVA content in the blends, suggests a major change in the strength of the structure of the solutions due to changes in the fluctuation network of hydrogen bonds between the solvated macromolecules of the two polymers and phase segregation in the blends of certain composition.

At temperatures above T_{gel} of the MC solution (40°C), the viscosity of the solutions of the blends is lower than the additive value throughout the composition range examined (Fig. 6, curve *2*). With increasing temperatures, two opposite processes occur in the solutions of the blends. On the one hand, gelation in the MC solutions is accompanied by phase segregation and an increase in viscosity [15, 16, 30, 31]. On the other hand, the increase in temperature causes the viscosity of the PVA solution to decrease because of the improvement of the solvent quality with respect to the polymer of interest and an increase in the energy of thermal motion of the macromolecules. Presumably, at 40°C the viscosity of the solutions of the blends is more strongly affected by the latter factor: Solvated PVA macromolecules hinder formation of gel throughout the solution body and act as a "lubricant" between the nucleation sites of the MC macromolecules. As a result, the viscosity becomes lower than the additive values.

Thus, by varying the amount of the polymer (in particular, PVA) introduced into an aqueous solution of MC, it is possible to modify the rheological properties of solutions and conditions of gelation in them, as well as to prepare mixed film materials in which the polymers can be both compatible and incompatible.

CONCLUSIONS

(1) The viscosities of dilute and concentrated solutions of blends of methyl cellulose and polyvinyl alcohol differ from the additive values, which suggests a change in the conformations of the macromolecules of the polymers in blends and structural rearrangement of the solutions.

(2) The polymers are thermodynamically compatible in blends with up to 15.0 wt % polyvinyl alcohol.

(3) In solutions of the blends with over 50.0 wt % polyvinyl alcohol, the gelation-onset and phase-segregation temperatures substantially increase.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Viscoelasticity and Surface Properties of Blends of Aqueous Solutions of Polyvinyl Alcohol and Carboxymethyl Cellulose

L. M. Trufakina

Institute of Petroleum Chemistry, Siberian Division, Russian Academy of Sciences, Tomsk, Russia

Received January 24, 2006

Abstract—Rheological properties of aqueous solutions of carboxymethyl cellulose, polyvinyl alcohol, and of their blends prepared under various conditions (temperature, concentration, time) were studied by viscometry and of ball indenter penetration.

DOI: 10.1134/S1070427206120202

Complexation of a polymer with another polymer or with a low-molecular-weight compound is of great practical interest [1–3] since this modification changes the physical properties of the polymer without chemical synthesis.

Among blends of water-soluble polymers, gels of polyacrylamide [4], polyacrylic acid and cellulose ethers and esters [5], polysaccharide and polyvinyl alcohol [6], etc. have been studied in detail.

The conditions of formation of polymer complexes, their rheological and surface properties, and the kinetics of formation and degradation of the complexes are required for their successful application.

At present the rheological approach is widely used as the most powerful tool to estimate the kinetics of formation of physical networks in polymer blends.

The aim of this study was to examine the variation of the rheological and surface properties of polymer complexes with time. The results of this study can be used to assess the possibility of storage and estimate the storage temperature and the shelf life of these composites.

The polymer complexes were prepared from water-soluble flexible-chain polyvinyl alcohol (PVA) and rigid-chain carboxymethyl cellulose (CMC).

EXPERIMENTAL

The molecular weight M of PVA in distilled water at 20°C, calculated by the equation $[\eta] = 5.6 \times 10^{-4} M^{0.67}$ [7], is 2.2×10^5. The molecular weight of CMC in 0.1 N NaCl, calculated by the equation $[\eta] = 7.3 \times 10^{-3} M^{0.99}$, is 3.67×10^5.

The dynamic viscosity of the polymer solutions was measured on Rheotest-2 rotary viscometer with a cylinder-cylinder working unit at shear rates of 1.5 to 1312 s^{-1}. The viscosity and shear stress of aqueous solutions of the polymers are listed in the table. The critical concentrations c_{cr} of the crossovers of PVA and CMC are 5 and 6%, respectively.

The polymer blends were prepared by the procedures described in our previous study [8]. The viscosity and the shear stress of the polymer complexes were measured on a rheoviscometer with a cone-plate working unit at shear rates of 0.56 to 4860 s^{-1}.

When solutions with the polymer concentrations close to the critical values (4–8 wt %) were used, the properties of the polymer blend substantially changed.

The structure formation rate in the PVA-CMC system was estimated, as influenced by the concentration,

time, and temperature, using the results of the rheological study. The dependence of the dynamic viscosity at T = 80°C on the gelation time at concentrations of the initial polymers in the range 4–8 % is shown in Fig. 1a. The increase in the viscosity suggests association of the molecules in the first reaction steps. The monotonic growth of the viscosity is also due to an increase in the total concentration of the initial polymers. At polymer concentrations higher than c_{cr}, an additional physical network is formed between themacromolecules. Under more rigorous conditions, i.e., at high polymer concentrations and low temperatures, the blend becomes more viscous due both to formation of additional hydrogen bonds between hydroxy groups of PVA molecules and to intramolecular cross-linking. On cooling from 80°C to 20°C, the viscosity increases from 2.5–3.0 to 6.0 Pa s. The complex is additionally stabilized by hydrophobic interactions promoted by hydrogen bonds [9].

The elastic modulus is the measure of the resistance of a material to deformation under the action of an external stress. This parameter can be measured by the method of ball indenter penetration [4, 10, 11]. The indenter radius was R = 7 mm. The cylindrical gel samples were 40 mm in diameter (D) and 40 mm in height (H). The elastic modulus was calculated by the equation

$$G = 3F/16h^{3/2}R^{1/2},$$

where F is the force acting on the indenter (N), and h is the penetration depth (mm) of a ball indenter of radius R (mm) into the flat sample surface.

The elastic modulus is related to the cross-link density, i.e., to the degree of system structuring. We studied the dependence of the elastic modulus of the gels on the concentration, temperature, and time.

The time dependence of the elastic modulus of the gels formed at 20°C is shown in Fig. 1b.

The gels can be conditionally divided into high-modulus (G > 500 Pa) and low-modulus (G < 500 Pa) gels [11]. The high-modulus gels are formed at the PVA concentration of 7–8%, which is higher than the cross-over concentration, and on cooling. In all cases, the elastic modulus increases during 4–5 days owing to formation of a cross-linked structure. The increase in the elastic modulus of the gels with G < 500 Pa is insignificant. These gels are stable.

The dependences of the creep of polymer complexes formed at the initial polymer concentration in the solution of 5% on the time of structuring at T = 20–80°C are shown in Fig. 2. The relaxation properties of the sample decrease with increasing temperature at a constant stress. The curves level-off with increasing structuring time.

The viscoelastic properties of an adhesive are important when a high-viscous polymer forms adhesive

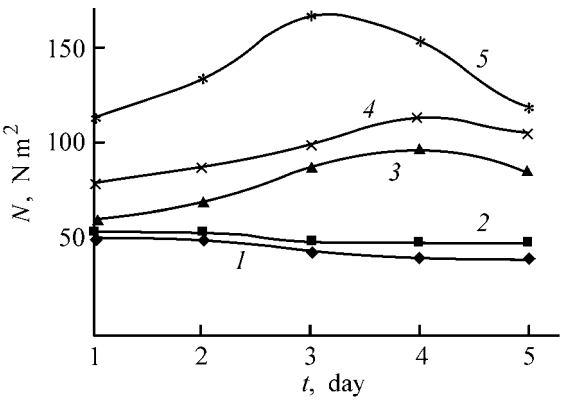

Fig. 3. Work of adhesion N of polymer complexes vs. time t of structuring at 20°C.

joints with the substrate surface [12, 13]. The rheological processes in the bulk of the polymer in the course of formation of adhesive joints have been extensively studied [9, 14]. The adhesive strength was evaluated by the work of detachment of a St.3 plate from the polymer complex under the action of an external force [13]:

$$W = W_{break}/S,$$

where S is the area of contact of the adhesive with the substrate (m^2), and W_{break} is the detachment adhesion ($N\ m^{-1}$).

To determine the features of formation of the surface of polymer blends with different structures and mechanical properties, we studied the influence of time, temperature, and concentration on these properties. The dependence of the work of adhesion of the polymer complexes on the reaction time is shown in Fig. 3. It is seen that the concentration of the initial solutions of the polymers affects this dependence. The time at which the curves level-off corresponds to completion of the surface formation. At the 7–8% concentration of the polymers in the initial solution, the surface layer is formed faster owing to the formation of supramolecular structures interfering with the work of adhesion. The adhesion mechanism of the detachment confirms the formation of hydrogen bonds decreasing the free volume and increasing the cohesion energy.

CONCLUSIONS

(1) The dynamic viscosity of aqueous solutions of polyvinyl alcohol, carboxymethyl cellulose, and their complexes was measured. The crossover concentration of polymers was determined.

(2) The elastic modulus of the polymer blends was determined in relation to concentration, temperature, and gelation time.

(3) The work of adhesion of the polymer complexes was studied by the method of detachment of a St.3 plate.

(4) The viscosity and the elastic modulus increase and the formation of the surface of polymer compositions accelerates with increasing total concentration of the initial monomers and with decreasing temperature.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

A Study of Swelling of Polyurethane Wastes with the Aim of Regeneration

A. V. Tokarev and N. V. Sirotinkin

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received March 10, 2006

Abstract—The optimum time of swelling (required for weakening of the intermolecular interaction) of polyurethanes of various compositions in a series of organic plasticizers was determined. The deterioration of the physicomechanical characteristics with plasticization allows a decrease in the expenses for secondary recovery of wastes formed in polyurethane production.

DOI: 10.1134/S1070427206120214

In the last decades, polyurethane compositions have found increased application in all branches of industry. As predicted, the Russian market of polyurethanes (PUs) can reach 210 thousand tons in 2007. The production of polyurethane materials on an increasingly large scale requires a search for efficient procedures for utilization or breakdown of these wastes.

At present, the main procedures for PU reprocessing are mechanical grinding with subsequent use of the resulting crumb as a filler for various composite materials, physical or physicomechanical treatment, and chemical reprocessing.

Mechanical degradation is the most acceptable procedure for utilization of PU foams, since their degradation requires lower power expenditure in comparison with the degradation of monolithic PUs [1, 2]. In addition, grinding of wastes formed in production of thermoplastic block PUs is very difficult because of their high elasticity at elevated temperatures: energy is mostly transformed into heat and only an insignificant part of energy is expended for degradation.

Physical methods, such as die casting, pressing, and extrusion, are suitable for reprocessing of thermoplastic linear or weakly cross-linked polyurethane systems [3, 4] and are inapplicable in the case of thermosetting plastics. Additional use of high temperatures can result in uncontrolled degradation of cross-linked PU to be recovered, which is reflected on the quality of the final product.

A huge number of foreign and Russian inventions are devoted to thermochemical degradation based on the reaction of PUs with hydroxyl- and amino-containing compounds, which can be regenerated to the initial components [5–7]. The drawbacks of this procedure are the high process temperature and formation of polyols nonuniform in molecular weight, which hampers their subsequent use.

One of the successful procedures for utilization of polyurethane wastes is plasticization, which partly destroys the structure and makes it possible to obtain secondary product, e.g., crumb, with high operation characteristics at minimal power and economic expenses; however, sorption of low-molecular-weight liquids or their vapor results in a decrease in the ultimate strength and elasticity of swollen PUs. The procedure used for processing of wastes formed in production of soles, multicellular PUs of ester nature [8], is based on a similar effect of polar plasticizers of the dimethylformamide type.

Previously [9], plasticizers of this type have been studied as agents promoting thermal degradation. Granulated wastes were dissolved in boiling DMF in the presence of amines and organotin compounds (degradation catalysts) and were added to hydroxy components. The resulting liquid and paste-like products were used as polyol substitutes (20%) in production of PU.

Finely divided polyurethane reclaim was prepared by dissolution of PU-elastomer foams in DMF at 90°C and subsequent precipitation of the polymer into methanol [10] or treatment of wastes preliminary degraded by heating with a mixture of methylene chloride (80%) and DMF (20%) [11].

Table 1. Composition of the polyurethane elastomers studied

Component	Content of components, wt %						
	PU-1	PU-2	PU-3	PU-4	PU-5	PU-6	PU-7
Polyoxytetramethylene glycol, MW 1000	63.06	63.06	–	65.76	–	70.19	61.16
Polyoxypropylene glycol, MW 1000	–	–	63.06	–	–	–	–
Polyethylene butylene glycol adipate P-6 BA, MW 2000	–	–	–	–	72.66	–	–
2,4-Toluylene diisocyanate	21.60	–	–	18.90	12.00	24.04	20.95
Toluylene diisocyanate T-80*	–	21.60	21.60	–	–	–	–
Methylenebis-*o*-chloroaniline (Diamet Kh)	15.34	15.34	15.34	15.34	15.34	–	–
Diamin-304**	–	–	–	–	–	–	17.88
Butanediol-1,4	–	–	–	–	–	5.77	–

* The product is an isomeric mixture of 2,4-toluylene diisocyanate (80%) and 2,6-toluylene diisocyanate (20%).

** The product is an eutectic mixture of Diamet Kh and 3,3'-dichloro-4,4'-diaminotriphenylmethane in the molar ratio of 1 : 1.

Table 2. Characteristics of the samples studied

Characteristic	PU-1	PU-2	PU-3	PU-4	PU-5	PU-6	PU-7
Isocyanate index, %	6.0	6.0	6.0	4.2	3.2	6.0	6.0
Density, kg m^{-3}	1140	1150	1155	1130	1170	1024	1180
Shore hardness A, arb. units	95	95	92	90	70	50	75
Nominal stress, MPa, at elongation:							
100 %	16.8	16.0	13.1	9.2	1.92	1.4	4.9
300 %	30.8	45.0	19.8	21.6	15.1	4.3	14.7
Nominal tensile strength, MPa	42.0	50.0	25.1	27.4	25.2	9.65	32.0
Relative elongation at break, %	320	310	380	380	500	670	300

It should be noted that the features of swelling of polymers, among them polyurethanes, in organic solvents have been widely covered in the classic [12, 13] and recent [14, 15] publications.

The reaction of oligoether microheterogeneous segmented polyurethanes with plasticizing agents remain inadequately studied. In this study, we examined this problem with the aim to develop an efficient procedure for secondary processing of castable PUs of varied chemical nature and to estimate their working capacity in corrosive media.

EXPERIMENTAL

The subjects of the study were polyurethanes widely used in various branches of technology [16] and prepared by the prepolymer procedure. The composition and characteristics of the synthesized samples are listed in Tables 1 and 2, respectively.

The preliminary choice of plasticizers is complicated by the structural features of the polymers in hand, in particular, by the presence of segments with different polarities in polyurethane chains and their ability to form hydrogen bonds of two types: between NH group and carbonyl of the urethane bond or between the NH group and the –C–O–C– group of the soft block. With increasing microphase separation, the first type of interaction predominates; as a result, the number of bonded carbonyl groups increases [17]. This results in the appearance of a strong physical network, along with the chemical network, in macromolecules. The nodes of this network are hard urethane–urea domains. Depending on their nature, solvents affect this network differently.

The capacity of hard chain fragments of polyurethanes for self-association has a significant effect on the resistance to the action of corrosive media [18]. Nonpolar solvents partly destroy hydrogen bonds in PU due to the fact that molecules of these liquids screen soft blocks in the polymer chain. As a result, the fraction of NH groups bound with hydrogen bonds in PU gradually decreases with increasing solvent

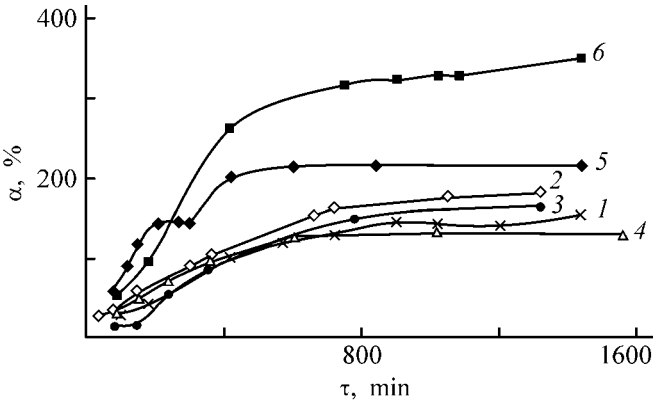

Fig. 1. Kinetic curves of swelling of the samples in DMF and DMSO. (α) Weight degree of swelling and (τ) time; the same for Figs. 2 and 3. DMF: (*1*) PU-1, (*2*) PU-2, (*4*) PU-4, (*5*) PU-5; and (*6*) PU-6; DMSO: (*3*) PU-2.

concentration. Highly polar aprotic liquids react with the NH group of PU through their proton-acceptor groups (C=O or S=O), entering into competitive interaction with carbonyl of its urethane group and dissolving both soft and partially hard blocks of segmented PU [15, 19].

Accordingly, we used in studying the swelling of polymers the following compounds of various classes as solvents: *N*,*N*-dimethylformamide (DMF), dimethyl sulfoxide (DMSO), toluene, cyclohexanone, tetrahydrofuran (THF), and dioctyl phthalate (DOP). All the solvents were of analytically pure grade and were purified by distillation.

To compare the results, we used the samples cut from plates 0.2 ± 0.02 cm thick with the same volume and shape. In all the runs, the temperature was kept at the level of 15 ± 0.2°C. Swelling was carried out in glassware. The samples were immersed completely in the liquid, so that, in the suspended state, they did not touch one another and the vessel bottom and walls. The tests involved determination of the sample weight before and after swelling. The weight degree of swelling α (%) was calculated by the formula $\alpha = (G_1 - G_0) \times 100/G_0$, where G_0 and G_1 are the sample weights before and after swelling (g). Before weighing a swollen sample after the prescribed period of time, the excess liquid was removed from the sample surface with filter paper.

The results of swelling of the polyurethanes studied in aprotic solvents are presented in Fig. 1. It is seen that, compared to DMSO (curve *3*), DMF (curve *2*) exerts a more pronounced plasticizing effect on the polar PU-2 phase. There are data [18] suggesting that the higher the fraction of the symmetric isomer in the composition of the diisocyanate (in the series TDI 100 < TDI 80/20 < TDI 65/35), the stronger the tendency to form stable associates and the higher the resistance of the polymers to corrosion media. However, it is seen from Fig. 1 that this trend is not observed with aprotic plasticizers. For example, the degree of swelling of PU-1 in DMF is lower than that of PU-2 (curves *1* and *2*, respectively).

Data of X-ray, spectral, and electron-microscopic analyses confirm that segmented polyurethanes, among them the materials studied, contain spatially segregated flexible (oligoether units) and hard (fragments involving diisocyanates) segments. The hard block provides strong intermolecular interaction in the chain, comparable to the chemical cross-linking and responsible for the high strength of the polymer; the flexible block is characterized by fairly weak intermolecular interaction and is responsible for elasticity. The rigid blocks are linked with each other by nonionic bonds to form 3*D* domains regularly arranged in the continuous phase (matrix) of the elastic block. Therefore, these polyurethanes can be regarded as two-phase systems in which dispersed particles, domains, are arranged in the amorphous dispersion medium, the elastic part of the polymer [13, 18, 20].

The characteristics of segmented PUs are governed by the content of the hard phase, nature of the elastic phase, and molecular weights of the blocks contained in the polymer. The larger the difference in the polarity of hard and elastic blocks of PU, the lower their thermodynamic compatibility and the higher the "purity" of phases [16]. The polarity of flexible blocks based on esters is higher than that of blocks built from oligoethers. At the same time, the content of the hard phase dispersed in the elastic phase in polyurethanes of ester nature is low in comparison with polyurethanes based on polyethers. Therefore, swelling of PU-5 (Fig. 1, curve *5*) in an aprotic solvent, starting with the flexible phase, proceeds more intensively than that of PU-1 (curve *1*). Since both phases of PU-1 are close in ability to resist to external stresses, the kinetic curve of swelling is monotonic. In the case of PU-5, the process is two-stage: the portion of curve *5* in the range 3–5 h is a conditional transition area from the process occurring in the soft phase, where the spatial network is fairly weak, to plasticization of not numerous, but strongly cross-linked hard segments.

The PU-6 sample synthesized in the presence of the chain extender 1,4-butanediol has an amorphous structure and considerably surpasses highly segregated PU-1 (Fig. 1, curves *6*, *1*) in the degree of swelling

in DMF. The same difference has been noted previously in comparison of swelling processes of these and other polyurethanes in toluene [21]. The PUs that virtually do not contain the hard microphase are characterized by the network of interchain hydrogen bonds outside domains of hard blocks, tending to degrade in toluene. It was confirmed that, as a result of this degradation, the fraction of free NH groups in the elastomer increases and associates of NH groups with the π-electron system of the aromatic ring of the solvent are formed. A similar mechanism is also possible in treatment of polyurethanes with aprotic compounds.

The fundamental distinction between PU-1 and PU-4 is that the isocyanate indices of the prepolymers used for curing. Apparently, the higher the content of isocyanate groups in the polymer, the larger the volume of urethane-urea self-associates localized in the domains of hard blocks. Thus, in PU-1 (Fig. 1, curve *1*) the conditions of formation of strength characteristics are better in the initial stage, which retards its swelling in comparison with PU-4 (Fig. 1, curve *4*). However, the kinetic curve of swelling of PU-4 with lower concentration of urethane groups flattens out after 12 h, whereas the absorption of the plasticizing agent with the hard phase of PU-1 continues.

Low-polarity liquids like toluene do not significantly affect hard domains and are not able to destroy segregations of hard blocks. This fact accounts for the rather low characteristics of equilibrium swelling (Fig. 2). The PU-1 and PU-3 samples cured with Diamet Kh have denser chemical network than PU-7 cross-linked with branched Diamin 304: steric hindrances appearing in the reaction of branched amines with the reactive terminal groups of the prepolymer hamper formation of an ordered developed spatial structure of the material, which leads to their better swelling (Fig. 2, curve *3*). Polyurethanes based on Diamet Kh are characterized by better physicomechanical characteristics and, hence, lower degree of swelling (Fig. 2, curves *1*, *2*), which is in good agreement with the data previously obtained for other models [22].

In polyether-urethane-urea PU-3 based on polypropylene oxide flexible blocks, the degree of microphase separation is lower and the amount of hard blocks dissolved in the flexible phase is higher in comparison with PU-1, whose flexible phase is less polar. With increasing polarity of flexible blocks and, as result, increasing volume of the polar phase, interchain interactions in the polymer matrix are broken under the action of low-polar toluene to a greater extent [as seen from a comparison of curves *1* and *3* (Fig. 2)], similarly to aprotic liquids.

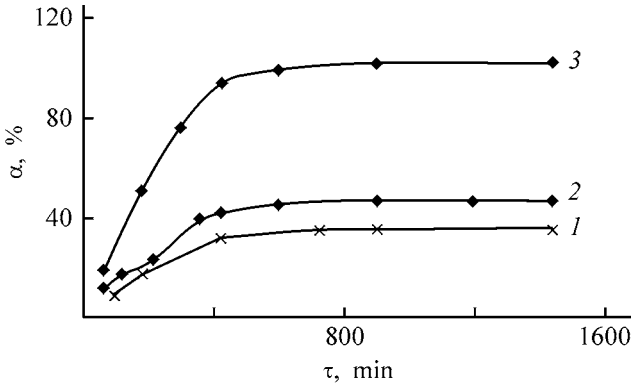

Fig. 2. Kinetics curve of swelling of polyurethanes in toluene. (*1*) PU-1, (*2*) PU-3, and (*3*) PU-7.

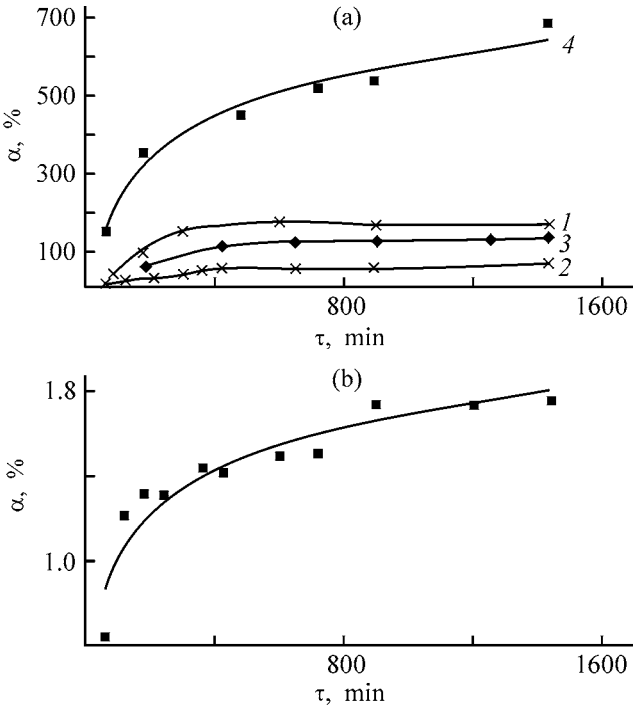

Fig. 3. Kinetic curves of swelling of (a) polyurethanes in THF and cyclohexanone and (b) PU-1 in DOP. (a) THF: (*1*) PU-1, (*3*) PU-3, (*4*) PU-5; cyclohexanone: (*2*) PU-1.

In swelling of polyglycol adipate urethanes in THF, stable complexes involving urethane group are formed [13]; cyclohexanone is also able to specifically interact with these substances, with an irreversible alteration of the structure.

The results of the action of monomeric THF on the samples containing the product of addition polymerization of this compound are shown in Fig. 3a.

Comparison of the results obtained with the data for the aprotic plasticizer (Fig. 1) shows that THF is

Table 3. Kinetic parameters of swelling of PU-1

Plasticizer	α	*A*	*C*
THF	120.5	0.24	45.47
DMF	87.0	0.17	14.86
Cyclohexanone	37.5	0.05	19.28
Toluene	22.5	0.04	8.90
DOP	1.3	0.12×10^{-2}	0.94

a stronger plasticizer with respect to PU-1 and PU-6. This is due to the fact that, structurally similar THF molecules split the chains of polyurethanes based on polytetrahydrofuran with lower energy consumption. The oligoether component of PU-3 is polyoxypropylene glycol, and hence PU-3 has a lower affinity for THF and better swells in DMF.

As can be seen from Fig. 3b, dioctyl phthalate does not exert any significant influence on self-associates of urea groups. It ruptures hydrogen bonds in the flexible phase of PU-1, leaving unchanged the physical network whose nodes are the domains of hard blocks, similarly to polyurethanes of the ester nature [8, 14].

Summarizing the data of Figs. 1–3b concerning the action of plasticizers of various chemical structures, we can conclude that the intensity of swelling decreases in the order tetrahydrofuran > dimethylformamide > cyclohexanone > toluene > dioctyl phthalate. Table 3 lists the degrees of swelling of PU-1 in the above solvents after 10 h of contact and the kinetic parameters of swelling, evaluated for the same time interval of the curves by the equation

$$Y = Ax + C.$$

Here *A* is the slope of the straight line of the swelling kinetics to the τ axis, characterizing the process rate, and *C* is the intercept on the τ axis by the straight line.

The results obtained quantitatively confirm the above conclusions about the level of the plasticizing activity of compounds of varied nature with respect to polyurethanes based on THF. It should be noted that dioctyl phthalate, which is hardly useful as plasticizing agent for PU-1, can find application in recovery of wastes. It is known that addition of plasticizers of the butyl benzyl phthalate [23] and also dibutyl phthalate or dioctyl phthalate type [24] to a mixture of thermoplastic and cross-linked milled microcellular PU has a positive effect.

CONCLUSIONS

(1) The difference in the degree of swelling of the oligotetrahydrofuran polyurethanes considered can reach two orders of magnitude, depending on plasticizer used.

(2) As a plasticizer, monomeric tetrahydrofuran is more active than dimethylformamide and dimethyl sulfoxide with respect to polyoxytetramethylene glycol urethanes and is less active in contact with polyurethane elastomers based on oligoglycol adipates and oligooxypropylene glycols.

(3) In regeneration of wastes of polyurethanes based on oligoethers, it is appropriate to use in the initial stage of regeneration plasticization to save energy and intensify the process.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

A Zero-Discharge Procedure for Production of Urea–Formaldehyde Resins

V. Z. Maslosh, N. P. Golovnenko, O. V. Maslosh, and N. F. Tyupalo

Severodonetsk Technological Institute, Dal' East-Ukrainian National University, Ministry of Education and Science of Ukraine, Severodonetsk, Lugansk oblast, Ukraine

Received August 2, 2006; in final form, May 2006

Abstract—A zero-discharge procedure was suggested for preparing urea–formaldehyde resins by polycondensation of urea, formaldehyde, and dimethylolurea at variable pH, with urea added continuously or in a single portion.

DOI: 10.1134/S1070427206120226

Urea–formaldehyde resins (UFRs), used as a binder in production of woodchip boards, wood fiberboards, and plywood are large-volume commercial products; the features of their preparation are fairly well understood [1]. The raw materials for their production, urea (U) and formaldehyde (F), are cheap and commercially available in large quantities. A specific feature of the production of all the commercial UFR brands is the use of 37% Formalin, which gives rise to large amounts of waste, so-called tar for water. Their amount in various UFR brands is 300–400 kg per ton, with the free F content ranging from 2.5 to 8.0 wt %. Various methods for their treatment or reprocessing have been described in the literature [2], but these processes require additional expenditure and equipment.

Our goal was to develop a zero-discharge procedure for UFR production. Published solutions to this problem involve using, instead of F, difficultly available and relatively expensive paraform or U precondensate (solution in U methylol derivatives in F) [3]. We examined the possibility of preparing UFR by joint polycondensation of U, F, and dimethylolurea (DMU).

EXPERIMENTAL

Dimethylolurea was prepared by condensation of U with F according to [4]. Urea–formaldehyde resins were synthesized as follows. A 500-ml glass flask was charged with 45 ml of water and 162 g (2 mol) of 37% F; pH 8.0–8.5 was adjusted by adding a NaOH solution, and 120 g (2 mol) of DMU was added (step I). After DMU dissolved completely, the mixture was heated to 60–70°C and kept at this temperature for 1 h; then 120 g (2.0 mol) of U was added (continuously over a period of 1–1.5 h in one series of experiments and in a single portion in another series). Then the mixture was heated to 94–98°C and kept at this temperature for 1 h. The mixture was acidified to pH 4.0– 4.5 by adding ammonium chloride and stirred for 0.5 h, after which a NaOH solution was added to pH 8.5–9.5, and the mixture was kept until the refractive index n reached a value of 1.4520–1.4560.

In industry, UFR is produced by polycondensation of F with U (molar ratio 1.33 : 1) at 94–98°C and variable pH. In the first step of the polycondensation, the concentration of F is relatively high, 23.8 wt % (Fig. 1, curve *1*), and its reaction with U yields methylol derivatives of U; in the process, the methylol groups (MGs) are accumulated and the F concentra-

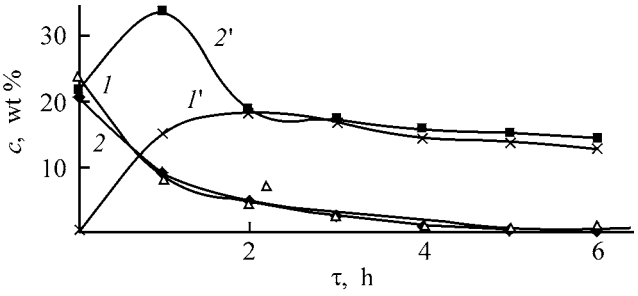

Fig. 1. Content c of (*1*, *2*) formaldehyde and (*1'*, *2'*) methylol groups vs. time τ of polycondensation of F with U. UFR: (*1*) commercial and (*2*) synthesized.

tion decreases (Fig. 1, curves *1*, *1'*). The reaction mixture mainly consists of mono- and dimethylolurea.

In preparation of UFR from DMU, the initial reaction mixture contains F and DMU, with a relatively high content of U and MGs: 21.1 and 21.85 wt %, respectively. The reaction of F with DMU is accompanied by accumulation of MGs and a decrease in the F concentration. The MG content reaches 33.6 wt % (Fig. 1, curves *2*, *2'*). In this case, the reaction mixture essentially differs in composition from the mixture formed in the industrial synthesis of UFR.

The qualitative composition of the reaction mixture was determined by ^{13}C NMR spectroscopy. The spectra were measured on a Varian-200 pulse spectrometer in D_2O–DMSO-d_6 (1 : 3) at 20°C. The analysis conditions and procedure of signal assignment were the same as in [5]. The ^{13}C NMR spectrum of the reaction mixture is shown in Fig. 2.

The ^{13}C NMR spectrum of the mixture formed in the reaction of F with DMU in 60 min (step I) contains, along with the peaks of disubstituted urea derivatives (nos. 8, 9), methylenemethoxy groups at the tertiary nitrogen atom (no. 7), and methylol and methylene ether groups mainly at the secondary nitrogen atom (nos. 4, 5), also new peaks of methylenemethoxy groups at tertiary and secondary nitrogen atoms (nos. 13, 3) (Fig. 2).

The spectrum shows that both linear and linear-branched products are formed in step I in alkaline solution. Methylol derivatives formed at the tertiary nitrogen atom are relatively unstable and occur in equilibrium with F.

As can be seen, the initial reaction mixture in step I of base condensation of U with F differs essentially from that in the reaction of DMU with F, but the quality parameters of the resulting UFRs are similar (see table).

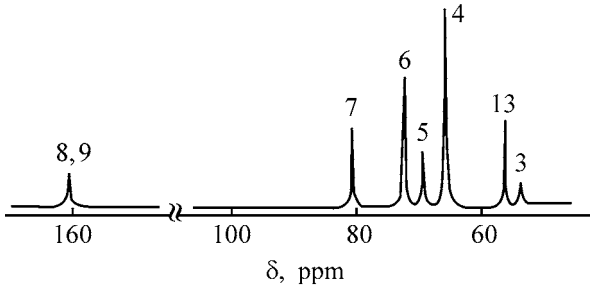

Fig. 2. ^{13}C NMR spectrum of the reaction mixture after the dissolution of DMU in formaldehyde. (δ) Chemical shift; the same for Fig. 3. Peak nos.: 8, 9, disubstituted ureas; 7, methylenemethoxy groups at the tertiary nirogen atom; 4, 5, methylol and methylene ether groups at the secondary nitrogen atom; 6, methylol groups at the tertiary nitrogen atom; and 13, 3, methylenemethoxy groups at the tertiary and secondary nitrogen atoms.

All the quality parameters of UFR samples synthesized from DMU meet the existing requirements, and the content of free F does not exceed 0.06 wt %, which is considerably lower, compared to the commercial UFR. However, the resins prepared from DMU essentially differ in fragment composition from the UFR prepared from F and U. Figure 3 shows the ^{13}C NMR spectra of the synthesized and commercial UFR samples. It is seen that all the samples contain methylene groups in the middle chain of the macromolecule (peak no. 1), methylene groups at the nitrogen atom bound to methylene ether groups (no. 5), methylol groups at the primary nitrogen atom (no. 4), methylene ether fragments (no. 7), and methylene groups in urea fragments with a free amino group (no. 9). In addition, commercial UFR contains methylene groups at the tertiary nitrogen atom (no. 2), methylene groups at the nitrogen atom with the oxy-

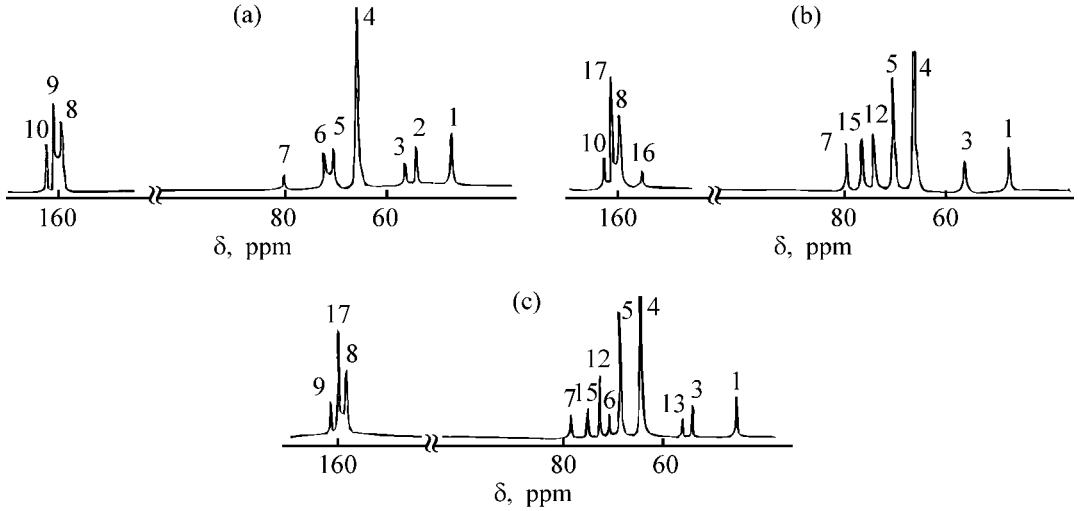

Fig. 3. ^{13}C NMR spectra of urea–formaldehyde resins. UFR: (a) commercial and (b, c) synthesized with urea added continuously and in a single portion, respectively. Peak nos.: 1, methylene groups in the middle chain of the macromolecule; 2, methylene groups at the tertiary nitrogen atom; 3, methylene groups at the nitrogen atom with the oxymethylene group; 4, methylene groups at the primary nitrogen atom; 5, methylene ether groups at the nitrogen atoms bound to the methylene group; 6, methylol groups at the tertiary nitrogen atom; 7, methylene ether fragments; 8, 9, 10, free urea and terminal amino groups; 12, 13, methylenemethoxy groups at secondary and tertiary nitrogen atoms; 15, DMU tetraethers; 16, uronic rings; and 17, trisubstituted amino groups of urea.

methylene group (no. 3), methylol groups at the tertiary nitrogen atom (no. 6), and free U (no. 10).

In contrast to the commercial UFR, urea–formaldehyde resin prepared from DMU with continuous addition of urea contains methylenemethoxy groups at the secondary and tertiary nitrogen atoms (peak nos. 12, 13), uronic rings (no. 16), and DMU tetraethers (no. 15). Urea–formaldehyde resin prepared from DMU with addition of U in a single portion differs from UFR prepared with continuous addition of U in that it contains small amounts of U (peak no. 10) and trisubstituted amino groups of urea (no. 17). These data suggest that UFR prepared from DMU has a more branched structure with a higher content of ether fragments, compared to commercial UFR. The ether fragments are responsible for the longer gelation time of the resins synthesized, compared to the commercial sample (see table), in view of the fact that the UFR stability is enhanced by etherification with alcohols [6].

CONCLUSION

Use of dimethylolurea as the starting compound allows preparation of urea–formaldehyde resins meeting the requirements of the existing standards and having a more branched structure, with the formation of tar water avoided.

Effect of Urea on the Phase Composition and Strength of Phosphogypsum Grains

L. P. Firsova

Lomonosov State University, Moscow, Russia

Received December 8, 2003; in final form, October 2006

Abstract—The effect of urea addition on the composition and strength of grains produced by pelletization of wet phosphogypsum and its subsequent drying was studied experimentally.

DOI: 10.1134/S1070427206120238

Phosphogypsum is a waste formed in manufacture of phosphoric acid in sulfuric acid processing of natural phosphorites. It is used as a secondary raw material for soil development in agriculture. The continued work on utilization of phosphogypsum in agriculture is aimed at its modification and primarily on its enrichment with bioactive micro- and macroadditives necessary for plant nutrition, including microelements (Mn, Cu, Zn, Mo, Co, B, and I), and also at granulation. It has been shown, however, that introduction of some microelements, e.g., boron in the form of boric acid, enriches the chemical composition of grains based on phosphogypsum, but strongly impairs their strength [1–4]. In this study, we examined the effect of urea additives, which enrich the composition of granules with biologically important nitrogen, on the strength properties of phosphogypsum grains.

EXPERIMENTAL

To prepare the grains, we used a phosphogypsum powder mostly composed of calcium sulfate hemihydrate formed in sulfuric acid decomposition of phosphorus-containing raw materials at Voskresensk chemical fertilizer plant. To stabilize the powder composition and, first of all, to prevent the transformation of calcium sulfate hemihydrate to the corresponding dihydrate, we successively washed the powder with a hot saturated $CaSO_4 \cdot 2H_2O$ solution and with acetone. The presence of 6.5–7.0% crystallization water in the stabilized powder indicates that it contains only a minor amount of calcium sulfate dihydrate. The porosity of the powder was about 65%. The hemihydrate $CaSO_4 \cdot 0.5H_2O$ formed 1–30-μm-long hexagonal prisms combined in druses of size 10–250 μm.

Before the beginning of granulation, the hemihydrate powder was wetted with distilled water or with aqueous solutions of urea (60–80%). Water-soluble compounds of bioactive microelements, which contained 0.1–5% boron, zinc, manganese, and molybdenum, were introduced into a part of the wetting solutions (the initial amount of these elements in the industrial phosphogypsum waste did not exceed 0.1%). The powder and a wetting solution were mixed for 1–3 min and then the wet stock was pelletized in a plate-type granulator. The l : s ratio in wetted phosphogypsum was varied within the range 0.2–0.5. For each wetting solution, we visually selected, based on the results granulation, the optimal l : s ratio, which allowed us to obtain spherical grains of diameter 1–5 mm in high yield at prescribed granulation modes. For example, the stock humidity of 27–30% was found to be the optimal for wetting solutions containing minor amounts of ammonium molybdate and zinc or manganese sulfate.

The pellets formed in granulation were dried in air at room temperature and a part of them were transferred from the granulator plate into desiccators, where they were preliminarily, before drying, kept in humid air for grain "maturation" accompanied by strengthening of the grains. During the maturation and drying, the static strength of the grains, p (kg cm^{-2}), was determined with an extensometer from the uniaxial force required for their destruction. Preliminarily, the 4–5 mm fraction was selected from the whole amount of grains of a given composition by sieving. The strength was found as an average of parallel measurements for 15–20 grains of this size and the same composition. As another characteristic of the grain strength, we

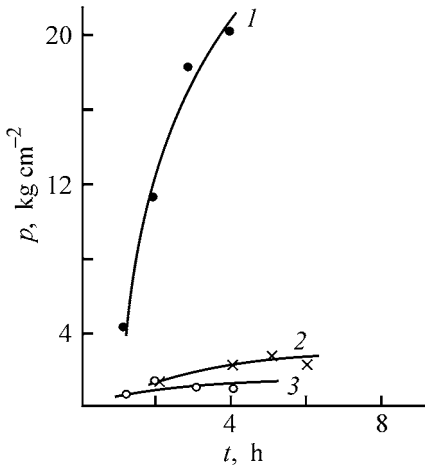

Fig. 1. Strength p of grains vs. drying time t. The grains were produced from a stock wetted with solutions of (*1*) 0.2% $MnSO_4$ and 60% urea, (*2*) 1.5% $MnSO_4$ (after maturation), and (*3*) 2% H_3BO_3 (after maturation).

determined the mass fraction of dust with a particle diameter less than 0.05 mm, which was formed in abrasion of a portion of grains in the rotating plate of the granulator.

The results obtained in determining the strength parameters of grains are presented in Fig. 1 and in the table. The phase composition of the powder formed in grain abrasion was determined by X-ray phase analysis on an ARL X-TRA (USA–Switzerland) diffractometer with a semiconductor detector. The X-ray patterns obtained for samples with and without urea are shown in Figs. 2a and 2b.

It follows from the data in Fig. 1 and the table that, in the absence of urea, some admixtures, e.g., boric acid, strongly reduce the grain strength. Introduction of urea into a wetting solution promotes strengthening of grains, including those containing zinc or manganese sulfates and ammonium molybdate.

Grain strength p in relation to the composition of a wetting solution*

Concentration of solution components, wt %		p, kg cm^{-2}	Fraction of dust, wt %
urea	microelement compounds		
0	$1.5MnSO_4$	6	1 ± 0.5
0	$1.5H_3BO_3$	1.5	3 ± 1
60	$0.4(NH_4)_2MoO_4$	20	0.8 ± 0.2
60	$0.2\mu nSO_4$	17	0.8 ± 0.2
80	$1.5ZnSO_4$	17	0.7 ± 0.2

* The strength parameters of "ripened" air-dry grains are given.

As shown previously [5, 6], recrystallization and topochemical transformation of calcium sulfate hemihydrate to dihydrate occur in wetted phosphogypsum grains. As a result of these processes, a rigid network responsible for the grain strength is formed mainly from dihydrate crystals. The redistribution of water among its hygroscopic and crystal states in the bulk of grains was confirmed by direct experiments.

The kinetics of strength gain by wetted grains, including those formed upon introduction of compounds of bioactive microelements, agrees with the variation of the fraction of crystal water and with the corresponding extent of transformation of calcium sulfate hemihydrate to the dihydrate [1–4]. When interpreting the fact that the grain strength increases under the action of urea additives in wetting solutions, we considered several hypotheses, e.g., that of formation of the $CaSO_4 \cdot 4Co(NH_2)_2$ crystalline phase. The results of our X-ray phase analysis confirm another assumption, according to which mostly anhydrous calcium sulfate is formed in the grains in the presence of urea.

Crystalline anhydrous $CaSO_4$ has a considerably higher density and hardness, compared with hydrated forms of calcium sulfate. Anhydrous $CaSO_4$, dihydrate, and hemihydrate have densities of 2900, 2600, and 2300 kg cm^{-3}, respectively. The hardness (on the mineralogical scale) is 3.5 for the anhydrite (anhydrous $CaSO_4$), 1.5 for gypsum (dihydrate $CaSO_4 \cdot 2H_2O$), and <1.5 for the hemihydrate ($CaSO_4 \cdot 0.5H_2O$). The X-ray patterns (Fig. 2a) of the powders obtained from air-dry urea-containing grains show a single main peak corresponding to the anhydrous form of $CaSO_4$. Grains formed in the absence of urea (Fig. 2b) contain hydrated forms $CaSO_4 \cdot xH_2O$, along with the anhydrite. The fractions of these forms are governed by the conditions of maturation and drying of the grains.

To elucidate the mechanism of urea action on the phase transformations in grains, additional studies of the processes of recrystallization and topochemical transitions between crystalline forms of calcium sulfate are necessary. Probably, urea changes the nucleation conditions. Being incorporated into the coordination sphere of calcium ions, urea forms complexes of the type of the known $CaSO_4 \cdot 4CO(NH_2)_2$, precludes formation of dihydrate nuclei, and promotes formation of anhydrite nuclei, including those on the sur-

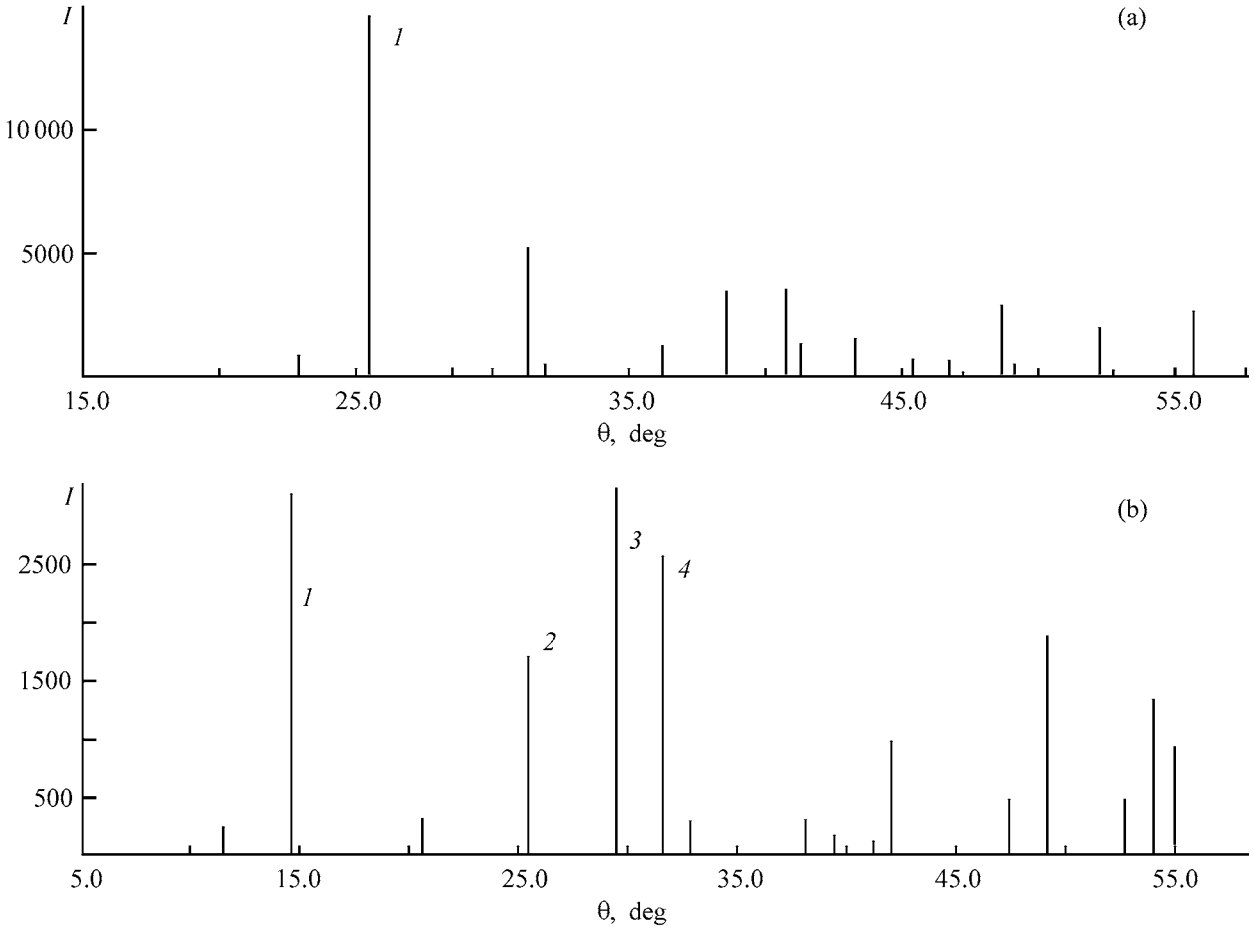

Fig. 2. X-ray patterns of phosphogypsum grains wetted with (a) urea solution and (b) solution free of urea. (*I*) Intensity and (θ) diffraction angle. (a) (*1*) peak of anhydrite. (b) (*2*) peak of anhydrite; (*1*, *3*, and *4*) peaks of $CaSO_4 \cdot xH_2O$ hydrates.

face of the existing hemihydrate crystals, which are then transformed to anhydrite crystals via a topochemical process.

CONCLUSION

It was shown experimentally that the static strength of phosphogypsum-based grains increases if urea is added to solutions used to wet phosphogypsum before granulation. In this case, the abradability (dusting) of the grains decreases. If urea is present in the wetting solutions, the grains are mostly constituted by anhydrite crystals.

Activity of Components of Melts of Binary Systems with a Common Anion

B. V. Patrov

St. Petersburg State Polytechnic University, St. Petersburg, Russia

Received September 28, 2006

Abstract—The model of regular solutions and the data on the enthalpy of mixing for binary systems with a common anion were used to calculate the activities of the components of the systems LiF–KF, NaI–CsI, NaCl–RbCl, and NaCl–$SrCl_2$.

DOI: 10.1134/S107042720612024X

Calculations of the activities of components of mutual melts from data on the surface tension have been described earlier [1]. It has been shown that activities found from surface tension data for the systems LiF–NaCl and LiF–KCl coincide with the activities calculated after Fellner [2].

In terms of the regular solution model [3], the activity coefficients of components of binary systems can be represented as

$$\ln \gamma_1 = \frac{A}{RT} x_2^2, \quad (1)$$

$$\ln \gamma_2 = \frac{A}{RT} x_1^2, \quad (2)$$

where A is the interaction parameter and x_1 and x_2 are the mole fractions of the components.

It is known that the component activities are related to the activity coefficient and the mole fraction:

$$a_1 = \gamma_1 x_1, \quad (3)$$

$$a_3 = \gamma_2 x_2, \quad (4)$$

Further we obtain

$$\ln a_1 = \ln x_1 + \frac{A}{RT} x_2^2, \quad (5)$$

$$\ln a_2 = \ln x_2 + \frac{A}{RT} x_1^2. \quad (6)$$

We express the interaction parameter A in these equations in terms of the molar enthalpy of mixing of components, ΔH^{M} (J mol^{-1}):

$$A = \frac{\Delta H^{\mathrm{M}}}{x_1 x_2}. \quad (7)$$

Experimental data on the surface tension are described by Burylev's equation for regular solutions [4]:

$$\sigma = \sigma_1 x_1 + \sigma_2 x_2 + C x_1 x_2, \quad (8)$$

here σ_1, σ_2 and x_1, x_2 are the surface tensions and mole fractions of the components of the binary systems; C is the constant of Burylev's equation.

The structural and energy variations in the systems with a common anion are more significant than those in systems with a common cation. Therefore, we studied the binary systems LiF–KF, NaI–CsI, NaCl–RbCl, and NaCl–$SrCl_2$ with a common anion. For these systems, there are experimental data on the surface tension [5, 6] and enthalpy of mixing [7], they have simple phase diagrams with an eutectic [8].

The average values of the constant C in Burylev's equation and of the interaction parameter A for the systems under study are as follows:

System	T, K	$-C$, mJ m^{-2}	$-A$, J mol^{-1}
LiF–KF	1171	91.47	19580
NaI–CsI	1013	17.25	5710
NaCl–RbCl	1083	21.09	3390
NaCl–$SrCl_2$	1167	33.34	4085

Enthalpy of mixing and the activities of the components of the systems under study

A comparison of the experimental values of the surface tension and those calculated by Burylev's equation demonstrated that the discrepancy does not exceed the measurement error (2%). Therefore, the melts under study are regular solutions, and Eqs. (1)–(7) are applicable to these melts. The calculated activities of the melt components are listed in the table.

CONCLUSIONS

1. It was shown that the common-anion salt melts under study are regular solutions.

2. It was demonstrated that, in the regular solution model, the activity coefficients of components of binary systems can be determined in terms of the interaction parameter, which can be found using experimental values of the enthalpy of mixing of the components.

3. The activities of the components of the binary systems with a common anion were calculated from the data on the surface tension and the enthalpy of mixing.

Abstract—The concentrations of particulates in dispersion media, as well as of true solutions, were analyzed by ratiometric method. The error in determination of the concentrations was estimated for the ratiometric, as well as for the conventional procedure based on the calibration connection equations.

DOI: 10.1134/S1070427206120251

Application of photometric methods entails certain technical difficulties associated with industrial (line) implementation of simple systems for analytical control over processes. The stability of the connection equations is governed by the stability and degree of monochromaticity of the light sources, by the adequacy of the set of calibration samples to the real process, and by the degree of contamination of the measuring part of the analytical system.

One of the promising ways for development of commercial photometric analyzers consists in implementation of the ratiometric principle with fixed difference of the optical bases and possible variation of the light wavelength.

Let us consider the transformation of the basic light absorption law for true solutions in the case of two optical bases and coordinated analytical signals. For light with a wavelength λ, passed through cells with different optical path lengths, we have from the light extinction law

$$I_1 = kI_0 \exp(-\varepsilon_1 L_1 c),\ I_2 = kI_0 \exp(-\varepsilon_2 L_2 c), \quad (1)$$

where I_0, I_1, and I_2 are the incident light intensity and the analytical signals on the photodetectors, respectively; ε_1 and ε_2, molecular extinction coefficients, $1\ g^{-1}\ cm^{-1}$; L_1 and L_2, optical path lengths of the cells, cm; c, concentration of the solutions, $g\ l^{-1}$; and k, optical transparency coefficient of the cells [1, 2].

For KU-13 quartz glass, the degree of contamination of the cells can be taken identical for all the optical channels with a high degree of accuracy. Then Eq. (1) can be transformed into

$$\ln(I_1/I_2) = c(\varepsilon_2 L_2 - \varepsilon_1 L_1). \quad (2)$$

From Eq. (2), c can be easily determined:

$$c = \frac{\ln(I_1/I_2)}{\varepsilon_2 L_2 - \varepsilon_1 L_1}. \quad (3)$$

For a fixed wavelength λ, $\varepsilon_1 = \varepsilon_2$, and Eq. (3) takes the form

$$c = \frac{1}{\varepsilon}\frac{\ln(I_1/I_2)}{L_2 - L_1}. \quad (4)$$

The mass extinction coefficient for an absorption line is a constant unaffected by the solution concentration and the optical path length of the cell. Passing to optical densities we rewrite Eq. (4) as

$$c = \frac{1}{\varepsilon}\frac{D_1 - D_2}{L_1 - L_2} = \frac{1}{\varepsilon}\frac{\Delta D}{\Delta L}, \quad (5)$$

where ΔD is the difference of the optical densities in the cells used, and ΔL, difference of the optical path lengths of these cells.

Thus, a knowledge of the mass extinction coefficient makes unnecessary calibration against a set of reference solutions, the more so as the difference of the optical path lengths of two cells is determined with a high accuracy, and the only contribution to the error in determination of c in Eq. (5) comes from the inaccuracy in measurement of the optical densities.

We tested the validity of Eq. (5) with solutions of copper and nickel sulfates, cobalt chloride, and colored iron complexes with thiocyanate; the optical path length of the cells was 5, 3, 2, and 1 cm. Using

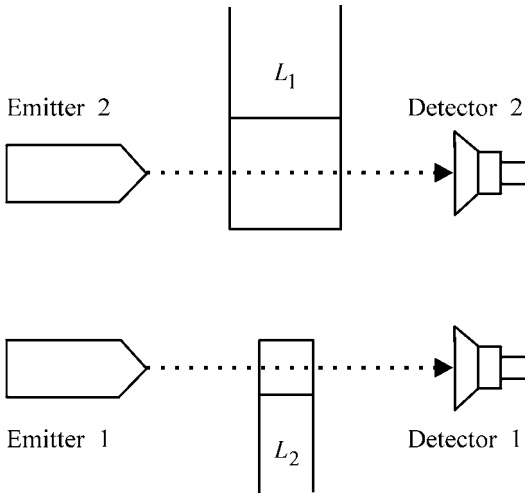
Element	λ, nm	Calculated coefficient ε, l g^{-1} cm^{-1}, for indicated optical path lengths of the cells						ε, l g^{-1} cm^{-1} [3]
		5–1	5–2	5–3	3–2	3–1	2–1	
Cu	680	0.126	0.123	0.131	0.135	0.139	0.14	0.13
Ni	405	0.89	0.98	0.89	1.02	0.95	1.03	0.9
Co	525	0.124	0.119	0.13	0.135	0.132	0.14	0.125
Fe	430	0.447	0.435	0.462	0.425	0.435	0.421	0.45

model solutions (Table 1), we determined the relative errors in determination of the concentrations by calibration connection equations and by Eq. (5). Equation (5) yielded an expression for the mass extinction coefficient

$$\varepsilon = \frac{1}{c}\frac{\Delta D}{\Delta L}. \qquad (6)$$



We compared the mass absorption coefficients ε obtained for various optical path lengths with the tabulated data for the working wavelengths (Table 2) [3].

Tables 1 and 2 suggest that the results of calculations by the ratiometric method well agree with those obtained by the conventional procedure of photometric measurements for colored solutions. The mass absorption coefficient calculated by formula (6) is identical to the tabulated value to within 7%. Hence, the error in calculation of the concentrations cannot be larger than 5%. Also, Table 2 suggests that, with increasing difference in the optical path lengths, the mass absorption coefficient calculated by the ratiometric method tends to the tabulated value.

Thus, the ratiometric scheme of photometric analysis of colored solutions is suitable for calculation of the concentrations and determination of the mass absorption coefficient of a complex mixture by Eq. (6).

The ratiometric scheme was implemented with a multibeam photometric correlator for in-line measurements. An original optical scheme (variation of two optical channels) allows implementation of the ratiometric method for flows under laboratory and industrial conditions.

With two optical cells and four independent optical spectral channels, it is possible to divide the flow under study and carry out measurements in two cells with different thicknesses at two wavelengths. The figure shows the schematic diagram of the ratiometric measurements for two cells and two wavelengths. Two cells with optical path lengths L_1 and L_2 are exposed

Ratiometric optical scheme.

to light sent by matched emitters. The photodetectors are linked by negative feedback for setting a common zero level. The power supply of the emitters has a common point for correction of the emitter–detector optopairs by the scheme suggested in [4]. The initial signal is measured with water passed through the cells. This allows estimation of the degree of contamination of the working surfaces of the cells. The output signals come to logarithmic amplifiers having a coordinated correction of the amplification coefficient. The amplified signal is the logarithm of the voltage proportional to the intensity of passed light, i.e., corresponds to the optical density. Hence, Eq. (5) can be written in terms of the amplifier output voltages:

$$c = \frac{1}{\varepsilon}\frac{\Delta D}{\Delta L} = a\frac{\Delta U}{\varepsilon}\frac{1}{\Delta L}, \qquad (7)$$

where a is the voltage scale coefficient.

CONCLUSION

The ratiometric method is suitable for analyzing the concentration of particulates in dispersion media, as well as of true solutions, and affords more efficient monitoring of processes in chemical and metallurgical industries without unnecessary sophistication of the analytical system.

Abstract—Reduction of white phosphorus in ethanol solutions on a dropping mercury electrode was studied by oscillopolarography. The effect of the type of electrolyte and potential sweep rate on the peak potential was demonstrated.

DOI: 10.1134/S1070427206120263

Use of solutions of white phosphorus has been reported [1], and, therefore, data on its redox properties are of interest.

We have noted previously [2–4] that alcohol solutions of white phosphorus are polarographically active and their polarographic waves are suitable for analytical purposes. Because polarographic studies of white phosphorus solutions are scarce, we continued our studies to elucidate the influence exerted by some process parameters, including the nature of electrolyte and potential sweep rate, on the peak potential of the oscillopolarographic curve of phosphorus.

White phosphorus was obtained by purification of a technical-grade yellow phosphorus by the known procedure: melting and subsequent treatment with 3.5% solutions of $K_2Cr_2O_7$ and H_2SO_4 [5]. The constants of the purified phosphorus (density at 20°C and melting point) were in agreement with published data (1.8 g cm^{-3} and 44°C). The method of the phosphorus preparation was changed for the sake of convenience. It was prepared in the form of cylindrical grains 3 mm in diameter and 3–5 mm long, instead of spheres [6]. For this purpose, melted phosphorus was collected into a heated pipette and charged in a glass pipe (inner diameter 3 mm) with a bottom stopper, filled with distilled water and submerged in a water bath. In the process, water was discharged from the pipe, with a 4–5-mm layer remaining. The pipe with phosphorus was cooled with a cold water to room temperature (22–23°C), and the crystallization of phosphorus was confirmed by touching its surface with a solid object. After that, the phosphorus mass was squeezed-out with a glass rod into a vessel with water, cut into 3–5-mm pieces, and stored under a layer of distilled water.

Ethanol to be used as solvent was distilled and the supporting electrolytes were of analytically pure and chemically pure grades. The polarographic measurements were performed on an O2-TsLA oscillopolarograph. The capillary used had the following characteristics: m = 0.89 mg s^{-1}, τ = 8.0 s at a mercury column height of 225 mm. The potential was measured relative to this mercury at 23 ± 1°C. The potential of this mercury (0.02 V) was measured experimentally relative to a saturated calomel electrode. Oxygen was removed from the solution by bubbling of nitrogen for 10 min. When determining the reduction current, account was taken of the current in the supporting electrolyte.

A weighed portion of white phosphorus was washed with ethanol and ether, dried in a flow of nitrogen, and transferred into a vessel (flask) for weighing and dissolution.

It has been demonstrated previously [2] that white phosphorus gives in oscillopolarograms a polarographic wave with a peak potential of –1.88 V (relative to the mercury bottom) on the background of a 0.1 M ethanol solution of LiCl (at a phosphorus concentration of 10×10^{-4} g-at l^{-1}) at a potential sweep rate of 1 V s^{-1}. A set of measurements related the nature and concentration of the supporting electrolyte to the peak potential:

Electrolyte, M	Potential, V	Electrolyte, M	Potential, V
0.05 LiCl	–1.98	0.1 $(C_2H_5)_4NI$	–1.54
0.1 LiCl	–1.88	0.1 NH_4Cl	–1.65
0.5 LiCl	–1.83	0.1 NH_4NO_3	–1.73
0.1 NH_4Cl	–1.65	0.1 NH_4CNS	–1.53
		0.1 NH_4CH_3COO	–1.80

As can be seen from these data, the nature of electrolyte strongly affects the reduction potential of white phosphorus. The reduction of white phosphorus is facilitated to the greatest extent if we use ammonium rhodanide (the least negative peak potential) as the supporting electrolyte. In our opinion, this is due to the higher adsorption of this salt on the cathode. The effect of the potential sweep rate on the peak potential is insignificant: 0.5 V s^{-1} –1.85 V, 1.0 V s^{-1} –1.88 V, and 2.0 V s^{-1} –1.92 V.

CONCLUSIONS

(1) A study of the oscillopolarographic reduction of white phosphorus in supporting electrolytes of varied nature in ethanol solutions demonstrated that the reduction of white phosphorus is facilitated to the greatest extent if ammonium rhodanide (the least negative peak potential of –1.53) is used as the supporting electrolyte.

(2) It was shown that the effect of the potential sweep rate on the peak reduction potential of white phosphorus is insignificant.

Electrochemical Methoxylation of Anethole on a Graphite Anode

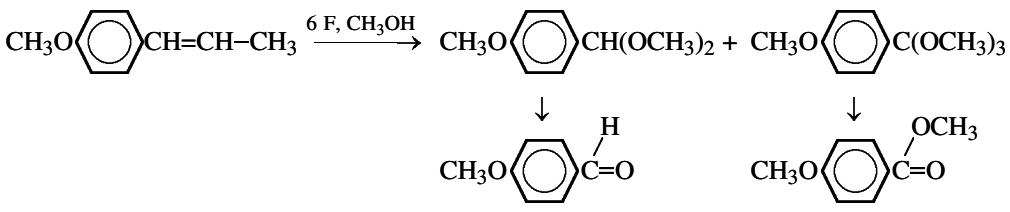
I. M. Osadchenko and A. P. Tomilov

Volgograd Research and Technological Institute of Meat-and-Milk Cattle Breeding and Animal Product Processing, Russian Academy of Agricultural Sciences, Volgograd, Russia

Received October 3, 2006

Abstract—A procedure is suggested for electrochemical methoxylation of anethole in an electrolyzer with a graphite cathode and potassium *p*-toluenesulfonate in methanol as supporting electrolyte; a mixture of two products is formed in the process.

DOI: 10.1134/S1070427206120275



Electrochemical alkoxylation of organic compounds on platinum, carbon, and graphite anodes has been reported [1]. The source of the methoxylating agent was methanol, acting as a solvent for both the organic substance and the electrolyte. Alcoholic solutions of alkalis and alcoholates were recommended for electrochemical alkoxylation of hydrocarbons, tertiary amines, and ethers. The alkoxylation pathway is strongly influenced by the concentration of the organic substrate [1]. If dimerization occurs concurrently with alkoxylation, the contribution of the former process, as a rule, increases with the concentration of the organic substrate.

The methoxylation of aryl-substituted unsaturated hydrocarbons, styrene and its derivatives, has been studied in detail; it was shown that electrochemical methoxylation of styrene gives dimethoxyphenylethane in 30% yield [1]. Anodic methoxylation of anethole (1-methoxy-4-propenylphenol) is of interest as a route to anisaldehyde (aubepine) diacetal, which can be readily converted by hydrolysis into the free aldehyde, a valuable fragrance compound and an intermediate for organic synthesis. Methoxylation of alkenylarenes, including anethole, in a methanolic solution of potassium or sodium trifluoroacetate in a diaphragmless electrolyzer with graphite electrodes was reported in [2]. However, the electrolyses may be complicated by anodic decomposition of trifluoroacetate.

The goal of this study is to simplify this process and extend its potentialities.

Previously [3] we have demonstrated the possibility in principle of electrochemical methoxylation of anethole at 55–65°C on a graphite anode in methanol, with potassium *p*-toluenesulfonate as supporting electrolyte. An advantage of this system is that the salt crystallizes and precipitates on cooling, and it can be readily separated by filtration. The filtrate is treated with 10% sulfuric acid and extracted with toluene; the extract is washed with a sodium carbonate solution and vacuum-distilled. In the process, anethole is gradually added to the electrolyte, because at low concentrations its oxidative dimerization is suppressed.

We examined the influence exerted on the methoxylation by the temperature, current density, amount of electricity, and electrolyte concentration. The best results were obtained under the following conditions: 55–65°C, anodic current density 0.02–0.05 A cm^{-2}, amount of electricity 5.5–6 F per mole of anethole, 3–5% supporting electrolyte concentration, and up to 0.4 M concentration of anethole in the electrolyte. Anisaldehyde and methyl *p*-methoxybenzoate were obtained in yields of up to 70 and 25%, respectively. The electrochemical methoxylation and hydrolysis follow the scheme

It should be noted that methyl *p*-methoxybenzoate (anisic acid methyl ester) is used as a stabilizer for fragrance compounds. As a target product we obtained a mixture of anisaldehyde and methyl *p*-methoxybenzoate. Their boiling points are close (248 and 256°C, respectively [4]), making difficult their separation by distillation.

EXPERIMENTAL

Anethole, toluene, and potassium *p*-toluenesulfonate were reagent-grade. The electrolyzer was a cylindrical glass vessel with a temperature-control jacket. Current leads and tubes for the stirrer, addition of anethole, and removal of the gas were fixed on the lid. The electrolyzer was charged with a mixture of 150 g of methanol and 3.5 g of potassium *p*-toluenesulfonate; the mixture was stirred at 55–65°C until the salt dissolved completely, and the electrolysis was performed at a current density of 0.03 A cm^{-2} (3 A current) with gradual addition of anethole (15 g in total; the running concentration did not exceed 0.4 M). The electricity was passed in an amount of 6 F per mole of anethole. After the electrolysis completion, the solution was cooled to ensure complete precipitation of the salt, the salt was separated, and the filtrate was evaporated to remove methanol, treated with 15 ml of 10% H_2SO_4, and extracted with toluene (3×20 ml). The toluene extract was washed with an aqueous solution of sodium carbonate and then distilled; toluene was distilled off at atmospheric pressure and vapor temperature of up to 110°C, and the target product, at reduced pressure (8–9 mm Hg) and vapor temperature of 120–125°C. An oily liquid (14 g) with a pleasant hawthorn odor was obtained; according to the chromatographic analysis, it contained 69% anisaldehyde and 25% methyl *p*-methoxybenzoate (total yield based on anethole 94%). The product can be used as a component of odorants, cosmetics, and aromatic food essences [5], and also as a component of agricultural chemicals for rodent and pest control [6, 7]. Anisaldehyde can be isolated from the product via bisulfite derivative. The product components were identified by gas chromatography (comparison of the retention times with those of the authentic samples).

CONCLUSION

The procedure developed for electrochemical methoxylation of anethole in methanol on a graphite anode with potassium *p*-toluenesulfonate as supporting electrolyte, yields a mixture of two valuable products, anisaldehyde and methyl *p*-methoxybenzoate and allows simplification of the process and extension of its potentialities.

Electrolytic Reduction of 2-Butyne-1,4-diol as a Route to *trans*-2-Butene-1,4-diol

E. V. Pyatnitsyna, M. M. El'chaninov, and A. P. Savost'yanov

South-Russian State Technical University (Novocherkassk Polytechnic Institute), Novocherkassk, Rostov oblast, Russia

Received December 21, 2005; in final form, September 2006

Abstract—The effect of the cathode material on the electrochemical transformations of 2-butyne-1,4-diol at atmospheric pressure was studied by chromatographic analysis. The optimal parameters of the selective synthesis of *trans*-2-butene-1,4-diol were determined.

DOI: 10.1134/S1070427206120287

Among the starting compounds for preparing polyurethanes [1], detergents, alkyd resins [2], Endosulfan insecticide, plasticizers, and drugs [3], compounds containing the required functional groups are of particular importance. Among such compounds is 2-butene-1,4-diol (BED) whose synthesis by catalytic hydrogenation of 2-butyne-1,4-diol (BYD) yields a ~90 : 10 mixture of *cis* and *trans* isomers.

With the aim to examine the effect of the *trans* isomer on the properties of SKU-90 urethane rubber, we developed in this study a procedure for regioselective synthesis of *trans*-BED.

EXPERIMENTAL

Previously *trans*-BED has been prepared from divinyl via dihalo derivatives [4, 5] and diacetoxy-2-butene [6, 7]. The drawbacks of these methods are multistep procedure, presence of isomers, and lacrimogenic properties of the intermediate dihalobutenes. Another pathway involves chemical reduction of BYD in a nitrogen atmosphere with chromium(II) sulfate [8]. However, such steps of this procedure as intermediate reduction of chromium(III) sulfate with zinc dust in a nitrogen atmosphere, followed by filtration (also in an inert atmosphere), prevent commercial implementation of the process.

To simplify the synthesis of the target product, we attempted electrochemical reduction of BYD in the presence of $CrSO_4$ on stationary solid cathodes. In this case, the reduction of $Cr_2(SO_4)_3$ to $CrSO_4$ with hydrogen liberated at the cathode occurs in aqueous solution at atmospheric pressure:

$$2Cr^{3+} + H_2^0 \longrightarrow 2Cr^{2+} + 2H^+,$$

$$HOH_2C{-}C{\equiv}C{-}CH_2OH \xrightarrow{2H^+,\ 2e} \begin{matrix} H & & CH_2OH \\ & \diagdown\!\!=\!\!\diagup & \\ HOH_2C & & H \end{matrix}$$

To evaluate the qualitative and quantitative characteristics of the BYD transformation, we examined the effect of the cathode material on the electrolytic reduction. The electrolysis conditions were as follows: catholyte temperature 20–60°C, pH 2–3, cathodic current density 0.02 A cm^{-2}, BYD concentration 1.16 M, and cromium(III) sulfate concentration 0.2 M. The amount of electricity passed was 300% of that reqiured theoretically for complete conversion of BYD into *trans*-BED.

The electrolytic reduction of BYD occurs on all the electrodes examined, but only on lead cathodes the BED yield based on BYD is reasonably high (see table), 60–70%, with 98–99% selectivity with respect to the desired product and 97–98% isomeric purity. Electrolysis on porous stainless steel provides high selectivity with respect to the desired product, but its yield based on BYD is lower. With copper, nickel,

Effect of cathode material on electrolytic reduction of BED

Cathode material	BYD conversion	BED yield based on BYD	Selectivity with respect to *trans*-BED
	%		
Smooth Cr18Ni10Ti steel	66.8	12.2	13.5
Copper	90.0	32.5	33.7
Porous Cr18Ni10Ti steel	62.5	42.5	100.0
Nickel	31.5	17.3	18.1
Lead	99.2	66.1	98.8
Zinc	72.6	15.5	23.7
Iron	64.0	17.3	18.0

zinc, and iron cathodes, both the product yield and the selectivity of the cathodic reduction were low (see table).

For the electrochemical synthesis we used a cell in the form of a cylindrical glass vessel (serving as a cathode chamber) with a temperature-control jacket. The vessel lid had opening for the anode chamber, thermometer, current lead to the cathode, and stirrer. The cathode and anode compartments were separated by a porous tubular diaphragm with a blind bottom. The anode was platinum, the anolyte was 15% sulfuric acid, and the catholyte was purified BYD in 0.2 M chromium(III) sulfate.

To purify BYD, a commercial solution of BYD was boiled with activated charcoal to remove tars. The resulting solution was evaporated in a vacuum, and BYD was crystallized from a mixture of ethyl acetate with methylene chloride.

The initial and final reaction products were analyzed with a Tsvet-104 chromatograph under the following conditions: column length 2.0 m, inside diameter 3 mm; carrier gas nitrogen; column temperature 60–200°C; support Chromaton Super 0.16–0.20 mm; stationary phase polyethylene glycol 15000. For better separation of *cis*- and *trans*-BED, the samples were acetylated by the procedure described in [9].

The reaction product was isolated as follows. After the disappearance of the initial BYD from the chromatogram, the contents of the cathode chamber were neutralized with a concentrated ammonia solution to pH 8–9, after which the precipitate of chromium(III) hydroxide was filtered off on a Büchner funnel. Water was distilled off from the filtrate in a water-jet-pump vacuum under heating on a water bath. The residue was distilled in a vacuum (10 mm Hg), and the fraction boiling at 125–127°C was collected. The yield of *trans*-BED was about 66%. The isomeric purity of the product exceeded 98%.

CONCLUSIONS

(1) Electrolytic reduction of butyne-1,4-diol on a lead cathode is a stable process at 20–60°C and cathodic current density of 10–90 A dm^{-2}.

(2) The lowest amount of the passed electricity ensuring complete reduction of butyne-1,4-diol is 2.5 A h per gram of the starting compound; the current efficiency by 2-butene-1,4-diol is 53%.

(3) Freshly prepared $Cr_2(SO_4)_3$ solution can be used repeatedly without a decrease in the yield of *trans*-2-butene-1,4-diol.

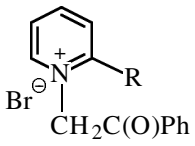
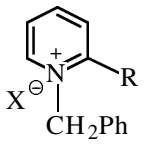
Protective Effect of 1-Benzyl-2-R-Pyridinium Halides in Steel Acid Corrosion

R. I. Yurchenko, T. N. Pilipenko, M. A. Yurchenko, and T. I. Krivovyaz



Kievskii Politekhnicheskii Institut National Technical University of Ukraine, Kiev, Ukraine

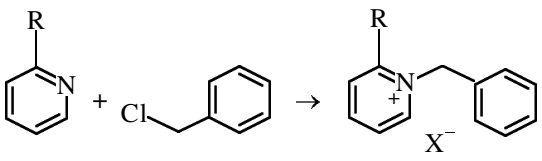
Received September 4, 2006



Abstract—The inhibiting effect of 1-benzoyl-2-R-pyridinium halides on the acid corrosion of steel was studied and compared with that of 1-phenacylmethyl-2-R-pyridinium halides.

DOI: 10.1134/S1070427206120299

Previously, using a fairly large data set, we have considered the correlation between the nature of substituent R in 1-phenacylmethyl-2-R-pyridinium bromides (**I**) and their protective properties in steel acid corrosion [1–3]. The coefficients of corrosion inhibition for these compounds range from 10 to 40 at room temperature and may reach almost 900 at 60°C [2]. We assumed that the major factor responsible for the corrosion inhibition may be adsorption of the carbonyl group of the phenacyl fragment and probably of substituents in the pyridinium ring. In order to confirm the decisive role of the carbonyl groups of **I** at elevated temperatures and to clarify the role of R, we studied protective properties of 1-benzyl-2-R-pyridinium halides (**II**, **II**') in the steel acid corrosion and compared them with the properties of 1-phenacylmethyl-2-R-pyridinium bromides (**I**) with the same R:



I

II, II'

where X = Cl (**II**), Br (**II**')

By alkylation of the corresponding pyridine derivatives with benzyl chloride, we synthesized 1-benzyl-R-pyridinium chlorides (**II**, X = Cl). The subsequent treatment with an alcoholic solution of KBr yielded **II**'

where X = Cl (**II**), R = H (**a**), NH_2 (**b**), NHCOCH=CHPh (**c**), NHCO-furyl-2 (**d**), NHCOAd-1 (**e**), NHCSNHPh (**f**); X = Br (**II**'), R = CH_3 (**a**) and NH_2 (**b**).

EXPERIMENTAL

Corrosion tests were performed by the conventional procedure [1] with samples of 08 KP steel with a working surface area of 14×10^{-4} m^2. The samples were kept in 3 M H_2SO_4 at 20°C for 24 h and at 60°C for 2 h. The efficiency of steel protection with substances synthesized at their concentration of 1×10^{-2} M was evaluated by the inhibition coefficient γ and degree of protection *Z*.

We found that, at 20°C, benzylpyridinium bromides (**II'a**, **II'b**) and the corresponding 1-phenacylmethylpyridinium bromides (**Ia**, **Ib**) differ only slightly in γ, but this difference becomes more substantial with increasing temperature. At 60°C, γ is 209 and 200 for **Ia** and **Ib** and 25.19 and 32.81 for **II'a** and **II'b**, respectively (Table 1).

A comparison of the inhibiting effects of 1-benzyl-2-R-pyridinium chlorides, bromides, and the corresponding phenacylmethylpyridinium bromides **I** showed that, at room temperature, replacement of chloride with bromide, variation of the substituent R in the 2-position of the pyridine ring, and passing from 1-benzyl-2-R-pyridinium bromides to phenacylmethylpyridinium bromides do not substantially change the protective properties of the pyridinium salts (Table 2). For example, the inhibition coefficient γ varies within the range of 6 units for compounds **II** and **II**',

Table 1. Inhibition coefficient γ and degree of protection *Z* of 08 KP steel corrosion in 3 M H_2SO_4 in the presence of 1×10^{-2} M 1-phenacylmethylpyridinium bromides (**Ia**, **Ib**) and 1-benzylpyridinium bromides (**II'a**, **II'b**)

Compound	20°C		40°C		60°C		80°C	
	γ	*Z*, %	γ	*Z*, %	γ	*Z*, %	γ	*Z*, %

Ib [1]	23.70	95.78	29.02	96.55	200.32	99.50	144.60	99.30
II'b	19.19	95.04	21.40	95.32	32.81	96.95	26.22	96.19

Table 2. Protective properties of 1-benzyl-2-R-pyridinium chlorides and the corresponding 1-phenacylmethyl-2-R-pyridinium bromides (1×10^{-2} M) for 08 KP steel in 3 M H_2SO_4

R	γ at indicated temperature °C		R	γ at indicated temperature °C	
	20	60		20	60
H	10.98* 11.30 [1]	23.00 221.20 [1]	NHCO-Furyl-2	18.36 24.30 [2]	38.33 317.15 [2]
NH_2	17.31 23.70 [1]	28.75 200.32 [1]	NHCOAd-1	17.28 26.60 [2]	51.11 432.45 [2]
NHCOCH=CHPh	23.68 32.10 [2]	33.79 365.90 [2]	NHCSNHPh	19.15 29.17 [3]	49.29 634.30 [3]

* Numerator, data for 1-benzyl-2-R-pyridinium chlorides; denominator, data for 1-phenacylmethyl-2-R-pyridinium bromides.

13 units at variation of substituent R in the series of pyridinium chlorides **IIa**–**IIf**, and 21 units for the corresponding compounds **I**. At 60°C, higher values of γ are observed for **II** and **II'**: 29–33 upon replacement of the anion (with the order of variation on replacing the anion remaining the same) and 23–51 in variation of R in the series of benzylpyridinium chlorides (**IIa**–**IIf**). The difference between the inhibiting effects of phenacylmethyl- and benzylpyridinium halides becomes especially pronounced. For compound **II'b**, i.e., it is a factor of 8 (by 167 units) lower than that for the corresponding 1-phenacylmethyl-2-aminopyridiniun bromide (**Ib**).

Thus, the data obtained confirm that high protecting effect of 1-phenacylmethylpyridinium bromides at 60°C is largely caused by carbonyl-containing groups at the nitrogen atom. Substituents R that can participate in adsorption of pyridinium salt on the steel surface also produce a noticeable, but weaker effect.

CONCLUSIONS

(1) A comparative study of the influence of 1-phenacylmethyl- and 1-benzylpyridinium halides on the steel acid corrosion showed the key role of the carbonyl group of 1-phenacylmethylpyridinium bromides in the inhibiting effect of these compounds at elevated temperatures.

(2) Functional groups of the pyridine ring are directly involved in adsorption on the metal surface and enhance the protective effect of the compounds studied.

BRIEF COMMUNICATIONS

Boric Acid

Yu. P. Perelygin and D. Yu. Chistyakov

Penza State University, Penza, Russia

Received September 12, 2006

Abstract—pH ranges of existence of boric acid and its ionic species $H_2BO_3^-$, HBO_3^{2-}, BO_3^{3-}, and $B(OH)_4^-$ in aqueous solutions are calculated using Mathcad software package.

DOI: 10.1134/S1070427206120305

Boric acid is widely used in electroplating [1], analytical chemistry [2], medicine [3], and other branches of industry [4].

Boric acid is a tribasic acid [4, 5]. The first-, second-, and third-step dissociation constants are as follows [4]:

$$K_1 = \frac{[H^+]\,[H_2BO_3^-]}{[H_3BO_3]} = 5.8 \times 10^{-10},$$

$$K_2 = \frac{[H^+]\,[HBO_3^{2-}]}{[H_2BO_3^-]} = 4 \times 10^{-13},$$

$$K_3 = \frac{[H^+]\,[BO_3^{3-}]}{[HBO_3^{3-}]} = 4 \times 10^{-14}.$$

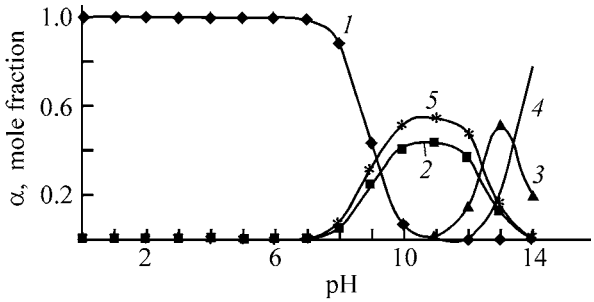
The acid properties of boric acid in aqueous solutions are caused by the liberation of protons by reaction (1) [3, 4]:

$$H_3BO_3 + H_2O \rightleftarrows [B(OH)_4^-] + H^+. \quad (1)$$

The equilibrium constant of this reaction has been reported [3] to be

$$K_4 = \frac{[H^+][B(OH)_4^-]}{[H_3BO_3]} = 7.3 \times 10^{-10}.$$

As seen, data characterizing the dissociation of boric acid are rather contradictory, which initiated this study.



The above equations and the material balance equation

$$[H_3BO_3] + [H_2BO_3^-] + [HBO_3^{2-}] + [BO_3^{3-}] + [B(OH)_4^-] = c \quad (2)$$

(boric acid concentration c was taken to be 0.1 M) were simultaneously solved using Mathcad software package at pH varied from 0 to 14 at a step of 1 pH unit (see figure). The results show that reaction (1) and the first step of dissociation of boric acid simultaneously occur in the pH range 7–14.

In a human body, pH of biological fluids does not exceed 8 [3]. In this case, it follows from our calculations that the acid–base properties of boric acid are due to the simultaneously occurring first-step dissociation and reaction (1) [at pH ≤8, fractions of $H_2BO_3^-$ and $B(OH)_4^-$ are below 0.06].

Boric acid exists as H_3BO_3 in the nickel-plating electrolyte (pH 4.5–5.5 [1]), and as H_3BO_3 and also as $H_2BO_3^-$ and $B(OH)_4^-$ species in buffer solutions at pH from 8.2 to 10 [2].

Calculated concentrations of boric acid and its ionic species, α, vs. pH: (*1*) H_3BO_3, (*2*) $H_2BO_3^-$, (*3*) HBO_3^{2-}, (*4*) BO_3^{3-}, and (*5*) $B(OH)_4^-$.

Academician Mikhail Grigor'evich Voronkov

DOI: 10.1134/S1070427206120317

On December, 6, 2006, Academician Mikhail Grigor'evich Voronkov is 85. He is the oldest active author of *Zhurnal Prikladnoi Khimii* (Russian Journal of Applied Chemistry). His first paper appeared in *Zhurnal Prikladnoi Khimii* 55 years ago (1951, 24, 93–94). Since that time, he has published 117 papers in the journal.

Academician Voronkov is an outstanding Russian scientist, well-known in the world. He heads one of Russia's leading scientific schools, which is concerned with basic research in the field of chemistry of organic derivatives of tetracoordinated hypo- and hypervalent silicon, germanium, and tin; and halogen-substituted thiols, hemdithiols, thioketones, and thiiranes containing the S–C–C–X group (X = F, Cl, Br, I). The success of these studies is favored by the broad and encyclopedic scientific knowledge of Voronkov and by his fantastic working capacity.

According to the site www.scientific.ru/whoiswho, he occupies now the first place among all Russian chemists-scientists in citation in the world's scientific literature (data of 1986–2004). His name is included in the reference book Leading Scientists of the World, published by the International Biographic Centre of Cambridge in 2006.

Voronkov is a member of a number of foreign academies and scientific societies, honorary professor of two foreign universities, and member of the editorial boards of four foreign chemical journals and *Russian Zhurnal Prikladnoi Khimii*.

Among Voronkov's achievements as a scientist is the formation of numerous areas of research in organoelement chemistry.

Particularly well-known in the USSR and abroad is his basic research in the field of chemistry, physical chemistry, biology and pharmacology of silatranes, germatranes, and their analogues (established by him), and other compounds of hypervalent silicon (draconoids, derivatives of lactams, amides, azoles, hydrazides of carboxylic acids, etc.). For his studies in the field of chemistry of organic derivatives of pentacoordinated silicon, Voronkov was awarded a State Prize of the Russian Federation in 1997. His studies

in the chemistry of silatranes and germatranes, commenced in 1962, generated interest among world's scientists in mid-1970s and have been carried in many countries (USA, Germany, France, Japan, Hungary, Poland, China, Israel, Mongolia, and others) since that time.

In recent years, Voronkov's attention was attracted by organosilicon compounds containing Si–F bonds and especially those of the intracomplex type. In particular, an original reaction of protolysis of the Si–C bond in phenylfluorosilane and new transformations of tetrafluorosilane have been studied. These reactions initiated an extensive study of silatrane analogues, quasi-silatranes.

He also paid a considerable attention to *Q*-hydrometallatranes exhibiting a high biological activity.

Methods for low-temperature generation of compounds of hypovalent (tricoordinated) silicon, silanones, have been developed under Voronkov's supervision. The generation of silanones formed the basis of his theory of formation and destruction of siloxane structures.

He was the first to carry out, in the middle of the last century, fundamental studies of heterolytic reactions of splitting of the Si–O–Si group by widely diverse reagents, which demonstrated that this group is substantially more reactive than the C–O–C group.

A prominent place in his studies was occupied by organic derivatives of elements belonging to the silicon subgroup, germanium and tin. Intracomplex organic compounds of pentacoordinated germanium, 1-organylgermatranes, were for the first time synthesized under Voronkov's supervision and their physicochemical properties and biological activity have been studied. A valuable contribution to organotin chemistry was made by studies of Voronkov's school, devoted to compounds containing a stanthiane bond (S–N), derivatives of hypervalent tin, homolytic reactions of addition to alkenylstannanes, and possible use of organotin compounds in organic synthesis.

At the very beginning of his scientific activities, Voronkov was attracted by reactions of organic compounds with elementary sulfur. One of these reactions (that of sulfur with arylhalogenalkanes and -alkenes) was named for him. In the 1960s–1970s, he developed a new area in organic chemistry of sulfur: high-temperature reactions of thiyl radicals.

In recent years, difficultly accessible classes of organic compounds of sulfur: sulfur-containing macroheterocycles, thioaldehydes and thioketones, α-halogen-thioketones, α-halogen-hemdithiols, dithiirane derivatives, condensed heterocyclic systems, 1,2-dithiolene-3-thiones, etc. have become objects of studies supervised by Voronkov.

Together with making a fundamental contribution to theoretical and synthetic chemistry, Voronkov's studies have resulted in the development of numerous practically valuable materials and technological processes (organosilicon coatings for various purposes, new materials for microelectronics, polysiloxane sorbents, ion-exchangers and complexites, additives to lubricant oils, aqueous quenching medium, medicinals of a new generation, original means of chemicalization of agriculture, etc.).

The first biologically active organic compounds of hypervalent silicon, silatrane, have found application in medicine and agriculture (these data are summarized in a book by Voronkov and V.P. Baryshok *Silatrany v medtsine i sel'skom khozyaistve* (Silatranes in Medicine and Agriculture) (2005).

Successful studies carried out by the large research team headed by Voronkov in the field of bioorganosilicon chemistry yielded organosilicon compounds exerting adaptogenic, carcinostatic, sedative, immunomodulating, immunodepressing, growth-controlling, and other kinds of influence on living organisms. A number of original medicinals having no analogues in the world's medicine (Ferakril, Argakril, Atsizol, Trekrezan, Silokast, Silimin, Kobazol, etc.) have been created under Mikhail Grigor'evich's supervision. Also, polymeric biocide coatings protecting various materials (metals, optical glass, wood, paper, etc.) from biocorrosion and biogrowth have been developed on the basis of biologically active organosilicon monomers.

In the late 1970s, an additional new original area of research in chemistry of organic derivatives of silicon, carbofunctional polyorganyl sesquioxanes, which are effective sorbents, ion-exchangers, and complexites, was opened-up under Voronkov's supervision. A number of these compounds have been introduced into analytical practice for high-precision and high-sensitivity determination of noble and rare metals in ores and minerals. These compounds have also been used in cigarette filters for deep purification of tobacco smoke to remove toxic and carcinogenic elements, deep purification of industrial wastewater and solid wastes to remove highly toxic elements, sorption filters, methods for recovery of precious metals from industrial waste, etc.

Foundations of the following new research areas have been laid under Voronkov's supervision:

(1) Polyfunctional organoelement silicon compounds, precursors of thin-film structures for modern technology of production of articles for micro- and optoelectronics and of special and superhard coatings;

(2) Polyunsaturated macrolinear and macrocyclic silicanes, promising precursors of silicon carbide fibers and ceramics.

All the above-mentioned Voronkov's studies are extensively cited in domestic and international literature. The importance of the research conducted by his scientific school is also indicated by the fact that virtually all of its pioneering scientific areas in the field of organosilicon chemistry have found followers among scientists both in our country and abroad.

During 64 years of scientific activities, Voronkov published 52 monographs (15 of these published in translation in the United States, Great Britain, Germany, Japan, Israel, Romania, Poland). These publications include fundamental monographs *Siloksanovaya svyaz'* (Siloxane Bond), *Electronnoe stroenie organicheskikh soedinenii kremniya, germaniya i olova* (Electronic Structure of Organic Compounds of Sili-

con, Germany, and Tin), a capital three-volume work *Geterosiloksany* (Heterosiloxanes), all published in Russian and English, and also a monograph *Kremnii i Zhizn'* (Silicon and Living), which proclaimed the birth of a new area of silicon chemistry, bioorganosilicon chemistry, 149 reviews and chapters in books, and about 2780 scientific articles. Under his supervision, 131 candidate dissertations were prepared and defended, 33 of his pupils became doctors of science.

All the studies supervised by Voronkov are being carried out in close cooperation with research institutes, higher school institutions, and specialized plants and organizations of our country, as well as with scientists from former CIS and other countries. Most of these studies are being carried out in the framework of creative, integration, and international projects and contracts. In recent years, research of this kind has been conducted in the framework of INTAS international project on chemistry of compounds of hypervalent silicon and of the integration project with the Institute of Inorganic Chemistry, Siberian Division, Russian Academy of Sciences (Novosibirsk); Institute of Chemical Kinetics and Combustion, Siberian Division, Russian Academy of Sciences (Novosibirsk); and Institute of Silicate Chemistry, Russian Academy of Sciences (St. Petersburg). These studies are devoted to multifunctional organoelement silicon compounds as syntones and reagents for microelectronic technologies. The biological activity of organoelement compounds is studied in cooperation with medical institutes: Military Medical Academy, 1st Central Military Medical Institute, Ministry of Defense of the Russian Federation (St. Petersburg), State Hematological Center, Russian Academy of Medical Sciences (Moscow), Institute of Traumatology and Orthopedics, Siberian Division, Russian Academy of Medical Sciences, and Institute of Reconstructive and Regenerating Surgery, Eastern-Siberian Scientific Center, Siberian Division, Russian Academy of Medical Sciences (Irkutsk), Institute of Clinical Immunology, Russian Academy of Medical Sciences (Novosibirsk), Siberian Institute of Physiology and Biology of Plants, Siberian Division, Russian Academy of Sciences (Irkutsk), and others. This integration enables exhaustive solution of numerous problems of theory and application of practically valuable organosilicon and other heteroatomic compounds created under Voronkov's supervision.

For his studies in the field of organic derivatives of silicon and their practical use, Voronkov was awarded a State Prize of the Russian Federation (1997), State Prize of the Ukrainian SSR (1981), Prize of the Council of Ministers of the USSR (1991), title of an Honorary Chemist of the USSR (1983), Nesmeyanov Prize of the Russian Academy of Sciences (2003), Kosta medal (2006) instituted by the Russian Chemical Society, Moscow State University, and InterBioScreen international foundation. For his contribution to the development of science and industry of Eastern Siberia, Voronkov was made an honorary citizen of Irkutsk oblast (2002).

For his scientific achievements and military service during the Great Patriotic War, Voronkov was awarded Order of Merit for the Fatherland (4th class), Order of Great Patriotic War (2nd class), Order of Red Banner of Labor, Order of People's Friendship, and 20 medals.

Despite his extreme old age and full loss of sight (in the last 25 years), Voronkov continues his active scientific activities and heads a large team of scientists in two institutes of the Russian Academy of Sciences: Irkutsk Institute of Chemistry, Siberian Division, and Institute of Silicate Chemistry.

OBITUARY

In Commemoration of Mikhail Mikhailovich Shul'ts

DOI: 10.1134/S1070427206120329

Mikhail Mikhailovich Shul'ts, Academician of the Russian Academy of Sciences, Hero of Socialist Labor, and known scientist in the field of physical chemistry, thermodynamics, chemistry and electrochemistry of glass, and membrane electrochemistry, passed away on October 9, 2006.

Shul'ts headed one of the best known Russian chemical schools. Forty-five scientists defended candidate dissertations prepared under his supervision. Six persons, members of his school, became doctors, and one of these was elected a corresponding member of the Academy of Sciences.

Shul'ts entered the chemical faculty of Leningrad State University in 1937, volunteered to the field forces with the advent of the Great Patriotic War, demobilized in 1944, and graduated from the faculty in 1947 to become a postgraduate student. Boris Petrovich Nikol'skii, an outstanding scientist and, later, an academician, was his supervisor. Shul'ts became the principal continuer of Nikol'skii's research work.

Shul'ts spent most of his life and conducted a major part of his studies at St. Petersburg (Leningrad) State University, where he successively worked as an assistant, docent, professor of the chair of glass electrochemistry at the Research Institute of Chemistry, professor of the chair of physical chemistry, and, in recent years, professor of the chair of thermodynamics and kinetics. In 1967–1972, he was dean of the chemical faculty. In 2006, he was elected honorary professor of St. Petersburg State University.

The main scientific achievements of Shul'ts at the University are associated with studies of the electrode properties of glasses and with the solution of a wide variety of theoretical and practical problems of ionometry, and especially pH-metry. Shul'ts suggested a rigorous proof of the metallic functions of the glass electrode and elucidated the mechanism of ion transport in membranes of varied nature. A set of glasses for pH-metry, glasses with metallic electrode functions, and glass redox electrodes were developed

under his supervision. The results of his studies in this area are exceedingly widely used in numerous branches of industry, agriculture, medicine, and scientific research.

Another important area of research conducted by Shul'ts at the University consisted in that he studied, together with professor A.V. Stronkin, fundamental problems of the thermodynamic theory of heterogeneous systems. Here, particular emphasis should be placed on the fact that the Le Chatelier–Brown principle was refined, thermodynamic laws of phase and chemical transformations in closed systems were established, and methods for analysis of complex systems forming solid solutions were developed.

After having passed to Grebenshchikov Institute of Silicate Chemistry (1972), Academy of Sciences of the USSR, to become director of this institute (till 1998), Shul'ts continued intensive scientific activities, remaining a professor at the chemical faculty of St. Petersburg State University, in already the third area of research, studies of the structure and thermodynamic properties of glasses and oxide melts. He

created and efficiently supervised the activities of a leading scientific school "Thermodynamics and Chemical Structure of Glasses and Oxide Melts."

Shul'ts's was twice awarded State Prizes of the USSR (for the theory of the glass electrode in 1973, and for studies of the ion transport in biological and model membranes in 1986), two times received the First University Prize, and was awarded the Mendeleev Prize of the St. Petersburg Government and Grebenshchikov Prize of the Russian Academy of Sciences.

His intensive research work was combined with pedagogical activities: Shul'ts delivered a general course of lectures on physical chemistry and special courses at the University, and minor special courses at the Technological University. At St. Petersburg State University and at the Institute of Silicate Chemistry, he supervised the work of postgraduate students and consulted doctoral candidates. The list of his research works comprises more than 500 items, including monographs, textbooks, and subject collections of works, edited by him.

The life and creative activities of Shul'ts are represented most completely in two brochures from the series Bibliografiya uchenykh RAN (Bibliography of Scientists Working at the Russian Academy of Sciences).[1]

Numerous pupils, comrades, friends, and colleagues of Shul'ts grieve over the loss of teacher, supervisor, and friend. His works will be in demand for many years to come.

A.G. Morachevskii, N.A. Smirnova, A.A. Belyustin, and I.S. Ivanovskaya

OBITUARY

In Commemoration of Vladimir Aleksandrovich Proskuryakov

DOI: 10.1134/S1070427206120330

Vladimir Aleksandrovich Proskuryakov, a known scientist, doctor of technical science, corresponding member of the Russian Academy of Education, professor of St. Petersburg State Technological Institute (Technical University), passed away on October 30, 2006.

All Proskuryakov's scientific and pedagogical activities had been associated with the development of science in the field of processing on natural fuels (shale, oil, coal) and with training of engineering and scientific cadre both in our country and abroad.

Proskuryakov was born on June 21, 1919, in Petrograd. In 1937, he entered the Lensovet Technological Institute in Leningrad. In 1941, he volunteered for military service to go to the frontline and served in the field force until the end of the war. He was severely wounded at Nevskii pyatachok bridge-head. In 1946, he continued his studies at the Lensovet Technological Institute and, having graduated from the institute in 1947, remained there as a postgraduate student. After defending his candidate dissertation in 1951, he was assigned to work as a lecturer at the chair of organic chemistry.

In 1959, Proskuryakov was elected head of the chair of pyrogenetic processes and held this position during 30 years. Owing to his organizational talent and to a clear target vision, Proskuryakov managed to transform a minor chair into a leading group of pedagogues and scientists and created a new specialty of basic organic and petrochemical synthesis. In 1964, the chair was officially named the chair of technology of petro- and coal-chemical industries.

Proskuryakov paid a considerable attention to training of scientific cadre: in 1967, the degree of doctor of technical science was conferred on him on the basis of a series of his works. In the 1970s–1980s, the chair had up to 30 postgraduate students. Ten lecturers and research workers of the chair defended their doctoral dissertations.

In 1965, Proskuryakov was appointed pro-rector of education, and in 1975, he became rector of the Institute. During this period of time, he worked hard to improve the education level at the institute, to supply the institute with modern equipment and computers, and to open-up new promising specialties. Thanks to his high scientific and pedagogical authority, Proskuryakov was elected a corresponding member of the Russian Academy of Education in 1974. He headed during 15 years the Leningrad department of Znanie (Knowledge) Society, was the chairman of the Council of rectors of Leningrad, and served as an expert and member of presidium of the Higher Attestation Commission.

During many years, Proskuryakov headed the Scientific council of the Technological Institute, was the chairman of the specialized council for conferment of doctoral degrees, actively worked in the methodological council of the institute and its scientific-technological commission, and was deputy Editor-in-chief of *Zhurnal Prikladnoi Khimii* (*Russian Journal of Applied Chemistry*) and a member of the editorial boards of the journals *Khimiya Tverdogo Topliva* (*Chemistry of Solid Fuel*) and *Goryuchie Slantsy* (*Oil Shale, Academy of Sciences of Estonia*).

Proskuryakov was a pioneer in the field of shale dressing and chemical utilization of the organic component of shale: kerogen. The technology he developed was used by the shale-dressing shop at Slantsy plant.

A prominent contribution to science and technology was made by the laboratory of chemistry and technology of processing of Kansk-Achinsk coal, headed by Proskuryakov.

Rather fruitful was the series of Proskuryakov's studies of oxidation of peat, shale, hydrocarbons, and heteroatomic components of oil. He performed original works devoted to purification of water to remove oil and oil products. These studies are well known to specialists in our country and abroad.

The results of Proskuryakov's scientific activities in the field of chemical processing of combustible fossils were reported in more than 500 scientific publications, including four monographs. He received more than 100 Inventor's certificates and patents. The textbook *Khimiya nefti i gasa* (Chemistry of Oil and Natural Gas) ran into three editions and was translated into French, Spanish, and Arabic.

For his meritorious pedagogical, scientific, administrative, and military services, Proskuryakov was awarded six orders and numerous medals of the USSR, and also orders of the Korean Peoples Democratic Republic, Czechoslovakia, and Bulgaria.

Proskuryakov was elected honorary doctor of Mersenburg and Vesprem technical universities.

He was a prominent scientist and excellent man. The memory of Vladimir Aleksandrovich Proskuryakov will be forever preserved in the hearts of his numerous colleagues, pupils, and all those who knew him.

The scientific and technological community grieves over the death of Vladimir Aleksandrovich Proskuryakov. He was a well-wishing and sympathetic person and excellent family man. He came in due time to help anybody, from a student to a professor. His activities earned well-deserved deep respect of students, postgraduate students, lecturers, and graduates of the Institute.

The Editorial board and the editorial staff of our journal present their deep condolences to relatives and friends of Vladimir Aleksandrovich Proskuryakov

BOOK REVIEWS

Tarasov, A.V., Besser, A.D., and Mal'tsev, V.I., *Metallurgicheskaya pererabotka vtorichnogo tsinkovogo syr'ya* (Metallurgical Processing of Secondary Zinc Raw Materials), Tarasov, A.V., Ed.,

Moscow: Gintsvetmet, 2004, 219 pp.

DOI: 10.1134/S1070427206120342

At present, processing of secondary raw materials is an important source for manufacture of a number of nonferrous metals, including lead and zinc. The annual world's consumption of zinc is about 10 million tons and zinc is among nonferrous metals that are in the highest demand by many branches of industry. The structure of zinc consumption in economically developed countries is rather stable, about 48% of the metal manufactured is consumed for anticorrosive coatings for steel and iron rolled products, and about 34%, for manufacture of zinc-based construction and cast alloys (brasses, alloys for precise casting). Thus, zinc plating and manufacture of alloys consume most part of zinc. Various technological schemes for utilization of zinc-containing materials have been developed and are used in a number of countries. These technologies provide a rather high recovery of zinc and accompanying components to give commercial products.

A.V. Tarasov's monograph considers in detail, for the first time in the domestic scientific-technological literature, the problem of processing of secondary zinc-containing materials. The book comprises a preface, introduction, ten chapters, conclusion, and bibliographic list for the whole monograph. In a brief preface (p. 5), the authors note the necessity for creating in Russia a new branch of industry for manufacture of zinc from secondary raw materials. The introduction (pp. 6–10) considers specific applications of zinc in the industry and ways of accumulation of secondary zinc-containing raw materials and notes the economical and ecological advantages of manufacture of secondary zinc, compared with its production from ores.

The first chapter (pp. 11–20) analyzes the present-day state of manufacture and use of zinc in the world. According to the International Lead and Zinc Study Group (ILZSG), the world's production of zinc steadily increased during the last ten years: from 7123 thousand tons in 1994 to 9849 thousand tons in 2003. A considerable increase was observed during this period of time in the Peoples' Republic of China, and the manufacture of zinc also increased in a number of other countries (Australia, Kazakhstan, Mexico, and Russia). According to the prognosis by ILZSG, the use of zinc for coating of steel rolled products and construction articles will grow in the first decade of the XXI century in machine-building and construction industries, which will stimulate further rise in consumption of zinc. In some countries, a considerable amount of zinc is used in manufacture of dry power cells. The second chapter (pp. 20–40) is completely devoted to characterization of secondary raw materials. These are mostly composed of wastes formed in manufacture of commercial products from zinc or zinc-containing materials and consumers' wastes, which are widely diverse and allow different degrees of zinc recovery.

The third chapter (pp. 41–53) summarizes the evidence concerning processing of steel with low content of zinc. Preparation of waste zinc-plated steel for utilization and various ways to recover zinc from wastes (dezincing) are considered. The fourth chapter (pp. 54–119) considers methods for processing of dusts from electric-arc furnaces (EAF), in which zinc-plated steels are remelted. In most countries, EAF dusts are regarded as harmful wastes and should be either processed or stabilized (converted into a glassy state) and then buried. The already used or promising technological schemes for dust processing (content of zinc in the starting dust of up to 18%) are described. These techniques include both pyrometallurgical and hydrometallurgical methods. There is good reason to believe that the EAF dusts could become the most important source of secondary zinc in the near future.

The fifth chapter (pp. 122–138) discusses processing of wastes with high content of zinc and low content of iron. Wastes of this kind are characteristic of plants using zinc as a material in the technological cycle of manufacture of commercial products. The recycling of such a secondary raw material is eco-

nomically feasible. The sixth chapter (pp. 139–152) is devoted to utilization of zinc-containing wastes in nonferrous metallurgy and chemical industry. In the seventh chapter (pp. 153–167), the authors discuss the possibility of joint processing of zinc concentrates produced from ores and secondary zinc-containing materials.

The very small eighth chapter (pp. 168–172) contains evidence concerning the liquation and liquation-chemical refining of raw zinc and the distillation and rectification techniques as finishing methods for metal purification. The ninth chapter (pp. 173–194) is devoted to processing of a specific type of secondary zinc-containing materials, dry power cells. In Asian countries, up to 60% of the whole amount of consumed zinc goes to manufacture of dry power cells (~11% in Europe and ~19% in the United States). The tenth chapter (pp. 195–199) discusses the ecological and social aspects of processing of secondary zinc-containing raw materials. In accordance with the classification in force in the Russian Federation, zinc and its compounds belong, as regards the toxicological effect on humans, to moderately hazardous substances (III class of hazard). In the conclusion (pp. 200–206), the authors present reference data on the output capacities of plants for manufacture of zinc from ores and secondary raw materials in various regions and countries. Three countries, China, Canada, and Japan, give 34% of the whole amount of zinc manufactured in the world. Particularly productive are the facilities for manufacture of primary zinc in China.

The bibliographic list (pp. 207–219) contains 196 references, of which 75% are references to foreign publications of the last decade. Many of these publications are hardly accessible to a wide audience of readers. On the whole, the monograph by Tarasov and co-authors has a descriptive nature, the authors virtually do not comment the material presented and give no assessments or recommendations. Nevertheless, the informational and educational value of the book is very high. The monograph is of indubitable interest; it can be of use for a wide audience of specialists and also can be recommended as a textbook in training of engineers-metallurgists of the corresponding specialization.
