With the anion exchanger based on Sh : PMVP, the sorption proceeds much better, which possibly due to formation of more stable surface complexes Pd–N_{Py}. The degree of recovery is as high as 74 and 95% (pH 3.1) for anion exchangers based on Sh : PEI : GMA and Sh : PMVP, respectively.

The sorption of palladium(II) ions in a weakly acid medium involves complex $PdCl_4^{2-}$ ions and aqua chloride $Pd(H_2O)Cl_3^-$ anions [14], which interact via anion exchange and coordination interaction with the deprotonated functional groups of the anion exchanger.

It may be assumed that, in a strongly acidic medium, protonated amino groups sorb complex anions on the shungite surface mostly by the ion-exchange mechanism, whereas the complexation predominates in a neutral medium. The presence of functional groups with donor atoms of nitrogen and oxygen in the modified shungites determines their chemical-analytical characteristics and ability to recover complex anions of palladium(II).

The pH value corresponding to 50% recovery of metal ions (pH_{50}) characterizes the selectivity of a sorbent. It may be assumed that pH_{50} lies within a rather narrow range for the anion exchangers under study and indicates that complex ions of palladium(II) are firmly fixed on the sorbents studied.

A quantitative measure of the applicability of a sorbent to concentration of an ion is the distribution coefficient *D* (ml g^{-1}) of this ion. Table 2 lists values of *D* and the sorption capacities of the anion exchangers for sets of experiments with different solution acidities. It can be seen that the sorbents suggested are rather efficient, with distribution coefficients reaching values of 10^3–10^5 ml g^{-1}.

The kinetic properties of sorbents are commonly characterized by determining the time in which the equilibrium is attained at a certain ratio of the volume of a solution being analyzed to the mass of a sorbent at constant temperature and concentration of the supporting electrolyte. It was found that the equilibrium in the distribution of metal ions between sorbents and solution is attained in 2 h for the anion exchanger based on Sh : PMVP, in 3 h for the commercial sor-

bent, and is not reached at all during the time of the experiment for the anion exchanger based on Sh : PEI : GMA. The degree of recovery of ion complex Pd(II) is high (>90%) for the sorbents under study and as low as 58% for the commercial anion exchanger AN-31. (Fig. 2). The results obtained indicate that the surface characteristics of the sorbents govern the kinetic parameters of the process. The amount of sorbed chloride complexes of palladium(II) decreases, under comparable conditions, in the order Sh : MVP > Sh : PEI : GMA > AN-31. The high affinity of the modified shungite containing pyridine nitrogen for Pd^{2+} ions predetermines the kinetic and sorption parameters of the process. Even though the anion exchanger based on Sh : PEI : GMA and the commercial AN-31 have the same ethylenediamine fragments, they markedly differ in sorption activity. This is probably due to the fact that metal ions may interact on the surface of chemically modified carbon sorbents both with functional groups of a grafted ligand and with residual groups on the surface of the material. The mechanism of sorption of platinum metal ions necessary involves their interaction with the π-conjugated electron system of the carbon matrix, and the process rate may be slow.

A necessary factor that determines the possibility of using a sorbent for concentration of palladium(II) complex ions in analysis of real objects is the selectivity of recovery in the presence of macrocomponents. In practice, it is frequently necessary to recover microscopic amounts of platinum metals from multicomponent systems containing considerable amounts of nonprecious metals. Because chlorides and sulfates of nonferrous metals are, as a rule, the main components of industrial solutions, the selectivity of new sorption materials with respect to Pd(II) chloride complexes on their background invites a special study. In this context, experiments on concentration of Pd(II) in model solutions containing cobalt chloride and sulfates of copper and nickel were carried out (Table 3). It was found that the highest selectivity is observed for the anion exchanger based on Sh : MVP, which sorbs 83–86% of palladium(II) ions at 10–100 times

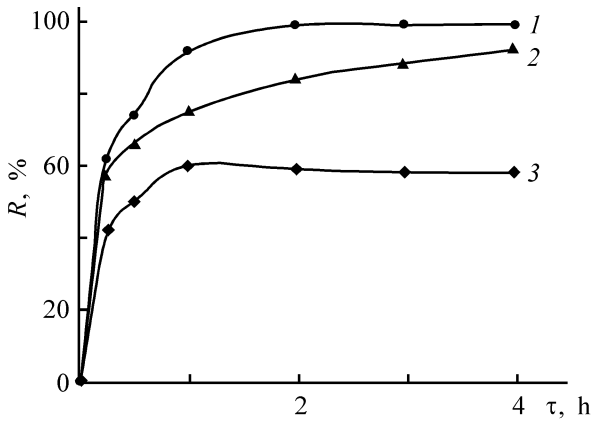

Fig. 2. Degree of recovery of palladium(II) chloride complexes, R, with anionites vs. the process duration τ. $c_{Pd^{2+}}$ = 11 mg l^{-1}, V_{el} = 50 ml, m_s = 0.5 g, 0.5 M HCl, 20°C. Anionite: (*1*) Sh : MVP, (*2*) Sh : PEI : GMA, and (*3*) AN-31.

higher content of nonferrous metals in solution. Because platinum metal ions tend to coordinate donor nitrogen atoms and form more stable complexes as compared with ions of transition metals, the sorption will be quantitative in a more acidic medium, which creates prerequisites for separation of ions of platinum metals from other ions.

The desorption of palladium(II) ions with various eluents was studied under static conditions. It was found that a minor amount of Pd(II) ions (5%) is desorbed upon treatment with water, 10–20% is eluted with a 0.5–1.0 M HCl solution, and more than 50%, with a solution of thiourea in 1 M HCl. A similar type of desorption of palladium(II) ions has been observed in treatment of activated carbons and carbon fabrics [15], which is caused by the complexity of the mechanism of sorption of palladium(II) ions, their uptake by different active centers, and various other factors: physical sorption (part desorbed by water), anion exchange (displaced by HCl solutions), formation of strong donor–acceptor bonds with the carbon matrix or functional groups, and reduction to the metallic state. The degree of desorption is 65% for a shungite containing grafted groups of PMVP at a concentration of the eluting solution of 5 wt % and more (Fig. 3). For a polyfunctional anion exchanger based on Sh : PEI : GMA, the desorption is enhanced as the concentration of thiourea increases.

CONCLUSIONS

(1) The optimal conditions of recovery of palladium(II) chloride complexes on shungites with grafted ethylenediamine and pyridine groups were found.

(2) It was shown that the structure of functional groups of anion exchangers is the major factor affecting the process. The sorption activity of the anion exchangers studied substantially exceeds that of the commercial AN-31.

(3) The selectivity of a modified shungite containing pyridine nitrogen enables efficient recovery of palladium(II) ions in the presence of concomitant elements, whose content in solution exceeds by several orders of magnitude that of the target component.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption Recovery of Sulfate Complexes of Iridium on Hydrated Zirconium Dioxide

Abstract—The sorption on a hydrated zirconium(IV) dioxide from solutions of trinuclear iridium(IV,IV,IV) and iridium(III,III,IV) oxosulfates was studied. The effect of temperature, sorbent grain size, concentration of sulfate complexes of iridium in solution, and acidity of the medium on the sorption recovery was considered.

DOI: 10.1134/S1070427206040112

In recent decades, an intense interest has been aroused in development of methods for concentration and separation of microscopic amounts of platinum metals (PM) with the use of oxohydrates of transition and main-group metals: iron, aluminum, zirconium, titanium, etc. [1, 2].

A particular place among sorbents of this kind is occupied by hydrated zirconium hydroxide (HZH), for which reproducible synthesis conditions yielding sorbents with stable ion-exchange properties have been well developed [3].

Previously, a set of studies has been carried out, concerned with sorption of PM chloro complexes on HZH [4–7], including iridium(III) and iridium(IV) chloro complexes from chloride and sulfate-chloride solutions [8, 9]. It has been shown that HZH selectively and irreversibly sorbs microscopic amounts of PM from acid solutions by the anion-exchange mechanism. In the course of time, ligand-exchange transformations occur in the HZH phase, which are accompanied by formation of PM aqua complexes [10]. Chloride, sulfate–chloride, and sulfate solutions are of particular interest for analysis and refining of noble metals [11].

In this study we examined the sorption properties of HZH with respect to sulfate complexes of iridium in sulfate acid solutions.

EXPERIMENTAL

Iridium may be present in sulfate acid solutions in widely diverse forms, depending on preparation conditions [12, 13]. As objects of study were chosen trinuclear oxosulfate complexes of iridium, the so-called blue iridium(IV,IV,IV) sulfates $\{K_{10}[Ir_3O_2(SO_4)_9]\cdot 2H_2O\}$ and green iridium(III,III,IV) sulfates $\{K_{10}[Ir_3O(SO_4)_9]\cdot 3H_2O\}$. The compounds were synthesized using the known procedures [14]. Hydrated zirconium dioxide was obtained from zirconium(IV) oxochloride by precipitation with a 1 M solution of sodium hydroxide by the method described in [15]. The grain size of the "working" fraction of the sorbent was 0.50–0.80 mm. When studying the effect of the sorbent grain size on the sorption, the grain diameter was varied from 0.125 to 0.800 mm. The static exchange capacity (SEC) was measured as the difference of the iridium concentrations in the starting solution and in that after contact with the sorbent. The content of iridium in solution was found spectrophotometrically by the method of "three acids" [16].

The sorption properties of HZH with respect to sulfate compounds of iridium(IV,IV,IV) and iridium(III,III,IV) were studied under static conditions (s : l = 1 : 50) in 0.01 M H_2SO_4 solutions under continuous agitation (in a Laboratory shakes type 358S shaking device at a rate of 200 cycles/min). The sorption kinetics of sulfate complexes of iridium (c_{Ir} = 1×10^{-4} M) was studied in freshly prepared sulfate acid solutions of blue iridium(IV,IV,IV) sulfate and green iridium(III,III,IV) sulfate at temperatures in the range from 20 to 90°C.

At room temperature, equilibrium in the distribution of blue and green iridium sulfates between the solutions and sorbent is attained in 20 h; the sorption

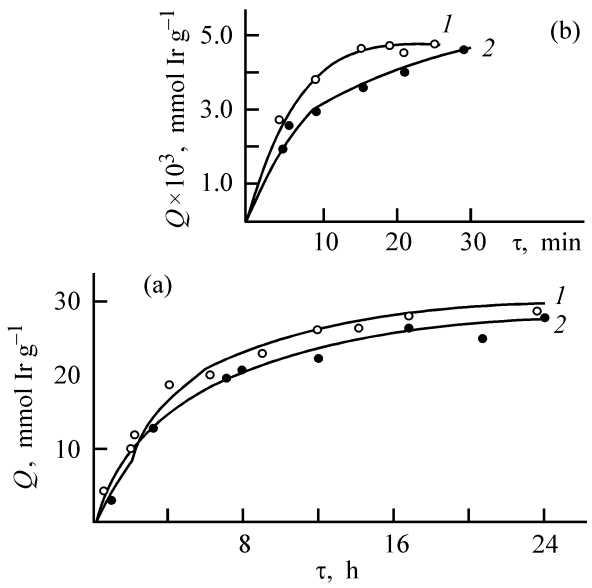

Fig. 1. Integral kinetic curves of iridium sorption on HZH from solutions. (Q) Sorption capacity and (τ) sorption time. (a) (*1*) Blue iridium(IV,IV,IV) sulfate and (*2*) green iridium(III,III,IV) sulfate; (b) (*1*) iridium(IV) chloro complex and (*2*) iridium(III) chloro complex.

half-times ($\tau_{1/2}$) are 3.6 and 4.2 h, respectively (Fig. 1, curves *1*, *2*). The recovery of blue iridium(IV,IV,IV) sulfate is about 60%, and that of green iridium(III,III,IV) sulfate, about 50%. These values do not exceed those in indium recovery from solutions of chloro complexes of the same concentration [8, 9]. It was of interest to compare the sorption capacities from solutions of chloro complexes and sulfate complexes of iridium. For example, approximately 90% of iridium(III) chloro complexes is sorbed from solutions of 1×10^{-4} M of $K_3[IrCl_6]$ in 0.01 M HCl, and about 100% of iridium(IV) is sorbed from a solution of $K_2[IrCl_6]$ in 0.01 M HCl under similar conditions (the sorption half-time is 6 and 4 min, respectively) [8, 9]. The dissimilar behavior of iridium complexes in sorption processes of its recovery from chloride and sulfate media with HZH is apparently due to different forms of its existence in these solutions and to different mechanisms of its sorption.

Effect of temperature on the sorption capacity and rate of iridium sorption from solutions for blue iridium(IV,IV,IV) sulfate and green iridium(III,III,IV) sulfate

T, °C	Time in which equilibrium is attained, h	$\tau_{1/2}$, h	SEC × 10^3, mmol g^{-1}
Blue iridium(IV,IV,IV) sulfate			
20	20	3.6	3.0
50	3	1.2	4.5
90	1	0.4	5.0
Green iridium(III,III,IV) sulfate			
20	20	4.2	2.5
50	3	0.8	3.1
90	2	0.8	5.0

Similarly to the case of iridium chloro complexes [8, 9], the rate of sorption recovery of blue and green iridium sulfates is also strongly affected by the sorbent grain diameter. As the radius of HZH particles increases, the sorption rate of sulfate complexes of iridium grows, which is characteristic of the diffusion control of sorption recovery. For example, as the radius of HZH particles decreases from 0.800 to 0.125 mm, the sorption time of sulfate complexes of iridium decreases from 20 to 8 h. The sorption half-time from a solution of blue iridium(IV,IV,IV) sulfate decreases from 3.6 to 2.4 h as the grain size of HZH decreases from 0.800 to 0.300 mm. The sorption half-time from a solution of green iridium(III, III,IV) sulfate decreases to a greater extent, from 4.2 to 1 h in the same range of sorbent grain sizes.

The temperature strongly affects the sorption process (see table). On heating the solutions, the rate of recovery of sulfate complexes of iridium with HZH grows. For example, as the temperature is raised from 20 to 90°C, the time in which equilibrium is attained in sorption from a solution of blue iridium sulfate falls from 20 to 1 h, and, accordingly, the sorption half-time decreases from 3.6 h to 25 min. In the case of green iridium sulfate, heating affects the recovery rate to a considerably lesser extent. In this case, the time in which the equilibrium is attained at 90°C is 2 h ($\tau_{1/2}$ = 47 min). The apparent activation energies are 13.7 and 18.2 kJ mol^{-1} for blue iridium(IV,IV,IV) sulfate and green iridium(III,III,IV) sulfate, respectively.

To determine the type of kinetics of sorption for solutions of blue and green iridium sulfates on HZH, we used the method of "sorption interruption" and the dependence of the degree of exchange, F, and examined $-\ln(1 - F)$ on the sorption time (Fig. 2).

The experimental data obtained in studying the interrupted sorption from iridium sulfate solutions were found to be less unambiguous. The time of contact between a solution of green iridium sulfate and HZH till interruption was 4 h. After the solution of green iridium sulfate is again brought in contact with the sorbent, there is virtually no increase in the sorption rate. This behavior is characteristic of a process controlled by outer diffusion and is probably due to a higher

stability of green iridium(III,III,IV) sulfate. A similar pattern is observed for trinuclear blue iridium(IV,IV,IV) oxosulfate only during the first 3 h of contact between its solution and HZH (if sorption is interrupted after 3 h of contact with a solution of blue iridium sulfate, the sorption rate does not increase). However, interruption of sorption after 4 h of contact with more labile complexes of blue iridium sulfate leads to a dramatic increase in the sorption rate on resuming the process. The whole set of data on the behavior of iridium sulfates in solutions gives no way of making an unambiguous choice between the inner- and outer-diffusion control. In all probability, the increase in the recovery rate after the sorption is interrupted in the case of blue iridium sulfate is due to a change of the state of the trinuclear iridium(IV,IV,IV) complex in solution in the course of time, rather than to changing type of kinetics [11, 12].

The linear dependence of F on $\sqrt{\tau}$ in the initial stage of sorption (Fig. 2a) and the linear dependence of $-\ln(1 - F)$ on τ (Fig. 2b) in sorption from solutions of blue and green iridium sulfates also confirm the diffusion type of the sorption kinetics.

The isotherms of sorption of sulfate complexes of iridium from a 0.01 M H_2SO_4 solution were obtained at equilibrium metal concentrations ranging from 1×10^{-4} to 1×10^{-3} M (Fig. 3). As the concentration in solution of both blue and green iridium sulfates increases, the amount of trinuclear iridium(IV,IV,IV) and iridium(III,III,IV) oxosulfates sorbed on HZH increases. The sorption isotherms are linear under the conditions studied. The same pattern was observed in sorption of chloro and sulfate complexes of other platinum metals [4–9]. The sorbent is not saturated by any of the complexes studied on raising the equilibrium concentration in solution not only by a factor of 10, but also by a factor of 100, as demonstrated by the example of sorption of palladium(II) chloro complexes [5].

Raising the concentration of H_2SO_4 in solutions of iridium(IV,IV,IV) and iridium(III,III,IV) sulfates from 0.01 to 2.0 M leads to a decrease in the amount of metal sorbed on HZH (Fig. 4, curves *3*, *4*). The sorption of green iridium sulfate is suppressed to a lesser extent by nitric and hydrochloric acid (Fig. 4, curves *1*, *2*). The competing action of sulfate ions can be attributed to a higher selectivity of HZH with respect to sulfate ions, compared with chloride and nitrate ions.

Recovery of green iridium(III,III,IV) sulfate from solutions in the presence of 0.5 M of HNO_3 and HCl is about 24%, and that in the presence of 0.5 M of

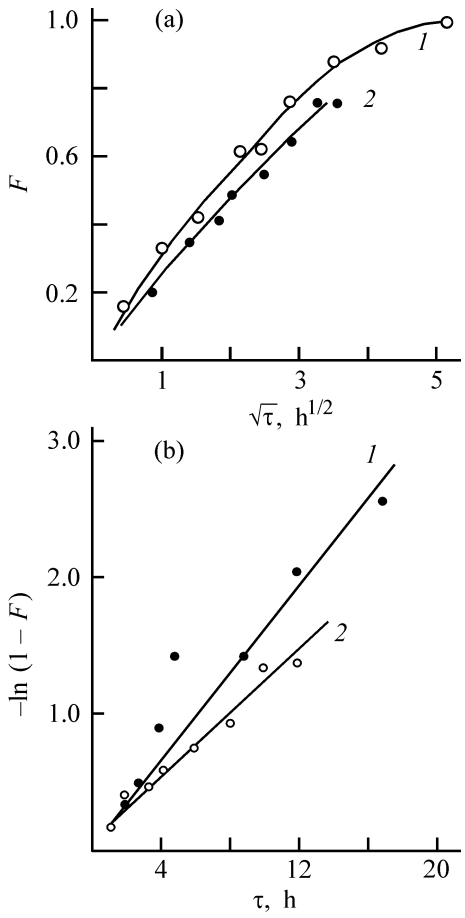

Fig. 2. (a) F–$\sqrt{\tau}$ and (b) $-\ln(1 - F)$–τ dependences for (*1*) blue and (*2*) green iridium sulfates. $F = Q_\tau/Q_\infty$, (Q_τ) sorption of ions from solution in time τ, and (Q_∞) equilibrium sorption.

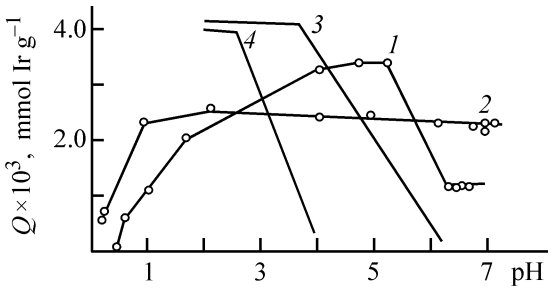

Fig. 5. Iridium sorptin on HZH vs. pH of the equilibrium solution. (*Q*) Static sorption capacity. (*1*) Blue iridium(IV,IV,IV) sulfate, (*2*) green iridium(III,III,IV) sulfate, (*3*) iridium(IV) chloro complex [8], and (*4*) iridium(III) chloro complex [9].

H_2SO_4, only 3%. It should be noted that mineral acids suppress sorption of iridium(IV) and iridium(III) from a solution of chloro complexes to a greater extent, compared with that of sulfate complexes. For example, the amount of iridium sorbed from a solution of iridium(III) chloro complex in the presence of 0.05 M HCl does not exceed 20% of its content in the solution [9]. As demonstrated in [8, 9], iridium chloro complexes are sorbed from weakly acidic solutions by the anion-exchange mechanism, and at higher concentrations of hydrochloric acid the competing action of chloride ions becomes more pronounced. The mechanism of recovery of sulfate complexes of iridium on HZH is more complicated than that operative in the case of iridium chloro complexes and is probably governed not only by ion-exchange processes.

The sorption capacity of HZH for sulfate complexes of iridium strongly depends on the pH of the solution. As can be seen in Fig. 5, the amount of Ir(IV) sorbed from a solution of blue iridium(IV, IV,IV) sulfate grows as the pH of the equilibrium solution increases from 0.5 to 3.5, remains virtually constant in the pH range from 4 to 5.5 (SEC = 3.32×10^{-3} mmol g^{-1}), and steeply falls as pH becomes even higher. At pH 6.5, the sorption capacity is 1.22×10^{-3} mmol g^{-1}. The pH range at which oxosulfate complexes of iridium are recovered to the greatest extent from a solution of a green sulfate is rather extended, from pH 2.0 to 7.0. The sorption capacity is constant (2.35×10^{-3} mmol g^{-1}) in this pH range. It should be noted that the amount of sorbed iridium chloro complexes decreases as the solution pH increases and becomes virtually zero at pH 4.2 (Fig. 5, curves *3*, *4*). The difference in the types of pH dependences of the sorption recovery of iridium from solutions of blue and green sulfates and chloro complexes of iridium is also due to different mechanisms of iridium recovery on HZH.

CONCLUSIONS

Sorption of microscopic amounts of trinuclear oxosulfate complexes of iridium(IV,IV,IV) and iridium(III,III,IV) from sulfate acid solutions on hydrated zirconium dioxide is distinguished by a slow sorption kinetics, compared with iridium(III) and iridium(IV) chloro complexes. The rate-determining stage of sorption from solutions of sulfate complexes of iridium is outer diffusion.

SORPTION AND ION-EXCHANGE PROCESSES

Comparative Study of Sorption Properties of Fullerene C_{60} and Dibenzo-24-crown-8 by Gas Chromatography and Solid-Phase Microextraction

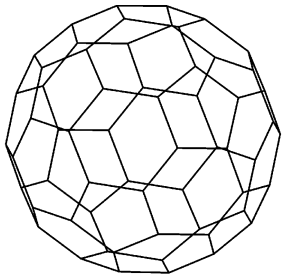
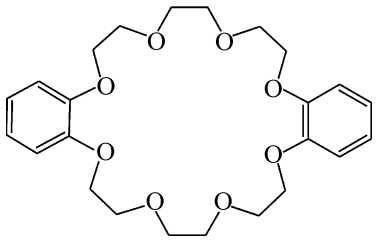
Abstract—Flat concentrators for flow solid-phase microextrcation, packed with carbon materials (C_{60} and Carbochrom C), DB-24C-8 crown ether, and its composite with fullerene were prepared and tested. The possibility of using these units for concentrating organic compounds of different classes in the vapor–gas phase and aqueous solutions was studied.

DOI: 10.1134/S1070427206040124



New selective thermally and chemically stable sorbents and stationary phases suitable for simultaneous analysis of hydrophilic and hydrophobic compounds are being extensively developed. Some of the new sorbents characterized by gas chromatography can be used for preconcentration of components of interest in real samples.

In this study we examined carbon materials (graphitized black and fullerene) and dibenzo-24-crown-8-ether (Fig. 1). Fullerenes are highly thermally stable and hydrophobic compounds resistant to oxidation and capable of donor–acceptor interactions. Graphitized thermal black (GTB) is a nonspecific sorbent with a small specific surface area (6–12 $m^2\ g^{-1}$), which is used for a long time in chromatography (Carbochroms and Carbopaks). The structure and physicochemical properties of fullerenes substantially differ from those of graphitized black [1–6]. A C_{60} molecule can be considered as an electron-deficient polyene with partially delocalized π electrons.



Previously we found [7] that C_{60}-containing stationary phase for gas chromatography strongly differs from graphitized black and has an increased affinity for aromatic compounds. A mixture of C_{60} with DB-24-crown-8 as a gas-chromatographic phase has an increased affinity for aromatic, amine, and hydroxy compounds and can be used for separating positional isomers [7].

In this study we examined these materials as sorbents for solid-phase microextraction (SPME) used for analysis of aromatic hydrocarbons, phenols, and nitriles. Many of these compounds are environmentally hazardous.

SPME is widely used for concentrating volatile and nonvolatile organic compounds from liquid and vapor phases [8–12]. It is an important step of sample preparation in practical analysis and has definite advantages over the conventional solid-phase extraction: shot time required, no organic solvents used, compact facility, combination of the sampling and sample preparation steps, and hence decreased detection limits.

Fullerene [60]

Dibenzo-24-crown-8

Fig. 1. Fullerene [60] and dibenzo-24-crown-8.

In this study we compared the sorption properties of fullerene black and DB-24-crown-8 by gas chromatography and solid-phase microextraction.

EXPERIMENTAL

Fullerenes C_{60}, C_{70}, C_{60} + C_{70} (75% + 25%, 85% + 15%), mixtures of fullerenes with more than 70 carbon atoms, and fullerene black were kindly supplied by Astrin Private Company (St. Petersburg).

The stationary phases for chromatography were prepared from fullerene C_{60} and dibenzo-24-crown-8 (Reaktiv-Servis Research and Production Complex Ltd.). Interton N-AW (0.2–0.25 mm), Interton N-AW (0.315–0.4 mm), and Interton N-AW (0.16–0.2 mm) (Chemapol, Prague) were used as supports for the stationary phases.

n-Alkanes (C_6–C_{20}), aromatic hydrocarbons (benzene, toluene, ethylbenzene, *p*-xylene), phenols (phenol, *o*-, *m*-, *p*-cresol, *m*-, *p*-chlorophenols), aromatic amines (aniline, *o*-, *m*-, *p*-toluidines), nitriles (acetonitrile, propionitrile, benzonitrile, phenylacetonitrile) were used to characterize the stationary phases. All the chemicals were of pure grade.

Distilled water, chloroform, dichloromethane, *o*-xylene, hexane (pure grade), and toluene (analytically pure grade) were used as solvents.

Gas chromatographic analysis was performed on Tsvet-500M and Tsvet-100 chromatographs equipped with flame ionization detectors. The chromatographic data were analyzed using the Multikhrom software. The flow rate of the carrier gas, nitrogen, in "analysis" and "desorption" operation modes was 22–25 and 10–30 ml min^{-1}, respectively. The flow rate of H_2 and air was 25 and 360 ml min^{-1}, respectively. A 3-m glass column with $d_{internal}$ = 4 mm was packed with 10 wt % Triton X-305 supported by Chromaton N-AW (0.25–0.315 mm). The temperature of the column and vaporizer was 70–150 and 275°C, respectively. The working scale of an electrometer was 10^{-9} A.

Nitrogen flows containing simple aromatic hydrocarbons in concentrations form 3.2 to 66.3 mg m^{-3} were produced with the aid of vapor phase sources of gas mixtures VPSGM (Monitoring Research and Production Association). This source produced a vapor containing (mg m^{-3}): benzene 7.7, toluene 7.1, ethylbenzene 3.2, and *o*-xylene 5.8. Extraction of vapor–gas mixtures was performed using the sorption unit (Fig. 2) and VPSGM.

Solid-phase extraction was performed on a flat microextractor packed with a solid sorbent or a stationary phase on a solid support (Fig. 2). We used C_{60} on Inerton N-AW, Carbochrom C, and DB-24-C-8 on Inerton N-AW as sorbents. The sorbent weigh ranged from 10 to 50 mg.

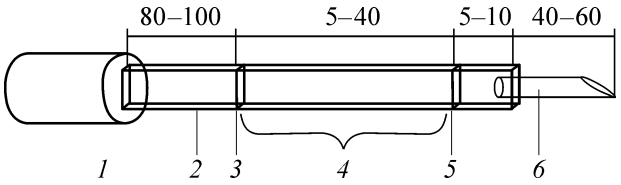


Fig. 2. Scheme of SPME unit: (*1*) threaded coupler, (*2*) flat rectangular column, (*3*, *5*) fiber glass seals restricting the sorbent bede, (*4*) sorbent bede, and (*6*) connecting needle.

The sorption unit was attached to the outlet connecting pipe of VPSGM, small internal excess pressure was produced, and the vapor phase was fed through a sorbing needle. The sorption time was measured with a stopwatch. The flow rate was determined with an IRG-10 electronic flow meter. For flow SPME, the vessel was filled with a model solution to be analyzed. The needle of the sorption unit was placed in the solution to be analyzed, which was fed with a 50-ml gas syringe. After a definite time, the sorption unit was removed from the vessel. To remove the residual water, the unit was purged with nitrogen until the last drop of the working aqueous solution was blown out but for no less than 30–45 s. Then the unit was attached to a working gas chromatograph.

To desorb the concentrated components from the sorption unit, a three-way gas cock was turned into the "desorption" position. The connecting needle (or needle concentrator as a whole) was fixed in the vaporizer of the gas chromatograph, the column with the sorbent was heated at 250°C with an external electric microfurnace, and the unit was continuously purged with the carrier gas. It should be noted that the sorption unit for TPME was located in the vaporizer chamber during the whole time of recording the chromatogram, which was no longer than 20 min. To study the composition of each model solution and vapor–gas mixture, 3–5 analytical cycles involving sorption, desorption, and recording of the detector signals were performed.

We studied aqueous-methanolic solutions containing 143 μg ml^{-1} of phenol and 139 μg ml^{-1} of *p*-cresol and aqueous solutions containing 100, 200, and 500 μg ml^{-1} and 1 and 2 mg ml^{-1} of acetonitrile. The solutions of the phenols and acetonitrile were analyzed using flat sorption units packed with C_{60}, dibenzo-24-crown-8 on Inerton N-AW (0.25–0.315 mm), and Carbochrom B. The model solutions of phenols

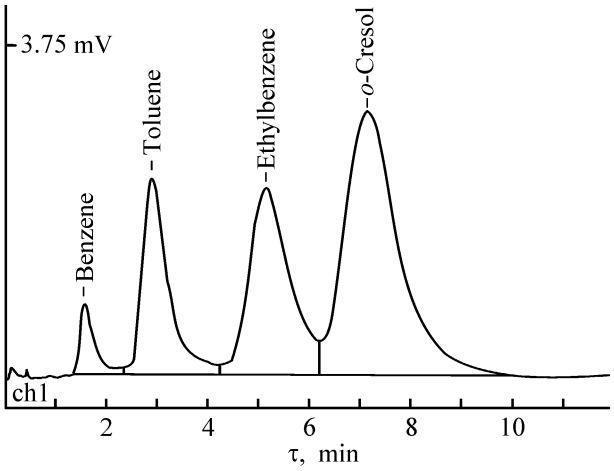

Fig. 3. Representative chromatogram of a hydrocarbon mixture concentrated from the gas–vapor phase with the aid of a flat concentrator packed with 10 wt % dibenzo-24-crown-8 on Inerton N-AW Column: 10 wt % Triton X-305 on Inerton N-AW. T_{column} = 90°C, $T_{vaporizer}$ = 250°C, $T_{furnace}$ = 200°C, flame ionization detector. (τ) Retention time; the same for Fig. 5.

and acetonitrile were prepared from the freshly prepared stock solutions.

The representative chromatogram of desorbed aromatic hydrocarbons is shown in Fig. 3.

To concentrate the analytes, a known amount of the sample (gas or liquid) was passed through the microreactor packed with the sorbent.

Sorption preconcentration for analytical purposes is performed in two different modes: complete sorption of the components and their equilibrium distribution between the sorbent and the sample. In some cases, the equilibrium preconcentration is preferable since it does not require a strict control of the time and flow rate of the examined gas thorough a sorption unit.

In the case of Carbochrom C, the peak area of *o*-xylene increases with increasing the gas volume passed through the column from 100 to 600 ml, which indicates complete sorption of the analytes (Fig. 4a). However, under these conditions, a rapid benzene breakthrough is observed.

The equilibrium concentration is attained on C_{60} supported by Inerton. As seen from Fig. 4b, a rapid breakthrough of benzene, toluene, and ethylbenzene through a column with C_{60} is observed. In the case of *o*-xylene, the sorption equilibrium is also attained, but within a time longer than that for the other aromatic hydrocarbons.

The equilibrium sorption of all the examined arenes in the sorption units packed with DB-24-crown-8

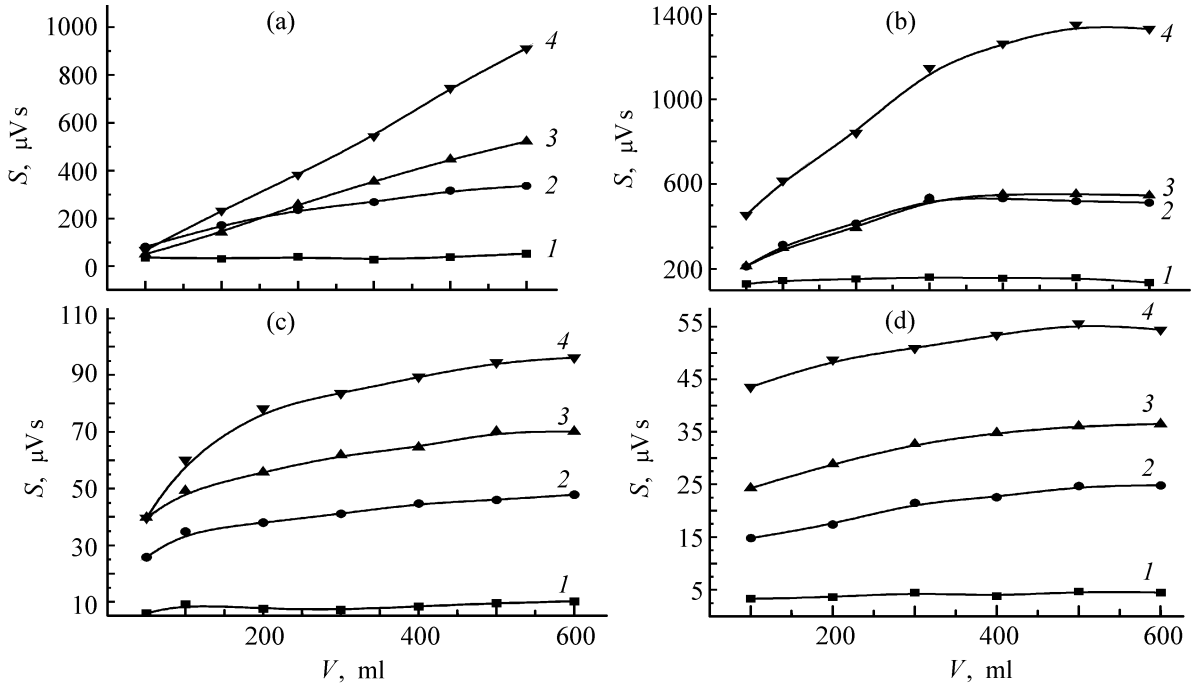

Fig. 4. Attainment of equilibrium sorption of a vapor–gas mixture containing (mg m^{-3}) benzene 7.7, toluene 7.1, ethylbenzene 3.2, and *o*-xylene 5.8 in a microreactor packed with (a) Carbochrom C, (b) 10% C60 on Inerton N-AW, (c) 10% DB-24-C-8 on Inerton N-AW, and (d) 10% DB-24-C-8 + 10% C_{60} on Inerton N-AW. Component: (*1*) benzene, (*2*) toluene, (*3*) ethylbenzene, and (*4*) *o*-xylene. (*S*) peak area and (*V*) volume passed through the column.

(Fig. 4c) and its mixture with C_{60} (Fig. 4d) is attained fairly rapidly. However, the peak areas of the desorption products are substantially smaller than those obtained with Carbochrom C carbon sorbents and fullerene. This is due to low sorption capacity of the crystalline crown ether caused by its small specific surface area.

Since dibenzo-24-crown-8 on Inerton and C_{60} on Inerton are characterized by increased retention of phenols and nitriles under the gas chromatographic conditions, we used the flat concentrators with these sorbents for analysis of aqueous solutions. We analyzed aqueous solutions of phenol–*p*-cresol mixtures. Preliminaryly, we determined the content of compounds of interest in aqueous solutions (in the case of phenols, in methanol) by the direct gas-chromatographic analysis.

We also used these sorbents for analyzing aqueous solutions with various acetonitrile concentrations. The dependence of the peak area of the desorbed products is linear (correlation coefficient 0.997) at the acetonitrile concentration ranging from 0.1 to 10 g l^{-1}. It should be noted the degree of concentration of acetonitrile (~10^4) on the flat concentrator packed with C_{60} on Inerton is higher than that obtained after direct injection of the sample into the chromatographic column.

Taking into account the results obtained with the model vapor–gas mixtures, we analyzed the thermolysis products of styrene–butadiene copolymer (Fig. 5).

The use of the concentrator allowed us to eliminate the sorption of high-boiling components on the wall of the gas syringe (cf. the chromatograms shown in Figs. 5a and 5b) and to increase the sample of the vapor–gas mixture and hence the sensitivity of the analysis.

We performed a large number of experiments to optimize the sorption conditions and elucidate the influence of the volume and flow rate of the vapor–gas mixture on the signal intensity of the flame ionization detector. We found that the main factor affecting the detection limit is the volume of the vapor–gas mixture. We determined the best conditions of preconcentration (flow rate 50 ml min^{-1}) and desorption (temperature of the external furnace ~200°C). The chromatographic peak areas of the model vapor–gas mixtures of aromatic hydrocarbons are reproduced well. The relative standard deviation does not exceed 0.12.

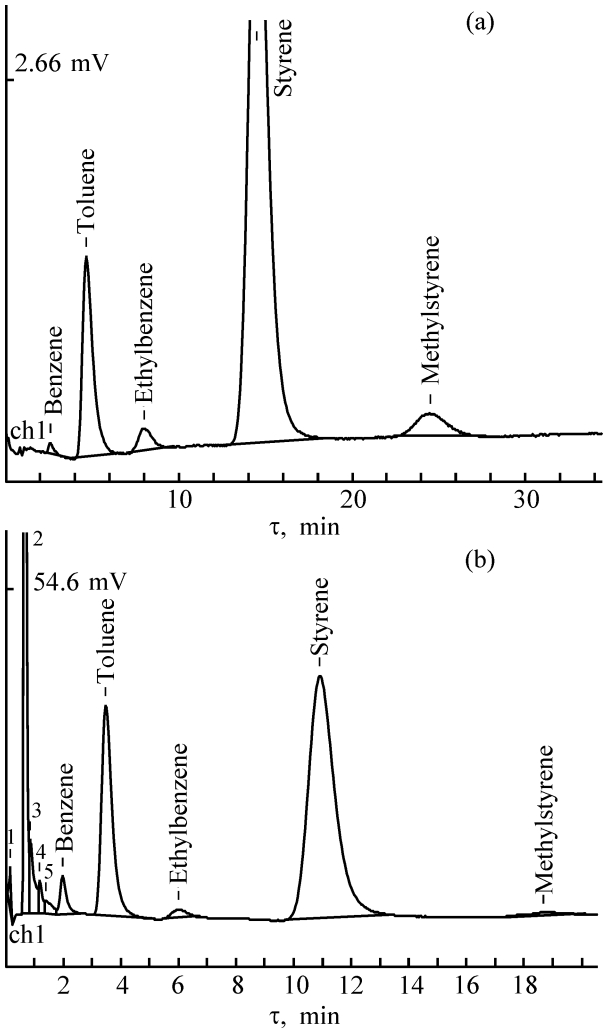

Fig. 5. Desorption chromatographic pattern of the thermolysis products of styrene–butadiene copolymer (a) concentrated on the flat concentrator with DB-24-crown-8 and (b) injected directly with a gas syringe. Tsvet 500 chromatograph; flame ionization detector; column packed with 10% Triton X-305 on Inerton N-AW. T_{column} = 70°C, $T_{vaporizer}$ = 250°C, $T_{furnace}$ = 200°C.

CONCLUSIONS

(1) Sorbents containing C_{60} and DB-24-crown-8 can be used for preconcentration and subsequent quantitative analysis of different classes of organic compounds in aqueous solutions and vapor–gas mixtures.

(2) The detection limit of benzene and its nearest homologs is ~0.01 mg m^{-3}. The polymer thermolysis products were analyzed and the residual concentration of acetonitrile was determined under the optimal conditions of SPME with the new sorbents.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of Sc(III) on Phosphorus-containing Cation Exchangers

Yu. V. Sokolova

Moscow State Institute of Steel and Alloys (Technological University), Moscow, Russia

Received October 4, 2005

Abstract—Kinetics of Sc(III) sorption from hydrochloric acid solutions on KRF-20t-60 cation exchanger is studied. The experimental data are analyzed in terms of the gel and film kinetic models. The Sc(III) diffusion coefficient in the resin phase is estimated. Static and dynamic sorption data are obtained on Sc(III) sorption from various process solutions on KRF-20t-60, PA-1, AFI-22 ion exchangers, and also on ion exchangers supported on polyacrylonitrile-based fibrous material. Desorption of Sc(III) from KRF-20t-60 is also studied.

DOI: 10.1134/S1070427206020136

It is advisable to use cation exchange resins for primary concentration of Sc(III) from solutions and pulps with low concentration of Sc (from several to tens mg l^{-1}), more so from saline solutions (at salt concentration from tens to hundreds g l^{-1}). In this case, ion exchangers should be highly selective with respect to Sc(III).

Thanks to high affinity of functional groups of phosphorus-containing ion exchangers for Sc(III), sorbents of this class demonstrate high selectivity with respect to Sc(III), and their use allows recovery of Sc(III) from acidic solutions (pH < 2.5) by the complexation mechanism, which makes it possible to perform separation of Sc from alkali and alkaline-earth elements, Al(III), and some other cations that do not form stable complexes under conditions when the dissociation of the functional groups of the resin is suppressed.

High selectivity of phosphorus-containing ion exchangers with respect to Sc(III) in its recovery from multicomponent saline solutions was found by several authors. Kazantsev et al. [1] demonstrated high performance of KFP resin in recovery of Sc(III) from the spent salt filter solution from production of titanium tetrachloride. AFI-21 and AFI-22 nitrogen–phosphorus-containing ion-exchange resins and SF-4 and SF-5 phosphonate resins were recommended for sorption recovery of Sc(III) from red mud from alumina production [2]. Phosphorylated cellulose was used for sorption concentration of Sc(III) from the filtrate obtained after separation of titanium(IV) hydroxide in production of titanium white [3]. Komissarova in her monograph [4] reviewed data on sorption concentration of scandium from various solutions on phosphorus-containing ion exchangers for analytical purposes as well as on Sc(III) speciation in hydrochloric and sulfuric acid solutions and the composition of adsorbed complexes.

In this study we examined static and dynamic sorption of Sc(III) from various process solutions on KRF-20t-60, PA-1, and AFI-22 ion exchangers.

EXPERIMENTAL

We studied the sorption recovery of Sc(III) from the following solutions. Solution no. 1: solution after filtration of zirconium basic sulfate (Verkhnedneprovsk Mining and Smelting Combine); solution no. 2: solution after sulfuric acid pressure leaching of silicate–carbonate ore (Zheltorechensk ore deposit); and solution no. 3: hydrochloric acid solution of spent salt filter from production of titanium tetrachloride (Ust'-Kamenogorsk Titanium and Magnesium Combine), obtained at a solid to liquid (3% HCl) phase ratio of 1 : 2.5. The compositions of these solutions are given in Table 1, and characteristics of the ion exchangers used, in Table 2. The resins were pretreated by the standard procedure [5]. The cation-exchange resins

* $pK_1 = 3.5$; $pK_2 = 9.5$.

were converted into the H form, and the ampholytes, into the H and chloride forms (solution nos. 1 and 3) or H and sulfate forms (solution no. 2).

Static sorption was carried out at a fixed $V : m$, where V is the solution volume and m, resin weight. The system was equilibrated to constant concentration of Sc(III) in the solution.

The kinetics of Sc(III) sorption was studied at a fixed $V : m$ using the solution volume limitation method. The experimental error caused by a decrease in the solution volume due to sampling was within 2%.

The equilibrium sorption isotherms were obtained by varying $V : m$.

The Sc(III), Zr(IV), V(IV + V), and Y(III) concentrations in the solution were determined by ICP. The lower limit of determination was 10^{-5}%, and the error of determination was within 20%.

The Fe(III) and free acid concentrations were determined volumetrically. U(VI), Ti(IV), and Al(III) were determined photometrically with Arsenazo III, hydrogen peroxide, and aurintricarboxylic acid, respectively [6], on a KFK-3 instrument. Na, K, Ca, and Mg were determined by atomic absorption. The sum of REEs in the solution was determined as follows. The sesquioxides obtained by ammonia precipitation were dissolved in 4–5 N HCl, and Sc(III) was separated by extraction with 0.16 M di-(2-ethylhexyl) hydrogen phosphate in a hydrocarbon solvent. Finally, REEs were determined photometrically with Arsenazo III.

The recovery of Sc(III) from solution no. 1 was monitored using the ^{46}Sc, ^{59}Fe, ^{95}Zr, and ^{91}Y tracers. The activity was measured on an IN-96 γ-ray radiometer to within 1%. The sensitivity of the method was 10^{-6}%.

In addition to the high salinity, among specific features of the investigated solutions is a high concentration of multicharged cations such as Zr(IV), Ti(IV), V(V), and U(VI), which considerably exceeded that of Sc(III). Previously we demonstrated that, in sorption recovery of Sc(III) from these solutions, the best performance was shown by KRF-20t-60 cation exchanger and PA-1 polyampholyte [7–9]. In this study, to optimize the sorption parameters, for

the indicated ion exchangers we examined the static sorption, sorption kinetics, and desorption of Sc(III).

The sorption kinetics on the phosphorus-containing ion exchangers was studied with an example of a hydrochloric acid solution of scandium trichloride and also with solution nos. 1–3.

To find the rate-determining stage, we examined the sorption kinetics of Sc(III) from the hydrochloric acid solution of $ScCl_3$ (c_{Sc} = 3.2 mg l^{-1}; c_{HCl} = 10 g l^{-1}) on KRF-20t-60 (mean radius of a swollen grain 0.12 cm). The results showed (Fig. 1) that the equilibrium was attained only in ca. 6 h, i.e., the sorption rate is low.

The kinetic data were processed using the Boyd–Adamson–Myers equation for the diffusion from the limited volume of the solution [10]:

$$F = 1 - \frac{6}{\pi^2} \Sigma \frac{1}{n} \exp(-Btn^2), \quad (1)$$

where F is the degree of sorption defined as the ratio of the current sorption to the limiting sorption; $Bt = (Dp^2t)/r_0^2$; r_0, mean radius of the swollen grain of the ion exchanger (0.12 cm); D, diffusion coefficient of the ion in the grain of the resin ($cm^2\ s^{-1}$); and t, sorption time (s).

For each F we estimated B by dividing the known Bt values by the sorption time, and then, from B we estimated the Sc(III) diffusion coefficient in the resin grain. The effective diffusion coefficient of Sc(III) was calculated to be 1.38×10^{-7} $cm^2\ s^{-1}$. From D and r_0 we estimated Bt for a fixed t, and then, the degree of sorption F (Fig. 1, curve *1*).

The experimental data were analyzed in terms of the film kinetic model using Eq. (2).

$$F = 1 - \exp(-Kt), \quad (2)$$

where $K = 3D/(\delta r_0 \alpha)$, D is the diffusion coefficient of an ion in the solution, $cm^2\ s^{-1}$; δ, thickness of the diffusion layer, which was taken equal to 10^5 molecular layers, i.e., to 0.001 cm; r_0, mean radius of the swollen grain of the resin (0.12 cm); and α, distribution coefficient, ml g^{-1}. From the distribution coefficients, we computed F (Fig. 1, curve *2*).

As seen from Fig. 1, the experimental points are between the curves obtained by Eqs. (1) and (2), suggesting commensurable contributions of both external and internal diffusion mechanisms to the sorption kinetics.

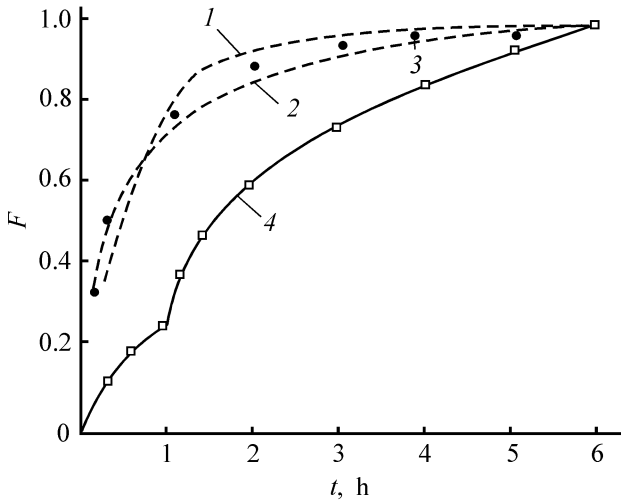

Fig. 1. Kinetic curves of Sc(III) sorption from the $ScCl_3$ solution (c_{Sc} = 3.2 mg l^{-1}; c_{HCl} = 10 g l^{-1}; $V:m$ = 100 ml g^{-1}) on KRF-20t-60: (*1*) calculation by Eq. (1), (*2*) calculation by Eq. (2), (*3*) experimental points, and (*4*) experiment with interrupted (for 30 min) contact of the phases. (F) Degree of sorption and (t) time.

In the experiment with interrupted phase contact, we can found a distinctly pronounced "diffusion memory" effect (Fig. 1, curve *4*): the sorption rate 1 h after interruption of the process for 30 min considerably increases again. It was demonstrated in studying the effect of stirring rate that, with increasing Reynolds number from 50 to 130, the process rate increased by a factor of 2.5 in 30 min, which gives an additional evidence in favor of the above conclusion.

Thus, to increase the Sc sorption rate on the selected cation exchanger, it is advisable to use fine fractions of the resin and to apply rigorous stirring.

A considerable increase in the process rate in the same system was obtained by using the sorbent prepared by inclusion of fine (112 μm and smaller) particles of the resin into a polyacrylonitrile matrix. The fibrous sorbents were synthesized at the Research Institute of Chemicals and Ultrapure Substances (Moscow) and Khimvolokno Research and Production Association (Tver) [11]. Kinetic data obtained with the fibrous sorbents showed that it takes only 20 min to establish the equilibrium in the same system, and that crushing of the resin to a grain size less than 52 μm had no effect on the process rate [12].

In recovery of Sc(III) from multicomponent solutions with the phosphorus-containing ion exchangers, the equilibrium was established in several days. However, the degree of sorption in 6 h was about 90% of the limiting value (Fig. 2), which makes it possible

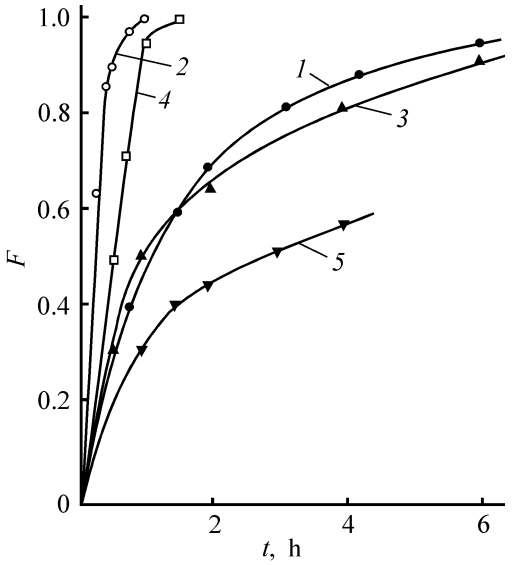

Fig. 2. Kinetic curves of Sc(III) sorption from (*1*, *2*, *5*) solution no. 1 ($V : m$ = 100 ml g^{-1}) and (*3*, *4*) solution no. 3 ($V : m$ = 20 ml g^{-1}) on (*1*, *3*, *5*) granulated PA-1 and (*2*, *4*) fibrous PA-1. Temperature (°C): (*1*–*4*) 22 and (*5*) 60. (*F*) Degree of sorption and (*t*) time.

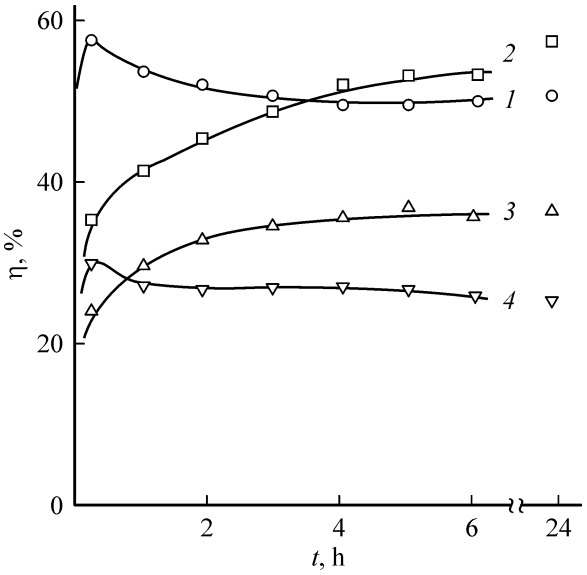

Fig. 3. Kinetic curves of sorption of the cations from solution no. 2 on AFI-22 ($V : m$ = 20 ml g^{-1}): (*1*) Sc(III), (*2*) Fe(III). (*3*) Ti(IV), and (*4*) Zr(IV). (η) Degree of sorption and (*t*) time.

to recommend these ion exchangers for practical application. With the fibrous sorbents, the equilibrium was established in 1–1.5 h (Fig. 2).

The kinetic data on the sorption of Sc(III) and concomitant elements from solution no. 3 with AFI-22 nitrogen–phosphorus-containing ion exchanger demonstrate that the degree of Sc sorption passes through a maximum at t = 20 min and then decreases (Fig. 3). The same trend was observed for Fe(III), while for Ti(IV) and Zr(IV), reversely, the degree of sorption increases on approaching the equilibrium (Fig. 3). These results suggest that, in multicomponent systems, ions penetrating to the resin grain are involved in multiple sorption–desorption equilibria, which are established in correspondence with the selectivity coefficients, thus decelerating the net process. Therefore, to recover Sc(III) efficiently, the sorption time should be limited to 20 min, since, at this time, the degree of sorption is maximal for Sc and minimal for hardly separable Ti(IV) and Zr(IV).

With increasing concentration of the multicharged interfering cations such as Fe(III) and, particularly, Zr(IV), the capacity of the phosphorus-containing ion exchangers for Sc(III) considerably decreased (Table 3).

We used the higher affinity of the phosphorus-containing ion exchangers for Zr(IV), as compared to Sc(III), for treatment of the hydrochloric acid solution of scandium trichloride to remove Zr(IV) by sorption on KRF-20t-60 in the H^+ and Sc^{3+} forms in the static and dynamic modes. The decontamination factor was about 50 [13].

The selectivity of this class of ion exchangers with respect to Sc(III) noticeably decreases in the case of sorption from multicomponent solutions at elevated temperature. For example, in sorption of Sc(III) from solution no. 1 at 60°C, the capacity of KRF-20t-60 for Zr(IV) considerably increased, and that for Sc(III) decreased as well as the sorption rate of Sc(III) (Fig. 2).

Table 3. Capacity E of KRF-20t-60 resin for Sc(III) in sorption from solution no. 1 ($V : m$ = 100 ml g^{-1}) at various Fe(III) and Zr(IV) concentrations in solution

[Fe(III)]	[Zr(IV)	E, mg l^{-1}

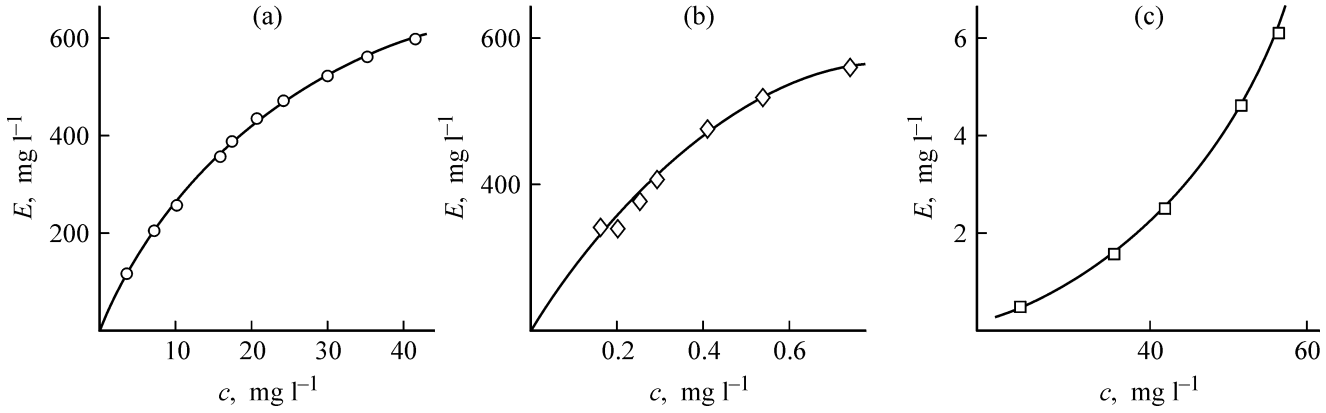

Fig. 4. Isotherms of Sc(III) sorption from solution nos. (a) 2, (b) 1, and (c) 3 on PA-1. (E) Capacity of the ion exchanger for Sc(III) and (c) equilibrium concentration of Sc(III) in solution.

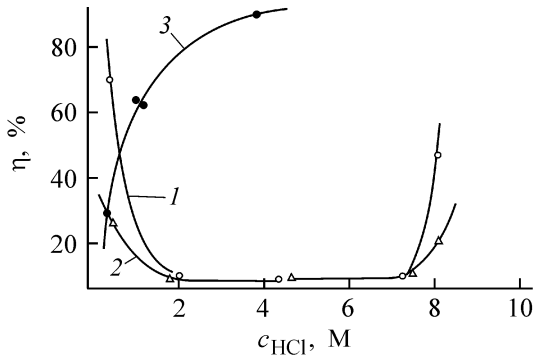

Fig. 5. Sorption of Y(III) on (*1*) KRF-20t-60, (*2*) PA-1, and (*3*) AFI-22 vs. the HCl concentration (c_{Sc} = 10 mg l^{-1}, c_Y = 14 mg l^{-1}; $V : m$ = 20 ml g^{-1}). (η) Degree of sorption and (c_{HCl}) HCl concentration in solution.

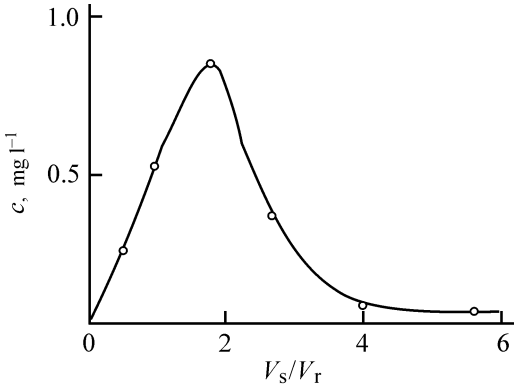

Fig. 6. Desorption of Sc(III) from KRF-20t-60 vs. the NH_4F specific volume. (c) Sc(III) concentration in solution of NH_4F and (V_s/V_r) solution to resin volume ratio.

The isotherms of Sc(III) sorption from solution nos. 1–3 on PA-1 polyampholyte are shown in Fig. 4. In the cases of solution nos. 1 and 2, the isotherms are convex, and the working exchange capacity of the ion exchanger for Sc(III) is about 600 mg l^{-1}. The necessary number of sorption steps, estimated by the method described in [9], is 2 and 4 for solution nos. 1 and 2, respectively. The Sc(III) sorption isotherm from solution no. 3 is concave, and the necessary number of sorption steps is 7–8. In this case, to obtain acceptable sorption parameters, it is necessary to correct the solution composition by, e.g., dilution.

One more specific feature of the phosphorus-containing ion exchangers (KRF-20t-60 and PA-1) is that the Y(III) and Ln(III) distribution coefficients are, generally, low. In this case, separation of, e.g., Y(III), can be realized over wide pH range (Fig. 5). Therefore, sorption concentration of Sc(III) on such ion exchangers considerably facilitates further processing of the resulting concentrates. On the contrary, AFI-22 demonstrates high affinity for Y(III).

It is known that sodium, potassium, and ammonium carbonates effectively desorb Sc(III) from phosphorus-containing ion exchangers [4]. However, it should be pointed out that it is inadvisable to use acidic and alkaline solutions in the same sorption cycle, since changing an acidic solution for alkaline one and back results in considerable osmotic stress, thus reducing the useful life of the resin. Furthermore, acidification produces CO_2, and the resin remains "fluidized" even after thorough washing with water to remove the acid prior to desorption, thus making the process design more complicated. Thus, a satisfactory result was obtained by the author only using additional treatment of the resin with a dilute ammonia solution before carbonate desorption of Sc(III).

It appeared advisable to use ammonium fluoride or bifluoride for Sc(III) desorption. The Sc(III) elution curve from KRF-20t-60 (after sorption from solution no. 2) with 4% NH_4F is shown in Fig. 6. The desorption efficiency was 92% at V_s/V_r = 4. The use of higher concentration of NH_4F resulted in precipita-

tion. At elevated temperature, no maximum was observed in the elution curve.

Scandium(III) can be separated from the eluate as a poorly soluble salt, e.g., Na_3ScF_6, and the NH_4F solution can be recycled after correction.

CONCLUSIONS

(1) Kinetics of Sc(III) sorption from the solution of $ScCl_3$ in HCl on KRF-20t-60 cation exchanger is controlled by the gel and film diffusion mechanisms. The Sc(III) effective diffusion coefficient in the resin grain is 1.38×10^{-7} $cm^2\ s^{-1}$.

(2) The static and dynamic sorption of Sc(III) from process solutions from production of zirconium basic sulfate [solution after filtration of zirconium basic sulfate (solution no. 1), solution after sulfuric acid pressure leaching of silicate–carbonate ore (solution no. 2), and hydrochloric acid spent salt filter solution from production of titanium tetrachloride (solution no. 3)] on KRF-20t-60 cation exchanger and PA-1 polyampholyte resin are studied. The working exchange capacity for Sc(III) of the indicated sorbents is about 600 $mg\ l^{-1}$ for solution nos. 1 and 2 and about 5 $g\ l^{-1}$ for solution no. 3. The sorption rate can be considerably increased by using polyacrylonitrile-supported fibrous sorbents.

(3) In sorption from a multicomponent salt solution on AFI-22 resin, the maximal capacity for Sc(III) was obtained far from the equilibrium. The capacity of the phosphorus-containing ion exchangers decreases with increasing temperature and concentration of multicharged cations in the solution.

(4) It was suggested to use 4% ammonium fluoride for desorption of Sc(III) from the phosphorus-containing ion exchangers.

SORPTION AND ION-EXCHANGE PROCESSES

Effect of the Nature and Concentration of Salting-out Agents on the Extraction of Cobalt(II) from Chloride Solutions with Trialkylamine

A. G. Kasikov, L. V. D'yakova, and E. G. Bagrova

Received January 18, 2006

Abstract—The effect of chlorides of Ca^{2+}, Ni^{2+}, Mg^{2+}, Al^{3+}, Li^{+}, Fe^{2+}, Cr^{3+}, Na^{+}, NH_4^{+}, La^{3+}, Nd^{3+} on the extraction recovery of cobalt from chloride solutions with mixtures based on trialkylamine was studied. The series of the salting-out activity of differently charged cations and the degree of their coextraction were determined.

DOI: 10.1134/S1070427206040148

Salts of various metals can strongly affect the extraction recovery of a target component from multicomponent solutions. This influence is primarily manifested in that well-extractable elements hinder the extraction of the target component. Occasionally, background salt components are not extracted themselves, but substantially affect the recovery of other elements. This influence is due to the fact that, depending on the nature and concentration of a salting-out agent, not only the activity of water changes, but also that of all other components of a solution. In this case, the distribution coefficients of an element may either increase (salting-out) or decrease (salting-in) [1].

Published data on extraction of cobalt(II) with tertiary amines in the presence of various salting-out agents are scarce [2–6]. There is no way of comparing the available published data for the salting-out agents used, because the extraction conditions and the compositions of the extraction mixtures were different. Moreover, there are no published data on extraction of metal chloro complexes in the presence of such elements as Cr(III) and lanthanides, which may be contained in secondary cobalt raw materials and can pass into solution in its hydrochloride processing. In this context, the influence exerted by the nature and concentration of a large number of metal chlorides on the extraction of cobalt(II) with organic mixtures based on tertiary amines was examined in this study.

EXPERIMENTAL

A 35 vol % solution of trialkylamine of the C_7–C_8 fraction (TAA) in an inert diluent (Escaid-100) with addition of 20 vol % modifying agent was used as an extracting agent. An alcohol (octanol) served as the modifying agent. It was introduced in order to preclude formation of a third phase, which could occur because of the low solubility of the amine salt in the inert diluent. Prior to extraction, TAA was converted to a chloride form by bringing it in contact with 4 M HCl at a 1 : 1 ratio of the organic and aqueous phases. The excess amount of the acid was removed by washing with water.

The salt background was created with metal chlorides of chemically pure and analytically pure grades. Weighed portions of these salts (taken with an accuracy of ±1 mg) were dissolved in distilled water to obtain the necessary concentration of cobalt ions and chloride anions.

The extraction and backwashing were performed in separation funnels with a mechanical shaker, with a single contact for 5 min at 20 ± 1°C.

The aqueous phases were analyzed for the content of cobalt and nonferrous elements by atomic-absorption spectrometry. The concentration of cobalt in the organic phase was found as the difference between its contents in the starting solution and in raffinates

Table 1. Effect of the nature of a salting-out agent on the recovery of cobalt(II) at o : a = 3 : 1 (initial concentration of Co^{2+} 6.5 g l^{-1})

Salting-out agent	Content of the chloride ion, M			
	6		8	
	D_{Co}	E, %	D_{Co}	E, %
LiCl	41.6	97.6	280.0	99.6
HCl	0.45	31.0	1.87	66.2
NaCl	0.45	31.0	1.84	64.8
NH_4Cl	0.40	28.4	1.34	57.2
$MgCl_2$	10.0	90.0	13.7	93.2
$CaCl_2$	6.3	86.3	10.1	90.9
$NiCl_2$	2.0	66.8	4.2	81.0
$FeCl_2$	0.48	32.4	1.90	66.4
$AlCl_3$	10.1	90.9	16.8	94.4
$CrCl_3$	2.0	66.8	4.1	80.3
$NdCl_3$	0.60	37.2	3.6	78.2
$LaCl_3$	0.52	34.2	3.6	78.2

or by analysis of solutions obtained after exhaustive backwashing of cobalt. The results obtained in studying the influence exerted by the nature of the salting-out agent on the distribution coefficient D_{Co} and degree E (%) of cobalt(II) recovery are listed in Table 1.

As can be seen in Table 1, an increase in the concentration of any of the salting-out agents makes higher the distribution coefficients of cobalt(II). The recovery of cobalt depends to an even greater extent on the nature of a salting-out agent. For example, the distribution coefficient of Co(II) in the presence of 8 M LiCl exceeds by a factor of more than 200 that in the presence of 8 M NH_4Cl. This large difference in the salting-out activity is in good agreement with the difference of the radii of the Li^+ and NH_4^+ cations.

Averaged radii of the cations of the salting-out agents used

Cation	Al^{3+}	Cr^{3+}	Li^+	Ni^{2+}	Fe^{2+}
Radius, Å	0.55	0.60	0.72	0.74	0.78

Cation	Mg^{2+}	Na^+	Ca^{2+}	Nd^{3+}	La^{3+}	NH_4^+
Radius, Å	0.69	0.96	1.02	1.04	1.14	1.51

It follows from the data presented that the ammonium cation has the largest radius among all the salting-out agents studied, whereas the Li^+ cation has an approximately 2.2 times smaller radius.

The effect of the cation radius and charge on the salting-out capacity is due to the fact that different cations bind in their hydrate shell different amounts of water, and, as a result, the fraction of water that can solvate the metal compound being extracted widely varies [8].

The salting-out action of the cations can be characterized as follows: the lower the degree of hydration of a salting-out agent, the higher the active concentration of the solute.

Thus, hydration of ions of the salting-out agent will lead to a decrease in the amount of free water and to an increase in the activity of $CoCl_2$. In other words, a decrease in the free concentration of water leads to an increase in the concentration of chloride ions, which favors formation of the anionic complex $CoCl_4^{2-}$.

Comparison of the salting-out capacities of the cations, judged from how their radii vary at the same charge, gives the following series: $Al^{3+} > Cr^{3+} > Nd^{3+} > La^{3+}$; $Mg^{2+} > Ni^{2+} > Fe^{2+} > Ca^{2+}$; $Li^+ > Na^+ > NH_4^+$.

Comparison of experimental data on the variation of the distribution coefficients of cobalt(II) with the nature of a salting-out agent gives similar dependences for single- and triple-charged cations. However, it should be noted that, despite that Cr^{3+} has a radius close to that of Al^{3+}, chromium(III) chloride is a considerably weaker salting-out agent. For double-charged cations, the experimental series does not coincide at all with the order in which the radii vary, because the degree of Co(II) recovery in the presence of $CaCl_2$ substantially exceeds that in the presence of $FeCl_2$.

The observed inconsistency of the experimental data can be attributed to the fact that, in addition to interaction with water, cations of the salting-out agents can also interact with Cl^- ions [9]. In particular, Cr^{3+} interacts with chloride ions to give chloro complexes by the scheme

$$[Cr(H_2O)]Cl_3 \rightleftarrows [Cr(H_2O)_5Cl]Cl_2 \rightleftarrows [Cr(H_2O)_4Cl_2]Cl.$$

This, first, leads to a decrease in the charge of a cation and, second, makes lower the concentration of free Cl^- ions.

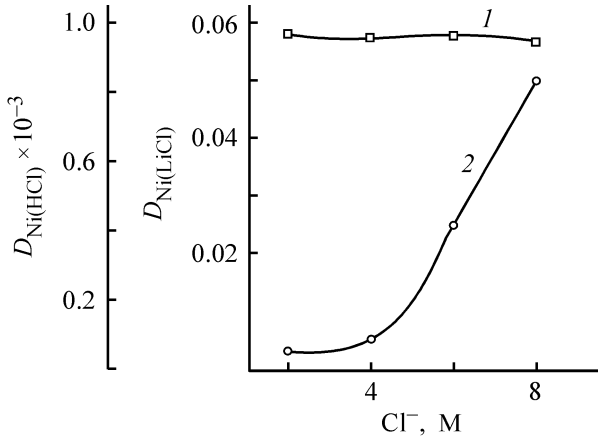
Iron(II) can also form complexes with chloride ions to give neutral octahedral complexes of the composition $Fe(H_2O)_4Cl_2$. Alkali and alkaline-earth elements and NH_4^+ form no inner-sphere complexes with Cl^- and, therefore, their influence on the distribution coefficient of Co(II) is only manifested via the varying degree of hydration of a cation.

Table 2. Parameters of coextraction of some salting-out metals with TAA solutions in an inert diluent and in TBP ($c_{Co_{in}}$ = 0.1 M) from solutions containing 8 M of Cl^-

Salting-out metal	Content of metals				Distribution coefficient		Co/M separation coefficient β
	initial solution		extract		$D_M \times 10^{-2}$	D_{Co}	
	g l^{-1}	M	g l^{-1}	M			
Inert diluent							
Ca(II)	160.3	4.0	0.52	0.013	0.33	10.1	3107
Ni(II)	230.6	4.0	0.15	0.003	0.065	4.2	6461
Mg(II)	97.2	4.0	0.50	0.020	0.51	13.7	2686
Al(III)	69.3	2.7	0.36	0.014	0.53	16.8	3170
Li(I)	55.5	8.0	0.22	0.030	0.40	280	70000
Fe(II)	223.4	4.0	2.00	0.036	0.09	1.9	211
Cr(III)	138.7	2.7	1.24	0.020	0.89	4.5	506
Tributyl phosphate							
Ca(II)	160.3	4.0	1.28	0.032	0.81	12.7	1567
Ni(II)	230.6	4.0	0.96	0.017	0.42	12.2	2904
Mg(II)	97.2	4.0	0.62	0.025	0.64	12.4	1938
Al(III)	69.3	2.7	0.47	0.018	0.66	26.9	4076
Li(I)	55.5	8.0	0.34	0.049	0.62	333.8	53839
Fe(II)	223.4	4.0	2.60	0.040	1.13	2.2	195

Comparison of the salting-out capacities of all the chlorides studied gives the following series: $LiCl > AlCl_3 > MgCl_2 > CaCl_2 > NiCl_2 > CrCl_3 > LaCl_3 \geq NdCl_3 \gg FeCl_2 \geq NaCl > NH_4Cl$.

Despite that H^+ is also strongly hydrated in aqueous solutions, the degree of Co(II) recovery from HCl is considerably lower than that from most of salt solutions. This is due to the fact that chlorides of tertiary amines can provide an additional extraction of hydrochloric acid [10], and the acid suppresses the extraction of $CoCl_4^{2-}$.



Thus, it follows from the series obtained that the extraction of Co(II) in the presence of most of salting-out metals proceeds better than that in the presence of HCl. The distribution coefficients are particularly high in the case of Co(II) extraction from LiCl and $AlCl_3$ solutions. A rather high degree of Co(II) recovery is achieved from 8 M Cl^- as salts of solutions containing Cr^{3+}, Ni^{2+}, and Nd^{3+}, which accompany cobalt in processing of secondary raw materials.

Commonly, the transfer of the salting-out metals used to the organic phase is neglected because of their exceedingly low extraction coefficients. However, very large amounts of a metal are to be introduced into a solution to create a 8 M chloride background. Therefore, it would be expected that noticeable amounts of metals pass into the organic phase even in the case of their insignificant coextraction. To determine the degree of coextraction of macrocomponents and the separation coefficients of Co and a salting-out metal, additional studies were performed.

As extracting agents were used 35 vol % solutions of TAA in an inert diluent (1) and tributyl phosphate (TBP) (2) [11]. The choice of the second mixture was due to the fact that TBP is also recommended as a modifier for tertiary amines, with this compound promoting, in contrast to alcohols, the recovery of cobalt (Table 2).

Table 2 shows that the degree of recovery of salting-out metals is indeed insignificant, because, for the most part, the distribution coefficient does not exceed 0.01. Accordingly, this circumstance provides a very high Co/M separation coefficient β; in particular, for Co/Li it is 70000 and 53389 for mixtures (1) and (2), respectively.

The separation coefficients for other salting-out metals are lower and decrease in the following order:

Distributions coefficients of nickel, D_{Ni}, vs. the concentration of chloride ion Cl^- in solutions of (*1*) HCl and (*2*) LiCl.

$Li^+ > Ni^{2+} > Al^{3+} > Ca^{2+} > Mg^{2+} > Cr^{3+} > Fe^{2+}$ for mixture (1) and $Li^+ > Al^{3+} > Ni^{2+} > Mg^{2+} > Ca^{2+} > Fe^{2+}$ for mixture (2).

Both the series were obtained by comparing the amounts of extracted elements (g l^{-1}). If all the salting-out elements are compared in their content in the extracts (M), the following series can be written: $Ni^{2+} < Ca^{2+} < Al^{3+} < Cr^{3+} < Ni^{2+} < Fe^{2+}$ for mixture (1) and $Ni^{2+} < Al^{3+} < Mg^{2+} < Ca^{2+} < Fe^{2+} < Li^+$ for mixture (2).

It can be seen that these series markedly differ from the sequences of variation of the separation coefficients. This is primarily due to a changed, because of the very low molecular weight, position in these series of the strongest salting-out agent, lithium.

To prevent contamination of cobalt extracts with impurities in processing of multicomponent solutions, the nature of the salting-out agent introduced into the system should be taken into account. For example, it is known that LiCl can markedly enhance the extraction of not only Co(II), but of many other elements as well [12].

To evaluate the extent of this influence on nickel(II), which commonly accompanies cobalt in processing of various kinds of raw materials [13, 14], the effect of a change in the concentration of LiCl and HCl on the distribution coefficient of Ni(II) was studied. It was found that an increase in the concentration of HCl has virtually no effect on D_{Ni}, whereas raising the concentration of LiCl results in that the distribution coefficient of nickel(II) grows to reach a value of 0.052, which is nearly two orders of magnitude higher than that in extraction from $NiCl_2$ solutions (see figure). Thus, it is necessary to take into account the influence exerted by a salting-out agent not only on the recovery of the target component, but on the coextraction of impurities as well.

CONCLUSIONS

(1) The series of the salting-out capacity of differently charged cations in extraction of Co(II) from chloride solutions with trialkylamine hydrochloride were experimentally obtained: $Li^+ > Al^{3+} > Mg^{2+} > Ca^{2+} > Ni^{2+} > Nd^{3+} > H^+ > La^{3+} > Cr^{3+} > Fe^{2+} > Co^{2+} > Na^+ > NH_4^+$.

(2) The separation coefficients of cobalt and salting-out agents were determined in extraction with mixtures based on trialkylamine with addition of various modifiers.

(3) It is recommended to use $NiCl_2$ as a salting-out agent in processing of nickel-containing cobalt solutions. Even though this compound has a comparatively low salting-out capacity, it does not lead to noticeable coextraction of other elements and does not require introduction of additional reagents into process solutions.

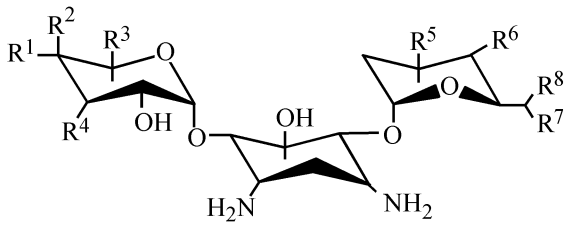
Abstract—Methods of modification of polymer hydrogels based on 2-hydroxyethyl methacrylate with the aim to improve their hydrophilic characteristics are described. The absorption of antibiotics such as aminoglycosides and the kinetics of their liberation from modified hydrogels are studied.



DOI: 10.1134/S107042720604015X

Polymer hydrogels are widely used as drug carriers. Binding of drug with a hydrogel provides not only its immobilization but also its controlled removal in prolonged use. It is important that binding of a drug with a hydrogel in some cases decreases the toxicity of the drug. For example, this was established for Gentamicin bonded with *N*-vinylpyrrolidone copolymer [1]. Soft contact lenses impregnated with drugs and used for treatment of ocular diseases are typical examples of medical hydrogels.

In this study we examined the absorption and liberation of such antibiotics as aminoglycosides with polymer hydrogels based on 2-hydroxyethyl methacrylate and used in production of soft contact lenses.

EXPERIMENTAL

As antibiotics we used aminoglycosides[1] (Kanamycin and Gentamicin) with the following structure:

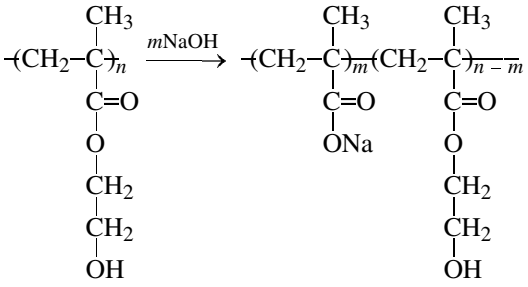
Aminoglycoside	R^1	R^2	R^3	R^4
Kanamycin	OH	H	OH	NH_2
Gentamicin	CH_3	OH	H	CH_3NH

Aminoglycoside	R^5	R^6	R^7	R^8
Kanamycin	OH	OH	H	H
Gentamicin	H	H	CH_3	NH_2

Aminoglycosides are commercially available in the form of sulfates. We also used them in the base form. The bases were synthesized by passing aqueous solutions of sulfates through a column packed with an anion-exchange resin. This process can be presented by the scheme:

$$\text{Aminoglycoside}\begin{matrix}\diagup\ NH_3\\ \ \ +\\ \diagdown\ NH_3\end{matrix}\ SO_4^{2-}$$

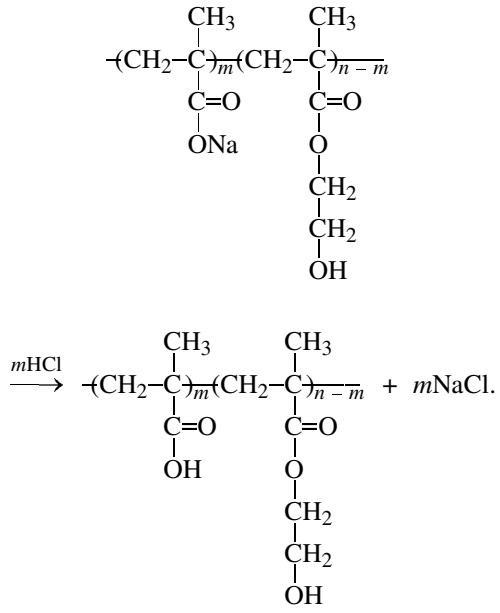
$$\downarrow \text{Anion-exchange resin}$$



$$\text{Aminoglycoside}\begin{matrix}\diagup\ NH_3OH\\ \ \ +\\ \diagdown\ NH_3\bar{O}H\end{matrix}$$

Hydrogels presenting weakly cross-linked polymers of 2-hydroxyethyl methacryalte were used as soft contact lenses.[2] The equilibrium water content in hydrogels of this type is 38 wt %. To increase the sorption

[1] Aminoglyocsides were purchased from the Sintez Joint-Stock Company (Kurgan, Russian Federation).



[2] Purchased from the Konkor Company (Vologda, Russian Federation).

activity with respect to aminoglycosides, the water content of hydrogels was increased by their partial conversion into the ionic form by treatment with 2% alkali at 95°C.

+ mHO–CH_2–CH_2–OH.

In some cases, hydrogels in the acidic form were used. For this purpose, after base hydrolysis, the hydrogels were treated with an acid (5% HCl) at room temperature:

After each treatment, the hydrogels were repeatedly washed with distilled water to remove excess reagents (NaOH and HCl) and by-products (ethylene glycol and NaCl).

The degree of hydrolysis of hydrogels was determined by titration. After converting the hydrogels to acid form we added to them 10 ml of 0.1 N NaOH to neutralize carboxy groups and then, 24 h latter, titrated excess NaOH with 0.1 N H_2SO_4. The degree of hydrolysis was estimated by formula (1) as the content of functional groups formed c_{COOH} (mol %) in the dried hydrogel:

$$c_{COOH} = 0.01(V_{NaOH} - V_{H_2SO_4})\,M/W, \qquad (1)$$

where V is the volume of 0.1 N NaOH solution (ml) added to the hydrogel; $V_{H_2SO_4}$, volume of 0.1 N H_2SO_4 solution (ml) spent for titration; M, molecular weight of 2-hydroxyethyl methacrylate (130); and W, weight of dry hydrogel (g).

The content of aminoglycosides sorbed with the hydrogel from concentrated solutions of antibiotics was determined gravimetrically. The hydrogel dried to constant weight was placed into an aminoglycoside solution. After a certain time, the hydrogels were removed from the solution, solution drops were removed from the surface with filter paper, and the hydrogels were dried to constant weight. The content of aminoglycoside (gram per gram of hydrogel) adsorbed with the hydrogel was evaluated by the formula

$$c_A = (m_2 - m_1)/m_1, \qquad (2)$$

where m_1 is the weight of the dry hydrogel and m_2 is the weight of the hydrogel with the absorbed aminoglycoside.

The hydrogels were kept in an antibiotic solution for 4 h. Further increase in time did not result in increasing amount of the antibiotic sorbed with the hydrogel.

Sorption of antibiotics from dilute solutions was studied spectrophotometrically. This procedure was used only for analysis of aminoglycosides in the form of sulfates, since this procedure is based on determination of sulfate ions.

In addition of a certain amount of $BaCl_2$ to an aminoglycoside sulfate solution, Ba^{2+} ions are bound in the form of water-insoluble $BaSO_4$. The consumption of Ba^{2+} ions in this reaction and, hence, the amount of sulfate ions in the solution are determined from the difference between the initial concentration of Ba^{2+} ions and their concentration found in the sample after a definite time. The Ba^{2+} ions were determined in the form of a colored complex with Chlorophosphonazo III [2].

In practice, the determination was performed as follows. The hydrogel containing aminoglycoside (approximately 0.1 g) was placed into 10 ml of saline, 2 ml of a 0.45 g l^{-1} $BaCl_2$ solution was added, and the solution was kept at room temperature for 24 h. Then, 5 ml of a 0.08 g l^{-1} solution of Chlorophosphonazo III in a standard buffer solution (pH 4.01)

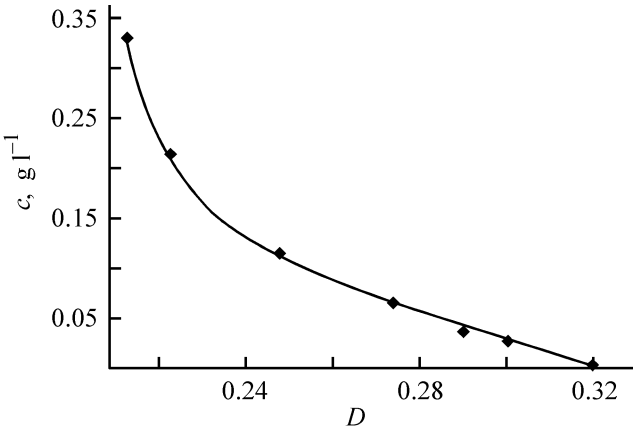


Fig. 1. Calibration plot for photometric determination of Gentamicin sulfate concentration in aqueous solution *c*. (*D*) Optical density.

was added, and the optical density of the solution was measured on a KFK-3 photocolorimeter at a wavelength of 670 nm after preliminary calibration. The calibration plot for Gentamicin sulfate is shown in Fig. 1 as an example.

In analysis of the solutions containing aminoglycoside in the base form, the concentration of aminoglycoside was determined by titration with 0.02 N HCl. Bromphenol blue was used as an indicator. The amount of aminoglycoside in the solution *A* was evaluated by the formula

$$A = V_{HCl} M_A \times 0.02/n, \quad (3)$$

where V_{HCl} is the amount of 0.02 N HCl (ml) spent for titration of the sample; M_A, molecular weight of aminoglycoside; and *n*, amount of amino groups in the aminoglycoside molecule.

Table 1. Physicochemical characteristics of hydrogels based on 2-hydroxyethyl methacrylate depending on the time of hydrolysis in 2% NaOH at 95°C

τ, min	Degree of hydrolysis, mol % of COONa groups	Water content of hydrogel, wt %, in the form		
		–COONa (water)	–COONa (saline)	–COOH (water)
0	0	38	37	38
30		49	40	34
60	1.30	55	41	34
90	2.16	62	43	33
120		70	50	31
180	3.12	78	57	30

In study of the desorption, th hydrogel (approximately 0.3 g) was saturated with the aminoglycoside, placed into 50 ml of saline at 20°C, and the antibiotic content in the solutions was determined at regular intervals. The amount of desorbed aminoglycoside was evaluated from the initial content of aminoglycoside in the hydrogel and the amount of the antibiotic that passed into the solution.

The water content in the hydrogels c_w (%) was determined gravimetrically at 20°C and evaluated by the formula

$$c_w = \frac{W_w - W_d}{W_w} \times 100, \quad (4)$$

where W_w is the weight of the moist hydrogel and W_d is weight of the hydrogel dried at 70°C to constant weight.

The mechanical characteristics of hydrogels were measured at equilibrium swelling on an RTM-1T universal tearing machine (Orientec, Japan).

The characteristics of hydrogels depending on the duration of their treatment with alkaline solution are presented in Table 1. It is seen that the hydrophilic characteristics of the modified hydrogels significantly increase, which is caused by appearance of ionic groups in the polymer structure and effects typical for polyelectrolytes along with osmotic phenomena. In total, this results in the fact that at the maximal degree of hydrolysis the amount of water adsorbed by 1 g of the polymer increases by a factor of approximately 6. It is of interest that such a significant effect is reached at very low degree of hydrolysis. As seen from Table 1, among 100 units of 2-hydroxyethyl methacrylate no more than three units transform into carboxylate anions. With increasing duration of alkaline treatment, the degree of hydrolysis increases; in this case, the water content can reach 90%. However, low mechanical strength (ultimate tensile strength 0.05 MPa) does not allow us to recommend this material for use. Hydrogels with a water content of up to 70% have quite acceptable strength characteristics (2.1 MPa). The characteristics of hydrogels based on ionic polymers essentially depend on the presence of electrolytes in water. For example, in the saline the water content in the hydrogel is significantly lower. This is due to the fact that excess Na^+ ions in the solution suppress dissociation of functional groups –COONa, which, in turn, decreases the hydration of polymer molecules. The effect of decreasing hydration is manifested to a larger extent in conversion of readily ionizable –COONa groups into acidic groups COOH.

In this case, the water content is even lower than that in the initial hydrogel, which is caused by associative interactions of carboxy groups resulting in pseudostructuring accompanied by some compaction of the hydrogel.

Figure 2 shows the dependences of the sorption of aminoglycosides on their concentration in aqueous solution for two hydrogels: ordinary hydrogel with c_w = 38 wt % and hydrogel subjected to alkaline treatment (c_w = 62 wt %). Figure 2 also shows the theoretical dependences plotted assuming that the concentration of the absorbed antibiotic in the aqueous part of the hydrogel is equal to that in the bulk of the solution. To plot the theoretical dependences, the aminoglycoside sorption c_A (gram of antibiotic per gram of dry hydrogel) for each concentration of the solution was evaluated by the formula

$$c_A = \frac{c_w A}{(100 - c_w) \times 100}, \quad (5)$$

where A is the aminoglycoside concentration in the solution (wt %).

It is seen that the experimental dependences practically coincide with the theoretical dependence for ordinary hydrogel. This means that in sorption of aminoglycoside with hydrogel there are no specific interactions of the antibiotic with the hydrogel. A different pattern is observed in sorption of aminoglycosides with hydrogel subjected to alkaline modification. First, c_A values are four times greater than those in sorption of antibiotics with nonmodified hydrogel. Second, the experimental and calculated dependences do not coincide. The increase in c_A is caused not only by increased water content of the modified hydrogels (from 38 to 62%), but also by specific ionic interactions of antibiotics with the partially ionized polymer.

Still higher values of sorption are observed in using aminoglycoside in the base form in comparison with the salt form. The c_A value for Kanamycin is 0.380 g per gram of the hydrogel. In this case, we also used the modified hydrogel with a water content of 62%. This result cannot be explained solely by ionic interactions, since hydroxides of primary and secondary amines (amino groups of both types are present in aminoglycosides) have fairly low ionization constants (of the order of 10^{-4} [3]), i.e., they are ionized to a significantly lesser extent than their salts. It is evident that in this case the specificity of interactions is largely caused by the fact that the major fraction of the glycoside in aqueous solution occurs in the amine rather than hydroxide form. The ability of

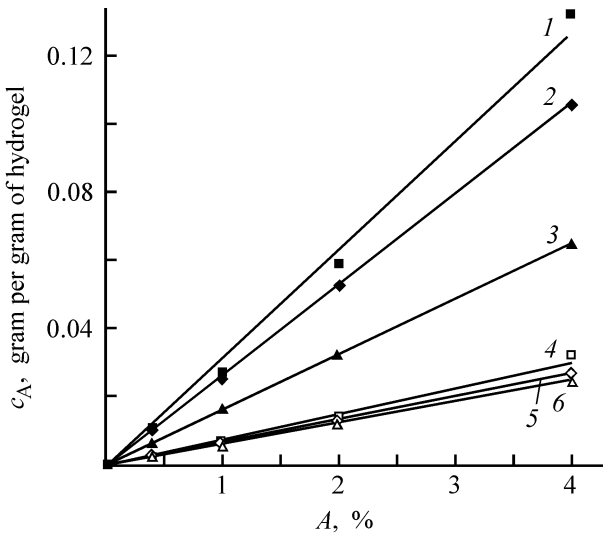

Fig. 2. Sorption c_A of (*2*, *5*) Kanamycin and (*1*, *4*) Gentamicin sulfates with (*1–3*) the initial hydrogel with c_w = 38 wt % and (*4–6*) alkali-modified hydrogel with c_w = 62 wt % vs. the antibiotic concentration in solution *A*. Dependences *3* and *6* were evaluated by Eq. (5).

amines to form hydrogen bonds, among them, with hydroxyl-containing compounds is well known. It is believed that combination of ionic interactions and hydrogen bonding results in high c_A values. A significant contribution of hydrogen bonds to sorption is suggested by the value of sorption of the aminoglycoside in the base form with the nonmodified hydrogel: 0.197 g per gram of hydrogel in sorption of Kanamycin from 4% solution. When the hydrogel after an alkaline treatment is converted into the acid form and the aminoglycoside is used in the base form, c_A reaches 0.52 g per gram of hydrogel. This high value of sorption is caused by the following factors: (1) direct acid–base interaction between carboxy groups of the hydrogel and amino groups of the aminoglycoside, resulting in binding of the aminoglycoside with the hydrogel due to salt formation; (2) formation of hydrogen bonds between hydroxy groups of the polymer and amino groups of the antibiotic; (3) conversion of the hydrogel from the weakly dissociated acidic form into the strongly dissociated state as a result of salt formation, which increases the water absorption of the hydrogel (from 33 to 64%) and the nonspecific sorption of the aminoglycoside.

Data on the sorption of Kanamycin (Table 2) show that successive modification of the hydrogel with alkali and then with acid and conversion of the aminoglycoside into the base form result in an increase in the sorption activity of the hydrogel by a factor of more than 20.

Table 2. Sorption of Kanamycin c_A from 4% aqueous solution with hydrogel based on 2-hydroxyethyl methacrylate (HEMA)

Hydrogel type	c_w, wt %	Kanamycin form	c_A, g per gram of hydrogel
PolyHEMA:			
initial	38	sulfate	0.025
		base	0.197
hydrolyzed with NaOH	62	sulfate	0.105
		base	0.380
after hydrolysis, treated with HCl	33	base	0.52

We used Kanamycin in the base form, since this form allows binding of the largest amount of the antibiotic with the hydrogel. After equilibrium saturation from a 4% solution of Kanamycin, the hydrogel was placed into the saline. We used the hydrogel subjected to alkaline treatment and also hydrogel converted then into acid form. The characteristics of these hydrogels are given in Table 2.

To describe the kinetics of the antibiotic desorption from the hydrogel, we used the relationship

$$c_{At} = kc_{A0}t^n, \quad (6)$$

where c_{At} is the amount of the aminoglycoside that passed from the hydrogel to the solution by the instant of time t (gram per gram of hydrogel); c_{A0}, initial content of aminoglycoside in the hydrogel (gram per gram of hydrogel); t, desorption time; k, constant characterizing the system hydrogel–solvent; and n, index characterizing desorption process.

The dependences were plotted using the log–log form of this relation (Fig. 3).

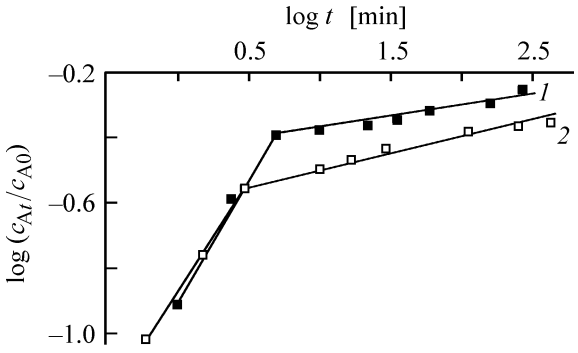

Fig. 3. Kinetic curves of desorption of Kanamycin in the base form from hydrogels into saline at 20°C. (t) Time. Hydrogel: (*1*) subjected to base hydrolysis and (*2*) converted into acid form after base hydrolysis. The characteristics of the hydrogels are presented in Table 2.

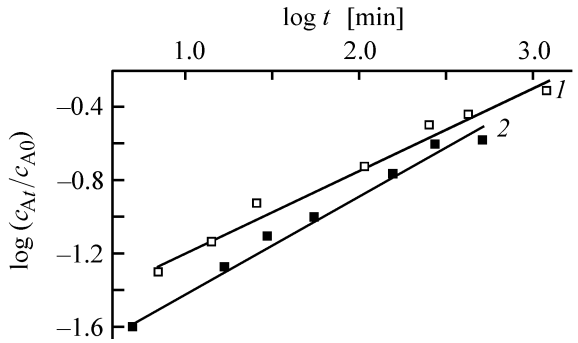

Fig. 4. Kinetic curves for slow stage of Kanamycin desorption from modified hydrogels. Hydrogel: (*1*) in salt form and (*2*) in acid form. c_{A0} (gram per gram of hydrogel): (*1*) 0.228 and (*2*) 0.406.

Figure 3 shows that in both cases the initial stage of the process is characterized by very fast desorption. In this stage, n is high: 0.69 for the hydrogel in the salt form (–COONa) and 0.75 for the hydrogel in the acid form (–COOH). This suggests anomalous character of aminoglycoside transfer into solution, caused not only by ordinary diffusion but also by other phenomena which can be related, e.g., to the difference in c_w of the hydrogels measured in water and in saline (Table 1).

It is known that similar phenomena are typical for ionic hydrogels, which are extremely sensitive to variation of pH and ionic strength of the solution. Thus, the hydrogel saturated with an antibiotic from an aqueous solution, when transferred into saline, gets somewhat collapsed, losing a part of water with the dissolved aminoglycoside. As a result, in the fast stage of the process 40% of Kanamycin is desorbed from the hydrogel in the salt form and 28%, from the hydrogel in the acid form.

After completion of the fast stage (within 3–5 min), the desorption rate abruptly decreases and the process continues in the prolonged mode for several hours. If the kinetic dependence of the desorption in the slow stage is interpreted considering the residual content of Kanamycin in the hydrogel after completion of the fast stage as its initial content, it takes absolutely normal form (Fig. 4) characterized by n close to 0.5

(0.53 for the hydrogel in the acid form and 0.5 for the salt form of the hydrogel), i.e., in this stage the process is governed by simple diffusion of Kanamycin from the hydrogel and is described by the Fick law. The above concept of the desorption mechanism is confirmed by the fact that in using antibiotic solution in saline the fast portion in the kinetic curves disappears.

A simple modification (base hydrolysis) of the hydrogels based on 2-hydroxyethyl methacrylate, characterized by low water content (38 wt %), allows significant increase in their swellability in water and, correspondingly, in the water content. This results in that the hydrogels gain the capability to sorb increased amounts of antibiotics (aminoglycosides) due to the natural increase in the hydrogel volume (nonspecific sorption) and to the specific sorption caused by ionic interactions and formation of hydrogen bonds. Desorption of aminoglycosides from modified hydrogels is a complex process. In the first stage, some amount of the aminoglycoside is rapidly liberated from the hydrogel due to its collapse in saline. This is followed by slow desorption lasting for several hours and controlled simply by diffusion. Considering specific therapeutic purposes, we can recommend different procedures for saturation of hydrogels with aminoglycosodes. When it is necessary to obtain a high concentration of an antibiotic in the therapeutic area for a short time, for saturation of hydrogels it is appropriate to use aqueous solutions with increased concentration of aminoglycosides. When a high local concentration of an antibiotic is undesirable, e.g., due to toxicity of some aminoglycosides, it is appropriate to perform sorption from solutions prepared in saline. In this case, the fast stage of desorption disappears and the antibiotic is liberated from the hydrogel in prolonged mode in the course of several hours.

CONCLUSIONS

(1) In base hydrolysis of polymer hydrogels based on 2-hydroxyethyl methacrylate, their swellability in water increases due to partially ionic character of the polymer in water. In parallel, the sorption activity of the modified hydrogel with respect to antibiotics such as aminoglycosides (Kanamycin, Gentamicin sulfates) increases due to an increase in the hydrogel volume and appearance of ionic interactions. Desorption of the aminoglycoside from the hydrogel into saline is a complex process. First, the fast stage of desorption is caused by some collapse of the hydrogel in the NaCl solution. Second, the slow stage of the antibiotic liberation from the hydrogel is described by a simple diffusion mechanism.

(2) Depending on therapeutic purposes, aminoglycosides can be sorbed with hydrogels either from aqueous solutions of the antibiotic or from solutions prepared in saline. In the first case, fast liberation of high concentrations of the aminoglycoside from the hydrogel is realized and in the second case, the antibiotic is desorbed in the prolonged mode in the course of several hours.

Abstract—A study was carried out of extractive refining of atmospheric gas oil with *N*-methylpyrrolidone in the presence of undecane to remove aromatic hydrocarbons and sulfur-containing compounds and thus obtain a summer diesel oil component.

DOI: 10.1134/S1070427206040161

Rapid growth of the number of diesel motor cars causes the consumption and production of diesel oils to increase. For example, in 1990–2006, the proportion of diesel cars increased worldwide from 14 to 40–50% [1]. Within 1999–2004, diesel oil production in Russia increased by 18.4%, from 46.8 to 55.4 mln tons [2]. By contrast to car gasolines consumed mostly inside Russia, diesel oils are mostly exported: In 2004, the domestic consumption and export were 25.8 and 29.6 mln tons, respectively [3]. This was paralleled by posing ever more stringent environmental requirements on the diesel oil quality [4]. These requirements can be met by using hydrogenation methods only if the end boiling point of the feed will be decreased, so that dialkylated dibenzothiophenes exhibiting low reactivity in hydrogenolysis will not enter the initial diesel fraction. However, this will decrease production of diesel oils. Lowering of the initial boiling point of the diesel fraction is also undesirable, as this would decrease production of jet fuel.

When light gas oils from secondary processes (catalytic and thermal cracking, coking), having an increased content of aromatic hydrocarbons, are involved in production of diesel and ship oils, this decreases the quality of the resulting oil products.

The above-mentioned contradiction, namely, the need in increasing both the production and quality of diesel oil, can be overcome by involving into processing atmospheric gas oil yielded in significant amounts on AVT (atmospheric-vacuum pipe still) installations. In extractive refining of atmospheric gas oil, dibenzothiophene derivatives and polycycloarenes, which are the most difficult to remove in hydrorefining, should be extracted most readily. Aromatic nitrogen-containing components (carbazole, indole, and quinoline homologs) poisoning hydrorefining catalysts are even more easily extracted with polar solvents [5].

Sulfur-containing compounds that partially remain in the raffinate from extractive refining of atmospheric gas oil are mostly saturated compounds such as dialkyl sulfides, thiacyclanes, and disulfides, which can be readily cleaved in hydrorefining. Thus, it seems possible to combine the resulting raffinate with lightened diesel fraction and obtain high grade diesel oil after hydrorefining of a combined flow under mild conditions.

Previously [6] we studied the extractive refining of atmospheric gas oil with 2-methoxyethanol (methyl Cellosolve) using methyl Cellosolve–water–pentane extraction system. We confirmed a high economic efficiency of the designed process for combined production of a diesel oil component from atmospheric gas oil by extraction with aqueous methyl Cellosolve in the presence of pentane, followed by hydrorefining of the raffinate [7].

A drawback of the method of extractive refining of atmospheric gas oil is that it requires fairly high aqueous methyl Cellosolve : feed and pentane : feed weight ratios of 5 : 1 and 1 : 1.5, respectively, which makes the process power-consuming.

In this study we developed a power-saving technology of extractive refining of atmospheric gas oil, suitable for highly selective extraction of polycycloarenes and organosulfur compounds that are difficult to remove by hydrorefining, at moderate extractant : feed ratios.

As selective solvent we chose *N*-methylpyrrolidone surpassing methyl Cellosolve in the selectivity and solvency with respect to arenes [8].

N-Methylpyrrolidone is widely used in oil refining and petrochemical industries as a selective solvent for recovery of benzene and its homologs from reformer naphthas, as well as of 1,3-butadiene, isoprene, acetylene; it is also used for selective refining of lubricating oils [9]. However, when installations for selective refining of lubricants at Russian refineries changed from phenol and furfural to more efficient *N*-methylpyrrolidone, this posed a serious problem. Namely, *N*-methylpyrrolidone can be oxidized at high temperatures to *N*-methylsuccinimide which is hydrolyzed into succinic acid exerting a corrosive impact on the equipment. All these reactions are especially accelerated at temperatures close to 300°C, which can be attained in regeneration of *N*-methylpyrrolidone.

We suggested previously [10, 11] to eliminate or mitigate these drawbacks of *N*-methylpyrrolidone in extractive refining of vacuum gas oils and fuel oil by using an *N*-methylpyrrolidone–undecane (or undecane fraction) extraction system. Undecane completely substitutes nonpolar solvent pentane, used for refining of the diesel fraction, namely, increases the refining selectivity, yield of the raffinate, the difference in the densities and settling rates of the equilibrium phases, and performance of the extractor. At the same time, undecane performs another two important functions essential for selective refining of atmospheric gas oil as well. First, undecane forms with *N*-methylpyrrolidone an azeotrope boiling at 179°C (which is 25°C lower than the boiling point of *N*-methylpyrrolidone). This decreases the probability of decomposition and corrosion of the equipment during regeneration of the reagent. Also, with undecane there are no *N*-methylpyrrolidone impurities in the raffinate, which is also essential: To be suitable as a diesel oil component, raffinate needs additional refining. As known, hydrorefining catalysts are poisoned even by weakly basic nitrogen-containing compounds, in particular, *N*-methylpyrrolidone.

Another drawback of *N*-methylpyrrolidone is its ability to form azeotropes with hydrocarbons boiling at temperatures lower than 280°C, which can be responsible for "oiling" of the extractant [12]. However, this holds only for systems comprised of *N*-methylpyrrolidone and saturated hydrocarbons with low mutual solubility, so that distillable azeotropic mixtures easily settle after condensation and cooling. *N*-Methylpyrrolidone does not form azeotropic mixtures with arenes occurring in atmospheric gas oil, which could really "oil" the extractant.

Table 1. Characteristics of atmospheric gas oil fractions from AVT-2 and AVT-6 installations

Characteristic	AVT-2, sample no.		AVT-6, sample no. 3
	1	2	
Boiling range, °C:			
initial boiling point	279	278	290
10%	298	311	320
30%	313.5	323	333
50%	326	341	352
70%	341	361	373
90%	366	384	397
Density at 20°C, g cm^{-3}	0.865	0.871	0.874
Refractive index at 20°C	1.4822	1.4885	1.4902
Cloud point, °C	4.0	+18	+19
Freezing point, °C	–1.0	+14	+14.5
Viscosity, mm^2 s^{-1}, at:			
20°C	12.5	19.62	20.0
50°C	5.0	8.03	8.15
Content, wt %, of compounds reactive in sulfonation	27.2	28.2	29.3
sulfur	1.13	1.15	1.17
Cetane index	49.3	50.3	51.0

Thus, we chose *N*-methylpyrrolidone–undecane (or undecane fraction) extraction system for refining of atmospheric gas oil. Decane and dodecane impurities in the undecane fraction do not deteriorate the above-mentioned characteristics, since both these alkanes, like undecane, form with *N*-methylpyrrolidone azeotropes with minimal boiling points.

EXPERIMENTAL

As feed we used three atmospheric gas oil samples from Kirishinefteorgsintez Production Association, Open Joint-Stock Company, taken from AVT-2 and AVT-6 installations (Table 1).

The total sulfur content in atmospheric gas oil and the resulting raffinates and extracts was determined by the lamp method according to GOST (State Standard) 19 121–73. The cetane index was calculated according to GOST 27 768–88:

$$CI = 454.74 - 1641.416\rho^{15} + 774.74(\rho^{15})^2 - 0.554t_{50} + 97.803(\log t_{50})^2.$$

The multistep extraction was carried out with a set of temperature-controlled funnels by the counterflow scheme simulating operation of a full-size extraction column [13]. Table 2 presents the conditions of experiments on extractive refining of sample nos. 1–3.

An azeotropic mixture of water, *N*-methylpyrrolidone, and saturated hydrocarbons was distilled off on a 15-TP fractionating column from the extract phase obtained by extractive refining of sample no. 1 with neat *N*-methylpyrrolidone (without undecane). The remaining *N*-methylpyrrolidone was vacuum-distilled, which yielded the extract in the bottoms. Partial removal of saturated hydrocarbons from the extract phase in the form of azeotropes decreases their content form 18.4 to 14.5 wt %. The saturated hydrocarbons isolated from azeotropic mixtures upon cooling to 0°C were combined with the raffinate.

The raffinate was recovered from the raffinate phase by back-extraction of *N*-methylpyrrolidone with water. Table 3 presents the characteristics of

the combination of the raffinate and extract yielded by extractive refining of atmospheric gas oil sample no. 1 with *N*-methylpyrrolidone (*N*-MP) and, for comparison, with methyl Cellosolve.

Despite the fact that *N*-methylpyrrolidone : feed ratio is by a factor of 1.5 lower than that in the case of methyl Cellosolve, the refining is more efficient. With *N*-methylpyrrolidone, undesirable components are removed more selectively and completely, as indicated by higher density, refractive index, and content of sulfur and compounds reactive in sulfonation in the extract, as well as by a higher degree of extraction of arenes and sulfur-containing compounds. Also, *N*-methylpyrrolidone provides a higher quality of the combined raffinate, namely, lower density, refractive index, and content of arenes and sulfur (by factors of 1.9 and 1.8, respectively) compared to methyl Cellosolve. When atmospheric gas oil is refined with *N*-methylpyrrolidone and methyl Cellosolve, the cetane index of the raffinate increases by 11 and 7 units, respectively.

Thus, extractive refining of atmospheric gas oil with *N*-methylpyrrolidone is more efficient than with methyl Cellosolve: At a lower reagent : feed ratio (2 : 1 against 3 : 1 by weight), the undesirable impurities are removed more selectively and completely, thus yielding a higher-quality raffinate.

Gas oil sample no. 2 and especially sample no. 3 are distinguished from sample no. 1 by the presence of higher-boiling fractions, as well as by fairly high cetane indices, despite enhanced content of arenes, which is due to the presence in them of *n*-alkanes C_{17^+} with cetane indices of over 100.

To increase the selectivity of refining of higher-boiling samples and to decrease the temperature of the extractant regeneration, we performed the extraction with *N*-methylpyrrolidone in the presence of undecane (Table 2).

The solvents from the extract phases were regenerated in three stages. First, a water–undecane–*N*-methylpyrrolidone azeotrope was distilled off on a 15-TP fractionating column. Then most of *N*-methylpyrrolidone was vacuum-distilled at the bottoms temperature of no higher than 250°C. The remaining small proportion of *N*-methylpyrrolidone (ca. 3 wt %) was vacuum-distilled as an azeotropic mixture with undecane, which was returned to the still in the desired amount.

From the raffinate phase, an undecane–*N*-methylpyrrolidone azeotropic mixture was distilled off; excess undecane was removed from the raffinate by vacuum fractionation.

Table 4 shows that the raffinate yielded by refining of sample no. 2 contains <10 wt % arenes; their content decreases by a factor of 3.5, and the sulfur content decreases by a factor of 2.45. The cetane index of the raffinate increases by 9 units, the point of 90% distillation of the raffinate under standard distillation decreased by 17°C relative to the feed. This can be attributed to a virtually complete removal of the highest-boiling components, namely, homologs of tricycloarenes and dibenzothiophene. The density, refractive index, and viscosity of the raffinate decrease. The freezing point of the raffinate remains virtually identical to that of the feed, but the cloud point increases by 4°C. However, the cloud and freezing points abruptly decrease after mixing the raffinate with the hydrorefined diesel fraction. For example, for 20 wt % atmospheric gas oil raffinate in the combined product the cloud and freezing points decrease to –24 and –28°C, respectively (for hydrorefined diesel fraction they are equal to –32 and <–35°C, respectively).

the presence of undecane is much more efficient compared to that with the methyl Cellosolve–pentane extraction system. The aqueous methyl Cellosolve : feed and pentane : feed weight ratios were much higher, namely, 5 : 1 and 1.5 : 1, respectively [6]. Nevertheless, the raffinate obtained with the *N*-methylpyrrolidone–undecane system has a much higher quality: The content of compounds reactive in sulfonation and sulfur is by 4.7 and 0.26 wt %, respectively, lower, and the cetane index is by 2.2 units higher.

Thus, the raffinate from extractive refining of atmospheric gas oil from the AVT-2 installation is suitable as a summer diesel oil component on the Russian domestic market. The sulfur content in the raffinate can be decreased by hydrorefining jointly with straight-run diesel fraction. In view of the fact that extractive refining of atmospheric gas oil removes benzothiophene and dibenzothiophene homologs, which are the least reactive in hydrogenolysis, it is unnecessary to perform the hydrorefining under more severe conditions.

Close results were obtained in extractive refining of the highest-boiling sample no. 3 from AVT-6 installation, but this required increased *N*-methylpyrrolidone : feed and undecane : feed weight ratios (Table 5).

CONCLUSIONS

(1) Extractive refining of atmospheric gas oil with *N*-methylpyrrolidone in the presence of undecane increases the selectivity of removal of undesirable arenes and organosulfur compounds and also decreases both the temperature of regeneration and probability of decomposition of the extractant because of formation of an undecane–*N*-methylpyrrolidone azeotropic mixture. Extractive refining of atmospheric gas oil gives raffinate in a yield of ca. 78% with the cetane index of 59 and <10 wt % content of arenes; the sulfur content is decreased by a factor of 2.5 compared to the feed.

(2) The raffinates obtained are promising as diesel oil components.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Electrodes Based on Nanodispersed Titanium and Tungsten Oxides for a Sensor of Dissolved Oxygen

Abstract—It is suggested to use films of nanodispersed Ti and W oxides as electrodes in a sensor for dissolved oxygen. It is shown that films of this kind have stable characteristics in electroreduction of O_2 in saline.

DOI: 10.1134/S1070427206040173

Oxygen dissolved in biologically active liquids plays an important role in redox processes. Therefore, development of sensitive methods for determining its concentration is a topical problem. Oxygen sensors are now used to control biological processes in fermenters and at plants for treatment and processing of biological wastes, to monitor the content of dissolved oxygen in water used at thermal power stations, and to make various technological analyses. However, the most important is application of such sensors in medical practice.

For example, in oxygen-inhalation hypoxia therapy, it is necessary to monitor that part of oxygen in blood plasma, which is not bound to hemoglobin; a similar analysis is required in hyperbaric-oxygenation therapy of lungs, in hypoxytherapy of cardiac and gastroenteric illnesses, in determining the effect of fetal hemoglobin on the blood pathology in oncology, in therapy of pathological pregnancy, etc.

The concentration of dissolved oxygen should also be monitored in preparation and storage of physiological solutions, blood plasma, and other biologically active fluids.

Because of its high sensitivity the electrochemical method is promising for analyzing oxygen concentration in biologically active fluids [1–4]. The operation of a sensor is based on electroreduction of oxygen, whose total concentration is described, for a number of metals, by the equations [1, 3, 4]

$$O_2 + 4H^+ + 4e \rightarrow 2H_2O, \quad \text{(I)}$$

for an acid medium and

$$O_2 + 2H_2O + 4e \rightarrow 4OH^-, \quad \text{(II)}$$

for an alkaline medium.

In this case, the process goes via an intermediate stage of hydrogen peroxide formation. For a number of metallic electrodes, a two-electron overall process without formation of hydrogen peroxide is also possible [1, 3–5]:

$$O_2 \rightarrow 2O_{ads}, \quad \text{(III)}$$

$$O_{ads} + 2H^+ + 2e \rightarrow H_2O, \quad \text{(IV)}$$

$$O_{ads} + H_2O + 2e \rightarrow 2OH^-; \quad \text{(V)}$$

reaction (IV) proceeds in an acid medium, and reaction (V), in an alkaline medium.

The specificity of electrochemical reactions on semiconductor electrodes primarily consists, in contrast to reactions on metallic electrodes, in a potential redistribution between the ionic double layer and the space charge region near the semiconductor surface, which can affect the kinetics of these reactions [5, 6]. For example, it has been shown for mixed oxides SiO_2/Nb_2O_5 [7] that oxygen reduction involves

two electrons to form hydrogen peroxide. At the same time, for a TiO_2^- electrode fabricated by anodic oxidation of titanium, the total number of electrons involved in the reaction may vary from $n_s = 4$ to $n_s = 2$ in passing from alkaline to acid solutions [8]. It is noteworthy that n_s affects the limiting sensitivity of an oxygen sensor. Electrodes based on ultradispersed semiconducting materials and, in particular, on transition metal oxides, exhibit a high catalytic activity [9–11] and are being extensively studied now.

In this study, nanodispersed Ti and W oxides, which are stable in many biologically active liquids, on Ti and InP substrates were examined as semiconducting electrode materials for oxygen sensors. The oxygen reduction in a 0.9% isotonic physiological and 7.5% hypertonic NaCl solutions was analyzed.

EXPERIMENTAL

TiO_2 nanoparticles were obtained by the sol–gel method from $TiCl_4$. The procedure used included synthesis of a sol of amorphous titanium peroxide from titanium hydroxide and its subsequent heat treatment [12]. Titanium hydroxide was synthesized by hydrothermal decomposition of Ti(IV) chloride. To completely shift the equilibrium toward formation of the target product, an NH_4OH solution was introduced into the reaction mixture. After the neutralization was complete, the pH of the medium was adjusted to 6.5–6.8. The precipitate formed was washed with distilled water to remove chloride ions. A sol of amorphous titanium peroxide was obtained by adding a solution of hydrogen peroxide to a titanium hydroxide solution. The subsequent heating of the sol of amorphous titanium peroxide at 100°C yielded a TiO_2 sol, which was converted to TiO_2 (anatase) at 400–430°C. Titanium served as a substrate for deposition of TiO_2 nanoparticles. The size of the semiconducting TiO_2 nanoparticles (d = 2.9–4.0 nm) was determined from the band gap of the semiconductor [9–11], found by measuring spectra of the photoelectrochemical current [6], using the method described in [13, 14]. The average thickness of the TiO_2 films (500 to 1000 nm) was determined from the change in the substrate mass after their deposition. The TiO_2 films were modified with Pt nanoparticles from a solution of chloroplatinic acid by exposure of the semiconductor to light in the spectral range of fundamental absorption [15].

TiO_2 particles were obtained on an InP substrate by the method used in semiconductor industry to produce protective TiO_2 films on crystals with p–n junctions. The deposition was performed in a quartz tube containing a heated TiO_2 powder and InP single crystals at its opposite ends. An inert gas (purified Ar) was passed through the working chamber. The InP samples were placed in the temperature zone 400–480°C. The average size d of the TiO_2 particles on InP was determined with a scanning electron microscope (d = 100–300 nm).

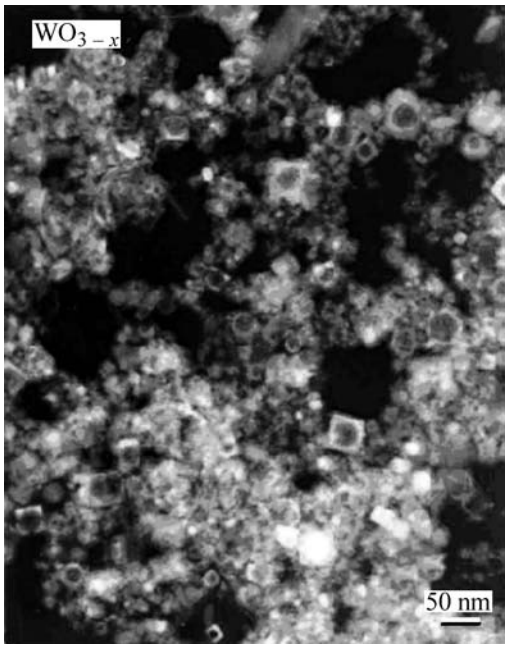

Fig. 1. TEM micrograph of WO_{3-x} nanoparticles.

Nanoparticles of a nonstoichiometric tungsten oxide WO_{3-x} were obtained by the method of electric explosion of conductors (EEC). The procedure included purification of a tungsten wire, formation of an oxygen-deficient atmosphere in the explosion chamber, and choice of the optimal energy range [16]. The average size of the nanoparticles, d, was determined by transmission electron microscopy (TEM). According to the TEM data, d varies within 5–50 nm, the nanoparticles are anisotropic, have the form of a sphere inscribed in a parallelepiped, and are not agglomerated (Fig. 1). The WO_{3-x} films were obtained by sedimentation from a sol of nanoparticles in water. Titanium served as a substrate onto which WO_{3-x} nanoparticles were deposited. The average thickness of the WO_{3-x} films (about 2000 nm) was determined from the change in the substrate mass after the deposition.

The electronic structure of the nanodispersed titanium and tungsten oxides was studied by X-ray photoelectron spectroscopy (XPS) on an ES-2402 spectrometer equipped with a PHOIBOS-100-SPECS en-

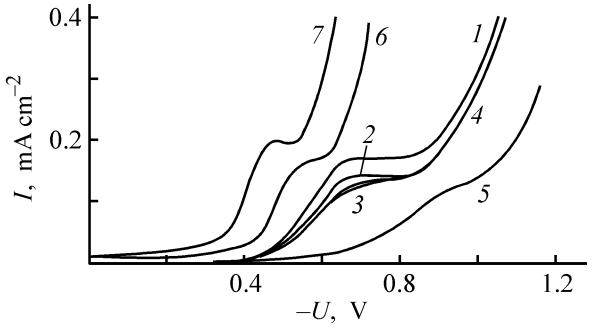

Fig. 2. *I–U* curves measured in oxygen reduction in a 0.9% NaCl solution at a potential sweep rate v = 10 mV s^{-1} in relation to a cycle number. Curves: (*1–5*) TiO_2/Ti electrodes; (*6*, *7*) TiO_2/Ti electrodes modified with Pt nanoparticles, (*6*) cycle 1, and (*7*) cycle 4. (*I*) Current density and (*U*) potential; the same for Fig. 3.

ergy analyzer. As the excitation source served an X-ray gun with a magnesium anode (E MgK_α = 1253.6 eV, P = 200 W). The absolute resolution, measured for the Au $4f_{7/2}$ peak of gold, was 0.9 eV, and the accuracy in determining the peak of the W $4f_{7/2}$ line, 0.05 eV. The procedure used to calibrate the spectrometer was described in [15]. The residual pressure in the vacuum chamber was 2×10^{-7} Pa. As substrates served 10 × 10-mm Al plates.

The W4*f* and Ti2*p* spectra were resolved into the interconnected component pairs, $4f_{7/2}/4f_{5/2}$ and $2p_{3/2}/2p_{1/2}$ (ΔE = 2.1 eV, I_1/I_2 = 0.77 and ΔE = 5.7 eV, I_1/I_2 = 0.5, respectively), to take into account the spin-orbit splitting. We employed the Gauss–Newton method for coupled parameters. The intensity of the components and their binding energies were varied. The width of the corresponding components and the relative contributions of the Gauss–Lorentz distributions in spectral resolution were fixed. The areas of the components were determined after the background was subtracted by the Shirley method [17]. The integral intensities of the components, obtained in this way, are proportional to the concentration of nonequivalent titanium and tungsten ions in the samples.

The current–voltage (*I–U*) dependences of the electrodes were measured in the potentiodynamic mode, using a special computerized electrochemical installation. The installation has the following characteristics: measurable currents in the range from 2×10^{-9} A to 10^{-1} A, potential sweep rate of 0.01–50 mV s^{-1}, and potential of the working electrode varying from 4 to –4 V. The electrochemical studies were performed in a cell with separated cathode and anode compartments. The electrode potential was measured relative to a silver chloride reference electrode. The oxygen concentration in solution was varied by adding a deaerated NaCl solution. For this purpose, argon was bubbled through the solution for 2–3 h. The solution was mixed in a certain proportion with the working NaCl solution containing dissolved oxygen. This was done in a box filled with Ar.

The polarization curves measured in oxygen reduction on the TiO_2 electrodes are shown in Fig. 2. As is known, the titanium foil used as a support for deposition of TiO_2 nanoparticles is covered with an oxide film under natural conditions and upon its annealing and anodizing. Oxygen is also reduced on this film, but its activity is lower as compared with the activity of films based on TiO_2 nanoparticles produced by the sol–gel method. This is also indicated by the *I–U* curves measured in oxygen reduction on films of TiO_2 nanoparticles (Fig. 2, curves *1–4*) and on TiO_2 films formed upon annealing of Ti (Fig. 2, curve *5*). As in the case of platinum metals, all the polarization curves show a single wave at potentials from –0.45 to –1.2 V, which may correspond to the overall process of oxygen reduction, (III)–(V), without formation of hydrogen peroxide. As can be seen from Fig. 2, the hydrogen evolution is clearly pronounced at U < –1.3 V.

The reduction of oxygen on TiO_2 films obtained upon annealing of Ti occurred at a potential shifted to the cathodic region by 0.23 V, compared with the electrodes based on TiO_2 nanoparticles, which points to a lower electrocatalytic activity of these films. The high overvoltage of oxygen reduction may cause difficulties in analysis for the oxygen content of, because in this case side reactions may proceed at the cathode in a number of biologically active solutions. To make the potential of oxygen reduction lower, the TiO_2 films were modified with Pt nanoparticles, because the potentials of O_2 reduction at the Pt electrode are more positive than those at the TiO_2 electrode [4]. However, the modification of the electrodes with Pt considerably deteriorated their stability, which was manifested in that their *I–U* characteristics were irreproducible in cycling (Fig. 2, curves *6*, *7*). In addition, the hydrogen evolution potential for such electrodes was markedly shifted to the anodic region. As a result, the region of potentials at which analysis for the content of oxygen in solution is possible became narrower. For TiO_2/InP electrodes, the reproducibility of the characteristics in cycling was better (Fig. 3, curves *1–3*). At the same time, the potentials of oxygen reduction at these electrodes were more positive than those at electrodes based on TiO_2 nanoparticles. The differences in current density between

TiO_2/Ti and TiO_2/InP electrodes based on nanoparticles are related both to a surface macroporosity and to nonuniformity of film deposition on the electrode surface, with these parameters affecting the current density in the opposite directions.

The most stable characteristics were exhibited by WO_{3-x}/Ti electrodes. Their *I–U* characteristics remained virtually unchanged already after the third cycle (Fig. 3, curves *4–7*).

Analysis of the structure of XPS spectra of the O1*s* level in these samples shows that, along with the signal related to the lattice oxygen (O^{2-}, E_b = 530.6 eV for tungsten oxide and E_b = 530.0 eV for titanium oxide), there are a strong signal due to the oxygen of OH groups (E_b = 531.0–531.8 eV) and a weaker signal associated with the oxygen from the H_2O molecule (533.0–533.8 eV). The results of resolution into components of normalized XPS spectra of the W4*f* and Ti2*p* levels of the samples studied are presented in Figs. 4a, 4b, and 4c and in the table. As can be seen from Fig 4a, the surface of nanoparticles from which the electrodes were fabricated is mainly formed by the W^{6+} states of tungsten ions with binding energies $E_b W4f_{7/2}$ = 36.1 eV and $E_b W4f_{7/2}$ = 35.7 eV and by W^{5+} states ($E_b W4f_{7/2}$ = 34.8 eV [17–18]. The components in the range E_b = 35.7 eV (W^{6+}) and E_b = 34.8 eV (W^{5+}) correspond to the main phase of protonated oxide $W_x^{5+}W_{1-x}^{6+}O_{3-x}\cdot(OH)_x$. The contributions from the W^{5+} and W^{6+} states (11.7 and 36.5%, respectively, see table) can be used to determine the nonstoichiometry coefficient (x = 0.243) and the composition of the main phase, $WO_{2.76}\cdot(OH)_{0.24}$. The signal at E_b = 36.1 eV can be attributed to formation on the surface of nanoparticles of a hydroxide phase, $WO_3\cdot nH_2O$, which was possibly formed from the main phase upon its contact with water.

The results obtained in resolution of the Ti2*p* spectra of the sample of titanium oxide nanoparticles are shown in Fig. 4. The components at $E_b Ti\,2p_{3/2}$ = 458.5 eV (Ti^{4+}, 69.7%, see table) and $E_b Ti\,2p_{3/2}$ = 457.5 eV (Ti^{3+}, 7.2%, see table) [18, 19] can be assigned to the phase of a protonated oxide $Ti_x^{3+}Ti_{1-x}^{4+}O_{2-x}\cdot(OH)_x$. The nonstoichiometry coefficient determined from the contributions of the Ti^{3+} and Ti^{4+} ions to the oxide phase (7.2% and 69.7%, respectively) can be used to find the nonstoichiometry coefficient (x = 0.093), which corresponds to a composition $TiO_{1.91}\cdot(OH)_{0.09}$. The component at $E_b Ti\,2p_{3/2}$ = 459.4 eV (Ti^{4+}, 23.1±0.7%, see table) can be attributed to formation of the phase $TiO_2\cdot nH_2O$ on the surface of nanoparticles.

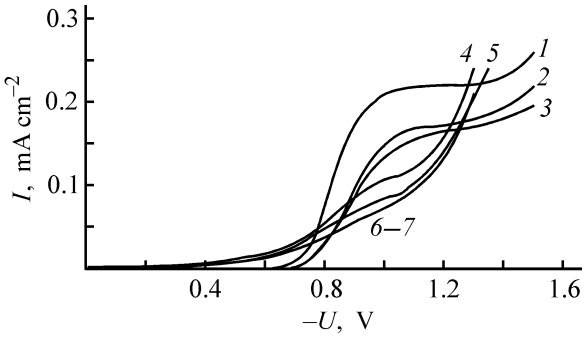

Fig. 3. *I–U* curves measured in oxygen reduction in a 7.5% NaCl solution at a potential sweep rate v = 10 mV s^{-1} in relation to a cycle number. Curves: (*1–3*) TiO_2/InP electrodes; (*4–7*) WO_{3-x}/Ti electrodes, (*4*) cycle 1, and (*5–7*) cycles 2–4.

Thus, according to the XPS data, the electrode surface is composed of nonstoichiometric oxides of tungsten, $WO_{2.76}\cdot(OH)_{0.24}$, and titanium, $TiO_{1.91}\cdot(OH)_{0.09}$, and of their hydroxide phases. The high catalytic activity of the nanoparticles under study in oxygen reduction can be attributed to formation of catalytically active W^{5+} and Ti^{3+} centers and to presence of OH groups in the oxide matrix. The comparatively high stability of tungsten oxide electrodes in redox processes, compared with titanium oxide electrodes, may be due to an increase in the contribution of the valence *d* states to the W–W bond. For example, a subband absent in the spectrum of stoichiometric oxides [20] is formed in the XPS spectra of the valence band of nonstoichiometric tungsten and molybdenum oxides. The integral intensity of this subband grows as the number of the $M^{(n-1)+}$ states increases. The formation of this subband is mainly due to contributions from the W5*d* states involved in the formation of W–W bonds in the oxides $WO_{2\le x<3}$ [21].

The oxygen reduction at the electrodes studied is characterized by mixed kinetics. It was shown that the limiting current of oxygen reduction for the semiconductor electrodes under study is the limiting diffusion current. This assumption was verified by studying how the maximum limiting current varies with the potential sweep rate *v* at potentials in the region of limiting currents. It was found that the plot of this dependence in the coordinates $i_d = f(\sqrt{v})$ [22] is a straight line, which shows that the oxygen reduction in this region is controlled by diffusion. In the region of potentials corresponding to currents lower than the limiting current, the polarization curve of oxygen reduction was described by the Tafel equation $\eta_c = a_k + b_k \log i$ [23], where η is the overvoltage of the reaction; a_k, Tafel constant; $b_k = 0.059/\alpha n$ and α, transfer coefficient (α = 0.5 [23]). The relation $\alpha n = 0.5$ was obtained, i.e., the number of electrons involved in oxygen reduction at the discharge stage is $n = 1$. The value $n = 1$ has been reported for platinum and silver in an acid medium and $n = 2$ for alkaline solutions, and also $n = 1$ for a number of other metals [1, 3, 4]. In the given case, the behavior of the semiconductor electrodes studied is similar to that of metallic electrodes, in which the applied potential drops across the ionic double layer. Such a behavior of the semiconductor electrodes is due to the fact that oxygen reduction occurs at cathodic potentials in the region of a pronounced accumulation of electrons at the surface and the shielding of the surface charge by these electrons is important. In this case, as also in the case of metals, the potential mostly drops across the ionic double layer [5, 6].

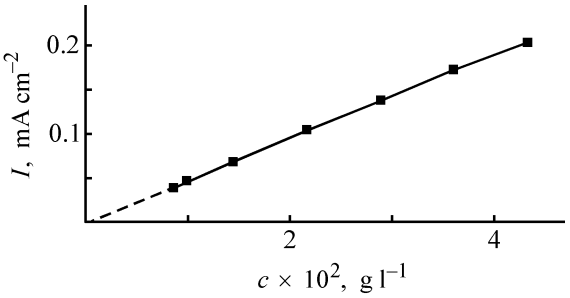

Fig. 5. Current *I* of oxygen reduction vs. oxygen concentration *c* for a TiO_2/InP electrode in a 0.9% NaCl solution. $v = 2$ mV s^{-1}.

We determined the dependence of the limiting current on the concentration of dissolved oxygen in a NaCl solution at potentials from –0.6 to 1.0 V, when the catalytic activity of the electrodes studied was at a maximum (Fig. 5). The current remained stable during several hours. From the results presented in Fig. 5, the total amount n_s of electrons involved in oxygen reduction was determined. For this purpose, we measured the dependence of the current of the working electrode on the time of the electrolysis in the potentiostatic mode at a potential in the range of diffusion currents of oxygen reduction and, using the data of Fig. 5, calculated the concentration of reduced oxygen. We found that $n_s = 2$ in NaCl solutions.

CONCLUSIONS

(1) The maximum sensitivity of electrodes based on nanodispersed Ti and W oxides to dissolved oxygen is reached at cathode potentials from –0.6 to –1.0 V (relative to a silver chloride reference electrode), at which the limiting diffusion current of oxygen reduction is observed.

(2) A single electron is involved at $\alpha = 0.5$ in the oxygen reduction at TiO_2 electrodes at the discharge stage. The total number of electrons involved in the oxygen reduction was found to be $n_s = 2$.

(3) The high catalytic activity of the electrodes based on nanodispersed tungsten and titanium oxides, WO_{3-x} and TiO_2, may be due to formation of W^{5+} and Ti^{3+} states and presence of OH groups in the oxide matrix.

(4) The stability of the TiO_{2-x} and WO_{3-x} electrodes in the course of oxygen reduction was studied. These electrodes have highly renewable characteristics in prolonged cycling, which makes them promising for manufacture of electrochemical sensors for dissolved oxygen. The higher stability of the electrodes based on WO_{3-x} nanoparticles in redox processes may be due to the increased strength of the W–W bond upon formation of W^{5+} states.

Received June 16, 2005; in final form, December 2005

Abstract—The electrochemical oxidation of Co(II) ions in fluorine-containing electrolytes on stationary and rotating disc electrodes was studied.

DOI: 10.1134/S1070427206040185

In recent years [1,2], thin-film chemical power sources (CPs) have been actively developed. CPs are rather widely used in various electronic circuits, miniature batteries with high specific electrical characteristics, displays, integrated circuits, high-quality amplifiers, etc. Thin-film cathodes are promising for development of rolled CPss, which have high specific capacity. There are great expectations for application of disordered nanostructure electrode materials [3]. The disordered structure ensures a high rate of introduction of cations (lithium, hydrogen, etc.) into the cathode mass.

Cobalt oxides find increasing use in batteries, for making higher their voltage, and in thin-film CPss [1], which poses the question of their manufacture. Pyrolytic and chemical methods are known, as well as the electrochemical technique involving oxidation of metallic cobalt at a constant anodic polarization [4]. A sufficiently simple method has been developed for synthesis of oxide compounds, including cobalt oxides, from fluorine-containing electrolytes via incomplete oxidation–reduction [5].

The aim of this study was to synthesize oxide compounds of cobalt by the electrochemical method and to determine the kinetics of this process.

EXPERIMENTAL

We used in the study solutions containing 10–30 g l^{-1} cobalt sulfate heptahydrate and 20–40 g l^{-1} ammonium fluoride. The current–voltage dependences were studied on a PI-50-1.1 potentiostat with an LKD-4 *XY*-recorder. The potential sweep rate was 2 to 20 mV s^{-1}. Platinum pressed into polyethylene served as a working electrode (0.13 cm^2) and a 4 cm^2 platinum plate, as a cathode.

The mass-transfer components were determined by the method of a rotating disc electrode (RDE). The same solutions as in the preceding case were used in the study, with and without a supporting electrolyte (1 M solution of sodium sulfate). The rate of disc rotation was varied within the range 200–600 rpm, which corresponds to $255 < Re < 766$ [6]. At the disc rotation rates chosen, convective diffusion can be disregarded. A saturated calomel electrode (SCE) served as reference in both cases. All the potentials in Figs. 1–4 are given relative to a standard hydrogen electrode.

To determine the diffusion coefficient, the viscosity of working solutions was evaluated using a capillary viscometer as the ratio of the times of gravity

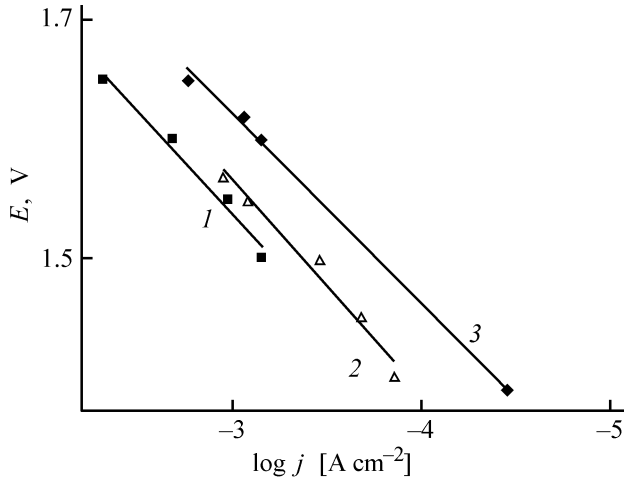

Fig. 1. *E*–log *j* dependences obtained for electrolytes of different compositions. (*j*) Current density. Curve numbers correspond to electrolyte numbers in Table 1; the same for Figs. 2 and 4.

out-flow of the working solution and water (equal volumes).

The polarization curves j–E plotted in the Tafel coordinates in Fig. 1 are linear. The electrochemical parameters of the Co(II) oxidation process are listed in Table 1, in which a and b are the Tafel coefficients, and β, the transfer coefficient of ions oxidized at the anode. At a constant concentration of metal ions in the electrolyte, the electrochemical parameters of the process depend on the concentration of a fluorine-containing additive.

The results obtained indicate that charge transfer is the slow stage at low polarizations. The number of electrons involved in the reaction is unity, because, as demonstrated by X-ray diffraction analysis, the compound obtained is close in composition to CoO(OH). According to the results of an atomic-absorption analysis and IR spectroscopy, the oxide–hydroxide compound of cobalt, formed at the anode, has a composition $Co_xO_y(OH)_z$, where $x = 0.65$–0.71, $y = 1.34$–1.79, and $z = 1.3$–1.52. The total concentration of cobalt is 47–53%. It should be noted that the content of the metal depends on the concentration of the ligand in the electrolyte. The particles of the compound are 80–120 nm in size.

The presence of OH^- groups and water in the samples studied is confirmed by their IR spectra containing the characteristic absorption bands at around 3400, 1620, and 1410 cm^{-1}, which correspond to stretching and bending vibrations of hydroxy groups, and by the results of a thermogravimetric analysis, according to which the total concentration of oxygen, including that in H_2O and OH^- groups, is 53–47%.

The cobalt oxide compound is formed at polarizations of 1.45–1.70 V. The limiting current is observed at potentials of 1.75–1.95 V, depending on the potential sweep rate. In this case, the oxide compound is formed with a lower current efficiency by the product under the diffusion control. This is indicated by the fact that the dependences of the current density on the potential sweep rate are linear (Fig. 2).

Raising the concentration of the metal and ligand ions in the electrolyte leads to an increase in the limiting currents (Fig. 2). As the potential increases further, the current again grows exponentially, which is due to a rise in hydrogen evolution rate.

The kinetics of Co(II) electrooxidation was studied in detail with a rotating disc electrode at different rotation rates.

In the general case, mass transfer in an electrolyte occurs via diffusion, migration, and convection, and,

N, rpm	ω, rad s^{-1}	j_{lim}, A cm^{-2}	$D \times 10^5$, cm^2 s^{-1}	δ × 10^5, m
Without supporting electrolyte				
600	62	0.073077	–	4.4
500	52	0.063077	–	4.7
400	42	0.057692	–	5.3
200	21	0.042308	–	7.7
With supporting electrolyte				
600	62	0.053846	6.0	3.8
500	52	0.048462	5.9	4.1
400	42	0.042308	5.7	4.6
200	21	0.030769	5.9	6.5

consequently, the limiting current is determined by these three processes. The contributions of diffusion and migration can be evaluated by RDE measurements in solutions with and without a supporting electrolyte.

The general run of the polarization curves obtained on RDE is illustrated by Fig. 3. The limiting diffusion and migration currents, diffusion coefficients, and thickness of the diffusion layer were calculated (Table 2).

As the rotation rate becomes higher, the limiting current increases (Fig. 4). The linear behavior of the j–$n^{1/2}$ dependence is also retained when a supporting electrolyte is introduced, with the limiting currents decreasing.

The diffusion coefficient was determined in terms of the theory developed by V.G. Levich, using the equation for the limiting diffusion current:

$$j_d = 0.62nFD^{2/3}\omega^{1/2}\nu^{-1/6}c_0,$$

where j_d is the limiting diffusion current (A cm^{-2}); n, number of electrons involved in the electrode reaction; F, Faraday constant (A s mol^{-1}); D, diffusion coefficient of ions being oxidized (cm^2 s^{-1}); ν, kinematic viscosity coefficient (cm^2 s^{-1}); ω, rotation angle (rad s^{-1}); and c_0, concentration of ions being oxidized (mol cm^{-3}).

Hence

$$D = [j_d\nu^{1/6}/(0.62nF\omega^{1/2}c_0)]^{3/2}.$$

The calculated diffusion coefficients are close, $(5.7–6.04) \times 10^{-5}$ cm^2 s^{-1} (Table 2).

CONCLUSIONS

(1) Electrooxidation of Co(II) in fluorine-containing electrolytes is accompanied by formation of cobalt oxide–hydroxide compounds $Co_xO_y(OH)_z$, where x = 0.65–0.71, y = 1.34–1.79, and z = 1.3–1.52.

(2) The optimum conditions for product formation are: NH_4F concentration 25 g l^{-1}, j_a = 0.5 A dm^{-2}, and T = 20–25°C.

(3) Electrooxidation of Co(II) occurs at low polarizations under the kinetic control, and at high polarizations diffusion becomes notiseable.

(4) The kinetic parameters of the process were calculated. A considerable contribution to mass transfer in fluorine-contaning electrolytes is made by migration, which results in high limiting currents, and, consequently, in high working current densities in these electrolytes.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Protective Properties of Electrochemical Polyaniline Coatings on Low-Carbon Steel

N. A. Ogurtsov and G. S. Shapoval

Institute of Bioorganic Chemistry and Petrochemistry, National Academy of Sciences of the Ukraine, Kiev, Ukraine

Received May 4, 2005

Abstract—Protective properties of polyaniline coatings electrochemically deposited in the galvanostatic mode from oxalic acid solutions onto the surface of low-carbon steel were studied by measuring polarization curves.

DOI: 10.1134/S1070427206040197

Electrically conducting polymers, such as, e.g., polyaniline, have been the object of intensive scientific studies during the last two decades. According to [1], they can reduce the rate of corrosion of low-carbon steel by a factor of 10^4. These materials can replace the widely used noxious pigments of the passivating type, based on chromates and lead compounds [2, 3]. Moreover, coatings based on these materials have already been developed and are employed in Germany for corrosion protection of carbon steel at wastewater treatment plants, sea ships, and port constructions [4]. This made it possible to replace, in a number of cases, stainless steel with carbon steel protected with a paint coating based on polyaniline [5].

The protective properties of polyaniline can be used not only as a component of paint coatings, but also in coatings that contain no additional polymeric binder. However, films of chemically synthesized polyaniline, and especially those in the doped form, show poor adhesion to the metal and, as a rule, cannot be used in practice. In contrast, electrochemically synthesized polyaniline can form sufficiently stable coatings on the metal surface. However, in this case, too, researchers encounter certain difficulties. The electrochemical synthesis of polyaniline is performed at anodic potentials in an acid medium, and, therefore, it is complicated by fast dissolution of the metal. Therefore, this process commonly cannot be performed on the surface of low-carbon steel. However, it has been found that in some solutions, e.g., in oxalic [6–10], *p*-toluenesulfonic [11], and phosphoric [10, 12, 13] acids, aniline can be polymerized.

Based on this circumstance, the Camalet et al. [6] suggested using electrosynthesis of polyaniline, instead of the environmentally hazardous phosphating and chromating, to produce an anticorrosive prime layer. At present, the protective properties of the above-mentioned coatings remain poorly understood. Separate experiments have been described in the literature, which employed methods for determining the amount of iron that passed into a 0.4 M NaCl + 0.1 M HCl solution [6, 7, 11] and the time dependence of the electrode potential in 0.1 M K_2SO_4 + H_2SO_4 solutions (pH 2 and 4.5) [9, 10, 13].

The aim of this study was to examine the influence exerted by the aniline polymerization conditions on the anticorrosive properties of the resulting coatings and the fundamental aspects of deposition of these coatings. In addition, the properties of polyaniline and conventional phosphate coatings were compared.

EXPERIMENTAL

Chemically pure grade NaCl and HCl and analytically pure grade oxalic acid were used in the study without additional purification; KCl of chemically pure grade was preliminarily twice recrystallized. Aniline of pure grade before use was purified by fractional distillation at reduced pressure in an argon flow and was stored under argon in a dark vessel with ground-glass stopper, placed in a refrigerator.

Polyaniline coatings were deposited and their properties studied on edges of cylindrical steel (St.3) electrodes (area 2.06 mm^2), whose lateral surfaces were insulated with epoxy resin. Preliminarily, the electrodes were polished with a fine emery paper (Carbimet, Grid 600, USA), after which their surface was degreased with soda, washed with distilled water, and

* Quantity of electricity expended for passivation of a steel electrode at i = 14.3 mA cm^{-2}.

dried with filter paper. For comparison, we used plates of UP phosphated cold-rolled steel (18 kg m^{-2}, ACT Laboratories, USA).

Polyaniline was electrochemically synthesized from oxalic acid solutions [polyaniline(oxalic acid)] on steel electrodes in the galvanostatic mode in a three-electrode cell with separated cathode and anode spaces. In deposition of polyaniline films, the current density was varied in the range 4–40 mA cm^{-2}. In the process, 0.2–0.6 M oxalic acid solutions containing 0.1–0.5 M of aniline, prepared immediately before use, were used.

The electrochemical properties of the thus obtained coatings were studied by measuring polarization curves in a single-chamber three-electrode cell. A platinum electrode served as an auxiliary electrode, and a saturated Ag/AgCl electrode, as reference. All the potentials are given relative to this electrode. Potentiodynamic curves were measured at a potential sweep rate of 10 mV s^{-1}. The curves obtained were transformed into Tafel curves, and extrapolation of Tafel portions of the anodic and cathodic polarization curves to intersection yielded the corrosion potentials E_{cor} and currents i_{cor} from which the corrosion retardation coefficients γ were calculated. Aqueous solutions of 3.5% NaCl and 0.1 N HCl were used as corrosion-active media.

All the electrochemical measurements were made at room temperature with a PI-50-1.1 potentiostat with a PR-8 programming unit. Voltammograms were recorded with an LKD4-003 *XY*-recorder.

The simplest and the most reliable method for synthesis of polyaniline on steel is the galvanostatic technique. The resulting chronopotentiometric curves show two gently sloping portions. The first of these, lying at negative potentials (about –0.4 V), corresponds to dissolution of the metal to the instant of its passivation, and has a characteristic time t_{pas}. The electropolymerization of aniline occurs within the second portion at potentials in the range 1.6–1.9 V, depending on the current density at the working electrode.

The duration of the induction period, t_{pas}, decreases as the current density i increases. Under galvanostatic conditions, these parameters are related by

$$i t_{pas}^n = C, \quad (1)$$

where n and C are constants.

Such a relationship between the parameters is frequently observed in passivation of metals in the galvanostatic mode [6, 7, 11, 14].

Table 1 lists the constants of Eq. (1), obtained in passivation of a steel electrode in media of various compositions. As expected, the passivation time and constants n and C depend both on the acidity of the medium and on the aniline concentration in solution. As can be seen from Table 1, $n \approx 1$ in electrode passivation in oxalic acid solutions in the absence of aniline, in agreement with published data [6, 7]. In this case, the quantity of electricity expended for electrode passivation is independent of the current density in the range studied and increases with the acid concentration.

As aniline is added to the solution, the quantity of electricity expended for electrode passivation markedly decreases. It may be assumed that this is due to adsorption of anilinium cations on the steel surface at cathodic potentials. In contrast to the results obtained by Camalet and co-authors [6, 7], coefficient n decreases in this case from 0.71 to 0.46 as the aniline concentration increases from 0.1 to 0.15 M. As can be seen from Table 1, such an increase in the aniline concentration leads to a threefold decrease in Q at a current density of 14.3 mA cm^{-2}. As a result, it is advantageous to perform the process at the maximum possible current densities, because the current expenditure for metal passivation becomes lower in this case.

The passivation ends in formation of a mixed oxalate-oxide layer, whose semiconducting properties do not preclude polymerization of aniline at anodic potentials [7]. Despite that the formation of polyani-

line at potentials of 1.6–1.9 V leads to a strong excessive oxidation of the polymer and depresses its electroactivity, the forming polyaniline layer retains its protective properties.

The results obtained in testing the protective properties of polyaniline coatings deposited under various conditions are listed in Tables 2–4. It can be seen that the coatings exhibit a pronounced protective effect (γ = 1.6–7.1), which exceeds in some cases that of the standard phosphate layer (γ = 2.1–2.6). For comparison, the anticorrosive properties of an oxalate layer obtained in electrode polarization in aniline-free solutions were analyzed. The protective effect γ of the last coating was found to be significantly lower in both neutral and acid media (1.6 and 1.2, respectively) than that in the case of a polyaniline coating (2.8 and 1.9).

Analysis of the results presented in Tables 2 and 4 shows that electrochemical polyaniline coatings obtained at low current density have better protective properties. For example, polyaniline coatings synthesized at I = 26.7 mA cm^{-2} have γ = 1.9 in an acid medium (Table 2), whereas for coatings synthesized at i = 5 mA cm^{-2}, γ = 3.8 (Table 4). Presumably, this is due to the fact that raising the current density leads to an increase in the potential at which aniline polymerizes and, apparently, to enhancement of the excessive oxidation of the polymer being formed.

It can be seen from Table 3 that polyaniline films obtained at higher quantities of passed electricity show higher corrosion retardation coefficients. For example, in a neutral medium, γ is 1.8 at Q = 3.2 C cm^{-2} and 6.8 at Q = 24 C cm^{-2}. This would be expected because the coating becomes thicker in this case [7]. The increase in the thickness of the polyaniline film also leads to an anodic shift of the corrosion potential of St.3 in neutral and acid media by 22 and 30 mV, respectively.

Comparison of the protective properties of coatings obtained in solutions of various acidities (Table 4) indicates that the corrosion retardation coefficients for coatings formed on St.3 in more acid media are significantly higher. In addition, coatings deposited from solutions with a higher aniline concentration and, accordingly, lower concentration of free acid exhibit poorer protective properties. These effects are apparently due to aggravation of the conditions of polyaniline synthesis, which requires fairly low pH of the medium, necessary for protonation of such a weak base as aniline [15].

An important factor in analysis of the mechanism of protective action of coatings is, in addition to

Table 2. Parameters characterizing the corrosion behavior of low-carbon steel with various coatings in NaCl and HCl solutions (coatings deposited at Q = 8.5 C cm^{-2} in 0.2 M $H_2C_2O_4$ with and without addition of 0.1 N $C_6H_5NH_2$)

the corrosion retardation coefficients, the direction in which the corrosion potential of a metal with a coating is shifted. As can be seen in Tables 2–4, the corrosion potential of St.3 with oxalate coatings in a neutral medium is shifted in the negative direction. This indicates that the cathodic reaction, which occurs for iron under conditions of this kind via oxygen depolarization with preferential control by the oxygen diffusion [16], is retarded. In an acid medium, in which the cathodic process is limited by hydrogen depolarization, oxalate coatings are apparently a weak obstacle for hydroxonium cations. In this case, a minor shift of E_{cor} in the positive direction is observed. This fact, taken together with the observation of a small corrosion retardation coefficient, suggests that retardation of the anodic reaction predominates in the acid medium.

Polyaniline-containing coatings exhibit, in both neutral and acid media, a positive shift of the corrosion potential of St.3. This gives reason to conclude, with account of the corrosion retardation coefficients obtained, which were found to be comparable in both the corrosive media, that polyaniline hinders the anodic reaction. This result is in agreement with published data, according to which polyaniline coatings on steel favor formation of a denser protective oxide layer [1, 17–19].

CONCLUSIONS

(1) The influence exerted by the conditions under which polyaniline coatings are formed on the surface of low-carbon steel on their protective properties and fundamental aspects of the process of synthesis of these coatings in an oxalic acid medium were studied.

(2) It is shown that carrying out polymerization at the maximum possible current density, aniline concentration, and low acid concentration makes it possible to markedly reduce the expenditure of electricity for anodic dissolution of iron during the induction period. However, the protective properties of polyaniline coatings are deteriorated in this case. The protective properties of polyaniline coatings are markedly improved as the concentration of free acid becomes higher.

(3) The polyaniline coatings obtained at low current density exhibit higher corrosion retardation coefficients. This is apparently due to a decrease in the extent of excessive oxidation of polyaniline synthesized at lower potentials.

(4) Analysis of the results obtained shows that the mechanism of protective action of polyaniline is based on retardation of the anodic reaction. In some cases, electrochemical polyaniline coatings surpass in corrosion protection efficiency ($\gamma = 1.6–7.1$) the standard phosphate coating ($\gamma = 2.1–2.6$).

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Synergism in Composite Electrolytic Nickel–Boron–Fluoroplastic Coatings

V. V. Ivanov, V. I. Balakai, A. V. Ivanov, and A. V. Arzumanova

Received December 2, 2005

Abstract—The possible synergism of manifestation of wear resistance and antifriction properties by composite electrolytic nickel–boron–fluoroplastic properties is analyzed. The results of calculation of the diagnostic properties of the coatings in terms of the "concentration wave" model are discussed in comparison with the relevant experimental data.

DOI: 10.1134/S1070427206040203

According to the "concentration wave" model [1], the basic properties of antifriction and wear-resistant composite coatings can be represented, in a two-component approximation [solid (s) + lubricating (lub)], as:

linear wear rate

$$I_l = \alpha\langle I_{l,lub}\rangle + (1 - \alpha)\langle I_{l,lub}\rangle + \Delta\alpha(\langle I_{l,s}\rangle - \langle I_{l,s}\rangle), \quad (1)$$

friction coefficient

$$f = \alpha\langle f_s\rangle + (1 - \alpha)\langle f_{lub}\rangle - \Delta\alpha(\langle f_s\rangle - \langle f_{lub}\rangle), \quad (2)$$

where $\alpha = \alpha_s$ and $(1 - \alpha) = \alpha_{lub}$ are the volume fractions of the solid and lubricating components of the composite coating, respectively; $\Delta\alpha = 4(1 - \alpha) \times \alpha^2[1 - k(1 - k_n)]$, relative magnitude of the synergistic effect; k, dimensional parameter that characterizes the dispersity of phases of the solid component and is equal to the ratio between the average size r_s of microparticles in the solid phases of the surface layer and the thickness Δx of this layer [$k = r_s/(\Delta x + r_s)$, $0.5 \le k < 1$]; and k_n, nanostructural parameter of the solid component of the composite layer, which characterizes the volume fraction of nanofragments of the solid phases in the surface layer Δx with a spherical or cylindrical shape ($r_s \approx \Delta x$ at $k \approx 0.5$; $0 \le k_n \le 1$).

To determine the volume fractions and averaged linear wear rates ($\langle I_{l,s}\rangle$ and $\langle I_{l,lub}\rangle$) and friction coefficients ($\langle f_s\rangle$ and $\langle f_{lub}\rangle$) for coating components, it is necessary to obtain data on the qualitative and quantitative phase composition of the composite coating. In this case, it is necessary to take into account not only the possible composition of the coating after its formation, but also the fact that the following processes may occur in friction at the surface of composite coatings: (a) chemical modification accompanied by formation of new phases; (b) dispersion of particles of the surface phases and their transition to the highly dispersed state, which hinders experimental phase analysis; and (c) redistribution of the chemical components of the system, which gives rise to local gradient fields of concentration of separate phases.

In this context, to obtain data necessary for prognostication of the properties of composite coatings in accordance with formulas (1) and (2), it is preferable to solve the phase problem analytically.

The phase composition of a composite coating not subjected to tribological treatment is determined by the technology of its preparation. Nickel–boron–fluoroplastic coatings were produced from an electrolyte of the following composition ($g\ l^{-1}$): nickel chloride hexahydrate 200–250, nickel sulfate heptahydrate 2.5–5.0, boric acid 25–35, chloramine B 0.5–1.5, salt of anionic polyhedral borate of general formula $M_zC_nB_mH_x$ (M is sodium, potassium, or ammonium; $z = 1, 2$; $n = 0, 2$; $m = 3, 9, 10, 12$; $x = 8, 10, 12$) 1.5–4.0; and F-4D-E fluoroplastic emulsion 10–20. Electrolysis modes: pH 1.0–5.5, temperature 18–30°C, cathode current density 0.5–10 $A\ dm^{-2}$ [2].

Table 1. Phase composition and concentration of components of composite coatings

Coating	Component of a composite coating	Phase composition	Mass fraction, %	Volume fraction, %	α
Ni–B	Solid	Ni, Ni_3B, Ni_2B, NiB	100	100	1.00
	Libricating	–	0	0	
Ni–B–fluoroplastic (1)	Solid	Ni, Ni_3B, Ni_2B, NiB	99.1	95.4	0.954
	Libricating	Fluoroplastic	0.9	4.6	
Ni–B–fluoroplastic (2)	Solid	Ni, Ni_3B, Ni_2B, NiB	97.9	89.8	0.898
	Libricating	Fluoroplastic	2.1	10.2	
Ni–B–fluoroplastic (3)	Solid	Ni, Ni_3B, Ni_2B, NiB	96.4	83.5	0.835
	Libricating	Fluoroplastic	3.6	16.5	

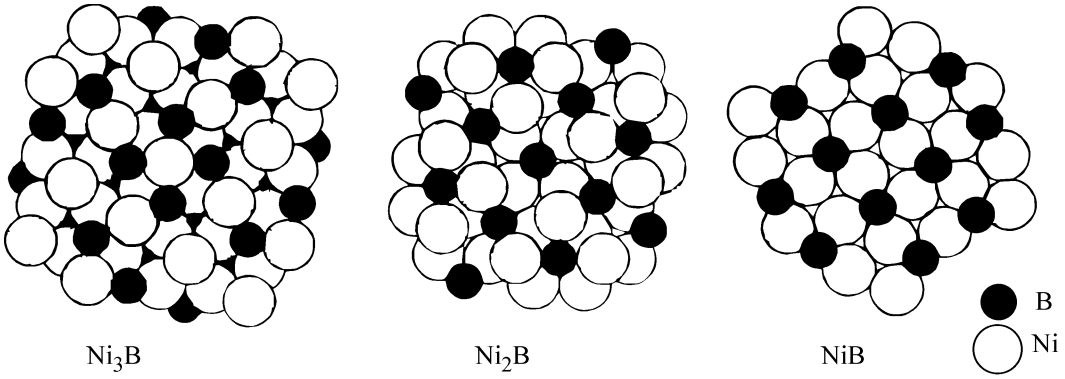
Table 2. Wear and antifriction properties of composite coatings

Coating	Δα, rel. units	Linear wear rate, μm h^{-1}		Friction coefficient	
		$\langle I_l \rangle^{calc}$	$\langle I_l \rangle^{exp}$	$\langle f \rangle^{calc}$	$\langle f \rangle^{exp}$
Ni–B	0	1.100	1.10	0.25	0.25
Ni–B–fluoroplastic (1)	0.098	0.767	0.74	0.218	0.21
Ni–B–fluoroplastic (2)	0.192	0.530	0.56	0.185	0.17
Ni–B–fluoroplastic (3)	0.269	0.434	0.42	0.155	0.15

After thermal treatment, the following phases of the solid component of composite coatings (Ni, Ni_3B, and Ni_2B) and an additionally introduced phase of the lubricating component (fluoroplastic) were found in the coatings [2]. After the steady state is attained under dry friction conditions at a specific load of 3 MPa (friction velocity $V = 0.048$ m s^{-1}), the NiB phase was found in the surface layers of all the composite coatings [2] (Table 1). The possible processes of chemical modification, which could yield the phases detected, are as follows:

$$Ni_3B \rightarrow Ni_2B + Ni \rightarrow NiB + 2Ni, \quad (3)$$

$$6Ni + 6B \rightarrow 2Ni_3B + 4B \rightarrow 3Ni_3B + 3B \rightarrow 6NiB. \quad (4)$$



It is noteworthy that the chain of transformations (3) is accompanied by removal of a part of Ni atoms from the crystal lattice of Ni_3B (and then from that of Ni_2B) and by deformation rearrangement of Ni networks and B layers (in Ni_3B) or only B layers (in Ni_2B) [3].

With the composition of the working electrolyte solution for coating deposition, possible mechanism of deposition of nickel- and boron-containing particles, modes in which these particles capture fluoroplastic microparticles in deposition of composite coatings, and possible processes of chemical modification in friction taken into account, it became possible to roughly determine the probable qualitative and quantitative phase composition of the solid and lubricating components and the value of α (Table 1).

Prescribed values of the linear wear rates in the dry friction mode for the phases of the solid component: Ni, Ni_3B, and Ni_2B (~1.1 μm h^{-1}) and NiB (~1.0 μm h^{-1}), and of the phase of the lubricating component, fluoroplastic (~7.5 μm h^{-1}), were used to calculate by formula (1) values of I_l (at $k \approx 0.5$ and $k_n \approx 0.17$). The results of this calculation are in a satisfactory agreement with the corresponding experimental data [2] (Table 2).

Taking into account the averaged values of the friction coefficient, $\langle f \rangle$, in the dry friction mode for the phases of the solid component: Ni, Ni_2B, and Ni_3B (~0.25) and NiB (~0.30), and phases of the lubricating component, fluoroplastic (~0.03), made it possible to calculate by formula (2) values of f (also at $k \approx 0.5$ and $k_n = 0.17$). They are in satisfactory agreement with experimental data [2] (Table 2).

Thus, the concentration wave model with the parameters $k \approx 0.5$ and $k_n = 0.17$ provides a satisfactory interpretation of experimental data on linear wear rate

Two-layer fragments of nickel boride structures in the direction perpendicular to the 3^2434 network of nickel atoms.

I_1 and friction coefficient f of composite coatings. An increase in the dimensional factor k or a change in the parameter k_n leads to a significant discrepancy between the experimental and calculated data. In terms of the model employed, this means that the dispersity of microparticles of the phases of the solid component of composite coatings is high and spherical or cylindrical nanofragments, which enhance the action of the lubricating component, are present among these microparticles. Now, the possibility of their formation in composite coatings will be analyzed.

All the structures of the nickel borides listed in Table 1 are described by atomic network packing of the types 3^2434 and 4^4 [4]. In the structure of Ni_3B, atomic networks 3^2434 of nickel form a system of trigonal and tetragonal prisms. Boron atoms in the trigonal prisms and nickel atoms in the tetragonal prisms close to a hexahedron form two superposed in a plane and slightly distorted square networks 44. In the structure of Ni_2B, the closest nickel networks 3^2434 are shifted with respect to each other and form a system of tetragonal antiprisms and tetrahedra of two types. Boron atoms occupy central positions in the antiprisms and form a square network. In the structure of NiB, nickel atoms form a system of empty trigonal prisms and tetragonal prisms occupied by boron atoms.

The low-boron nickel phases are contained in the solid component of composite coatings and undergo dispersion in friction both under a mechanical action of the conjugated surface of the tribosystem and via a dynamic process of structural-phase disordering, accompanied by multiple reversible phase transformations of a symmetric phase into a dissymmetric phase. The possible structures of dissymmetric phases are $P2_12_12_1$ (4), $Pmc2_1$ (4), $Pna2_1$ (4), $Pmn2_1$ (4) for the rhombic phases Ni_3B and NiB [$Pbnm$ (z = 4)] and $I422$ (4), $I4cm$ (4), $I\bar{4}2m$ (4), $I\bar{4}c2$ (4), $I4/m$ (4), $Ibam$ (4), $Ima2$ (4), $Fmmm$ (8), $Fmm2$ (8) for the tetragonal phase Ni_2B [$I4/mcm$ (z = 4)]. In this case, nanoparticles can be probably formed in the form of multilayer packages composed of two-layer fragments, such as those shown in the figure.

It may be assumed that part of these nanoparticles will correspond in their characteristic size (1.2–2.5 nm) and shape (nearly spherical or cylindrical) to those theoretically taken into account in formulas (1) and (2) by the parameter k_n. It is noteworthy that formation of such nanoparticles is less probable for the NiB phase, in which the atomic density [$\psi = z(V_{Ni} + V_B)/V_{unit.cell} = 0.80$] is approximately 10% lower than that in the Ni_2B and Ni_3B phases (0.88 and 0.89, respectively).

CONCLUSION

The synergism in nickel–boron–fluoroplastic composite coatings was analyzed. This effect is manifested as an improvement of the wear resistance and antifriction properties of the coatings, compared with the magnitudes of the same properties calculated in terms of the additive model (positive synergism). The synergism of the soid and lubricating components of the composite coatings studied presumably consists in the "concentration" of the lubricating phases on the friction surface, which improves the antifriction properties and the wear resistance of the solid phases of the coating, and in the presence of spherical or cylindrical nanoparticles of some solid phases, which act as solid lubricants.

Abstract—Zirconium orthophosphate $Zr_3(PO_4)_4$ and double phosphates of zirconium and alkali metals $AZr_2(PO_4)_3$ (A = Na, K, Rb, Cs) with a $NaZr_2(PO_4)_3$ structure were synthesized and characterized by X-ray diffraction and electron microprobe analyses and capillary condensation of nitrogen. The catalytic properties of the phosphates in the dehydration of methanol were studied.

DOI: 10.1134/S1070427206040215

The development of competitive, effective, and environmentally safe fuels is among the global trends of progress in chemistry. Dimethyl ether (DME) is one of the most promising types of diesel fuel [1, 2]. At present, DME is produced on the commercial scale by conversion of natural gas with dosed access of atmospheric oxygen to synthesis gas, subsequent formation of methanol in steam on copper–zinc–aluminum catalysts, and dehydration of methanol to give DME on mechanical mixtures of aluminum, silicon, and boron oxides or on molecular sieves [3–5]. It is still a topical task to develop new catalysts for these processes, which should be more active, selective, and less subject to coking.

Zirconium-containing phosphates with a structure of the $NaZr_2(PO_4)_3$ type (NZP) are of interest as catalysts for dehydration of alcohols because of the high stability of their structural skeleton, which ensures their resistance to action of water at high temperature and enables regeneration of a catalyst at elevated temperatures without any changes in its phase composition.

The structural family of NZP includes compounds and solid solutions described by the crystal-chemical formula $(M1)_{0\to1}(M2)_{0\to3}\{[L_2(TO_4)_3]^{p-}\}_{3\infty}$, where $\{[L_2(TO_4)_3]^{p-}\}_{3\infty}$ is the framework of the structure (p is the charge of the framework); $(M1)_{0\to1}$ and $(M2)_{0\to3}$ are types of out-of-framework cationic positions with a designation of the number of positions in each type [6]. The framework of the structure is formed by LO_6 octahedra and TO_4 tetrahedra with sharing common vertices; M1 and M2 voids of different sizes can accommodate a wide variety of cations compensating the framework charge. Most of members of the NZP family contain phosphorus as an anion-forming element T. The structure-forming cations L, with mainly covalent nature of the metal–oxygen bond, are in oxidation states from +5 to +1. These are, for example, Group IV *d*-transition metals. The out-of-framework positions M1 and M2 can include identical cations or a certain set of mainly low-charged cations in oxidation states from +1 to +4 or may remain vacant, depending on the oxidation state of the ions in positions L and T, so as the compound as a whole be electroneutral.

Owing to a wide isomorphism of cations of varied nature in all the crystallographic positions, phosphates of the NZP structure can exhibit acid, base, or redox properties and can be used in organic synthesis as multifunctional catalysts with controlled properties.

It is known that phosphates of an NZP-like structure, $CuZr_2(PO_4)_3$, $Cu_{0.5}L_2(PO_4)_3$ (L = Ti, Zr, Sn), $AgZr_2(PO_4)_3$, and $Na_{1+x}Fe_xZr_{2-x}(PO_4)_3$ are active catalysts for dehydration and dehydrogenation of butyl alcohols and isopropanol [7–10]. It should be noted that the catalytic properties of NZP phosphates in methanol transformations have not been studied.

The aim of this study was to examine the catalytic properties, such as activity and selectivity, of zirconium-containing phosphates $Zr_3(PO_4)_4$ [$\equiv Zr_{0.25}Zr_2(PO_4)_3$] and $AZr_2(PO_4)_3$ (A = Na, K, Rb, Cs) with a structure of the NZP type and kinetic parameters of dehydration of methanol on these compounds.

EXPERIMENTAL

The following reagents of chemically pure grade were used as starting substances in synthesis of the phosphates $Zr_3(PO_4)_4$ and $AZr_2(PO_4)_3$ (A = Na, K, Rb, Cs): zirconium oxychloride $ZrOCl_2 \cdot 8H_2O$, phosphoric acid H_3PO_4, and chlorides of alkali metals ACl (A = Na, K, Rb, Cs). Stoichiometric amounts of chlorides of alkali metals were added to a 1 M solution of zirconium oxychloride (to prevent hydrolysis, it was dissolved in distilled water acidified with hydrochloric acid). Then a 1 M solution of phosphoric acid, also taken in agreement with the stoichiometry of a phosphate, was added at room temperature with continuous stirring. The gel formed upon heating was dried at 353 K and thermally treated under conditions of free access of air at 873 and 1073 K for no less than 20 h in each stage. The final temperature of synthesis of $Zr_3(PO_4)_4$ was 1153 K. It is determined by the temperature of crystallization onset (1073 K) and the decomposition point of this compound (1173 K). The final temperature of synthesis of $CsZr_2(PO_4)_3$ was 1273 K. Pure crystalline cesium zirconium phosphate can be obtained at 1073 K; however, this requires prolonged crystallization, which can be made shorter by raising the synthesis temperature. The stage-by-stage heating of the samples was alternated with their dispersion to make the mixtures homogeneous.

The chemical composition and homogeneity of samples of the phosphates synthesized were monitored using a CamScan MV 2300 (VEGA TS 5130 MM) scanning electron microscope with YAG detectors of secondary and reflected electrons and a Link INCA ENERGY 200C energy-dispersive X-ray microanalyzer with a semiconductor Si(Li) detector. The PAP correction method was used to calculate the composition. The accuracy of determination of sample compositions was 2 at. %. The microprobe analysis of the phosphates demonstrated their homogeneity and correspondence to the theoretical composition.

The phase composition of the powders synthesized was determined by X-ray phase analysis on a DRON 3.0 diffractometer with Ni-filtered Cu K_α radiation in the range of 2θ angles 10°–50°. The recording rate was 2 deg min^{-1}. The X-ray data for the phosphates synthesized indicate that the positions and intensities of the diffraction peaks are close to published data [11, 12]. The calculated unit cell parameters are listed in Table 1.

Table 1. Unit cell parameters of the phosphates synthesized (space group $R\bar{3}c$, $Z = 6$)

Phosphate	a, Å	c, Å	V, Å^3
$Zr_{0.25}Zr_2(PO_4)_3$	8.802(3)	23.060(4)	1547(1)

Volume fraction of pores,* %	25	3
Average pore size, Å	98	86

* Pore diameter in the range from 0 to 300 Å.

The porosity parameters of the phosphates were calculated from adsorption–desorption isotherms measured on a Micromeritics ASAP 2020 installation by the method of capillary condensation of nitrogen at 77 K. The results of the calculations are listed in Table 2. To calculate the volume fraction of pores in the samples, their pycnometric density was measured (Table 2) using *n*-decane as a pycnometric liquid. The volume fraction of pores was calculated as the ratio of their volume in 1 g of a phosphate to the volume of 1 g of the phosphate. The specific surface area of sodium zirconium phosphate and the volume fraction of pores for this phosphate are 4 and 8 times, respectively, larger than the corresponding values for cesium zirconium phosphate at close average pore sizes for both samples (Table 2). Possibly, the higher temperature of synthesis of the cesium-containing phosphate reduces its porosity and specific surface area and makes its particles coarser.

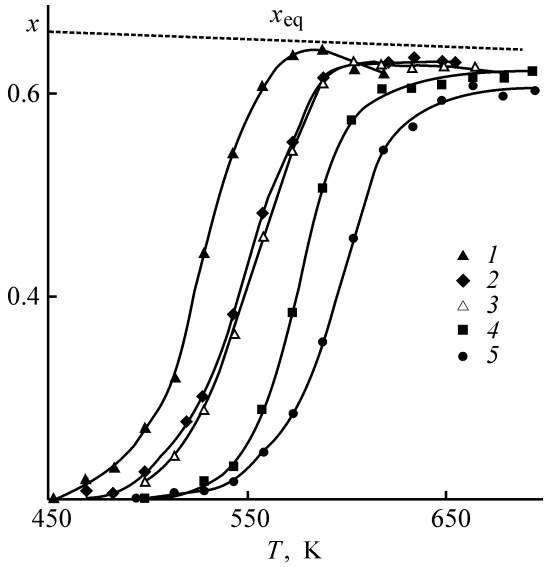

Fig. 2. Degree of methanol conversion, x, on the phosphates (*1*, *3*) $NaZr_2(PO_4)_3$, (*2*) $Zr_3(PO_4)_4$, (*4*) $KZr_2(PO_4)_3$, and (*5*) $CsZr_2(PO_4)_3$ vs. temperature T. Feed rate of methanol vapor (ml min^{-1}): (*1*) 0.20 and (*2*–*5*) 0.88.

We studied the catalytic properties of zirconium phosphate and double alkali metal zirconium phosphates in the conversion of methanol in a flow-through steel reactor in a flow of argon under atmospheric pressure in the temperature range 453–693 K. A 0.300-g weighed portion of a phosphate was mixed with quartz (average particle diameter 1 mm). The alcohol vapor from a temperature-controlled bubbler was fed into the reactor in an argon flow at a total rate of 1.2 l h^{-1}. The reaction products were analyzed on an LKhM-5 chromatograph with a thermal conductivity detector, columns packed with activated charcoal and Porapak T, and computer processing of chromatograms. From the results of the analysis, we calculated the conversion of the alcohol x (%), selectivity S (%), and the yield of target products A (mmol h^{-1} g^{-1} or mmol h^{-1} m^{-2}) by the formula

$$A = FxS/W.$$

Here F is feed rate of the alcohol vapor (mmol h^{-1}), and W, weighed portion of the catalyst (g) or its surface area (m^2).

All the phosphates under study exhibited a catalytic activity in the dehydration of methanol, which was reproducible in different sets of experiments. No products of dehydrogenation and decomposition of methanol were detected in the temperature range studied. The temperature dependences of the DME yield and of the spent amount of the alcohol for zirconium phosphate and sodium zirconium, potassium zirconium, and cesium zirconium phosphates as catalysts are shown in Fig. 1. The 2 : 1 : 1 molar ratio of the spent amount of alcohol to that of the products, DME and water, which is characteristic of the dehydration of methanol

$$2CH_3OH \rightleftarrows H_3COCH_3 + H_2O,$$

is reflected in the positions of the corresponding curves in Fig. 1 (the yield of water coincides with that of DME and is not shown in the figures). This is a criterion of validity of the calibrating factors we used and points to correctness of the experiments. The least active catalyst, as regards the yield of the products of alcohol dehydration, was rubidium zirconium phosphate (at the maximum temperature of 693 K, the methanol conversion was as low as 11%). The phosphates investigated can be ranked in order of decreasing catalytic activity as $Zr_3(PO_4)_4 \approx NaZr_2(PO_4)_3 > KZr_2(PO_4)_3 > CsZr_2(PO_4)_3 \gg RbZr_2(PO_4)_3$.

The temperature dependences of methanol conversion x on these phosphates are shown in Fig. 2. The equilibrium degree of methanol conversion was calculated using the temperature dependence of the equilibrium constant $K_{eq} = 2.145\exp(1239.8/T)$ [13]. The methanol conversion approaches the equilibrium value x_{eq} = 88–90% (dashed line in Fig. 2) at different temperatures for different catalysts.

To determine the reaction order of methanol dehydration for the phosphate $NaZr_2(PO_4)_3$, we varied

the flow rate of the alcohol vapor, V, from 0.20 to 1.27 ml min^{-1} at a constant reactor temperature of 543 K. The dependence of the degree of methanol conversion, x, on the reciprocal rate of feeding of its vapor into the reactor, $1/V$, is shown in Fig. 3. The rate of the heterogeneous-catalytic reaction in the flow-through reactor is given by the expression [14]

$$r = dx/d(1/V).$$

The linear portion of the $x = f(1/V)$ dependence corresponds to low conversions and points to the zero order of the dehydration reaction. For the zero-order reaction, the conversion rate is independent of reagent concentrations, i.e., $r = k$, where k is the reaction rate constant. This means that $x = k(1/V)$.

The experimental values of the methanol conversion at feed rates of the methanol vapor exceeding 0.61 ml min^{-1} (zero order of the dehydration reaction) are fitted by a straight line (Fig. 3) with a linear correlation coefficient of 0.999. We find from the equation of this straight line that the rate constant of methanol dehydration is $k = 0.013$ mmol min^{-1}.

We constructed the Arrhenius dependences $\ln x$–T^{-1}, for which the linear correlation coefficient was 0.98–0.99. The activation energies of the dehydration of methanol, E_a, and the logarithms of the preexponential factors, $\ln A_0$, are listed in Table 3. The activation energy and the preexponential factor, obtained for zirconium phosphate, are lower than the corresponding values for alkali metal zirconium phosphates; and for these latter, the two parameters increase with the atomic number of an alkali metal.

The activity of the phosphates under study in the dehydration of methanol can be accounted for by their acid properties, which are determined by coordination-unsaturated Zr^{4+} cations carrying a large charge and exhibiting a high polarizing effect. These ions are possible centers of alcohol adsorption [15, 16]. This is confirmed by the high activity of the phosphate $Zr_3(PO_4)_4$, which contains no alkali metals, in the conversion of methanol. The activity of this phosphate may also be due to its poorer crystallinity (and, as a consequence, to its high specific surface area and porosity), compared with alkali metal zirconium phosphates.

Comparison of the activities (Figs. 1 and 2) and specific surface areas of sodium zirconium phosphates, and of the volume fractions and surface areas of pores in these compounds (Table 2), shows that the catalytic properties depend on all of these factors. The greater these parameters, the higher the activity of the phosphate in the dehydration of methanol. It should be noted that the alkali metal introduced into the structure affects the activity of phosphates in the reaction under consideration not only owing to its electronic structure, but also indirectly, because of a rise in the final temperature of synthesis of the samples, observed as the size of alkali metal atoms increases. This leads to formation of a less defective crystal structure with a lower porosity.

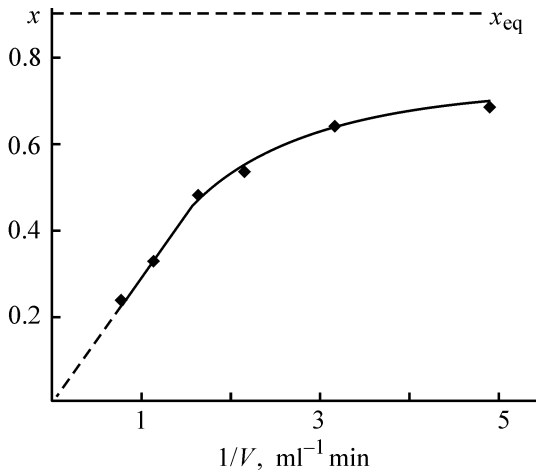

Fig. 3. Degree of methanol conversion, x, on the phosphate $NaZr_2(PO_4)_3$ in the dehydration vs. the reciprocal feed rate of methanol vapor, $1/V$.

The influence of the nature of an alkali metal in alkali metal zirconium phosphates is manifested in the difference in their activities calculated per unit surface area of a catalyst (Table 4). In the tem-

Table 3. Activation energy of the dehydration of methanol, E_a, and logarithm of the preexponential factor, $\ln A_0$, for the phosphates under study

Phosphates	E_a, kJ mol^{-1}	$\ln A_0$
$Zr_{0.25}Zr_2(PO_4)_3$	85	18
$NaZr_2(PO_4)_3$	105	22
$KZr_2(PO_4)_3$	126	25
$CsZr_2(PO_4)_3$	130	26

Table 4. Activity of the phosphates $NaZr_2(PO_4)_3$ and $CsZr_2(PO_4)_3$ in methanol conversion at various temperatures

Phosphate	A, mmol h^{-1} m^{-2}, at indicated temperature, K			
	513	528	543	558
$NaZr_2(PO_4)_3$	0.02	0.05	0.09	0.15
$CsZr_2(PO_4)_3$	0.01	0.02	0.04	0.11

perature range corresponding to the kinetic control of methanol conversion, the activity of the phosphate $NaZr_2(PO_4)_3$ is twice that of $CsZr_2(PO_4)_3$. This can be accounted for by the fact that cations of alkali metals affect the electron density on oxygen atoms bound to zirconium atoms, thereby changing their electropositive and, consequently, acid properties.

The catalysts under study can compete with industrial catalysts for methanol dehydration. For example, the dehydration of methanol in a flow-through reactor on synthetic aluminosilicates was studied in [17]. The authors of that study used for comparison a commercial catalyst DME-FCAT. Comparison of the catalytic activities and methanol conversions at the same temperature for the samples we studied, aluminosilicates examined in [17], and commercial catalysts DME-FCAT suggests that the phosphates $Zr_3(PO_4)_4$ and $NaZr_2(PO_4)_3$ possess a higher output capacity, because they can provide higher, nearly equilibrium degrees of conversion at a 2–10 times greater load on the catalyst.

CONCLUSIONS

(1) Zirconium phosphate $Zr_3(PO_4)_4$ and alkali metal zirconium phosphates $AZr_2(PO_4)_3$ (A = Na, K, Rb, Cs) with NZP-type structure were synthesized by the sol–gel method and characterized by X-ray diffraction analysis, electron microprobe analysis, and capillary condensation of nitrogen.

(2) A study of their catalytic properties in the dehydration of methanol demonstrated that they are active and selective catalysts and compare well with commercial catalysts for methanol dehydration.

(3) It was shown that the activity and the working temperature range of alkali metal zirconium phosphate catalysts depend on the conditions of their synthesis and their composition, porosity, and specific surface area, and also on load.

CATALYSIS

Loss of Activity by Vanadium Sulfuric Acid Catalysts under the Action of Arsenic(III) Oxide Vapor

V. N. Krasil'nikov, A. P. Shtin, and V. I. Malkiman

Abstract—Chemical processes leading to inactivation of vanadium sulfuric acid catalysts by arsenic(III) oxide vapor were studied. The interaction and solubility in the system $VO(H_2AsO_4)_2$–$VOAsO_4$–H_3AsO_4–H_2O and the composition of oxovanadium arsenate in a mixed oxidation state, used as a starting substance in synthesis of $(V^{IV}O)(V^{V}O)_2(As_2O_7)_2$, were examined.

DOI: 10.1134/S1070427206040227

Vanadium catalysts for conversion of sulfur dioxide are comparatively stable against As_2O_3 vapor. Nevertheless, the activity of the catalysts gradually decreases upon a prolonged contact with an insufficiently purified gaseous reaction mixture and may be completely lost if concentration of impurities is too high. By the term "catalyst poisoning" is commonly understood the considerable and abrupt loss of activity, caused by contact with trace amounts of a catalytic poison. There exist various concepts concerning the nature of the inactivating effect of arsenic(III) oxide on vanadium sulfuric acid catalysts. In Boreskov's opinion [1], As_2O_3 is oxidized in the course of sulfur dioxide conversion to As_2O_5, which further reacts with the active component to form a compound of composition $V_2O_5 \cdot As_2O_5$, which is volatile at $T > 550$°C. As a rule, there is no arsenic in the first catalyst bed of a reactor, in which temperature may be as high as 600–650°C. However, arsenic is deposited in the subsequent beds, and especially in the third and fourth, in which the temperature commonly does not exceed 450°C, in the maximum amounts, presumably in the form of the compound $V_2O_5 \cdot As_2O_5$. At temperatures lower than 600°C, the surface of catalyst grains can be blocked by arsenic(V) oxide. According to another interpretation, As_2O_5 reacts with molten potassium bisulfate to give potassium arsenates or sulfate–arsenates [2], in which case sulfur trioxide is released into the gas phase.

Interpretations of the mechanism by which arsenic(III) oxide is oxidized on vanadium catalysts are also ambiguous. According to [3], oxidation of SO_2 and As_2O_3 involves various activating centers. Van'kov and Perevozchikov [4] regard potassium bisulfate as the most probable oxidant of As_2O_3 and believe that the presence of arsenic in the active component favors transition of vanadium to the highest oxidation state, V(V). At the same time, Boreskov believes [1] that vanadium(V) is the agent that oxidizes arsenic(III) on the vanadium(V) catalyst.

The concentration of As_2O_3 vapor in the contact gas mixtures in manufacture of sulfuric acid depends on the degree of their purification. It is believed that, at plants of nonferrous metallurgy in the Ural region, the most arsenic-contaminated gas mixtures are used by Krasnoural'sk copper-smelting combine (KUMK), because the service life of vanadium catalysts for sulfur dioxide conversion at this plant is strongly limited [5]. To reveal the nature of the inactivating influence exerted by arsenic(III) oxide, we examined grains of SVD catalyst (vanadium sulfate catalyst on diatomite) that had worked for 1.5 years in a reactor for sulfur dioxide conversion under conditions of an increased concentration of As_2O_3 vapor and completely lost its catalytic activity for this reason.

EXPERIMENTAL

Samples of grains of an inactivated catalyst were taken at different points of catalyst beds II, III, and

Results obtained in a chemical analysis of grains of an SVD-type catalyst inactivated in operation in a sulfuric acid reactor at KUMK

Bed	As(V)	V(IV)	V(V)	V_{tot}
	wt %			
I	–	–	–	–
II	0.98	2.60	0.56	3.16
III	2.68	3.47	3.54	7.01
IV	3.05	3.44	3.86	7.30

IV of the reactor, in which the concentration of arsenic compounds was very high. The grains taken for study were stored under conditions that provided their total isolation from the environment. The phase analysis of the samples was made using a DRON-3 UM X-ray diffractometer with Cu K_α radiation and a POLAM S-112 polarization microscope with optical-immersion control. The chemical analysis of the samples for the content of potassium, vanadium(V) and (IV), sulfur, and arsenic was performed by the standard commonly accepted procedures. Particular attention was given to analysis of the chemical and phase composition and structure of the surface (0.1–0.2-mm-thick) layer of the grains. Individual chemical compounds necessary for the experiments and, in particular, $VOAsO_4 \cdot 3H_2O$ and $VO(H_2AsO_4)_2$ were synthesized by previously developed techniques [6–8] with reagents of, at least, chemically pure grade.

The table lists the results of a chemical analysis of grains taken from catalyst beds II, III, and IV of a reactor for sulfur dioxide conversion at KUMK. To the observed increase in the concentration of arsenic(V) on passing from bed II to bed IV corresponds the rise in the total concentration of vanadium, in agreement with the opinion that it is transferred together with arsenic in the form of a volatile compound $V_2O_5 \cdot As_2O_5$ [1, 9]. At the same time, the high concentration of vanadium(IV) in the grains (especially in their surface layer) gives reason to assume that arsenic(V) compounds containing reduced vanadium can be formed in the grains. In 0.1–0.2-mm-thick sections from the surface of grains, the concentration of As(V) was as high as 11.6–12.2 wt %.

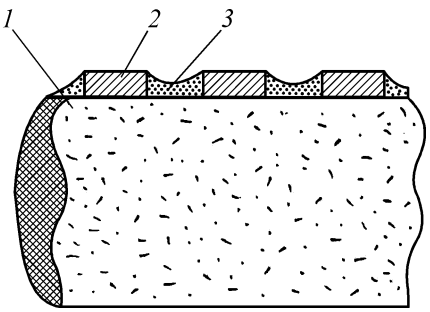

Fig. 1. Schematic cross-sectional view of a grain of inactivated SVD-type catalyst. (*1*) Cross-section of a grain, (*2*) deposited crystals of arsenic compounds, and (*3*) gray-blue glass.

Grains of a freshly prepared SVD catalyst are yellow and have a rough surface; the coloration of grains of an inactivated catalyst is light blue or gray-blue, and the grain surface is smooth and hard. An analysis of sections of the grain surface under a microscope demonstrated that the crust covering the grains is a gray-blue glass well soluble in water. According to the results of a chemical analysis, the content of vanadium(V) in this glass is virtually zero, that of vanadium(IV) is close to 7.5 wt %, and the content of arsenic(V), 21 wt %. After the glass is removed by dissolution in water, regularly arranged black cylindrical outgrowths composed of coarse well-formed lamellar crystals become visible on the grain surface (Fig. 1). A characteristic feature of these crystals is a clearly pronounced dichroism (their coloration varies from greenish brown, nearly black to light green with their rotation in polarized light under a microscope). This fact indicates the possible presence of vanadium in two oxidation states, (V) and (IV), in their structure. Optical properties of this kind are observed for crystals of a phase of composition $(V^{IV}O)(V^{V}O)_2(As_2O_7)_2$, synthesized by partial oxidation of $VO(AsO_3)_2$ with atmospheric oxygen upon heating [6] and by dehydration of $(V^{IV}O)(V^{V}O)_2(HAsO_4)_4 \cdot 5H_2O$ and $(V^{IV}O)(V^{V}O)_2(HAsO_4)_4$ in an inert medium at 450°C [7, 8].

The contents of vanadium(V), vanadium(IV), and arsenic(V) in aggregates of crystals detached from the surface of grains from catalyst bed IV of the reactor are 10.6, 4.9, and 30.2 wt %, respectively; the average concentration of potassium does not exceed 0.5 wt % (V^V/V^{IV}) ~2]. This indicates that potassium is not contained in the compound that forms outgrowths on the surface of catalyst grains. In the atmosphere of saturated water vapor, inactivated grains very rapidly disintegrate, with crystals in the surface outgrowths being decomposed into light yellow and blue phases, whose crystal-optical constants and interplanar spacings coincide with published values for $VOAsO_4 \cdot 3H_2O$ (light yellow coloration) [10] and $VO(H_2AsO_4)_2$ (blue) [11]. Consequently, the compound found in the outgrowths on the surface of inactivated catalyst grains is close in chemical nature and composition to the above-described oxovanadium

arsenates, i.e., it includes vanadium in two oxidation states, V(V) and V(IV).

The following transformations were observed in a saturated water vapor for $(V^{IV}O)(V^{V}O)_2(As_2O_7)_2$:

$$(V^{IV}O)(V^{V}O)_2(As_2O_7)_2 + 2H_2O = (V^{IV}O)(V^{V}O)_2(HAsO_4)_4, \quad (1)$$

$$(V^{IV}O)(V^{V}O)_2(As_2O_7)_2 + 7H_2O = (V^{IV}O)(V^{V}O)_2(HAsO_4)_4 \cdot 5H_2O. \quad (2)$$

Reaction (1) is an intermediate stage of reaction (2), and, therefore, the best way to synthesize hygroscopic $(V^{IV}O)(V^{V}O)_2(HAsO_4)_4$ is thermolysis of $(V^{IV}O)(V^{V}O)_2(HAsO_4)_4 \cdot 5H_2O$ with slow heating to 120–130°C. AS a result of contact with an excess amount of water at room temperature, $(V^{IV}O)(V^{V}O)_2(HAsO_4)_4 \cdot 5H_2O$ decomposes to give crystals of $VOAsO_4 \cdot 3H_2O$ and $VO(H_2AsO_4)_2$.

A comparison of the crystal-optical properties and X-ray diffraction patterns of $(V^{IV}O)(V^{V}O)_2(HAsO_4)_4 \cdot 5H_2O$, $(V^{IV}O)(V^{V}O)_2(HAsO_4)_4$, $(V^{IV}O)(V^{V}O)_2(As_2O_7)_2$, and crystals from the outgrowths on the surface of grains of an inactivated SVD catalyst demonstrated that each of these compounds may be present in the outgrowths. Apparently, an arsenate of composition $(V^{IV}O)(V^{V}O)_2(As_2O_7)_2$ is originally formed on the grain surface and then, in storage in air, it absorbs water vapor and transforms into $(V^{IV}O)(V^{V}O)_2(HAsO_4)_4$ or $(V^{IV}O)(V^{V}O)_2(HAsO_4)_4 \cdot 5H_2O$. A similar transformation may occur in washing grains with water to remove the glass and crystal aggregates from their surface. In addition to $(V^{IV}O)(V^{V}O)_2(As_2O_7)_2$, presence of oxovanadium(V) orthoarsenate of composition $VOAsO_4$ or $V_2O_5 \cdot As_2O_5$ was revealed [1], even though not indisputably, by X-ray phase analysis in out-growths on grains of an inactivated catalyst that worked in the middle part of catalyst bed IV.

Figure 2 compares X-ray diffraction patterns of $(V^{IV}O)(V^{V}O)_2(HAsO_4)_4 \cdot 5H_2O$ and a preparation composed of ground crystal aggregates scraped-off from grains of an inactivated SVD crystal, preliminarily washed in water to remove the glass. The X-ray diffraction pattern of the preparation of crystal aggregates differs from that for $(V^{IV}O)(V^{V}O)_2(HAsO_4)_4 \cdot 5H_2O$ only in the presence of a line (marked by arrow) coinciding in position with the strongest line in the X-ray diffraction pattern of $(V^{IV}O)(V^{V}O)_2(As_2O_7)_2$ [6, 7]. The X-ray diffraction pattern of the aggregates cut-off from the grains not washed with water contained only lines of $(V^{IV}O)(V^{V}O)_2(As_2O_7)_2$, whereas

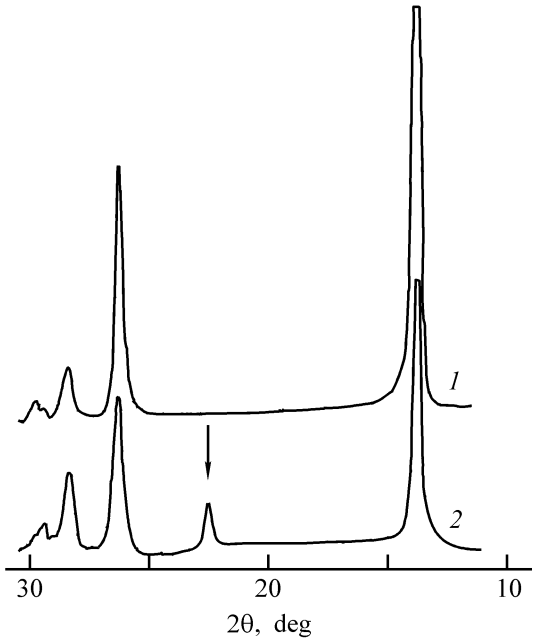

Fig. 2. X-ray diffraction patterns of (*1*) $(V^{IV}O)(V^{V}O)_2(AsO_4)_4 \cdot 5H_2O$ and (*2*) crystal aggregates removed from the surface of grains of the SVD catalyst. Arrow denotes the strongest line belonging to $(V^{IV}O)(V^{V}O)_2(As_2O_7)_2$.

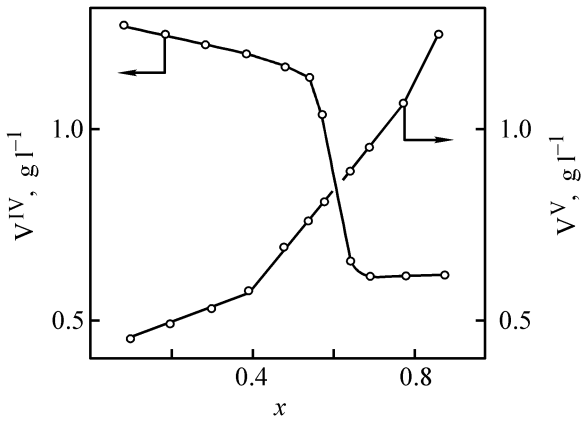

Fig. 3. Content of vanadium(V) and vanadium(IV) in the liquid phase of the system $VO(H_2AsO_4)_2$–$VOAsO_4$–H_3AsO_4–H_2O vs. x in the isomolar set of compositions of the section $(1 - x)VO(H_2AsO_4)_2 + xVOAsO_4 \cdot 3H_2O$.

after washing, lines of $(V^{IV}O)(V^{V}O)_2(HAsO_4)_4 \cdot 5H_2O$ and $(V^{IV}O)(V^{V}O)_2(HAsO_4)_4$ appeared in the pattern.

To reveal the possibility of formation of oxovanadium arsenates in a mixed oxidation state (IV, V), other than $(V^{IV}O)(V^{V}O)_2(HsO_4)_4 \cdot 5H_2O$, which serves as the main starting substance in synthesis of $(V^{IV}O)(V^{V}O)_2(As_2O_7)_2$, the interaction and solubility in the system $VO(H_2AsO_4)_2$–$VOAsO_4$–H_3AsO_4–H_2O

was studied at room temperature. The starting mixtures of solid oxovanadium(IV) and oxovanadium(V) arsenates comprised an isomolar set of compositions from the section $(1 - x)VO(H_2AsO_4)_2 + xVOAsO_4 \cdot 3H_2O$ at a total molar content of the arsenates equal to 0.01 M. The initial concentration of arsenic acid was constant (2 M).

Analysis of the solubility curves of vanadium for the system under study (Fig. 3) shows that, at $x \geq 0.6$, the concentration of vanadium(IV) in solution abruptly decreases and then remains constant at $x > 0.7$. The curve describing the dependence of the concentration of vanadium in solution on x shows two weak bends at $x = 0.4$ and 0.75. According to the results of a microscopic analysis, the bottom phase is constituted at $x = 0.1–0.5$ by blue crystals of $VO(H_2AsO_4)_2$ and by a new compound, whose formation is evidenced by the presence of black squared plates. At $x = 0.6–0.7$, the bottom phase has the form of black squared plates that well reflect light; at $x > 0.7$ yellow crystals of $VOAsO_4 \cdot 3H_2O$ are additionally present. The liquid phase acquires a dark green coloration, which is the most intense at $x = 0.6–0.7$. Microscopic, X-ray phase, and chemical analyses revealed that the new phase is identical to the previously obtained [7] compound of composition $(V^{IV}O)(V^{V}O)_2(HAsO_4)_4 \cdot 5H_2O$. The study performed demonstrated that no other oxovanadium arsenates in mixed oxidation state are formed in the given system.

The most probable agent that oxidizes As_2O_3 on vanadium catalysts is vanadium(V). This is confirmed by the results of a study of reaction of As_2O_3 with $K_4V_2O_3(SO_4)_4$ and $K_3VO(SO_4)_3$, compounds simulating the active component of vanadium catalysts [8], in sealed argon-filled quartz ampules at 300–450°C:

$$K_4V_2O_3(SO_4)_4 + As_2O_3 = \{4K_2VO(SO_4)_2 + As_2O_5\}, \quad (3)$$

$$K_3VO(SO_4)_3 + As_2O_3 = \{4K_2VO(SO_4)_2 + 2K_2S_2O_7 + As_2O_5\}. \quad (4)$$

Under the same conditions, vanadium(V) oxide reacts with arsenic(III) oxide [12]:

$$2V_2O_5 + As_2O_3 = V_4As_2O_{13} \quad (5)$$
$$[4V^{(V)} + 2As^{(III)} = 4V^{(IV)} + 2As^{(V)}].$$

Reactions (3) and (4) are written with account of the constant mass of the samples; the reaction products are enclosed in braces because they form blue glasses and were not isolated in the form of crystals. As the concentration of As_2O_3 is lowered, green hygroscopic glasses containing vanadium in two states, V(V) and V(IV), are formed in the reaction mixtures.

The interaction of sulfur dioxide with oxovanadium(V) orthoarsenate at 400–450°C occurs in accordance with the most probable reaction

$$2VOAsO_4 + SO_2 = (VO)_2As_2O_7 + SO_3\uparrow. \quad (6)$$

The composition of the X-ray amorphous phase $(VO)_2As_2O_7$ was determined from the results of chemical [quantitative analysis for the content of V(V), V(IV), and arsenic] and gravimetric analysis (evaluation of the sample mass in the course of the reaction). Thus, reactions (3)–(6) show that vanadium(V) in the active component of sulfuric acid catalysts is the only oxidizing agent both for SO_2 and for As_2O_3. Raising the reaction temperature leads only to elimination of sulfur trioxide (reversible process) in the first case, and to removal of vanadium from the active component and to volatilization of vanadium at high temperatures, presumably in the form of $VOAsO_4$ or $V_2O_5 \cdot As_2O_5$, and its transfer to reaction zones having lower temperatures [1]. Sulfur dioxide reduces vanadium even in the structure of $VOAsO_4$. Therefore, this compound, present on the surface of catalyst grains in catalyst beds III and IV, can react with sulfur dioxide to give compounds of vanadium(IV) or vanadium in a mixed oxidation state (IV, V) and, in particular, $(V^{IV}O)(V^{V}O)_2(As_2O_7)_2$. In any case, formation of oxovanadium arsenates leads to removal of vanadium from the active component and, consequently, adversely affects the performance of the catalysts.

CONCLUSIONS

(1) A study of grains of an SVD catalyst that lost its activity upon prolonged operation under conditions of insufficient purification of contact gases to remove arsenic(III) oxide vapor revealed aggregates of crystals composed of arsenates of oxovanadium in a mixed oxidation state, $(V^{IV}O)(V^{V}O)_2(As_2O_7)_2$ and a gray-blue glass with an exceedingly high content of vanadium(IV) and arsenic.

(2) In activation of sulfuric acid vanadium catalysts lose their activity upon a prolonged contact with As_2O_3 vapor is caused by blocking of the working surface of their grains by compounds of arsenic with vanadium(V) and (IV) and vanadium in a mixed oxidation state (V, IV). The formation of com-

pounds of arsenic and vanadium on the surface of catalyst grains leads to an irreversible change in the composition of the active component and, accordingly, to inactivation of the catalyst. As_2O_3 and SO_2 are oxidized at the same active vanadium centers.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Regioselective Synthesis of Alkyl Derivatives of 3,5-Diamino-1,2,4-triazole

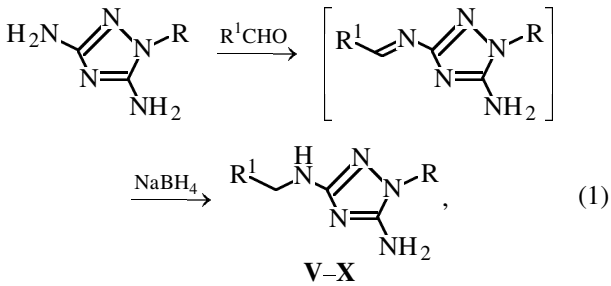
Abstract—New procedures were suggested for regioselective synthesis of alkyl derivatives of 3,5-diamino-1,2,4-triazole.

DOI: 10.1134/S1070427206040239

Alkyl derivatives of 3,5-diamino-1,2,4-triazole of general formula **I** are used in medicine as blockators of histamine [1, 2] and neurokinin [3] receptors, inhibitors of peroxide oxidation of lipids [4], and agents for treating diabetes and other diseases [5, 6].



I

The most important synthetic routes to compounds **I** are based on condensation of hydrazines $RNHNH_2$ with *N*-alkyl-*N*'-cyano-*S*-methylisothioureas [2, 6, 7], 3-R^1-2-cyanoiminothiazolidines [4], or *N*-alkyl-*N*'-cyano-*O*-phenylisoureas [3, 8], or on base-catalyzed cyclization of 1-alkyl-3-isopropylidenaminoamidinothioureas [9] prepared by the reaction of isopropylidenaminoguanidine with alkyl isothiocyanates. The major drawbacks of methods [2, 4, 6–9] is the use of difficultly available expensive chemicals or low yield of the target products. Furthermore, the reactions of *N*-cyano compounds with substituted hydrazines ($R \neq H$) sometimes yield mixtures of regioisomers [8].

It seems more promising to prepare compounds **I** from readily accessible 3,5-diamino-1-R-1,2,4-triazoles (R = H, Alk, Ar). For example, by alkylation of 3,5-diamino-1-phenyl-1,2,4-triazole with 2-methoxybenzyl chloride under the conditions of deprotonation of the amino group (THF, *t*-BuOK), Dunstan et al. [3] prepared 3-amino-5-*o*-methoxybenzylamino-1-phenyl-1,2,4-triazole in 30% yield [3]. However, alkylation is not a versatile route to compounds **I**, because at R = H this reaction occurs at the 1-position of the triazole ring [7, 10].

The goal of this study was to develop new procedures for regioselective synthesis of alkyl derivatives of 3,5-diamino-1,2,4-triazole of general formula **I**. We found that an efficient route to 3-alkylamino-5-amino-1-R-1,2,4-triazoles (R = H, Bn, Ph) is hydrogenation of Schiff bases prepared by reactions of 3,5-diamino-1-R-1,2,4-triazoles **II**–**IV** with aldehydes.

Condensation of diamines **II** and **III** with aldehydes at eqimolar ratio of the reactants or at a small excess of diamine in ethanol occurs regioselectively at the 3-amino group [10]. Hydrogenation of Schiff bases with sodium borohydride was performed without their isolation from the reaction mixture [scheme (1)]; in the process, we obtained 5-amino-1-benzyl-3-benzylamino-1,2,4-triazole **V**, 5-amino-1-benzyl-3-*p*-methoxybenzylamino-1,2,4-triazole **VI**, 5-amino-3-*o*-methoxybenzylamino-1-phenyl-1,2,4-triazole **VII**, 5-amino-1-phenyl-3-(2-furylmethyl)amino-1,2,4-triazole **VIII**, 5-amino-3-(4-benzyloxybenzyl)amino-1-phenyl-1,2,4-triazole **IX**, and 5-amino-1-phenyl-3-(3-phenylpropyl)-amino-1,2,4-triazole **X**:

V–**X** (1)

where R = Bn (**II**, **V**, **VI**), Ph (**III**, **VII**–**X**), R^1 = Ph (**V**), *p*-$MeOC_6H_4$ (**VI**), *o*-$MeOC_6H_4$ (**VII**), 2-furyl (**VIII**), = *p*-$BnOC_6H_4$ (**IX**), $PhCH_2CH_2$ (**X**).

The yields and properties of **V**–**X** are given in the table.

To prepare 3-alkylamino-5-amino-1,2,4-triazoles (R = H), it is advisable to use instead of expensive 3,5-diamino-1,2,4-triazole **IV** its more available derivatives: nitrate **XI** [11, 12] or 1-acetyl-3,5-diamino-1,2,4-triazole **XII** [13]. To prepare alkyl derivatives from nitrate **XI**, it is necessary to add to the reaction

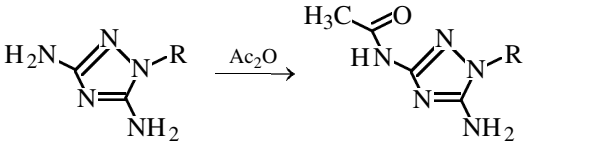
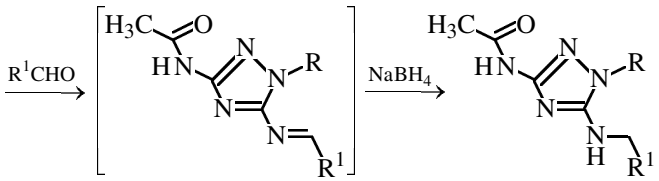
mixture an equivalent amount of NaOH to adjust the required pH 7–9.

With acetyl derivative **XII** used as the starting compound, the first step is base hydrolysis to diamine **IV**; this is followed by the reaction with an aldehyde and hydrogenation of the resulting Schiff base [scheme (2)]:



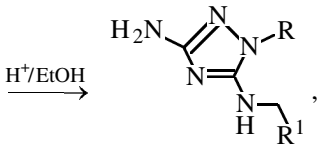
(2)

where R^1 = Ph (**XIII**), *p*-$MeOC_6H_4$ (**XIV**), *p*-ClC_6H_4 (**XV**), *m*-$NO_2C_6H_4$ (**XVI**), *m*-BrC_6H_4 (**XVII**), 3,4-$(MeO)_2C_6H_3$ (**XVIII**), 2-thienyl (**XIX**), $PhCH_2CH_2$ (**XX**, **XXI**).



All the steps can be performed in the one-pot mode without isolation of the intermediates. By this scheme we prepared 5-amino-3-benzylamino-1,2,4-triazole **XIII**, 5-amino-3-*p*-methoxybenzylamino-1,2,4-triazole **XIV**, 5-amino-3-*p*-chlorobenzylamino-1,2,4-triazole **XV**, 5-amino-3-*m*-nitrobenzylamino-1,2,4-triazole **XVI**, 5-amino-3-*m*-bromobenzylamino-1,2,4-triazole **XVII**, 5-amino-3-(3,4-dimethoxybenzyl)amino-1,2,4-triazole **XVIII**, 5-amino-3-(2-thienylmethyl)amino-1,2,4-triazole **XIX**, and 5-amino-3-(3-phenylpropyl)-amino-1,2,4-triazole **XX**. It should be noted that in the synthesis of **XX** we obtained as the second product 3,5-bis(3-phenylpropyl)amino-1,2,4-triazole **XXI**. The yield of **XXI** decreased with a decrease in the temperature in the step of condensation of diamine **IV** with 3-phenylpropanal, with a simultaneous increase in the yield of **XX**. Thus, condensation of diamine **IV** with aliphatic aldehydes is less selective than the condensation with aromatic aldehydes.

The yields and properties of **XIII**–**XXI** are listed in the table.

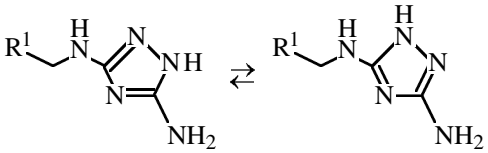


To prepare 5-alkylamino-3-imino-1-R-1,2,4-triazoles, we suggested a procedure based on the following reaction sequence:

II, **III** **XXII**, **XXIII**

XXV–**XXIX**

XXX–**XXXIV**



where R = Bn (**XXII**, **XXVI**, **XXXI**), Ph (**XXIII**, **XXV**, **XXVII**–**XXX**, **XXXII**–**XXXIV**); R^1 = *o*-$MeOC_6H_4$ (**XXV**, **XXX**), *p*-MeC_6H_4 (**XXVI**, **XXVII**, **XXXI**, **XXXII**), *m*-$NO_2C_6H_4$ (**XXVIII**, **XXXIII**), 2-thienyl (**XXIX**, **XXXIV**).

The synthesis of acetyl derivatives **XXII** and **XXIII** is described in [14]. The condensation of **XXII** and **XXIII** with aldehydes was performed in refluxing DMF, because under milder conditions the reaction is very slow. By so doing, we obtained 3-acetylamino-5-*o*-methoxybenzylidenamino-1-phenyl-1,2,4-triazole **XXIV** (see table) in 72% yield. To prepare the alkyl derivatives, the Schiff bases were hydrogenated without isolation; by so doing, we prepared 3-acetylamino-5-*o*-methoxybenzylamino-1-phenyl-1,2,4-triazole **XXV**, 3-acetylamino-1-benzyl-5-*p*-methylbenzylamino-1,2,4-triazole **XXVI**, 3-acetylamino-5-*p*-methylbenzylamino-1-phenyl-1,2,4-triazole **XXVII**, 3-acetylamino-5-*m*-nitrobenzylamino-1-phenyl-1,2,4-triazole **XXVIII**, and 3-acetylamino-5-(2-thienylmethyl)amino-1-phenyl-1,2,4-triazole **XXIX**. By hydrolysis of **XXV**–**XXIX**, we prepared 3-amino-5-*o*-methoxybenzylamino-1-phenyl-1,2,4-triazole **XXX**, 3-amino-1-benzyl-5-*p*-methylbenzylamino-1,2,4-triazole **XXXI**, 3-amino-5-*p*-methylbenzylamino-1-phenyl-1,2,4-triazole **XXXII**, 3-amino-5-*m*-nitrobenzylamino-1-phenyl-1,2,4-triazole **XXXIII**, and 3-amino-5-(2-thienylmethyl)amino-1-phenyl-1,2,4-triazole **XXXIV**. The yields and properties of **XXX**–**XXXIV** are given in the table.

The structures of the compounds were determined by elemental analysis and ^1H NMR spectroscopy, and their purity was confirmed by HPLC.

The position of the R^1CH_2 group in **V**–**X** and **XXX**–**XXXIV** was determined from the ^1H NMR spectra taking into account the facts [7, 14] that the chemical shift of the protons of the unsubstituted amino group in 3-alkylamino-5-amino-1-R-1,2,4-triazoles is about 6 ppm, and in 5-alkylamino-3-amino-1-R-1,2,4-triazoles, about 5 ppm. Isomeric triazoles **VII** and **XXX** were described previously [3], and their structure was determined by single crystal X-ray diffraction. The ^1H NMR spectra of **VII** and **XXX** are similar to those given in [3].

Alkyl derivatives **XIII**–**XX** can exist in the form of tautomers **A** and **B**:

A **B**

The prototropy can lead to strong broadening of the signals of the amino and imino groups. According to the ^1H NMR spectra, in DMSO tautomer **B** prevails (the signal of amino group protons is observed at 4.8–5.6 ppm, see table).

EXPERIMENTAL

The ^1H NMR spectra were taken on a Varian Unity-300 spectrometer (300 MHz, DMSO-d_6, internal reference TMS). HPLC analysis was performed on a Milikhrom-5 chromatograph equipped with a UV detector. An 80 × 2-mm column was packed with Separon C18; eluent methanol, elution rate 80 μl min^{-1}, detection at 210 nm. The starting compounds **II** and **III** were prepared by procedures described in [10, 15].

3-Alkylamino-5-amino-1-R-1,2,4-triazoles V–IX. A solution of 0.06 mol of diamine **II** or **III** and 0.06 mol of appropriate aldehyde in 100 ml of ethanol was refluxed for 1 h, after which 3.42 g (0.09 mol) of $NaBH_4$ was added in small portions at a rate providing uniform boiling of the reaction mixture. The mixture was refluxed for an additional 30 min, after which the solvent was distilled off, and 40 ml of water was added to the residue. The resulting solution was cooled, and the precipitate was filtered off, washed with water, and recrystallized.

5-Amino-1-phenyl-3-(3-phenylpropyl)amino-1,2,4-triazole X. A solution of 0.74 g (0.0055 mol) of 3-phenylpropanal in 5 ml of ethanol was added dropwise over a period of 10 min with vigorous stirring at 0–5°C to a solution of 1.05 g (0.006 mol) of **III** in 10 ml of ethanol. The mixture was stirred for 2 h, after which 0.34 g (0.009 mol) of $NaBH_4$ was added in portions at 20–30°C. The mixture was stirred for 30 min, heated to boil, and refluxed for 30 min. The solvent was distilled off, 10 ml of water was added to the residue, the oil that separated out was extracted with chloroform (3 × 5 ml), and the extract was filtered through a bed of alumina (4 cm in diameter, 3 cm high). The solvent was distilled off, and compound **X** was crystallized from acetonitrile.

3-Alkylamino-5-amino-1,2,4-triazoles XIII–XIX. *a*. A solution of 2.9 g (0.072 mol) of NaOH in 2 ml of water was added to a suspension of 10 g (0.063 mol) of nitrate **XI** in 20 ml of ethanol. The mixture was refluxed for 5 min, after which a solution of 0.057 mol of appropriate aldehyde in 10 ml of ethanol was added, the mixture was refluxed for 1 h, and 3.3 g (0.086 mol) of $NaBH_4$ was added in portions. The mixture was refluxed for an additional 30 min, the solvent was evaporated to a small volume, and 40 ml of water was added to the residue. The resulting solution was cooled, and the precipitate thus formed was filtered off, washed with water, and crystallized.

b. A solution of 4.8 g (0.12 mol) of NaOH in 10 ml of H_2O was added with stirring to a suspension of 14.1 g (0.1 mol) of acetyl derivative **XII** in 50 ml of ethanol. The mixture was refluxed until it became fully homogeneous (10–15 min), after which it was neutralized with acetic acid to pH 7–9, and 10.1 g (0.09 mol) of appropriate aldehyde was added dropwise with stirring. The mixture was refluxed for 20 min, after which 5.13 g (0.135 mol) of $NaBH_4$ was added in portions over a period of 10 min. The mixture was refluxed for an additional 20 min and evaporated to a small volume. The residue was diluted with 100 ml of water, and the resulting solution was evaporated by half and cooled. The precipitate thus formed was filtered off, washed with water, and crystallized.

5-Amino-3-(3-phenylpropyl)amino-1,2,4-triazole XX and 3,5-di(3-phenylpropyl)amino-1,2,4-triazole XXI. A solution of 12.06 g (0.09 mol) of 3-phenylpropanal in 10 ml of ethanol was added with vigorous stirring over a period of 10 min at 0–5°C to the reaction mixture obtained as described above by hydrolysis of 14.1 g (0.1 mol) of acetyl derivative **XII.** The mixture was stirred for 2 h, after which 5.7 g (0.15 mol) of $NaBH_4$ was added in small portions at 20–30°C. The mixture was stirred for 30 min, heated to boil, and refluxed for 30 min. The solvent was distilled off, 300 ml of water was added to the residue, and the precipitate (compound **XXI**) was filtered off, washed with water, dried, and crystallized.

The filtrate and wash waters were evaporated to a volume of 50 ml; the precipitate that formed on cooling (compound **XX**) was filtered off and crystallized.

3-Acetylamino-5-*o*-methoxybenzylidenamino-1-phenyl-1,2,4-triazole XXIV. A mixture of 1 g (0.0046 mol) of **XXIII**, 0.75 g (0.0055 mol) of 2-methoxybenzaldehyde, and 1 ml of DMF was refluxed for 1 h, diluted with 10 ml of water, and extracted with chloroform (3 × 10 ml). The extract was dried over $CaCl_2$ and filtered through a bed of alumina (4 cm in diameter, 3 cm high); the solvent was distilled off, and the residue was crystallized.

5-Alkylamino-3-acetylamino-1-R-1,2,4-triazoles XXV–XXIX. A mixture of 0.01 mol of **XXII** or **XXIII** and 0.012 mol of appropriate aldehyde in 2 ml of DMF was refluxed for 1 h and diluted with 20 ml of ethanol. To the resulting solution, 0.68 g (0.018 mol) of $NaBH_4$ was added in small portions at 50–60°C, after which the mixture was refluxed for 30 min. The solvent was evaporated to a small volume, and 40 ml of water was added to the residue. The precipitate thus formed was filtered off, washed with water, and crystallized.

5-Alkylamino-3-amino-1-R-1,2,4-triazoles XXX–XXXIV. A mixture of 0.005 mol of **XXV–XXIX**, 10 ml of ethanol, and 3 ml of concentrated HCl was refluxed for 2 h and then neutralized with a 10% aqueous solution of sodium acetate. The precipitate thus formed was filtered off, washed with water, and crystallized.

CONCLUSIONS

(1) Condensation of 3,5-diamino-1-R-1,2,4-triazoles (R = Alk, Ar) with aldehydes at an equimolar ratio of the reactants, followed by hydrogenation of the resulting Schiff bases, is a one-pot method for regioselective synthesis of 3-alkylamino-5-amino-1-R-1,2,4-triazoles.

(2) 3,5-Diamino-1,2,4-triazole (R = H) reacts selectively only with aldehydes in which the carbonyl group is conjugated with the aromatic ring. Condensation with aliphatic aldehydes followed by hydrogenation yields a mixture of 3-alkylamino-5-amino-1,2,4-triazoles and 3,5-dialkylamino-1,2,4-triazoles.

(3) Condensation of 5-amino-3-acetylamino-1-R-1,2,4-triazoles with aldehydes in dimethylformamide, followed by hydrogenation of the resulting Schiff bases (without their isolation) with sodium borohydride and by acid hydrolysis of the reduction products, 5-alkylamino-3-acetylamino-1-R-1,2,4-triazoles, is a convenient method for regioselective synthesis of 5-alkylamino-3-amino-1-R-1,2,4-triazoles (R = Alk, Ar).

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis of 6-Methyluracil-5-sulfonyl Chloride

I. P. Pogorelova, V. D. Orlov, and A. D. Isak

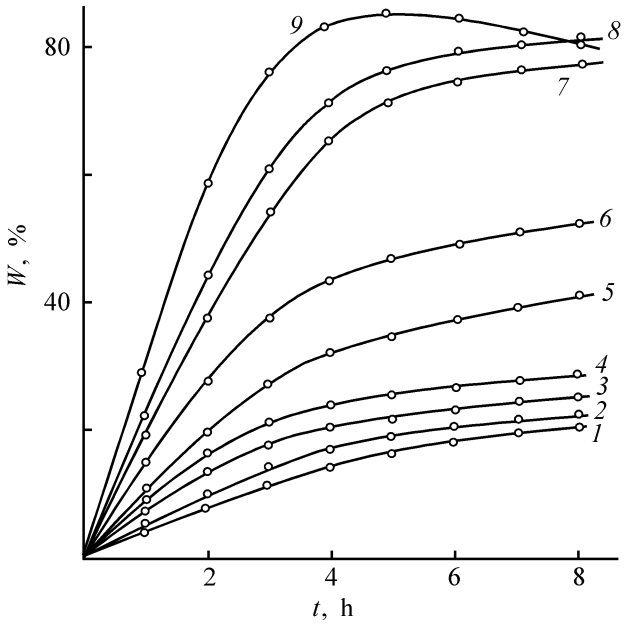
Rubezhnoe Branch, Dal' East-Ukrainian National University, Rubezhnoe, Lugansk oblast, Ukraine

Received November 25, 2005

Abstract—Sulfochlorination of 6-methyluracil with chlorosulfonic acid in the presence of thionyl chloride was studied. The lactam–lactim tautomerism of 6-methyluracil was considered. Ways to increase the yield of the sulfonyl chloride were suggested. The mechanism of the effect exerted by thionyl chloride additions was discussed.

DOI: 10.1134/S1070427206040240

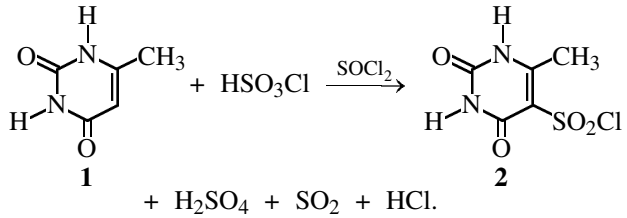
Sulfochlorination reactions are widely used in organic (in particular, pharmaceutical) chemistry. Sulfonyl chlorides are intermediates in syntheses of active and dispersible dyes, herbicides, and fungicides [1]. Among six-membered heterocyclic compounds containing two nitrogen atoms, a prominent place is occupied by pyrimidine derivatives used as drugs (sulfamide drugs such as Sulfadimethoxine, Sulfamonomethoxine; antitumor agent Fluorouracil; antibiotic Amecytin, etc.) [2, 3].



Of particular interest in this respect is readily available methyluracil, which is used in syntheses of sulfonamides, sulfonyldiureides, sulfonylhydrazides, and sulfonates; some of these compounds showed biological activity.

Data on sulfochlorination of 6-methyluracil are relatively few. As shown in [4–6], uracil and 6-methyluracil **1** react with a tenfold excess of chlorosulfonic acid to form uracil-6-sulfonyl chloride and 6-methyluracil-5-sulfonyl chloride **2** in a low yield (≤22%).

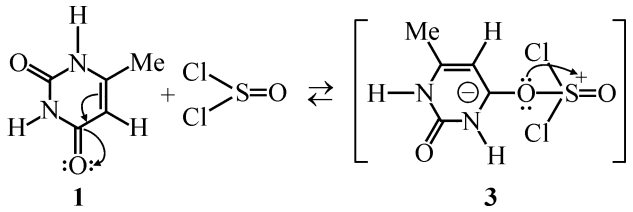
To develop a more efficient procedure for preparing 6-methyluracilsulfonyl chloride, we examined the effect of various factors on the sulfochlorination of **1** [7, 8].



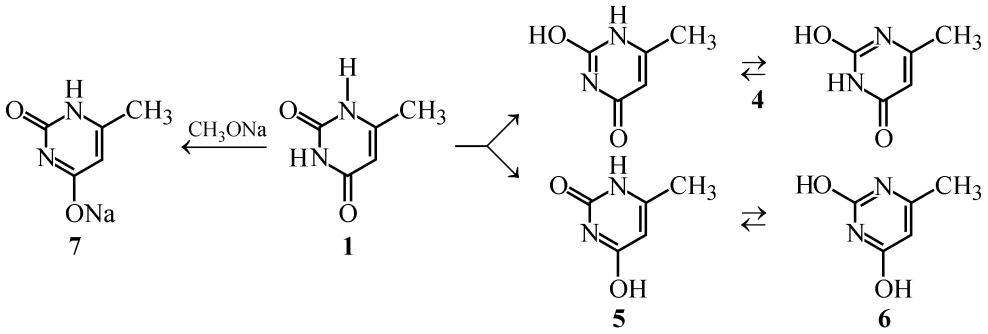
At 30°C, compound **1** does not noticeably react with chlorosulfonic acid; the reaction starts only at 35°C, and the yield of **2** under these conditions does not exceed 15%. With increasing temperature, the reaction rate and sulfonyl chloride yield increase, but even after the sulfochlorination for 7 h at 75°C the yield of **2** does not exceed 28% (see figure). When the reaction mixture is poured onto ice to isolate the product, a considerable part of **2** undergoes hydrolysis and transforms into 6-methyluracilsulfonic acid, which was isolated from the solution by salting-out with NaCl. Thus, the desired sulfonyl chloride is unstable and is readily hydrolyzed in aqueous solution. To suppress the hydrolysis, the reaction mixture was poured onto a 1 : 1 mixture of ice and acetic acid.

It was found in [9, 10] that the use of chlorosulfonic acid in combination with thionyl chloride (volume ratio 1.5 : 1) considerably increases the rate of formation and yield of **2** (see figure). In contrast to $SOCl_2$, addition of SO_2Cl_2 or $POCl_3$ does not noticeably af-

Yield of 6-methyluracilsulfonyl chloride W vs. time t (*1*–*4*) in the absence and (*5*–*9*) in the presence of thionyl chloride. T, °C: (*1*, *5*) 45, (*2*, *6*) 55, (*3*, *7*) 65, (*4*, *8*) 75, and (*9*) 85.



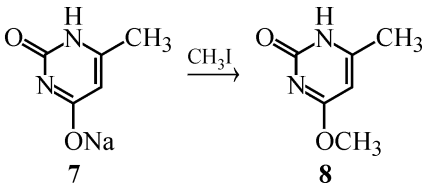
fect the sulfochlorination rate and yield of the target product. Sulfochlorination of 6-methyluracil follows the scheme



As seen from the figure, addition of $SOCl_2$ results in that the rate of formation of **2** increases by a factor of 3–4 even at 45°C, with the yield of **2** reaching 40%. Similar relationships are observed at higher temperatures.

The highest yield of **2** (82%) was obtained after heating at 85°C for 5 h. Further increase in the temperature decreases the yield of the target product because of formation of the sulfone (see figure, curve *9*).

The favorable effect of thionyl chloride on the rate of formation and yield of sulfonyl chlorides is apparently due to the presence of a lone electron pair at the S(IV) atom. The S atoms in SO_2Cl_2 and $SOCl_2$ differ in the electronic structure and affect the substrate differently. In contrast to the S atom in chlorosulfonic acid and sulfuryl chloride, in which all the valence electrons are fully involved in formation of six covalent bonds, in thionyl chloride a lone *p*-electron pair remains on the sulfur atom, and it may compensate the electron density deficiency on the O atom in the 4-position of methyluracil, facilitating electrophilic substitution of the H atom by the SO_2Cl group:



The ready incorporation of the SO_2Cl group in the 5-position of methyluracil is due to its lactam–lactim tautomerism. 6-Methyluracil can exist in the form of five tautomers, four of which contain one or two hydroxy groups. Nonaqueous titration shows that 1 mol of sodium methylate is spent per mole of methyluracil, suggesting the presence of only one OH group (structures **4**, **5**):

As shown by quantum-chemical calculations, ^1H NMR spectra, and certain chemical transformations, structure **5** is the most favorable energetically. In this structure, the 5-position will be the most reactive owing to the concerted effect of CH_3 and OH groups. Sulfochlorination occurs at a higher rate via intermediate **3** (see above).

Experiments showed that methyluracil reacts with sodium methylate to form monosodium derivative **7**, which reacts with methyl iodide CH_3I to form compound **8**:

The structures of **7** and **8** were confirmed by IR and NMR spectra and by elemental analysis.

EXPERIMENTAL

The ^1H NMR spectra were recorded in $CDCl_3$ on a Tesla BS-487c spectrometer operating at 80 MHz. The chemical shifts (δ, ppm) are given relative to TMS. The IR spectra were measured on a UR-20 spectrometer (KBr pellets).

6-Methyluracil-5-sulfonyl chloride 2. A four-necked flask equipped with a power-driven stirrer, a thermometer, a reflux condenser, and a dropping funnel was charged with 7.6 g (0.054 mol) of 6-methyluracil **1** dried in an oven at 110–115°C for 3–4 h. The flask was placed on a water bath, and 10 ml (16.5 g, 0.138 mol) of freshly distilled thionyl chlo-

ride was added with vigorous stirring. The contents were stirred for 20–30 min, after which 16 ml (28.6 g, 0.265 mol) of freshly distilled chlorosulfonic acid was added dropwise at such a rate that the reaction mixture temperature did not exceed 30–35°C. The reflux condenser was connected through a $CaCl_2$ tube with a beaker absorbing the released gases.

The mixture was heated to 60–65°C and kept at this temperature with vigorous stirring for 4.5–5 h, after which it was heated to 75–80°C and kept for an additional 5.5–6 h. The reaction progress was monitored chromatographically on Silufol UV-254 plates, eluent ethyl acetate. After the reaction completion, the mixture was cooled to 0–5°C and poured with vigorous stirring onto a mixture of 50 g of crushed ice and 35 ml of glacial acetic acid, keeping the temperature in the range from –5 to 0°C. 6-Methyluracil-5-sulfonyl chloride precipitated as a white crystalline substance; it was filtered off and washed several times with ice-cold water and acetic acid. Yield 9.95 g (82%). White needle-like crystals, mp 269–270°C (from glacial acetic acid).

Found, %: C 26.91, H 2.61, N 12.40, Cl 15.94, S 14.48.

$C_5H_5ClN_2O_4S$.

IR spectrum, cm^{-1}: 985, 1030 ($\omega_{C=C}$); 1305 (C=N–); 1675, 1730 ($\nu_{C=O,\ =N-C=O}$); 3275 (ν_{NH}); 1355, 1380 ($\nu_{S(CH_3)}$). ^1H NMR spectrum, δ, ppm ($CDCl_3$): 2.45 s (3H, C^6–CH_3); 11.68 d (1H, N^1–H), 5.85 s (1H, C^4–OH).

4-Methoxy-6-methyluracil. Sodium metal (1.25 g, 0.054 mol) was dissolved in 50 ml of absolute methanol, and 6.25 g (0.050 mol) of methyluracil was added. The mixture was heated at 65°C for 45 min with stirring. To the resulting colorless solution, 3.7 ml (0.060 mol) of methyl iodide was added, and the mixture was heated with weak refluxing for 4–5 h until the methyluracil spot disappeared from the chromatogram (Silufol UV-254, eluent ethyl acetate). On cooling, colorless needle-like crystals precipitated. The precipitate was filtered off, washed with water, and dried. Yield of 4-methoxy-6-methyluracil 6.31 g (89.9%), mp 192–193°C.

Found, %: C 51.63, H 5.71, N 19.86.

$C_6H_8N_2O_2$.

Calculated, %: C 51.42, H 5.75, N 19.99.

IR spectrum, cm^{-1}: 1020 ($\omega_{C=C}$); 1025 ($\nu_{S(=C-O-C)}$); 1245 ($\nu_{as(=C-O-C)}$); 1055–1275 (C=N–); 1685, 1745 ($\nu_{C=O,\ =N-C=O}$); 1380 ($\nu_{S(CH_3)}$); 2825 (OCH_3); 2850 ($\nu_{S(OCH_3)}$); 2870 ($\nu_{S(CH_3)}$); 2965 ($\nu_{as(CH_3)}$). ^1H NMR spectrum, δ, ppm ($CDCl_3$): 2.11 s (3H, C^6–CH_3), 4.92 d (1H, C^5–H), 4.01 s (3H, C^4–OCH_3), 11.92 s (1H, N^1–H).

CONCLUSIONS

(1) Sulfonation of 6-methyluracil with a mixture of chlorosulfonic acid and thionyl chloride allows the rate of formation and yield of 6-methyluracil-5-sulfonyl chloride to be appreciably increased, with the yield reaching 82%.

(2) In solution, 6-methyluracil mainly occurs in the lactim form (4-hydroxy-6-methyl-1,2-dihydropyrimidin-2-one).

(3) The favorable effect of thionyl chloride on the sulfochlorination rate and yield of sulfonyl chloride is due to the fact that the lone electron pair of the S atom of thionyl chloride eliminates the electron density deficiency on the oxygen atom, thus facilitating the electrophilic substitution of hydrogen by the SO_2Cl group.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Preparative Synthesis of Menthone Oxime Esters

Abstract—Procedures are developed for the preparation of menthone oxime esters as accessible perfumes and fragrant additives synthesized from natural raw materials.

DOI: 10.1134/S1070427206040252

Oxime ethers and esters exhibit a wide range of biological activity and are accessible perfumes and fragrant additives [1, 2].

The goal of this study is development of procedures for preparing menthone oxime esters. Menthone is prepared from natural raw materials (*L*-menthone is prepared by vacuum distillation of *Mentha arvensis* essential oil after separation of *L*-menthol [3]); it exhibits fresh mint odor. Menthone oxime **I** is a valuable perfume with a black currant scent and is widely used for preparing fragrant additives and food aromatizers [3]. Interesting scents can also be expected from menthone oxime esters.

Menthone oxime esters were prepared by reactions of menthone oxime **I** with alkanoic acid anhydrides **IIa**–**IId** in absolute diethyl ether in the presence of catalytic amounts of 57% $HClO_4$ or with alkanoic, alkenoic, or arenecarboxylic acid chlorides **IIe**–**IIo** in the presence of pyridine. The syntheses were performed at 20–23°C for 24–36 h and involved simple mixing of the reactants; they did not require efficient cooling or prolonged stirring. Menthone oxime esters **IIIa**–**IIIo** were prepared in 76–90% yield.

I **IIIa**–**IIIo**

III, R = CH_3 (**a**), C_2H_5 (**b**), $(CH_2)_2CH_3$ (**c**), $CH(CH_3)_2$ (**d**); R' = $CH_2CH(CH_3)_2$ (**e**), $(CH_2)_4CH_3$ (**f**), $(CH_2)_5CH_3$ (**g**), $(CH_2)_6CH_3$ (**h**), $(CH_2)_8CH_3$ (**i**), $CH{=}CH_2$ (**j**), $C(CH_3){=}CH_2$ (**k**), C_6H_5 (**l**), CH_2Cl (**m**), C_6H_4Cl-4 (**n**), 1/2 $[(CH_2)_4]$ (**o**).

Menthone oxime esters **IIIa**–**IIIo** are colorless or weakly colored viscous liquids; their characteristics are listed in the table.

The IR, UV, and ^1H NMR spectra of menthone oxime esters **IIIa**–**IIIo** confirm their structure. The IR spectra of **IIIa**–**IIIo** contain absorption bands (cm^{-1}) of the groups CH_{Alk} (3000–2800), C=O (1743–1766), C=N (1632–1634), CH_2 (1455–1460), and C–O (1280–1000); the spectra of aromatic esters **IIIl** and **IIIn** also contain absorption bands (cm^{-1}) of the groups CHAr (3100–3000), Ar (1595–1600, 1485–1487, 1386–1400, 1310–1313), and CH_{Ar} (902–683), and the IR spectra of **IIIm** and **IIIn**, also C–Cl bands (592 amd 527 cm^{-1}, respectively). The UV spectra of oxime esters exhibit the following absorption maxima (nm): **IIIa**–**IIIi** and **IIIm**, 208 (ε = 8000); **IIIj** and **IIIk**, 209 (ε = 15000); **IIIl**, 207 (ε = 23000), 226 (ε = 14000), and 260 (ε = 11000); **IIIn**, 207 (ε = 28000), 220 (ε = 6000), and 252 (ε = 8000); and **IIIo**, 208 (ε = 15000). In the ^1H NMR spectra of menthone oxime esters **IIIa**–**IIIo**, the CH_3 proton signals appear at 0.75–1.10 ppm, and the CH and CH_2 proton signals, at 1.10–3.00 ppm. The CH_3CO group in **IIIa** gives a singlet at 2.12 ppm; the CH_3CH_2CO group in **IIIb**, a triplet at 1.22 ppm (CH_3) and a quartet at 2.42 ppm (CH_2); the $(CH_3)_2C$ group of **IIId**, a doublet at 1.21 ppm; the $CH{=}CH_2$ group in **IIIj**, a multiplet at 5.70–6.30 ppm; the $CH_3C{=}C$ group in **IIIk**, a singlet at 2.00 ppm; the $C{=}CH_2$ group in **IIIl** and **IIIn**, two broadened singlets at 5.62 and 6.16 ppm; the aromatic protons in **IIIl** and **IIIn**, multiplets at 7.30–8.30 ppm; and the CH_2Cl group in **IIIm**, a singlet at 4.23 ppm.

[1] Organoleptic evaluation of the odors of menthone oxime esters **IIIa**–**IIIo** was performed by the Tasting Council at the Accredited Chek-out and Analytical Laboratory of the Tereza-Inter Limited Liability Company (Moscow).

EXPERIMENTAL

The IR spectra of **IIIa**–**IIIo** were recorded on a Nicolet Protege-460 IR Fourier spectrometer (KBr). The UV spectra were measured on a Specord UV–Vis spectrometer from 1×10^{-3} M solutions of the compounds in methanol. The ^{1}H NMR spectra were taken on a Tesla BS-587A spectrometer (100 MHz) from 5% solutions in $CDCl_3$ using octamethylcyclotetrasiloxane as internal reference. The molecular weight *M* was determined cryoscopically in benzene. Menthone oxime **I** was prepared as described in [4, 5].

Menthone oxime esters IIIa–**IIId** (general procedure). Menthone oxime **I** (0.01 mol) and 0.02 mol of appropriate anhydride **IIa**–**IId** were dissolved in 10 ml of absolute ether, and 1–2 drops of 47% $HClO_4$ were added with cooling to 15°C. The components were mixed by shaking, and the mixture was allowed to stand at 20–23°C for 24–36 h. Then the mixture was diluted with water, and the product was extracted with hexane. The organic layer was separated, washed with water and 5% $NaHCO_3$, and dried over $CaCl_2$. The solvent was removed, and the product was vacuum-dried (2×10^{-2} mm Hg).

Menthone oxime esters IIIe–**IIIo** (general procedure). Menthone oxime **I** (0.01 mol) was dissolved in 0.011 mol of absolute pyridine, and 0.011 mol of appropriate acid chloride **IIe**–**IIn** was added with

gentle shaking while cooling to 15°C. To prepare **IIIo**, 0.02 mol of **I**, 0.022 mol of pyridine, and 0.01 mol of **IIo** were taken. The mixture was allowed to stand at 20–23°C for 24–36 h. Then the mixture was diluted with water, and the product was extracted with hexane. The organic layer was separated, washed with water and 5% $NaHCO_3$, and dried over $CaCl_2$. The solvent was removed, and the product was vacuum-dried (2×10^{-2} mm Hg).

Menthone oxime esters **IIIa**–**IIIo** were purified by column chromatography (neutral alumina, Brockmann grade II, eluent hexane).

CONCLUSIONS

(1) Menthone oxime reacts with carboxylic acid anhydrides and chlorides to form the corresponding esters.

(2) Menthone oxime esters are accessible perfumes and fragrant additives synthesized from natural renewable raw materials.

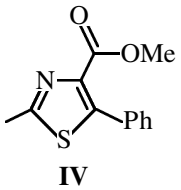
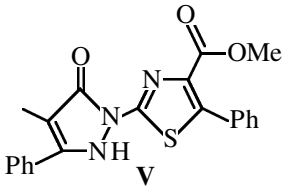
Abstract—Absorption and luminescence spectra of a series of functionally substituted azothiazoles in dimethylformamide and transparent polymeric matrix (bulk copolymer of methyl methacrylate and methacrylic acid) were studied. Kinetics of decolorization of liquid and solid solutions under the action of the integral light of a mercury lamp was measured to evaluate their lightfastness.



DOI: 10.1134/S1070427206040264

Azo derivatives form the most numerous group of organic dyes, covering the total color spectrum from yellow to black and differing in the lightfastness and resistance to hydrolysis and effect of various chemicals. Azo dyes are used in dyeing of plastics, fibers, and fabrics, and as color-forming components of photomaterials [1–4]. However, their color and service characteristics are determined by the nature of fragments bonded with the azo group and by the number, character, and location of electron-donor and electron-acceptor substituents [5]. In accordance with [6–9], the purposeful synthesis of new azo dyes can be of interest for laser engineering and other branches of high technology.



In this study, we examined optical properties and lightfastness of a series of functionally substituted azothiazoles (ATs) of the general formula

where R is Ph (**I**), *p*-HOC_6H_4 (**II**), and *p*-$Me_2NC_6H_4$ (**III**),

IV

V

Liquid and solid solutions of ATs in dimethylformamide (DMF) and transparent polymeric matrix (PM), a bulk copolymer of methyl methacrylate (MMA) and methacrylic acid (MAA), were considered. This PM is widely used today for preparation of laser dye active media (new class of solid-state materials in quantum electronics), resistive materials for microelectronics, and polygraphic printing plates [10–12]. The synthesis and properties of this copolymer doped with laser dyes were studied in [13–15].

EXPERIMENTAL

Compounds **I**–**III** [16] and compounds **IV** and **V** [17, 18] were synthesized by the methods described elsewhere.[1] All these compounds are highly dispersed powders colored from yellow to red and purple; mp, °C: **I**, 152–153; **II**, 105–106; **III**, 179–180; **IV**, 265–266; and **V**, 197–200.

We used DMF [GOST (State Standard) 20289–74], n_D^{20} = 1.4310, ρ = 945 kg m^{-3}, bp 152°C; MMA (GOST 20370–74), main substance content 99.99%, bp 100°C, n_D^{20} = 1.4130, ρ = 936 kg m^{-3}; MAA [TU (Technical Specification) 6-09-487–76], main substance content 99.50%, bp 163°C, n_D^{20} = 1.4314, ρ = 1015.3 kg m^{-3}; copolymerization initiator, azobis(isobutyronitrile) (AIBN) [MRTU (Interrepublican Technical Specification) 6-09-5749–68], mp 106°C.

[1] Azothiazoles were synthesized in the Arbuzov Institute of Organic and Physical Chemistry, Kazan Scientific Center, Russian Academy of Sciences, Kazan.

Comparative spectral characteristics of AT in DMF and PM* (concentration of **IV** in DMF 2.5×10^{-4} M, in PM 1.0×10^{-4} M; concentrations of the other ATs in DMF and PM 1.0×10^{-3} M)

* DMF and MMA–MAA copolymer within the λ = 380–548 nm range have close values of transmittance, which within the 400–500 nm range vary within 88–91%.

Polymer samples as 0.5–0.6-mm-thick plates were prepared by bulk radical copolymerization of MMA and MAA in the presence of AT. The MMA : MAA ratio, 9 : 1 (by weight), was optimal to attain the required optical and service properties of the organic glass obtained [10]. The AIBN concentration in the monomer mixture was 0.1 wt %. The AT concentration in liquid and solid solutions was varied within the (0.1–2.3) $\times 10^{-3}$ M range. The reaction temperature was 45°C. Polymerization was performed for 3 h at 110°C.

The absorption spectra of ATs in DMF and PM were recorded on an SF-18 spectrophotometer. The solution layer thickness was 1.07 mm. The AT luminescence was excited by a He–Ne laser radiation with λ = 440 nm. The luminescence spectra were recorded on a GIPO device. The integral light of a DRG 230 mercury lamp was used to evaluate the lightfastness of the polymer samples.

The absorption spectra of ATs in DMF are shown in Fig. 1. The concentration of all the solutions was 1×10^{-3} M, except for the most strongly colored compound **IV**; its liquid and solid solutions had lower concentration by a factor of 4 and 10, respectively. The spectral characteristics of ATs are listed in the table.

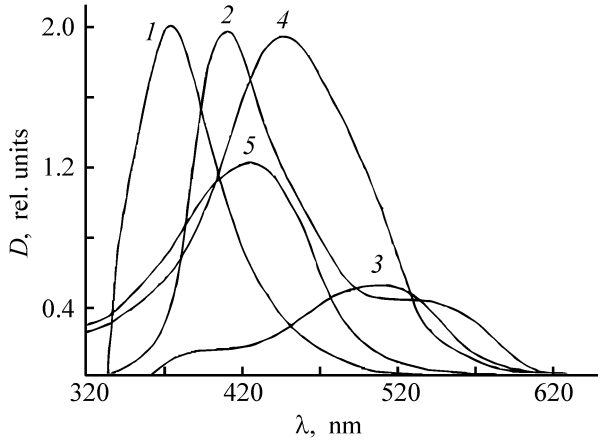

Fig. 1. Absorption spectra of ATs in DMF. (*D*) Optical density and (λ) wavelength. Concentration of **IV** 2.5×10^{-4}, concentration of the remaining ATs 1.0×10^{-3} M. Compound: (*1*) **I**, (*2*) **II**, (*3*) **III**, (*4*) **IV**, and (*5*) **V**.

As seen, the wavelength of the absorption maximum increases in the order **I** < **II** < **V** < **IV** < **III**, i.e., the color deepens from yellow to reddish-purple. The band half-width $\lambda_{0.5}$ decreases (increase in brightness and color purity) in the order **IV** > **V** ~ **III** > **II** > **I**. The molar extinction coefficient ε and hence the color intensity of AT in DMF increases in the order **III** < **V** < **I** ~ **II** < **IV**. For the solid matrix (PM) this order is violated as follows: ε for **V** becomes higher than for **II**. This may be explained by the effect of labile hydrogen atom of OH group of compound **II** on the kinetic parameters of the radical copolymerization of MMA with MAA.

To find correlation between the spectral characteristics and structure of AT molecule, we compared the following three groups of compounds: (1) **I**, **II**, and **III**, (2) **I** and **IV**, and (3) **IV** and **V**. The π-electron chromophore system of monoazo compounds **I**–**III** includes, on the one hand, a thiazole core with methoxycarbonyl and phenyl substituents, and, on the other hand, phenyl, phenolic, and *para*-dimethylaniline fragments. For compound **I** in DMF, λ_a^{max} is located on the boundary of the UV and visible spectral ranges, which determines its yellow color. The comparison of the spectra of **I**–**III** in the solution shows that the OH group introduced into the benzene ring shifts λ_a^{max} by 35 nm to longer wavelengths. Still larger bathochromic shift (by 131 nm) is observed when the OH group in the AT aromatic core is substituted by the stronger electron-donor group NMe_2.

The color deepening in the series **I**–**III** is accompanied by broadening of the absorption band (increase in $\lambda_{0.5}$), i.e., by a decrease in the brightness and purity

of the dye color. Introduction into the thiazole core of the *p*-dimethylaniline fragment gives a hypochromic effect, i.e., decrease in ε. Compounds **II** and **III** in DMF have complex absorption bands with additional shoulders in the region of longer and shorter wavelengths. Approximate location of their maxima in the spectrum is shown in the table in parentheses. The long-wave shoulder of the absorption band of compound **II** can originate from H bonding between its molecules through OH groups. Formation of such H bonds between azo dye molecules was found in [19]. The resulting red color of **II** in the solution can be caused by the sum of complementary colors: greenish-yellow and purple [1]. The absorption band of **III** in DMF has a short-wave inflection at λ ~ 390 nm, close to λ_a^{max} of compound **I**. In contrast to solutions, the absorption bands of **II** and **III** in PM have no shoulders.

We found that substitution of DMF by a less polar solvent, dioxane, does not change λ_a^{max} of compound **I** but shifts it for **III** to shorter wavelengths. Similar effect was observed for monoazo dyes in [6] and was attributed to solvation by the more polar solvent.

The chromophore system of compound **IV** combines two identically functionalized thiazole rings linked by the azo group. Substitution of the benzene ring in **I** by the thiazole ring causes color deepening from yellow to orange (bathochromic shift of λ_a^{max} 75 nm) and increase in the absorption intensity (ε increases by a factor of approximately 4). This effect may be caused by an increase in the delocalization of π electrons in the common chromophore system due to increased size of the conjugation system in **IV**. As mentioned above, compound **IV** exceeds in this parameter all the other ATs including **V**.

Disturbance of the symmetry of **IV** due to introduction of a pyrazole ring with carbonyl and phenyl substituents between identical N- and S-containing heterocycles (this corresponds to the structure of **V**) is accompanied by a hypsochromic shift (by 25 nm) and a considerable (by a factor of 6.5) decrease in ε.

The absorption bands in the spectra of ATs in the polymer matrix are broadened in comparison with solutions, especially for **II** and **IV** ($\lambda_{0.5}$ increases by 15 and 23 nm, respectively). In addition, their ε decreases (by a factor of 2.7 and 1.7, respectively). These effects may be caused by partial degradation of AT molecules under the action of initiator radicals and propagating radicals during copolymerization in the MMA–MAA mixture. At the same time, for **III** and **V**, the difference in $\lambda_{0.5}$ values in DMF and PM is substantially smaller (8 and 10 nm, respectively)

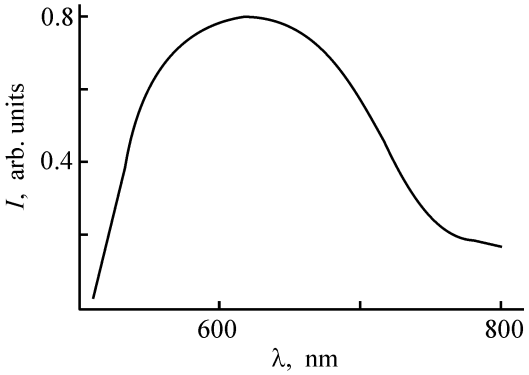

Fig. 2. Luminescence spectrum of compound **IV** in DMF. Solution concentration 1×10^{-4} M. (*I*) Intensity and (λ) wavelength.

and ε remains actually the same, which is indicative of high stability of their molecules during formation of PM.

In the first AT group, compound **III** is fairly resistant to degradation during copolymerization (the difference in ε in DMF and PM is small), whereas for **II** ε in PM is lower by a factor of 2.7. Thus, substitution of hydroxyl in the aromatic ring by the *p*-dimethylamino group increases the molecular stability of AT under conditions of radical polymerization. The comparison of **V** and **IV** shows enhanced stability of **V**, which differs from **IV** by the presence of the pyrazole ring.

With an increase in solution concentration, the intensity of AT absorption increases at different rates W_ε correlating with ε (see table). As seen, the W_ε values in PM are lower than in the solution by a factor of 2 and more. Compound **IV**, for which a luminescence spectrum in DMF was observed (Fig. 2), is characterized by the maximal value of W_ε.

To evaluate the lightfastness of ATs, we examined the kinetics of decolorization of their solutions and polymeric samples under the action of the integral light of a mercury lamp. The kinetic data in the D_t/D_0–t axes are shown in Figs. 3 and 4.

It follows from different shapes of the kinetic curves that the structure of AT affects its lightfastness. The solutions of **II** and **IV** were decolorized at a constant rate during the irradiation (Fig. 3, curves *3*, *5*). The rate of decolorization of **V** gradually decreases (Fig. 3, curve *4*). Solutions of **III** and **I** are decolorized only in the beginning of the irradiation (up to t = 0.5 h), whereupon the D_t/D_0 ratio becomes virtually constant (Fig. 3, curves *1* and *2*, respectively). The least-absorbing compound **III** exhibits the highest lightfastness in the solution. In this case, decoloriza-

Compound: (*1*) **III**, (*2*) **I**, (*3*) **III**, (*4*) **V**, and (*5*) **IV**.

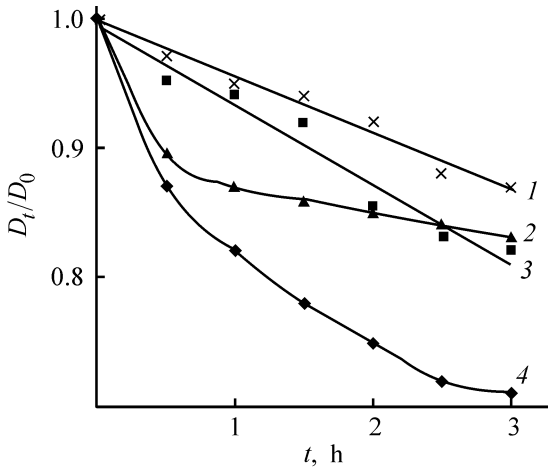

Fig. 4. Kinetic curves of photodecolorization of ATs in PM. Concentration of **II**, **III**, and **V** 1×10^{-3} M and of **IV** 1.0×10^{-4} M. Compound: (*1*) **V**, (*2*) **II**, (*3*) **III**, and (*4*) **IV**.

tion does not exceed 10% after 3 h of irradiation, which can be caused by quenching of the excited electronic states by solvent molecules [20].

Photodecolorization of ATs in PM is substantially lower than in the solution. For instance, after 2 h of irradiation the maximal decrease in the optical density of AT in PM does not exceed 25%, which is by a factor of almost 3 less than in DMF.

The comparison of Figs. 3 and 4 shows that the shapes of certain kinetic curves related to liquid and solid media are different. This fact can be explained by mutual influence of photochemical aging of PM and AT and the specific influence of AT on the kinetic parameters of the synthesis of the polymeric samples. The exception is compound **IV**, whose photochemical aging mechanism is apparently the same in DMF and PM. This compound demonstrates the lowest lightfastness in both liquid and solid media. Compound **V** has the maximal lightfastness in PM (Fig. 4) and, as noted above, shows enhanced stability under the conditions of the synthesis of polymeric samples. For compounds **II** and **III** in PM, the lightfastness and stability of AT also correlate: to the greater lightfastness of **III** corresponds the higher stability of its molecules during polymerization.

CONCLUSIONS

(1) The influence of the chemical composition on the absorption spectra of functionally substituted azothiazoles in dimethylformamide and transparent polymer matrix, for which λ_a^{max} varied within the 380–511 nm range, was examined. In the series of compounds **I**, **II**, and **III** with phenyl, phenol, and *p*-dimethylaniline substituents, respectively, bound to the azo group, the bathochromic shift and broadening of the absorption band take place. For compound **III**, the hypochromic effct was additionally observed.

(2) As a rule, the absorption bands of azothiazoles in solutions are narrower than in the polymeric matrix.

(3) The difference in the chemical composition substantially affects the character of the kinetic curves and degree of photodecolorization of azothiazoles, whose value in the polymeric matrix is by a factor of almost 3 smaller than in dimethylformamide.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Dependence of the Dielectric Constant on the Structure of Extruded Polyvinylidene Fluoride Films

Abstract—The structure of extruded polyvinylidene fluoride films obtained at different die drawing ratios and melt temperatures was studied by X-ray scattering, differential scanning calorimetry, and gravimetry. Their dielectric constant and mechanical properties were examined. The influence exerted by the structure of the amorphous phase and by the molecular weight of the polymer on the dielectric constant of the samples was revealed.

DOI: 10.1134/S1070427206040276

Polyvinylidene fluoride (PVDF) occupies a particular place among other thermoplastic polymers owing to its dielectric properties, and primarily to high dielectric constant. The interest in PVDF was due to a pronounced pyro- and piezoelectric effect observed in this polymer [1]. At the same time, understanding of the nature of the dielectric properties of PVDF is complicated by a considerable heterogeneity of its structure, polymorphism and diverse morphologier of the crystalline phase, and inhomogeneity of amorphous zones [2].

It is known that crystalline regions of PVDF show at least four polymorphic modification (α, β, γ, and α_p), which differ in the conformational structure of chains and packing of macromolecules in the unit cell of crystallites [2], with the piezoelectric properties attributed to the presence of ferroelectric crystals of β-type. It is also known that the dielectric properties of PVDF are determined to a greater extent by the structure of the amorphous phase, rather than by that of the crystalline phase, and the former cannot be regarded as a structurally uniform medium. The dielectric properties of PVDF films can be optimized by modifying the chain packing density in the amorphous phase and initiating formation of microscopic defects and discontinuities [3, 4].

Extrusion of flexible-chain polymers from a melt makes it possible to form a structure constituted by parallel folded crystals (lamellas) whose surface is oriented perpendicular to the flow direction of the melt and which are connected with one another by a certain number of tie chains. Apparently, the oriented nature of extruded PVDF films affects their dielectric characteristics. It was shown in [5] that a material with increased content of strongly anisotropic crystallites of β-type, which also contains microscopic defects in the polymer bulk, can be obtained on the basis of extruded films. It is of interest in this context to carry out a detailed study of the structure and properties of extruded films, which will make it possible not only to characterize the film as a sample for further studies, but also to relate the dielectric properties of the samples to their oriented molecular organization.

It is noteworthy that PVDF films are for the most part industrially manufactured by extrusion, whereas research is carried in the overwhelming majority of cases on samples produced by casting from a solution, compaction, or cast molding. Thus, a study of properties of extruded films will enable a comparison of experimental data for samples obtained in laboratory and industrial films.

EXPERIMENTAL

Two industrially manufactured PVDF brands with M_w 1.9×10^5 and 4.5×10^5 were used. A melt was extruded through a planar-slit die. The degree of sample orientation was varied by changing the rotation rate of the receiving calendar and was characterized by the die drawing ratio λ equal to the ratio between the cross-sectional area of the film and that of the die.

Three temperature modes with different die temperatures T_d were used in film forming.

The supramolecular structure was studied by X-ray scattering at large (DRON-2.0 X-ray diffractometer) and small (Kratki camera with a VIP-2-50-60 high-voltage source) angles with CuK_α radiation.

The dielectric constant was measured with an E7-11 device at a frequency of 1 kHz and room temperature by the contact method without deposition of electrodes onto the film.

The enthalpy of melting and degree of crystallinity were determined from curves of differential scanning calorimetry (DSC). The sample density was found gravimetrically. Mechanical properties of the films were measured on an R-5 tensile-testing machine (Ivanovo, Russia).

The dielectric constant ε' was determined for samples formed from PVDF with $M_w = 1.9 \times 10^5$ at a forming temperature of 200°C. The measurements demonstrated that the highest values are observed for samples extruded at the lowest die drawing ratio (ε' = 8.4 was achieved at λ = 6.5). At higher λ, the dielectric properties steadily decrease as the degree of film orientation increases (Fig. 1, curves *1* and *2*). To explain this fact, changes in the sample structure upon an increase in λ were analyzed. It was found that the film density is virtually independent of λ (Fig. 2, curve *1*), whereas the degree of crystallinity markedly grows as the die drawing ratio increases (Fig. 2, curve *2*). This fact suggests that the density of the amorphous regions substantially decreases as the degree of orientation increases. To verify this assumption, we calculated the density of the amorphous phase of extruded samples.

The density of a partly crystalline polymer can be represented as [6]

$$\rho = \rho_a(1 - \chi_{vol}) + \rho_c\chi_{vol}, \quad (1)$$

where χ_{vol} is the volume degree of crystallinity; ρ_c, crystal density; and ρ_a, density of the amorphous phase.

The weight degree of crystallinity χ can be written as [6]

$$\chi = \chi_{vol}(\rho_c/\rho). \quad (2)$$

It follows from Eqs. (1) and (2) that

$$\rho_a = \frac{\rho_c\rho(1 - \chi)}{\rho_c - \chi\rho}. \quad (3)$$

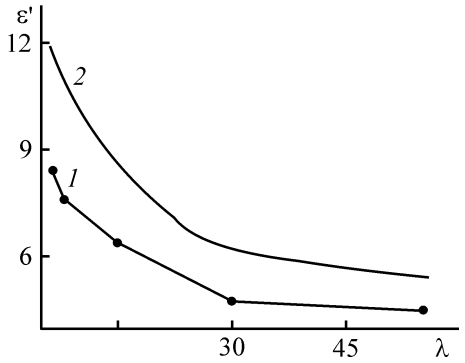

Fig. 1. (*1*) Dielectric constant ε' and (*2*) dielectric constant of the amorphous phase (calculation) of extruded PVDF films vs. the die drawing ratio λ. $M_w = 1.9 \times 10^5$, T_d = 200°C; the same for Figs. 2, 3, and 5.

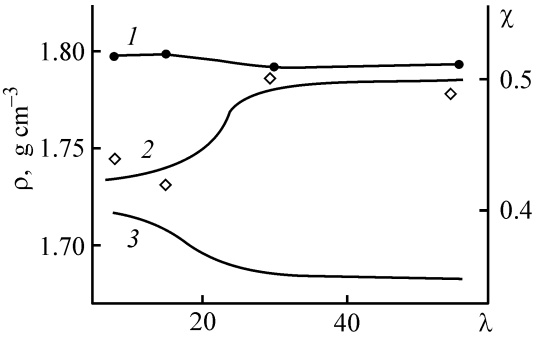

Fig. 2. (*1*) Density ρ (*2*) degree of crystallinity, χ, and (*3*) density of the amorphous phase (calculation) of extruded PVDF films vs. the die drawing ratio λ.

As shown by large-angle X-ray data, the crystalline phase of all the samples studied is completely composed of crystallites of β-modification. The density of a PVDF crystal of α-form is $\rho_c = 1.92$ g cm^{-3} [7]. The dependence of ρ_a on λ, calculated by Eq. (3) (Fig. 2, curve *3*), confirms the above assumption that the density of the amorphous region decreases as the die drawing ratio increases. This result is in agreement with the known evidence that, in contrast to orientation drawing of extruded samples, die drawing does not make larger the number of tie chains in the amorphous phase of the polymer. In addition, curve *2* in Fig. 2 shows that the potentialities of die drawing in raising the degree of crystallinity are also limited: die drawing is effective in this regard at λ < 25–30, whereas at higher die drawing ratios, the degree of crystallinity ceases to grow with λ because of the slipping of polymer chains as a result of an increase in the melt flow velocity and decrease in the influence exerted by orientation on the crystallization process. The fact that the difference in density between the crystalline and amorphous phases becomes more pronounced is also indicated by an increase

in the intensity of small-angle X-ray scattering in the films at higher λ (Fig. 3).

The structure of an extruded film can be represented as a set of crystalline lamellas connected by amorphous interlayers and arranged in parallel to one another and perpendicular to the film surface. In terms of this model, the following relation for the dielectric constant of a two-phase system is valid for an electric field directed parallel to the interface between the constituent layers [9]:

$$\varepsilon' = \varepsilon'_a(1 - \chi_{vol}) + \varepsilon'_c\chi_{vol}, \quad (4)$$

where ε'_c is the dielectric constant of the crystal, and ε'_a, that of the amorphous phase.

With account of (2), an expression for ε' can be derived:

$$\varepsilon'_a = \frac{\varepsilon'\rho_c - \varepsilon'_c\chi\rho}{\rho_c - \chi\rho}. \quad (5)$$

Because all the samples used in the experiment in question are composed of crystallites of α-type and crystallized under the same temperature conditions, ε'_c was taken to be 3 for all the films [10]. The values of ε'_a, calculated by expression (5), were found to exceed the overall macroscopic ε' for the films obtained at all values of λ (Fig. 1, curve *3*). This fact, and also similar shape of the dependences of ε'_a and ε' on λ, indicate that the structure of the amorphous phase makes an important contribution to formation of the dielectric properties of PVDF films.

As can be seen in Figs. 1 and 2, ε'_a and ρ_a decrease as the degree of orientation becomes higher. The relationship between these parameters can be revealed by analyzing the mechanism of relaxation phenomena in PVDF.

It is known [6] that macromolecules may be present in intercrystallite spaces of amorphous-crystalline polymers in different states (as strained and unstrained tie chains, regular and irregular loops, free ends), which leads to splitting of the α-transition and gives rise to an additional glass transition point [11]. It is this fact that accounts for the appearance in PVDF, in addition to the main glass transition point at –40°C, of a "second glass transition point" at 50–80°C. This temperature is attributed by many authors to the α_c-transition [12–14] and indicates that strained tie chains (STC) are present in the amorphous phase. For the samples studied, this process is observed as a thermal transition in DSC thermograms in the temperature range 40–60°C (Fig. 4).

Thus, the noncrystalline phase of the polymer is not homogeneous and contains, in addition to the truly amorphous phases composed of unstrained tie chains, loops, and chain ends, also a zone intermediate between the crystalline and amorphous phases, which contains strained tie chains and is manifested in that a higher glass transition point appears. According to [15], it is in this intermediate region that the presence of crystallites restricts the dipole mobility of macromolecules. Thus, the decrease in ε'_a with increasing λ can be attributed to an enhanced orientation of tie chains and their transition to the strained state. This leads to a decrease in the concentration of mobile polar groups in the amorphous phase, which make the largest contribution to the overall ε'.

It is noteworthy that a *trans–trans* conformation, which has a higher dipole moment than the spiral *trans–gauche* conformation characteristic of the isotropic part of the amorphous phase, may be favorable

* Melting point was the same (169°C) for all the samples.

for STC. The present study disregards the possible conformational nonuniformity of the amorphous phase. At the same time, this factor can strongly affect both the dielectric properties and the mechanical behavior of the films.

The fraction of the intermediate amorphous-crystalline interlayer is determined by such parameters of supramolecular formations as orientation, size, and perfection of the crystallites. The small-angle X-ray diffraction patterns in Fig. 3 show for all the samples a peak indicative of the existence of a large period $L \approx 12.5$ nm. It may be concluded, with account of the increase in the degree of crystallinity of the films with λ (Fig. 2), that the crystallites also grow in size. The deformation behavior of extruded PVDF films obtained at different λ (Fig. 5) also points to significant differences in their structure, and, consequently, they may also differ in the percentage content of this interlayer.

The accuracy of the DSC experiment was insufficient for evaluating the fraction of STC; however, its increase with λ can be judged from the observed change in mechanical characteristics (Fig. 6). In addition to demonstrating that the modulus of elasticity grows with the degree of orientation λ, the stress–strain curves also show an increase in the breaking strength, which is directly related to a rise in the fraction of strained, i.e., loaded chains. Noteworthy is the fact that the elongation at break very weakly increases with λ at small λ, where the degree of crystallinity χ increases and ρ_a decreases. At the same time, the elongation at break is markedly different for samples that were obtained at λ of 30 and 55 and, correspondingly, have close values of χ and ρ_a (Fig. 2). It may be assumed that the forming process at large λ leads, because of the chain slipping at a high flow velocity of the melt, to strong differences in the extent to which chains are strained in the amorphous phase. This difference in the extent of strain leads, on loading a sample, to successive transfer of strain on rupture of more strained chains to those strained to a lesser extent, which leads to an increase in the elongation at break and to weakly pronounced yield point.

The table shows that varying the forming temperature in extrusion of films does not change the degree of crystallinity; however, ε', ρ, and ρ_a of the samples decrease as the melt temperature becomes higher. In the whole range of die drawing ratios, the elastic

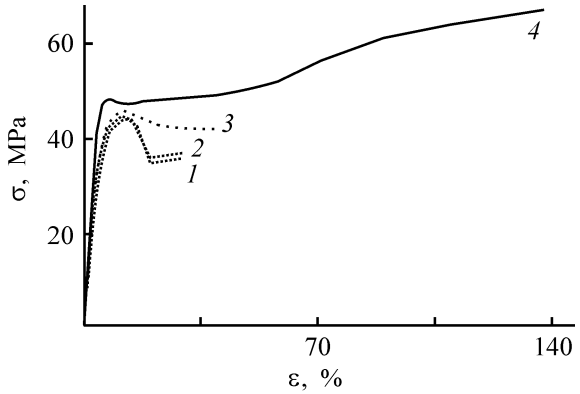

Fig. 5. Stress–strain (σ–ε) curves in the orientation direction for PVDF films extruded at die drawing ratios of (*1*) 8, (*2*) 15, (*3*) 30, and (*4*) 55.

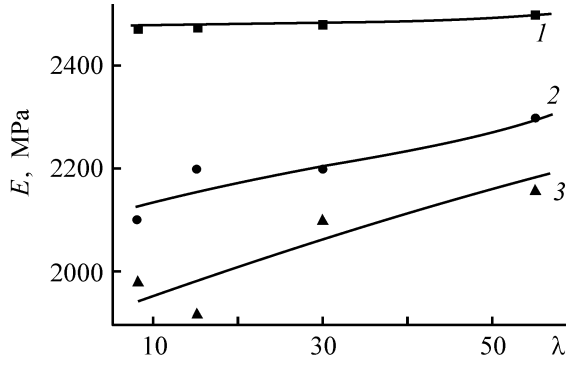

Fig. 6. Modulus of elasticity E vs. the die drawing ratio for PVDF films ($M_w = 1.9 \times 10^5$) extruded at T_d of (*1*) 220–225, (*2*) 205–210, and (*3*) 200°C.

modulus of films increases with the melt temperature (see table), which indicates that the degree of sample orientation grows. Thus, the increase in the degree of orientation with the forming temperature, which causes with a high probability a rise in the fraction of STC in the amorphous phase, impairs the dielectric properties and confirms the above conclusion about the adverse effect of orientation on ε' of extruded films.

The parameters of the crystalline phase of films with different M_w were the same; however, films with $M_w = 4.5 \times 10^5$ had a lower ε' than those prepared from a polymer with $M_w = 1.9 \times 10^5$ (see table). At the same time, samples with $M_w = 4.5 \times 10^5$ had higher values of ρ_a than films prepared from a lower-molecular-weight polymer. The densification of the amorphous phase, observed as the molecular weight increases, is a phenomenon that is typical of flexible-chain polymers and is associated with a high density of intermolecular contacts in the melt of a high-molecular-weight polymer and with hindrance to "disentangling" of its chains in the course of crystallization. The large values of ρ_a and modulus of elasticity of films with a higher M_w (see table) point to an increased content of STC in their amorphous phase. In the given case, the dense packing of tie chains may cause steric hindrance to motion of polar groups and be a reason for the decrease in ε' of the film.

Thus, our study revealed the influence exerted by forming conditions and molecular weight of the polymer on the structure and dielectric properties of extruded PVDF films. It was shown that raising the degree of orientation and densification of the amorphous phase restrict the dipole mobility of chains in amorphous interlayers and, as a result, lead to a decrease in the dielectric constant of the samples.

CONCLUSIONS

(1) The conditions of crystallization of polyvinylidene fluoride films in forming from a melt affect the density of the amorphous phase and the dielectric constant of the samples.

(2) Raising the melt temperature and the die drawing ratio leads to a decrease in the dielectric constant of extruded polyvinylidene fluoride films.

(3) The polyvinylidene fluoride films produced from a polymer with a higher M_w have a lower dielectric constant.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Structural Features and Initiating Properties of the Hexaadduct of Polystyryllithium and Fullerene C_{60} in Tetrahydrofuran and Their Role in Synthesis of Heteroarm Star-Like Polymers

Abstract—Structural transformations of the hexaadduct of polystyryllithium and fullerene C_{60} in the course of interaction with a proton donor or 1,1-diphenylethylene and at initiation of styrene polymerization were studied, and their role in the formation of heteroarm star-like polymers with C_{60} center of branching and arms of polystyrene and poly-2-vinylpyridine was elucidated.

DOI: 10.1134/S1070427206040288

Synthesis and study of star-like polymers are of particular importance because they can be used as viscosity-modifying agents, surfactants, oil additives, biologically compatible and biodegradable materials, micelle-forming agents [1, 2], nanocontainers [3], materials with nonlinear optical properties [4], liquid-crystal [5] and conducting polymers [6], highly ordered porous films [7, 8], Langmuir films [9], etc.

Among known types of star-like polymers, μ-star polymers containing arms of various chemical nature (polar–nonpolar) or block arms (nonpolar–*block*-polar) are of primary importance. Such starts exhibit the properties of "smart" polymers in solutions at formation of nanomicelles and at conversion into nanostructures [10]; on the support surface they form monolayers with changing morphology depending on the solution type [11, 12], act as nanoreactors [13] in synthesis of nanocomposite materials containing stable metal nanoparticles, and possess interesting optical and electrooptical properties [14].

These μ-star polymers can be prepared by various methods, and among them the procedures based on controlled anionic polymerizations are the most effective. Two main approaches are used: "arm first" and "core first." In the "arm first" method, "living" linear polymers (or diblock copolymers) are prepared first and are then combined using a divinyl derivative to form the core of macromolecule in the course of cross-linking and copolymerization. For example, star-like polymers with arms of diblock copolymers polystyrene (PS)–poly-2-vinylpyridine (P2VP) were prepared by this procedure [13]. In the "core first" method, a core is prepared first, which actually acts as polyfunctional initiating agent and new polymeric arms are grown on the active centers of this core. Using this procedure, the stars with arms of PS and P2VP $[(PS)_n(P2VP)_n]$ were prepared [15]. In both cases, the size of the macromolecule core formed from cross-linked diene agent is rather large, and large contribution of the core to the total molecular weight of the polymer (MW) not only hinders calculation of the number of branches, but also affects the polymer properties.

In this paper we suggested an alternative procedure for preparing heteroarm star-like polymers with alternating PS and P2VP arms and macromolecular branching center C_{60} whose small size allows us to consider it as a "point" center. Owing to combination in the star-like macromolecule of hydrophobic PS arms and pH-sensitive P2VP arms, these polymers should be able to form micelles and supramolecular aggregates in solutions, whose structure can be rearranged under the effect of external factors such as acidity and special additives, and to exhibit properties

of "smart" polymers. The "point" branching center does not hinder penetration of various agents to the "point" center, which suggests that these polymers can be used as nanocontainers and nanoreactors. Moreover, the star-like polymers allow preparation of nanocomposites and highly porous films.

In this paper we also analyzed the data on the properties of hexaadduct of polystyryllithium and fullerene C_{60} [$(PS)_6C_{60}Li_6$] as the initiating agent of polymerization of 2-vinylpyridine (2VP) and styrene in THF and studied structural changes in the hexaadduct in the course of its conversion into polyfunctional initiating agent.

EXPERIMENTAL

Materials. Tetrahydrofuran, benzene, toluene, and 1,1-diphenylethylene (DPE) (Aldrich) were purified in accordance with requirements to highly sensitive anionic systems [16]. Powdered lithium chloride was calcined in a vacuum (10^{-6} mm Hg). Fullerene (C_{60} content >99%) purchased from the Fullerenovye Tekhnologii Limited Liability Company was pretreated by the known method [17].

Monomers. Styrene was purified by the procedure given in [18] using prepolymerization in benzene in the presence of oligostyryllithium (OSL). 2-Vinylpyridine (Fluka) was treated with Al_2O_3 to remove the stabilizing agent and sublimed in a vacuum from CaH_2; 2VP was used as solution in THF. Traces of moisture were removed from the vacuum system with calcined CaH_2.

Polymerization and synthesis of polymers. The polymerization was performed in a special high-vacuum (10^{-6} mm Hg) all-soldered glass apparatus with break seals.

Oligostyryllithium (OSL) with an average degree of polymerization of 4 was prepared by the reaction of *sec*-butyllithium with styrene in benzene, and polystyryllithium (PSL) was obtained at room temperature in the presence of OSL [18].

The model adducts $(PS)_nC_{60}Li_n$ with the PSL : C_{60} ratio of 6.2 : 1, 5 : 1, and 4 : 1 were prepared in a benzene–toluene mixture at room temperature; the reaction time was 1 h.

The heteroarm polymers $(PS)_nC_{60}(P2VP)_n$ were synthesized in several steps. First, $(PS)_nC_{60}Li_n$ was prepared from PSL and C_{60} (at given reactant ratio) at room temperature in a benzene–toluene mixture. The solution samples were taken and deactivated. Then, the reaction of the adducts with DPE was carried out in the presence of LiCl (C_{60}–Li : DPE : LiCl = 1 : 2 : 2); THF was added to the reaction mixture by condensation in a vacuum. The mixture was kept at –30°C for 15 min and cooled to –78°C, and then 2VP was added. The mixture was polymerized for 1 h.

Polymerization of styrene in the presence of hexaadduct $(PS)_6C_{60}Li_6$ was carried out in the mixed solvent (50% THF) at –40°C [19].

The reaction mixtures were deactivated using a solution of butanol in toluene (1 : 3) without admitting air. The heteroarm polymers were precipitated from the reaction mixture with hexane; the styrene polymers were precipitated with methanol and dried in a vacuum.

The exclusion chromatography of polymers was performed on a chromatograph (Waters, the United States) equipped with 994 UV and 410 RI detectors at 30°C using the columns packed with linear Styrogel and Styrogels 10^4 and 10^3 Å; the eluent was chloroform containing 0.1% Et_3N. The chromatograph was calibrated with linear P2VP and PS references.

Hexaadduct of polystyryllithium and fullerene C_{60} [$(PS)_6C_{60}Li_6$] is a product of addition of maximally possible number of chains of the "living" polystyrene to a single C_{60} molecule [20–22]. The reaction of PSL and C_{60} (6 : 1 reactant ratio) yields a homogeneous product with a highly symmetrical regular structure. One fullerene center is linked with six PS arms of given molecular weight (from several to hundred thousands monomer units) [21] and six C_{60}–Li centers. In the active state, $(PS)_6C_{60}Li_6$ is a hexafunctional organolithium compound exhibiting various initiating properties in polymerization of vinyl monomers [19, 23, 24]. In polymerization of styrene in nonpolar solvents, only one C_{60}–Li center acts as initiating agent. As a result, only one additional (seventh) PS arm is grown on the six-arm molecule [19, 24]. In polar solvents (THF), styrene polymerization proceeds through the radical-anion mechanism by electron transfer from the hexaadduct to the monomer molecule [19]. Thus, in polymerization of nonpolar monomers, the hexaadduct does not behave as polyfunctional initiating agent.

The conditions of involving two active centers of $(PS)_6C_{60}Li_6$ in polymerization of methyl methacrylate (MMA) were found in [23], and the resulting hybrid macromolecule was described as $(PS)_6C_{60}(MMA)_2$. Hexaadduct $(PS)_6C_{60}Li_6$ was also used to initiate polymerization of *tert*-butyl methacrylate (TBMA) in THF after its preliminarily reaction with DPE [25]; the resulting data suggested formation of $(PS)_6C_{60}(PTBMA)_6$ macromolecule.

Statistical distribution of the products of PSL addition to fullerene C_{60}. Some disadvantages complicate the use of $(PS)_6C_{60}Li_6$ as initiating agent. Since attainment of precise PSL : C_{60} ratio of 6 : 1 is virtually impossible, the reaction mixture can contain free PSL, which can also initiate polymerization of vinyl monomers. Therefore, in our experiments the reactant ratio was taken maximally close to 6 : 1 or slightly lower; however, in this case (excess C_{60}) the question on the contribution of the other structures (penta-, tetra-, tri-, etc.) arises.

Amsharov [26] suggested the scheme of statistical distribution of the products of PSL reaction with fullerene C_{60} to form adducts with addition number from 1 to 6 at equal probability of all the addition events. In accordance with this scheme, at the PSL : C_{60} ratio varied within 5–6, the reaction should yield the star-like products with the number of arms n = 3–6. At PSL : $C_{60} \le 4$, the reaction product can contain up to 10% mono- and diadducts. To check this experimental approach, we performed a comparative chromatographic analysis of the model adducts of PSL with fullerene prepared at PSL : C_{60} ratios of 6.2 : 1, 5 : 1, and 4 : 1. Polystyrene (M_n 2.24×10^3, M_w/M_n 1.07) was used as PSL precursor. The PSL excess at the first ratio should provide formation of the hexaadduct only. In accordance with star-like regular structure, polymers with the number of arms from 3 to 6 (n = 3–6) should have similar hydrodynamic size. This is chromatographically confirmed by close "peak" molecular weights of the resulting adducts (M_p 10.01×10^3, 9.34×10^3, and 8.92×10^3) and narrow molecular-weight distribution M_w/M_n (1.19,[1] 1.12, and 1.16) (Fig. 1, refractometric detection) and 1.09, 1.11, and 1.16 (photometric detection at λ 330 nm, selective to fullerene-containing compounds), respectively. The contents of the adducts with various n prepared at PSL : C_{60} ratios of 6 : 1, 5 : 1, and 4 : 1, calculated in accordance with [26], are listed in Table 1. At a PSL : C_{60} ratio of 6 : 1, the reaction product contains the hexaadduct only, with an insignificant PLS impurity. At a PSL : C_{60} ratio of 5 : 1, various star-like structure are formed in the reaction mixture, and the content of the hexaadduct is only 30%. These results agree with the experimental data (Fig. 1, curves *2–4*). As seen, the peaks of adducts are narrow and symmetrical. At a PSL : C_{60} ratio of 4 : 1, the chromatographic peak becomes slightly broader (Fig. 1, curve *4*), which is probably due to the presence of mono- and diadducts (Table 1).

[1] Taking into account PSL precursor.

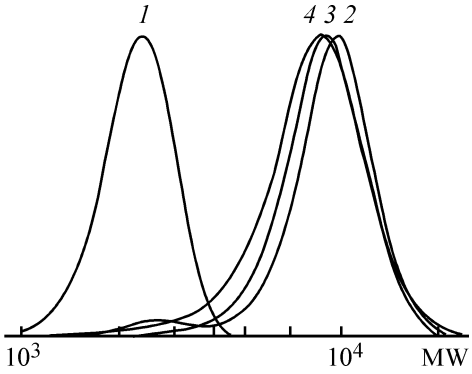

Fig. 1. Chromatographic curves (*1*) PS precursor; model adducts $(PS)_nC_{60}H_n$ at PSL : C_{60} ratio (*2*) 6.2 : 1, (*3*) 5 : 1, and (*4*) 4 : 1. (MW) Molecular weight, the same for Figs. 2–4.

Thus, using this statistical approach, we can determine the fractions of adducts with different number of arms formed in synthesis of star-like organolithium initiating agents based on polystyrene derivatives of fullerene.

Features of 2VP polymerization initiated by hexaadduct modified with DPE in the presence of THF. Heteroarm polymers $(PS)_nC_{60}(P2VP)_n$ with arms of PS and P2VP were prepared by polymerization of polar monomer (2VP) and adduct $(PS)_nC_{60}Li_n$ preliminarily modified with DPE in mixed solvent containing about 50% THF. The adducts were synthesized from PSL precursor with the following characteristics: M_n 6.35×10^3 and M_w/M_n 1.06 (Fig. 2, curve *1*). The chromatographic data[2] on the precursor adducts and heteroarm polymers are listed in Table 2. As seen, when synthesis is performed at PSL : C_{60} ratios of 6.2 : 1 and 6.0 : 1, the reaction mixture, along with the main fullerene-containing product ($M_p \approx 39 \times 10^3$), contains the fraction ($M_p \approx 20 \times 10^3$) containing no fullerene (photometric data, λ 330 nm) (Fig. 2, curves *3*, *4*).

Table 1. Statistical distribution of adducts $(PS)_nC_{60}H_n$ with various n

PSL : C_{60} ratio	Content of $(PS)_nC_{60}H_n$ adduct, %					
	hexa-	penta-	tetra-	tri-	di-	mono-
6 : 1	100	–	–	–	–	–
5 : 1	30	40	20	8	2	–
4 : 1	9	25	34	22	9	1

[2] Chromatographic values of M_p can be considered only as qualitative characteristics of star-like polymers.

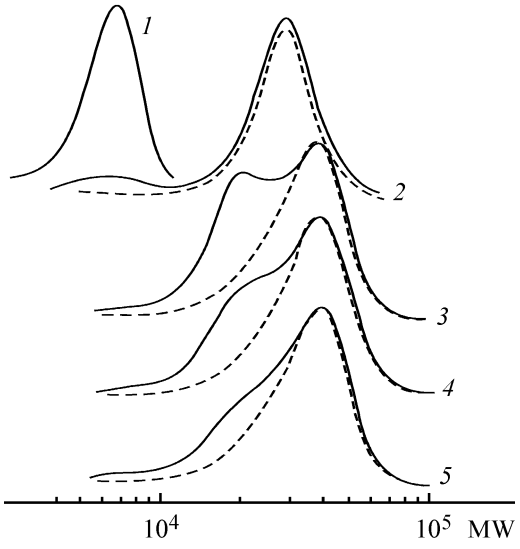

Fig. 2. GPC curves: (*1*) PS precursor, (*2*) $(PS)_nC_{60}Li_n$ macroinitiating agent; heteroarm polymers $(PS)_nC_{60}(P2VP)_n$ prepared in the presence of macroinitiating agents at PSL : C_{60} ratio of (*3*) 6.2 : 1, (*4*) 6.0 : 1, and (*5*) 5.0 : 1. *Solid curves*, refractometric detection; *dashed curves*, UV detection, λ 330 nm; the same for Fig. 3, 4.

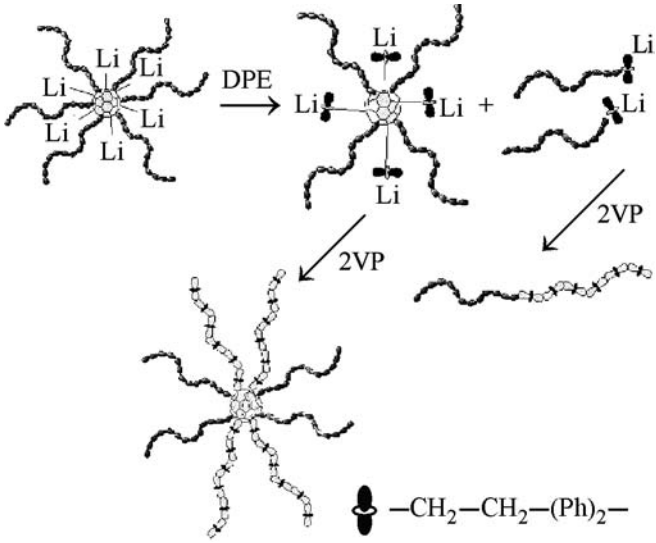
Since the hexaadduct macroinitiating agent $(PS)_nC_{60}(P2VP)_n$ was first prepared with a slight excess of PSL (PSL : C_{60} ratio 6.2 : 1), the experimental results can be interpreted assuming simultaneous participation of two initiating agents (namely, hexaadduct and "free" PSL) in 2VP polymerization. The star-like hybrid polymer $(PS)_nC_{60}(P2VP)_n$ could be formed with the hexaadduct initiator, whereas "free" PSL provided formation of the linear diblock copolymer.



When the synthesis was performed at a PSL : C_{60} ratio of 6.0 : 1, the reaction mixture also involved the fullerene-free fraction, but in smaller amounts (Fig. 2, curve *4*). In this case, formation of this fraction can also be caused by excess PSL due to the possible error in reagent weighing. However, this conclusion contradicts the molecular weight of the resulting fraction ($M_p \approx 20 \times 10^3$) (Fig. 2, curve *4*), because the polymer with this molecular weight can be prepared only at a concentration of "free" PSL significantly higher than the experimental measurement error.

Table 2. Molecular properties of adducts $(PS)_nC_{60}H_n$ and heteroarm polymers $(PS)_nC_{60}(P2VP)_n$ [photometric detection (λ 330 nm)]

PSL : C_{60} ratio	Chromatographic characteristics			
	adduct $(PS)_nC_{60}H_n$		hybrid polymer	
	$M_p \times 10^{-3}$	M_w/M_n	$M_p \times 10^{-3}$	M_w/M_n
6.2 : 1	30.0	1.17	38.6	1.18
6.0 : 1	30.1	1.12	39.8	1.17
5.0 : 1	28.7	1.13	39.1	1.17

To find a more convincing explanation of our experimental results, we synthesized a hybrid polymer using $(PS)_nC_{60}Li_n$ macroinitiating agent prepared at PSL : C_{60} ratio of 5.0 : 1, because in this case no "free" PSL should remain in the reaction mixture. Although the narrow peak of the precursor adduct in the chromatographic pattern is similar to those registered at PSL : C_{60} ratios of 6.2 : 1 and 6.0 : 1 (Table 2), the reaction mixture prepared at a PSL : C_{60} ratio of 5.0 : 1 also contained the fullerene-free fraction (Fig. 2, curve *5*).

To explain this phenomenon, we put forward the following hypothesis. The hexaadduct prepared in nonpolar solvents undergoes certain transformations at addition of polar solvents. Lithium counterions are solvated by THF. The adduct structure with six nonsolvated anionic centers at the fullerene core become labile. In the reaction with DPE, the PSL arms are eliminated from the fullerene core; as a result, we obtained the tetraadduct and two PSL chains. In accordance with published data [20], the tetraadduct is stable in polar solvents. Hence, two types of initiating agents can be present simultaneously in the reaction system, namely, tetraadduct with four active centers and linear polystyryllithium. Thus, in the course of synthesis 2VP can polymerize on these initiating agents yielding either hybrid star-like polymer or diblock copolymer:

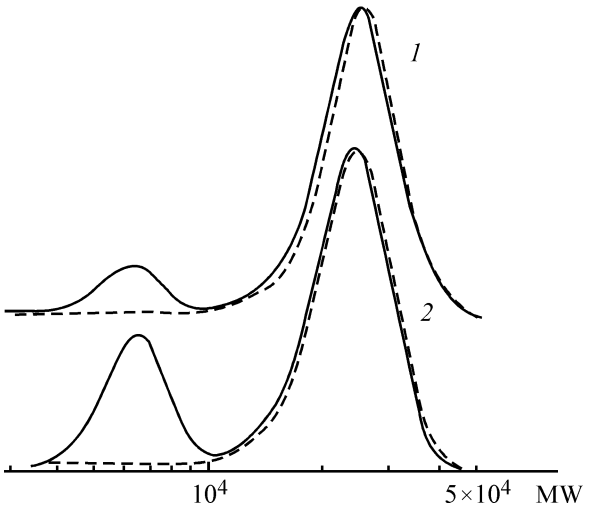
Elimination of PSL chains from hexaadduct $(PS)_6C_{60}Li_6$ in the presence of DPE or proton-donor agent in polar medium. To check the above hypothesis, we prepared the hexaadduct at PSL : C_{60} ratio of 6.1 : 1 in a nonpolar solvent (benzene–toluene). We too excess PSL, because it provides formation of the hexaadduct only, and, moreover, the PS precursor is a reliable chromatographic reference. After synthesis, one portion of the reaction mixture was sampled and deactivated with alcohol. The remainder was mixed with THF (up to 50% by volume), and DPE was added to the reaction mixture. The reaction of the hexaadduct with DPE was carried out at –30°C for 1 h, after which the mixture was deactivated in a vacuum.

After deactivation of the hexaadduct in the benzene–toluene mixture, the typical chromatographic pattern was observed (Fig. 3, curve *1*); it contained two peaks (hexaadduct and precursor polymer) with the height ratio h_1 (hexaadduct)/h_2 (PS precursor) of 6.6. After the reaction of the hexaadduct with DPE in THF and subsequent deactivation, the content of "free" PS sharply increased (Fig. 3, curve *2*); h_1/h_2 2.3.

These data confirm the elimination of PSL arms, but cannot explain whether elimination proceeds in reaction with DPE or by solvation with polar THF. To solve this problem, we carried out the following experiment. A solution of the hexaadduct in nonpolar solvent was mixed with THF (50%) and the mixture was deactivated with alcohol in a vacuum. The chromatographic pattern recorded after deactivation was similar to that recorded after the reaction of the hexaadduct with DPE and subsequent deactivation. The resulting peak ratio h_1/h_2 was 2.4.

At first glance, this result suggests that reorganization of the hexaadduct and cleavage of the PS chains are predominantly induced by the polar solvent (THF), whereas the effect of DPE is secondary. It only reacts with the active centers of both tetraadduct and linear PSL. However, this conclusion contradicts the radical-anion mechanism of styrene polymerization initiated with hexaadduct in the presence of THF [19]. If THF provides elimination of the PSL arm, then styrene polymerization should proceed under the effect of this "free" radical and not by the radical-anion mechanism as given in [19].

Structural changes in the hexaadduct $(PS)_6C_{60}Li_6$ in the course of styrene polymerization in the presence of THF. The experiment on polymerization of styrene in the presence of THF using $(PS)_6C_{60}Li_6$ initiating agent was carried out with the PSL precursor (M_n 4.2×10^3 and M_w/M_n 1.06).



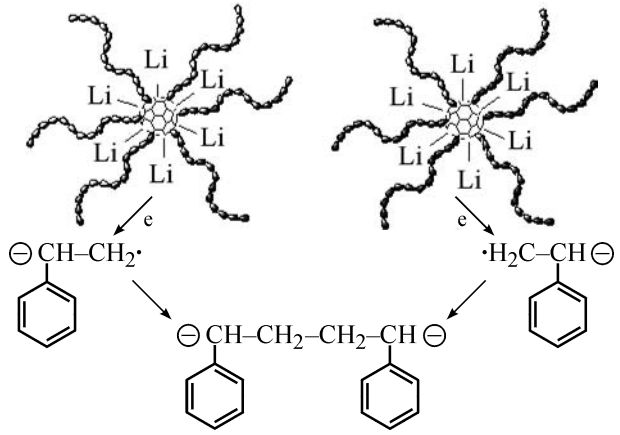


Fig. 3. GPC curves: (*1*) hexaadduct $(PS)_6C_{60}Li_6$ prepared in benzene–toluene mixture at PSL : C_{60} ratio of 6.1 : 1 and deactivated in nonpolar medium and (*2*) after reaction with DPE in THF and subsequent deactivation.

As seen from the experimental data, the reaction mixture contained the fullerene-free fraction and its molecular weight (M_p 40.6×10^3) was higher than the theoretical molecular weight per C_{60} core (M_{theor} 21.0×10^3) by a factor of approximately 2. If only one PS chain were eliminated from each hexaadduct molecule, the molecular weight of the resulting linear polystyrene would be close to the theoretical value, and if two chains were eliminated, it would be smaller than the theoretical value by a factor of 2. The experimental peak molecular weight (M_p 40.6×10^3) only suggests the radical-anion mechanism of polymerization. Each hexaadduct transmits one electron to the monomer (styrene) molecule to form radical anions, which then recombine into dianions. Styrene polymerizes under the action of the resulting bifunctional initiating agent:

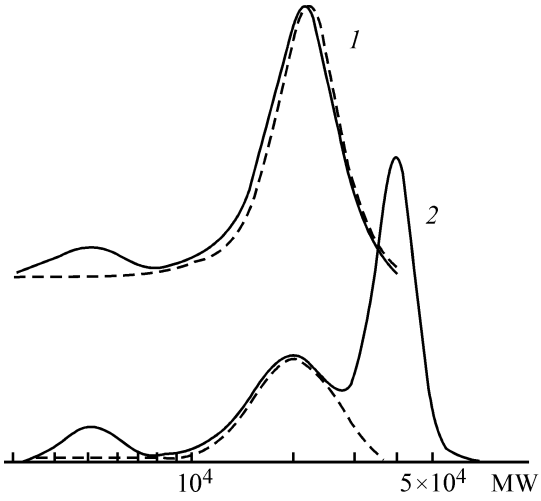

Fig. 4. GPC curves: (*1*) hexaadduct $(PS)_6C_{60}Li_6$ prepared in benzene–toluene mixture and (*2*) product of styrene polymerization in the presence of THF.

The only question concerns subsequent transformations of the hexaadduct after the loss of one electron, if styrene polymerization proceeds by the radical-anion mechanism. As seen, the chromatographic pattern of the hexaadduct precursor prepared and deactivated in the nonpolar medium contains two peaks, namely, hexaadduct and PS precursor (Fig. 4, curve *1*); the h_1/h_2 ratio is 8.9. The chromatographic pattern of the product of styrene polymerization shows three peaks corresponding to PS precursor, fullerene-containing product, and macromolecular fraction containing no fullerene (photometric data). After polymerization, the peak of the fullerene-containing product remained almost constant, whereas the ratio of the adduct and "free" PS sharply changed, h_1/h_2 = 3.1. This fact is attributable to elimination of PSL chains from the hexaadduct on treatment with a proton-donor agent (alcohol, water) in the stage of deactivation of the reaction mixture.

Hence, THF only promotes weakening of C_{60}–Li bonds due to solvation of counterions and destabilization of the hexaadduct structure. Additional agent (in the latter case, proton donor) causes elimination of the PSL bonds from the hexaadduct converting them into the tetraadduct. These results confirm not only the radical-anion initiation of styrene polymerization in the polar medium, but also elimination of PSL arms from the hexaadduct under the effect of the additional agent.

Synthesis of heteroarm polymers after modification of hexaadduct in nonpolar medium. To confirm the solvent effect on the reaction of the hexaadduct with DPE, we performed synthesis of polymers $(PS)_nC_{60}(P2VP)_n$ under various experimental conditions. The synthesis was performed at a PSL : C_{60} ratio of 6 : 1; the time of reaction of the hexaadduct $(PS^-)_6C_{60}(Li^+)_6$ with DPE in the nonpolar medium was increased to 1 h and reaction temperature was increased to –10°C, after which THF was added; the PSL precursor with $M_n \approx 6.91 \times 10^3$ and M_w/M_n 1.05 was used. The chromatographic data showed that the fraction of diblock copolymer ($M_p \approx 16 \times 10^3$) strongly decreased in comparison with the previous experiment (Fig. 1, curve *4*). Hence, the conditions of hexaadduct modification strongly affect the reaction of DPE with active C_{60}–Li groups. The reaction with DPE in nonpolar medium probably proceeds slowly and is far from completion by the time of adding THF. As a result, hexaadduct $(PS)_6C_{60}Li_6$ retains some amount of unmodified centers able to eliminate PS arms under the effect of DPE. In reaction in the nonpolar medium, the effect of elimination processes strongly decreases, which allows us to optimize the conditions of the synthesis of the heteroarm polymer $(PS)_nC_{60}(P2VP)_n$ with the structure close to desired one (n = 6).

CONCLUSIONS

(1) Heteroarm star-like polymers with "point" C_{60} center of branching and arms of polystyrene and poly-2-vinylpyridine were prepared from polyfunctional initiating agent, hexaadduct $(PS)_6C_{60}Li_6$ modified with 1,1-diphenylethylene.

(2) The dependences of the structure and initiating properties of the hexaadduct on polarity and nature of the modifying agent were elucidated. A proton donor or 1,1-diphenylethylene in THF causes elimination of up to two PSL chains from the hexaadduct, which affects the composition of the initiating system and structure of the products of synthesis of heteroarm polymers.

(3) The experimental data confirm the radical-anion mechanism of initiation of styrene polymerization in THF in the presence of $(PS)_6C_{60}Li_6$.

(4) The reaction of $(PS)_6C_{60}Li_6$ with 1,1-diphenylethylene in nonpolar medium causes more complete conversion of the active groups of the hexaadduct into the initiating groups, which promotes formation of hybrid macromolecules with a required structure.

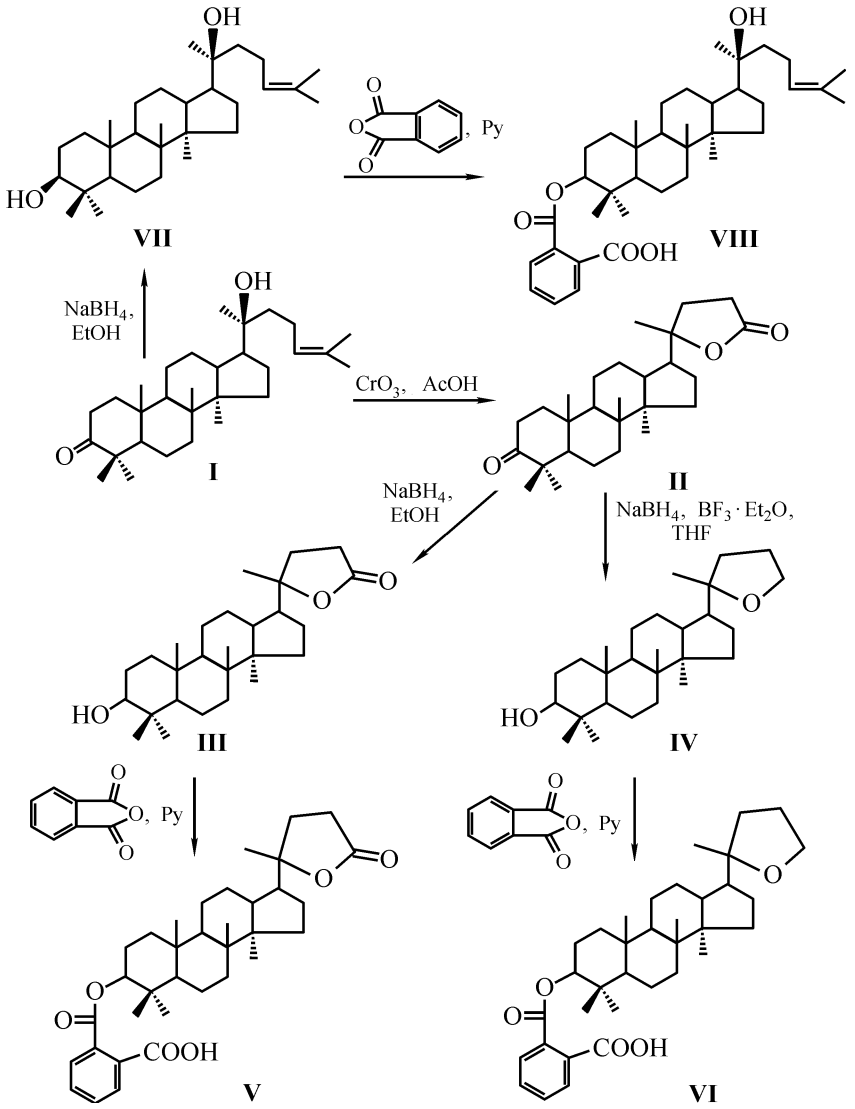
Abstract—Polymeric derivatives of dammarane triterpenoids with both labile and strong (covalent) polymer–triterpenoid bonds were prepared from *N*-vinylpyrrolidone copolymers.

DOI: 10.1134/S107042720604029X

Treatment of virus diseases requires development of effective nontoxic antiviral preparations. Synthesis of polymeric derivatives of low-molecular-weight biologically active substances (BASs) opens prospects for development of improved medicinals of reduced toxicity, enhanced efficiency, and prolonged effect.

Polymers based on *N*-vinylpyrrolidone (VP) are among the most widely used polymeric carriers [1, 2]. VP copolymers containing amino groups show promise as BAS carriers. Alkylation with various alkyl halides of VP copolymers with primary and tertiary amines allows preparation of polymers containing, along with the ionic ammonium group, alkyl substituents providing hydrophobic interaction in aqueous solutions [3]. Preparation of water-soluble derivatives (salts) of polyene antibiotics Levorin and Nystatin on the basis of such copolymers was reported in [4].

Previous studies revealed more pronounced antiviral properties of polymeric derivatives of certain triterpene acids compared to the nonmodified acids [5].



The goal of this study was to develop procedures for preparing from VP copolymers polymeric derivatives of triterpenoids of the dammarane series differing in the type and lability of the polymer–triterpenoid bond.

Among dammarane triterpenoids, the highest antiviral activity is exhibited by alnincanone, 24-methyl-20*S*,24*R*-epoxydammaran-3-one [6]; however, its content in plant sources is insufficient for more comprehensive biological studies. As a model compound we chose 20(*S*)-hydroxydammar-24-en-3-one (dipterocarpol) **I**. It can be prepared in amounts required for the studies from *Dipterocarpus alatus* latex [7].

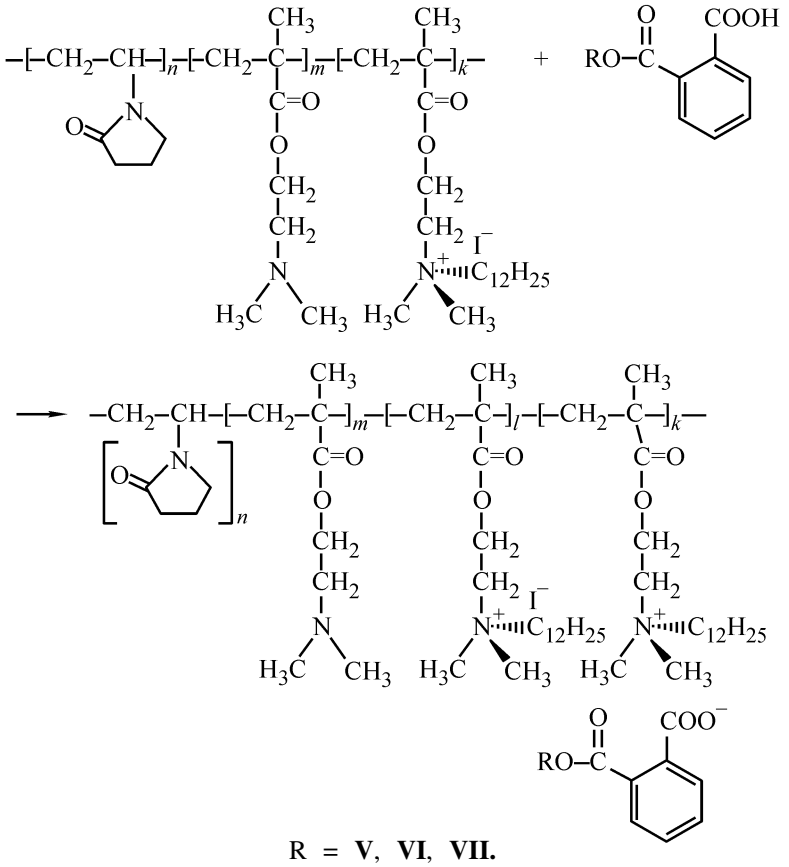
We prepared dammarane derivatives containing at C-17 an open chain (**VII**), a γ-lactone ring (**III**), and a tetrahydrofuran ring (**IV**). Diol **VII** was prepared by reduction of dipterocarpol with sodium borohydride in ethanol. To prepare compounds **III** and **IV**, dipterocarpol was oxidized with chromic anhydride in acetic acid to lactone **II**. Reduction of **II** with sodium borohydride in ethanol yielded hydroxy lactone **III**, and reduction with sodium borohydride in the presence of $BF_3 \cdot OEt_2$ in THF yielded epoxydammaranol **IV**. From compounds **III**, **IV**, and **VII** (Scheme 1) containing the 3β-hydroxy group, we prepared by refluxing with phthalic anhydride phthalic acid monoesters **V**, **VI**, and **VIII**, respectively (Scheme 1). Through the free carboxy group, these compounds were bonded to an amino group of the polymer.

To prepare polymeric derivatives of triterpenoids of the dammarane series with a labile BAS–polymer bond (BAPs), we used a copolymer of VP with dimethylaminoethyl methacrylate (DMAEM) and with its derivative quaternized with dodecyl iodide ($DMAEM \cdot C_{12}H_{25}I$) [8]. Polymeric salts of phthalic acid monoesters were prepared by Scheme 2.

As solvent we used methanol in which all the reactants (triterpenoid hydrogen phthalates and the polymer) and products (polymeric salts) are soluble. After the synthesis completion, methanol was gradually replaced by water [4]. As a result, we obtained polymeric derivatives which, in contrast to the starting

Scheme 1.

triterpenoid hydrogen phthalates, are soluble in water. The UV spectra of all the derivatives contain absorption bands of the corresponding triterpenoid hydrogen phthalates **V**, **VI**, and **VIII** (λ_{max} = 274 nm), which allowed determination of the BAS content in the polymeric products. The results are given in Table 1.



It is known that polyvinylpyrrolidone (PVP) forms complexes with many substances [1, 2]. We attempted to prepare PVP derivatives of triterpenoid hydrogen phthalates by the procedure similar to that used for preparing salts of VP–DMAEM–DMAEM · $C_{12}H_{25}I$ copolymer. We failed to obtain water-soluble products. Addition of water to a solution of the reactants in methanol resulted in precipitation of triterpenoid hydrogen phthalates. This fact confirms that, to obtain a water-soluble product, the starting copolymer should contain ionic groups.

The products were separated by gel permeation chromatography (GPC) on a column packed with Sephadex LH-20 gel (eluent ethanol). The absorption of the fractions taken was measured at 274 nm (the starting polymer is virtually transparent in this range). The chromatograms of all the polymeric salts obtained

Scheme 3.

exhibit peak I in the same region as for the unmodified BAS (Fig. 1). There is also a weak peak II in the region of small retention volumes corresponding to polymer-containing fractions (for comparison, we show a chromatogram of a copolymer of VP with *N*-hydroxyphthalimide ester of acrylic acid). The UV spectra of fractions I and II are similar to the spectra of the low-molecular-weight BAS and starting polymer, respectively.

To prepare polymeric derivatives of hydrogen phthalates **V**, **VI**, and **VIII** in which the BAS is linked to the polymer by a strong covalent bond, we used a copolymer of VP with allylamine (AlAm) [9].

The reactions of triterpene hydrogen phthalates with this copolymer were performed in CH_2Cl_2 in the presence of *N,N'*-dicyclohexylcarbodiimide (DCC), as shown in Scheme 3.

The reaction should yield derivatives in which BAS is linked to the polymeric carrier by an amide bond. The characteristics of the reaction products are given in Table 2. Their composition, similarly to the polymeric salts, was determined by UV spectroscopy, as the absorption band at λ_{max} = 274 nm was observed in the spectra of all the products. As seen from Table 2, in all the cases, as in the case of the polymeric salts, the derivatives containing ≤12 wt % triterpenoid hydrogen phthalate are water-soluble (run nos. 5–7). At a high BAS content, as in the case of betulinic and betulonic acid derivatives [5], the solubility in water is lost (run no. 4).

The chromatograms of covalent derivatives of triterpenoid hydrogen phthalates (Fig. 2) differ from those of polymeric salts (Fig. 1). As seen from Fig. 2, for the covalent derivatives, with the same gel (LH-20) and eluent (ethanol), peak I is weak, and peak II, on the contrary, strong. The UV spectra of the fractions corresponding to peak II, as those of the initial BASs, contain a band with λ_{max} = 274 nm. Similar chromatograms are obtained with Sephadex G-75 gel and water as eluent. This fact confirms that, in contrast to the derivatives obtained in run nos. 1–3, in the products from run nos. 4–7 the BAS is strongly bound to the polymeric carrier, because its chromatographic behavior is similar to that of the carrier.

EXPERIMENTAL

20(*S*)-Hydroxydammar-24-en-3-one I. Dipterocarpol **I** was eluted with hexane–ethyl acetate (15 : 1) in the course of chromatographic separation (silica gel, 5/40 μm) of an ethyl acetate solution of *Dipterocarpus alatus* latex; mp 133–135°C [7]. IR spectrum, cm^{-1}: 3480, 1690. Yield 67%.

25,26,27-Trinordammaran-3-on-20(*S*),24-olide II. Dipterocarpol **I** (10 g) was dissolved in 50 ml of benzene and 30 ml of acetic acid; 4 g of CrO_3 and 3 ml of H_2O were added, The mixture was cooled with ice and allowed to stand for 12 h at room temperature, after which it was diluted with water. The precipitate was filtered off and washed with water, 5% sodium carbonate solution, and again water to neutral reaction. The dry precipitate was chromatographed on a column packed with silica gel.

Fractions containing dipterocarpol lactone **II** were combined, and the solvent was evaporated. The residue was crystallized from ethyl acetate. Yield of dipterocarpol lactone **II** (25,26,27-trinordammaran-3-on-20(*S*),24-olide) 7.9 g, mp 180–182°C (published data [7]: mp 184–186°C). IR spectrum, cm^{-1}: 1765 (C=O in γ-lactone), 1695 (C=O).

25,26,27-Trinordammaran-3β-ol-20(*S*),24-olide III. Dipterocarpol lactone **II** (2 g) was refluxed with 250 mg of $NaBH_4$ in 85 ml of isopropyl alcohol for 24 h, after which the solution was diluted with water and acidified to pH < 2. The precipitate was filtered off, washed with water, dried, and recrystallized from ethyl acetate. Yield of reduced lactone **III** 1.5 g

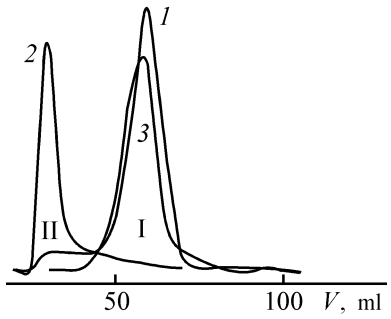

Fig. 1. Chromatograms (LH-20, eluent ethanol): (*1*) dammar-24-ene-3β,20(*S*)-diol hydrogen phthalate **VIII**, (*2*) copolymer of VP with *N*-hydroxyphthalimide ester of acrylic acid, and (*3*) polymeric salt of dammar-24-ene-3β,20(*S*)-diol hydrogen phthalate **VIII** and VP–DMAEM–DMAEM · $C_{12}H_{25}I$ copolymer (run no. 1).

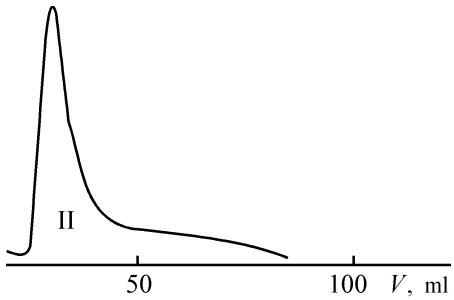

Fig. 2. Chromatogram (LH-20, eluent ethanol) of the derivative of dammar-24-ene-20(*S*),3β-diol hydrogen phthalate **VIII** and VP–AlAm copolymer (run no. 5).

(75%), mp 199–201°C (published data [7]: mp 203–204°C). IR spectrum, cm^{-1}: 3450 (OH), 1765 (C=O in γ-lactone).

Dammar-24-ene-20(*S*),3β-diol VII. Dipterocarpol **I** [20(*S*)-hydroxydammar-24-en-3-one] was reduced with $NaBH_4$ under the same conditions as compound **II**. Diol **VII** was obtained in 40% yield; mp 132–134°C (published data [10]: mp 131–133°C). ^{13}C NMR spectrum, δ, ppm: 78.4 (C-3β–OH).

25,26,27-Trinor-20(*S*),24-epoxydammaran-3β-ol IV. A solution of 5 g of dipterocarpol lactone **II** in 100 ml of THF and 10 ml of $BF_3 \cdot OEt_2$ were added over a period of 3 h at –15°C to 1.28 g of sodium borohydride in 50 ml of THF. The mixture was allowed to stand for 2 h at –15°C, after which it was refluxed on a water bath for 5 h. Then the mixture was cooled, diluted with a fivefold volume of water, and acidified with 2 N HCl to pH < 2. The precipitate was filtered off, washed with water, and dried. The residue (4.7 g) was chromatographed on a column packed with 150 g of silica gel (70/230 μm). Elution with hexane–5% ethyl acetate gave 2.9 g (65%) of **IV**, mp 182–183°C (published data [7]: mp 180–182°C). IR spectrum, cm^{-1}: 3450 (OH stretching vibrations) [7]. ^1H NMR spectrum, δ, ppm: CH_3 (0.79 s, 0.89 s, 1.05 s, 0.9 s, 0.69 s, 0.79 s); 3.09 t; 3.6 m.

Hydrogen phthalates of compounds **III**, **IV**, and **VII**. Hydroxy derivative **III**, **IV**, or **VII** (0.01 mol) and phthalic anhydride (0.02 mol) were refluxed in pyridine for 48 h, after which the mixture was diluted with a fourfold volume of water and acidified with 10% HCl to pH < 2. The white precipitate was filtered off, washed with water to neutral reaction, and dried; the residue was recrystallized from petroleum ether–ethyl acetate.

Dammar-24-ene-20(*S*),3β-diol hydrogen phthalate VIII: mp 208–210°C. ^1H NMR spectrum, δ, ppm: 4.8 (α-H at C-3) and 7.5–7.9 (4H).

25,26,27-Trinor-20(*S*),24-epoxydammaran-3β-ol hydrogen phthalate VI: mp 219–221°C. ^1H NMR spectrum, δ, ppm: 4.75 (α-H at C-3) and 7.6–7.9 (4H).

25,26,27-Trinordammaran-3β-ol-20(*S*),24-olide V: mp 258–260°C. ^1H NMR spectrum, δ, ppm: 4.75 (α-H at C-3) and 7.6–7.9 (4H).

Synthesis of polymeric derivatives of triterpenoids. Polymeric salts of triterpenoids were prepared from the VP (87.8 mol %)–DMAEM (9.2 mol %)–DMAEM · $C_{12}H_{25}I$ (3.0 mol %) copolymer, [η] at 25°C in 0.1 M CH_3COONa 0.13 dl g^{-1}, molecular weight M_η = 21 000, by the following procedures.

Example 1. VP–DMAEM–DMAEM · $C_{12}H_{25}I$ copolymer (0.35 g) was dissolved in 30 ml of methanol, and 0.044 g of dammar-24-ene-3β,20(*S*)-diol hydrogen phthalate **VIII** was added. The mixture was stirred for 24 h at room temperature. The polymeric salt was isolated by gradual replacement of methanol as solvent by water (stepwise addition of water with distillation of methanol) [4]. The polymer was isolated from the resulting aqueous solution by freeze drying. Yield 0.38 g (96%) (run no. 1).

Under similar conditions we prepared the polymeric salts of hydrogen phthalates **V** [yield 61% (0.24 g) (run no. 2)] and **VI** [yield 94% (0.37 g) (run no. 3)].

Polymeric derivatives of triterpenoids with a polymer–BAS covalent bond were prepared from the VP (94.5 mol %)–AlAm (5.5 mol %) copolymer, [η] at 25°C in 0.1 M CH_3COONa 0.12 dl g^{-1}, M_η = 18 000.

Example 2. A solution of 0.23 g of VP–AlAm copolymer, 0.075 g of **VIII**, and 0.025 g of DCC in 4.5 ml of CH_2Cl_2 was kept for 2 h at –18°C and then for 72 h at –5°C. The molar ratio of the reactants was 1 : 1 : 1. Then the polymer was precipitated into diethyl ether, and the precipitate was separated on a glass frit and vacuum-dried to constant weight. The low-molecular-weight impurities were separated by gel permeation chromatography on a column packed with Sephadex LH-20 gel (h = 44 cm, d = 1.5 cm), eluent ethanol. The high-molecular-weight fraction was collected, and ethanol was distilled off on a rotary evaporator.

Run no. 5: polymeric derivative of **VIII**, yield 89% (0.31 g); run no. 6: polymeric derivative of **VI**, yield 69% (0.24 g); run no. 7: polymeric derivative of **V**, yield 64% (0.22 g).

CONCLUSIONS

(1) Previously unknown 25,26,27-trinordammaran-3β-ol-20(*S*),24-olide hydrogen phthalate **V**, 25,26,27-trinor-20(*S*),24-epoxydammaran-3β-ol hydrogen phthalate **VI**, and dammar-24-ene-20(*S*),3β-diol hydrogen phthalate **VIII** were prepared.

(2) Procedures were developed for preparing polymeric water-soluble derivatives of **V**, **VI**, and **VIII** with *N*-vinylpyrrolidone copolymers, with both labile and strong covalent bonding of the polymer with the triterpenoid.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Radical Polymerization in the Presence of Vinyl-Substituted Transition Metal β-Diketonates

O. V. Shevchenko, I. S. Voloshanovskii, and T. I. Berbat

Mechnikov National University, Odessa, Ukraine

Received June 22, 2005; in final form, December 2005

Abstract—The influence of vinyl-substituted cobalt(II), copper(II), nickel(II), and iron(II) β-diketonates on radical polymerization of methyl methacrylate and styrene was studied.

DOI: 10.1134/S1070427206040306

Transition metal β-diketonates are used as a free radical source in initiation of radical polymerization [1, 2]. However, a few papers reported on deceleration of polymerization [1, 3] and formation of polymeric products with decreased molecular weight [4] in the presence of these compounds. The inhibiting properties of β-diketonates and their use in oxidation and stabilization of polymers were studied in greater detail [5]. Thus, the inhibiting effect of β-diketonates on polymerization, influencing the polymerization kinetics and molecular-weight properties of the products, was studied nonsystematically.

Previously [6, 7] we prepared a series of vinyl-containing β-diketonates and studied their copolymerization with vinyl monomers. We found that the polymerization rate v_p and MW of the products decreased and the polydispersity index (PI) increased with increasing amount of the monomeric β-diketonate in the initial mixture [8]. This can be due to complexation of the propagating radical with the quasiaromatic β-diketonate ring [9]. We also showed that vinyl-substituted cobalt(II) β-diketonates not only catalyze but also inhibit the polymerization at their concentrations higher than 10^{-2} M.

The aim of this study was to examine the decelerating and stopping effect of vinyl-substituted Co(II), Ni(II), Cu(II), and Fe(III) β-diketonates on polymerization.

EXPERIMENTAL

To initiate polymerization of styrene (St) and methyl methacrylate (MMA), we used cobalt(II) 7-octene-2,4-dionate (Co-OD), cobalt(II) 3-allylpentane-2,4-dionate (CoAPD), cobalt(II) 1-phenyl-6-heptene-1,3-dionate (Co-PHD), cobalt(II) 3-allyl-1,1,1-trifluoropentane-2,4-dionate (Co-ATPD), copper(II) 7-octene-2,4-dionate (Cu-OD), iron(III) 5-methyl-5-hexene-2,4-dionate (Fe-MHD), copper(II) 5-methyl-5-hexene-2,4-dionate (Cu-MHD), nickel(II) 2-allyl-1-phenylbutane-1,3-dionate (APBD-Ni), and nickel(II) 1-phenyl-6-heptene-1,3-dionate (PHD-Ni). Vinyl-substituted β-diketones were prepared by the procedure described in [6, 7], and their metal complexes, by the procedure described in [10]. Polymerization of St and MMA was performed in the bulk and in solvents [toluene (Tl), dimethylformamide (DMF), and methyl ethyl ketone (MEK)]. The monomer concentration was 3.54 M. The polymerization rate was determined dilatometrically and gravimetrically. The molecular weight of the polymers was estimated by gel permeation chromatography on a Waters-2000 chromatograph using monodisperse references (Waters).

We studied MMA polymerization initiated by vinyl-substituted Co(II), Ni(II), Cu(II), and Fe(III) β-diketonates. The initial polymerization rates v_p^0 were determined. The results are summarized in Table 1. As seen from Table 1, the initial polymerization rate does not increase with increasing Co-OD concentration over 10^{-2} M. The initial polymerization rate v_p^0 increases when the concentration of Co-APD and Co-PHD increases up to 0.5×10^{-2} and 10^{-2} M, respectively. When the initiator content is higher than this limiting concentration (LC), v_p^0 decreases, i.e., these compounds become inhibitors. The v_p^0 increases with decreasing the FeMHD concentration.

Table 1. Initial rate v_p^0 of MMA polymerization at 70°C and different concentrations c_c of vinyl-substituted cobalt(II), copper(II), and iron(III) β-diketonates

Table 2. Reaction orders of St polymerization with respect to vinyl-substituted cobalt(II) and nickel(II) β-diketonates

Monomer	T, °C	Reaction order with respect to initiator				Monomer	T, °C	Reaction order with respect to initiator			
		Co-OD	Co-APD	Ni-APBD	Ni-PHD			Co-OD	Co-APD	Ni-APBD	Ni-PHD
St	70	0.4	0.4	0.3	0.3	MMA	60	–	–	0.4	0.4
	85	0.4	0.3	0.3	0.3		70	–	–	0.5	0.4

At the 3.0×10^{-2} M concentration of Cu-OD and Cu-MHD, even thermal polymerization is inhibited. When the concentration of these complexes is 10^{-2} M, the polymerization is very slow. Hence, LC for these compounds is $(1.0–2.0) \times 10^{-2}$ M. We failed to determine the LC for the Ni(II) chelates, since their solubility of in MMA is 10^{-2} M. The solubility of vinyl-substituted cobalt(II) and nickel(II) β-diketonates in St does not exceed 0.5×10^{-2} M, and hence it is also impossible to determine the LC for these complexes. The fact that the examined vinyl-substituted metal β-diketonates exhibit both the initiating and inhibiting properties affects the reaction order of polymerization with respect to the initiator. At low concentrations of these complexes, the $\log v_p^0$–$\log c_c$ dependence (c_c in the chelate concentration) is linear and can be used to determine the reaction order with respect to the initiator (Table 2). In all cases, the reaction order of the polymerization of St and MMA was 0.3 – 0.4 and 0.4 – 0.5, respectively. However, the reaction order with respect to peroxy and dinitrile initiators is 0.5.

The fact that the reaction orders with respect to the chelate are underestimated suggests the occurrence of a latent inhibition process up to reaching of LC. The fact that the reaction orders of St polymerization with respect to the initiator are lower than those for MMA polymerization can be due to higher reactivity of growing St radicals in their coordination to the metal atom of the chelate. This can be due to several reasons: first, St radicals are donors (the Alfrey–Price factor e for ST and MMA is +0.8 and – 0.4, respectively) and the metal atoms are always acceptors; second, coordination of the secondary St radical to the metal atom is more sterically favorable that that of tertiary MMA radicals; and third, the reactivity of tertiary MMA radicals is lower than that of secondary St radicals. Thus, the LC of initiation or small polymerization orders with respect to the initiator can be used as criteria of the inhibiting effect. Since the solubility of vinyl-substituted copper(II) and iron(III) β-diketonates in St is 3×10^{-2} M, the v_p^0 vs. c_c dependence for St polymerization in the presence of these complexes also passes through a maximum (Fig. 1). The LC for Cu-APD, Cu-OD, Cu-MHD, and

	5	2.64	3.95	1.49		5	1.92	4.01	2.08

* M_n and M_w are number-average and weight-average molecular weights; M_w/M_n is the polydispersity index.

Fe-MHD is 0.5×10^{-2}, 0.5×10^{-2}, 0.1×10^{-2}, and 0.25×10^{-2} M, respectively.

Since metal β-diketonates exhibit both initiating and inhibiting properties, the propogating polymer radicals can be involved in two reactions with different activation energy:

$$\sim R^{\cdot} + H_2C{=}\underset{\displaystyle X}{\underset{|}{CH}} \xrightarrow{E_P} \text{Polymer},$$

$$\sim R^{\cdot} + \text{chelate} \xrightarrow{E_i} \text{Low-reactive radicals or nonradical products},$$

where E_p is the activation energy of chain propagation and E_i is the activation energy of chain termination on the inhibitor.

It is known that the activation energy of chain propagation for styrene is 29.1 kJ mol^{-1} [11] and the activation energy of addition of radicals to common inhibitors is 4.2–8.3 kJ mol^{-1} [12]. The activation energy of formation of radical–β-diketonate adducts is unknown. If this energy is lower than E_p, the first step should be the most temperature-dependent. In this case the inhibiting properties of the β-diketonates will be weaker than the initiating properties, which can affect the LC of the initiator and MW of the polymer.

To determine the temperature dependence of the ratio of the initiation and inhibition reactions, we studied the kinetics of MMA polymerization initiated by Co-APD (Table 3) and determined the molecular-weight parameters of the resulting polymers (Table 4). As seen from Table 3, the LC at 60 and 70°C is 0.25×10^{-2} and 0.5×10^{-2} M, respectively, which confirms the above assumptions. In addition, comparison of the degree of polymerization determined dilatometrically (S_d) and gravimetrically (S_g) also confirms that the inhibiting effect of the chelate decreases with increasing temperature. The difference between S_d and S_g can be due to the fact that the inhibited reaction yields the low-molecular-weight fraction which is removed after reprecipitation from ethanol. Hence S_d is usually higher than S_g. However, at 70°C this difference is significantly smaller than at 60°C.

The molecular-weight parameteres of poly(methyl methacrylate) prepared at 50 and 70°C are presented in Table 4. The MW of the polymer prepared in the presence of benzoyl peroxide decreases by a factor

of approximately 1.5 when the reaction temperature increases by 20°C. As seen from Table 4, MW increases with temperature, thus confirming the weakening of the inhibiting effect under these conditions. However, the increase in the MW can be due to other reasons. Among them is copolymerization of the vinyl-substituted β-diketonate with MMA, which results in formation of reactive sites in the polymer and growth of the side chains [9].

There is another fundamental reason why the inhibiting effect of β-diketonates decreases in the course of polymerization. It is known that donor additives substantially enhance the initiating power of β-diketonates [1, 2]. To determine whether activation of radical generation affects the polymerization kinetics, we studied MMA polymerization initiated by Co-ADP in Tl, MEK, and DMF (Table 5). As seen from Table 5, the LC of the initiator in Tl is 10^{-2} M and is close to the LC in the bulk polymerization with this initiator (0.5×10^{-2}). The LC in MEK is also 10^{-2} M. The LC in DMF having the maximal donor power increases by a factor of 10 (10.0×10^{-2}). The difference in S_d and S_g (Table 5) also suggests the inhibition of the polymerization in the presence of these chelates. In Tl and MEK, S_g is substantially lower than S_d. In DMF this difference is smaller.

Thus, in donor solvents, the inhibition of the polymerization with the chelate decreases. Donor additive has probably a dual effect on the polymerization. On the one hand, formation of an adduct between the chelate and the additive favors generation of radicals and hence enhances the initiating power [1, 2]. On the other hand, a donor additive blocks the inner coordination sphere of the chelate, thus complicating its reaction with propagating radicals.

Polymerization of St and MMA initiated by the vinyl-substituted metal β-diketonates is characterized by two features which are untypical for polymerization

Table 5. Polymerization of MMA in the presence of Co-APD at 70°C (c_{MMA} = 3.54 M)

Solvent	$c_c \times 10^2$, M	$v_p^0 \times 10^5$	$v_p^{av} \times 10^5$	S_d	S_g

in the presence of peroxy initiators and are related to the inhibition. Polymerization of MMA in the presence of all the examined initiators is characterized by long induction periods (Fig. 2). The styrene polymerization has no induction period. This fact can be due to a change in the valence state of the metal in the chelate up to the polymerization start, which was shown previously [13]. However, in the case of styrene polymerization the metal valence also changes but the induction period is absent. In addition, the time dependence of the MMA conversion is linear, whereas in the case of styrene polymerization this dependence is nonlinear even at the monomer conversion of several percents (Fig. 3), which is manifested in strong dif-

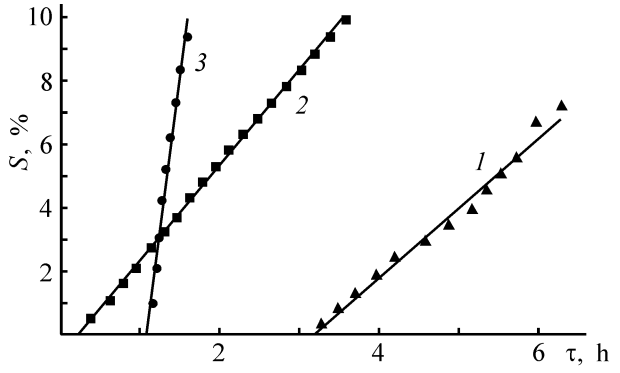

Fig. 2. Conversion of MMA S in the presence of (*1*) Cu-OD, (*2*) Cu-APD, and (*3*) Co-APD vs. time τ. $c_c = 5 \times 10^{-3}$ M and T = 70°C.

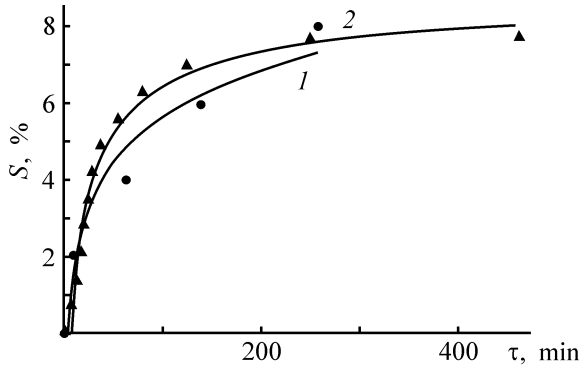

Fig. 3. Conversion of St in the presence of (*1*) Co-APD and (*2*) Cu-APD vs. time τ. $c_c = 5 \times 10^{-3}$ M and T = 85°C.

ference between the initial and average (v_p^{av}) polymerization rates. This fact can be explained as follows. It is known that the products of radical reactions involving β-diketonates can irreversibly form stable complexes with the chelate, which results in catalyst poisoning [14]. The carbonyl group of MMA can coordinate with the chelates to form stable complexes preventing catalyst poisoning with the reaction products.

Since the vinyl-substituted metal β-diketonates are polyfunctional components of radical polymerization (initiators, inhibitors, monomers), their inhibiting effect is masked. The processes initiated by vinyl-substituted β-diketonates substantially depend on the type of the monomer and the metal. The ligand structure affects only the quantitative parameters but does not affect the general course of the process. The inhibition of polymerization can be controlled to a definite extent by variation of the polymerization conditions (chelate concentration, temperature, use of donor solvents).

CONCLUSIONS

(1) Vinyl-substituted transition metal β-diketonates are both initiators and inhibitors of radical polymerization. The ratio of the initiating and inhibiting effects depends on the chelate concentration, the type of the metal atom in the chelate, and the polymerization conditions.

(2) The dependence of the polymerization rate on the chelate concentration is nonlinear. In addition, styrene polymerization is strongly decelerated even at small conversion of the monomer. The polymerization of methyl methacrylate is characterized by long induction periods.

(3) The inhibiting effect of the metal complexes decreases with increasing the polymerization temperature and when using donor solvents.

Abstract—Unsymmetrical dimethylhydrazine is used to design novel polyurethane-based film materials, film-forming aqueous dispersions, and closed-cell polyurethane foams.

DOI: 10.1134/S1070427206040318

Until recently unsymmetrical dimethylhydrazine (UDMH) was widely used as a rocket propellant [1]. However, as a result of reduction of strategic armaments, large amounts of UDMH have been accumulated worldwide, and, because of strong toxicity, its storage represents a danger to the environment [2]. The problem of UDMH utilization is still very topical, and only a few processes exist including direct breakdown through neutralization with an electrochemically activated solution of NaCl [3], introduction of UDMH as a high-energy additive into hydrocarbon fuel, and conversion into low-toxic compounds [4–6]. Presently, processes for utilization of UDMH through conversion into its low-toxic derivatives for various purposes are in progress. The resulting products can be used, e.g., as starting reagents (precursors) in various physicochemical processes [7–12].

Our thought is that utilization of UDMH through the use in production of macromolecular compounds, e.g., polyurethanes and ionomers, shows good prospects. Up to now, the efforts of utilizing UDMH in macromolecular chemistry were directed essentially to modification of polymers [4]. Note here that the high reactivity of the tertiary nitrogen atom of UDMH results in formation of hydrazinium derivatives, and only in the cases when the quaternization of this atom is sterically hindered, the amine hydrogen could be reactive. Thus, the applicability of UDMH in the synthesis of polyurethanes was regarded as doubtful until recently.

In this study we examined the possibility of using UDMH in synthesis of polyurethanes, and also the effects of the reagent ratio and process conditions on the synthesis and properties of various types of polyurethane elastomers.

Polyurethane elastomers. It is known that, in two-step synthesis of a polyurethane elastomer, violation of the stoichiometric ratio of reagents may result in formation of a cross-linked polymer. A different result was obtained when isocyanate prepolymer (PP), prepared from 4,4'-diphenylmethane diisocyanate (DPMDI) and poly(oxytetramethylene) glycol (PTMEG-1000), was reacted with UDMH [13, 14]. In this case, high-molecular-weight compounds soluble in DMF were formed with increasing mole fraction of the prerpolymer by a factor of 2, 5, and even 10. The polymeric films prepared from the resulting DMF solutions demonstrated mechanical characteristics well comparable with the traditional polyurethane elastomers (Table 1).

To estimate the number-average molecular weight of the polymers, we used the end-group analysis [15]. The amounts of the amide and attached hydrazide groups were determined by potentiometric titration in glacial acetic acid with an acetic acid solution of $HClO_4$ [16]. The number of nitrogen atoms in PU samples was determined by the Kjeldahl method, and MW (Table 2) of certain oligomers, ebullioscopically. Such a comprehensive approach to analysis allowed estimation of the number-average molecular weight of the elastomers obtained and some conclusions on their structure. As in our previous study [17], we noted the formation of two types of the structure. Only at prepolymer to UDMH ratios of 1 : (6–1) and 2 : 1

Table 1. Formulation and selected properties of UDMH-based polyurethane elastomers

Sample	PP : UDMH	Intrinsic viscosity [η], dl g^{-1}	Density ρ, g cm^{-3}	Tensile strength σ, MPa	Relative elongation ε, %

(catalyzed reaction), oligomers or linear low-molecular-weight polymers are formed, while in all other cases, weakly branched (comb-shaped) polymers (through intermediate biuret structures) [18]. The intrinsic viscosity [η] of the polymers changed antiparallel to the PP fraction (Table 1). Generally, a decrease in the viscosity (at the same or slightly different MW) is an indication of a branched structure, unless the length of the side chains is comparable with that of the backbone and the macromolecule has a star-like shape [19].

Analysis of the structure of the elastomers (PP : UDMH = 2 : 1) obtained at 60 and 80°C by the uncatalyzed reaction reveals the formation of branched polymers. Generally, such reactions, e.g., the formation of the allophanate and biuret structures, proceed at higher temperatures (120–140 and 100°C, respectively) [19]. The tendency of UDMH to form hydrazinium cations suggests that the synthesis of the UDMH-based elastomers proceeds via formation of ionic reactive centers like that in the Ritter reaction, in which *N*-substituted amides of carboxylic acids are synthesized through the intermediate stage of formation of the carbonium cation [20]. The suggested mechanism is supported by the following findings: (a) the highest activity in the catalytic processes was shown by $SnCl_2(acac)_2$, providing the formation of hydrazinium chloride and (b) introduction of HCl into the reaction system considerably accelerates the reaction.

The structure of the UDMH-based polyurethanes was confirmed by the IR spectra. The spectra show all the bands typical of polyurethanes: 2865 and 2950 cm^{-1} (CH_2), 1115 cm^{-1} (C–O–C of the glycolic fragment), 1650 and 1710 cm^{-1} (associated and free CO groups) (intensities of these bands increased considerably against those in the prepolymer), and 3320 cm^{-1} (NH). The band at 2270 cm^{-1} (NCO group) is lacking, i.e., all the NCO groups were converted.

Water-dispersible polyurethane ionomers. The routes to preparation of hydrophilic and water-soluble polyurethane elastomers based on UDMH, 1,6-hexamethylene diisocyanate (1,6-HMDI), and PTMEG-1000 can be found in [21]. The hydrophilicity of the resulting polymers could be increased by a factor of 5–10, depending on the concentration of ionic

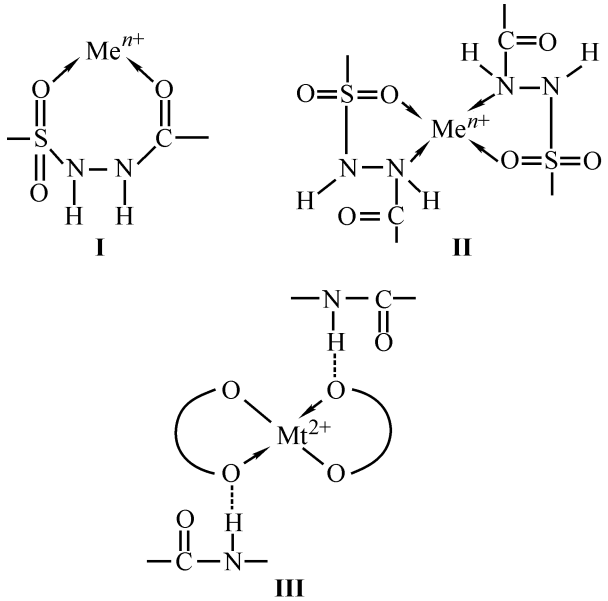
WDP-17/6	0.75	H_2SO_4	30.4	2.3	–

groups and functionality of quaternizing agents. The products are obtained as organic or aqueous-organic solutions, and, occasionally, as thermoreversible gels.



Polyurethane ionomers synthesized using pyromellitic dianhydride (PADA) are amphoteric. One fragment of their macrochain contains tertiary nitrogen atoms capable of quaternization, and the other fragment, carboxy groups, tending to salt formation. Depending on the ratio between these groups in the polymer, stable aqueous ionomer dispersions with various particle sizes from 185 to 520 nm (pH 3.15–3.95) were obtained. The films prepared from these dispersions demonstrate good mechanical properties (tensile stress 20 MPa and elongation at break up to 800%). Their hydrophilicity ranged from 20 to 150%.

The colloidal-chemical properties of the polyurethane dispersions strongly depend on the dilution: particle size abruptly increases from 57 to 550 nm (Table 3). This is a surprising finding in view of the same number of ionic sites.

Polyurethane foams. Thanks to their unique properties, polyurethane foams find a very broad spectrum of applications. Structural-chemical and physical modification of these polymers allows imparting novel performance characteristics to them. Unsymmetrical dimethylhydrazine was used as an initiator in synthesis of branched polyurethanes [22]. The resulting close-cell polyurethane elastomers demonstrated good performance: density 0.03 – 0.07 g cm^{-3} and water absorption 0.18 – 0.83 g cm^{-3}.

Resistance of polymers against biocorrosion. In the recent decades the problem of biocorrosion of structural materials, particularly, with micromycetes (mould fungi *Aspergillus*, *Penicillinum*, etc.) has become very topical [23, 24]. We examined the resistance of the branched polyurethane elastomers modified with inorganic additives against micromycete-induced biocorrosion.

Like other living bodies, mould fungi are sensitive to toxic metal ions, which react with functional groups of proteins, thus deteriorating their structural organization and function [25]. Linear and branched polymers modified with inorganic fungicidal additives such as $ZnCl_2$, $SnCl_2$, and $Zn(acac)_2$ can be involved in complexation with the semicarbazide and urethane fragments of macrochains by the inter- (**I**) and intramolecular (**II**, **III**) mechanisms [26]:

In designing biocorrosion-resistant polymers, the necessary condition is their safety for the human, i.e., lack of diffusion of metal-containing modifiers to the polymer surface, which can be realized through fixation of metal ions on the semicarbazide and urethane fragments of the polymer matrix [27].

Table 4. Biocorrosion of branched polyurethanes modified with inorganic additives

Sample code*	Initial polymer		Polymer after corrosion test				
	tensile strength σ, MPa	relative elongation, ε_{rel}, %	tensile strength σ, MPa	relative elongation, ε_{rel}, %	K_δ, %	K_ε, %	severity of corrosion [29] after 20/30-day tests

* PTMEG-1000, DPMDI, and UDMH; PP : ADMG = 20 : 1 [13].

To characterize the interaction in the system micromycete–bioactive compound, the value of the fungicidal activity is used, i.e., specific inhibiting effect of a given compound on mould fungi. In the case of polymers, such parameters are also used as resistance to fungal growth and biodeterioration (deterioration in the physicochemical characteristics of polymers under the action of microorganisms) [28].

Therefore, the resistance of polyurethanes to micromycete-induced biocorrosion can be characterized by the fungicidal (fungistatic) activity [29] and biodeterioration. The biodeterioration under the action of mould fungi was characterized by the relative change in the strength properties such as tensile stress σ and relative elongation ε:

$$K_\sigma = (\sigma/\sigma_0) \times 100\%,$$

$$K_\varepsilon = (\varepsilon/\varepsilon_0) \times 100\%.$$

As seen from Table 4, branched polymers PU 13/0–16 demonstrate biocorrosion resistance (i.e., fungistatic activity) and increase in the elasticity (K_ε > 100%).

In phase-segregated systems such as the investigated polymers, the rigid-block domains and transition regions are the most susceptible to any attack, which is controlled by the degree of association of the –NH– and –C=O groups. For all the samples studied, the perfection of the domain structure may be characterized by the intensity ratio of the IR bands at 1540 (δ, free NH groups), 3330 (ν, associated NH groups), and 1230 cm^{-1} (ν, associated C=O); ν = 1705 and 1730 cm^{-1} correspond to the C–O stretching vibrations in the self-associates of the rigid-block segments and in the carbonyl groups not involved in H bonding.

The disturbance of the system of physical bonds of polyurethanes under the action of organic acids and water, produced by micromycetes (for example, *Aspergillus niger* is a citric acid producer), resulted in a slight increase in the elasticity.

The susceptibility of the urethane and semicarbazide fragments to the action of micromycetes can be quantified by comparison of the intensities of the corresponding IR bands. As an internal reference one may take the band at 1600 cm^{-1} characteristic of the benzene ring. In the spectra of samples PU 13–PU 16, after the exposure to micromycetes we observed a slight redistribution in the band intensities: the intensity of the band at 1670 cm^{-1} (CO of the semicarbazide fragment) increased and that at 1730 cm^{-1} (carbonyl group of the urethane fragment) decreased, which can be attributed to the action of low-molecular-weight organic acids produced by micromycetes [30]. In all the samples the intensity of the band at 1540 cm^{-1} (δ, free NH groups), related to the band at 1600 cm^{-1} (benzene ring), remained unchanged after the exposure to the test cultures of micromycetes, suggesting that our samples are resistant to the action of these microorganisms. This is supported by the fact that the band at 1120 cm^{-1} sensitive to the action of micromycetes remained practically unchanged also.

Antitranspiration and antiphytotoxic activities of water-dispersible polyurethane ionomers. The UDMH-based water-dispersible polyurethanes (WDP) are capable of forming thin films on the surface of mesophile (plants), which are permeable for water vapor and CO_2. The films decelerate the transpiration, but to a lesser extent than the photosynthesis, thus providing more efficient utilization of water in plants (Table 5).

Single treatment of a plant with a WDP emulsion (water content in emulsions ranged from 90 to 98%)

Table 5. Effect of various aqueous dispersions of polyurethane ionomers on the yield and protein and gluten contents in Odesskaya-162 winter wheat grain in drought

Sample	Weight, g		Content in grain, %	
	grains in Wagner tank	1000 grains	protein	gluten
WDP-1	21.8 ± 0.6	38.5 ± 0.2	12.2 ± 0.3	26.2 ± 0.8
WDP-2	19.4 ± 0.9	36.2 ± 0.2	11.7 ± 0.5	25.0 ± 0.6
WDP-3	18.6 ± 0.9	35.7 ± 0.5	11.5 ± 0.7	24.6 ± 0.3
WDP-4	21.0 ± 0.7	37.8 ± 0.5	12.0 ± 0.1	25.8 ± 0.5
SPU-5	17.5 ± 0.8	34.6 ± 0.4	11.2 ± 0.3	24.0 ± 0.4
WDP-6	20.4 ± 0.4	37.0 ± 0.5	11.7 ± 0.5	24.8 ± 0.6
SPU-7	16.2 ± 0.6	33.4 ± 0.9	10.9 ± 0.5	23.8 ± 0.6
WDP-8	22.5 ± 0.5	39.2 ± 0.4	12.6 ± 0.4	28.4 ± 0.9

under drought conditions facilitated the water and gaseous metabolism, ear formation (this growth stage is the most sensitive to deficiency of water), and also induced some protective reaction on the surface of leaves, thus reducing the crop loss and the protein loss in the winter wheat grain in drought [31].

Based on the results obtained one may recommend the polyurethane dispersions (WDP-2, WDP-4, and WDP-6) for optimization of the water metabolism and production in drought.

EXPERIMENTAL

Commercial unsymmetrical dimethylhydrazine was distilled in flowing inert gas (nitrogen or argon) prior to use. Commercial poly(oxytetramethylene) glycol with MW 1000 (PTMEG-1000) was dried. Commercial 4,4'-diphenylmethane diisocyanate (DPMDI), toluene diisocyanate (mixture of 2,4- and 2,6-isomers) (TDI), and 1,6-hexamethylene diisocyanate (HMDI) were purified by vacuum distillation. Commercial pyromellitic dianhydride (PADA) was used without additional purification. DMF was purified by standard procedures.

Polyurethane elastomers. A two-stage synthesis was employed [14]. In the first stage, the prepolymer was synthesized by the reaction of PTMEG-1000 with a diisocyanate (1 : 2 molar ratio) at 80–85°C for 2 h with vigorous stirring. The reaction was considered as complete when the theoretical molecular weight was achieved, which corresponded to the 6.29% content of the NCO groups. The resulting prepolymer was cooled to 40–45°C, and the estimated amount of UDMH (PP : UDMH ratio varied from 10 : 1 to 1 : 1) was added dropwise with stirring [13]. The mixture was stirred for 1 h at 40–45°C, then the temperature was raised to 55°C, the estimated volume of DMF was added, and the reaction was continued for an additional 4 h. Finally, the DMF solution of polyurethane was degassed in a vacuum. To prepare films, the solution was cast onto glass or Teflon supports. The samples were initially dried at room temperature and then in an oven at 60°C for several hours.

At PP to UDMH ratios of 1 : (6–1), oligomers or linear low-molecular-weight film-forming polymers, and in all other cases, film-forming polymers soluble in organic solvents were formed.

Inorganic modifiers such as tin(II) and zinc(II) chlorides and zinc(II) acetylacetonate were introduced into the polymers at the synthesis stage in an amount from 0.1 to 5 wt %. Polymer 13/0 was prepared without modifying additive.

The molecular weights of the polymers were estimated from the amount of amide and attached hydrazide groups determined by nonaqueous potentiometric titration (end-group analysis), and from the amount of the nitrogen atoms (Kjeldahl method) [15].

Aqueous polyurethane dispersions. A weighed portion of PTMEG-1000 and estimated amount of HMDI were continuously stirred in a nitrogen or argon atmosphere for 2 at 90–95°C. To the resulting prepolymer, the solvent (acetone) was added to obtain a 30% solution, and the mixture was stirred for 15 min to attain homogeneity. Then the estimated amount of UDMH was added dropwise [21]. After the chain extension was completed, the solution was neutralized with an equimolar amount of HCl. The reaction mass was stirred again and diluted with distilled water. The resulting dispersion was gently stirred, and acetone was removed in a water-jet pump vacuum. Finally, the dispersion was cast onto a Teflon support,

Table 6. Composition of aqueous polyurethane dispersions based on WDP-38

Sample	Dry residue	Water	Acetone	Isopropanol
	%

SPU-8	0.5	90.6	1.8	7.1

dried at room temperature to form a film, and then in an oven at 60°C to constant weight. Table 6 shows the compositions of the aqueous polyurethane dispersions used in this study for characterization of the antitranspiration and antiphytotoxic activity of water-dispersed ionomer polyurethanes.

Polyurethane foams. The foams were prepared from the compounds having at least two reactive hydrogen atoms: mixtures of polyesters (P-2200, PDA-800) and polyethers (POPG-2500, POPG-3003, POPG-3603-2P, POPG-5003) with MW from 800 to 5000, $HO–[CH_2CH(CH_3)O]_n–OH$ and $H–[O[(CH_2)_2O]_2–OC(CH_2)_4–COOCH_2CH(OH)–CH_2O]_m–H$; 2,4(2,6)-toluene diisocyanate $CH_3C_6H_3(NCO)_2$; catalysts, diazabicyclooctane and bis(2,4-pentanedionato)Sn(II) dichloride; water; organosilicon stabilizer for foams; and Nujol [32]. The blowing agent was CO_2 formed by the reaction of the isocyanate with water.

The IR spectra of the samples in KBr were recorded on an UR-20 spectrophotometer (Carl Zeiss, Jena, Germany) over the range 400–4000 cm^{-1}. Attenuated total internal reflection infrared spectra were recorded using a germanium ATR plate as an internal reflection element with an aperture angle of 45°; $N = 14$ (KRS-5 trapezium prism, $N = 21$, $\varphi = 450$).

Mechanical characteristics [tensile strength σ (MPa) and relative elongation ε (%)] of the polymer films were determined on an RM-30-1 tensile testing machine at an extension rate of 100 mm min^{-1}, using standard procedures.

The rheological properties of the polymers were studied by viscometry. The unit weight of the polyurethane films was determined by hydrostatic weighing in isooctane.

Determination of the fungicidal activity of the polyurethane samples, growth of test cultures of micromycetes, preparation of conidium suspensions, contamination of the samples, and testing were carried out according to GOST (State Standard) 9.049–91 [29].

Antitranspiration and antiphytotoxic activities of water-dispersible polyurethane ionomers.[1] The plants were cultivated in 8-kg Wagner tanks at a 60% total moisture capacity and daylight. Details of the experimental procedure were reported elsewhere [31].

CONCLUSIONS

(1) Novel polyurethane elastomers are synthesized using unsymmetrical dimethylhydrazine at various prepolymer to UDMH ratios; the reaction involved formation of ionic reactive centers. Only at prepolymer to UDMH ratios of 1 : (1–6) and 2 : 1 (catalyzed reaction), oligomers or linear low-molecular-weight film-forming polymers are formed, and in all other cases, weakly branched (comb-shaped) polymers are obtained.

(2) The structures of the polymers were confirmed by the IR spectra, by the amount of the amide and attached hydrazide groups detemined by nonaqueous potentiometric titration (end-group analysis), and also by the amount of the nitrogen atoms (Kjeldahl method).

(3) The resistance of the polymeric materials to micromycete-induced biocorrosion is studied. Generally, the biodegradability of polyurethanes is insignificant, and they demonstrate prolonged fungicidal effect. The nature of biodegradation of polyurethanes is controlled by their structure. The products of metabolism of micromycetes have a stronger effect on branched polyurethanes, and in the linear polymers, the degree of biodegradation is low.

(4) Novel polyurethane-based aqueous dispersions are prepared. They can be used as efficient regulators of water and gaseous metabolism in winter wheat in drought, to optimize the water metabolism and production.

(5) Novel polyurethane foams are prepared using unsymmetrical dimethylhydrazine and its derivatives. The possibility of controlling the mechanical characteristics of the polyurethane foams and the presence

[1] Study was performed in cooperation with the Institute of Plant Physiology and Genetics, National Academy of Sciences of Ukraine; Grishko Central Botanical Garden, National Academy of Sciences of Ukraine; and Uzhgorod National University.

of ionic centers in their structure allow their application as a polufunctional matrix in development of organo-organic and organo-inorganic hybrid materials.

BRIEF COMMUNICATIONS

Formation of Tricuprotetraborate $3CuO \cdot 2B_2O_3 \cdot 6H_2O$ in Aqueous Solutions

E. M. Shvarts and R. G. Belousova

Institute of Inorganic Chemistry, Riga Technical University, Salaspils, Latvia

Received December 27, 2005

Abstract—The reaction of copper sulfate, boric acid, and sodium hydroxide in an aqueous solution was studied in relation to the molar ratio and concentration of components, solution pH, temperature, and reaction duration. The conditions under which tricuprotetraborate hexahydrate $3CuO \cdot 2B_2O_3 \cdot 6H_2O$ is formed were determined.

DOI: 10.1134/S107042720604032X

Only few hydrated copper borates are known: amorphous $2CuO \cdot B_2O_3 \cdot 3H_2O$ and $3CuO \cdot 2B_2O_3 \cdot nH_2O$ (n=5, 4, 2, 1) [1, 2]. They are finely grained blue powders, which require a very long time to be formed (115 days to 2 years). The amorphous copper borates $3CuO \cdot 2B_2O_3 \cdot nH_2O$ (n = 5, 4, 2, 1) mentioned in [2] have not been isolated, either. Some minerals are known, which are crystalline copper(II) borates: bandylite $CuB(OH)_4Cl$ and henmilite $[Ca_2Cu(OH)_4B(OH)_4]_2$ [3]. In addition, the following synthetic borates have been described: $Na_6\{Cu_2[B_{16}O_{24}(OH)_{10}]\} \cdot 12H_2O$ [4], $K_5H\{Cu_4O[B_{20}O_{32}(OH)_8]\} \cdot 32H_2O$ [5], and $Cu(NH_3)_4B_4O_7 \cdot 6H_2O$ [1].

Most of synthetic copper borates are water-insoluble, they precipitate from solutions as very finely dispersed particles and readily adsorb various impurities. That is why it is very difficult to judge the real composition of borates.

Previously, we tried to obtain a product of the exchange reaction between copper(II) sulfate and borax and to use it for presowing treatment of sugar beet seeds. A dose of 5 g per 1 kg of seeds led to an increase in harvest of root crops and beet tops and in the percentage of beet sugar. The product, the so-called copper borate, was found to be a mixture of several copper borates with H_3BO_3 and was finely dispersed, which caused considerable difficulties in filtration.

The aim of this study was to obtain an individual copper(II) borate that would be sufficiently dispersed, but suitable for filtration. We varied the conditions of the reaction between copper(II) sulfate, orthoboric acid, and sodium hydroxide. The dependence of the composition of the resulting copper borate on the reaction conditions is illustrated by Table 1. Copper borate $3CuO \cdot 2B_2O_3 \cdot 6H_2O$ was obtained at pH 7.5–8.0,

* Stoichiometric ratio of the components. ** Double amount of the reaction mixture. *** Fivefold amount of the reaction mixture.

a nonstoichiometric ratio $CuSO_4 : H_3BO_3 : NaOH$ = [1 : 4 : (3.25–3.5)], and high concentrations of the components. Strict observation of all the conditions is very important for the individual compound to be isolated.

The isolated product $3CuO \cdot 2B_2O_3 \cdot 6H_2O$ is a greenish finely dispersed powder insoluble in cold and hot water, but soluble with decomposition in mineral and organic acids and ammonia. Thermal-analysis curves show that $3CuO \cdot 2B_2O_3 \cdot 6H_2O$ is stable in air up to 40°C. When temperature is raised to 180°C, the mass loss is 14.15%, which corresponds to elimination of four moles of water. The two remaining water molecules are gradually lost on heating to 465°C. In the temperature range 465–878°C, there is no mass loss any more, but three exothermic peaks at 600, 630, and 758°C and a endothermic minimum at 888°C are observed in the DTA curve. The mass loss at 1000°C is 21.82%.

An analysis of the conditions of the reaction between $CuSO_4$, H_3BO_3, and NaOH (Table 1) shows that pure borate $3CuO \cdot 2B_2O_3 \cdot 6H_2O$ is obtained at high reagent concentrations and high temperature (80°C), at pH 7.5–8.0. The synthesis duration is 4 h; heating and stirring favor formation of particles suitable for filtration. Copper(II) borate contains $Cu(OH)_2$ as an admixture at a higher pH 9 and sodium sulfate admixtures at pH below 7.5. A twofold increase in the volume of the reaction mixture results in a higher content of admixtures in the products, and a fivefold increase in the volume, in a considerable decrease in the copper(II) content in the product. We could not identify the product, but believe that this may be a mixture of various borates. At a stoichiometric ratio of the reagents in accordance with the equation

$$3CuSO_4 + 4H_3BO_3 + 6NaOH \rightarrow 3CuO \cdot 2B_2O_3 \cdot 6H_2O + 3Na_2SO_4 + 3H_2O$$

the resulting solid phase contains a considerably greater amount of copper(II) oxide and a smaller amount of boron oxide, and it also can be a mixture of various products.

EXPERIMENTAL

Synthesis of $3CuO \cdot 2B_2O_3 \cdot 6H_2O$. A weighed portion of $CuSO_4 \cdot 5H_2O$ (7.45 g) was dissolved in 19 ml of distilled water at 50–60°C; 7.4 g of boric acid was dissolved in 50 ml of distilled water at 80°C. The solutions were combined, thoroughly mixed, and then cooled to 60°C. Solid NaOH (3.875–4.17 g) was dissolved in 6.5–7.0 ml of distilled water, the solution was cooled and added to the reaction mixture in small portions with stirring. Then the temperature was slowly raised in the course of 2 h to 80°C, and the heating and stirring were continued for additional 2 h. The precipitate was filtered off from the hot solution, washed with 50 ml of a warm 1% solution of orthoboric acid, and dried in air. The analitical data for the product are listed in Table 2.

Table 2. Composition of copper(II) borate $3CuO \cdot 2B_2O_3 \cdot 6H_2O$

Main component	Found, %		Calculated, %
	1	2	
CuO	45.55	49.06	49.11
B_2O_3	28.77	28.65	28.65
H_2O	21.73	21.82	22.23

The Cu(II) content was determined by titration, EDTA with PAN as an indicator [6]. The boron content in the substance was determined by alkalimetric titration in presence of *D*-mannitol, with the pH-metric determination of the equivalence point by the method of constant pH. The interfering copper(II) was masked by adding EDTA. The water content was determined from the mass loss on heating to 700°C. The content of Na_2SO_4 impurity was determined gravimetrically (by precipitation in the form of $BaSO_4$). Thermal analysis curves were recorded on a Q-1500 D derivatograph.

CONCLUSIONS

The conditions under which tricuprotetraborate hexahydrate $3CuO \cdot 2B_2O_3 \cdot 6H_2O$ is formed are as follows: $CuSO_4 : H_3BO_3 : NaOH = 1 : 4 : (3.25–3.5)$, pH 7.5–8.0, 80°C. The synthesis duration is 4 h. Under other conditions, amorphous finely dispersed tricuprotetraborate with a significant amount of admpurities [Na_2SO_4, $Cu(OH)_2$, etc.] is formed.

Abstract—Gold nanoparticles in aqueous dispersions of 100-nm polystyrene microspheres were prepared by photochemical synthesis under exposure to monochromatic light with an excitation wavelength of 254 nm. The kinetic relationships in formation of gold nanoparticles were examined in relation to the $H[AuCl_4]$ and polymer concentration in the photolyte.

DOI: 10.1134/S1070427206040331

Nanoparticles of transition metals, especially gold, show much promise for the development of functional nanophase materials for medical, biochemical, and cytometric applications [1, 2]. Microspheres of polymers with grafted functional groups can be considered as model systems for deposition of metal nanparticles and development of specific labels in diagnostics of genetic and pathogenic diseases.

In this study we carried out photochemical synthesis of gold nanoparticles in aqueous polystyrene dispersions.

Gold nanoparticles were prepared from solutions of analytically pure grade $H[AuCl_4]$. All solutions were prepared in double-distilled water. We used polystyrene carboxylated with 4,4'-azobis(4-cyanoisovaleric acid) in the form of a latex consisting of 100-nm microspheres, stabilized with sodium dodecyl sulfate.

A preliminary study of the aggregation stability of the latex dispersions showed that introduction of $H[AuCl_4]$ in concentrations above 0.1 mM leads to destabilization of the systems, manifested in coagulation and precipitation of the latex particles. The gold nanoparticles were synthesized in the presence of the latex in $H[AuCl_4]$ solutions with concentrations from 2×10^{-4} to 2×10^{-2} M, which were mixed with latexes containing 5×10^{-3} and 5×10^{-2} wt % polystyrene. The resulting compositions were irradiated for 4 h with a monochromatic light at the excitation wavelength λ_{exc} = 254 nm and the light flux intensity of 4.8×10^{16} quanta cm^{-2} s^{-1}. Irradiation was carried out in quartz cells with the optical path length of 1 cm. Formation of nanostructures was monitored spectrophotometrically (an SF-2000 spectrophotometer) from the appearance of absorption within 200–700 nm. Figure 1 presents the absorption spectra of aqueous dispersions of 100-nm polystyrene microspheres, containing 2×10^{-4} M $H[AuCl_4]$. After 60-min UV ir-

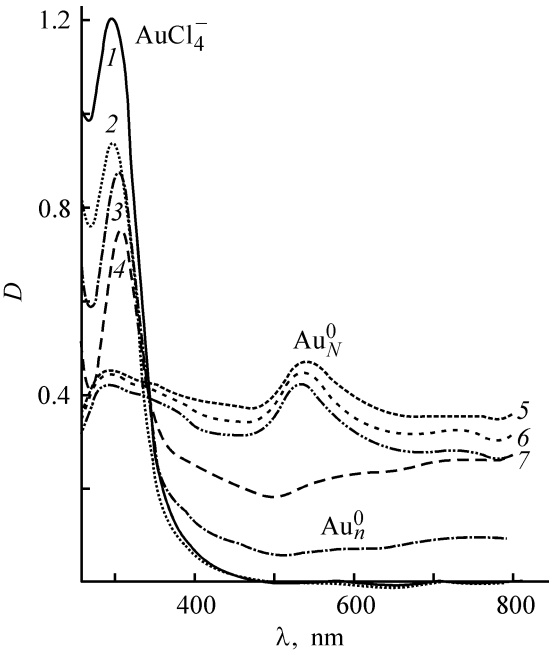

Fig. 1. Absorption spectra of an aqueous dispersion of 100-nm polystyrene microspheres, containing 2×10^{-4} M $H[AuCl_4]$, recorded during photolysis with monochromatic light (λ_{exc} = 254 nm). (*D*) Optical density and (λ) wavelength. Time, min: (*1*) 0, (*2*) 30, (*3*) 60, (*4*) 90, (*5*) 120, (*6*) 150, and (*7*) 180.

radiation of the dispersions, the absorption band at 300 nm, corresponding to $[AuCl_4]^-$ ions, tended to decrease in intensity due to partial photoreduction of Au(III) to Au(I). The initially yellow solution gets colorless. After 60-min irradiation, the absorption in the visible region builds up, and a structureless band with a minimum at 480 nm appears in the spectrum, which suggests the presence of small gold clusters up to 0.8–1.5 nm in size [3]. After 100-min irradiation, a broad band appears at 540 nm, corresponding to colloid polydisperse gold species, and the system acquires a pink color. This period is equal to the induction period in formation of metal particles, which, under identical conditions, exceeds that in formation of silver particles (70 min) [4].

A longer induction period in the case of gold can be due, first, to a three-quantum Au(III) → Au(0) transition, while Ag(I) → Ag(0) is a one-quantum transition, and second, to a strong oxidative power of Au(III) (the $[AuCl_4]^-/Au^0$ couple has a redox potential of +1.00 V [5]) with respect to the small gold clusters being formed. Irradiation of the photolyte initiates two simultaneous processes, formation of the colloid phase and dark reoxidation of intermediate small clusters with Au(III) ions and dissolved oxygen [6]. Hence, a stable growth of the number of gold particles is observed only after Au(III) is completely converted to Au(I) and Au(0). The optical densities thus attained do not exceed 0.5 rel. units. Irradiation of the systems for more than 120 min causes the optical density to decrease throughout the wavelength range studied. This is due to sedimentation of the system and is accompanied by formation of dark loose precipitates on the cell bottom. At the same time, we showed previously [4] that the systems based on silver particles are stable during 300-min irradiation.

This fact can be explained as follows. When silver ions are introduced into solution, they enter into an exchange reaction with carboxy groups of the polymer microspheres. Hence, clusters form and grow directly on the microsphere surface. In the case of gold, the initial gold complex is anionic, which does not favor formation of such bonds, and the rate of the three-quantum Au(III) → Au(0) transition exceeds that of diffusion of Au(I) ions to the microsphere surface. Gold particles are formed, most probably, in the photolyte volume rather than on the microsphere surface. Because of oxidation effect of Au(III) ions, the number of the nuclei is significantly smaller than that in silver-based systems. This leads to formation of polydisperse systems with larger particles, which subsequently settle down.

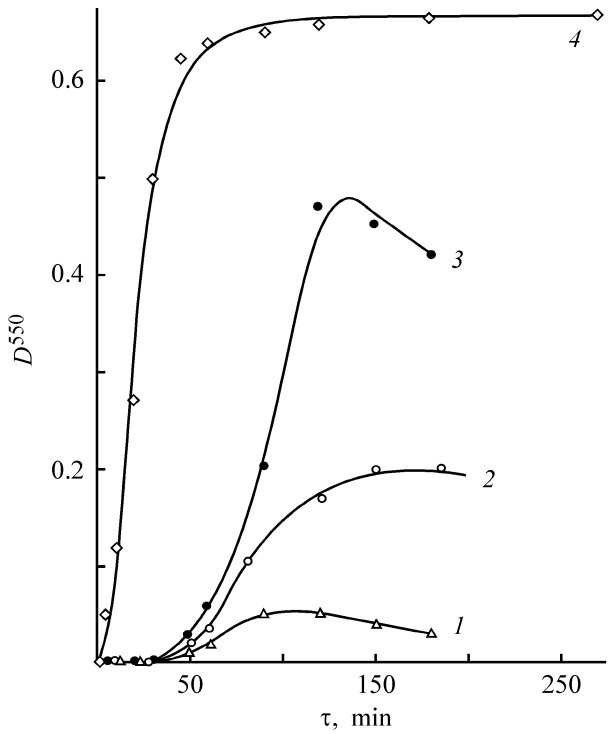

Fig. 2. Kinetic curves of formation of gold nanoparticles during photolysis of systems containing polystyrene and $H[AuCl_4]$. (D^{550}) Optical density and (τ) time. Polystyrene content, wt %: (*1–3*) 5×10^{-3} and (*4*) 5×10^{-2}. $H[AuCl_4]$, M: (*1*, *4*) 2×10^{-3}, (*2*) 1×10^{-4}, and (*3*) 2×10^{-4}.

We analyzed how the average size and degree of polydispersity of the nanoparticles are influenced by the concentration of the $H[AuCl_4]$ introduced into the polystyrene dispersion. As suggested by appearance in the spectra of broad absorption bands, the polydispersity of the systems increases with the $H[AuCl_4]$ concentration increasing from 2×10^{-4} to 2×10^{-3} M, other photolysis conditions being identical. Also, the average size of the gold particles tends to increase, as suggested by the position of the absorption maximum, namely, 550 (2×10^{-4} M)–700 nm (2×10^{-3} M) after irradiation for 100 min. This is due to an increase in the Au(III) oxidant concentration and the ensuing decrease in the number of the nuclei formed. As a result, the size of the gold particles being formed increases in proportion to the amount of $H[AuCl_4]$ introduced. Large particles efficiently settle down, as seen from decreases in the maximal optical densities. For example, an increase in the $H[AuCl_4]$ concentration by an order of magnitude (Fig. 2) causes the optical density D to decrease also by an order of magnitude. Introduction of $H[AuCl_4]$ in concentrations above 2×10^{-3} M causes only the growth of structureless bands corresponding to formation of

gold clusters, and during irradiation for up to 250 min no particles are formed.

An increase in the amount of the dry residue of the polymer in the system from 5×10^{-3} to 5×10^{-2} wt % favors more efficient formation of metal particles, as manifested in a decrease in the induction period to 5 min, in appearance in the spectrum of absorption bands with a maximum at 550 nm, characteristic for colloidal gold, and in an increase in the optical densities to 0.7 rel. unit during 60-min irradiation. Figure 2 (curve *4*) shows that further irradiation to 270 min does not cause any kinetic changes in the system. Probably, reduction of $[AuCl_4]^-$ ions can involve radicals generated by photolysis of 4,4'-azobis(4-cyanoisovaleric acid), sensitive to light with λ_{exc} = 254 nm [7].

CONCLUSION

A procedure was developed for photochemical synthesis of gold nanoparticles in aqueous polystyrene dispersions. The average size and polydispersity of the gold particles formed in these dispersions are governed by the amount of the dry residue of the polymer and the concentration of $H[AuCl_4]$ introduced.

St. Petersburg State Polytechnic University, St. Petersburg, Russia

Received March 14, 2006

Abstract—The standard Gibbs energies and standard potentials of reactions expected to occur in discharge of the negative electrode of a nickel–iron battery were calculated.

DOI: 10.1134/S1070427206040343

The following equation was suggested for describing the discharge and charging of an iron electrode in an alkaline electrolyte as far back as the beginning of the past century [1–3]:

$$Fe + 2OH^- = Fe(OH)_2 + 2e,\ E^0 = -0.876\ V. \quad (1)$$

In the general form, this equation adequately reflects the initial and final states of the active paste. However, Kabanov and Leikis [4, 5] believe that process (1) occurs in two stages: first, iron is oxidized to $HFeO_2^-$ ions and then a loose porous $Fe(OH)_2$, weakly bound to the metal, precipitates from solution:

$$Fe + 3OH^- \rightarrow HFeO_2^- + H_2O + 2e,\ E^0 = -0.748\ V, \quad (2)$$

$$HFeO_2^- + H_2O \rightarrow Fe(OH)_2 + OH^-,\ \Delta G^0_{298} = -24.7\ kJ. \quad (3)$$

A study of anodic films on iron in alkaline solutions by the ellipsometry and chronoamperometry [6–8] made it possible to suggest the following mechanism of growth of anodic films on iron. A denser anodic film adjacent to the metal is formed via deposition of a $Fe(OH)_2$ layer onto the electrode. Its growth in the course of time is limited by the velocity of migration of Fe^{2+} ions, formed in anodic polarization, under the action of the potential and concentration gradients toward the interface between the film and solution. $HFeO_2^-$ ions are possibly formed, together with $Fe(OH)_2$, in anodic polarization of iron [reaction (2)]. The near-electrode layer is supersaturated with $HFeO_2^-$ ions and, as a result of hydrolysis, they precipitate on the electrode in the form of $Fe(OH)_2$ [reaction (3)], capturing ions from the solution and forming an outer hydrated film. Further, the outer film degrades, loses water, and, giving up OH^- ions to the diffusing Fe^{2+} ions, becomes denser.

In the case of a strong anodic polarization of the iron electrode, the following processes may occur in a solution of the hydroxide of an alkali metal [9, 10]: first anodic process, reaction (1); and the second,

$$Fe(OH)_2 + OH^- \rightarrow \delta\text{-}FeOOH + H_2O + e, \quad (4)$$
$$E^0 = -0.634\ V.$$

Teplinskaya et al. [9, 10] believe that the compound Fe_3O_4 is formed by the reaction between iron hydroxides in different oxidation states:

$$Fe(OH)_2 + 2\delta\text{-}FeOOH \rightarrow Fe_3O_4 + 2H_2O, \quad (5)$$
$$\Delta G^0_{298} = -74.9\ kJ,$$

rather than by an electrochemical process.

An additional potential plateau, lying between the two known potential plateaus [reactions (1), (4)] was recorded in [11] when studying the anodic dissolution of an iron electrode at 35–55°C. An X-ray phase analysis of electrodes withdrawn from solutions after discharge at potentials of the additional plateau demonstrated that, in the electrodes, the amount of iron(II) hydroxide formed during the first anodic process decreases, and that of magnetite increases. Based on this fact, Novakovskii et al. [11] concluded that the conversion of $Fe(OH)_2$ into Fe_3O_4 is described by the reaction equation

$$3Fe(OH)_2 + 2OH^- \rightarrow Fe_3O_4 + 4H_2O + 2e, \quad (6)$$
$$E^0 = -1.022\ V.$$

Standard Gibbs energies of various substances and ions according to [12, 13]

Substance	ΔG^0_{298}, kJ mol^{-1}	Substance	ΔG^0_{298}, kJ mol^{-1}
Fe	0	δ-FeOOH	–465.0
Fe_3O_4	–1014.2	O_2	0
$Fe(OH)_2$	–483.7	H_2O	–237.2
$HFeO_2^-$	–379.1	OH^-	–157.3

In the case of anodic polarization of an iron electrode within the range of the first potential plateau at 55°C, a considerable amount of magnetite is formed together with the main discharge product, $Fe(OH)_2$. Novakovskii et al. [11] believe that there occurs direct electrochemical conversion of Fe into Fe_3O_4:

$$3Fe + 8OH^- \rightarrow Fe_3O_4 + 4H_2O + 8e, \quad (7)$$
$$E^0 = -0.913 \text{ V}.$$

At elevated temperatures, the surface of separators and battery vessels is covered with a black deposit of magnetite, which indicates that magnetite may be formed in solution. The formation of magnetite is hindered on passing from LiOH solutions to those of NaOH and KOH.

In view of the wide diversity of reactions that occur in discharge of the negative electrode of a nickel–iron battery and their different orders suggested by different authors, the standard Gibbs energies and standard potentials of the above-mentioned reactions were calculated and the order of processes occurring at the electrode was refined. The calculations were based on the published standard Gibbs energies of formation [12, 13] (see table).

The resulting values of the standard potentials suggest the following sequence of electrochemical reactions in discharge of the negative electrode. Reaction (1) occurs at a potential of –0.876 V; reaction (2) is possible at –0.748 V to give $HFeO_2^-$ ions hydrolyzed by reaction (3); reaction (4) occurs at –0.634 V; the reaction between iron hydrates in different oxidation states [reaction (5)] yields Fe_3O_4. It should be noted that the difference of the standard potentials of reactions (4) and (1), equal to 0.242 V, is in good agreement with the abrupt potential change (0.24 V) in the discharge curve measured on a smooth iron electrode in an aqueous solution of NaOH at a current density of 2.4×10^{-5} A cm^{-2} [4].

Because the standard potential of reaction (6) is –1.022 V and significantly differs from the experimental values obtained in [11], the additional potential plateau in discharge curves at elevated temperatures is possibly due to electrochemical reaction (3) whose potential lies between the potentials of reactions (1) and (4). Magnetite is possibly formed by the reactions

$$3HFeO_2^- + 1/2O_2 = Fe_3O_4 + 3OH^-, \quad (8)$$
$$\Delta G^0_{298} = -348.8 \text{ kJ},$$

$$3Fe(OH)_2 + 1/2O_2 = Fe_3O_4 + 3H_2O, \quad (9)$$
$$\Delta G^0_{298} = -275.0 \text{ kJ},$$

which involve oxygen dissolved in the electrolyte. Reaction (8) also proceeds in the electrolyte bulk, which results in that a black deposit of magnetite is formed on the surface of separators and battery vessels.

Reaction (7) has a more negative standard potential than reaction (1) and, presumably, does not occur in the discharge of the iron electrode. Because iron reacts with water in accordance with the equation

$$Fe + 2H_2O \rightarrow Fe(OH)_2 + H_2, \quad (10)$$
$$\Delta G^0_{298} = -9.3 \text{ kJ},$$

the discharge process and the subsequent charging occur across a film of iron hydroxide [reaction (1)].

The theoretical emf of the nickel–iron battery, calculated from the standard potentials of the reactions occurring at the positive [14] and negative electrodes, is 1.367 V. This value is in good agreement with the theoretical emf of 1.37 V, reported in the monograph [15].

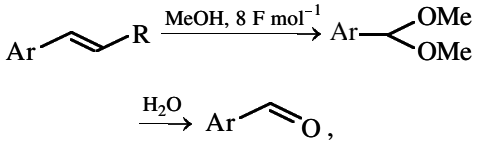
Electrochemical Methoxylation of Alkenyldichloroanisoles

V. R. Islamgulova, S. G. Akhmerova, V. G. Gil'mkhanova, and A. P. Tomilov



State Research Institute of Organic Chemistry and Technology, Moscow, Russia

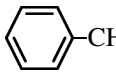
Received December 8, 2005

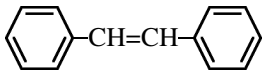
Abstract—Electrochemical oxidation of chlorinated alkenylanisoles in anhydrous methanol was studied.

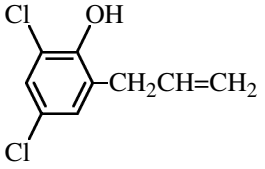
DOI: 10.1134/S1070427206040355

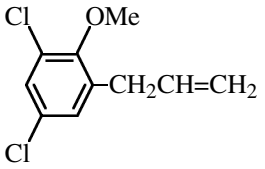
Electrochemical oxidation of alkenylarenes in methanol results in selective cleavage of the C=C bond of the alkenyl substituent and can be described in the general form by the equation [1]

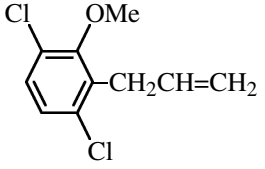
where Ar = Ph, *o*-MeC_6H_4, *p*-$MeOC_6H_4$.

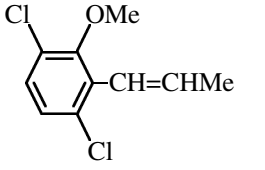












The cleavage of the C=C bond yields the corresponding acetals whose hydrolysis, in turn, yields aldehydes. Conditions ensuring high yield of acetals were reported [2–5].

To prepare acetals, it is advisable to use as supporting electrolyte either trifluoroacetic acid salts or *p*-toluenesulfonic acid [2] and to perform the process at as low concentration of the starting compound as possible (by adding it in small portions in the course of the electrolysis) to minimize formation of dimeric and polymeric by-products. This reaction is a simple route to aromatic aldehydes. Introduction of the methyl or methoxy group into the *p*-position does not noticeably affect the yields of the acetal and aldehyde.

We examined the possibility of using this reaction for preparing aromatic aldehydes containing Cl atoms in the benzene ring, in particular, 2,5-dichloro-6-methoxybenzaldehyde.

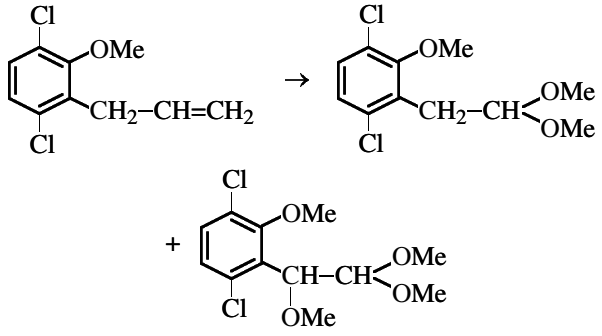
Since the yield of acetal can depend on the oxidation potential of the starting compound, we determined this quantity on a rotating platinum electrode for 2-allyl-4,6-dichloroanisole, 2-allyl-3,6-dichloroanisole, 2-(propen-1'-yl)-3,6-dichloroanisole, and 2-allyl-4,6-dichlorophenol. The results are listed in the table, together with the data for 1-methoxystyrene and (propen-1-yl)benzene given for comparison.

Oxidation half-wave potentials E_{ox} of alkenylarenes (anhydrous methanol, 0.5 M $LiClO_4$, Pt anode)

Compound	E_{ox}, V
	1.50
	1.15
	1.23
	2.05
	2.17
	2.26

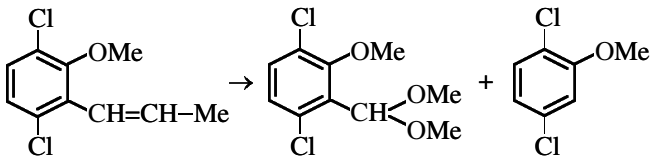
The table shows that introduction of two Cl atoms shifts the oxidation potential of alkenylanisoles toward more positive values.

It is interesting that chlorinated alkenylphenol is oxidized considerably more readily, which is apparently due to the possible formation of a quinoid derivative (E_{ox} = 1.23 V) in the anodic region; this derivative is reduced to hydroquinone (E_{red} = –1.05 V) in the cathodic region. Oxidation of anisoles is irreversible, as indicated by the absence of cathodic peaks in the cyclic voltammogram at reverse potential scanning.



Preliminary experiments performed under the conditions favorable for the cleavage of the C=C bond (anhydrous methanol, *p*-toluenesulfonic acid supporting electrolyte [2, 3]) failed. Better results were obtained with NaF as supporting electrolyte. In this case, noticeable oxidation of methanol starts at an anode potential of +0.8 V, and hence the transformation of alkenyldichloroanisoles will occur by the mechanism of indirect electrochemical oxidation:

$$MeOH \xrightarrow[-e]{} MeO^{\cdot} + H^{+},$$



$$>C{=}C< + MeO^{\cdot} \rightarrow >\dot{C}-\underset{|}{C}-OMe,$$

$$>\dot{C}-\underset{|}{C}-OMe \xrightarrow{MeO^{\cdot}} \overset{MeO}{\underset{|}{-C}}-\underset{|}{C}-OMe \xrightarrow[-2e]{2MeOH} >C\begin{matrix}OMe\\OMe\end{matrix}$$

Preparative electrolyses showed that, at continuous supply of the substrate so as to maintain its minimal concentration in the solution, the methoxylation of 2-allyl-3,6-dichloroanisole occurs without formation of substituted benzaldehyde acetal, and two products are formed:

However, in the methoxylation of 2-(propen-1'-yl)-3,6-dichloroanisole under the same conditions, the C=C bond is cleaved, and 2,5-dichloro-6-methoxybenzaldehyde dimethyl acetal is formed in a yield of about 50% by the reaction

Trimethyl 2,5-dichloro-6-methoxyorthobenzoate was obtained as by-product in ~17% yield. We failed to increase the yield of the acetal by varying the electrolysis conditions.

EXPERIMENTAL

Voltammetric measurements were performed on a PI-50-1 potentiostat with a rotating platinum disk electrode. The supporting electrolyte was 0.5 M $LiClO_4$ in dry acetonitrile. The potential scanning rate was 50 mV s^{-1}, and the electrode rotation rate, 3000 rpm. The reference electrode was Ag/0.1 M $AgNO_3$.

The starting compounds were purified by vacuum distillation (2 mm Hg) before measurements.

Syntheses were performed in a diaphragmless cell equipped with a graphite anode (S = 26.6 cm^2), a platinum cathode, a thermometer, and a reflux condenser. The solution was stirred with a propeller stirrer.

The electrolyzer was charged with 30 ml of absolute methanol and 0.12 g of KF. The electrolysis was performed with a current of 2.65 A (current density 0.1 A cm^{-2}). Immediately after switching on the current, 10 mmol of a substrate [2-(propen-1'-yl)-3,6-dichloroanisole or 2-allyl-3,6-dichloroanisole] dissolved in 8 ml of methanol was added; its amount corresponded to 8 F of electricity per mole of the substrate. After the whole amount of the substrate was added, the electrolysis was continued for a certain period, so that the total amount of electricity was 10 F per mole of the substrate. The electrolysis was performed at 55–60°C.

After the electrolysis completion, methanol was removed on a rotary evaporator, the bottoms were extracted with benzene to separate the supporting electrolyte, and the extract was analyzed chromatographically.

CONCLUSIONS

(1) Introduction of chlorine atoms into alkenylanisole molecule appreciably shifts the oxidation potential toward positive values. An increase in the oxidation potential complicates cleavage of the C=C bond.

(2) In oxidation of 2-allyl-3,6-dichloroanisole, substituted benzaldehyde acetal is not formed, whereas from 2-(propen-1'-yl)-3,6-dichloroanisole 2,5-dichloro-6-methoxybenzaldehyde dimethyl acetal was obtained in a yield (based on the substrate) not exceeding 50%.

Abstract—Aklylation of 1,1-dimethylhydrazine with higher alkyl chlorides was studied. The resulting 1-alkyl-1,1-dimethylhydrazinium chlorides were tested as modifiers of oil asphalt for preparation of asphalt concrete.

DOI: 10.1134/S1070427206040367

Nitrogen-containing cationic additives such as Katamin, Katapin, BP-3 are widely applied in road building for oil asphalt modification. Alkyl ammonium (especially quaternary) salt additives increase adhesion of oil asphalt to mineral components of asphalt concrete mixtures, thus improving the performance characteristics of pavements [1, 2].

One of the simplest ways to solve the problem of utilization of highly toxic propellant component, 1,1-dimethylhydrazine, which arose at the end of XX century, is its quarternization with alkyl halides into quaternary salts to find further technical application [3–5].

In this study, we treated a mixture of technical-grade fatty primary alcohols C_{10}–C_{16} with thionyl chloride to obtain a mixture of the corresponding chloroalkanes to be used for quarternization of 1,1-dimethylhydrazine. The yield of quaternary hydrazinium salts (1-alkyl-1,1-dimethylhydrazinium chlorides) was 97%:

$$2R\text{–}OH + SOCl_2 \rightarrow 2R\text{–}Cl + H_2O + SO_2,$$

$$NH_2NMe_2 + R\text{–}Cl \rightarrow [NH_2NMe_2R]^+Cl^-,$$

where R = Alk(C_{10}–C_{16}).

As known, 1-alkyl-1,1-dimethylhydrazinium chlorides (alkyl C_{10}–C_{16}), when administered perorally, are moderately toxic hazard class III substances; when contacting skin, they exhibit no toxicity and, according to their skin-resorptive effect, are classed with hazard class IV substances [5, 6]. Thus, 1-alkyl-1,1-dimethylhydrazinium chlorides belong to the same toxicity classes as quaternary ammonium salts used for asphalt modification.

This fact, along with a high thermal stability, which allows 1-alkyl-1,1-dimethylhydrazinium chlorides to be introduced into molten asphalt, as well as close structures of ammonium and hydrazinium salts, suggest the possibility of using 1-alkyl-1,1-dimethylhydrazinium chlorides for modifying oil asphalt used for preparation of asphalt concrete.

We studied the properties of asphalt concrete mixtures as influenced by the amount of the quaternary hydrazinium salts introduced into asphalt and estimated the optimal amounts at 1.7–2.5% of the asphalt weight (0.1–0.15% of asphalt concrete weight). In this case, the compression strength of the asphalt concrete mixtures prepared from crushed carbonate rock, natural sand, and 6% of modified asphalt is 1.5–2 times that of mixtures prepared with unmodified asphalt. The water resistance coefficient of the asphalt concrete prepared from modified asphalt increases by 0.06–0.07 units relative to the asphalt concrete prepared from unmodified asphalt. The hydrazinium salts that we synthesized surpass in the modifying properties the analogous ammonium salts (see table).

primary fatty alcohols. These alcohols were treated with thionyl chloride [7] to obtain a mixture of the corresponding chloroalkanes in 95% yield. For the product synthesized, found, %: C 71.65, H 12.25, and Cl 16.10.

A flask equipped with a reflux condenser and a stirrer was charged with 45 g of C_{10}–C_{16} chloroalkanes with the chlorine content of 16.1% and 12 g (0.2 mol) of 1,1-dimethylhydrazine. The resulting mixture was refluxed for 8 h (the boiling point of the reaction mixture during the synthesis slowly increased from 67 to 84°C). After cooling, the reaction mixture crystallized; 50 ml of *p*-xylene was added, and the mixture was stirred and filtered. The residue on the filter was washed with two 20-ml portions of xylene, squeezed, and vacuum-dried at 50°C and a pressure of 10 mm Hg to constant weight. Yield of 1,1-dimethyl-1-alkylhydrazinium chloride 55.4 g (97%). Melting point of the product 62–70°C. Found, %: C 65.61, H 11.75, N 9.68, and Cl 12.96.

Asphalt concrete was prepared, and its physical properties were determined, by the techniques from [8]. Into 990 g of BND 90/130 oil asphalt heated to melting, 10 g of alkyldimethylhydrazinium chloride was introduced with stirring, which yielded 1000 g of modified asphalt containing 1% alkyldimethylhydrazinium chloride. This asphalt (600 g), 4000 g of crushed carbonate rock (5–20 mm fraction), and 5400 g of natural sand (0.071–5 mm fractions) yielded 10 kg of asphalt concrete mixture containing 0.06% alkyldimethylhydrazinium chloride, 5.94% asphalt, and 94% mineral filler. Asphalt concretes containing 0.1, 0.15, and 0.2% alkyldimethylhydrazinium chloride were obtained similarly.

CONCLUSIONS

(1) Asphalt concrete was prepared from oil asphalt modified with a mixture of alkyldimethylhydrazinium chlorides (0.1–0.15 wt% relative to asphalt concrete) synthesized from 1,1-dimethylhydrazine. Its compression strength is 1.5–2 times that of asphalt concrete obtained from unmodified asphalt, and the water resistance coefficient is by 0.06–0.07 units higher.

(2) The hydrazinium salts synthesized surpass in the modifying properties the analogous ammonium salts.

INFORMATION

RePlast International Conference

DOI: 10.1134/S1070427206040379

The Third RePlast Conference was held within the scope of the Interplastika-2005 Exhibition on December 14–15, 2005 at the Moscow Business Center. The main objective of the Conference was polymer recycling. The Conference was organized by the *Plastics: Plastics Processing Industry* journal and Messe Düsseldorf–Moscow Ltd.

The Conference participants were more than 100 researchers, technologists, and businessmen from 60 organizations of seven countries (Austria, Belarus Republic, Germany, Italy, Russia, Slovakia, and Ukraine).

The Conference Program included five plenary sessions. In the Opening Session there was outlined the topicality of the problem of plastics recycling. It was demonstrated that, counted in the volume units, the worldwide production of polymers exceeds that of steel, cast iron, rolled metal, and nonferrous metals combined, being about 400 millions cubic meters, i.e., the mankind lived, first, in the Stone Age, then in the Bronze and Iron Ages, and now it is living in the Polymer Age. It was important also to outline the dynamics of polymer production: the worldwide production of polymers outdistances that of metals by 15–29% annually. But the more polymers, the more wastes, which makes the problem of recycling very topical.

Session 1 included two lectures. R. Binder (Austria) reported on recent developments in recycling of polyethylene terephthalate (PET), and Ch. Fellner (Austria), on the problems of single-step reprocessing of various plastics.

Session 2 included five presentations. Advances in recovery of metallic inclusions from raw material to eliminate sudden interrupts and breakage of facilities in production of plastic goods were overviewed by A.A. Sandulyak (Russia). The problems of magnetic separation in recycling of plastics were analyzed by O.A. Dolgopolov (Russia).

The great interest has been expressed by the participants in the lecture presented by E. Condini and J. Martini (Italy) and devoted to modern processes of recycling of PET bottles, developed at the Amut Company. The last two lectures of this Session were devoted to production of binders from polystyrene foam wastes and their application in the foundry [O.I. Shinskii (Ukraine)] and also to manufacture of face slabs from polystyrene foam [A. Werner and E. Adler (Germany)].

Session 3 included four presentations. V.V. Devyatkin (Russia) reported on the major drawbacks of the legal control in management of wastes as secondary raw materials. He demonstrated the need in improvement of legislation in this area. Yu.M. Demidov (Russia) reported on novel extrusion facilities developed at the Ekokhimmash for polymer reprocessing. Scientific principles of polymer recycling were considered by G.E. Zaikov (Russia). Finally, the presentation entitled Recycling as a Special Column in the Plastics Catalogue-2006 was made by D.V. Ishchenko (Russia).

Session 4 included four presentations. I.A. Kirsh (Russia) considered new prospects for the technology of reprocessing of polymeric composites, developed at the Moscow State University of Applied Biotechnology.

The use of recycled PET in contact with foodstuffs was the topic of the lecture presented by P. Niedl (Austria). F. Matel and R. Jchocova (Slovak Republic) reported on industrial applications of sound insulating materials based on tire reprocessing products. The last lecture of this Session was devoted to the progress in crushing of polymer wastes on crushers from BSZ Atlant Private Company [Yu.P. Belyaev (Belarus Republic)].

Session 5 also included four presentation. S.S. Khachatryan (Russia) considered commercial application of wood–polymer composites, and P. Pecchiardi and Kralij (Italy) reported on new recycling processes.

The last two contributions were devoted to reprocessing of recycled PET without predrying and crystallization in twin-screw extruders [M. Berndt (Germany)] and to presentation of the Solid Domestic Wastes Bulletin [S.S. Emel'yanova (Russia)]. The discussions performed at the Conference showed that the problems of polymer recycling are very topical, being yet far from final solution.

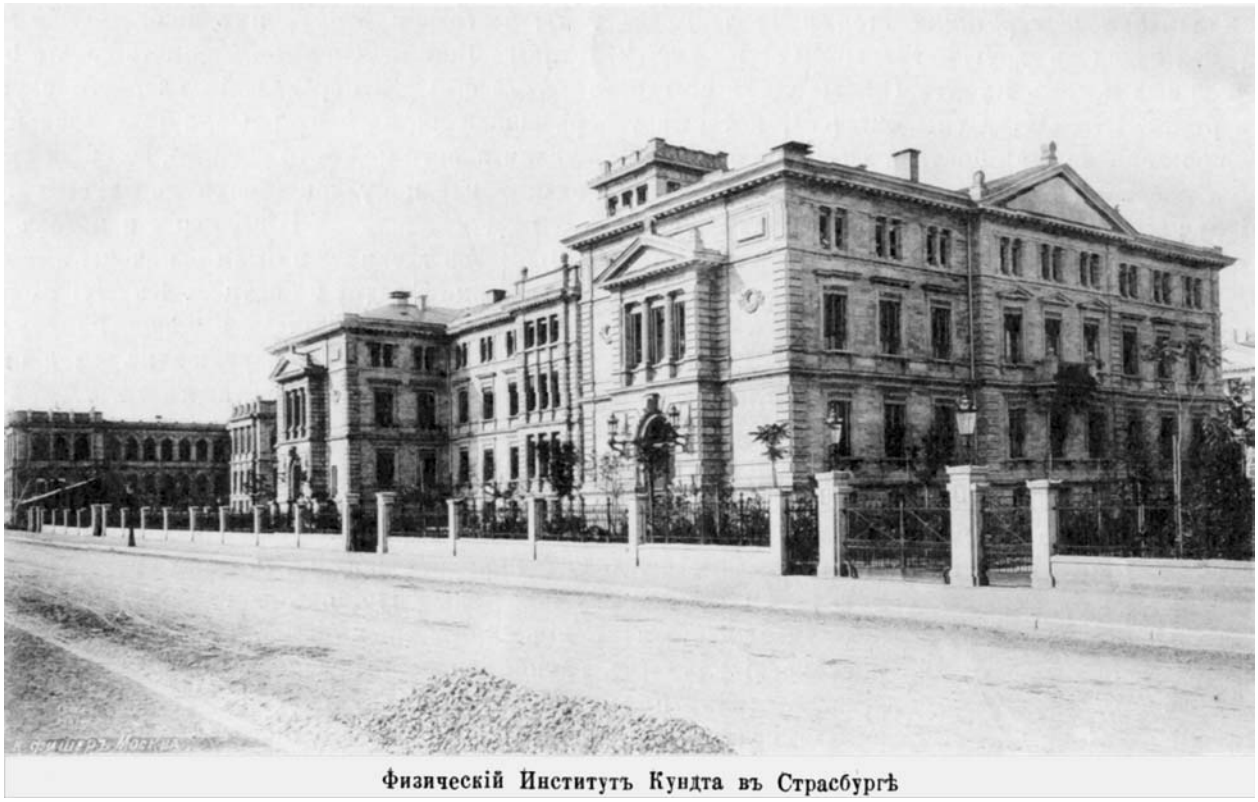
Academician Dmitrii Petrovich Konovalov (To 150th Anniversary of His Birthday)

DOI: 10.1134/S1070427206040380

D.P. Konovalov, one of prominent Russian physical chemists of the late XIX and early XX centuries, made an outstanding contribution to the development of the theory of solutions, delivered lectures at a number of higher-school institutions in St. Petersburg, created the known school of physical chemistry, occupied a number of high administrative positions, and was elected president of the Russian Physicochemical Society (in 1923–1924 and 1927).



Dmitrii Petrovich Konovalov was born on March 10 (22), 1856, in Verkhedneprovsk uezd of Yekaterinoslav province (now Dnepropetrovsk oblast, Ukraine) into a wealthy nobleman's family. Having received primary education at home, he entered Yekaterinoslav classical gymnasium in 1866 and finished it with a gold medal in 1873. Konovalov expressed particular interest in physicomathematical and natural sciences. Immediately after finishing the gymnasium, he entered the metallurgical department of the Mining Institute in St. Petersburg. Founded by Empress Catherine II in 1773, this higher-school institution, one of the oldest in Russia, had an excellent pedagogical staff and was very popular with youths. Chemistry was taught by K.I. Lisenko, a prominent specialist in technical chemistry, lecturers of chemical-metallurgical disciplines included K.D. Sushin, V.V. Bek, and N.A. Iossa.

In 1878, Konovalov successfully finished the Mining Institute. He received the title of a first-class mining engineer and his name was put up on the marble board of honor in the conference hall of the Institute. However, Konovalov considered his knowledge in the field of chemistry and, in particular, organic chemistry insufficient and joined as an external student the physicomathematical faculty of St. Petersburg University, to spend there nearly two academic years. Konovalov performed his first experimental studies under supervision of A.M. Butlerov (1828–1886) in his laboratory. In addition, the young scientist had an opportunity to attend lectures on mineral technology by Butlerov, analytical and organic chemistry by N.A. Menshutkin, higher mathematics by P.L. Chebyshev and K.A. Posse, and physiology by I.M. Sechenov. In the autumn of 1879, D.I. Mendeleev (1834–1907) returned from a long-term business trip and

Konovalov had an opportunity to make acquaintance with him and attend his lectures.

In the beginning of 1879, Konovalov became a member of the Russian Physicochemical Society on Butlerov's recommendation. In 1880, the first Konovalov's scientific study was published in a number of periodic editions. The study, performed under Butlerov's supervision, was concerned with the action of sulfuric acid of isobutyl alcohol and that of nitric acid on butylenes derivatives. Konovalov was on very friendly terms with Butlerov and received an excellent experimental training in his laboratory. However, Konovalov's expectations of his future scientific activities were associated with physicochemical problems. To receive further education and obtain a scientific degree, Konovalov decided to go, at his own expense, to one of major research centers in France or Germany. On Mendeleev's advice, he chose the laboratory of a young German physicist, professor A. Kundt (1839–1894) at Strasbourg University (Germany) [1]. During his business trip abroad, Mendeleev made acquaintance with Kundt, who produced a very good impression on him. In May 1880, Konovalov came to Stras-

Kundt's Institute of Physics in Strasbourg.

bourg with a recommendation letter from Butlerov and was cordially welcomed there. After passing the physical practicum and accomplishing a minor task on Kundt's instructions, Konovalov obtained a working place and commenced studies of the saturated vapor pressure over liquid mixtures. During the preparatory period, Konovalov spent a certain time at the laboratory of physical chemistry, headed by professor R. Fittig (1835–1910). However, he soon realized that the scientific level of Butlerov's laboratory is higher in all respects and concentrated his whole attention on Kundt's laboratory. Already in August and October 1881, the German journal *Wiedemanns Annalen* published the results of Konovalov's studies of the vapor pressure. The material of the first of his publications was submitted as dissertation. After passing the required examination, Konovalov successfully defended in July 1881 the dissertation *Über die Dampfspannung der Flüssigkeitsgemische* (On Vapor Pressure of Liquid Mixtures) and received his Ph.D. and the degree of a master of natural science from Strasbourg University [2]. During his stay abroad, Konovalov visited scientific and industrial centers in France and Switzerland. In Paris, he made acquaintance with H. Le Chatelier (1850–1936), M. Berthelot (1827–1907), and other prominent French scientists. Konovalov particularly highly appreciated studies performed by H. Sainte-Claire Deville (1818–1881) and his classical works in the field of thermal dissociation of compounds. Konovalov also expressed a considerable interest in various chemical plants in Western Europe.

In the end of July 1881, Konovalov returned to Russia and, after summer vacations, continued studies of solutions at Butlerov's laboratory. However, a vacancy soon appeared and Konovalov was elected a laboratory assistant to the laboratory of analytical chemistry at St. Petersburg University, headed by professor N.A. Menshutkin (1842–1907). Laboratory assistant's duties included preparation of practical works for students, help in setting of demonstration experiments for lectures, and pedagogical work in laboratory practicum. Despite the wide range of duties, Konovalov passed master's examinations in 1882, with Mendeleev and Butlerov as the examiners in chemistry, and continued work on dissertation. He submitted in an extended form as master's dissertation the study "On Vapor Pressure of Solutions." The dissertation was successfully defended on March 11, 1884, with Mendeleev and Menshutkin as opponents. In conformity with the regulations of that time, the full text of

the dissertation was published beforehand [3]. Later, this study was twice republished in 1909 and 1928.

Having received his master's degree, Konovalov started to deliver as a privatdocent a facultative course of lectures in physical chemistry for third- and fourth-year students. Simultaneously, Menshutkin suggested to Konovalov to commence studies in chemical kinetics. The first results obtained in this field were published by Konovalov and Menshutkin already in May 1884. They observed catalytic effects in decomposition of ether vapor and Konovalov soon started to study them on his own. In 1885, he published in *Zhurnal Russkogo Fiziko-Khimicheskogo Obshchestva* (Journal of the Russian Physicochemical Society) and also as a separate edition [4] his study "Role of Contact Actions in Dissociation Phenomena," submitted as a doctoral (Chem. Sci.) dissertation. The dissertation was defended on November 4, 1885. In April 1886, at the age of only thirty, Konovalov was appointed extraordinary professor at the chair of analytical and technical chemistry of St. Petersburg University. When recommending Konovalov for this position, Menshutkin mentioned the "excellently passed master's examination and talent in formulation of independent tasks and setting his own work and experiments" [5]. In 1890, after Mendeleev left the University, Konovalov headed the chair of inorganic chemistry, with organic chemistry still taught by Menshutkin and lecturing in technical and analytical chemistry taken up by A.E. Favorskii (1860–1945, academician of the Academy of Sciences of the USSR since 1929) and V.E. Tishchenko (1861–1941, academician since 1935). Konovalov was the closest, among any of the known Russian chemists, to Mendeleev as a scientist, practical figure, and man. Mendeleev highly appreciated Konovalov's works; the relationship between the scientists was maintained after Mendeleev left the University.

One of the closest Konovalov's disciples, A.A. Baikov (1870–1946, academician of the Academy of Sciences of the USSR since 1932), wrote in his memoirs: "From the very first steps of his activities as a professor, Konovalov became an outstanding and brilliant lecturer. His lectures were distinguished by unusual simplicity, clarity, and logicality of presentation. This was the time of a rapid and vigorous development of physical chemistry, which made novel and significant changes in the basic chemical problems. Konovalov, closely involved in the activities of this scientific movement, delivered lectures in inorganic and general chemistry for first-year students of the physicomathematical faculty. In his presentation, this main subject of natural science acquired a fundamentally new character and produced a deep and indelible impression on listeners... The laws of a labile chemical equilibrium, theory of solutions, relationship between chemical and electrical phenomena and chemical dynamics were presented in the course of chemistry and enabled widest generalizations linking into a harmonious whole numerous, previously absolutely uncoordinated factors. The outstanding service of Konovalov as a professor consists in that he was the first to take this way and significantly changed the manner of presentation and teaching of inorganic and general chemistry" [6].

In 1893, Konovalov and Tishchenko were sent to a business trip to the United States to Chicago, to visit the World Exhibition timed with the 400th anniversary of the discovery of America. During six months, the scientists familiarized themselves not only with exhibits (Konovalov was one of supervisors of the group of experts of the largest department), but also visited a large number of industrial plants. As a result of this trip, a book *Promyshlennost' Soedinennykh Shtatov Severnoi Ameriki i sovremenye priemy khimicheskoi tekhnologii* (The Industry of the United States of North America and Modern Methods of Chemical Technology) (St. Petersburg, 1894) was published by Konovalov.

Soon after returning from the United States, Konovalov was appointed an ordinary professor of St. Petersburg University. In 1890–1894, the scientist paid a considerable attention to the construction of a new building for chemical laboratories of the University. The opening ceremony of the building was held on October 16, 1894. In 1895–1896, Konovalov was among those who organized and held the All-Russia Industrial and Art Exhibition in Nizhni Novgorod. Later, he became a member of the Organizing Committee of the Russian section at the World Exhibition in Paris. Here, it should be kept in mind that Konovalov taught in those years not only at St. Petersburg University, but also at the Institute for Railway Engineers and at the Mining Institute (beginning in 1900). He also continued his intensive scientific activities. N.P. Vrevskaya, the widow of the closest Konovalov's disciple M.S. Vrevskii (1871–1929, corresponding member of the Academy of Sciences of the USSR since 1929), wrote in her memoirs devoted to her husband and his colleagues: "The brilliant, talented, and full of creative force Dmitrii Petrovich Konovalov was then at the summit of his fame" [7].

This, in all respects fruitful period of Konovalov's life terminated in the end of 1903, when the scientist, remaining a professor at the University, became director of the Mining Institute. As noted in the mono-

graph [5], at the turn of the XX century, the Mining Institute was distinguished among the rest of the higher-school institutions by the comparatively free mode of students' life and existence of independent student organizations. The period of time from 1904 till 1906 was difficult for Russia in political regard. Having come in conflict with the student organizations of the Mining Institute, the new director took a position of principle, did not make a compromise, and resigned already on June 27, 1905. In continuation of the conflict, in the autumn of 1906, the honored professor, doctor of chemistry, and senior state councillor, Konovalov, also terminated teaching at St. Petersburg University. In the summer of 1907, the scientist fully devoted himself to administrative activities, he was appointed director of the Mining department of the Ministry of Trade and Industry, and in May 1908, was elevated to become deputy minister of trade and industry. He occupied this position during nearly eight years, till the end of 1916.

Only in March 1916, Konovalov returned to pedagogical activities: he was elected professor of Petrograd Technological Institute and was engaged in 1916/17 and 1917/18 academic years in the development of a new course of chemical technology. After nearly ten years' break, Konovalov also resumed his scientific activities. For the summer of 1918, Konovalov went with his family to his homeland, Yekaterinoslav province. Because of the civil war and famine in Petrograd, his stay at homeland was prolonged, and he could return to Petrograd only in the spring of 1922. In those years, Konovalov taught at higher-school institutions of Yekaterinoslav, University and Mining Institute, and was actively involved in the organization of the State chemical laboratory, which was later transformed into the Research Institute of Chemistry and Power Engineering.

Meanwhile, the life in the country gradually returned to the normal course. In December 1921, Konovalov was elected a corresponding member of the Russian Academy of Sciences on recommendation of prominent Russian scientists, academicians V.N. Ipat'ev (1867–1952), N.S. Kurnakov (1860–1941), P.P. Lazarev (1878–1942), and A.E. Fersman (1883–1945). At that same time, he received an offer to become president of the Principal Board of Weights and Measures in Petrograd. After he have his preliminary consent, Konovalov was elected to this position on February 25, 1922 and started to execute his duties in March of the same year. Simultaneously, he became head of the chair of mineral technology at the Technological Institute. On January 13, 1923, Konovalov was elected a full member of the Russian Academy of Sciences.

After returning to Petrograd, Konovalov continued research in the field of thermochemistry of organic compounds, wrote the textbook *Materialy i protsessy khimicheskoi tekhnologii* (Materials and Processes of Chemical Technology) (Petrograd; part 1, 1924; part 2, 1925), and supervised preparation of a posthumous publication of *Osnovy khimii* (Fundamentals of Chemistry) by Mendeleev. At the IV Mendeleev Congress, which was held in September 1925, Konovalov was chairman and presented a report "About Russia's Chemical Industry." On December 9, 1928, the Academy of Sciences celebrated the 50 years of Konovalov's scientific activities.

The central place in Konovalov's scientific legacy is occupied by his studies of solutions. Konovalov was one of the most convinced followers of Mendeleev's concept of the nature of solutions, based on the interaction between a solute with a solvent. A detailed analysis of Konovalov's works in the field of solutions can be found in monographs by Yu.I. Solov'ev [9–11] and A.Ya. Kipnis [12], as well as in quite a number of other publications [13–20]. In particular, B.P. Nikol'skii noted that Konovalov was one of the first scientists who understood the importance of the thermodynamic method in studies of solutions. Among Russian scientists who developed this approach later were G. Tamman (1861–1938) at Derpt (Yur'ev, now Tartu, Estonia) University, I.F. Shreder (1858–1918) at the Mining Institute in St. Petersburg, and, especially, Vrevskii at St. Petersburg University.

Konovalov's study "On Vapor Pressure of Solutions" was analyzed in close detail by A.V. Storonkin [18]. He believes that the principal result of this study is the establishment of general thermodynamic concepts, now named Konovalov's laws. The discovery of these laws is the most important result of the whole scientific activities of Konovalov. The basic works of Gibbs in thermodynamics of heterogeneous systems, published in 1875–1878, were not known to anybody as yet. Konovalov's laws, combined with the laws discovered by his disciple, Vrevskii [7], constitute the general thermodynamic theory of solutions. The thermodynamic concepts established by Konovalov are also valid for heterogeneous systems of other types. Therefore, Konovalov can be regarded, with good reason, as one of the founders of the thermodynamic theory of phase equilibria. When assessing the scientific importance of the classical Konovalov's study "On Vapor Pressure of Solutions," Storonkin concludes: "In this study, Konovalov laid foundation of the general thermodynamic theory of solutions and heterogeneous systems, theoretically substantiated one of the most important methods of substance separation, distilla-

tion, and made an outstanding theoretical and experimental contribution to the chemical theory of solutions" [18]. The importance of Konovalov's laws for modern science and chemical technology was considered in [17–19].

In addition to the materials of his master's dissertation "On Vapor Pressure of Solutions," Konovalov published several series of studies in other areas of physical chemistry. They are devoted to osmotic pressure of solutions, solubility issues, critical phenomena of phase separation of, electrical conductivity of solutions, catalysis, and thermochemistry. With the exception of measurements of the calorific power of carbon-containing compounds, all the studies were carried out during the period from 1885 till 1907. As noted by Nikol'skii [17], Konovalov was the first to give, as far back as 1890, a thermodynamic description of the osmotic pressure, which virtually coincides with the modern approaches. Konovalov's studies in electrochemistry of nonaqueous solutions were performed in 1891–1893. The scientist examined the electrical conductivity of binary systems composed of aromatic amines and aliphatic acids. In these systems, the maximum electrical conductivity corresponds to compositions with a certain stoichiometric ratio of components, whereas pure components show virtually no conductivity. Thus, Konovalov was the first to discover a class of electrolytes that were later named "solvoelectrolytes." The existence of electrolytes of this kind confirms the opinion of supporters of the "chemical" or "hydrate" theory of solutions, being an example of interaction between the solvent and the solute [5, 20]. Konovalov's works in the field of physicochemical foundations of the theory of catalysis were analyzed in detail by S.Z. Roginskii [21]. Konovalov, in particular, demonstrated that the catalytic action of a solid is determined not only by its nature, but also by the state of its surface. Taking into account the state and nature of the surface is a distinctive feature of modern theories of heterogeneous catalysis.

The high appraisal of Konovalov's scientific activities was made by the Russian Physicochemical Society in 1914, which awarded him a major Mendeleev Prize for "the whole set of his outstanding studies in the field of solutions and scientific-pedagogical activities which gave rise to the original school of Russian physical chemists [22, 23]. In addition to the already mentioned Baikov and Vrevskii, the best-known representatives of Konovalov's school include professors E.V. Biron (1874–1919), I.I. Zhukov (1880–1949, corresponding member of the Academy of Sciences of the USSR since 1946), V.Ya. Kurbatov (1878–1957), and N.N. Tuturin (1866–1912). Among those who worked under Konovalov's supervision in Yekaterinoslav were A.I. Brodskii (1895–1969, corresponding member of the Academy of Sciences of the USSR since 1943) and S.Z. Roginskii (1900–1970, corresponding member of the Academy of Sciences of the USSR since 1939).

Konovalov's contribution to the development of physical chemistry was also highly appraised by the world community: he was elected honorary member of the London Chemical Society (in 1914), honorary member of the Swiss Society of Natural Science, corresponding member of the Göttingen Scientific Society (1923), honorary member of the French Chemical Society (1926), and member of the International Committee of Weights and Measures (1926).

To Konovalov's life have been devoted monograph by Solov'ev and Kipnis [5], articles by Baikov [6], Storonkin [18], V.V. Mikhailov [23], and other materials [14, 24–27].

Dmitrii Petrovich Konovalov died of pneumonia on January 6, 1929, at the age of 72. At a meeting of the Department of Applied Chemistry of the Russian Physicochemical Society, devoted to Konovalov's memory, Tishchenko voiced the opinion of Russian chemists: "In Dmitrii Petrovich's person, we lost an exceedingly gifted man with astute mind, high spirit, strong will, and strength of the sense of duty and love for work" [5]. The main thing in Konovalov's live was work, he had worked much and hard during his whole life till his very last days.

BOOK REVIEWS

Martem'yanova, Z.S. and Esina, N.O., *Struktura elektroliticheskikh pokrytii. Atlas* (Structure of Electrodeposited Coatings: Atlas)

Yekaterinburg: Ural'sk. Otd. Ross. Akad. Nauk, 2005, 192 pp.

DOI: 10.1134/S1070427206040392

About forty years ago, systematic studies of the fundamental aspects of electrocrystallization of a number of refractory metals, as well as germanium and silicon, from molten electrolytes of various compositions were commenced at the Institute of High-Temperature Electrochemistry, Ural Division, Russian Academy of Sciences on the initiative and under supervision of A.N. Baraboshkin (1925–1995), an academician of the Russian Academy of Sciences. By now, staff members of the laboratory of electrocrystallization at the Institute of High-Temperature Electrochemistry have accumulated a vast and largely unique body of data on electrocrystallization from molten electrolytes, revealed fundamental aspects of structure formation and growth of electrolytic deposits, developed methods for deposition of solid layers of refractory metals with a thickness of several millimeters. Electrolytic deposits and their structure and growth have been studied using a set of modern physical, physicochemical, and electrochemical techniques. The main content of the book by Z.S. Martem'yanova and N.O. Esina is presented in the form of micrographs of very high quality.

The atlas comprises two parts: the first of these (pp. 4–132), including nine chapters, considers deposition of polycrystalline coatings and the second (pp. 133–187), including two chapters, discusses oriented electrodeposition. Each part has its own list of references.

Continuous deposits are complex structures. In deposition on a foreign substrate, their development occurs in three stages: nucleation of separate crystals on a substrate, growth of separate crystals till their merging into a continuous layer, and collective growth of crystals in the continuous deposit. The main parameters that affect the structure of continuous cathodic deposits in electrolysis of molten salts as the following: melt composition, concentration of discharging ions, cathode current density, material and structure of the substrate, anode current density, and oxidation state of ions of the metal being deposited in the melt. All these factors were taken into account in the experimental study of the processes that occur in deposition of continuous layers.

The first three chapters of the first part of the book are devoted to preparation of continuous deposits of molybdenum from a chloride–molybdate and a number of molybdenum-containing chloride melts of various cation compositions. Chapter 4 considers the structure of continuous electrodeposited layers of molybdenum alloys with tungsten, nickel, rhenium, and niobium. Chapter 5 discusses the results obtained in a study of continuous tungsten coatings deposited on various substrates by electrolysis of oxide and oxide–chloride molten electrolytes. Chapter 6 is devoted to the structure of rhenium coatings, and chapter 7 describes the results obtained in studies of electrodeposition of chromium, titanium, and hafnium. Chapter 8 presents data on the structure of silicon deposits produced by electrolysis of a chloride–fluoride melt on polycrystalline and single-crystal substrates made of various materials. The temperature dependence of the structure of silicon deposits on graphite, glassy carbon, and singlecrystal silicon was clearly revealed. Also presented are data on the structure of silicon coatings deposited from a LiF–KF–K_2SiF_6 fluoride melt. Germanium coatings were deposited onto a tungsten substrate from a Na_2WO_4–Na_2GeO_3 melt. The small chapter 9 presents the structural characteristics of uranium dioxide deposits produced by electrolysis of a 3LiCl–KCl–UO_2Cl_2 chloride melt at various current densities and temperatures. The bibliographic list in the first part of the atlas contains references to 39 studies performed at the Institute of High-Temperature Electrochemistry, Ural Division, Russian Academy of Sciences.

In the brief introduction to the second part of the atlas, the authors note that oriented metal layers find steadily increasing use in various fields of technology and allow deeper elucidation of the mechanism of electrooxidation processes. Chapter 1 of the second part presents results of an experimental study of single-crystal layers of molybdenum and tungsten, produced by electrolysis of molten salts. Molybdenum

layers of thickness 100 μm were deposited onto single-crystal molybdenum substrates with various orientations. At 800°C, the current densities were in the range 0.01–1.0 A cm^{-2}. Chloride solutions containing $MoCl_3$ were subjected to electrolysis. Tungsten was deposited onto single-crystal tungsten substrates with various orientations from a Na_2WO_4–K_2WO_4–WO_3 melt. Chapter 2 is devoted to electrodeposition of rhenium from molten electrolytes onto oriented rhenium and tungsten substrates. The bibliographic list in the second part of the atlas includes references to 12 studies by staff members of the Institute of High-Temperature Electrochemistry.

The Institute of High-Temperature Electrochemistry, Ural Division, Russian Academy of Sciences was organized with participation of professors M.V. Smirnov, S.V. Karpachev, and A.N. Baraboshkin. The Institute is the only specialized scientific institution in the world which studies the electrochemistry of ionic melts and solid electrolytes. The book-atlas by Martem'yanova and Baraboshkin, which has no analogs in the world literature, makes a kind of final review of the research in one of the areas of Institute's activities. The processes of electrocrystallization of refractory metals have exceedingly wide prospects for application in various fields of technology. The book is very well published and is, undoubtedly, of interest for specialists in the electrochemistry of ionic melts.

Abstract—Results of tribological studies of modern polymeric materials (thermoplastics, thermosetting materials, composites) used to fabricate water-lubricated bearings are considered. Particular attention is given to carbon-fiber-reinforced plastics modified with powdered metals, fullerene-containing additives, and carbon nanotubes.

DOI: 10.1134/S1070427206050016

INTRODUCTION

The machine-building industry has conventionally used in friction units such metallic antifriction materials as babbit alloys, bronzes, and aluminum alloys, which can only work with oil lubricants. In recent years, an increasingly close attention has been given to the environmental safety of the friction units of modern ships, hydraulic turbines, pumps, shipping locks, and oil-extracting and oil-processing equipment operating in water. This problem can be mostly solved if oil lubrication of friction units is eliminated by using such natural lubricant as water. The problem of elimination of oil lubrication of friction units is also important for heavy and chemical machine building, road-building and mining machines, hoisting machinery, and food, textile, perfumery, and other industries.

This review considers the main types of modern polymeric materials used in water-lubricated bearings.

1. WATER AS A LUBRICANT

To have a general notion of lubrication with water in sliding friction, it is of use to consider the Hersey diagram (Fig. 1) [1]. The diagram is the plot of dependence of the friction coefficient on the Hersey parameter $\eta N/P_N$, where η is dynamic viscosity; N, rotation rate or sliding velocity of counterbodies; and P_N, contact pressure. Zones of (*1*) boundary and (*2*) mixed friction exist to the left of the minimum value of the friction coefficient, and (*3*) region of liquid friction, to the right.

The viscosity of water is more than 100 times lower than that of oils (Fig. 2). This means that, in most cases of lubrication with water, bearings operate during a considerable part of their service life under conditions of boundary and mixed friction. The characteristics of boundary and mixed friction are primarily determined by the materials of the contacting surfaces, and, therefore, their choice is exceedingly important. However, the practical choice is governed not only by the properties of materials, but also by their price, simplicity of production and processing, and design parameters of a friction unit. The concept

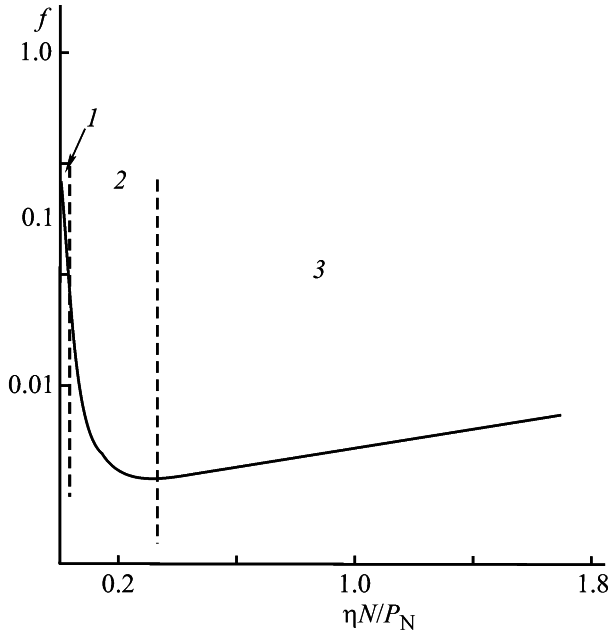

Fig. 1. Friction coefficient f vs. the Hersey number (Hersey diagram) [1]. (η) Dynamic viscosity (Pa s), (N) shaft rotation rate (rpm), and (P_N) normal contact pressure (MPa). Friction region: (*1*) boundary, (*2*) mixed, and (*3*) liquid.

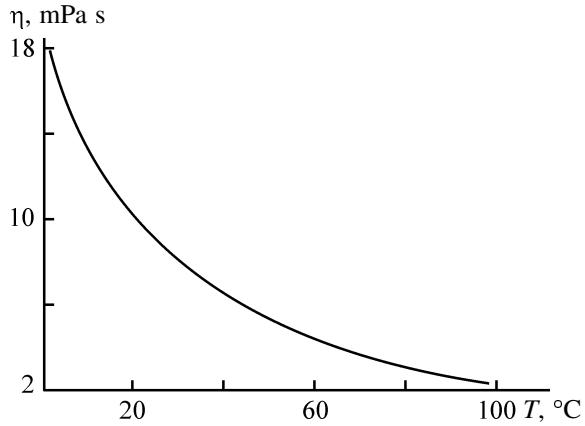

Fig. 2. Viscosity η of water vs. temperature T [1].

of how materials should be chosen with account of design and service parameters was formulated in [1]. In this review, we only consider the problem in terms of the materials science, with the specific conditions of operation in water only briefly mentioned.

2. EFFECT OF CORROSION

Naturally, attention should be given in the case of water lubrication to such a factor as corrosion of friction surfaces. Use of insulators as a material of one of the two surfaces or as a protective coating must diminish the effect of corrosion [2–4].

3. EFFECT OF CONTAMINANTS

In the case of contaminated water, preliminary filters or other devices are commonly used to remove the contaminants. However, these measures frequently fail to prevent ingress of soil, sand, clay, or other impurities into the clearance between the counterbodies. Therefore, the abrasion nature of wear should be taken into account in choosing the materials for counterbodies. The extent of this wear largely depends on the place of the operation mode in the Hersey diagram [1].

Table 1. List of selected tribological parameters of materials and friction units

Parameter	Designation	Illustrating figure
Friction coefficient	f	
Linear wear intensity	I_h	
Energy-related wear intensity	I_w	
Range of working pressures	P_C–P_{SS}	3a
Load-carrying capacity	P_C	3a
Alignment time	τ_R	
Lifetime of a friction unit after emergency failure of lubricant supply	τ_L	3b
Volume wear rate	ν_w	
Critical pressures for change of wear mechanism	P'_C, P''_C...	3c
Optimization parameter of alignment of mating friction surfaces	Q	3d

As contaminants find their way into the clearance, the nature and extent of the subsequent damage will be determined by the properties of the friction surfaces. If the contaminants are softer than these surfaces, the damage will be insignificant. If, however, the contaminant particles are harder than the friction surfaces, the softer surface will suffer scuffing.

4. TRIBOLOGICAL STUDIES OF POLYMERIC MATERIALS FOR WATER-LUBRICATED BEARINGS

Table 1 and Fig. 3 summarize the most important, in our opinion, parameters of the tribotechnical properties of materials and friction units [5].

The choice of materials to be lubricated with water cannot be based on the behavior of a material in the case of a dry sliding friction, with only the increased heat removal by water additionally taken into account. The wear and other parameters of dry sliding friction can be grossly misleading if extended to water-lubricated sliding friction. In particular, such an approach ignores chemical aspects of the interaction between water and counterbodies.

Many friction units operating in the boundary region of lubrication with water are characterized by low sliding velocities, frequent service interruptions, wide range of loads, and comparatively short sliding way during the service life. As examples of friction units of this type can serve rudder bearings of ships of various classes and purposes, guide units of hydraulic turbines, bearings of valves, etc. Friction units of other types, for which comparatively high sliding velocities and loads are typical, are bearings of propeller shafts in ships, shafts of hydraulic turbines and pumps, etc.

The main materials used in the case of water lubrication are ceramics and carbon and polymeric materials. The review will only consider modern polymeric materials or composites on their base, with the exception of wood or rubbers, which have long been used in water-lubricated bearings and are considered in detail in the literature [6–11].

4.1. Polymeric Antifriction Thermoplastics

The following materials have found the widest application among water-lubricated antifriction thermoplastics: (i) polytetrafluoroethylene (PTFE) and its copolymers of various technical names and commercial brands: Ftorlon-4 and Ftoroplast-4 (Russia); Teflon (the United States); Polyflon (Japan); Algoflon (Italy), Hostaflon (Germany), Fluon (the United Kingdom); (ii) various flexible-chain polyamides (PA): Kapron, Kaprolon, Fenilon (Russia); Nylon, Kaprolan, Nylon-11 (the United States); Rilsan (France); (iii) polyformaldehydes: SFD and STD (Russia); Delrin (the United States); Hostaform (Germany); (iv) polycarbonates: Diflon (RF); Makrolon (Germany); Lexan, Murloc (the United States); Penlite, Upiloc (Japan); (v) polyphenylene oxide: Ariloks (Russia) and Noryl (the United States); and (vi) polyurethanes: Thordon XL, Thordon (Canada), etc.

Polytetrafluoroethylene and its copolymers occupy a particular place among the known antifriction thermoplastics. The low values of its friction coefficient (0.2 to 0.002, depending on the load), high softening point, and the highest water and chemical resistance among all the polymers favored its wide use in friction units. At the same time, PTFE most clearly demonstrates the disadvantages characteristic of antifriction thermoplastics: poor strength and low heat conductivity, tendency toward cold flow, dependence of the friction coefficient on the sliding velocity, high coefficient of linear thermal expansion. Therefore, pure PTFE is comparatively rarely used in bearings, with the exception of cases of contact with corrosive media.

Various brands of filled materials containing PTFE as a matrix, modifier, or filler are manufactured. For example, filled fluoroplastics of KV, 80 FG, 7V2A, and F40G40 brands are used in ship and machine building [12–16].

Polyamides are inferior to fluoroplastics in antifriction properties and heat, water, and chemical resistance, but markedly surpass them in strength, elastic modulus, and feasibility of processing. The main disadvantage of PA, compared with fluoroplastics, is the instability of linear dimensions of bearings in their prolonged operation in water. This instability gives no way of fabricating precision bearings with clearances characteristic of metallic bearings [17–19]. The swelling in water is also typical of materials manufactured by Thordon Co. (Canada), which are used to fabricate bearings for ships and hydraulic turbines [20–23].

Comparison tests of polymers of various classes

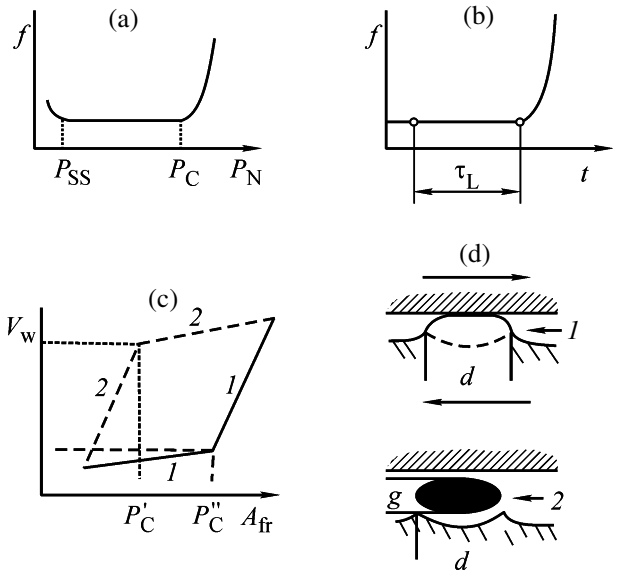

Fig. 3. Some important parameters characterizing the tribological properties of a friction unit and its components [5]. (a) Schematic dependence of the friction coefficient f on the normal contact pressure P_N; the interval of working pressures (from P_{SS} to P_C) throughout which the friction coefficient is permanently low is shown. (P_C) Load-carrying capacity of the friction unit. (b) Schematic dependence of the friction coefficient f on time t in the case of an emergency failure of lubricant supply. (τ_L) Lifetime of a friction unit from the time of termination of lubricant supply till the onset of scuffing, judged from the sharp rise in the friction coefficient. (c) Schematic dependences of the volume wear V_w of a counterbody being tested on the work A_{fr} of the friction force for two modes of variation of this work: (*1*) via an increase in the normal contact force F_N at an invariable friction path L = const and (*2*) via an increase in L at F_N = const. (P'_C, P''_C) Critical pressures corresponding to a change of the friction and wear mechanism. (d) Illustration of the physical meaning of the parameter $Q = I_h H_B/3P_N(d/g)$, the probability that the contact spot *1* will transform into a wear particle 2 upon a relative shift of the counterbodies by a distance equal to the contact spot diameter d. (H_B) Brinell hardness and (g) height of the wear particle.

demonstrate [1, 24–39] that, as a rule, presence of water in a tribocontact reduces the friction coefficient, compared with the case of dry friction, owing to the lubricating action of a water film. For certain polymers (e.g., polyphenylene oxide), the plasticizing effect of water is enhanced in the case of friction, compared with exposure to water without friction, and changes the strength and deformation properties of the surface layers, with the friction coefficient also affected [26]. For polyethylene (PE), the friction coefficient in a sulfuric acid vapor is lower than that in water, because the chemical modification of the PE surface raises the free energy of the polymer by mak-

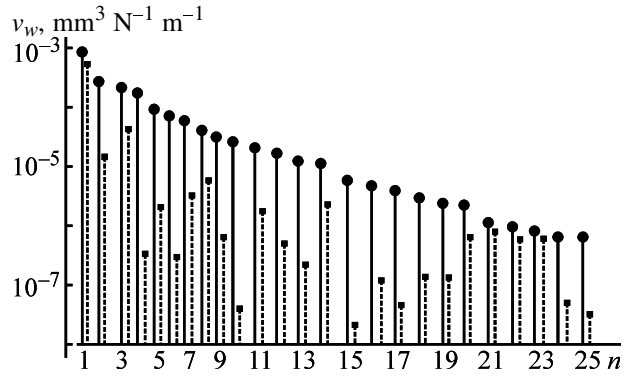

Fig. 4. Wear rate v_W for different materials in the case of lubrication with distilled water (solid lines) and in dry friction (dashed lines) [28]. Counterface, S80 stainless steel; temperature 25°C; friction unit constituted by a finger (truncated cone) moving on a disc (sample). (*n*) Sample number. (1) Polyester-17 449, (2) LY558 epoxy resin, (3) polyphenylene oxide, (4) PTFE + 25% carbon fibers of type I (CFI), (5) PTFE + 25% glass, (6) polyester + 25% CFI + 10% Pb, (7) polyimide + MoS_2, (8) PTFE + 25% mica, (9) polyester + 60% carbon fibers of type II (CFII), (10) polyphenylene oxide + 25% CFI, (11) polyimide, (12) polyacetal, (13) PTFE + bronze + graphite, (14) PTFE + 25% asbestos, (15) epoxy resin + 60% CFI, (16) epoxy resin + 60% CFII, (17) phenol–formaldehyde resin + cotton + PTFE, (18) polyimide + graphite, (19) polyphenylene + 60% CFII, (20) PTFE + 25% coke, (21) polyacetal + 25% glass, (22) PTFE + 25% CFII, (23) polyacetal + 45% CFII, (24) polyphenylene oxide + 25% CFII, and (25) PTFE + CFII + 20% Cu.

ing larger the relative content of the polar component and reduces the surface tension of the fluid [32].

The friction coefficient frequently decreases in the presence of water, compared with the case of dry friction [40, 41]. However, the wear rate of a polymer subjected to friction in water most frequently substantially increases, compared with the case of dry friction [1, 26, 28, 33]. For example, Lancaster [28] demonstrated that this is the case for 29 different polymers and polymeric composites, including composites based on epoxy resins, polyacetals, PTFE, polyesters, polyphenylenes, polyimides, and polyphenylene oxides (Fig. 4). However, this property depends on the type of a filler; at least, PTFE with different fillers may exhibit both a decrease and an increase in the wear resistance [40, 41].

On passing from pure water to seawater and dilute solutions of some salts, all the three cases are possible: the wear rate may decrease, remain unchanged, or increase [27, 28].

A comparative study of the tribotechnical characteristics of a number of polymeric materials (polyvinyl butyral, phenol–formaldehyde resin of the resol type, polyethylene terephthalate, PA 6, high-density PE, and some copolymers) in their friction with steel in water has been carried out [35]. It revealed substantial differences in the dependences of the friction coefficient and wear on load in the range 0.25–2 MPa for different polymers and the fact that the results obtained cannot be described by common dependences. The differences are accounted for by the different adsorption interactions of water with the surface of the polymers and steel.

Presence of ether and hydroxy groups in polymer molecules favors formation of wear-resistant structures, which has been confirmed by a study of wear products [36]. It is noted that the adsorption of water by the surface of PA (in friction) is enhanced as the density of amide groups grows in the order PA-12, PA-5, and PA-46 [37].

The extremely high wear rates of various polymers in water can be hardly understood in terms of a common mechanism, because manifestations of the interaction of water with a friction surface are widely diverse (absorption, adsorption, diffusion, plasticization, chemical reactions) and depend on time, temperature, applied stress, sliding velocity, surface topography of a counterbody, etc. [1, 26, 28]. It has been shown experimentally that, in the case when the tribological properties in dry friction are improved because of the formation of a polymeric transfer film on the counterbody, the wear in friction in water is enhanced because water precludes formation of films of this kind [24, 26, 28, 38, 39]. This is accounted for by the high surface tension of water, which, being adsorbed on the surface of a material, hinders formation of transfer films. Frequently, it is also very difficult to remove water layers from surfaces because of the formation of hydrogen bonds with the atoms of the surface [42]. Water differently interacts with polar and nonpolar surfaces [43], by changing the microhydrodynamics of the fluid in the contact zone.

In the case of friction of steel against polyetheretherketone (PEEK), a semicrystalline thermoplastic with high strength and good mechanical properties, in water, diffusion of water into the surface layer of the polymer enhances wear by making lower the hardness of the surface, although wetting of the polymer in the absence of friction has no effect on the hardness [44]. The friction against polyphenylene sulfide (PPS) under the same conditions leads (because of the formation of FeS and improvement of adhesion) to tribotransfer of a polymeric film onto the surface of steel. If carbon fibers are added to PEEK, and carbon

and glass fibers, to PPS, this improves the wear resistance of the polymer, especially at high contact pressures [45]. In the case of friction against edges of reinforcing fibers, the wear is smaller than that in friction along the fibers. Thus, the result obtained with reinforced polymers depends both on the topography of a friction surface and on parameters of the counterbody [28, 31]. The wear rate of the composite material in water substantially decreases if, e.g., a small amount of an abrasive (0.1% Al_2O_3 particles 3 μm in diameter) is introduced into the material of the surface layer, which can be attributed to the polishing effect [28], although other explanations are also possible. In [39], a positive effect of addition of 10% polyurethane to polyoxymethylene (POM) under conditions of water-drop lubrication was mentioned.

In [46], the influence exerted by the mode of sliding on the wear of cross-linked PE in friction against the same material was noted: in the case of a reciprocating sliding of a finger over a plate, the wear in water is 10 times that in dry friction, whereas in a reciprocating-rotational sliding, the excess is insignificant. In the case of a plane-against-plane friction, the wear also decreases.

In principle, the processes that occur in the friction zone with polymers involved are rather complex and may lead to formation of at all unknown compounds. This has been demonstrated for the example of friction of a number of polymers (PTFE, PA-6, PMMA) against steel in a study of the friction surface of the counterbody and particles formed in wear of the polymers [47]. Therefore, it is exceedingly difficult to fully characterize the effect of water on tribochemical processes in the friction zone.

The aforesaid leads to a rather general conclusion that presence of water in the zone of a tribological contact involving polymeric materials may affect in totally different ways the friction coefficient and wear, compared with the case of dry friction: these parameters may decrease, increase, or remain unchanged, depending on the applied load [48].

Sufficiently strong and stable polymers of the PEEK type, reinforced with carbon fibers [45], or PE with ultrahigh molecular weight [49] can be used for operation in water.

In some cases, application under conditions of water lubrication of composite materials based on polymers widely used in tribology (PTFE) requires a special study of their behavior in an aqueous medium because of the unpredictable effect of water on the components used. For example, it has been found that use of a metallic grid made of stainless steel, combined with powdered graphite, for reinforcement of PTFE reduces the wear by a factor of 300 in the case of dry friction [50], but it is difficult to predict the behavior of a material of this kind in a medium in which water promotes oxidation of the metal, penetrates into the material along phase boundaries thereby changing its properties, and is involved in tribochemical reactions.

In [51], we determined how additions of fullerene black affect the load-carrying capacity of F-4 fluoroplastic in the case of sliding friction with water lubrication. The fullerene black (C–C_{60}) remaining after most of fullerenes were extracted with toluene, i.e., a waste product formed in manufacture of fullerenes, was used in the study. However, this black still contains up to 12% higher fullerenes [52]. Introduction of only 1% black (C–C_{60}) into F-4 fluoroplastic raises its load-carrying capacity by 30%. There are indications that introduction of C_{60} fullerene into Kapron improves its antifriction and antiwear properties in the case of water lubrication [53].

Materials based on F-4 with addition of 1–10% fullerene black were suggested in [54]. In this case, the antifriction and antiwear properties of the materials are improved both in dry friction and in the case of water lubrication.

4.2. Polymeric Antifriction Thermosetting Materials

The strength and rigidity of antifriction materials become several times higher on passing to thermosetting composites reinforced with fabrics, textolites [55].

Phenol–formaldehyde resins have been long used as matrices [1], and cotton cloth or synthetic fabric, as the reinforcing material [56]. Textolites are used to fabricate plain bearings for various machines, e.g., bearings of rolling mills. However, cotton and synthetic fibers strongly swell in water, and, therefore, precision plain bearings fabricated from such textolites are unsuitable for prolonged operation in water because of the dimension instability.

At the same time, the machine-building industry uses a group of large plain bearings, for which elimination of oil lubrication is exceedingly important. These are bearings of propeller shafts and rudders in ships of various classes, floating cranes and drilling rigs, shafts and guide units of hydraulic turbines, unique pumps, etc. The working conditions of the bearings in these devices widely vary. The bearings of ship rudders and units of hydraulic turbines are slow-running (sliding velocities of 0.005 to 0.5 m s^{-1}) and

operate in the unfavorable mode of boundary (or "semidry") friction at high contact pressures of up to 50 MPa (it will be recalled that the contact pressures in most of standard bearings do not exceed 0.25–0.5 MPa). The journal bearings of ship propeller shafts (including those of the stern-shaft type), bearings of turbine shafts, and end seals of turbines and pumps are high-speed (sliding velocities of 12–15 m s^{-1} and up to 40 m s^{-1} for some pumps) and operate in the hydrodynamic friction mode, with the contact pressures being considerable in some cases. For example, the edge contact pressures are 15–20 MPa for stern-shaft bearings. The materials to be used in plain bearings of both groups should satisfy the requirements of a high dimension stability (absence of swelling), shock resistance, and workability.

A group of materials suitable for highly reliable precision plain bearings operating with water lubrication is constituted by carbon-reinforced plastics with a thermosetting matrix.

4.3. Carbon-Reinforced Plastics Based on Thermosetting Matrices

4.3.1. General information. In contrast to all the known fillers of antifriction polymers, carbon fabrics have high strength, elastic modulus, and heat conductivity, do not change their dimensions in water (zero swelling), and the products of dispersion of carbon fabrics, formed in the process of friction, possess properties of a solid lubricant (graphite).

The industry manufactures a wide variety of structural carbon-reinforced plastics on the basis of various binders and reinforcing materials. The dependence of the mechanical and thermal properties of high-strength and high-modulus carbon-reinforced plastics on their chemical composition and reinforcement scheme has been studied [57–62]. However, the structural carbon-reinforced plastics have not been used as antifriction materials and, therefore, their tribotechnical properties have not been analyzed in detail. It was shown in [6, 63–73] that the tribotechnical properties of various classes of carbon-reinforced plastics in friction in water differ by one or two orders of magnitude and the friction coefficient and wear resistance of these materials strongly depend on the structure of the carbon fiber, chemical composition, structure of the polymeric matrix, modifiers, and processing parameters.

In the course of these studies, a relationship between the molecular, topological, and supramolecular structures of the polymeric matrix, on the one hand, and the physicochemical properties of the matrix and the polymeric composite material (PCM), on the other, was established. The results of the studies were used to formulate the criteria to be used in choosing the starting components of the polymeric matrix of PCM [74].

It was found for the first time that the wear resistance of polymers in friction in water depends to the greatest extent on the chemical nature of thermosetting oligomers and curing agents. The highest wear resistance in boundary friction in water is observed for dense-network epoxy polymers containing a strictly specified amount of active "doping" elements: chlorine, nitrogen, phosphorus, and nickel. Contrariwise, presence of titanium leads to a dramatic increase in the extent of wear.

It was shown in a study of friction of a number of epoxy compounds with various counterbodies that the best result in friction in water is obtained in the case of filling with carbon fibers and an Al_2O_3 ceramics as a counterbody [75].

The relationship between the structure of the carbon fiber, direction of reinforcing fibers in fabrics, and properties of PCM was determined. It was shown that the highest wear resistance [linear wear intensity of $(0.3–0.5)\times10^{-9}$ at a boundary friction and contact pressure of 50 MPa] is observed for epoxy carbon-reinforced plastics based on low-modulus carbonized fibers whose structure is constituted by fine disoriented crystallites and a considerable amount of the amorphous phase, which serves as a soft component in friction. An X-ray diffraction analysis of the supramolecular structure of carbon fibers obtained at different temperatures (700–2800°C) and of structural changes in the course of friction revealed a strong dependence of the wear resistance of the carbon-reinforced plastic on the preparation conditions of carbon fibers.

Optical and electron microscopy, X-ray diffraction, and chemical analysis were used to study the processes occurring on the contact surfaces of friction units constituted by a carbon-reinforced plastic and stainless steel, titanium alloy, or bronze. The high wear resistance of carbon-reinforced plastics is due to the successive occurrence of tribohydrolysis, secondary tribopolymerization of the polymeric matrix to give a separating antifriction tribopolymeric layer, chemical modification of the counterbody surface, and changes in the structure of the reinforcing carbon fiber [74].

A set of studies revealed a relationship between the structure and basic properties of carbon-reinforced

plastics based on thermosetting matrices and made it possible to formulate the criteria to be used when choosing the starting components.

(1) The molecular, topological, and supramolecular structure of the thermosetting polymer (matrix) should provide occurrence on the contact surface of tribohydrolysis and secondary tribopolymerization to give a separating antifriction layer (film of a friction polymer), which results in that the rule of a positive gradient of shear resistances along the normal to the contact surface is observed.

(2) Active elements (e.g., chlorine and nitrogen) should be present in the composition of the epoxy oligomer and the curing agent. These elements promote a favorable modification of the counterbody surface, which improves its antiwear properties. Surfactants, e.g., oleic acid should be additionally introduced into the phenol oligomers.

(3) The supramolecular structure of the thermosetting matrix should be microheterogeneous and should contain a molecular-dispersed phase, which can act as a soft structural component in friction.

(4) The glass-transition point of the polymeric matrix should exceed the temperature in the friction contact zone. A polyfunctional epoxy matrix (glass-transition point 180°C) is recommended for heavily loaded slow-running bearings (sliding velocities not exceeding 1.0 m s^{-1}) operating with water lubrication. A modified phenol–formaldehyde matrix is recommended for high-speed bearings (sliding velocities of 1.0 to 40 m s^{-1}).

(5) The reinforcing material should have a high heat conductivity to provide efficient heat removal from the friction zone.

(6) The products of dispersion of the reinforcing material, formed in the process of friction, should have properties of a solid lubricant or acquire these properties in the course of the contact interaction.

(7) The specific surface area of carbon-fiber reinforcing materials should exceed 100–150 $m^2 g^{-1}$ (to facilitate dispersion in the course of friction interaction), and the limiting volume of the sorption space (for water vapor) should be larger than 0.2 $cm^3 g^{-1}$, with a pore radius of gyration less than 0.5–2 nm.

(8) To facilitate orientation of turbostratic crystals in a friction interaction, the crystallite dimensions should be smaller than 3–5 nm and the angle of misorientation of crystallites should not exceed 15–20°.

(9) The binder content in a carbon-reinforced plastic should be no less than 40%.

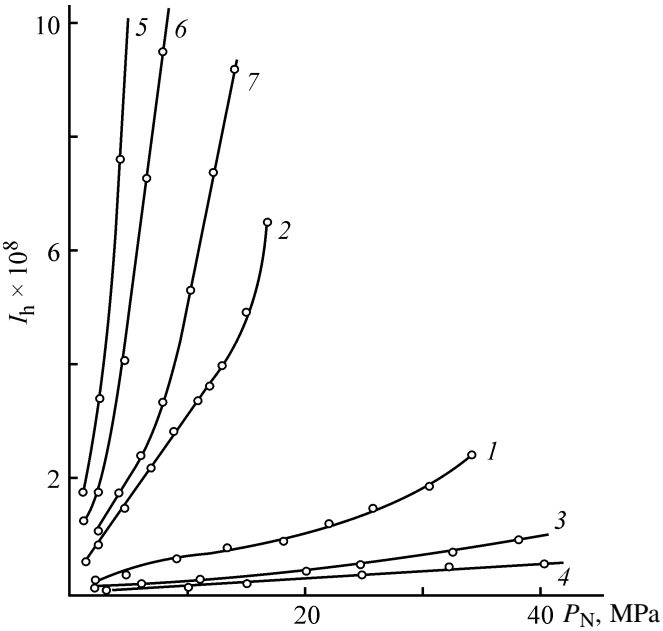

Fig. 5. Linear wear intensity I_h (friction against 18Kh2N4MA hard steel) vs. the contact pressure P_N for various polymer-based materials. Water lubrication, sliding velocity 1 m s^{-1}; the same for Figs. 6 and 8. (*1*) Kaprolon, (*2*) Thordon XL, (*3*) FUT (along direction X), (*4*) UGET (along direction X), (*5*) F-4, (*6*) F-4K20, and (*7*) F-4K20 modified with 1% fullerene black (C–C_{60}).

4.3.2. Tribological properties of carbon-reinforced plastics with phenol–formaldehyde and epoxy matrices. Carbon-reinforced plastics of the UGET and FUT brands [TU (Technical Specifications) 5.966-11704–99] with an epoxy and phenol–formaldehyde matrices, respectively, show a good performance as materials for water-lubricated plain bearings in a wide range of contact pressures [67, 73, 74]. Carbon-fiber fabrics are used as a reinforcing material in these carbon-reinforced plastics. A binder based on a chlorine-containing tetrafunctional oligomer has been used in manufacture of UGET materials [76]. The UGET materials, intended for heavily loaded slow-running plain bearings, are used in friction units of ship rudders, hoisting machines, valves, guide units of hydraulic turbines, etc.

Materials of the FUT type have been produced with an LBS resol phenol–formaldehyde lacquer [77]. The FUT materials are intended for fast-running friction units (1–40 m s^{-1}): journal bearings of ship propeller shafts, end and slit seals in hydraulic turbines, bearings and seals in pumps, etc.

Figures 5 and 6 show the results obtained in tests of carbon-reinforced plastics and, for comparison, data for a number of thermoplastics in friction against steel

Table 2. Selected physical and tribological properties of antifriction polymeric materials used in water-lubricated bearings

Material	Physical properties				Tribological properties			
	ρ, kg m^{-3}	σ_t, MPa	E, GPa	ε, %	P_m, MPa	$I_h \times 10^8$	$I_w \times 10^6$, mm J^{-1}	χ
UGET	1450	250	15	0	60	0.4	1.5	0.11
FUT	1450	150	15	0	35	0.6	5	0.06
Kaprolon B	1150	65	2	5	30	2	29	0.02
Thordon XL	1200	35	0.5	1.3	15	6	210	0.02
F-4	2000	10	0.5	0	7	10	410	0.03
F-4K20	2100	12.5	0.85	0	12	9	140	0.08

Note: (ρ) Density, (σ_t) tensile strength, (E) modulus of elasticity, (ε) change in linear dimensions on keeping in water for a year, (P_m) maximum admissible contact pressure (load-carrying capacity), ($I_h \times 10^8$) linear wear intensity, ($I_w \times 10^6$) energy-related wear intensity, and (χ) friction coefficient for friction against 18Kh2N4MA steel at P_m, water lubrication, and sliding velocity of 1 m s^{-1}.

[78]. Table 2 lists selected parameters characterizing the mechanical properties of the materials and the tribological properties at the maximum admissible pressure at the tribocontact. It can be seen that the strength and elastic properties of the carbon-reinforced plastics severalfold exceed the corresponding parameters of thermoplastics; in addition, carbon-reinforced plastics exhibit dimension stability, no swelling in water, and a coefficient of linear thermal expansion typical of metals. The main advantage of antifriction carbon-reinforced plastics is their high wear resistance at substantial contact pressures. The carbon-reinforced plastics are inferior to thermoplastics in antifriction properties, but many times surpass them in wear resistance.

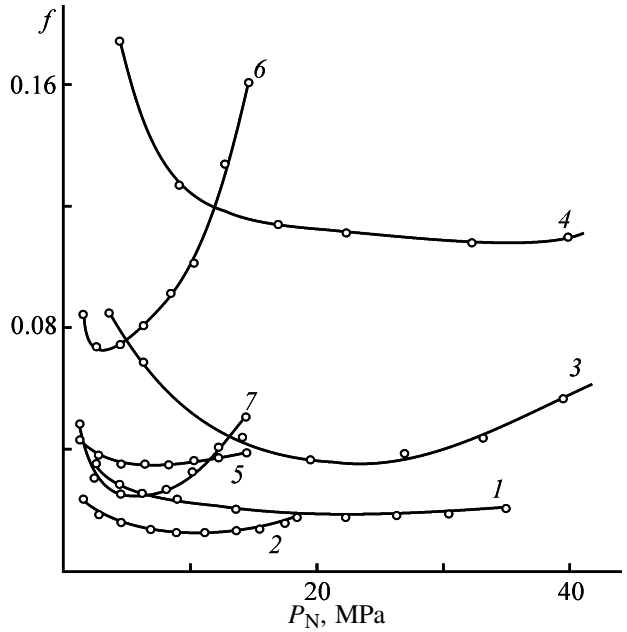

Fig. 6. Friction coefficient f (friction against 18Kh2N4MA hard steel) vs. the contact pressure P_N for various polymer-based materials. (*1*) Kaprolon, (*2*) Thordon XL, (*3*) FUT (along direction *X*), (*4*) UGET (along direction *X*), (*5*) F-4, (*6*) F-4K20, and (*7*) F-4K20 modified with 1% fullerene black (C–C_{60}).

4.3.3. Anisotropy of the physical and tribological properties of antifriction carbon-reinforced plastics. Because of their layered structure (Fig. 7), carbon-reinforced plastics show anisotropy of properties; in addition, the anisotropy is due to the fact that the ratio between the amounts of fibers in the warp and weft of the fabric used is 10 : 8. It is noteworthy that the tensile strength in the transverse direction Z is approximately 20 times lower than that along the fabric layers. The behavior of carbon-reinforced plastics in compression markedly differs from that in tension. In this case, the strength in direction Z exceeds by approximately a factor of 1.5 that in directions X and Y. This fact is rather important, because a material mostly experiences compressive loads in bearings.

The heat conductivity coefficient in directions X and Y exceeds by a factor of approximately 50 that in direction Z, which is accounted for by the pronounced difference in heat conductivity between the matrix and carbon fibers [6]. A similar anisotropy should be observed for other physical properties of carbon-reinforced plastics: thermal diffusivity, electrical conductivity, etc. It was shown in [79] that the linear dimensions of articles made of carbon-reinforced plastics remain virtually unchanged in prolonged operation in water (for 5 years) and their strength and elasticity parameters decrease by no more than 8–10%.

In [80], the anisotropy of the tribological properties of carbon-reinforced plastics was studied for varied composition and nature of binder modifiers and different brands of steel used as a counterbody. The

counterbody was slid along direction *X*, i.e., along fibers of the warp of fabric layers, and along *Z* axis, perpendicularly to these fibers. The tests demonstrated that the anisotropy of the friction coefficient was comparatively low: the coefficient along *Z* axis was only 10–20% higher. The orientation of the sliding direction affects to a greater extent the wear intensity, which decreases by a factor of 1.4–1.6 in friction along *Z* axis (Fig. 8). Apparently, this is due to the following. In wear particle formation and friction along *Z* axis, it is necessary to destroy fibers by shear deformation across the fiber axis (i.e., to rupture intramolecular covalent bonds), whereas in wear along *X* axis, it is necessary either to destroy the considerably less strong matrix or to cleave fibers along their axis (i.e., to rupture intermolecular van der Waals bonds).

4.3.4. Effect of materials of counterbodies on the tribological properties of carbon-reinforced plastics in lubrication with water. When carbon-reinforced plastics are used in water-lubricated friction units, various metals serve as counterbodies. The effect of these metals on the tribological properties of friction units was studied in [81, 82]. The type of a metal affects the friction coefficient comparatively slightly (within 10–25%). However, the load-carrying capacity of a friction pair and the wear intensity of the carbon-reinforced plastic change very noticeably. The best are the friction pairs constituted by FUT and BrO10Ts2 bronze and by UGET and BrO10Ts2. However, bronze is a comparatively expensive metal and is inferior to steels in strength, and, therefore, shafts are commonly made of steel with a bronze facing. The hard alloyed steel 18Kh2N4MA sufficiently well works with both the carbon-reinforced plastics, but this steel is also comparatively expensive and has insufficient workability. The most workable and corrosion-resistant steel is the 08Kh18N10T low-hardness stainless steel, but it satisfactorily works only with the UGET carbon-reinforced plastic. In operation with this steel, the wear intensity of FUT is 2.5–3 times that in operation with the 18Kh2N4MA steel and 8–10 times that in operation with a bronze. The load-carrying capacity of the FUT–08Kh18N10T pair is also lower (<10 MPa).

Seemingly, the pair constituted by UGET and low-hardness stainless steel could be chosen, but this can be done only for friction units with low sliding velocities because of the properties of the carbon-reinforced plastic itself. Thus, an important applied problem arises: a material satisfactorily working in pair with a comparatively inexpensive kind of steel, the most frequently used in water-lubricated friction units, is to be sought for. A possible way to solve this problem is

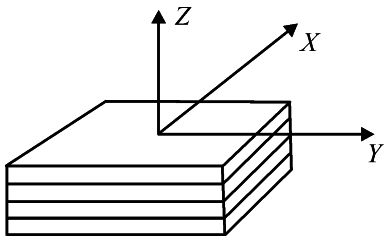

Fig. 7. Schematic structure of a carbon-reinforced plastic. *X*, direction along fibers of the warp of the reinforcing fiber; *Y*, that along fibers of the weft; and *Z*, that perpendicular to the plane of the reinforcing fabric.

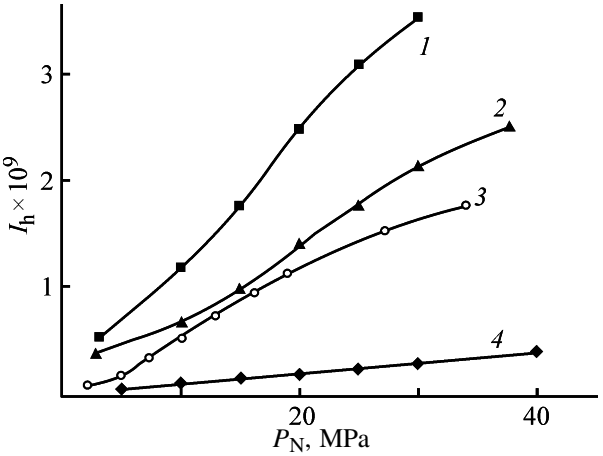

Fig. 8. Linear wear intensity I_h vs. the contact pressure P_N for carbon-reinforced plastics variously oriented with respect to the direction of sliding friction against 18Kh2N4MA steel. (*1*) FUT, along *X* axis; (*2*) FUT, along *Z* axis; (*3*) UGET, along *X* axis; and (*4*) UGET, along *Z* axis.

to modify carbon-reinforced plastics. Another way is to change fundamentally the nature of components of the plastics, both binders and fillers.

4.3.5. Modification of carbon-reinforced plastics with Ftoroplast-4. Ftoroplast-4 (F-4, Russian analog of Teflon) was studied as one of the first antifriction modifiers in the form of a highly dispersed powder. The URAL-T15R carbon fiber used as filler was treated with powders with a particle size of 0.1 μm. The study demonstrated that modified carbon-reinforced plastics have virtually the same strength as the untreated ones. The load-carrying capacity increased by a factor of 2, the linear wear intensity decreased by 20–30%, and the friction coefficient became 15–20% lower [41] in lubrication with water and friction against the 18Kh2N4MA hard steel.

4.3.6. Modification of carbon-reinforced plastics with powdered metals. Introduction of powders of various metals into composites is a widely used procedure. The choice of metals is commonly limited to

their small number, in accordance with the existing concepts of their antifriction and antiwear properties, and is largely governed by the intuition of researchers. In [83] were reported the results obtained in a study of the influence exerted by powdered-metal modifiers (introduced into carbon-reinforced plastics) on the tribological properties of the friction pair constituted by FUT and 08Kh18N10T steel in lubrication with water. The influence exerted by addition of powders of copper (5%), mixture of aluminum and tin (3.5%), nickel (5%), and B-83 babbit was studied. The best results were obtained upon introduction of B-83 babbit into a carbon-reinforced plastic: the load-carrying capacity increased by 15% and the linear wear intensity and friction coefficient decreased by factors of 2–2.5 and 1.2–1.4, respectively. Also noteworthy are the results obtained upon introduction of a nickel powder: at a comparatively small increase in the friction coefficient (by 10–20%), the load-carrying capacity increased by a factor of 1.7 and the linear wear intensity decreased by a factor of 5–7.

Also, the influence exerted by modifiers having the form of a mixture of F-4 and powdered metals was studied. However, the positive effects observed in this case were less significant than those achieved upon introduction of B-83 babbit and nickel.

4.3.7. Modification of carbon-reinforced plastics with fullerene blacks and carbon nanotubes. In [84], we studied how additions of fullerene black or a mixture of various carbon nanotubes to the epoxy binder of carbon-reinforced plastics of the UGET type affect the alignment of mating surfaces and tribological properties of the plastics in sliding friction against 18Kh2N4MA steel and lubrication with water. The antiwear properties are improved to the greatest extent upon introduction into the binder of a minor amount (5%) of carbon nanotubes: The load-carrying capacity of the carbon-reinforced plastic increased (by a factor of 1.4), and the volume wear and linear wear intensity substantially decreased (by a factor of 2–7) at an insignificant decrease in the friction coefficients (by no more than 10%). The introduction of 5% fullerene black into the binder improved the antiwear properties, which consisted in that the range of contact pressures at which a stable low friction coefficient is observed was extended. However, wide use of fullerene black and, especially, nanotubes is hindered by their comparatively high production cost.

CONCLUSIONS

In our opinion, the polymeric materials presently used to fabricate water-lubricated bearings can be conditionally divided into three groups. The first group of materials, intended for lightly loaded bearings (with pressures of up to 10 MPa), is constituted by PTFE-based composites. It is noteworthy that, retaining the low friction coefficients typical of pure F-4, composites based on F-4 and modified with 1% fullerene black acquire a wear resistance characteristic of F-4K20 composite. It should be noted that fullerene black is present in the F-4 matrix as a separate phase, and conglomerates of black particles contain crystallites of C_{60} fullerene and graphite, i.e., the black is dispersed on the supramolecular, rather than molecular level. It may be assumed that the wear resistance of composites formed by F-4 and fullerene black is improved because, in the course of their propagation, microcracks appearing in the course of tests are closed (healed) at fullerene molecules owing to their high electron-acceptor properties, and do not go around fullerene-containing particles as ordinary inclusions. The free chain radicals generated in mechanical degradation of F-4 are covalently bound to fullerene molecules.

The second group of materials, intended for bearings working at medium pressures (up to 20–25 MPa), is constituted by thermoplastics (mainly polyamides, polyurethanes, polyesters, polyformaldehydes, etc.) or composites on their base.

Finally, the third group of materials, intended for heavily loaded bearings working in a wide range of contact pressures (up to 40–45 MPa), is constituted by plastics based on thermosetting matrices and, primarily, carbon-reinforced plastics.

In our opinion, further substantial progress in the improvement of strength parameters of plastics (by a factor of several tens) can be provided by manufacture of fibers (and then fabrics) with high filling with carbon and other nanotubes, with simultaneous reinforcement of matrices with nanoparticles, acceptors of free radicals.

ACKNOWLEDGMENTS

The study was performed in the framework of the scientific program no. 14 (coordinator I.G. Goryacheva) of basic research of the Department of Power Engineering, Machine Building, Mechanics, and Control Processes, Russian Academy of Sciences (Institute of Problems in Machine Science, Russian Academy of Sciences) and scientific program "National Technological Resources," section "Technologies of New Materials" (Prometei Central Research Institute of Structural Materials).

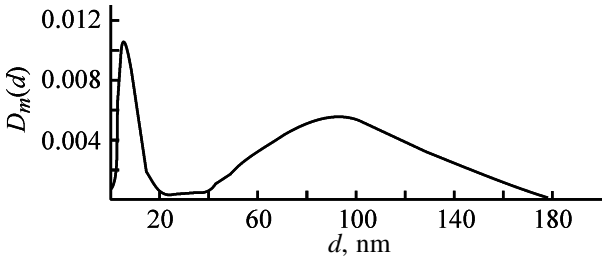
Abstract—Production of ultradisperse copper powders by reduction of various copper salts with *L*-ascorbic acid was studied.

DOI: 10.1134/S1070427206050028

Synthesis and studies of ultradisperse powders (UDPs) of copper and development of electrically conducting formulations based on them is a topical area in modern science and technology. These composite materials find wide application in electronics as components of electrically conducting glues and pastes used in low-temperature soldering of parts of instruments, assembly of integrated circuits and flexible printed-circuit boards.

Previously, methods for production of copper UDP by reduction of copper sulfide with glycerol have been developed and patented [1, 2]. It was shown in [3] that chemical modification of copper UDPs makes it possible to obtain on their basis formulations with enhanced stability (epoxy formulations, more than 10 years; novolac formulations, >6 years) and low electrical resistivity (10^{-6}–10^{-7} Ω m).



It has been shown [4] that reduction of various copper salts with sodium hypophosphite and hypophosphorous acid is performed under milder conditions (reaction temperature <95°C, reaction time 2–35 min), compared to the reduction with glycerol (130–200°C, 15–240 min), and formulations based on the resulting powders show sufficient stability and electrical conductivity. The UDPs obtained under these conditions have particle size of 8–100 nm, with about 45 wt % of particles being less than 30 nm in size. It was shown that, upon introduction of 1-naphthol and glycerol, copper-UDP-based formulations prepared by the hypophosphite method become comparable in stability and electrical conductivity with copper ultradisperse powders prepared by the reduction with glycerol.

It was noted that it is preferable to reduce copper(II) compounds with hypophosphite ions in the water–hexanol system, rather than in an aqueous medium, because hexyl alcohol adsorbed on the surface of UDPs enhances their stability and electrical conductivity via blocking of the surface of copper particles to preclude their oxidation by atmospheric oxygen. It was also shown that additional treatment of copper UDPs with formic acid makes them more stable and electrically conducting.

In this study, we examined the reduction of various copper salts with *L*-ascorbic acid. The choice of *L*-ascorbic acid is based on the fact that the reduction occurs at a low temperature of 25–60°C and does not require any intricate equipment.

The synthesis procedure is based on the reduction of copper sulfate with *L*-ascorbic acid (or with its optical isomer, *D*-erythorbic acid) in an aqueous or aqueous-ammonia medium [5]. The reaction yields an ultradisperse powder of copper and dehydroascorbic acid. The difference was in that aminoacetic acid was used as a complexing agent, in addition to ammonia, and various copper salts were reduced: formate, acetate, nitrate, and basic carbonate.

The resulting ultradisperse powders of copper were washed with water and treated with a 1% solution of hydroquinone in ethanol and stored under a layer of a 0.05% solution of stearic acid in ethanol, as mentioned in [1]. The copper UDPs obtained were used to prepare formulations with SF-010 phenol–formaldehyde novolac resin, with the content of the metallic phase equal to 80 wt %. The effect of various factors

Particle size distribution function for an ultradisperse copper powder prepared by reduction of copper sulfate with *L*-ascorbic acid. [$D_m(d)$] Weight function of particle size distribution and (d) particle size.

on the stability and electrical conductivity of the formulations was analyzed.

EXPERIMENTAL

Copper salts were reduced with *L*-ascorbic acid as follows: An aqueous solution of a copper salt was prepared in one vessel, and an aqueous solution of *L*-ascorbic acid, in another; the latter was neutralized to pH 5.5–6.5 by adding a minor amount of an alkali (NaOH or KOH) and heated to 30–35°C. Then the solution of the reducing agent was added dropwise to the solution of the copper salt under thorough continuous stirring. As a result, a UDP was formed in 3–20 min, depending on the copper salt taken. The UDP was washed with water to neutral reaction of the washing water, treated with solutions of hydroquinone and stearic acid in ethanol, and stored under a layer of a solution of stearic acid in ethanol, as described above. The yield of the metallic phase was 75–90%, depending on conditions.

According to X-ray phase analysis, the UDP obtained contained no impurities of oxides, and the average particle size was 50–55 nm. The figure shows the weight function of particle size distribution for the copper powder produced by reduction of copper sulfate with *L*-ascorbic acid. The distribution was calculated from small-angle X-ray scattering curves. It can be seen that the distribution shows two peaks at 10 and 100 nm. The weight-average size of particles, calculated from the particle size distribution function, is about 52 nm, in agreement with the results of X-ray phase analysis.

To improve the oxidation resistance, all the UDPs were treated with a solution of hydroquinone and stearic acid in ethanol.

The formulations with SF-010 phenol–formaldehyde resin, prepared on the basis of copper UDP, were kept at 140–145°C for 4 h. The stability and electrical conductivity of the copper powders were evaluated by changes in the electrical resistivity ρ of the formulations on their base during tests. The resistance of the formulations was measured in the dc mode (12 V, 2.5 mA) at room temperature (20–25°C).

Owing to their increased dispersity, the copper UDPs obtained were rather active and were easily oxidized in air; therefore, the formulations produced on their base had a rather high resistivity and were unstable in the course of time.

To eliminate these disadvantages, we examined the effect of complexing agents on the reduction of copper sulfate with *L*-ascorbic acid and on the properties of the copper powders obtained. The results obtained are listed in Table 1. As complexing agents served ammonia (sample no. 3) and aminoacetic acid (sample nos. 4, 5). A 1 M solution of ammonia or an aminoacetate buffer solution with pH 9 was introduced into a solution of *L*-ascorbic acid to pH 7. Then the solution of the reducing agent was gradually, under continuous stirring, added to a solution of copper sulfate.

It is known from the literature [6] that introduction of complexing agents shifts the redox potential of the Cu^{2+}/Cu couple to a more negative region. If the difference between the redox potentials of the reducing agent and the metal being reduced is large, a highly dispersed powder may be formed fast, occasionally even instantaneously. If the difference is small, the metal is obtained in the form of a solid layer, which mostly leads to formation of metallic films and coatings. Thus, the properties of the powders obtained can be modified by varying the concentration of the complexing agent. It was noted that, if ammonia is introduced in the amount suggested in [5], a mirror is formed on the vessel walls, which results in that the yield of the copper powder decreases dramatically. In this study, the amount of the complexing agent was chosen so as to preclude formation of a mirror. The optimal amount of the ammonia solution added was that providing pH 6–7. A smaller amount of the complexing agent failed to noticeably improve the stability and the electrical conductivity of the powders. At a higher ammonia concentration, a mirror was formed. The amount of aminoacetic acid was chosen in a similar way.

Table 1 shows that the complexing agents (ammonia and aminoacetic acid) favor a decrease in the specific surface area of the powders and make higher their stability and electrical conductivity, and treat-

Note: (τ_r, T_r) Time and temperature of reduction of copper salts with *L*-ascorbic acid.

ment of the powders with formic acid (sample nos. 2, 5) leads to a considerable increase in their stability and electrical conductivity, compared with the initial samples (nos. 1, 4). This agrees with the results of earlier studies [4].

Apparently, the best parameters are observed for the formulation based on the copper UDP prepared by the reduction of copper sulfate with a solution of aminoacetic acid and additionally treated with formic acid (sample no. 5).

The reduction of various organic (formate, acetate, citrate) and inorganic (sulfate, basic carbonate) salts of copper with *L*-ascorbic acid in an ammonia medium is illustrated in Table 2.

It can be seen that copper formate (sample no. 3) and basic copper carbonate (sample no. 4) are reduced at 25–30°C; copper sulfate (sample no. 1), at 30–40°C; and copper acetate and citrate (sample nos. 2, 5), at 50–60°C. All the formulations have virtually the same electrical resistivity. The most stable formulations were those based on copper sulfate, acetate, and formate (sample nos. 1–3). Therefore, the best results are obtained, as also in the case of reduction with other reducing agents, with copper formate and sulfate.

Thus, use of *L*-ascorbic acid as a copper-reducing agent makes it possible to obtain ultradisperse powders of copper and formulations on their base under milder conditions at low temperatures. These formulations are comparable in their parameters with those produced by reduction with glycerol [1–3] and sodium hypophosphite [4] and can compete with similar materials based on silver [7–9].

CONCLUSIONS

(1) Ultradisperse copper powders were prepared by reduction of various copper salts with *L*-ascorbic acid.

(2) Ultradisperse copper powders obtained in the presence of ammonia and aminoacetic acid as complexing agents possess increased stability and electrical conductivity.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Thermal Stability of Limestone with a Low Iron Content

A. A. Kabanov

Astaf'ev Krasnoyarsk State Pedagogical University, Krasnoyarsk, Russia

Received December 21, 2005

Abstract—The thermal stability of reagent-grade calcite and limestone samples with high and low content of iron compounds was compared. The causes of the revealed differences were discussed.

DOI: 10.1134/S107042720605003X

The properties and thermal stability of limestone with a high content (0.81 wt %) of iron(II, III) as compared to analytically pure grade $CaCO_3 \cdot 0.17H_2O$ have been considered in [1–3]. It was of interest to ascertain how they will change on passing to low iron(II, III) concentrations.

We used limestone from the Slyudyankinskoe deposit (Irkutsk oblast). Its 0.08-nm fraction was sieved after dispersion and kept over P_2O_5 for 10 days. Then the preparation was degassed at 200°C for 6 h and stabilized again by keeping over P_2O_5 for no less than 10 days. The limestone sample thus pretreated was taken as the starting sample.

The quantitative analysis of the samples was carried out according to GOSTs (State Standards) 4530–76 and 5382–91. The X-ray analysis was performed on a DRON-3 diffractometer. The mass spectra were obtained on an MI-1305 ionization spectrometer. Thermal measurements were performed in air on a Q-1500D derivatograph. The Mössbauer spectra were recorded on an electrodynamic spectrometer based on an AI-5006-3M-V100 analyzer in the constant acceleration mode. The spectra were processed on an ES-1022 computer. The ^{57}Co isotope with an activity of 0.5 GBq in a chromium matrix was the γ-radiation source. The kinetic curves of the limestone decomposition were taken at 825 ± 0.5°C with 0.100-g samples using the volumetric analysis. All the methods have been considered in more detail in [1–4].

According to the chemical analysis, limestone contains (wt %): main substance $CaCO_3$ 78.67, Ca (species other than $CaCO_3$) 8.14, Fe 0.02, K + Na 0.13, Si 2.21, Al 0.24, Mg 0.96, S 1.60, and other impurities 8.03. The X-ray phase analysis (Fig. 1) shows that the starting limestone contains $CaCO_3$ in the form of calcite, dolomite $CaMg(CO_3)_2$, calcium oxide, and gypsum $CaSO_4 \cdot 2H_2O$. The concentrations of other crystalline phases, if present, are less than 0.50%. The calculations based on the data of chemical analysis (with due regard to the data of Fig. 1) give the following mineralogical composition of the starting limestone (wt %): calcite $CaCO_3$ 78.67 (probably, with H_2O), CaO (probably, with H_2O) 3.94, gypsum $CaSO_4 \cdot 2H_2O$ 3.83, dolomite $CaMg(CO_3)_2$ 8.60, and the remaining phases 4.96.

The data on the iron minerals were obtained from the Mössbauer spectra of the samples heat-treated at 825°C for 6 days (Fig. 2). It follows from the spectrum that the isomer chemical shift is δE = 0.2 mm s^{-1}. The sensitivity in determining iron by this method is 20–30-fold higher than that of the X-ray phase analysis; to determine the effect of iron(II, III) impurities on the limestone decomposition, it is necessary to take into account the products of decomposition of its compounds at a base temperature of 825°C. The shape and parameters of the spectrum show [5] that the doublet peak in the center belongs to wüstite FeO and diffuse peaks of weak intensity at its edges, to magnetite Fe_3O_4. As a whole, the Mössbauer spectrum (Fig. 2) confirms the low concentration of iron(II, III) in the limestone.

The limestone derivatogram shows that the weight loss in air becomes noticeable starting from 360°C (Fig. 3). The maximal rate of its decomposition is at 868 ± 1°C, and the sample weight gets stabilized at about 889°C. According to the mass-spectrometric data (Fig. 4), the maximal decomposition rate of the limestone in a vacuum of 10^{-6} mm Hg is at 620 ± 1°C. A significant difference between the maximal decomposition rates (at 248°C) in air and in a vacuum is typical for calcite [6].

Three experimental maxima of limestone dehydration rate (Fig. 4) are indicative of the presence of at

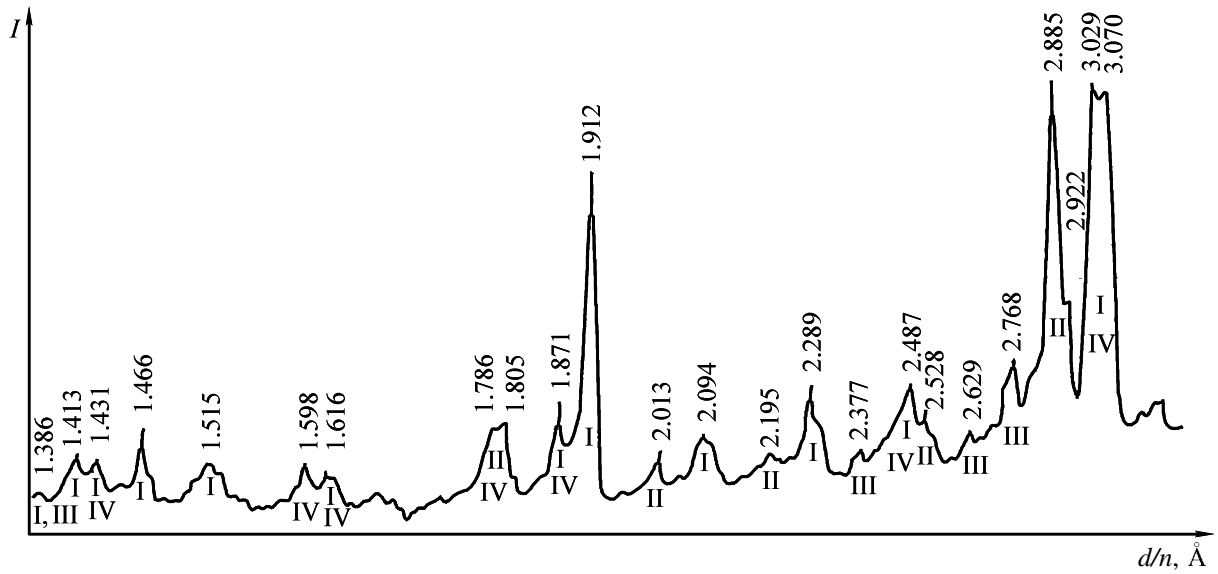

Fig. 1. X-ray diffraction pattern of the starting limestone. (*I*) Absorption intensity and (*d*/*n*) interplanar spacing. (I) $CaCO_3 \cdot 0.03H_2O$, (II) dolomite $CaMg(CO_3)_2$, (III) hydrated oxide $CaO \cdot H_2O$, and (IV) gypsum $CaSO_4 \cdot 2H_2O$.

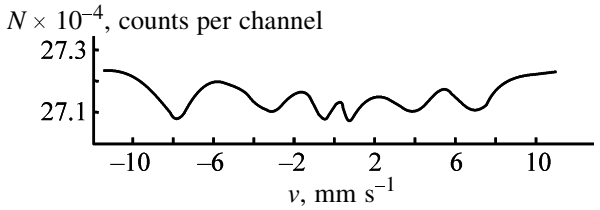

Fig. 2. Mössbauer spectrum of the limestone heated at 825 ± 1°C for 6 h. (*N*) Intensity and (*v*) velocity of the γ-ray source.

least three centers of water localization in limestone. The total concentration of water in the limestone and its fractions in these centers can be calculated from the integral peak intensities (Fig. 4). However, first it was necessary to calibrate these areas with respect to the amount of the released water. For this purpose, we used the thermogravimetric curve (Fig. 3). The range 360–520°C in this curve shows that the limestone weight is lost solely due to H_2O release. At the same time, Fig. 4 shows that the release of water from the limestone occurs starting from 50°C (curve *1*). This

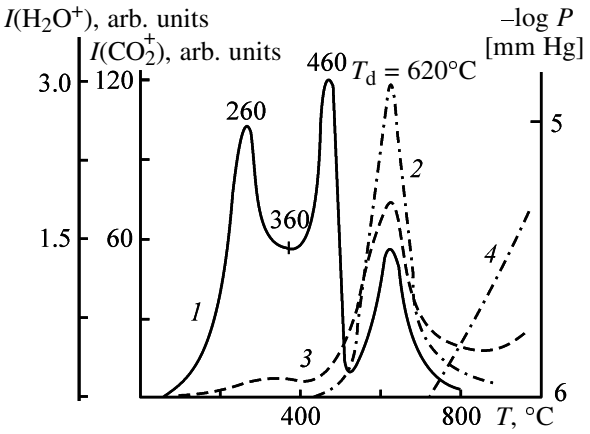

Fig. 4. Mass-spectrometric monitoring of thermal decomposition of the starting limestone. m = 0.01 g, $dT/d\tau$ = 18.0 K min^{-1}, 10^{-6} mm Hg. (*I*) Intensity and (*T*) temperature. (*1*) H_2O, (*2*) CO_2, (*3*) pressure P in the reactor, and (*4*) H_2O signal from the vessel glass.

process is not detected gravimetrically because of lower sensitivity of this method compared to mass spectrometry.

It was taken into account in the calibration that the starting limestone samples lose 3×10^{-3} g of H_2O before 520°C (Fig. 3). This region in Fig. 4 corresponds to the integral of curve *1* taken up to T = 520°C. The part of curve *1* (Fig. 4) from 50 to 360°C corresponds [7–9] to complete dehydration of gypsum $CaSO_4 \cdot 2H_2O$. The X-ray analysis (Fig. 1) and the calculation based on the data of the chemical analysis and mass spectrometry (Fig. 4) confirm this result and lead to a formula of calcium sulfate dihydrate. The 360–550°C portion of curve *1* (Fig. 4) corresponds to the temperature range of the dehydration of $Ca(OH)_2$ [10]. The X-ray diffraction pattern (Fig. 1) and the calculation based on the results of chemical analysis and mass-spectrometric data (Fig. 4) show that $CaO \cdot H_2O$, indeed, is dehydrated in this temperature range. And, finally, the third maximum at 620°C (Fig. 4, curve *1*) corresponds to the dehydration of calcite [1–4, 6]. The calculation leads to the formula $CaCO_3 \cdot 0.03H_2O$. The starting limestone loses this water only in a vacuum of 10^{-6} mm Hg at 800°C, when the decomposition of calcite itself is also complete. As a whole, the gravimetric analysis and mass spectrometry revealed 1.96 wt % H_2O in the starting limestone samples.

The kinetic curves of the analytically pure grade reagent $CaCO_3 \cdot 0.17H_2O$ (curve *1*) and of the limestone samples from the Slyudyankinskoe (curve *2*) and Solomenskoe (curve *3*) deposits are presented in Fig. 5 for comparison. All samples were prepared for the experiment [2–4] by the similar method. The kinetic curve of the limestone from the Slyudyankinskoe deposit (curve *2*) is more similar to that of reagent-grade $CaCO_3 \cdot 0.17H_2O$ than to that of the limestone from the Solomenskoe deposit (curve *3*). The similarity is manifested in the decomposition rate (as seen from the slope of the curves), in the rate of attaining the "intermediate" equilibrium, and, which is the most important, in the diffusion control of the process. This follows from the linearity of the kinetic curve after the first equilibrium is attained and reflects the independence of the decomposition rate from the sample amount.

The fact that the decomposition of the limestone from the Slyudyankinskoe deposit (85%) is complete in a shorter time can be accounted for by the presence in the starting limestone of free CaO and by high concentration of inert impurities (21.37%). They facilitate

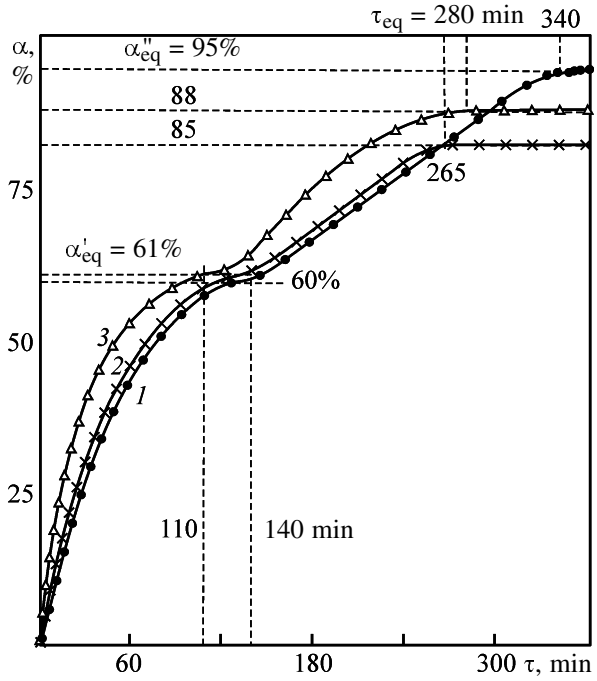

Fig. 5. Kinetic curves of the limestone decomposition at 825 ± 0.5°C. (α) Degree of the sample decomposition, (τ) time, (α'_{eq}, α''_{eq}) degree of decomposition by the moment of reaching the first and the second equilibrium, respectively, and (τ_{eq}) time of attaining the second equilibrium. the formation of a thick protective layer on the calcite particles that have not yet decomposed, or sorb CO_2 released from the calcite. To compare the effects exerted by the impurities of iron compounds and water on the calcite thermal stability, we present the main data on the thermal stability of different calcite samples (see table).

By comparing the data of the table, we can conclude that water bound to calcium carbonate is present not only in reagent-grade $CaCO_3$ but also in natural limestones. It is removed only after the decomposition of all the calcite modifications at 800°C in a vacuum of 10^{-6} mm Hg is complete. The fact that the maximal decomposition rates in a vacuum and in air differ by 245–250°C (see table) is typical for calcium carbonate and limestones. This conclusion was made previously in studying the thermal stability of $CaCO_3$ [6]. Without H_2O bound to $CaCO_3$, the crystalline calcite phase seems to be formed neither in laboratory conditions nor in the nature. This water plays the role of a structure-forming factor. Therefore, the effect exerted by this water on the limestone thermal stability is difficult to evaluate quantitatively. At the same

* Fe denotes total content of iron(II, III); H_2O denotes H_2O concentration after the treatment for 6 h at 200°C in air; T_{min}, temperature corresponding to the endothermic peak in the DTA curve; T_{max}, temperature corresponding to the maximal rate of CO_2 evolution in a vacuum of 10^{-6} mm Hg (mass-spectrometric data); H_2O (in $CaCO_3$), fraction of water directly bound to calcite; τ'_{eq}, time of attaining the first equilibrium at 825 ± 0.5°C.

time, it may be already considered that the higher the concentration of this water, the more stable the limestone. The table shows that iron(II, III) in the form of various compounds is a major impurity decreasing the thermal stability of limestone. This is consistent with the effect exerted by the additions of iron compounds on the thermal stability of reagent-grade $CaCO_3 \cdot 0.17H_2O$ [11].

CONCLUSIONS

(1) The limestone from the Slyudyankinskoe deposit (Irkutsk oblast) contains 21.33 wt % impurities, including 1.96% water, which is not removed by drying of dispersed limestone in air at 200°C for 6 h.

(2) The real composition of the limestone is as follows (wt %): $CaCO_3 \cdot 0.03H_2O$ 79.10, dolomite $CaMg(CO_3)_2$ 8.60, gypsum $CaSO_4 \cdot 2H_2O$ 3.83, hydrated calcium oxide $CaO \cdot H_2O$ 5.20, and other impurities 3.27.

(3) In the thermal stability and thermal decomposition kinetics at 825°C, the limestone from the Slyudyankinskoe deposit is closer to analytically pure grade calcite than to the limestone from the Solomenskoe deposit in which the iron(II, III) concentration is higher by a factor of 40.

(4) The fact that the limestone from the Slyudyankinskoe deposit shows slightly lower thermal stability than reagent-grade $CaCO_3$ can be accounted for by lower (by a factor of 4) content of water bound to $CaCO_3$ and by higher (by a factor of 4) iron(II, III) concentration.

SORPTION AND ION-EXCHANGE PROCESSES

Sorption of Uranium, Radium, and Thorium from Saline Solutions on Hydrolyzed Wood Lignin

Abstract—Sorption of U, Ra, and Th from multicomponent aqueous salt solutions on hydrolyzed wood lignin is studied. The mechanism of radionuclide sorption from saline solutions is suggested on the basis of the results of sequential extraction.

DOI: 10.1134/S1070427206050041

Making decision on a sorbent for deactivation of natural waters is a difficult task. Such a sorbent should meet a series of requirements; the major among them is its ability to tightly fix radionuclides. Because of a great diversity of radionuclide speciation in natural waters, it appears advisable to use polyfunctional sorbents, e.g., hydrolyzed wood lignin. We demonstrated previously [1, 2] that it tightly absorbs Th, U, and Ra from aqueous solutions of various acidities. In this case, Ra and Th are effectively sorbed at pH 3–9, and U, at pH 6–9. Our results showed that the sorption of radionuclides on lignin may proceed by several mechanisms including surface absorption of colloids and pseudocolloids, ion exchange, complexation with ionic species of radionuclides, and formation of strong sorption complexes with organic-bound species. An IR study of the U-loaded sorbent showed for the first time that the interaction of the carboxy and phenolic groups of lignin with uranium occurs as ion exchange between the hydrogen ion and uranyl and its hydrolyzed species, and also by the coordination mechanism with the formation of oxonium complexes.

In this study we examined the capacity of hydrolyzed wood lignin to sorb radionuclides from multicomponent aqueous salt solutions.

EXPERIMENTAL

Working solutions were prepared by adding potassium, calcium, and ammonium nitrates, ammonium dihydrogen phosphate, and magnesium and ammonium sulfates to a solution of dioxouranium nitrate [$UO_2(NO_3)_2$]. The elements were taken in amounts typical of soil solutions in loam podzolic soils [3]. The salinity of the resulting solution amounted to 3.3 mg-equiv l^{-1} (Table 1). The radionuclidic composition corresponded to the natural mixture of isotopes [4]. The initial concentrations of the radionuclides were as follows: Th 1.0 and 10.0 mg l^{-1}, U 1.0 and 10 mg l^{-1}, and Ra 1.19 and 11.90 ng l^{-1}, which is higher by 1–3 orders of magnitude than the maximal permissible concentrations of ^{232}Th, ^{238}U, and ^{226}Ra in potable water [5]. The initial (before sorption) pH of the liquid phase was 6. The sorption experiments were carried out in the static mode at room temperature. Each experiment was replicated three times. In all the experiments, the sorption time was 24 h. The particle size of hydrolyzed lignin was 0.25–0.5 mm. The Komarov's lignin fraction in the sorbent was 82 wt % at the ash content of 6%. Prior to use, weighed portions of hydrolyzed lignin were kept in distilled water for 1 day, to increase its specific surface area. After the sorption, the phases were separated by filtration. The degree of recovery and distribution coefficient were estimated from the metal concentration loss in the liquid phase. The concentrations of Th, U, and Ra were determined by the photometric, luminescence, and emanation methods, respectively [6–8]. The tightness of fixation of the radionuclides on the sorbent was studied by sequential extraction with distilled water and 1 M solutions of CH_3COONH_4 and HCl. The residual radionuclides in the sorbent phase constitute the so-called tightly fixed fraction. The statistical data treatment was carried out by the standard methods [9].

It is well known that the salinity of the liquid phase considerably influences the sorption efficiency [10–12]. Analysis of the published data shows that, in saline solutions, sorption on lignin is a resultant of several processes, whose contribution depends directly on the sorbent and sorbate properties. According the the theoretical concepts [10–12], the suppression of the sorption may be caused by the competition for the active sites on the background of a manyfold excess of alkaline-earth metal and other cations and also by the formation of poorly sorbable species, among them complex ions of the sorbate. Very likely, a decrease in the sorption originates from the salt effect, i.e., an increase in the solubility of precipitates in the presence of electrolytes not containing the same ions [15]. At the same time, in the presence of sufficiently high concentrations of the precipitating ions, in multicomponent systems, some additional precipitation and coprecipitation reactions can occur, as well as coagulation of radio- and pseudocolloids, thus favoring the recovery of radionuclides from the liquid phase. Furthermore, addition of electrolytes into sorption systems containing humus substances increases the association of humic acids and surface tension on the sorbents, thus promoting the physisorption of radionuclides on them [16, 17].

Our results show that the sorption of Th on hydrolyzed lignin is controlled primarily by reactions promoting its absorption (Table 2; Figs. 1a, 1b). The high degree of radionuclide recovery is observed in both the radioactive saline solutions and the solutions without addition of inorganic salts. Depending on the experimental conditions, from 95.2 to 98.9% of Th was sorbed on lignin. Increasing salinity only slightly influenced the sorption tightness (Figs. 1a, 1b). Thus, with and without addition of the mineral salts, the water-soluble and exchangeable fractions of Th in the sorbent phase were small (their total content was within 8.5%). The water-soluble fraction, which is less tightly bound to the sorbent, ranged from 2.3 to 8.4%. With increasing initial radionuclide concentration, the content of this fraction significantly ($p < 0.05$) increases. The exchangeable fraction of Th was smaller by a factor of 10 and more as compared to the water-soluble fraction, and at an initial Th concentration of 1.0 mg l^{-1}, its content was lower than the detection limit. Generally, from 91.5 to 97.0% of Th sorbed from the saline solutions was tightly bound to the sorbent. With increasing salinity, the degree of Th recovery significantly ($p < 0.01$) increased. In this case, from 28 to 41% of the adsorbed Th was very tightly fixed on the sorbent, i.e., was not eluted with reagents commonly used for such a characterization. Comparative analysis of the sorption characteristics shows that introduction of calcium, potassium, ammonium, and magnesium salts into the solution increased the selectivity of Th sorption on lignin in five cases of six. In four cases, the Th distribution coefficient significantly ($p < 0.001$ and 0.05) exceeded the values obtained without addition of the mineral salts. Particularly, at an initial Th concentration of 10.0 mg l^{-1} it increased from 127.5 to 320 ml g^{-1}. Thus, in most cases, with increasing salinity, the Th sorption selectivity significantly increases as well as the tightly fixed fraction, whereas the less tightly bound fractions (soluble in water and ammonium acetate solution) decrease. The sorption from less concentrated Th solutions is characterized by higher distribution coefficients and desorption parameters, all other conditions being equal. It follows from the corresponding chemical equilibrium equations and solubility products that, in our sorption system, highly selective precipitation of Th as a phosphate should occur [SP $Th_3(PO_4)_4 = 2.6 \times 10^{-79}$] [18]. Our estimates show that the initial phosphate concentration in the solution was at least 1.9×10^{-11} M. In our experiments, the Th concentration was 4.3 and 43.0 μM, i.e., the liquid phase contained Th and phosphate in concentrations sufficient for the precipitation of thorium phosphate. However, visually we observed no formation of a precipitate. Most likely, the precipitation is suppressed through stabilization and masking of the Th cations and its hydrolyzed species with some organic com-

pounds [12, 19–21]. Note that the presence of organics is inevitable in weakly acidic solutions in equilibrium with lignin. Our results show that Th is sorbed by the same mechanism from both saline solutions and solutions with no addition of mineral salts. As the dominating mechanisms we suggest the coordination of hydrolyzed Th species to the electron-donor groups of the sorbent and also the adsorption of Th complexes with humus acids, including colloid and pseudocolloid complexes. It may be suggested also that, in saline solutions, these processes are promoted by the solubilization of humus acids associated with the lignin matrix, followed by their coagulation. Less tightly fixed Th species are, presumably, those physisorbed or absorbed through incorporation of Th in the associates formed by the low-molecular-weight fraction of humus matter. In weakly saline solutions (solution no. 2), the increase in the fraction of less tightly bound Th species in the sorbent phase is accompanied by the statistically significant ($p < 0.05$) decrease in the sorption efficiency and selectivity. Most likely, this is due to changes in the surface properties of lignin and also due to the salt effect. In this case, the indicated suppressing effects surpass the contribution of the factors promoting the sorption. In more concentrated saline solutions, the major factor controlling the sorption is thought to be the coagulation.

The sorption of uranium is characterized by small contribution of the ion-exchange mechanism and relatively equal distribution of U between other fractions obtained by sequential extraction (Figs. 1c, 1d). The efficiency and selectivity of U sorption depend on its initial concentration to a larger extent than on the salinity of the liquid phase. The tenfold increase in the U concentration resulted in a statistically significant ($p < 0.001$) decrease in the distribution coefficient from several hundreds to 12–17 ml g^{-1}, which was accompanied by the decrease in the sorption efficiency from 94.5–98.4 to 66–73%. In this case, we observed a change in the fraction distribution of U. The acid-

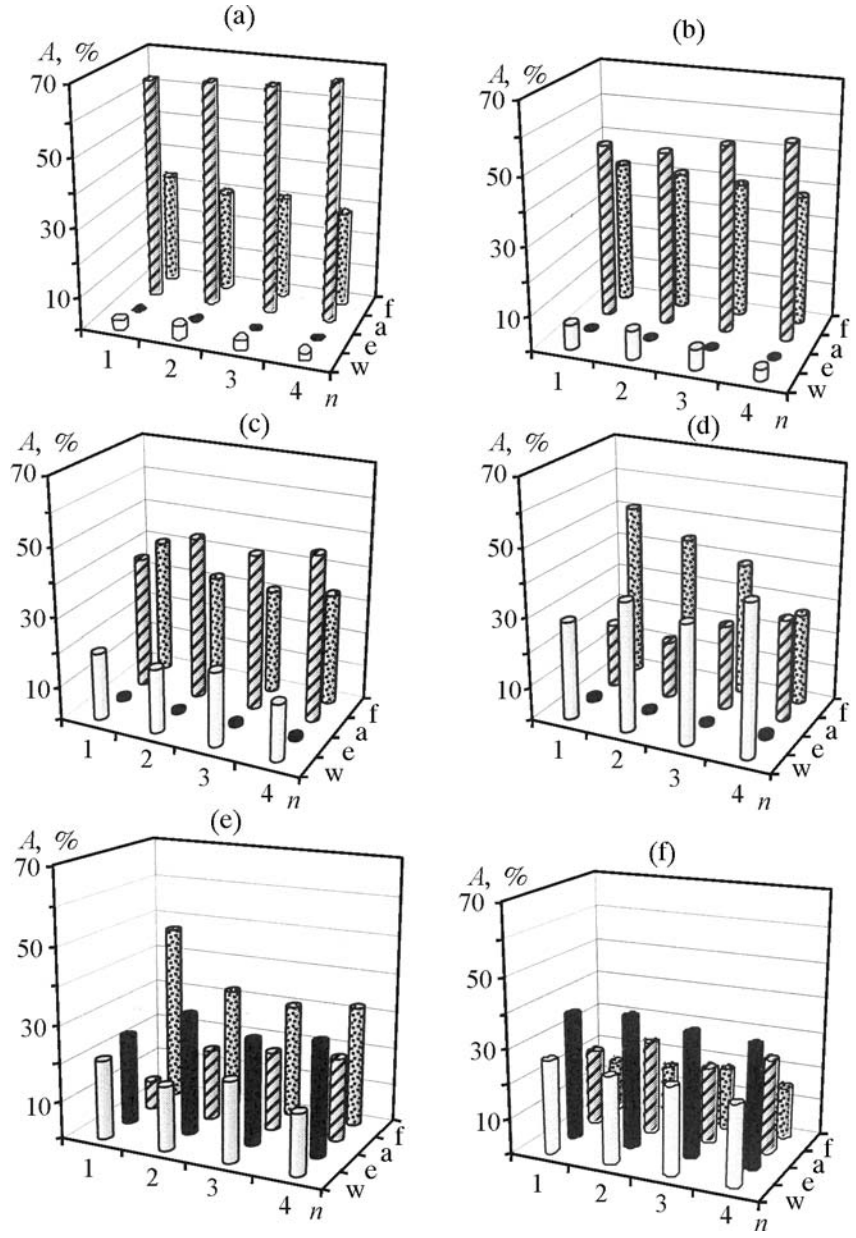

Fig. 1. Fraction distribution of radionuclides in hydrolyzed lignin at various initial radionuclide concentrations. (*A*) Sorption and (*n*) solution number. Fractions: (w) water-soluble, (e) exchangeable, (a) acid-soluble, and (f) tightly fixed. Radionuclide concentration in the liquid phase, mg l^{-1}: Th: (a) 1.0 and (b) 10.0, U: (c) 1.0 and (d) 10.0, Ra (ng l^{-1}): (e) 1.19 and (f) 11.9.

soluble fraction decreased from 39–49 to 17–30%, while the water-soluble fraction increased from 16.8–22 to 29–44%. At the same time, an increase in the salinity of the liquid phase had practically no effect on the sorption, all other conditions being equal. At higher initial concentration of U in the liquid phase, the salt effect was more clearly pronounced. In this case, with increasing salinity, the fixed fraction significantly decreased ($p < 0.05$). These results suggest that the contributions of different sorption mechanisms depend primarily on the initial U speciation in the liquid phase, and only in the second place, on the functionality and other characteristics of lignin. Strong fixation of U is suggested to occur through coordination of its hydrolyzed species to the active electron-donor sites of the sorbent, adsorption of U complexes with humus acids, and precipitation of poorly soluble uranyl phosphates on the lignin surface. A significant contribution of the latter mechanism is supported by both our and published data. For example, in the case

of solution no. 4 (Table 1), after addition of ammonium dihydrogen phosphate, the equilibrium concentrations of the dihydrogen phosphate, hydrogen phosphate, and phosphate ions are estimated to be 0.24×10^{-3}, 1.5×10^{-5}, and 1.9×10^{-11} M, respectively ($K_{disII} = 6.34 \times 10^{-8}$, $K_{disIII} = 1.26 \times 10^{-12}$). It was demonstrated [22] that, in weakly acidic and neutral natural waters with a phosphate concentration above 1 μM, U occurs predominantly in the form of uranyl phosphate complexes. Therefore, in the liquid phase of our sorption system, various uranyl phosphate complexes should be formed, which, competing with the hydrolysis and complexation with humus acids and thus changing the initial U speciation, could significantly alter the sorption mechanisms and parameters. At a U concentration of 10.0 mg l^{-1} (42.0 μM), the solubility products of several phosphate complexes are attained at once (SP $UO_2HPO_4 = 2.11 \times 10^{-11}$, SP $NH_4UO_2PO_4 = 4.36 \times 10^{-27}$, and SP $KUO_2PO_4 = 7.76 \times 10^{-24}$) [11, 18]. We monitored their formation by changes in the color and clarity of the initial uranyl nitrate solutions and also in the U sorption efficiency. With increasing salinity of the uranyl nitrate solution, the water- and acid-soluble fractions of U in the sorbent phase increased. The increase in the former fraction can be attributed to the facilitated physisorption of soluble organic and uranyl phosphate complex ions and compounds. Most likely, the most part of the acid-soluble fraction is composed by the above-mentioned poorly soluble phosphates.

In the solutions with a uranium concentration of 1.0 mg l^{-1}, the salinity level only slightly influenced the sorption capacity of lignin. In this case, not the salt concentration, but the fact itself of the increased salinity of the initial solutions is of the critical importance for the change in the sorption characteristics. The reason could be in some specific reactions not affected drectly by the ionic composition of the liquid phase, but indirectly subjected to its modifying effect. The processes promoting strong fixation of U on lignin are coordination of hydrolyzed uranyl ions to the active electron-donor sites and adsorption of complexes with humus acids. In solutions of higher salinity, these processes are promoted by the coagulation, as demonstrated by a strong tendency of lignin to absorb hydolyzed radionuclide species [11] and also by the clearly pronounced dependence of the U sorption on its initial concentration in the liquid phase.

The sorption on lignin reduced the Ra concentration in the saline solutions by a factor of 3.5–11 (Table 2). The degree of Ra recovery ranged from 79 to 92%, from 37 to 54% of the adsorbed element being tightly fixed on the sorbent. The Ra sorption selectivity increased in the saline solutions, but remained rather low (distribution coefficient ranged from 23 to 150 ml g^{-1}). Generally, the selectivity increased with increased salinity, as demonstrated by five experiments. Statistically significant difference of the selectivity from the reference solution (no addition of mineral salts) was observed in two experiments ($p < 0.05$). In this case, on the one hand, the presence of competing ions stimulated an increase in the selectivity, but on the other hand, the same effect was observed with decreasing salinity level within the experimental range (0.3–3.3 mg-equiv l^{-1}). In the solutions of higher salinity (solution no. 4) with a lower initial radionuclide concentration, we observed significant changes in the fraction composition of the adsorbed species (Fig. 1e, 1f).

The desorption of radium is characterized by relatively uniform distribution of Ra between the fractions obtained by sequential extraction (Figs. 1c, 1d). A considerable amount of Ra was found in the solution obtained after treatment with 1 M ammonium acetate, which is consistent with the alkaline-earth nature of the sorbate, suggesting a significant contribution of sorption by the ion-exchange mechanism. At the same initial Ra concentration, the salinity level only slightly influenced the amounts of the water-soluble and exchangeable fractions in the sorbent phase, demonstrating strong fixation of Ra. At the same time, with increasing Ra concentration, we observed a statistically significant decrease of the tightly fixed fraction from 30–32 to 15–18% ($p < 0.05$). At a Ra concentration of 1.19 ng l^{-1}, with increasing salinity level, the amount of the acid-soluble fraction increased from 7.7 to 19–22% and the tightly fixed fraction decreased from 47 to 30–32%.

Our results show that the selectivity and efficiency of sorption on hydrolyzed wood lignin increase with increasing salinity and decreasing starting radionuclide concentration in the liquid phase. Furthermore, the sorption characteristics could be strongly affected by the mobilization of the native ions from the sorbent into the solution. Previously Khmelinin [23] reported that addition of salts into the liquid phase promotes solubilization of the potassium, sodium, calcium, and magnesium ions from lignin. It is known also that, when the calcium ions and organic substances are simultaneously present in the solution, the degree of Ra recovery with natural sorbents generally increases [24]. In this regard we suggested that the increased efficiency and selectivity of radionuclide sorption from saline solutions is caused by its ion-exchange

reactions stimulated by the solubilization of the native elements from lignin, and also by the occlusion of the radionuclide with formation of colloidal aggregates of humus acid compounds with components of the liquid phase. The observed statistically significant decrease in the degree of recovery ($p < 0.001$) and distribution coefficient ($p < 0.01$) in solution no. 4 with a total salinity of 3.3 mg-equiv l^{-1} and a Ra concentration of 1.19 ng l^{-1} can be attributed to partial degradation of these colloidal structures by virtue of the salt effect.

CONCLUSIONS

(1) In aqueous solutions with a salinity from 0.3 to 3.3 mg-equiv l^{-1}, containing potassium, calcium, and ammonium nitrates, ammonium dihydrogen phosphate, and magnesium and ammonium sulfates, hydrolyzed lignin keeps its sorption capacity with respect to uranium, radium, and thorium. Several mechanisms controlling the sorption characteristics of radionuclides in saline solutions act simultaneously. The sorption of Th is characterized by small amount of water-soluble and exchangeable Th species in the lignin phase, while the sorption of U, by a small amount of the element in the exchangeable fraction and nearly equal distribition between the other fractions. In the case of Ra, the element is practically equally distributed among the fractions different in the tightness of fixation on lignin.

(2) The increase in the salinity level and decrease in the initial Th and Ra concentrations result in increasing degree of recovery and sorption selectivity of the elements, as demonstrated by the increase in their distribution coefficients and in the fraction of tightly fixed radionuclide species. The coagulation of colloid compounds can play a significant role in absorption of Th from saline solutions. The increased Ra sorption efficiency from saline solutions is caused, most likely, by ion-exchange reactions stimulated by the solubilization of the native elements from lignin, and also by the occlusion of the radionuclide with formation of colloidal aggregates of humus acid compounds with components of the liquid phase.

(3) At a fixed U concentration, increasing salinity has no effect on its absorption or results in statistically insignificant changes. With increasing U concentration from 1.0 to 10.0 mg l^{-1}, the distribution coefficient as well as the fraction of tightly fixed U species significantly decrease. Strong fixation of U is suggested to proceed through coordination of its hydrolyzed species to the active electron-donor sites of the sorbent, adsorption of U complexes with humus acids, and precipitation of poorly soluble uranyl phosphates on the lignin surface.

Abstract—The possibility of using anthracite to produce activated carbon in the form of microporous and mesoporous anthracite, a cation exchanger, and composite sorption materials was analyzed and the porometric properties of a variety of sorption materials based on anthracite from the Donets coal basin were studied. A flowsheet for integrated processing of anthracite to give a set of four products was composed.

DOI: 10.1134/S1070427206050053

The intensive development of sorption techniques imposes increasingly stringent requirements to such properties of adsorbents as the sorption capacity determined by their porous structure, content of surface functional groups, and service characteristics associated with purity, abrasion resistance, and cost [1].

A promising application field of carbon adsorbents is storage of gaseous and liquid substances and accumulation of gases, which makes it possible to raise the sorption capacity of a cylinder with an adsorbent and enables its use at lower pressures (≤35 atm) without any decrease in volume [2].

Fossil coals used as one of the main raw materials for production of various carbon adsorbents satisfy these requirements to a considerable extent [3–6].

Among a wide variety of precursors for production of activated carbons, anthracite is one of the best suitable raw materials [7–11].

An important prerequisite for production of adsorbents from anthracite is that the fine fraction produced in coal mining is virtually a waste. Moreover, such grainy starting material does not require any additional grinding; only a necessary fraction is to be selected. All these factors make anthracite fines an inexpensive, readily accessibly, and plentiful raw material for manufacture of high-quality highly porous sorption materials.

The attractiveness of this kind of raw materials is also due to the high content of carbon and low ash content, as well as to the high mechanical strength of the final product, activated carbon.

All the above-mentioned application fields of adsorbents predetermine the necessity for integrated processing of anthracite, which extends the assortment of inexpensive adsorbents, including composite sorption materials [12], which compare well in quality and service characteristics with industrially manufactured activated carbons.

This study is devoted to a search for ways of integrated use of highly metamorphized anthracite in manufacture of sorption materials. Previous publications describe production of a single type of activated carbon in anthracite processing [8–10, 13]. Here we made an attempt to process anthracite to obtain an assortment of adsorbents differing in the pore structure and, consequently, used in different sorption processes. Conversion of anthracite fines into activated carbons is a topical task, because this would allow manufacture of inexpensive mechanically strong adsorbents suitable for a wide variety of applications.

The integrated processing of anthracite into various-purpose carbon adsorbents consists in that technological procedures are carried out successively and in parallel with the aim of the most complete utilization of anthracite.

Integrated use of such a raw material is intimately associated with the most advanced and economical form of organization of the chemical process, combined production [14]. A characteristic example of combining is, in this case, utilization of wastes formed in the main process to organize additional processing of anthracite into disperse powders to be used in manufacture of composite sorption materials [15].

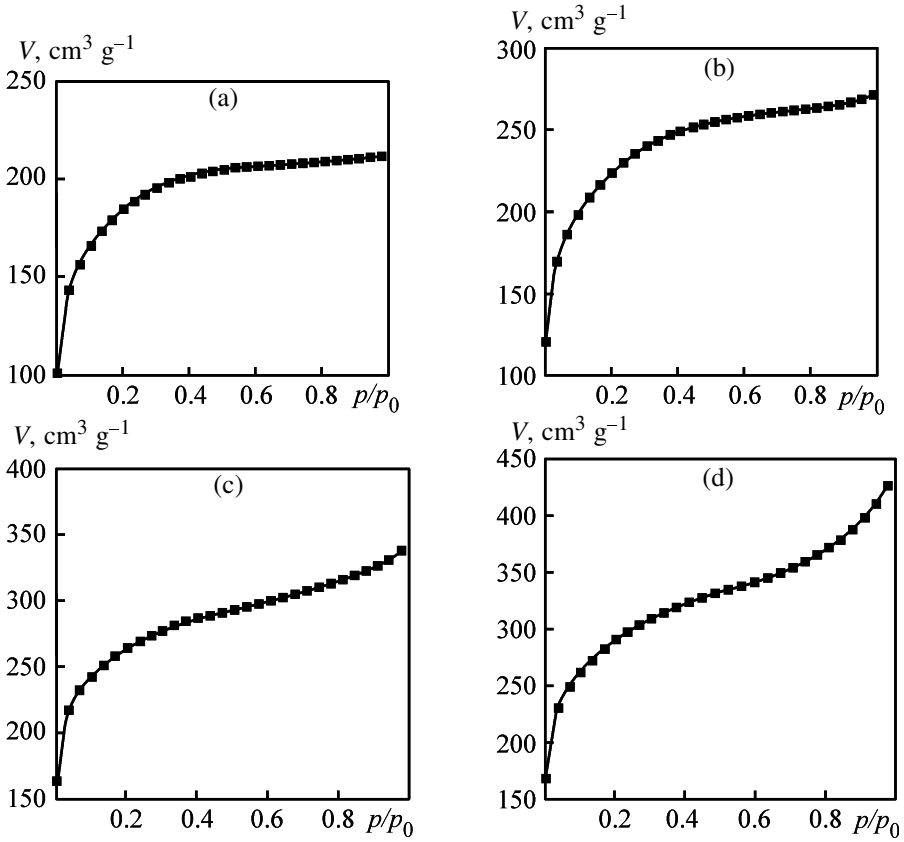

Fig. 1. Adsorption isotherms of sorption materials produced from anthracite. Adsorbent: (a) microporous, (b) cation exchanger, (c) mesoporous, and (d) composite sorbing material. (V) Volume of sorption pores and (p/p_0) relative pressure.

The basic principles to which the authors adhered in designing a scheme for integrated processing of anthracite consist in that the technology developed should be low-waste and power-saving.

Anthracite of brand A from the Donets coal basin (Sverdlovsk, Lugansk oblast, Ukraine) served as the starting material. The content of the main components in the raw material was as follows (%): A^c = 4–5, V^{daf} = 6–7, C^{daf} = 95. The anthracite particle size was 0.5–2.0 mm; initial volume of sorption pores for benzene, less than 0.01 $cm^3\ g^{-1}$; and bulk density, 0.94 $g\ cm^{-3}$.

The starting raw material was subjected to the following kinds of processing:

(i) physical activation with steam to give a microporous adsorbent;

(ii) chemical activation with $NaNO_3$ as a catalytic additive to give a mesoporous adsorbent;

(iii) physical activation with steam, with the subsequent oxidation with air, to give a cation exchanger;

(iv) formation of composite sorbing materials with a novolac resin as a binder.

An important characteristic of sorption materials is their pore structure. Therefore, the study is mainly focused on porosity characteristics of anthracite samples obtained in processing.

The pore structure of the sorption materials obtained was analyzed on the basis of the isotherms of low-temperature adsorption of nitrogen, measured with a Quantachrom Nova 2200 device. The data obtained were used to calculate the BET specific surface area and other porometric characteristics.

The adsorption isotherms of the sorption materials produced from anthracite and studied here are shown in Figs. 1a–1d.

The adsorbent produced by physical activation has a rather developed porous structure with predominance of micropores. The pore structure parameters are given in the table.

Chemical activation with a catalytic additive changes the porous structure of anthracite (Fig. 1b). The adsorption isotherm clearly shows an increase in the fraction of mesopores. This indicates that the pore

Variation of porometric parameters of activated carbons produced from anthracite

Sorbent	Combustion loss ω, %	V_S for C_6H_6, $cm^3\ g^{-1}$	S_{sp} by BET, $m^2\ g^{-1}$	V_{micro}, $cm^3\ g^{-1}$	ΣV, $cm^3\ g^{-1}$	V_{micro}/V_{tot}
Microporous adsorbent	65–70	0.35–0.42	593	0.25	0.33	0.76
Carbon cation exchanger	68–70	0.39–0.40	731	0.27	0.42	0.65
Mesoporous adsorbent	82–85	0.60	831	0.30	0.52	0.58
Composite sorbing materials	45–50	0.54–0.67	936	0.35	0.66	0.53

structure can be varied by selecting the type of activation.

Oxidation of preliminarily activated anthracite with atmospheric oxygen makes it possible to change the pore structure, which is manifested in that the volume of nitrogen absorbed at –196°C increases. Figure 1c shows an absorption isotherm of oxidized anthracite, cation exchanger.

Compounding of activated anthracite with a novolac phenol–formaldehyde resin as a binder yields a sorption material with a highly developed porous structure, with predominance of the mesoporous component (Fig. 1d).

The calculated pore structure parameters are listed in the table.

A set of experiments made it possible to compose a flowsheet for integrated processing of anthracite, which yields an assortment of carbon adsorbents of four brands. A versatile flowsheet is suggested (Fig. 2), according to which one or another type of carbon sorbents can be produced from anthracite, depending on production needs determined by the market demand and availability of raw materials.

The production of an assortment of adsorbents from anthracite fines is described below.

Production of a microporous adsorbent. Ground coal from bunker *1* is fed by mechanical transporter *2* into furnace *3* and is activated in a fluidized bed. Solid particles are separated from the steam-and-gas phase in cyclone *4*. Gaseous reaction products are removed by ventilator to sanitary treatment. The activated carbon produced is discharged from the reaction chamber at 850–875°C into a tubular water-cooled bunker *6*, where it is cooled to 50°C in a continuously moving bed. The resulting activated anthracite is delivered by a transporter *7* to vibrosieve *8* for sieving into fraction. The fine fraction is delivered into receiver *9*, and the coarse fraction, into bunker *11*.

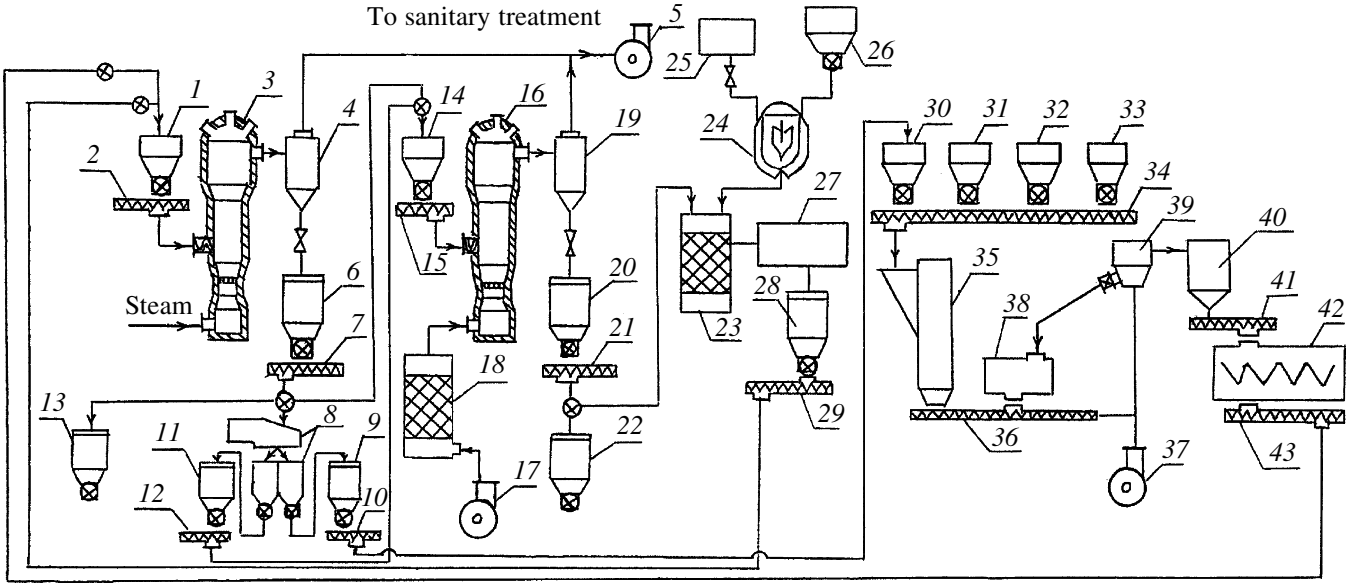

Fig. 2. Flowsheet of integrated processing of anthracite. For comments, see text.

Production of a carbon cation exchanger. After fractionation, a part of the coarse fraction from the final-product receiver *11* (particle size 0.5–2 mm) is delivered by transporter *12* into bunker *14* and then fed by transporter *15* into furnace *16*, where the carbon material is oxidized by humidified air produced by bubbling the air delivered by ventilator *17* through spray column *18*. The oxidation is performed at 350–400°C. Particles carried away from the furnace are caught in the cyclone. The oxidized product, which is a carbon cation exchanger, is discharged from the reaction chamber in a water-cooled tubular bunker *20*, where it is cooled in a moving layer, and then delivered by transporter *21* into finished-product receiver *22*.

Production of mesoporous anthracite. To perform chemical activation, the process is carried out as follows. Anthracite from bunker *1* is charged by transporter *2* into furnace *3* and activated in a fluidized bed to a combustion loss of 30%. The partly activated carbon is discharged from the reaction chamber at 850–875°C into a water-cooled tubular bunker *6* and then delivered by transporter *7* into bunker *14*, after which it is fed by transporter *15* into furnace *16*, where it is subjected to an oxidative treatment at 350–400°C by the procedure described above.

The oxidized anthracite is discharged into bunker *20* and delivered by transporter *21* into impregnating column *23*, into which is poured a sodium nitrate solution prepared in mixer *24* from water delivered from tank *25* and $NaNO_3$ supplied from bunker *26*. The oxidized anthracite is impregnated for 3 h. The chemically modified anthracite is delivered into a drum drier *27* for drying. Then it arrives to a receiver *28* for modified anthracite and is transported by screw conveyer *29* into activating furnace *3* and activated with steam at 850°C. This procedure yields a mesoporous anthracite. The finished product is delivered to vibrosieve *8* to be sieved into fractions. After fractionation, particles less than 0.5 mm in size are fed into bunker *9* for further use in manufacture of composite sorbing materials by the procedure described below.

Production of composite sorbing materials. The fine fraction of activated anthracite (particle size less than 0.5 mm) is delivered from bunker *9* by a pneumatic transporter to the section for manufacture of composite sorbing materials, into bunker *30*. In bunkers *31*, *32*, and *33*, mounted in parallel, are contained, respectively, carbon black, activated fiber, and binder (novolac resin) used for producing composites. To obtain disperse powders of a certain composition, the components are delivered by screw conveyor *34* into mixer *35*, in which the starting components are mixed and particles are preliminarily ground. The ground product is supplied by screw conveyor *36* and an air flow forced by ventilator *37* into a system for an air-flow separation and further into classifier *39*, where the product is separated into two fractions. One of these, with a particle size of less than 100 μm, is returned into vibration mill for grinding. After being ground in the vibration mill, the product is again delivered to the system for air-flow separation, etc. The finely dispersed mixture from cyclone *40* is delivered by screw conveyor *41* to compaction into extruder *42*. The resulting formed material is supplied by transporter *43* into bunker *1*, and then by transporter *2*, into furnace *3*. After activation, the finished product is discharged into cooling bunker *6*, and then by transporter *7*, into bunker *13* for the finished product.

The process presented makes it possible to produce an assortment of four sorption materials in a process with zero waste of raw materials.

CONCLUSIONS

(1) An assortment of sorption materials was produced from anthracite: microporous and mesoporous anthracite, a cation exchanger, and composite sorption materials.

(2) A study of the porometric characteristics of the adsorbents obtained revealed that the resulting activated carbons possess high specific parameters of porosity. The porous structure of the final product can be varied by changing the method used for processing of the starting raw material.

(3) A scheme of the suggested integrated technique for anthracite processing was composed. The scheme makes it possible to obtain an assortment of activated carbons (four brands).

SORPTION AND ION-EXCHANGE PROCESSES

Modified Anthracites as Selective Sorbents for Platinum Metals

Abstract—Methods of preliminary modification were used to obtain activated carbons with low ash content (0.2%), developed π-conjugated electronic system, large surface area, and wide pore size distribution, from exclusively microporous carbons to those of mesoporous type. The adsorption of compounds of platinum-group metals on activated anthracite from single-component (as regards the platinum metal: Pd, Pt, or Rh) and multicomponent (Pd, Pt) solutions containing compounds of concomitant metals was studied.

DOI: 10.1134/S1070427206050065

The capacity of natural coals and other carbon materials for selective sorption concentration of microscopic amounts of platinum-group metals (PGMs) from highly mineralized acid solutions has been established previously [1, 2]. Such a selective recovery of PGMs on activated carbons is primarily due to the interaction of complex ions of platinum metals with the π-conjugated electronic system of the carbon matrix, namely, to formation of a metal–carbon bond, which is considerably less characteristic of ions of concomitant base metals [4, 5], and to spontaneous partial or complete reduction of their ions, caused by the electron-donor properties of activated carbons. This is confirmed by high sorption capacity for PGMs of carbon materials with a minimum content of oxygen-containing surface functional groups, whose presence commonly markedly diminishes the amount of reactive carbon atoms on the surface of activated carbon, weakens their reducing capacity, and hinders access of sorbates to the carbon matrix. In addition, it is known that an increase in the specific surface area of activated carbons also enhances the sorption of PGMs.

The aim of this study was to obtain from available natural carbon raw materials new highly efficient adsorbents with high capacity and selectivity for PGM ions. Anthracite, which has a comparatively low ash content and developed π-electron polyconjugation system owing to specific features of metamorphism [6–8], was chosen for this purpose. To disadvantages of anthracite belong the difficult accessibility of its natural microporosity to gases in the course of activation and the low reactivity of its external surface.

A new combined method of coal preparation has been developed [9–11]. This method is based on preliminary demineralization of the starting coals, oxidative treatment of anthracite, and its subsequent activation. This approach is fairly versatile: variation of the chemical modification conditions makes it possible to control the subsequent activation process and thereby to process anthracite into an activated carbon whose surface and structural characteristics could be varied in a wide range. Particular attention was given to revealing the relationship between the preparation conditions of activated anthracites and their selectivity in sorption recovery and concentration of PGMs from multicomponent salt solutions.

EXPERIMENTAL

Anthracites from Ukraine (Progress mine, Torezantratsit Production Association) and France (La Mure deposit) were chosen for study. The coals were demineralized with a mixture of hydrochloric and hydrofluoric acids, with the result that the ash content of the samples decreased from 4.2 and 5.3% to 0.46 and 0.47% for the Ukrainian and French anthracites, respectively. The chemical modification was performed with perchloric acid or magnesium perchlorate [9–11];

Table 1. Anthracites under study

Table 2. Elemental composition of the initial, demineralized, and chemically modified anthracites after activation

Coal	C	O	H/C	O/C
	wt %			
AU-1	92.1	4.2	0.038	0.045
AU-3	91.9	6.7	0.011	0.073
AF-2	90.6	3.1	0.067	0.034
AF-4	86.3	5.8	0.075	0.067
AF-6	87.6	4.4	0.087	0.050
AF-8	97.6	0.3	0.021	0.003
AF-10	96.7	1.3	0.020	0.013

in so doing, the ash content of the samples decreased to 0.14%. In some of the experiments, coals were thermally treated at 100°C for 10 h in an inert atmosphere for the development of the porosity and activation.

The anthracites were thermally activated by short-time (10-min) heating of the samples to 850°C ("thermal shock") in a flow of CO_2 and then heated for varied time (5 to 72 h) in order to obtain coals with different combustion loss (10 to 70%).

The composition and physicochemical properties (specific surface area, pore volume, presence and nature of functional groups) of the adsorbents obtained were studied by elemental and X-ray diffraction (XRD) analysis, nitrogen adsorption at 77 K (BET), and X-ray photoelectron spectroscopy (XPS).

The coals studied and their designations are listed in Table 1. The elemental compositions of the starting, demineralized, chemically modified, and graphitized carbon samples are listed in Table 2.

Model solutions of PGM chlorides were produced from the commercial chemicals, distilled water, and hydrochloric acid, with the concentrations of Pd(II), Pt(IV), and Rh(III) in the working solutions varied within the range 0.01–0.5 g l^{-1}. The adsorption of PGMs from multicomponent solutions was studied using the initial solutions with fixed concentrations of Pd(I) and Pt(IV), to which excess amounts of chlorides of typical concomitant metals, Fe(II), Co(II), Ni(II), Cu(II), and Cr(III), were added to obtain various Pd(Pt)/M(II) ratios.

The adsorption of Pd(II), Pt(IV), and Rh(III) complexes from aqueous hydrochloric acid solutions on activated carbons was studied by the method of separate weighed portions under standard conditions at the same s : l ratio (m = 0.1 g, V = 10 ml) at 25 ± 1°C. After a virtually constant distribution of metals between the liquid and solid phases was attained (the time in which the equilibrium was established was determined separately and found to be, in most of experiments, 24 h), the coal was separated from the solution.

The concentration of metals in solutions was determined as follows: Pd(II), by the reaction with the thiocyanate ion; Pt(IV) and Rh(III), by the reaction with tin(II) chloride; microscopic amounts of metal compounds in solutions and on carbons after the sorption were found by the atomic-absorption technique and previously developed catalytic methods [12].

The adsorption equilibrium in the systems studied was quantitatively characterized by the sorption capacity A (mg g^{-1}) of a coal and by the degree of PGM recovery (%).

As follows from the data obtained, preliminary chemical modification of anthracite strongly alters the coal structure. For example, treatment of anthracites with perchloric acid or magnesium perchlorate leads not only to a considerable oxidation of the coal surface (Table 3), but also to intercalation of perchlorate ions into the interlayer space. According to XPS data, ClO_4^- ions are presumably located in the interlayer space of coal in the form of perchloric acid or are directly bound to the matrix. In the case of activation of modified samples in a flow of CO_2, ClO_4^- ions are partly removed from anthracite, which promotes additional development of the microporous structure of activated carbons.

Table 3. Composition of functional surface groups for Progress anthracite modified with perchloric acid before and after its activation

AU-2	284.4 (20.7)	285 (50.3)	286.5 (10.6)	287.9 (4.5)	289.3 (3.2)	290.7 (3.4)	531.3 (1.9)	533.3 (3.1)	536.7 (0.5)	–	–
AU-3	284.4 (9.8)	285 (66.0)	286.5 (8.7)	287.9 (2.9)	289.3 (2.6)	290.8 (1.9)	532.2 (3.6)	533.4 (2.6)	535.9 (0.4)	200.6 (0.17)	207.2 (0.05)

The influence exerted by oxidation of coal and its intercalation with $HClO_4$ or $Mg(ClO_4)_2$ on the development of porosity is determined by the nature of anthracite, oxidizing agent, modification conditions (temperature and time of treatment, type and concentration of an oxidizing agent) (Tables 2, 3). The highest degrees of surface oxidation and intercalation of ClO_4^- ions into the interlayer space of anthracites were obtained upon their modification with perchloric acid, whereas treatment of the coal surface with magnesium perchlorate leads to a significant (up to 20–25%) combustion loss because of the "explosive" nature of the reaction between a coal and the oxidizing agent. Treatment of activated carbons with perchloric acid results in that predominantly carboxy and, in lesser amounts, carbonyl and phenol groups appear on its surface (Table 3).

The subsequent activation of modified samples changes the surface "chemistry": the total amount of oxygen-containing groups decreases, the fraction of aromatic carbon increases, and the remaining oxygen passes from a more reactive (in hydroxy groups of aliphatic chains) to a less reactive bound state in aromatic ether bridges (compare the intensity of C1*s* and O1*s* signals in Table 3). Also, the weight fraction of carbon increases because of the partial loss of hydrogen and oxygen, which is due both to a decrease in the number of surface functional groups and to further crystallization of the carbon matrix (Tables 3, 4). Thus, a combination of oxidative chemical modification and subsequent activation does not lead to any noticeable accumulation of surface functional groups.

One more factor of importance in modification of anthracites is that the surface area of the sorbents obtained increases. As can be seen in Table 5, activation of modified starting anthracites makes it possible

Adsorption conditions: 1 M HCl and 0.01 mg ml^{-1} Pd(II); sorvent weighed portion m = 0.1 g; solution volume V = 10 ml; adsorption time 24 h; the same for Figs. 3, 4. (c_{eq}) Equilibrium concentration of Pd(II). (*A*) Adsorption. Anthracite: (*1*) AF-4, (*2*) AF-6, (*3*) AF-10, and (*4*) AF-8; the same for Fig. 3.

to raise, by a factor of at least 1.5 (from 860 to 1430 m^2 g^{-1} for La Mure anthracite), their specific surface area, compared to activated starting anthracites. In pyrolysis of activated carbons, graphitized samples are activated to a considerably lesser extent because of the rearrangement and ordering of the anthracite structure: the surface is developed in 24 h only to 300 m^2 g^{-1}, but in this case, too, treatment

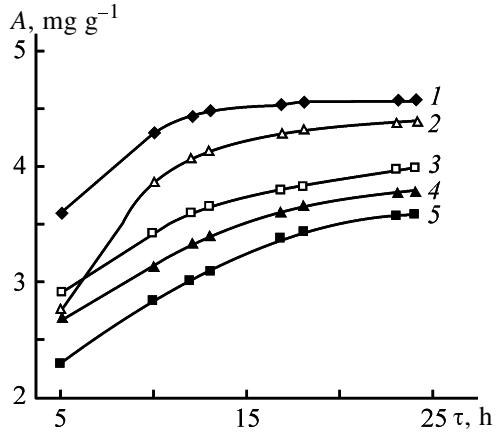

Fig. 3. Effect of the duration of activation of La Mure anthracites τ on the adsorption A of palladium.

with perchloric acid also enhances the reactivity of pyrolyzed samples in the course of activation via oxidation of their surface (Table 5). However, the effect of chemical modification on the activation process is considerably weaker than that in the case of starting anthracites.

The data obtained, combined with the results of previous studies [1–3], suggest that the increase in the specific surface area and total volume of micro- and mesopores in activated carbons as a result of their chemical modification must significantly improve the sorption properties of activated anthracite in recovery of PGMs from aqueous solutions. These suggestions were verified in a study of Pd(II) adsorption on coal samples subjected to various kinds of preliminary treatment and activation for different times.

A study of the kinetics of palladium adsorption on AU-3 (Fig. 1) showed that the kinetic curves tend to level-off in 10–20 h, with more than 90% of microgram amounts of palladium adsorbed on coal. On a modified, but not activated anthracite sample AU-2, virtually complete adsorption of minor amounts of palladium is not reached even in 3 days. This can be attributed to a lesser accessibility of the carbon matrix partly shielded by oxygen-containing SFGs and to a less developed porosity.

Figures 2 and 3 show that the highest sorption capacity of activated carbons for palladium is observed for modified and activated anthracites. The changes in the adsorption of palladium on pyrolyzed anthracite samples also correspond to changes of their surface. For example, comparison of the influence exerted by the surface properties on the sorption capacity of the sorbents obtained (preliminarily modified or graphitized samples) (Fig. 4) shows that, vir-

tually irrespective of the pretreatment conditions (modification with chemical agents or graphitization), the specific surface area is the dominating factor: the larger the surface area, the higher the sorption capacity of activated carbon.

The second factor determining the sorption capacity is the developed π-conjugated electronic system of the coal matrix. Analysis of the data obtained (XPS, XRD) confirms that the most graphitized samples, activated pyrolyzed anthracite not subjected to chemical modification (97.6% C), exhibits the sorption capacity for PGMs comparable with that of less graphitized anthracite modified with magnesium perchlorate and activated (87.6% C) (compare data for a fixed specific surface area in Fig. 4).

Thus, combination of two factors, the developed π-polyconjugated electronic system of the coal matrix and the large surface area of activated carbons, determines the sorption capacity of these materials for PGMs.

In choosing anthracite-based sorbents for practical use, account should be taken of the efficiency of the process of coal preparation as a whole. For example, Figs. 2–4 clearly show that preliminary chemical modification makes markedly shorter the time of activation in production of sorbents with a sufficiently developed surface, and, consequently, with a comparatively high sorption capacity for PGMs: the largest surface area of anthracite modified with perchloric acid can be obtained after 5–7 h of activation, to which also corresponds the highest sorption capacity for palladium. For pyrolyzed anthracite, close values of the sorption capacity for palladium can be obtained upon activation under identical conditions for 24 h.

The following important conclusion can be made on the basis of these results: the adsorption capacity of activated carbon for palladium increases from 10 mg g^{-1} for unmodified activated anthracite to 28–30 mg g^{-1} for coals treated with perchloric acid (Fig. 5).

A comparison of the adsorption behavior of chloride complexes of platinum(IV), palladium(II), and rhodium(III) on AU-3 anthracite samples modified with perchloric acid (Fig. 5) confirmed the previously revealed decrease in the sorption capacity in the order Pd > Pt > Rh [1–3].

Also, we checked the possibility of using the anthracites studied for selective adsorption of microscopic amounts of PGM from multicomponent solutions. The results obtained confirmed that modified anthracites, as well as other carbon sorbents, recover

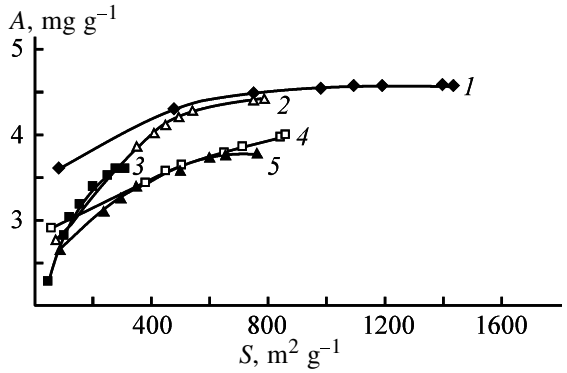

Fig. 4. Adsorption A of palladium vs. the specific surface area S of various samples of activated modified La Mure anthracites. Anthracite: (*1*) AF-4, (*2*) AF-6, (*3*) AF-7, (*4*) AF-2, and (*5*) AF-10.

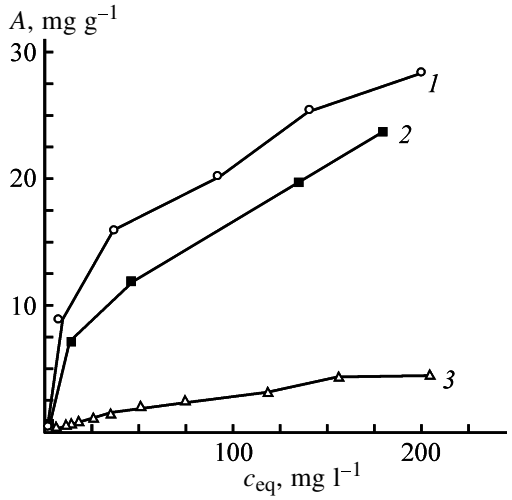

Fig. 5. Isotherms of adsorption of (*1*) palladium, (*2*) platinum, and (*3*) rhodium on Progress anthracite AU-3 activated after modification with perchloric acid. Weighed portion of the sorbent $m = 0.1$ g; solution volume $V = 10$ ml; adsorption time 24 h. (c_{eq}) Equilibrium concentration of PGM. HCl concentration, M: (*1, 2*) 1.0 and (*3*) 0.01.

more than 80–95% of PGMs from solutions containing compounds of other common concomitant metals, as demonstrated for the example of recovery of platinum and palladium (Table 6). The amount of metals adsorbed on coal from solutions containing Pd(II) in the presence of base metals was determined. It was found (Table 7) that the concomitant metals are recovered to a considerably lesser extent than palladium: at the initial Pd : M ratio of 1 : 50, the same ratio on the sorbent does not exceed 1 : 4. The results obtained suggest that the activated carbons under study can be used for concentration of palladium from multicomponent solutions and selective separation of palladium from an excess amount of chromium, nickel, and cobalt.

Table 6. Recovery of Pt(IV) and Pd(II) from multicomponent hydrochloric acid solutions: AU-3; m = 0.1 g; V = 10 ml, 1 M HCl; Pt(IV) 100 μg, Pd(II) 91 μg, sum of chlorides MCl_x of Cu(II), Ni(II), Co(III), Fe(II), Cr(III)

Metal being recovered	Recovered Pt(Pd), %, at indicated Pt(Pd) : MCl_x ratio*			
	1 : 1	1 : 10	1 : 50	1 : 1000
Platinum	92.8	90.6	95.6	85.0
Palladium	85.5	90.5	86.5	77.9

* The Pt(Pd) : MCl_x ratio is the ratio of Pt(Pd) to each metal ion in the mixture of chlorides of the metals indicated.

Table 7. Content of palladium and concomitant metals on activated carbon after sorption of palladium(II) from a multicomponent solution. Adsorbent AU-3, m = 0.1 g; V = 10 ml, 1 M HCl, initial amounts: 200 μg of Pd and 10 mg of each of the concomitant elements

Mixture in solution	Found on coal after sorption		
	μg	% of introduced amount	Pd : M
Pd(II)	142.5 (188*)	71.2 (94*)	
Fe(II)	482	4.82	1 : 3.39
Ni(II)	<18.75	<0.1875	>1 : 0.13
Cu(II)	432.75	4.32	1 : 3.04
Cr(II)	<22.5	<0.225	>1 : 1.58
Co(II)	<10	<0.1	>1 : 0.07

* Burning of activated carbon after sorption can give organometallic compounds of palladium of the type of undeterminable volatile carbonyls; the sorption of palladium, defined as the difference of its amounts in the starting solution and in the filtrate after separation of the adsorbent, is given in parentheses.

CONCLUSIONS

(1) Activated carbons with a developed π-conjugated electronic system, specific surface area of up to 1500 $m^2 g^{-1}$, low ash content (>0.2%), and controlled pore size distribution (from exclusively microporous to mesoporous) were produced by varying the conditions of modification and activation of anthracites. Preliminary chemical modification of anthracites allows a substantial shortening of the time of their activation to give carbon materials with the best adsorption properties with respect to PGMs.

(2) Activated natural anthracites completely recover platinum, palladium, and rhodium in the micro- and milligram range of concentrations from acid aqueous solutions, and platinum and palladium, from solutions with an excess content of concomitant base metals. It was shown for the example of palladium recovery that the main part (>90%) of compounds of concomitant metals remain in the solution after sorption.

(3) It was confirmed that the main factors determining the sorption capacity of carbon materials for PGMs are the developed π-conjugated electronic system of the carbon matrix and the specific surface area. The maximum sorption capacity for palladium may reach values close to 30 mg g^{-1} for anthracites preliminarily treated with perchloric acid.

(4) It was demonstrated that the approach to modification and activation of anthracite, developed in the study, provides synthesis of efficient selective PGM adsorbents from available natural materials.

SORPTION AND ION-EXCHANGE PROCESSES

Ion Exchangers Based on Homo- and Copolymers of Vinyloxyethylamine and Glycidyl Methacrylate

E. E. Ergozhin and K. I. Imanbekov

Bekturov Institute for Chemical Science, Ministry of Education and Science of Kazakhstan Republic, Almaty, Kazakhstan

Received October 4, 2005; in final form, February 2006

Abstract—An efficient method is developed for synthesis of highly permeable ion-exchange resins through the reaction of glycidyl methacrylate with polyvinyloxyethylamine and its copolymers with nitrogen-containing monomers with preservation of the nitrogen functional groups in the latter monomers. The synthesis conditions are optimized, and physicochemical and sorption properties of the resulting polymers are examined.

DOI: 10.1134/S1070427206050077

Polyvinyloxyethylamine (PVOEA, monoethanolamine polyvinyl ether) and its copolymers with 2-methyl-5-vinylpyridine (2M5VP), 4-vinylpyridine (4VP), and *N*-vinylpyrrolidone (NVP), containing reactive and complexing functional groups, represent a particular class of water- and organo-soluble polymers [1, 2]. The presence of the VOEA units with primary amino groups in the structure of such homo- and copolymers provides high reactivity in polycondensation with epoxy compounds (no need in additional hardeners like di- and polyamines), thus allowing maintenance of the complexing capacity of the tertiary nitrogen atom of the pyridine and lactam rings.

In this study we synthesized the polyfunctional ion-exchange resins by the reaction of glycidyl methacrylate (GMA) with VOEA homo- and copolymers containing the pyridine and lactam rings and characterized their properties.

EXPERIMENTAL

Glycidyl methacrylate, VOEA polymers, and its copolymers with *N*-vinylpyrrolidone and vinylpyridines (VOEA–NVP, VOEA–4VP, and VOEA–2M5VP; VOEA : vinylpyridine = 25 : 75 mol/mol) were synthesized by the standard procedures [1–4].

Polycondensation of GMA with homo- and copolymers of VOEA was carried out in DMF in a three-necked flask equipped with a mechanical stirrer, a thermometer, and a dropping funnel. The mixture was stirred with heating to the onset of gelation. Then the gel was transferred into a porcelain bottle and cured at 60–120°C under argon. The subsequent processing of the polymers and their physicochemical characterization were performed by the standard methods [5, 6].

The static sorption of the copper ions was studied by the separate portion method. Potentiometric titration was carried out on an OR-265 digital pH-meter at 25°C. The stock solution was prepared from copper sulfate (analytically pure grade). The ionic strength of the solution (μ) was varied by adding Na_2SO_4. The IR spectra of the as-prepared polymers and metal-containing samples were recorded on UR-20 and Specord spectrophotometers using the KBr technique [7]. The potentiometric titration was performed using the separate portion method [8].

To optimize the synthetic route, we studied the effects of the component ratios and curing temperature and time.

We found that the characteristics of the final products are influenced to a greater extent by the starting reagent concentrations and the nature of VOEA polymers (Table 1). In all cases, the static exchange capacity (SEC) and nitrogen content in the resins increased with increasing concentration of VOEA or its copolymer in the initial mixture. The SEC of the anion exchangers is largely controlled by the nature of the VOEA polymer. The exchange capacity of the polyelectrolytes based on homo- and copolymers of VOEA increased in the order PVOEA < VOEA–4VP < VOEA–2M5VP, which can be attributed to the fact that, among the indicated polyamines, the aliphatic one is the most reactive, allowing protection of the pyridine groups against quaternization in the course of

Table 1. Influence of nature and ratio of starting components on SEC of resulting GMA–polyamine anion exchangers (curing temperature 100°C; 3 h)

VOEA-based polymer	Epoxy : NH_2 initial molar ratio	c_{N_2}, wt %	SEC_{HCl} (0.1 N HCl), mg-equiv g^{-1}

	1.0 : 2.0	8.32	2.95
	1.0 : 3.0	9.18	3.23

Table 2. SEC and nitrogen content in anion-exchange resins obtained at various temperatures (epoxy : NH_2 initial molar ratio 1.0 : 2.0; curing time 3 h)

VOEA-based polymer	T, °C	c_{N_2}, wt %	SEC_{HCl} (0.1 N HCl), mg-equiv g^{-1}
PVOEA	60	8.42	6.00
	80	9.27	6.53
	100	9.30	6.58
VOEA–4VP	60	6.45	4.60
	80	7.60	5.41
	100	8.80	6.20
	120	8.81	6.24
VOEA–2M5VP	60	6.10	4.35
	80	7.40	5.24
	100	8.00	5.70
VOEA–NVP	60	6.65	2.35
	80	7.50	2.60
	100	8.32	2.95

curing. This is demonstrated by the retention of the band of the low-basic pyridine ring at 1554 cm^{-1} and also by the lack of the band of the quaternized heterocycle at 1532 cm^{-1}. In the IR spectra of the polymers, the intensity of the bands of bending (1570 cm^{-1}) and asymmetric (3360 cm^{-1}) and symmetric (3290 cm^{-1}) stretching vibrations of the N–H bond decreases, which is consistent with the reference IR data for the initial linear polymer of VOEA and its copolymers with 4VP and NVP [1, 2], polyvinylpyridines [7], and strongly basic commercial anion-exchange resins VP-1Ap and VP-100 [9].

At the optimal ratio of the starting components, we studied the effect of the curing temperature on the characteristics of the resulting resins. Table 2 shows that, with increasing temperature, SEC increases. The maximal SEC of the resins based on VOEA homopolymer was observed at 80°C, and that of the resins based on VOEA–4VP, VOEA–2M5VP, and VOEA–NVP copolymers, at 100°C. Increase in the curing time at the optimal temperature also improves SEC of the resins (Table 3).

As a measure for the chemical resistance of the resins we used the SEC loss after their treatment with 5 N solutions of sulfuric acid or NaOH for 30 min at 100°C, or with 10% H_2O_2 at 25°C for 24 h (Table 4).

The network polyelectrolytes based on GMA and VOEA homopolymers and copolymers with 4VP and 2M5VP were found to be stable in the indicated aggressive media.

The acid–base and sorption characteristics of the resins were studied by potentiometric titration in the absence (Fig. 1, curves *1, 3*) and in the presence of Cu ions (curves *2, 4*). The titration curves suggest the polyfunctional structure of the resins based on PVOEA and its nitrogen-containing copolymers. The pK_a values estimated by the Henderson–Hasselbach equation are 8.65 and 8.90 for the resins based on PVOEA and VOEA–NVP, respectively. In the presence of Cu ions, the potentiometric titration curves shift toward lower pH values.

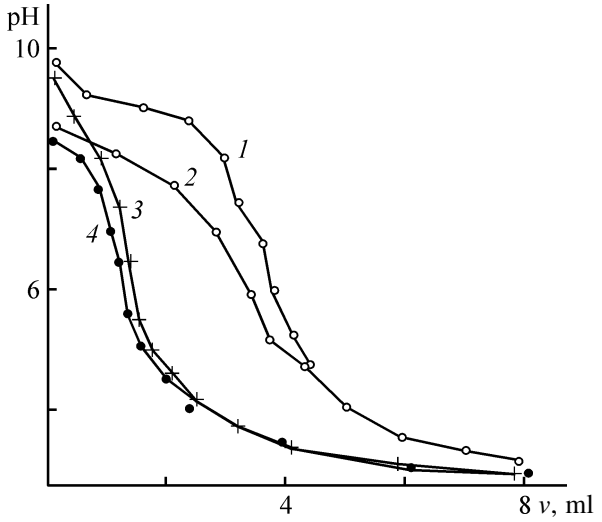
Table 3. SEC and nitrogen content in anion-exchange resins at various curing times τ (epoxy : NH_2 initial molar ratio 1.0 : 2.0; GMA : VOEA–VP = 1.0 : 1.0; curing temperature 100°C)

VOEA-based polymer	τ, h	c_{N_2}, wt %	SEC_{HCl} (0.1 N HCl), mg-equiv g^{-1}
PVOEA	1.0	6.22	4.41
	2.0	9.21	6.55
	3.0	9.30	6.58
	4.0	9.30	6.58
VOEA–4VP	1.0	6.05	4.20
	2.0	8.40	6.00
	3.0	8.80	6.20
	4.0	8.81	6.24
VOEA–NVP	1.0	5.56	1.91
	2.0	6.74	2.38
	3.0	8.32	2.95
	4.0	8.51	3.00

Table 4. Chemical resistance of anion-exchange resins (epoxy : NH_2 initial molar ratio 1.0 : 2.0; GMA : VOEA–VP = 1.0 : 1.0; curing temperature 100°C; 3 h)

VOEA-based polymer	SEC_{HCl} (0.1 N HCl), mg-equiv g^{-1}	Swellability, ml g^{-1}	Chemical resistance with respect to indicated agent, %		
			5 N H_2SO_4	5 N NaOH	10% H_2O_2
PVOEA	9.30	4.50	95	96	91
VOEA–4VP	8.80	4.25	98	97	93
VOEA–2M5VP	8.00	4.20	98	97	94

The IR spectrum of the complex of the PVOEA-based resin with copper shows a low-frequency shift by 60 cm^{-1} of the N–H stretching vibration band at 3300 cm^{-1} and a decrease in the intensity of the C–O–C stretching vibration (1100 cm^{-1}). In the case of the resin based on VOEA–2M5VP, containing Cu ions, the band at 1490 cm^{-1} (pyridine ring) is broadened. Furthermore, all the complexes with Cu(II) demonstrate a decrease in the intensity and a low-frequency shift by 30 cm^{-1} of the stretching vibration band of the carbonyl groups of the GMA polymer and lactam ring.



To conclude, the polycondensation of GMA with homo- and copolymers of VOEA yields novel chelating medium-basic network polymers, which could be used for recovering transition and noble metals.

CONCLUSIONS

(1) The chemical resistance of anion-exchange resins synthesized from glycidyl methacrylate and homo- and copolymers of vinyloxyethylamine in 5 N solutions of sulfuric acid and NaOH is 95–98%, and that in such a strong oxidizing agent as 10% H_2O_2, 91–94%.

(2) The IR spectra of the resins based on the copolymers of vinyloxyethylamine with 2-methyl-5-vinylpyridine and 4-vinylpyridine confirm preservation of the complexing pyridine groups after the reaction with glycidyl methacrylate.

(3) The pK_a values of the resins based on glycidyl methacrylate and the homopolymer of vinyloxyethylamine or vinyloxyethylamine–*N*-vinylpyrrolidone copolymer, estimated by the Henderson–Hasselbach equation, suggest the formation of medium-basic anion exchangers.

Potentiometric titration curves of anion-exchange resins at various concentrations of Cu ions (μ = 1.0): (*1, 2*) PVOEA/GMA and (*3, 4*) VOEA–NVP/GMA. (*v*) Volume of 0.1 N HCl consumed for titration.

SORPTION AND ION-EXCHANGE PROCESSES

Kinetics of Reverse Osmosis Desalination of Aqueous Sodium Sulfanilate

S. I. Lazarev, A. S. Gorbachev, V. A. Shaposhnik, and V. M. Stamov

Tambov State Technical University, Tambov, Russia

Received November 10, 2005; in final form, March 2006

Abstract—Kinetics of reverse osmosis desalination of aqueous sodium sulfanilate is studied on a laboratory pressure filter unit, in relation to the solution concentration, temperature, and pressure in the intermembrane channel.

DOI: 10.1134/S1070427206050089

The goal of this work was to study the membrane methods in desalination of aqueous solutions of low-molecular-weight organic compounds, as applied to intermediate products of organic synthesis and also to wastewaters from chemical and related branches of industry. As a model we used aqueous sodium sulfanilate, since it is a component of many process solutions and wastewaters from production of bleaching agents [1].

The major kinetic characteristics of reverse osmosis separations are the retention factor and transmembrane flux [2–6].

In this study we examined the influence of the process parameters on the kinetics and other performance characteristics of the reverse osmosis. The experiments were carried out in a unit with loop circulation of the solution and a two-compartment pressure filter cell using MGA90T [Vladipor, Vladimir (Russia)] and ESPA (Hydronautic) composite membranes. The flow speed in the intermembrane channel was 0.4 m s^{-1}. The simulated solution was prepared by dissolving dry sodium sulfanilate (98.7%; analytically pure grade) in distilled water. The experimental procedure was described in detail in [7].

Data on the retention factor for MGA-90T and ESPA as influenced by the sodium sulfanilate concentration and temperature are given in Figs. 1 and 2.

The results show that the retention factor is a linear function of the process parameters. It increases with increasing concentration of the organic compound in the solution. The observed high retention factors can be explained taking into account the interrelation between the solubility of the compound and the sorption capacity of the membranes [8]. Since sodium sulfanilate is infinitely soluble in water, water is preferentially sorbed in the pores and on the surface of the membrane, which is confirmed by low distribution coefficient and diffusion-controlled permeability of the membranes.

At the same process parameters, the retention factor is slightly higher for ESPA membrane, which can be attributed to the differences in the structural characteristics and the sign of the charge of the membranes [5, 7, 9].

We found that K decreases with increasing temperature, suggesting the temperature effect on the crystal lattice of the active layer of the membrane.

Analysis of the experimental data reveals that K is strongly influenced by such parameters as the nature and concentration of the solute, pressure in the system, and temperature. Therefore, in this study we made efforts to employ one of the known theoretical models for prediction of the retention factor.

As a basic equation we used that derived in [10] in terms of the convective diffusion model:

$$K = 1 - \{1 + (\gamma - 1)[1 - \exp(\nu h/D_m)]\exp(-\nu\delta/D_0)\}^{-1}, \quad (1)$$

where D_0 and D_m are the diffusion coefficient in the bulk and membrane phase, respectively, which are the functions of the solute concentration and temperature; $k = 1/\gamma$ is the distribution coefficient, which is determined from the sorption data for reverse-osmosis membranes; h, thickness of the membrane; ν, filtration rate; δ, thickness of the laminar sublayer at the mem-

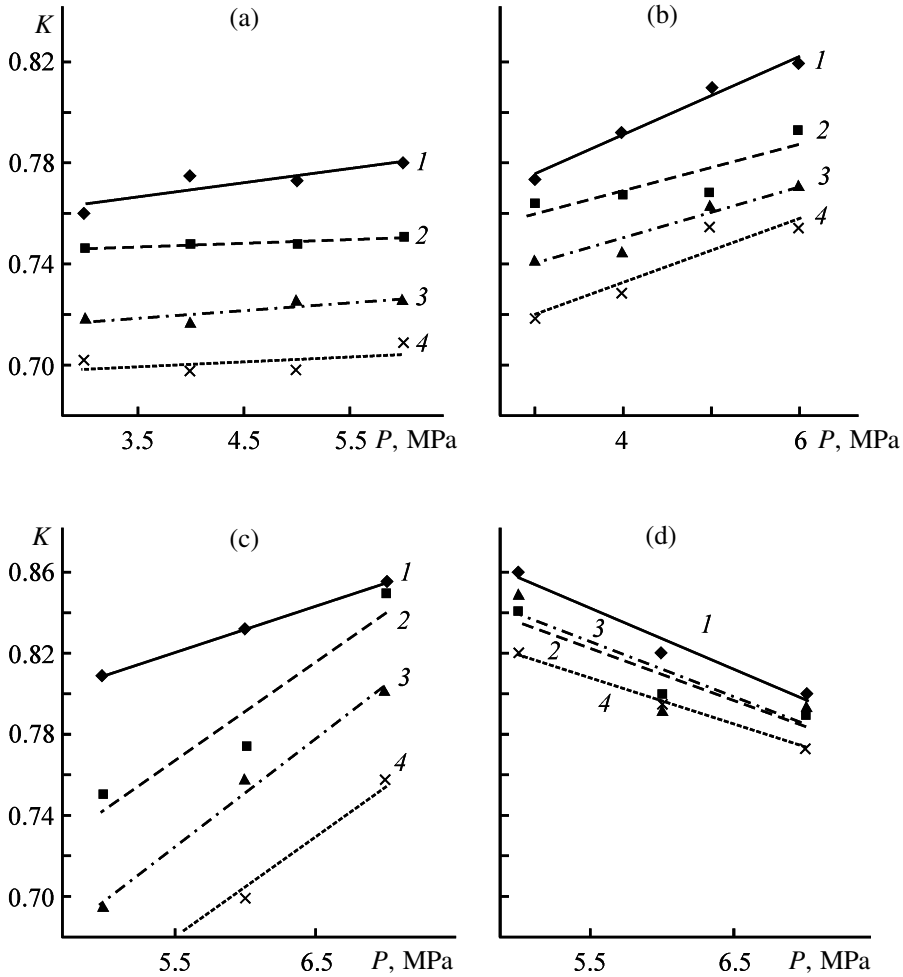

Fig. 1. Retention factor K of sodium sulfanilate on MGA-90T membrane as a function of the pressure P. Initial sodium sulfanilate concentration (g l^{-1}): (a) 10, (b) 50, (c) 200, and (d) 300; the same for Figs. 2–4. brane surface; and γ, parameter characterizing the sorption on the membrane.

After rearrangement, for the investigated system, Eq. (1) takes the form of Eq. (2):

$$K = 1 + \{1 + (1/kk_1 - 1)[1 - \exp(Ghkk_2/P_d)] \times \exp(-G \times 0.00021k_3/D_0w^{1/2})\}^{-1}, \quad (2)$$

where k_1, k_2, and k_3 are the membrane- and solution-specific coefficients; k is the distribution coefficient; P_d, diffusion-controlled permeability coefficient defined as $P_d = D_m k$; G, permeate flux; and w, solution flow speed in the intermembrane channel.

After fitting the experimental data by Eq. (2), we obtained k_1, k_2, and k_3 for the investigated membranes and solutions (Table 1).

The transmembrane flux of the solvent is one of the most important characteristics of reverse osmosis. It characterizes the process efficiency and depends on such system parameters as the kinds of membranes and solutions, solute concentration, temperature, pressure, and hydrodynamic regime of the separating unit.

Let us consider the influence of the solute concentration on the transmembrane flux. The experimental data obtained at various transmembrane pressures are presented in Figs. 3 and 4.

Our results showed that, with increasing sodium sulfanilate concentration, the permeate flux decreases for both types of membranes. This is due to the increase in the osmotic pressure (in accordance with the van't Hoff theory) and the formation of a boundary diffusion (gel) layer (sodium sulfanilate is a low-molecular-weight organic compound with a fairly low mass transfer coefficient), which increases the resistance to the solvent flux. It should be noted also that

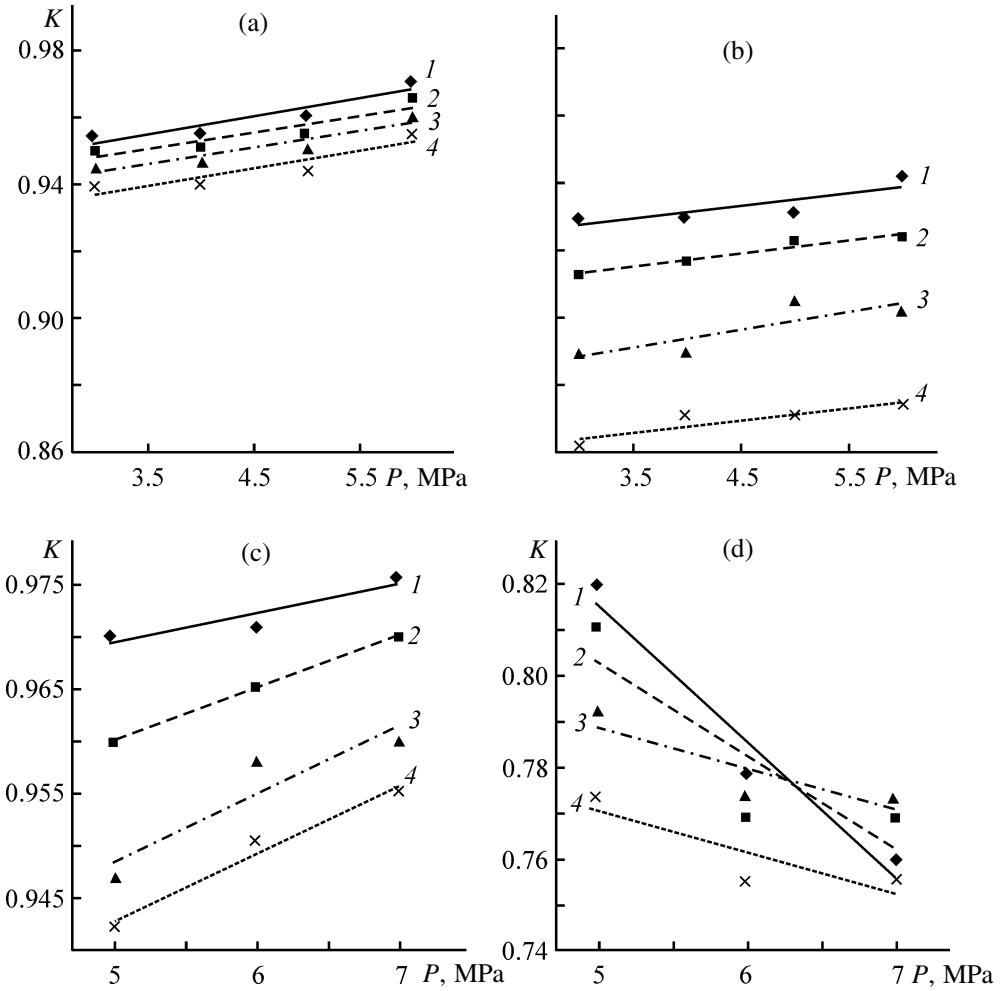

Fig. 2. Retention factor K of sodium sulfanilate on ESPA membrane as a function of the pressure P.

the osmotic pressure increases with increasing solute concentration, thus weakening the driving force of the separation process.

Analysis of the dependence of the water permeability on the transmembrane pressure suggests that the pressure drop on the membrane is the major driving force of the process (parameters increase with increasing pressure).

We found also that the transmembrane flux increases with increasing temperature, suggesting the temperature effect on the crystal structure of the active layer of the membrane. Our results show that the flux depends also on the type of membrane. Thus, the flux across ESPA membrane is slightly higher than that across MGA-90T, all other conditions being equal. This is probably due to the differences in the structure of the active layer [8, 11, 12] and in the nature of interaction of the membrane with the solute and solvent.

Finally, the major factors influencing the transmembrane flux are the working pressure in the system, solution temperature, and solute concentration.

Table 1. Coefficients of Eq. (2) for estimating the retention factor

Membrane	k_1	k_2	k_3
MGA-90T	–3.32485	–3.59228	1.280075
ESPA	–0.18511	–0.03646	0.011113

On the basis of the experimental dependences of the water permeability on the pressure, concentration, and temperature, we derived the following equation for the transmembrane flux:

$$G = k(P - \Delta\pi)c^n (T/T_0)^m, \quad (3)$$

where k, n, and m are the empirical coefficients; T_0 and T, reference (293 K) and working temperature of

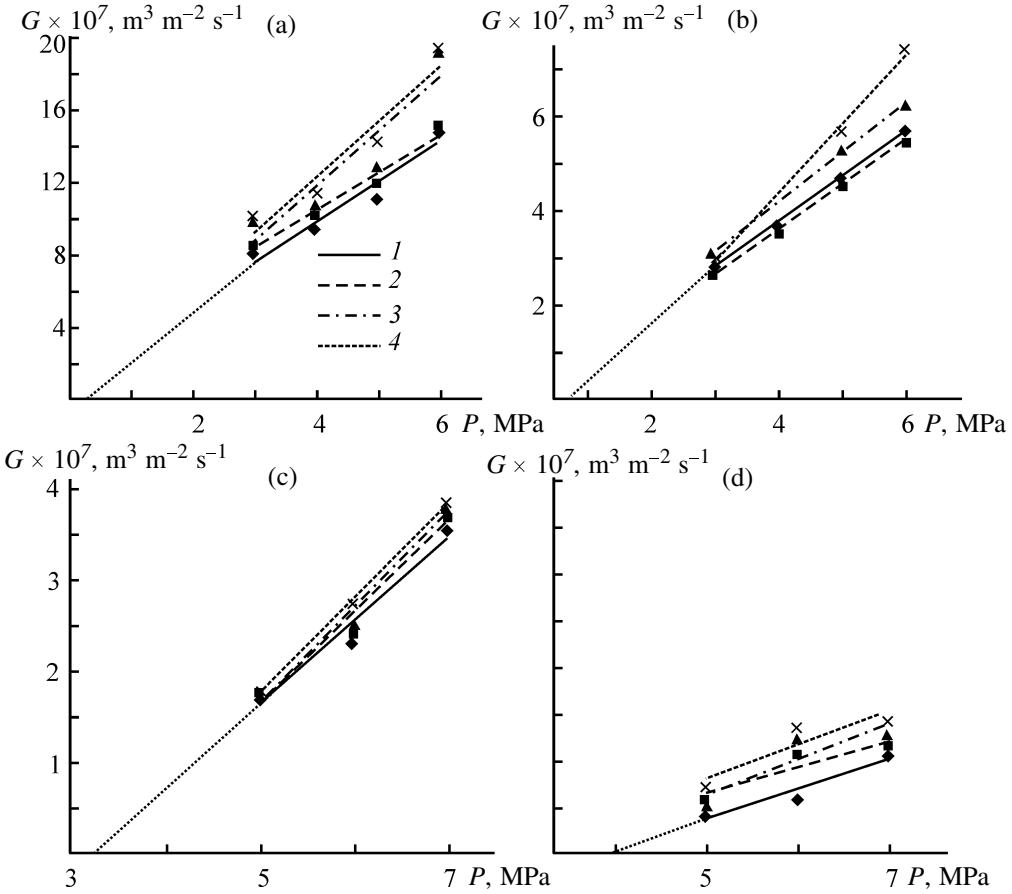

Fig. 3. Transmembrane flux G across MGA-90T membrane as a function of the pressure P.

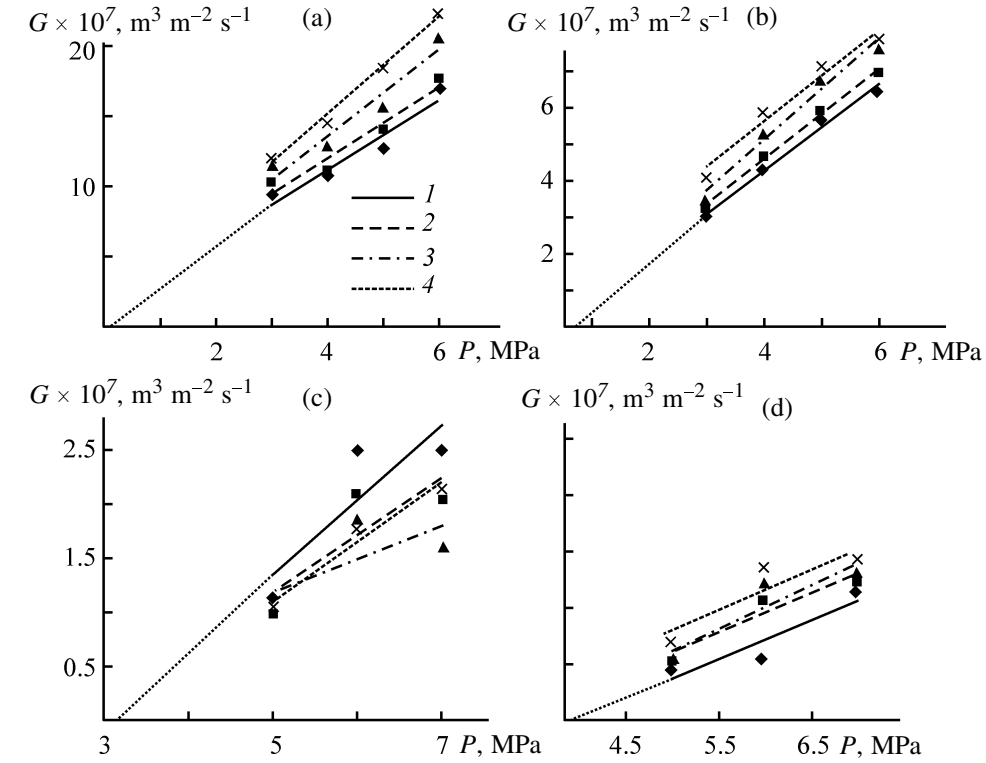

Fig. 4. Transmembrane flux G across ESPA membrane as a function of the pressure P.

Table 2. Coefficients of Eq. (3) for estimating the fluxes

Membrane	$k \times 10^7$	n	m
MGA-90T	5.745294	–0.39065	2.894219
ESPA	8.615161	–40.48844	3.17998

the solution to be separated; and c is the initial solution concentration.

The empirical coefficients are given in Table 2. The experimental and theoretical retention factors and fluxes are consistent to within 15%.

CONCLUSIONS

(1) The effects of the sodium sulfanilate concentration, transmembrane pressure, and solution temperature on the retention factor of MGA-90T and ESPA membranes are studied. The retention factor linearly increases with increasing solute concentration up to 250 g l^{-1} and decreases with increasing temperature. The retention factor is slightly higher for ESPA membrane as compared to MGA-90T.

(2) The transmembrane flux increases with increasing pressure and temperature, which is consistent with the common views, and decreases with increasing solute concentration, as a result of the increase in the osmotic pressure. The flux across ESPA membrane is slightly higher than that across MGA-90T.

Abstract—The effect exerted by the supporting electrolyte and cathode material on the anodic dissolution of niobium in ethanol solutions was studied.

DOI: 10.1134/S1070427206050090

The goal of this study was to develop an electrochemical method for preparing Nb(V) alkoxide. The latter can serve as the starting material for preparation of ultrapure Nb(V) and Nb(V) oxide, which are widely used in various areas of industry.

The anodic dissolution of a metal in the corresponding alcohol in the presence of a supporting electrolyte is one of promising but insufficiently studied methods of preparing transition metal alkoxides. At the same time, in an extensive monograph [1] reviewing in detail the properties and methods of preparation of all the presently available metal alkoxides, the electrochemical method is given the least attention. Alkoxides prepared by the electrochemical method are listed in a review [2], demonstrating the potential of the method.

As a rule, it is recommended to perform the synthesis in a diaphragmless electrolyzer from electrolytes chosen empirically, with as high electrical conduction as possible. The influence of electrolysis conditions on the yield of alkoxides virtually was not studied. The existing views on the mechanism of the alkoxide formation are controversial. According to Lemkuhl et al. [3], who synthesized iron, cobalt, and nickel alkoxides using alkali metal halides as electrolytes, the initial anodic process is the discharge of halide ions. Then, the atomic halogen reacts with a metal of the anode to form the corresponding halide, which is reduced to the alkoxide on the cathode, i.e., the reaction pattern is as follows:

Anode:

$$Hal^- \rightarrow Hal^\bullet + e,\ M + 2Hal^\bullet \rightarrow MHal_2;$$

Cathode:

$$MHal_2 \xrightarrow{+e} [MHal_2]^- \xrightarrow{+e} [MHal_2]^{2-} \xrightarrow{+2HOR} H_2 + 2Hal^- + M(OR)_2. \quad (1)$$

Based on the general views on the possible mechanism of the formation of transition metal alkoxides by the anodic dissolution in alcohol electrolyte solutions, Shreider et al. [4] suggested the following reactions as the most probable:

Anode:

$$M - e \xrightarrow{Hal^- + OR^-} M(OR)_nHal_m\ [+M(OR)_pHal_q\downarrow],$$

Cathode:

$$M(OR)_nHal_m + e \rightarrow M(OR)_nHal_m^{-\bullet} \xrightarrow{-Hal^-} M(OR)_nHal^\bullet_{m-1} \xrightarrow{+ROH,\ -1/2H_2} M(OR)_{n+1}Hal^\bullet_{m-1} \xrightarrow{+e} \ldots \xrightarrow{+ROH,\ -1/2H_2,\ -Hal^-} M(OR)_{n+m}. \quad (2)$$

Contrary to Shreider et al. [4], who ruled out the alcohol dissociation with the formation of RO^- and a proton with its subsequent reduction on the cathode, Bukhtiarov et al. [5] detected by cyclic voltammetry intense hydrogen evolution during the electrolysis of alcohol solutions in aprotic solvents on the cathode made of transition metals. Based on these observations, Bukhtiarov et al. [5] suggested an alternative mechanism of the alkoxide formation, involving ionization of a metal with the formation of the corresponding cations on the anode and decomposition of an al-

cohol molecule accompanied by evolution of hydrogen and formation of the RO^- anion on the cathode. In the bulk of a solution, alkoxide anions react with the metal cations to form alkoxide. The reaction pattern can be presented as follows:

$$\text{Anode: } M^0 \rightarrow M^{2+} + 2e,$$

$$\text{Cathode: } ROH + e \rightarrow OR^- + 1/2H_2,$$

$$\text{In solution bulk: } M^{2+} + 2RO \rightarrow M(OR)_2. \quad (3)$$

Thus, with rather scarce and controversial data available on the electrochemical formation of transition metal alkoxides, we started a systematic study of this process with niobium ethylate as example. Shreider [4] obtained for the first time niobium ethylate by the electrochemical method involving electrolysis of an ethanol solution of triethylamine hydrobromide with a platinum cathode and a niobium anode. Niobium pentaethoxide was isolated and identified, but the Shreider's experiment is the only example of niobium alkoxide electrosynthesis described in detail in the literature.

This study is the first step of the investigation of the electrochemical synthesis of niobium alkoxide; we examined the anodic dissolution of niobium in an ethanol solution of various electrolytes.

EXPERIMENTAL

According to the published data, alkoxide synthesis is a moisture-sensitive process. Therefore, particular attention was given to the ethanol drying. After performing a number of the experiments, we used in the study the following method.

Water was preliminarily separated from ethanol by distillation of a ternary azeotrope with benzene [6]. Then the solution was treated with sodium metal and diethyl oxalate. After distillation, the ethanol fraction (boiling point point 78.2–78.3°C) contained 0.03–0.05 wt % H_2O. The content of water in the alcohol was determined by Fischer titration.

As supporting electrolytes were used chemically pure grade salts. Tetraethylammonium acetate was prepared by mixing an aqueous solution of tetraethylammonium hydroxide with an excess amount of dilute acetic acid. After that, the solution was evaporated to dryness and the residue was dried at 100–120°C/5 mm Hg.

The experiments were performed in a diaphragmless electrolyzer in the form of a 90 cm^3 glass cylinder equipped with a temperature-control jacket and a magnetic stirrer. The electrolyzer was hermetically closed with a lid, in which a thermometer, an outlet pipe with a calcium chloride tube, and electrode current leads were inserted. A flat niobium anode was arranged between the two cathodes.

The niobium anode (working area 8 cm^2) was made of an Nb-1 niobium sheet [GOST (State Standard) 16099–80], and the cathodes (working area 18 cm^2), of a 1-mm platinum wire. Prior to the electrolysis, the electrodes were weighed after trimming and degreasing with Vienna lime. After the experiment was complete, the solution was removed for further treatment. The weight of the dissolved metal was determined from the weight loss of the anode.

The product was isolated by fractional distillation. First alcohol was distilled off, and then niobium pentaethoxide, a light-yellow liquid, was distilled in a vacuum (boiling point 165°C/1.5 mm Hg).

The current–voltage dependences were measured on an IPC-2000 electronic potentiostat and processed on a computer. For the measurements we used a 45 cm^3 diaphragmless cell equipped with a temperature-control jacket. The electrodes and an outlet rube were inserted into the cell lid. The electrode system consisted of a stationary working electrode made of the corresponding metal (working area 0.5 cm^2), a platinum auxiliary electrode, and a silver chloride reference electrode.

To measure the anodic curve, the cell was charged with an electrolyte solution of the required concentration and was purged with dry argon through the outlet tube for 0.5 h. Then, the trimmed electrode was set into the cell preheated to the required temperature and was polarized by the prescribed program.

To record the cathodic curves in the presence of niobium ethoxide, the electrodes were withdrawn and trimmed prior to each measurement, and niobium ethoxide was added to the electrolyte just before the measurement. The current–voltage curves were processed on a computer.

Niobium forms penta-, tetra-, and trialkoxy compounds [1], i.e., it may exist in the penta-, tetra-, or trivalent state. With lithium chloride, lithium *p*-toluenesulfonate, triethylamine hydrohalides, or tetraethylammonium quaternary salts in ethanol as electrolytes, the niobium anode dissolves with the formation of a Nb(V) compound. This is confirmed by calculation of the current efficiency and by the lack of solution coloration typical for Nb(III) and Nb(IV) alkoxides [1]. At the same time, it was shown experimentally [1] that, at a cathodic current density from 0.01 to

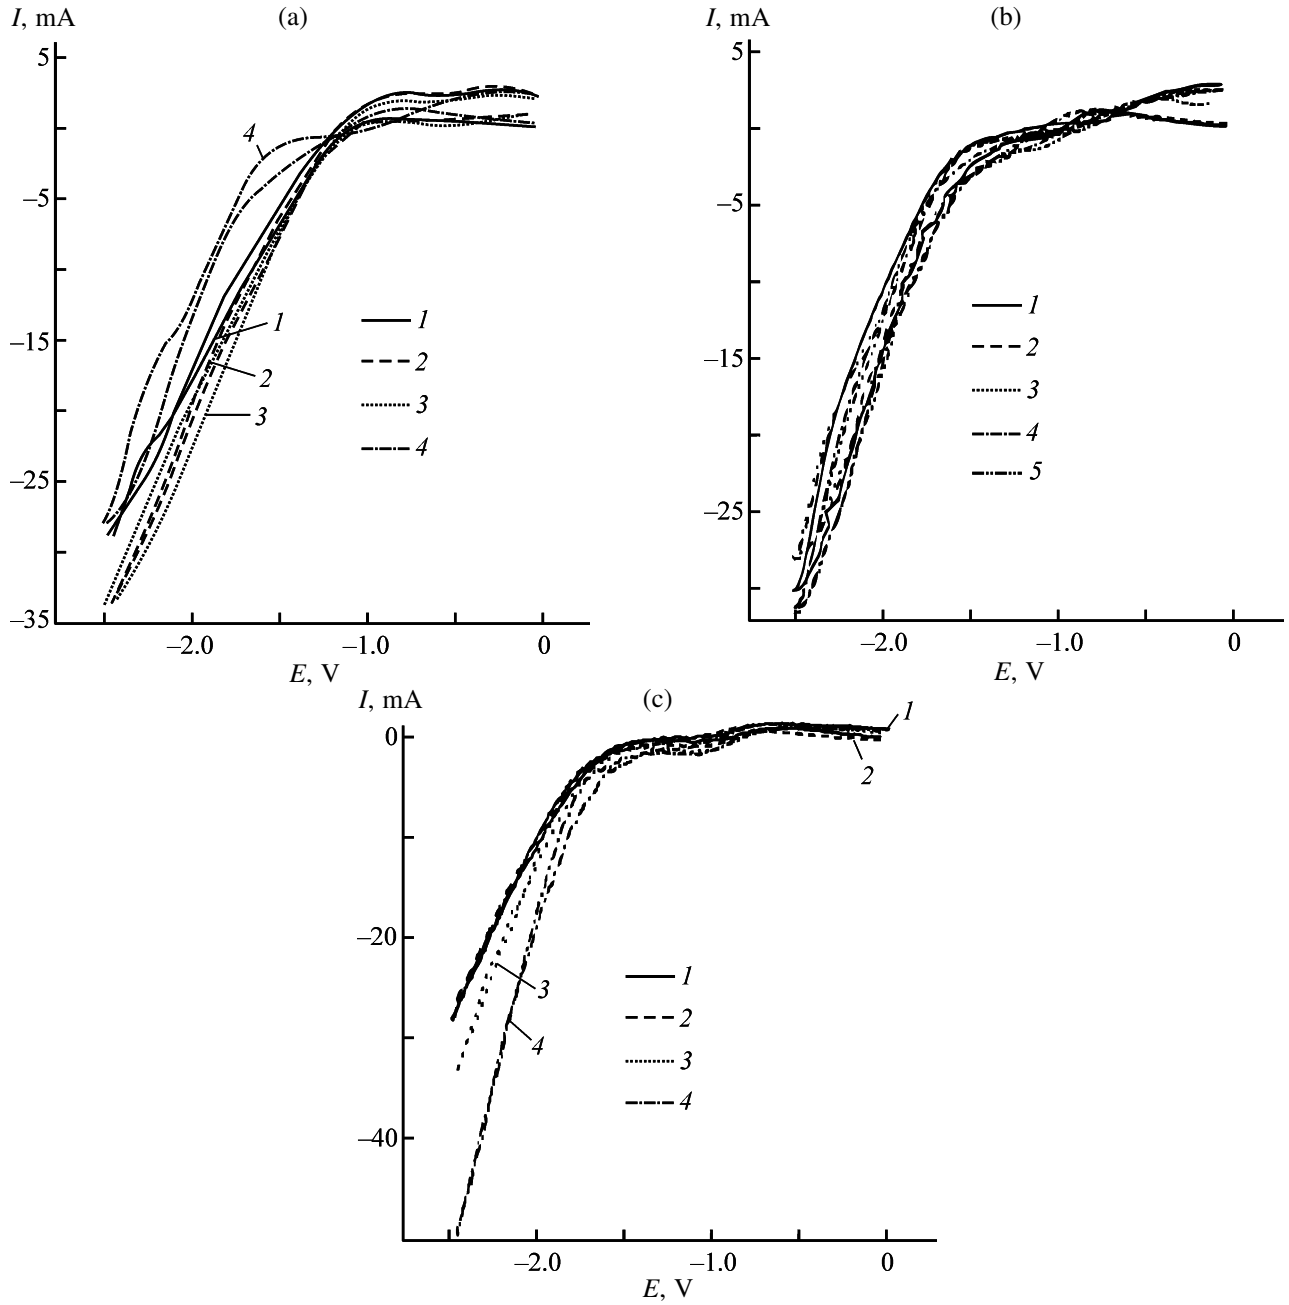

Fig. 1. Current–voltage curves measured in a 0.5 N solution of LiCl in ethanol (0.027% water) in the presence of $Nb(OEt)_5$ additions. T = 25°C, V = 0.2 V s^{-1}; the same for Fig. 2. (*I*) Current strength and (*E*) potential (vs. silver chloride electrode); the same for Fig. 2. Cathode: (a) Pt, (b) Ni, and (c) stainless steel. $Nb(OEt)_5$ concentration (M): (*1*) 0, (*2*) 0.001, (*3*) 0.01, (*4*) 0.02, and (*5*) 0.04.

0.0025 A cm^{-2}, niobium pentaalkoxide can be reduced to the tetraalkoxide on the cathode, with a colorless solution becoming brown in the course of the electrolysis. After testing a number of cathodic materials (lead, niobium, titanium, stainless steel, molybdenum, nickel, and platinum), we chose metals with the lowest hydrogen overvoltage, platinum and nickel, as the working materials.

The cathodic reduction was also examined voltammetrically. The reduction of niobium pentaethoxide on the cathodes made of different materials was determined by measuring the voltammograms on platinum, nickel, and stainless steel at the cathodic polarization in a 0.5 N solution of lithium chloride supporting electrolyte at different concentrations of niobium pentaethoxide (Figs. 1a–1c). The curves obtained

show that niobium pentaethoxide is reduced only on the steel electrode (Fig. 1c). The parameters characterizing this process are listed in Table 1.

Table 1 shows that the current spent for the reduction of niobium pentaethoxide depends on the concentration of the substance in a solution and does not noticeably depend on the cathodic current density in the examined range. Thus, the current–voltage curves obtained are in agreement with the results of the preparative electrolyses.

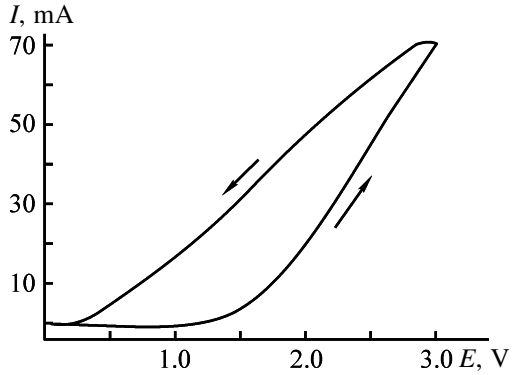

Fig. 2. Current–voltage curve obtained on Nb in a 0.5 N solution of Et_4NCl in ethanol (0.027% water).

The effect of the electrolyte on the efficiency of the anodic dissolution of Nb was studied in two series of experiments. The fact that the solution remains colorless indicates that the dissolution occurs to Nb(V). In the first series of the experiments (Table 2) we studied the effect of the anion, with tetraethylammonium as cation. As seen from Table 2, niobium dissolves at a current efficiency exceeding 95% [as calculated for Nb(V)]. Hence, the anion only slightly affects the anodic dissolution of niobium. The effect of the cation is also weak, at least in the case when niobium is dissolved in chloride solutions (Table 3). The further study showed that, whereas the supporting electrolyte affects the dissolution of a niobium anode only slightly, its influence on the formation of niobium alkoxide is decisive. Table 2 shows that niobium ethylate is best formed in chloride solutions, whereas in bromide solutions it is not formed at all. Although with tetraborate and acetate anions the alkoxide is formed, its yield (based on Nb) is considerably lower than in chloride solutions. We do not have sufficient data yet to account for this trend, and the study in this area is being continued.

To study the anodic process in more detail, we measured the current–voltage curves. One of typical cyclic voltammograms obtained at anodic polarization of a niobium electrode in an ethanol solution of tetraethylammonium is shown in Fig. 2. The voltammogram has a clear hysteresis. At forward potential scanning, the dissolution is not observed up to 1.2 V, whereas at the reverse scanning the electrode dissolution continues down to 0.25 V. Presumably, the anodic polarization breaks the passivation film on the elec-

Table 4. Potentials of the niobium transition from the active to the passive state in solutions of various compositions.* Solvent: ethanol containing 0.027% water

$Et_4NOOCCH_3$	1.60	0.40	1.20

* $\Delta E = E_a - E_p$.

trode surface, making the electrode active. The potential of the onset of the niobium dissolution at forward scanning can be designated as the potential of transition to the active state, and the potential of the passivation at reverse scanning, as the passivation potential E_p. The similar effect was also observed for solutions of lithium chloride and tetraethylammonium acetate (Table 4). As can be seen, the supporting electrolyte significantly affects the potential of transition to the active state, but does not noticeably affect the passivation potential. From the viewpoint of easiness of niobium anode activation, it is preferable to use lithium chloride as electrolyte.

The experiments performed showed that the current efficiency in dissolution of a niobium anode depends only slightly on the supporting electrolyte and is close to 100% [as calculated for Nb(V)] in all the media studied. This result and the closeness of the passivation potentials for different electrolytes show that, contrary to Lemkuhl's suggestion, niobium ionization rather than oxidation of the anion takes place in the course of the anodic process. Another important observation consists in that the yield of niobium ethylate based on Nb significantly depends on the supporting electrolyte anion. Probably, the anion is involved in the synthesis reaction. Presumably, the intermediate formation of alkoxy halides, suggested in [4], plays a certain role in the alkoxide synthesis.

CONCLUSIONS

(1) The anodic dissolution of niobium is accompanied by transition of niobium into the pentavalent state. The supporting electrolyte affects only slightly the current efficiency of the metal dissolution.

(2) The supporting electrolyte strongly affects the yield of niobium alkoxide. The highest yield is observed in chloride electrolytes.

(3) To avoid the reduction of Nb(V) to Nb(IV), it is advisable to use cathode materials with the lowest hydrogen overvoltage.

Abstract—The influence exerted by the nature of cation of a supporting electrolyte and by the current density on the electroreduction of oxygen to hydrogen peroxide in acid K_2SO_4 solutions (pH 0.9–1.4) in gas-diffusion hydrophobized carbon black electrodes with varied electrolyte porosity was studied.

DOI: 10.1134/S1070427206050107

It is known that the rate of electrochemical processes is strongly affected by the supporting electrolyte and various additives [1]. For example, addition of tetraalkylammonium salts affects the electroreduction of CO and CO_2 [2], acetophenone [3], 1,1,2-trifluorotrichloroethane [4, 5], and trichlorofluoromethane [6], electrodeposition of gold [7] and copper [8], and electroreduction of oxygen to H_2O [9–11] and of H_2O_2 to water [12]. Changes in the reduction kinetics of oxygen and H_2O_2 in the presence of tetraalkylammonium cations are due to their adsorption on the electrode and to changes in parameters of the electrical double layer [1, 9].

In [9], a 0.26 M solution of H_2O_2 was prepared on a hydrophilic porous glassy-carbon electrode from oxygen dissolved in a 0.1 M H_2SO_4 solution under atmospheric pressure with addition of trioctylmethylammonium chloride ($[CH_3(CH_2)_7]_3CH_3NCl$) with a current efficiency of up to 55% at a geometric current density of 30 mA cm^{-2}. In [10, 11], a three-phase system constituted by an acid aqueous electrolyte, organic phase, and oxygen gas with 2-ethyl-9,10-anthraquinone as electron-transfer catalyst and addition of tetrabutylammonium perchlorate and trioctylmethylammonium chloride was used to accelerate the electrosynthesis of H_2O_2 on electrodes of this type.

It is known that porous gas-diffusion hydrophobized electrodes are widely used for intensifying electrosynthesis with gas reagents poorly soluble in water [13].

It has been shown that the electroreduction of oxygen to hydrogen peroxide in an acid medium on porous hydrophobized carbon black electrodes strongly depends on the extent to which an electrolyte penetrates into the pore space [14, 15]. An increase in pH makes lower the rate of further reduction of H_2O_2 to water. Addition of a salt with a common anion into an acid solution diminishes the diffusion- and migration-related hindrance in proton transfer deep into the electrode, which leads to an increase in the pH of the catholyte and in the current efficiency. Raising the rate of agitation of a solution makes higher the content of protons in the near-electrode layer and, consequently, leads to an increase in the rate of reduction of hydrogen peroxide to water. The rate of oxygen reduction is also strongly affected by the cathode current density [16].

In this context, it is of scientific and practical interest to study the influence exerted by the nature of electrolyte cations and current density on the electrosynthesis of H_2O_2 on porous hydrophobized electrodes of varied structure. Also, mention should be made of the close attention to electrosynthesis of acid solutions of H_2O_2, associated with their use for *in situ* oxidation of various organic compounds both for synthesis and for mineralization of wastewater [17, 18].

In this study we examined the influence exerted by addition of tetraalkylammonium salts to electrolytes on the kinetics of accumulation of hydrogen peroxide in acid aqueous solutions in electroreduction of oxygen on gas-diffusion hydrophobized carbon black electrodes with varied electrolyte porosity.

EXPERIMENTAL

The experimental conditions and the electrolyzer design were similar to those described in [13–15, 19]. The preparative electrolysis was performed in the galvanostatic mode at a geometric current density of 50–100 mA cm^{-2} at 20°C in the course of 6–7 h in an electrolyte of composition 0.2 M K_2SO_4 + 0.087 M H_2SO_4 (pH 1.4) with and without addition of tetrabutylammonium bromide (0.01 M). The current density was calculated per unit apparent frontal surface area (5 cm^2). The catholyte volume was 0.023 l. Oxygen was delivered into the electrode from its backside under atmospheric pressure. The catholyte was agitated by bubbling argon via a tube 1.5 in diameter permanently at a rate of 10 ml min^{-1} (agitation mode no. 1) or hourly for 1 min at a rate of 38 ml min^{-1} before sampling the solution for analysis for H_2O_2 (agitation mode no. 2). The catholyte and anolyte were separated by an MF-4SK-100 cation-exchange membrane. The electrodes were fabricated from an electrode paste containing an A-437E acetylene black and 8 or 60 wt % 4D fluoroplastic (Teflon). The electrode paste was preliminarily heated to 300°C, and electrodes were sintered in air at 360°C in the course of 10 min. To eliminate hindrance to oxygen supply into the electrode, the electrodes were fabricated with a high porosity of 65 vol %. The electrolyte porosity was measured by hydrostatic weighing [20]. It was, on the average, 7.6 and 1.3 vol % for electrodes with 8 and 60 wt % fluoroplastic, respectively. The fraction γ of current expended for the synthesis of hydrogen peroxide was determined by gasometry [19]. The electrode potential was measured relative to a silver chloride reference electrode (EVL-1M1). Polarization curves were measured at a potential sweep rate of 4 mV s^{-1} under continuous agitation of the electrolyte. A solution of 0.025 M K_2SO_4 + 0.12 M H_2SO_4 (pH 0.9) served as the main electrolyte, to which the following salts were added: tetrabutylammonim bromide (TBAB), tetrabutylammonim iodide (TBAI), diethyldibenzylammonium bromide (DEDBAB), tetraethylammonium chloride (TEAC), and allyltrimethylammonium bromide (ATMAB). Also, in some experiments K_2SO_4 was replaced with LiCl or $CsNO_3$.

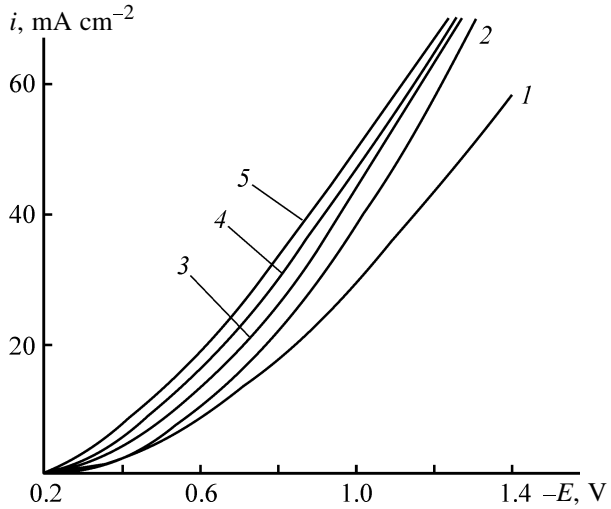

Fig. 1. Polarization curves for electroreduction of oxygen on a gas-diffusion carbon black electrode containing 60 wt % fluoroplastic in solutions of various compositions. (*i*) Current density and (*E*) electrode potential; the same for Fig. 2. Solution composition: (*1*) 0.11 M H_2SO_4, (*2*) 0.025 M K_2SO_4 + 0.12 M H_2SO_4, (*3*) 2 + 0.05 M TEAC, (*4*) 2 + 0.01 M DEDBAB, and (*5*) 2 + 0.01 M TBAB.

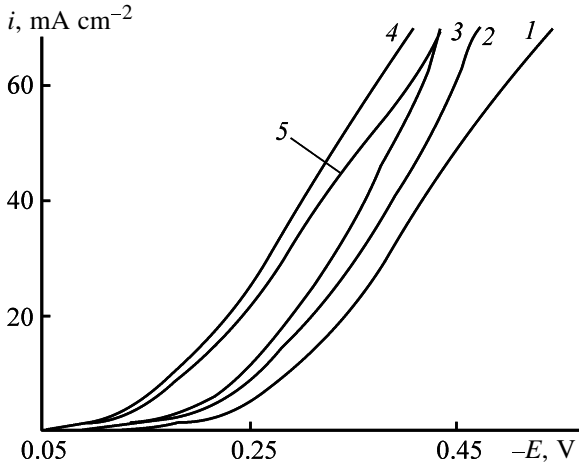

Fig. 2. Polarization curves for electroreduction of oxygen on a gas-diffusion carbon black electrode containing 8 wt % fluoroplastic in (*1*) 0.1 M H_2SO_4 solution, (*2*) solution of 0.025 M K_2SO_4 + 0.12 M H_2SO_4, and (*3*–*5*) that with TBAB added in various concentrations. TBAB concentration (M): (*3*) 0,001, (*4*) 0.01, and (*5*) 0.1.

The polarization curves obtained are shown in Figs. 1 and 2. It should be noted that the fraction γ of the current expended for the synthesis of H_2O_2 in all of the electrolytes studied, except for acid solutions without additives, is high. This indicates that the curves refer virtually only to the oxygen reduction to H_2O_2. The influence exerted on the reduction of oxygen by the kinds of anions of the salts used or of alkali metal cations was insignificant. The values of γ and the polarization curves for electroreduction of O_2, obtained in solutions of 0.025 K_2SO_4 + 0.12 M H_2SO_4, 0.05 M LiCl + 0.12 M H_2SO_4, and 0.05 M $CsNO_3$ + 0.12 M H_2SO_4 are identical. The reduction of oxygen begins in these solutions at +0.05 V. Simi-

lar results were obtained in solutions of 1.0 M $CsNO_3$, 1.0 M LiCl, and 0.5 M K_2SO_4.

The enhancement of the electrode polarization at a higher Teflon content (60 wt %) (see table, Fig. 1) is due to a decrease in the volume of electrolyte-filled pores at a higher content of fluoroplastic, which makes thinner the zone of the oxygen electroreduction. The true working surface area of the electrode decreases and the true current density increases, which enhances the electrode polarization.

The polarization curves obtained in solutions with TBAI and ATMAB additives are not shown in Fig. 1 because they coincided with the curves measured in solutions with TBAB and TEAC, respectively. Figure 1 shows for comparison the curve obtained in 0.1 M H_2SO_4 (pH 0.9). Figures 1 and 2 show that addition of tetraalkylammonium salts accelerates the oxygen reduction; this effect is also observed upon addition of these salts to 0.1 M solutions of H_2SO_4 and HCl. Addition of TBAB has the strongest effect, and that of TEAC, the weakest. No specific effect of the unsaturated bond present in the tetraalkylammonium cation (ATMAB) or of the benzene ring in DEDBAB on the oxygen reduction was observed. The presence of tetraalkylammonium salts in an alkaline electrolyte (0.5 M NaOH) has no effect on the polarization characteristics of the oxygen reduction. The influence exerted by the salt concentration on the electrode polarization is illustrated for TBAB as example (Fig. 2, curves *3–5*). Raising the TBAB concentration from 10^{-4} to 10^{-2} M accelerates the process, but further increase in this concentration to 0.1 M leads to a decrease in the rate of oxygen reduction, which is commonly the case in practice of electrosynthesis, e.g., in dehalogenation of 1,1,2-trifluorotrichloroethane [4]. As the current density is raised, the effect of tetraalkylammonium cations on the electrode polariza-

tion tends to decrease. This is particularly noticeable when performing a preparative electrolysis. The results obtained in the preparative electrolysis are shown in Figs. 3 and 4 and listed in the table. The data in the table correspond to the conditions in which curves *1–3* in Fig. 3 were measured.

An increase in the current density makes higher the rate of accumulation and the concentration of hydrogen peroxide, but, in this case, the change in γ and, consequently, in the current efficiency depends on the electrolyte porosity of the electrode. For example, upon an increase in i from 50 to 100 mA cm^{-2}, the slope of the dependence $\gamma = f(c_{H_2O_2})$ decreases by a factor of 3.8 on electrodes containing 8 wt % fluoroplastic and increases by a factor of approximately 1.2 on electrodes with 60% fluoroplastic (see table). As the current density increases in the case of electrodes containing 8 wt % Teflon, the H_2O_2 concentration, γ, and current efficiency become higher. Raising the Teflon content to 60 wt % leads to a decrease in the extent to which the H_2O_2 concentration grows, with a decrease in γ and current efficiency observed. This is accounted for by the fact that, as the fluoroplastic content decreases, the volume of electrolyte-filled pores increases and the reaction zone extends deeper into the electrode, away from its frontal surface. As a result, the hindrance to proton transport into the electrode is enhanced and thereby the rate of further reduction of H_2O_2 is lowered. To illustrate the effect of mass transfer of protons, Fig. 3 shows curves of H_2O_2 accumulation in different catholyte agitation modes. In an excess of water in neutral and alkaline solutions, synthesis of H_2O_2 involves water and, therefore, the effects observed above are not revealed [15].

The table shows that the addition of TBAB and an increase in the current density have no effect on the run of the dependence of γ and current efficiency on the H_2O_2 concentration [14, 15]. The accumulation curves obtained in the presence of TBAB (Fig. 3) have the common shape [9, 14, 18] and are described by the equation [14, 15]

$$c = \frac{AI|b|V^{-1}\{\exp[(-AI|a|V^{-1} - k)\tau] - 1\}}{-AI|b|V^{-1} - k},$$

where c is the concentration of H_2O_2 in the catholyte (M); A, electrochemical equivalent of H_2O_2 (mol A^{-1} h^{-1}); I, current (A); a and b, coefficients of the equation $\gamma = f(c_{H_2O_2})$ (see table); V, catholyte volume (l); τ, electrolysis time (h); and k, rate constant of H_2O_2 decomposition (h^{-1}).

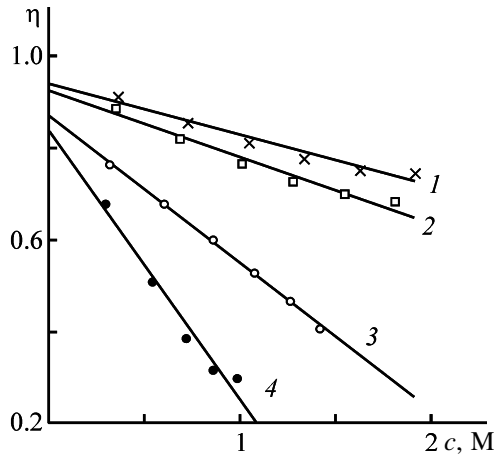

Fig. 4. Differential current efficiency η vs. the concentration c of H_2O_2 in an electrolyte (*2, 4*) without and (*1, 3*) with TBAB added. Teflon content, wt %: (*1, 2*) 8 and (*3, 4*) 60.

The rate of hydrogen peroxide decomposition in the presence of TBAB, as well as that in other acid solutions, is described by a first-order equation. A certain decrease in the rate of H_2O_2 decomposition in the presence of TBA sulfate, reported in [12], was not observed in this study.

The increase in γ upon addition of TBAB to the electrolyte may be due to an increase in the rate of oxygen reduction to H_2O_2 and to a decrease in the rate of further reduction of H_2O_2 to water. The decrease in the rate of H_2O_2 reduction is due to a decrease in the surface activity of protons in the presence of tetraalkylammonium ions. For example, it was shown in [12] that, being adsorbed on the electrode, tetrabutylammonium sulfate markedly diminishes the rate of H_2O_2 reduction to water. The calculations made in [9] for an acid solution containing trioctylmethylammonium chloride (TOMAC) show that tetraalkylammonium cations adsorbed on the electrode can raise the pH of the diffuse part of the electrical double layer from 0.9 to 9.4. Under these conditions, oxygen is reduced on the electrode, with water molecules involved, to give the peroxide ion (HO_2^-) and OH^-, and the H_2O_2 molecule is only formed after HO_2^- is removed from the electrode surface and interacts with a proton in the catholyte bulk. The rate constant of oxygen reduction to H_2O_2 increases in the presence of tetraalkylammonium cations. For example, the rate constant in 0.1 M H_2SO_4 increases from 5.1×10^{-13} to 9.9×10^{-10} m s^{-1} in the presence of 0.017 M TOMAC. The TOMAC layer formed on the electrode surface favors an increase in the content of oxygen in

the catholyte and makes lower its diffusion coefficient [9]. The decrease in the diffusion coefficient of oxygen, observed when a certain concentration of TBAB is reached, makes lower the rate of O_2 reduction (Fig. 2).

The effect of TBAB on the H_2O_2 accumulation depends on the electrode structure. For example, in 6 h of electrolysis on electrodes containing 60 wt % fluoroplastic in the presence of TBAB, the concentration of H_2O_2 increased by 0.32 M and the slope of the $\gamma = f(c_{H_2O_2})$ dependence decreased by a factor of 2.5, whereas on electrodes containing 8 wt % fluoroplastic, the concentration of H_2O_2 and the value of γ increased only slightly (see table). As demonstrated above, the higher the electrolyte porosity of the electrode, the stronger the hindrance to transport of protons into the electrode, and, hence, the weaker the effect of TBAB and the change in the rate of H_2O_2 reduction to water. A study in a 0.5 M NaOH solution demonstrated that, under the given conditions, addition of TBAB to an alkaline electrolyte has no effect on the H_2O_2 accumulation. The attainment of constant γ may be due to the fact that pH is higher than 7 within the electrode and reduction of H_2O_2 to water virtually does not occur in alkaline solutions on carbon black [13].

The table lists the integral current efficiencies, but an important quantity for determining the output capacity of the process at a given instant of time is the differential current efficiency. Figure 4 shows how addition of TBAB affects this parameter (see table, run nos. 2, 3, 5, 6). The differential current efficiency was calculated using the formula reported in [21] by differentiating the accumulation curve. Figure 4 shows that the differential current efficiency linearly depends on the concentration of H_2O_2, but the slope of this dependence somewhat exceeds that for the integral current efficiency. In this case, the effect of TBAB in electrolysis on electrodes with 60 wt % Teflon is stronger than that on electrodes with 8 wt % Teflon.

CONCLUSIONS

(1) Addition of tetraalkylammonium salts to an acid electrolyte accelerates the oxygen electroreduction to H_2O_2. The strongest influence is exerted by tetrabutylammonium chloride. Replacement of K_2SO_4 with $CsNO_3$ or LiCl has no effect on the polarization characteristics of the electrode.

(2) An increase in the current density and addition of tetrabutylammonium bromide to an acid electrolyte make higher the concentration of H_2O_2. In this case, the change in the fraction of the current expended for oxygen reduction to H_2O_2 and in the current efficiency depend on the electrolyte porosity of the electrode. An appropriate combination of the electrolyte porosity, composition of the electrolyte, and mode of its agitation can provide that the current efficiency will increase with the current density. The effect of the above-mentioned factors is based on a change in the parameters of the electrical double layer and in the pH in the pore space of the electrode and in the near-electrode layer.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Contact Reduction of Copper(II) on Aluminum in Ammonia Solutions

A. F. Dresvyannikov and I. O. Grigor'eva

Kazan State Technological Uiversity, Kazan, Tatarstan, Russia

Received December 27, 2005

Abstract—A procedure for obtaining copper in the form of finely dispersed metal from alkaline ammonia solutions with a low copper concentration was developed.

DOI: 10.1134/S1070427206050119

Finely dispersed copper powder is used in production of cables and conducting parts of electric installations, as the base component of bronzes and brasses and copper–nickel alloys, for deposition of corrosion-resistant coatings, and as component of certain compositions in powder metallurgy. It is usually produced by traditional processes: electrolysis of aqueous solutions of copper compounds, reduction of Cu_2O and CuO with hydrogen, or from aqueous solutions of Cu(II) salts [1]. These methods are frequently inapplicable for obtaining copper or its compositions from such sources as liquid and solid technogenic media accumulated in various plants: in machine-building (electroplating), metallurgy, production of batteries, etc. Such wastes constitute a serious environmental hazard, as copper compounds are toxic [2]. Copper can be recovered from technogenic media as a metal by electrolysis. However, its efficiency is not always high [3, 4], which makes indispensable the development of combined methods of waste treatment.

It should be noted that hydrometallurgical methods of copper recovery are based on selective dissolution of copper-containing minerals in dilute acids or ammonia. As a rule, copper is recovered from these solutions in the elemental state by reduction with hydrogen in autoclaves [1], by electrolytic precipitation [5, 6], or by electrolysis [7, 8]. To increase the electrolysis efficiency, bulk electrode materials with a developed surface (graphite) are used [9]. The current efficiency in the electrolysis of copper etching solutions containing ammonium salts and ammonia reaches 94% [10]. In certain cases, elemental aluminum is used as a reducing agent. Compositions for the contact deposition of copper from ammonia electrolytes with operating pH range 11.9–13.5 are known [11]. However, data on the contact deposition of copper on aluminum from dilute ammonia solutions are virtually lacking. Therefore, in this study we examined the deposition of copper on both compact and dispersed aluminum from dilute (10^{-2}–10^{-4}) solutions in aqueous ammonia.

EXPERIMENTAL

Polarization measurements were carried out by the potentiometric method with a PI 50-1 potentiostat and a YaSE-2 electrochemical cell. Cathodic polarization curves were recorded in model solutions under study on a copper electrode (a cylinder 0.5 cm in diameter pressed in fluoroplastic). Anodic polarization curves were recorded on an aluminum (A999 grade) electrode in supporting Na_2SO_4 solutions. The potential sweep rate was 2 mV s^{-1}; an EVL-1M silver chloride electrode was used as a reference electrode, and a platinum electrode, as an auxiliary electrode. In addition, chronopotentiometric curves of an aluminum electrode were taken in solutions under study. In this case, potentials were also measured relative to silver chloride electrode.

Dispersed aluminum (DA) of ASD-4 grade was also used in the study. The aluminum activity was checked by gas-volumetric monitoring of its dissolution in 2 M aqueous NaOH. The content of the metal phase was determined to be $96.21 \pm 0.47\%$.

The compositions of the model solutions containing copper(II) ions, hereinafter referred to under the corresponding numbers, are given in Table 1.

The reaction of Cu(II) with DA was carried out in a temperature-controlled glass vessel at room temperature with stirring at a constant rate of 250 rpm. Pre-

liminary experiments were carried out with an inert gas bubbled through solutions and under the conditions of natural aeration. These experiments showed that the presence of atmospheric oxygen had no noticeable effect on the rate of the reduction Cu(II) powder by DA powder; therefore; further studies were carried out at natural aeration. The reaction course was monitored by the solution color changing from deep violet to colorless and by the appearance of particles with the color characteristic of copper.

Samples of the reaction mixture were taken at certain time intervals and titrated by a standard Na_2EDTA solution [12]. The Cu(II) content in the reaction mixture was also monitored at regular intervals by atomic absorption spectrometry (an AAS-1N spectrometer, Carl Zeiss).

The precipitate was separated from the solution by decanting, washed with a 3.0 M NaOH solution to remove excess aluminum and with distilled water to neutral reaction, and treated with a 0.4% naphthenate soap solution for the stabilization. Then the resulting powder was dried to constant weight in a vacuum.

The contents of the main component and impurities in the precipitate were determined by X-ray fluorescence analysis (a VRA-20L Carl Zeiss installation) and by X-ray diffraction (a DRON-3M installation). To decrease the background from scattering of the primary X-ray beam in air, we used long-wave FeK_α radiation with a β-filter. The recording mode was as follows: U_a = 30 kV, I_a = 15 mA, range of recording 2θ angles from 20° to 140°.

The samples were identified by comparison of their X-ray patterns with reference data (ASTM). The fractional composition of powders was determined by the sedimentation method (Figurovskii's balance) [13]. The size, shape, and morphology of particles were estimated by scanning electron microscopy (an REMMA-202 microscope-analyzer).

Numerous studies, e.g., [14, 15], show that the reactivity of aluminum in alkaline media is higher than that in acid media. According to the published data [14], the rate of aluminum dissolution reaches a maximum (150–170 g m^{-2} h^{-1}) in 5–7 M alkali. In this case, the potential ranges from –1.4 to –1.8 V. The difference of the aluminum and copper standard potentials in alkaline solutions is very large (more than 2 V [16]); therefore, an intense contact exchange in the Al–Cu(II) system is thermodynamically possible.

Specific features of contact deposition of copper on aluminum in ammonia solutions are well illustrated by corrosion diagrams and cyclic voltammograms.

The cathodic polarization curves on a copper electrode (Fig. 1) have a typical shape for a multistep (in particular, two-step) process of copper(II) deposition from dilute electrolytes containing complex ions. This process is associated with the conjugate course of the reduction of copper(II) ions and proton donors. The cathodic curve ascends and then the limiting diffusion current of copper(II) reduction is observed. The subsequent current growth is caused by hydrogen evolution.

A different pattern is observed in more dilute solutions: first a long interval (up to 1.5 V) of low current is observed, as the copper deposition is characterized by a fairly high overvoltage. A small peak in this region is most likely of the diffusion nature.

We found that an increase in the copper(II) and ammonia concentrations shifts the cathodic curve to more electronegative values (Figs. 1b, 1c), whereas variation of the alkali concentration in solutions does not noticeably affect the shape and position of the cathodic curves.

The anodic polarization curves taken on the aluminum electrode have a simpler shape: the region of active dissolution gradually transforms into the region of diffusion limitations. An increase in the concentration of copper(II) ions in solutions with a relatively low

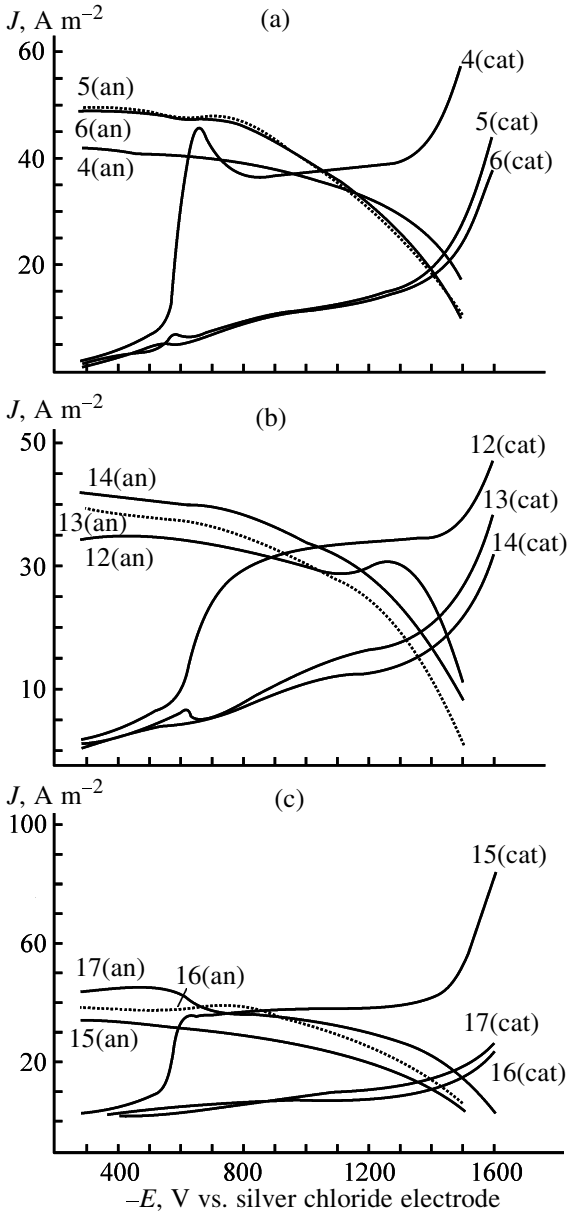

Fig. 1. Anodic (an) and cathodic (cat) polarization curves of copper deposition on aluminum at various concentrations of copper(II) ions in solution. Solution nos.: (a) 4–6, (b) 12–14, and (c) 15–17. (*J*) Current density and (*E*) potential. Figures at curves correspond to the numbers of solutions in Table 1; the same for Figs. 3 and 4.

ammonia concentration (0.9038 M NH_4OH) increases the anodic current (Figs. 1a, 1b). We emphasize that increasing concentration of OH^- ions facilitates the anodic dissolution of aluminum (Figs. 1a, 1b). The activating effect of OH^- ions is also manifested as a shift of the corrosion potential to more negative values. An increase in the ammonia concentration results in the growth of the aluminum dissolution current. As the concentrations of copper(II) ions and ammonia increase, the compromise potential becomes more electropositive.

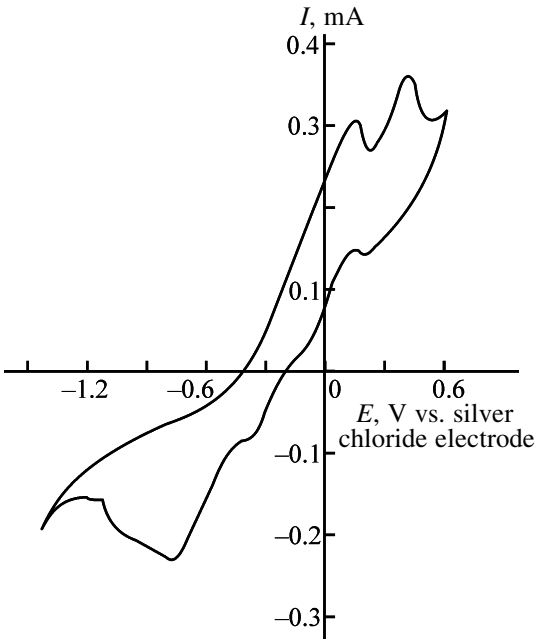

Fig. 2. Cyclic voltammogram of a copper electrode. (*I*) Current and (*E*) potential; the same for Fig. 3.

To obtain more complete information on the behavior of copper and aluminum electrodes under contact exchange conditions, we carried out electrochemical measurements in the mode of cyclic potential variation. To elucidate the influence of solution components on the copper contact deposition, we took cyclic voltammetric (CVA) characteristics on a platinum electrode.

A typical voltammogram on a copper electrode is shown in Fig. 2. It is evident that the copper reduction (and oxidation) passes in steps: $Cu^{2+} \rightarrow Cu^{1+} \rightarrow Cu^0$. This is manifestsed as two maxima in the voltammogram. However, it is necessary to take into account that copper(I) accumulated on the electrode surface is not completely reduced to the metal state and a part of it, most likely, passes into solution.

The voltammetric characteristics for the solutions on a platinum electrode are given in Fig. 3. The measurements were carried out over the potential range from –1.5 to 0.8 V.

In all the experiments, the region of oxygen evolution was observed at high potentials.

The cathodic branch of the cyclic voltammogram begins from 0.7 V and is characterized by a high current of water oxidation, and then at a potential of –0.2 V a cathodic current appears. Initially this cur-

rent is caused by the oxygen desorption, and then, by the copper(II) reduction, which occurs in steps. At the same time, the measurements with variation of the scanning range have shown that copper is deposited even near the first maximum. A potential noticeably higher than the equilibrium potential in any of solutions under study corresponds to this process. This fact suggests that, in these electrolytes, a prephase reduction of copper ions occurs, i.e., a layer of adsorbed atoms is formed on the platinum surface. In connection with the possibility of stepwise copper reduction, it is interesting to consider the problem of the formation of a layer of adsorbed atoms at potentials exceeding the equilibrium potential in these conditions. It is likely that this process also occurs in steps, in spite of the fact that it is limited to the adsorption and no new phase is formed.

The second peak in the cathodic region is also clearly seen. It is followed by exponential growth of the cathodic current, which corresponds to the hydrogen evolution. As the polarization direction is changed, the cathodic current is retained up to a potential of about –1 V, after which the current appears in the anodic direction. In the case of low copper(II) concentrations in solution, a current peak is observed at a potential of about –0.9 V, which corresponds to the oxidation of hydrogen accumulated on the electrode in the previous steps of the process. The ascent of the anodic part of the curve at a potential of –0.2 V, most likely, is due to the adsorption of oxygen, which passes into the stage of its release as a separate phase at 0.6 V.

As the concentration of copper ions in solution is increased, current peaks in the cathodic region become more pronounced. The contribution of the copper reduction current to the total cathodic current increases, and the hydrogen component of the current decreases. The region of the limiting current, which has the diffusion nature, also becomes better defined. At high copper concentrations, a clear extended step of the limiting current of copper reduction is observed in the range from –0.1 to 0.6 V.

The potential corresponding to the current sign change in the anodic region also changes. In the anodic region, as the concentration of copper increases, the current peak of the dissolution of the metal accumulated on the platinum electrode when the potential changes from –0.3 up to –1.3 and then from –1.3 up to –0.6 V increases.

The quantity of electricity determined by the area limited by the curve in the specified range of potentials is equal to the quantity of electricity which is

expended for copper dissolution on sweeping the potential to the anodic region from –0.5 to 0.3 V.

The CVA curves plotted in the Tafel coordinates show that the quasiequilibrium potential in the positive region corresponds to the oxygen adsorption–desorption, and the quasiequilibrium potential in the cathodic region, to the equilibrium potential of the copper electrode in this solution. The exchange current can be calculated from the linear portions of the polarization curves, which allows quantitative estimation of the reaction kinetics in this range of potentials. Certain characteristic parameters found from the voltammograms are given in Table 2.

To gain a notion of the dynamics of the copper–aluminum contact exchange, we took chronopotentiograms in working solutions in the absence of external current (Fig. 4). The reproducibility of these curves is insufficient; nevertheless, it can be noted that the contact exchange potential is close to the aluminum corrosion potential and generally tends to grow. Variations of the potential in the chronopotentiograms taken in solutions with a relatively low ammonia concentration are caused, most likely, by the fact that the copper reduction occurs in two steps, [Cu(II) → Cu(I) → Cu(0)]. The peaks observed in the chronopotentiograms correlate with the intermittently occurring exfoliation of copper from the support. The range of potentials where the contact deposition of copper takes place corresponds to its cathodic deposition and, therefore, this step is limiting.

An increase in the copper(II) concentration shifts the aluminum electrode potential to more positive values and results in the formation of a less porous layer of the deposit. A simulations increase in the concentration of alkali and ammonia results in a potential shift to more positive values by 0.5–1.0 V.

The electrochemical and gravimetric measurements have shown that the contact deposition of copper is accompanied by a considerable conjugate hydrogen

evolution (Table 3). It mainly occurs on the copper surface, as the overvoltage of hydrogen evolution on it is lower than on aluminum. At a relatively high concentration of copper ions, a dense precipitate is formed. It covers the aluminum surface and correspondingly reduces the anodic and total currents of the process. The contribution of the cathodic evolution of hydrogen in the course of the exchange is less than in more dilute copper solutiuons. An increase in the concentration of copper ions results in an increase in the current efficiency by copper. In more concentrated copper(II) solutions (~0.1 M), an increase in the ammonia concentration increases the yield of hydrogen and correspondingly decreases the yield of copper by a factor of 3–6. Thus, the growth of the ammonia concentration inhibits the contact deposition of copper.

The reported results (Table 3) show that the rate of aluminum dissolution j_a(Al) in dilute copper(II) solutions somewhat increases. As this rate is much higher in this case than the rate of copper(II) reduction j_c (Cu), we can conclude that the process of hydrogen evolution prevails:

$$j_a(\mathrm{Al}) = j_c(\mathrm{Cu}) + j_c(\mathrm{H}), \quad (1)$$

$$j_c(\mathrm{H}) = j_a(\mathrm{Al}) - j_c(\mathrm{Cu}). \quad (2)$$

According to Eq. (1), the rate of aluminum anodic dissolution is equal to the total rate of the conjugate reactions of cathodic hydrogen evolution and copper deposition. It seems reasonable that, at a sufficient duration of the contact exchange process (for example, more than 100 s), both cathodic reactions practically completely occur on the surface of copper that has been deposited on the aluminum support. In this case, the fraction of cathodic areas of the electrode surface is close to unity. The cathodic electrochemical behavior of such a sample can be considered, to a rough approximation, as the cathodic behavior of the copper electrode. Therefore, to a first approximation, we can take the current of aluminum dissolution to be equal to the current in the cathodic polarization curve at this potential, which, in turn, was found from the chronopotentiogram for this instant of time.

The evolution of hydrogen reduces the current efficiency of the copper cathodic reduction in dilute solutions at a sufficiently high current density of aluminum dissolution. In such case, the compromise electrode potential is frequently close to the aluminum corrosion potential in a supporting electrolyte solution. This fact indicates that the reduction of proton donors, occurring simultaneously with the reduction of copper complexes on the surface of freshly precipitated copper, exerts a principal influence on the contact exchange.

Thus, the behavior of the aluminum electrode in alkaline copper-containing solutions depends on the

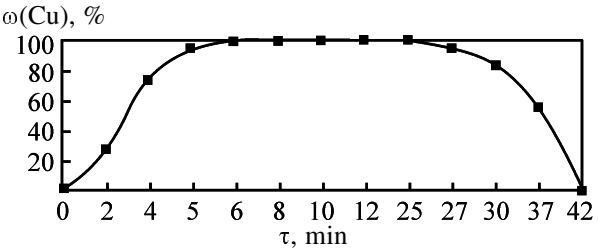

Fig. 5. Kinetic curve of copper contact deposition on dispersed aluminum. $C(Cu^{2+})$ = 0.0954 M, $C(NH_3 \cdot H_2O)$ = 0.5 M, m(Al) = 0.0430 g. [ω(Cu)] Amount of deposited copper and (τ) time.

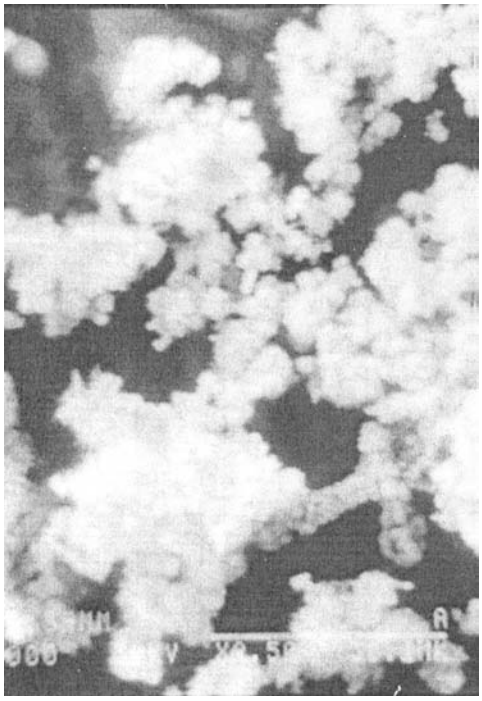

Fig. 6. Photomicrograph of a dispersed copper deposit.

occurrence of the following complex of reactions: aluminum ionization on anodic areas of the surface, cathodic reduction of copper(II), and cathodic evolution of hydrogen on aluminum and copper. The overall process rate is determined by the dissolution of aluminum and depends on the potential of the electrode at a given time instant and also on the state of its surface. However, it is rather difficult to judge the rate of the aluminum anodic dissolution by recording anodic polarization curves of the aluminum electrode in supporting electrolyte solutions, as at these potentials the conjugate reaction of hydrogen cathodic evolution occurs.

Taking into account the fact that the deposition of elemental copper can be intensified by increasing the area of contact between the solid and liquid phases, we also carried out experiments with dispersed aluminum.

We reduced copper(II) in an ammonia solution both with addition of an alkali and without it. We found that the reduction of copper(II) with metallic aluminum occurs directly in an ammonia medium. A typical kinetic dependence of the copper(II) deposition on dispersed aluminum (DA) is shown in Fig. 5. It is seen from this dependence that the complete deposition (99.9%) of elemental copper is attained within 6–7 min. It is interesting that the amount of the deposited elemental copper decreases on the further contact of the highly dispersed precipitate with the solution, which is caused by the oxidation of copper with atmospheric oxygen entering into the solution during stirring. The oxidized copper passes into the ammonia solution as complex ions $[Cu(NH_3)_n]^{2+}$, n = 2–4.

Examination of the influence of the ammonia concentration on the copper(II) reduction has shown that the complete reduction is reached at an ammonia concentration of no less than 0.5 M or at its concentration exceeding the copper(II) concentration in the solution by a factor of 5.5 and more.

Taking into account the possibility of intensifying the process by aluminum activation in an alkaline medium, we also carried out experiments involving the pretreatment of DA with an alkali. The experiments have shown that virtually complete deposition of copper metal is reached at a 2.4-fold weight excess of aluminum when it is introduced simultaneously without preliminary activation with an alkali, and at a 1.6-fold excess of aluminum when it is introduced in portions in the activated form. This difference results from the increased aluminum activity in the second case because of removal of the oxide layer by concentrated alkali. We found that a 1.3-fold weight excess of aluminum is the minimum required to reach the highest degree of copper deposition.

A microscopic examination showed that the copper deposit consists of particles of different size (according to a sedimetric analysis, particles of size 30–50 μm dominate) and predominantly spherical shape (Fig. 6). The shape factors calculated by Hausner's method [13] correspond to these qualitative characteristics. The factor of prolateness and the factor of voluminosity are x = 1.2 and y = 0.75, respectively, which allows the particles to be assigned to group I (smooth) or II (plaited sphere) in accordance with Hausner's classification. The surface factor z = 0.997 indicates that the precipitated particles are sufficiently smooth, opaque, and have a developed porosity. A large number of subindividuals of size 0.1–1 μm are observed on their surface. Furthermore, a large

Table 4. Data of X-ray phase analysis of a copper deposit on an aluminum foil and of a deposit obtained using dispersed aluminum (DA)

hkl	Interplanar spacing, Å		Coherent scattering region, Å		Microstress	
	DA	foil	DA	foil	DA	foil

200	1.8071	1.8076	398.3527	347.8750	0.0018	0.0031
220	1.2778	1.2781	705.8520	560.1756	9.0835	0.0018
311	1.0897	1.0900	591.4928	481.2208	0.0013	0.0024
222	1.0433	1.0436	808.3518	630.9424	1.1146	0.0011

number of individual submicroparticles are observed, which seem to be formed by the disintegration of large aggregates as a result of gaseous hydrogen evolution.

We can point out that the precipitates are rather homogeneous in the chemical composition. The X-ray patterns of the precipitates obtained on an aluminum foil and dispersed aluminum indicate that the precipitates contain no oxo and hydroxo compounds of aluminum and copper. Furthermore, we found that the precipitate of elemental copper on a foil has smaller coherent scattering regions and microstresses than the copper powder obtained with dispersed aluminum (Table 4). The content of elemental copper in both cases reaches 98.5–98.7%, the remainder being aluminum.

CONCLUSIONS

(1) Contact deposition of copper on compact and dispersed aluminum was studied. An increase in the concentrations of an alkali and copper(II) in solutions increases the rate of a contact exchange, whereas an increase in the ammonia concentration decreases it.

(2) According to electrochemical measurements, the rate of hydrogen evolution substantially increases in dilute solutions, becoming several times higher than the rate of copper reduction: $j_a(\mathrm{Al}) = j_c(\mathrm{Cu}) + j_c(\mathrm{H})$.

(3) Quantitative deposition of copper(0) occurs under optimal conditions within 6–10 min, and after 20–25 min copper dissolves due to oxidation with atmospheric oxygen, and copper(II) ammonia complexes are formed.

(4) The use of dispersed aluminum in alkaline ammonia solutions makes it possible to obtain technical-grade (98.5–98.7% purity) powders of elemental copper consisting of particles with preset size, shape, and morphology.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Inhibition of Corrosion and Hydrogenation of Carbon Steel in Media Containing Hydrogen Sulfide and Carbon Dioxide with Low Concentrations of Salts of Oxyethylated Amines

Abstract—Impedance spectroscopy was used to study the protective action of salts of higher aliphatic oxyethylated amines as universal inhibitors of the hydrogen sulfide and carbon dioxide corrosion and hydrogenation of carbon steel.

DOI: 10.1134/S1070427206050120

The hydrogen sulfide and carbon dioxide corrosion of the metal is one of the most important reasons for corrosive failure of steel equipment at oil and gas fields. A grave danger in the case of exposure to such media consists in the enhancement of hydrogenation, which leads to embrittlement of the metal and to its corrosive cracking. Despite the existing wide choice of inhibitors, it is necessary to develop new efficient inhibitors and, primarily, those exerting an integrated influence (simultaneous inhibition of the hydrogen sulfide and carbon dioxide corrosion, prevention of a local damage and hydrogenation of the metal) by studying the mechanism of their protective action. In addition, one of modern requirements to inhibitors is their high performance even at low concentrations [1], which lowers the cost of the corrosion protection and diminishes the environmental impact.

In this study, we examined the performance of salts of higher aliphatic oxyethylated amines as universal inhibitors of hydrogen sulfide and carbon dioxide corrosion and hydrogenation of carbon steel. We used impedance spectroscopy to refine, if possible, the mechanism of the inhibiting action and specific features of the influence exerted by an inhibitor on the anodic and cathodic processes and adsorption in the pores of a film.

EXPERIMENTAL

We performed corrosion tests with St.3 steel by the gravimetric method in solutions of NaCl (50 g l^{-1}) and HCl (0.005–0.05 M) with and without H_2S and CO_2. The necessary concentration of hydrogen sulfide (200 mg l^{-1}) was created by introducing a calculated amount of sodium sulfide and generating H_2S by the reaction with HCl. Some solutions were saturated with carbon dioxide (1.6 g l^{-1}, deoxygenated medium). An excess pressure of CO_2 (1 atm) was created as described in [2], in plastic vessels equipped with nipple valves. Carbon dioxide was pumped from a cylinder with manometric pressure monitoring, further continued during the whole experiment (24 h). As inhibitors served homological mixtures of salts of higher oxyethylated amines (OEAs) and acetic and ethylhexanoic acids of the general formula

$$R\text{–}NH^{+}Ac^{-}\begin{matrix}(CH_2CH_2O)_xH\\(CH_2CH_2O)_yH,\end{matrix}$$

where R = C_{10}–C_{14}, C_{16}–C_{18}; $x + y = n = 3$; and Ac, the corresponding acyl, both as an active species and in 20% solutions in a mixed organic solvent.

The concentration of the inhibitors was in the range 25–100 mg l^{-1}. We calculated the protective effect Z (%) by the formula

$$Z = [(K_0 - K_{inh})/K_0] \times 100,$$

where K_0 and K_{inh} are the corrosion rates in the media under study in the absence and presence of an inhibitor, respectively.

Electrochemical measurements were made by the potentiometric method (P-5827M potentiostat) in a

Table 1. Protective effect Z of OEA salts in NaCl solutions containing CO_2 and H_2S at an excess CO_2 pressure P_{CO_2} = 1 atm. Test duration 24 h, room temperature, c_{NaCl} = 50 g l^{-1}, c_{H_2S} = 200 mg l^{-1}, c_{CO_2} = 1.6 g l^{-1}

three-electrode cell with separated anode and cathode spaces. A silver chloride electrode served as reference, and Pt, as an auxiliary electrode. The potentials are given relative to a standard hydrogen electrode.

We studied the hydrogen permeability in a two-chamber cell separated by a vertical steel membrane (St. 3, 300 μm) at the corrosion potential [3]. The duration of the tests was 3 h. The suppression coefficient of the hydrogen diffusion, γ, was found by the formula $\gamma = i_H^0/i_H$, where i_H and i_H^0 are the fluxes of solid-phase diffusion in the system with and without an inhibitor, respectively. All the experiments were performed at room temperature.

We studied the electrochemical impedance of steel electrodes in the frequency range from 60 kHz to 10 MHz at an ac voltage amplitude of 10 mV with a potentiostat and a Solartron 1250 spectrum analyzer (the United Kingdom). The working (S_{el} = 0.785 cm^2) and auxiliary platinum (S_{Pt} = 54 cm^2) electrodes were arranged coaxially. The working electrode was polished, degreased, and subjected to cathodic activation (ΔE = –0.2 V) for 15 min to remove the air-oxide film, after which is was kept in solution for a quasistationary potential to be attained (15 min), and the impedance was measured at E_{cor}. A quantitative analysis of the experimental data obtained was made with software developed for IBM PC, which enables calculations for arbitrary equivalent circuits with a number of elements of up to 12 [4]. The calculational part of the program is based on a simplex search method for finding an extremum of a function of several variables. The criterion used for circuit assessment is the root-mean-square deviation s; a circuit is considered satisfactory at $s \leq 5\%$.

Table 2. Protective effect Z of OEA salts (25 mg l^{-1}) in HCl solutions containing CO_2 and H_2S. Test duration 24 h, room temperature, c_{H_2S} = 200 mg l^{-1}, c_{CO_2} = 1.6 g l^{-1}

	0.05	81	88	90	89

In NaCl solutions containing hydrogen sulfide and carbon dioxide, OEA salts exhibit a protective effect of 65–75%, which increases by approximately 10–15% in the simultaneous presence of H_2S and CO_2 and with increasing c_{inh} (Table 1).

Making lower the pH value and the degree of mineralization of the medium enhances the protective effect of inhibitors (Table 2). In hydrogen sulfide and hydrogen sulfide–carbon dioxide media, Z of ~90% can be obtained even at c_{inh} = 25 mg l^{-1}. The length of the hydrocarbon substituent of OEA and the anion of an organic acid affect the performance of additives only slightly.

OEA salts shift E_{cor} to the positive region (Fig. 1), especially in the presence of H_2S, and strongly decelerate the anodic reaction. Depending on the composition of the corrosion medium, the cathodic process is hindered or, by contrast, facilitated (hydrogen sulfide media).

Introduction of OEA acetates with a concentration

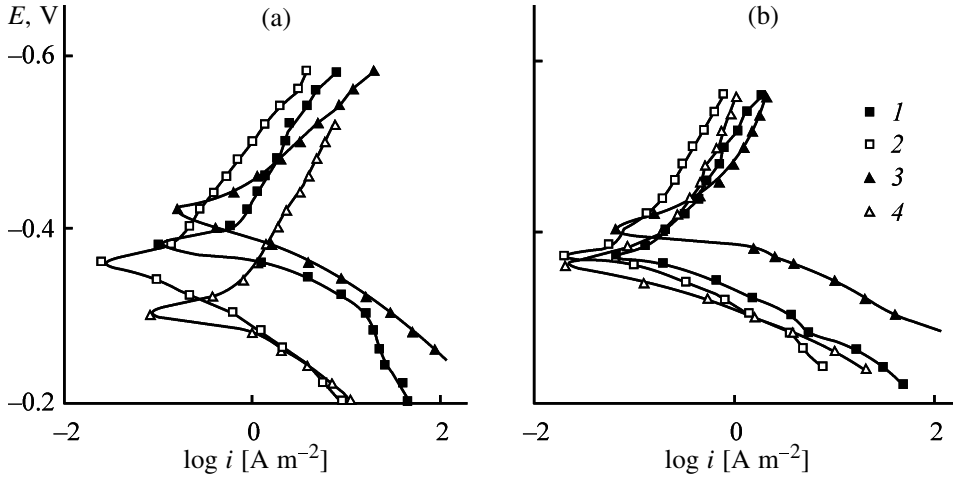

Fig. 1. Potentiostatic polarization curves obtained on St. 3 steel in (a) NaCl and (b) HCl solutions containing H_2S and CO_2 (*1, 3*) in the absence and (*2, 4*) in the presence of C_{10}–C_{14} OEA acetate. Room temperature, immobile electrode, c_{NaCl} = 50 g l^{-1} (pH 6), c_{HCl} = 0.005 M, c_{H_2S} = 200 mg l^{-1}, c_{CO_2} = 1.6 g l^{-1}, c_{inh} = 100 mg l^{-1}. (*E*) Potential and (*i*) current density. (a) (*1*) NaCl, (*2*) *1* + inhibitor, and (*3*) *1* + H_2S. (b) (*1*) HCl + CO_2, (*2*) *1* + inhibitor, (*3*) *1* + H_2S, and (*4*) *3* + inhibitor.

of 25 mg l^{-1} into 0.005 M HCl solutions makes lower the hydrogen permeability of the steel membrane (Table 3, $\gamma > 1$). Under these conditions, salts of OEA and ethylhexanoic acid enhance the hydrogenation of steel.

In the presence of H_2S or CO_2, all the products studied suppress the diffusion flow of hydrogen into the steel, i_H. The salt of ethylhexanoic acid and C_{10}–C_{14} OEA is the most effective: γ increases to 2.5–2.7. In hydrogen sulfide–carbon dioxide media, the hydrogenation-inhibiting effect of OEA salts is virtually independent of their nature.

The impedance has on a complex plane (Fig. 2) up to three overlapping semicircles, and, therefore, no less than three time constants are generally necessary for describing the experimental data. The impedance data were analyzed using equivalent electric circuits, simplified models that, nevertheless, yield a qualitative and, in some cases, semiquantitative information about the behavior of the metal in a corrosion medium [5].

When choosing an equivalent circuit, we took into account the fact that films of varied nature exist on the electrode surface. An X-ray diffraction analysis revealed on the electrode surface Fe_3O_4 with trace amounts of Fe_2O_3 in HCl solutions at an excess CO_2 pressure of 1×10^5 Pa; iron oxides and $FeCl_3$ in a CO_2-saturated solution, Fe_3O_4 and $FeCO_3$ in neutral salt media; and FeS and FeS_2 in the presence of H_2S. Taking into account the experimental conditions (15-min preliminary keeping at E_{cor} and approximately 30-min measurement of the impedance), we assumed that an oxide or sulfide–carbonate film, or a film of even more complex composition, with a thickness of at least several monolayers, can be formed on the electrode surface during the experiment. In hydrogen sulfide media, the film is visually observed on the electrode. Undoubtedly, the forming films are defective, because otherwise the corrosion process would be dramatically decelerated, which is not the case in the experiment.

The electrical properties of iron oxides and sulfides strongly depend on the stoichiometry of the compounds. The oxides Fe_3O_4 and Fe_2O_3, which exist

Table 3. Coefficients of suppression of hydrogen diffusion across the membrane, γ, in the presence of inhibitors in 0.005 M HCl containing H_2S and CO_2. Test duration 2 h, room temperature, c_{H_2S} = 200 mg l^{-1}, c_{CO_2} = 1.6 g l^{-1}, c_{inh} = 25 mg l^{-1}

at the potentials of active dissolution of iron, have a minor deficiency of oxygen and are *n*-type semiconductors [6, 7]. The iron(II, III) oxides formed at $E \approx -0.4$ V (s.h.e.) in a sodium sulfate solution are nondefective equimolar compositions [6]. In the case in question, the corrosion potential of the steel electrode in various solutions ranges from –0.26 to –0.49 V, i.e., the deviations of the oxide composition from the stoichiometry must be insignificant (including those in the presence of Cl^- ions) and, accordingly, the electrical conductivity of the oxide must be close to the minimum value. Nonstoichiometric iron sulfides, Fe_xS_y, are semiconductors [8, 9], whereas FeS and FeS_2 have a rather high conductivity [7, 9]. There is certain evidence that iron carbonate belongs to semiconductors with widely varying conductivity, and it is an insulator according to [10]. Dielectric films can be formed via polymolecular adsorption of the organic corrosion inhibitor.

A general equivalent circuit (Fig. 3a) was suggested in [11] for an electrode with a porous dielectric film. In this circuit, R_s is the resistance of a solution outside the surface film; C_{film} and R_{film}, the capacitance of the film proper and resistance of the solution within its pores; and Z_1, impedance of the metal–electrolyte interface at the bottom of the pores. The particular form of Z_1 depends on the nature of the reactions occurring at the electrode. If, e.g., the process includes stages of charge diffusion and transfer, Z_1 is described by the Ehrschler–Randles scheme and the total impedance can be represented by the equivalent circuit in Fig. 3b [11]. By contrast, the equivalent circuit in Fig. 3a, in which Z_1 is represented by a parallel RC circuit, was used for a low-carbon steel electrode in a solution of HCl with addition of higher amines (decylamine, dodecylamine) [12]. In this circuit, we interpreted the resistance and capacitance in the interface impedance, not included in Z_1, as the resistance of the solution within the pores of the inhibitor film and capacitance of the film itself.

If measurements are made at the corrosion potential, the Faraday impedance contains contribution from the cathodic and anodic reactions. In this case, the equivalent circuit suggested in [13] (Fig. 4a) can be used to simulate processes at the metal–electrolyte interface, and the full impedance of the electrode with a porous surface film can be represented by the equivalent circuit in Fig. 3c. In this circuit, R_{an} and R_{cat} are the charge-transfer resistances in the anodic and cathodic reactions, respectively. To refine the model, we used, instead of the final diffusion im-

pedance, the generalized final diffusion impedance

$$Z_D = R_D \tanh (j\omega\tau)^p/(j\omega\tau)^p,$$

where R_D is the diffusion resistance; τ, characteristic time of diffusion; $0 \le p < 1$; C_{dl} is replaced with a constant-phase element CPE [14], which models the distributed capacitance: $Z_{CPE} = K(j\omega)^{-n}$ {$j = (-1)^{1/2}$; ω, angular frequency; K, proportionality factor; and n, exponent characterizing the phase deviation [15]}.

The electric circuit in Fig. 3c is satisfactory according to the criterion of rms deviation ($s \le 5\%$) (Fig. 5). The value of C_{film} in solutions with addition of C_{10}–C_{14} OEA acetate is 0.6–1.4 μF cm^{-2} (Table 4), whereas that in uninhibited media is as high as 37 μF cm^{-2}. If the dielectric constant is taken to be $\varepsilon \approx 2$ for the inhibitors studied in accordance with the data of [12], the thickness of the inhibitor film at C_{film} = 0.6–1.4 μF cm^{-2} will be 3.5–6 nm, which corresponds to tens of monolayers. However, the values of certain impedance parameters, obtained in minimization of s for the equivalent circuit in Fig. 3c, have unclear physical meaning. For example, the exponent n in the expression for the CPE frequently has too low values (~0.6, and occasionally <0.5). The value of K is, in some cases, higher in a solution with

an inhibiting additive than in the inhibitor-free solution. That is why the model presented in Fig. 3c is, in our opinion, not quite adequate to the processes under study. This is probably due to the fact that this equivalent circuit presumes that only a film whose substance is an insulator is present on the electrode surface. Taking into account the presence on the electrode of also porous conducting [16, 17] and semiconducting [18] films results in a rather complex equivalent circuit whose impedance contains more than 12 parameters. Practical use of so complex equivalent circuits is extremely difficult.

In this context, let us consider, as in [19], the equivalent circuit presented in Fig. 4b. This circuit is constructed on the basis of the equivalent circuit in Fig. 4a, suggested in [12] for an electrode corroding in a neutral solution. In the equivalent circuit in Fig. 4b, R_{ads} and C_{ads} are elements defined by adsorption of intermediates formed in the anodic reaction; the meaning of the rest of the elements of the circuit was explained above. However, this circuit takes into account the presence of films of the inhibitor and corrosion products only indirectly, via a certain change in the values of the elements of the electrical model. Presumably, this equivalent circuit can also model the corrosion behavior of a steel electrode in carbon dioxide media, in which several depolarizers can be simultaneously involved in the cathodic reaction (H_2CO_3, H_3O^+, O_2) and processes may occur with both diffusion and kinetic control [20].

The values of the elements of the equivalent circuit in Fig. 4b are listed in Tables 5 and 6. In all the

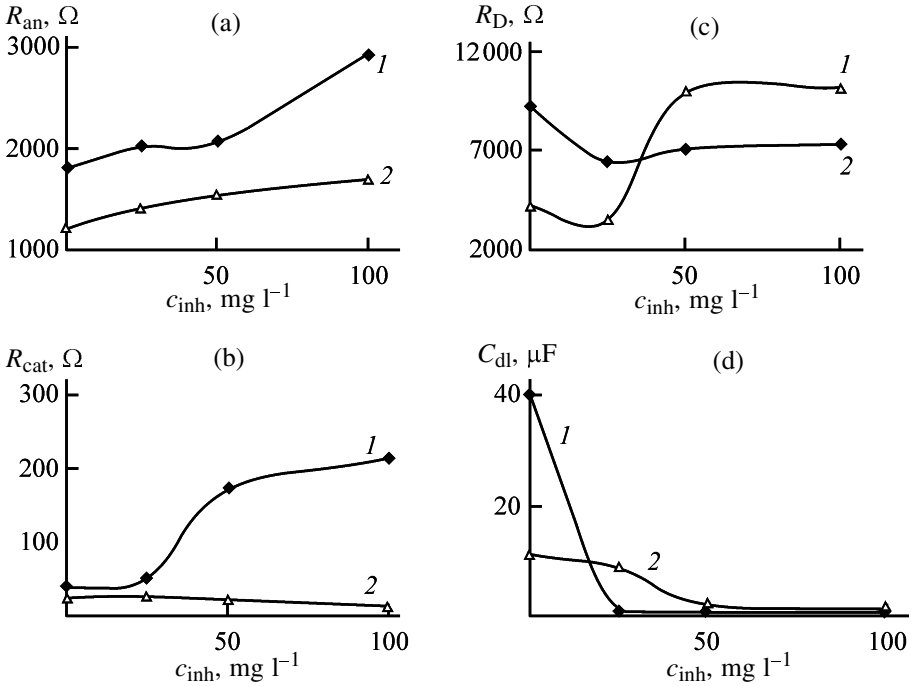

Fig. 6. Charge-transfer resistance in (a) anodic (R_{an}) and (b) cathodic (R_{cat}) reactions, (c) diffusion resistance R_D, and (d) capacitance C_{dl} of the electrical double layer vs. the concentration c_{inh} of the C_{10}–C_{14} OEA acetate in (*1*) NaCl and (*2*) NaCl + H_2S solutions. c_{NaCl} = 50 g l^{-1} (pH 6), c_{H_2S} = 200 mg l^{-1}.

media, adsorption of the inhibitor leads to an increase in R_{cat} (except in NaCl + H_2S and NaCl + H_2S + CO_2 solutions), R_D, τ, R_{ads}, and R_{an} and to a decrease in C_{ads} (except in carbon dioxide solutions), p, and C_{dl}. As the inhibitor concentration increases, these changes become, as a rule, more pronounced (Fig. 6). Thus, the results of the impedance measurements demonstrate that adsorption of an inhibitor hinders both the anodic (increase in R_{an}) and cathodic (increase in R_{cat}, R_D, τ) reactions. In a hydrogen sulfide medium, the cathodic polarization becomes less pronounced upon introduction of an inhibitor (Fig. 1). However, the presence of H_2S shifts the corrosion potential by 0.16–0.21 V in the positive direction. Therefore, the impedance measurements made at E_{cor} show a lower rate of the cathodic reaction in the inhibited solution, compared with that containing no inhibitor. In hydrogen sulfide media, the deceleration of the cathodic process is due only to an increase in R_D and τ, whereas the charge-transfer resistance R_{cat} decreases. In other media, introduction of C_{10}–C_{14} OEA acetate makes lower the rates of both stages of the cathodic process, charge transfer and diffusion. In the presence of an inhibitor, the double-layer capacitance C_{dl} reaches values of 0.5–1.5 μF cm^{-2}, which is due to the formation of very thin inhibitor films on the electrode surface.

CONCLUSIONS

(1) In the presence of H_2S and CO_2, salts of hydroxyethylated amines are combined inhibitors of general corrosion and hydrogenation of steel even at low concentrations. Their protective effect increases with the acidity of the medium to reach a value of 90%.

(2) In hydrogen sulfide–carbon dioxide media, salts of hydroxyethylated amines decrease the flux of hydrogen diffusion into steel by a factor of 2–2.7.

(3) According to impedance measurements, the additive effectively decelerates the anodic (increase in R_{an}) and cathodic (increase in R_{cat}, R_D, τ) processes.

(4) The decrease in the capacitance of the electrical double layer to 0.5–1.5 μF upon introduction of C_{10}–C_{14} OEA acetate indicates that thin inhibitor films are formed on the electrode surface. A polylayer adsorption occurs to virtually a full extent on the porous deposit of oxide, sulfides, or carbonates.

Abstract—Composite membranes consisting of an inert ceramic matrix based on aluminum and zirconium oxides and of an ion-exchange component, hydrated zirconium dioxide, were prepared. The selectivity of these membranes to Cl^- ions was studied.

DOI: 10.1134/S1070427206050132

Process cycles of many industrial enterprises involve the formation of highly toxic wastes, including soluble inorganic compounds. A promising method of removing such impurities from solutions is electrodialysis, as it allows continuous recovery of both cations and anions and their simultaneous concentration [1–4]. This method involves the use of both cation- and anion-exchange membranes made of organic polymers. The presence of oxidizing anions in solutions results in irreversible deterioration of mechanical and ion-selective properties of anion-exchange membranes. In this connection, an urgent problem is obtaining anion-exchange membranes with increased resistance to oxidants.

Hydrated oxides of multiply charged metals are highly stable in corrosive media [5]. At the same time, in acid media these compounds show anion-exchange properties. For example, the anion exchange with hydrated zirconium(IV) dioxide (HZD) proceeds according to scheme (1) [6, 7]:

$$ZrO_m(OH)_{p-1}(OH_2)^+ + An^- \rightleftarrows ZrO_m(OH)_{p-1}(OH_2)^+An^-, \quad (1)$$

where m and p are integers.

This fact suggests that hydrated zirconium oxide $ZrO_m(OH)_p$ can be used for production of chemically stable anion-exchange membranes.

The aim of this study was to develop such membranes and to examine their anion-exchange properties. For comparison we also studied a dispersed HZD ion exchanger obtained by similar methods.

EXPERIMENTAL

We used inert ceramic membranes based on Zr and Al oxides as starting materials. They had the following characteristics: molar ratio $Al_2O_3 : ZrO_2 = 7 : 3$, pore diameter 0.19 μm, specific surface area 4.5–5.0 $m^2 g^{-1}$. The membranes had the shape of tubes (internal diameter 10 mm, wall thickness 1 mm, length 20 cm).

Series I of samples of the anion-exchange membranes was prepared as follows. An inert membrane was filled with HZD in stages by a direct precipitation of particles of the ion-exchange component in the matrix volume. Each cycle of the preparation procedure included the following stages.

(1) Preparation of a $ZrO_m(OH)_p$ sol by gradual addition of 1 M NH_4OH solution to 1 M $ZrOCl_2$ with vigorous stirring. The volume ratio of the solutions was approximately 1 : 1. The temperature of the reaction mixture was maintained at a level of 330 K. The sol was left to stand for 48 days at 298 K.

(2) Impregnation of the membrane by the sol for 24 h.

(3) Treatment of the membrane with 1 M NH_4OH.

(4) Washing with deionized water to neutral reaction.

(5) Drying at 298 K to constant weight.

For more complete filling of matrix pores, operations 1–5 were multiply repeated. Membranes with various degrees of filling were prepared by this procedure.

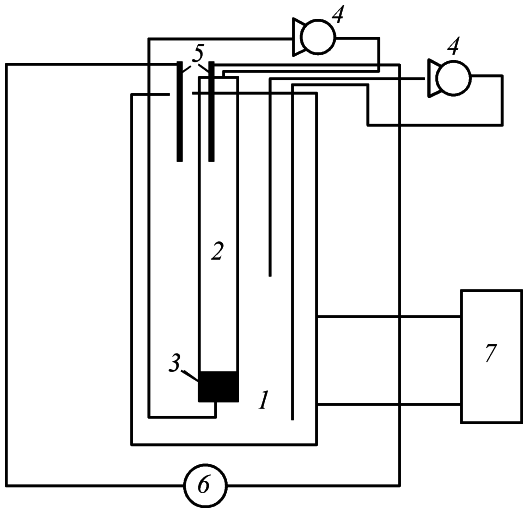

Fig. 1. Scheme of an installation for measuring the membrane potential: (*1*) vessel, (*2*) tubular membrane, (*3*) stopper, (*4*) pumps, (*5*) silver chloride electrodes, (*6*) voltmeter, and (*7*) thermostat.

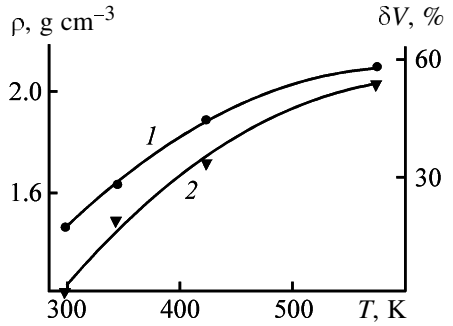

Fig. 2. Temperature dependences of the (*1*) bulk density ρ and (*2*) relative volume change δV of dispersed HZD.

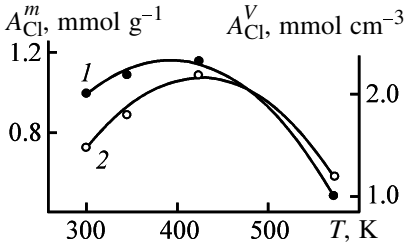

Fig. 3. Total anion-exchange capacity (*1*) A^m_{Cl} and (*2*) A^V_{Cl} of dispersed HZD as a function of the drying temperature T.

Series II of membrane samples was prepared similarly. In this case, the drying temperature in stage 5 was 343 K. Samples of series III were dried at 423 (cycles 1–8 of the ion-exchange component introduction), 573 (cycle 9), and 423 K (the subsequent cycles).

We also prepared samples of dispersed HZD. The procedure was as follows: (1) preparation of a $ZrO_m \cdot (OH)_p$ sol as described above; (2) precipitation of a $ZrO_m(OH)_p$ gel with a 1 M NH_4OH solution; (3) washing with deionized water to neutral reaction; (4) drying at 298 (HZD-I), 343 (HZD-II), 423 (HZD-III), and 573 K (HZD-IV) to constant weight.

The effective sizes of membrane pores were determined by mercury porosimetry using a Promoter 2000 porosimeter. To remove capillary-condensed water from membrane pores, samples were preliminarily dried to constant weight at 423 K.

To determine the total anion-exchange capacity for Cl^- ions per unit weight A^m_{Cl}, we kept a weighed sample (0.1 g) in 0.1 M HCl (100 cm^3) for 24 h. The membranes were washed with deionized water to neutral reaction and treated with 50 cm^3 of 0.1 M NaOH. The eluate was acidified with a 0.1 M HNO_3 solution, the Cl^- content was determined by potentiometric titration with an $AgNO_3$ solution [8], and A_{Cl} was calculated.

The selectivity of membranes to anions was estimated by measuring the membrane potential E_m [7]. A membrane under study, filled with an HCl solution (0.07–0.10 M), was placed into a vessel containing 0.01 M HCl (Fig. 1). One of the membrane openings was insulated. The internal and external solutions circulated in two independent contours under the action of a Zalimp PP 2-15 peristaltic pump. The circulation rate was 1.67×10^{-6} $m^3\ s^{-1}$. Silver chloride reference electrodes were placed inside and outside the membrane. The membrane potential was measured with a V7-34A high-resistance voltmeter.

The bulk density ρ of dispersed HZD samples was determined volumetrically [9]. In this case, A^m_{Cl} was determined by the technique given above. From the results obtained, we calculated the total anion-exchange capacity of an ion exchanger per unit volume A^V_{Cl}.

Sorption experiments and measurements of the membrane potentials were carried out at 298 K. This temperature was maintained with a UTU-2/77 fluid thermostat.

The dependences of the bulk density and relative volume change δV for dispersed HZD samples are shown in Fig. 2. Here $\delta V = (V_0 - V)/V_0$, where V_0 and V are the apparent volumes of an ion exchanger dried at 298 K and at higher temperatures, respectively. It is seen that, as T increases, δV and, correspondingly, ρ increase. Figure 3 illustrates the dependences of the total anion-exchange capacities per unit volume

and unit weight of the ion exchanger on the drying temperature. In the range 298–423 K, A_{Cl}^{V} and A_{Cl}^{m} increase as the drying temperature increases. Further increase in the drying temperature results in deterioration of the anion-exchange properties of the material. Thus, the decrease in δV and ρ of the ion exchanger after drying at 298–423 K is apparently associated with the removal of physically bound and capillary-condensed water. The decrease in the ion exchanger volume is naturally accompanied by an increase in the volume exchange capacity.

The deterioration of the ion-exchange properties of HZD-IV ion exchanger is apparently caused by the condensation of ion-exchange groups:

$$\equiv Zr\text{–}OH + HO\text{–}Zr \equiv \longrightarrow \equiv Zr\text{–}O\text{–}Zr\equiv + H_2O. \quad (2)$$

The dependences of the total anion-exchange capacity per unit weight for membranes of series I–III on the number n of cycles of filling the matrix with an ion-exchange component are shown in Fig. 4. It is seen that A_{Cl}^{m} increases as the number of filling cycles is increased up to 4. Further introduction of the ion exchanger into the membrane volume does not appreciably increase its anion-exchange capacity. It should also be noted that the drying temperature does not noticeably affect the anion-exchange capacity of the membranes of series I and II. In series III, a pronounced minimum corresponding to n = 9 in the A_{Cl}^{m}–n dependence is observed. Thus, the increase in the drying temperature from 423 to 573 K results in the deterioration of the anion-exchange properties of the membranes.

The dependences of the effective pore diameter d of the membranes of series III on the number of cycles of HZD introduction are shown in Fig. 5 (because of the necessity of thermal pretreatment, the use of mercury porosimetry for samples of other series was not appropriate). It is seen that d decreases in the range of n 0–8, sharply increases at n = 9, and decreases again as n increases further. Thus, the modification of ceramic membranes consists in successive filling of their pores with the ion-exchange component. The pore structure and the anion-exchange properties are determined by the number of cycles of HZD introduction, on the one hand, and by the drying temperature, on the other.

As should be expected, the stage-by-stage introduction of the ion-exchange component in the membrane matrix affects the charge-selective properties of this latter. In all the cases, we recorded emf arising in

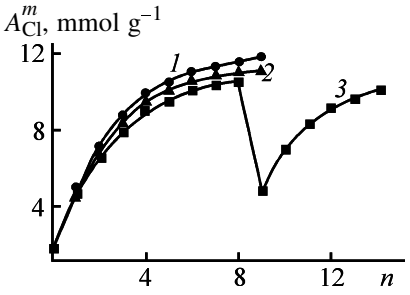

Fig. 4. Total anion-exchange capacity A_{Cl}^{m} as a function of the number n of cycles of filling the matrix for membrane samples of series (*1*) I, (*2*) II, and (*3*) III.

the following circuit.

Ag	AgCl, KCl	Internal solution	Membrane	External solution	KCl, AgCl	Ag

(3)

In the case of membranes modified with HZD, the emf was stabilized within a certain period of 0.5–6 h. The stabilization period became shorter as the number of HZD layers was increased and the thermal treatment temperature was decreased.

Thus, the membranes containing an ion-exchange component represent a barrier virtually impermeable to negatively or positively charged ions. In this connection, the leveling of concentrations by diffusion becomes impossible.

The results obtained suggest that in this case the examined membranes exhibit charge-selective properties and the recorded emf corresponds to the membrane potential E_m.

The dependences of the membrane potential on the number of successive cycles of HZD introduction into an inert ceramic membrane are shown in Fig. 6. For samples of series I and II, the membrane potential shifts to more negative values with increasing n and tends to certain constant values, which nevertheless

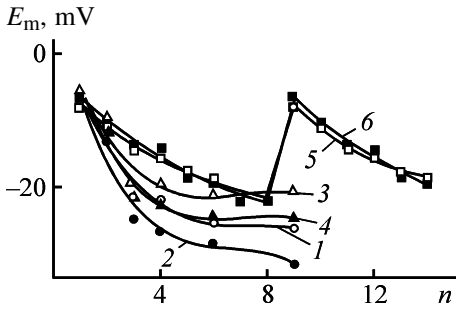

Fig. 6. Membrane potential E_m as a function of n for membranes of series (*1, 2*) I, (*3, 4*) II, and (*5, 6*) III. Internal solution 0.01 M HCl; external solution (*1, 3, 5*) 0.07 M HCl and (*2, 4, 6*) 0.1 M HCl.

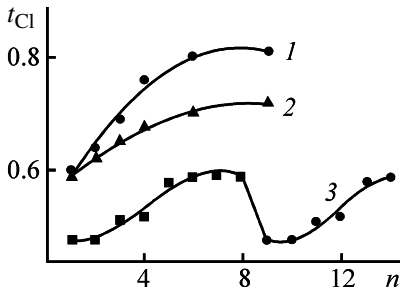

Fig. 7. Transport number t_{Cl} of Cl^- ions as a function of n for membrane samples of series (*1*) I, (*2*) II, and (*3*) III.

are higher than the theoretically calculated values (–50 and –59 mV at the internal solution concentrations of 0.07 and 0.1 M, respectively). In the case of series III samples, E_m decreases with increasing n from 1 to 8, approaching a certain constant value, sharply increases at $n = 9$, and again decreases as n increases further. A comparison of the E_m–n curves for various samples shows that the decrease in the drying temperature results in a decrease in the membrane potential.

The results obtained allow us to make some quantitative estimations.

At a high concentration of the 1,1-electrolyte (HCl), at variation of its content in the more concentrated solution, the equation relating the membrane potential to the potentiometric transport number t_{Cl} of potential-determining ions has the form [7]

$$E_m = \frac{RT}{F}\left[\ln(c_{Cl,1}/c_{Cl,2}) + 2\int_1^2 (1 - t_{Cl})\,d\ln c_{Cl,2}\right], \quad (4)$$

where R is the universal gas constant; F, Faraday constant; T, temperature; and $c_{Cl,1}$ and $c_{Cl,2}$, concentrations of potential-determining ions in less and more concentrated solutions, respectively.

The integration is performed within the limits of concentrations from $c_{Cl,3}$ (external solution) to $c_{Cl,2}$ (internal solution). From Eq. (4) we obtain

$$t_{Cl} = 1 - \frac{F}{2RT}\frac{d[E_m - RTF^{-1}\ln(c_{Cl,1}/c_{Cl,2})]}{d\ln a_{Cl,2}}, \quad (5)$$

where a_{Cl} is the activity of Cl^- ions.

As in all the cases the deviations of the membrane potentials from the theoretically calculated values $[E_m - RTF^{-1}\ln(c_{Cl,1}/c_{Cl,2})]$ do not change when the internal solution concentration increases from 0.07 to 0.1 M, we can state that the differentials in Eq. (5) are constant in this concentration range and, hence, the transport numbers of Cl^- ions can be calculated by formula (6):

$$t_{Cl} = 1 - \frac{F\{(E''_m - E'_m) - RTF^{-1}[\ln(c_{Cl,1}/c''_{Cl,2}) - \ln(c_{Cl,1}/c'_{Cl,2})]\}}{2RT(\ln c''_{Cl,2} - \ln c'_{Cl,2})}, \quad (6)$$

where primed and double-primed quantitites correspond to the concentrated internal solution of lower (0.07 M) and higher (0.1 M) concentration, respectively.

The dependences of potentiometric transport numbers of Cl^- on the number of layers of the ion-exchange component, calculated on the basis of the data of Fig. 6, are presented in Fig. 7. It is seen that the transport numbers increase as the amount of HZD in the membrane increases. It should also be noted that the decrease in the drying temperature in the final stage of the process results in a significant improvement of the anion-selective properties of the membranes.

For samples of series I and II, the t_{Cl} values approach a certain constant value as the number of successive introductions of the ion-exchange component into the ceramic membrane increases. The t_{Cl}–n dependence can be approximated by the sigmoidal function

$$E_m = a_1 + a_2[1 + e^{(n - a_3)/a_4}]^{-1}, \quad (7)$$

where a_1–a_4 are empirical coefficients.

It follows from Eq. (7) that, at $n \to \infty$, t_{Cl} approaches $a_1 + a_2$. Taking into account that a_1 and a_2 are, respectively, 0.58 and 0.23 (series I), 0.48 and 0.28 (series II), we obtain t_{Cl} 0.81 (series I) and 0.76

(series II). For samples of series III, a similar trend in the range of n 1–8 is observed. In this case, the coefficients a_1 and a_2 are 0.47 and 0.12, respectively; hence, the transport numbers approach 0.59 at $n \to \infty$.

Thus, the introduction of HZD into pores of a ceramic membrane imparts anion-selective properties to it, which is associated with a decrease in the pore size, on the one hand, and with an increase in the surface charge density, on the other. An increase in the drying temperature from 298 to 423 K does not result in the deterioration of the anion-exchange properties of membranes. Nevertheless, the increase in temperature, apparently, results in an increase in the pore size owing to the HZD "shrinkage". The disappearance of anion-selective properties after drying at 578 K is probably due not only to an increase in the pore size of an HZD-containing membrane, but also to a decrease in the anion-exchange capacity of a sorption-active component.

It should be noted that the method used for the introduction of the ion-exchange component does not make it possible to obtain a membrane ideally selective to anions, which is probably caused by charge limitations. At low pH values of solution, colloidal HZD particles are charged positively. The surface of the membrane containing the ion-exchange component also has a positive charge. Thus, the penetration of particles of the $ZrO_m(OH)_{p-1}(OH_2)^+$ sol into pores of a membrane filled with HZD is hampered. The pore size and the surface charge density seem to be among factors restricting such a penetration. When the temperature increases from 298 to 423 K, the role of the second factor apparently increases. At a drying temperature of 573 K, the pore size of the membrane filled with HZD increases, and the anion-exchange capacity appreciably decreases, which facilitates the penetration of positively charged sol particles into pores.

CONCLUSIONS

(1) Composite membranes consisting of aluminum and zirconium oxides as the base of an inert ceramic matrix and hydrated zirconium dioxide as an ion-exchange component were prepared. The procedure consisted in the precipitation of a gel of hydrated zirconium dioxide in pores of the membranes followed by drying at various temperatures.

(2) The anion-exchange capacity of the composite membranes and the effective pore size are determined by the drying temperature in the final stage of the preparation process.

(3) The selectivity of the membranes prepared to Cl^- ions was studied by the electrochemical method. The potentiometric transport numbers of Cl^- were found to increase as the matrix is filled with the ion-exchange component and reach 0.59–0.81 depending on the drying temperature. These values are comparable with those for heterogeneous membranes based on organic polymers. As the upper temperature limit for electrodialysis processes is 323 K, it should be expected that the exploitation of composite membranes will not lead to a significant deterioration of their anion-selective properties.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Calculation of the Velocity Field of a Fluid in a Hydrocyclone

Yu. G. Chesnokov, A. V. Bauman, and O. M. Flisyuk

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received February 22, 2005; in final form, November 2005

Abstract—Influence exerted by parameters dependent on the design dimensions of a hydrocyclone and by the flow rate on the distribution of the fluid velocity in a hydrocyclone was studied.

DOI: 10.1134/S1070427206050144

Calculating the components of a fluid velocity in a hydrocyclone is important because a theoretically substantiated method for calculation of the process of suspension separation in a hydrocyclone cannot be developed without accomplishing this task. A calculation of this kind involves integration of equations describing the motion of solid particles in a hydrocyclone at a prescribed particle size. These equations include the fluid velocity, which should be found beforehand. As shown in [1], determination of the velocity profile of a fluid in the main flow core, which exerts the strongest influence on separation processes, can be reduced under certain conditions to integration of a certain ordinary differential equation, which can be done in a comparatively simple way by numerical methods.

It is assumed that the intensity of turbulent pulsations in the main flow core is comparatively low and the fluid can be considered ideal. The flow is assumed to be steady and axially symmetric. In this case, it is convenient to use the cylindrical coordinate system (r, θ, z) whose z axis coincides with the symmetry axis. Nondimensional variables will be used in calculations. When passing to dimensionless variables, we use as length, velocity, and pressure scales the quantities R_0, $u_0 = Q/(2\pi R_0^2)$, and $p_0 = \rho u_0^2$, respectively, where R_0 is the radius of the cylindrical part of the hydrocyclone; Q, flow rate of the fluid; and ρ, its density. The axial, radial, and tangential velocity components of the fluid are designated as u, v, and w, respectively. The stream function ψ for the meridian motion of the fluid can be sought for as $\psi = z^m F(s)$, where m is a certain number and $s = r/z$. With the assumptions made in [1], we obtain the following ordinary differential equation for the function $F(s)$:

$$(1 + s^2)\frac{d^2F}{ds^2} - [s^{-1} + 2(m - 1)s]\frac{dF}{ds} + (m - 1)mF = -as^2F^{(m-4)/m} - bF^{(m-2)/m}, \quad (1)$$

where a and b are constants.

The boundary conditions for Eq. (1) have the form

$$F(0) = F(s_0) = 0, \quad (2)$$

where $s_0 = \tan\alpha$ and α is the half opening angle of the cone formed by the surface of the conical section of the hydrocyclone.

Let us denote by r_1 and z_1 the coordinates of the lower edge of the discharge pipe in some meridian section of the hydrocyclone. The flow rate of the fluid (in dimensionless variables) through this pipe is expressed in terms of the stream function as $\psi(r_1, z_1)$. Therefore, one of the parameters (a or b) in Eq. (1) can be found from the condition

$$\psi(r_1, z_1) = 1. \quad (3)$$

The expressions for the axial, radial, and tangential velocity components in terms of the stream function have the form

$$u = z^{m-2}F's^{-1}, \quad (4)$$

$$v = z^{m-2}(F' - mFs^{-1}), \quad (5)$$

$$w = w_0 r_0 r^{-1}\{1 + bmz^{2(m-1)}F^{2(m-1)/m}[r_0^2 w_0^2(m - 1)]^{-1}\}^{1/2}. \quad (6)$$

In relation (6), w_0 is a constant (independent of the coordinate z) value of the tangential velocity component at the wall of the conical section of the hydrocyclone. More precisely, this quantity is to be understood as the value of the tangential velocity component at the outer boundary of a thin hydrodynamic boundary

layer formed near the wall. This velocity is proportional to the average velocity of the fluid at the apparatus inlet, and the proportionality factor (so-called velocity drop coefficient at the apparatus inlet) can be calculated by empirical formulas presented in the monograph [2]. It primarily depends on the ratio between the diameter of the inlet pipe and that of the hydrocyclone.

Formulas (4) and (5) show that the axial and tangential velocity components take at $m = 2$ a constant (independent of z) value at conical surfaces $s = \text{const}$. As shown in [1], the function $F(s)$ can be found at this value of m analytically. According to formula (4), the axial velocity component changes its sign at the surface $s_2 = \text{const}$, where the value of s_2 is found from the equation

$$dF(s_2)/ds = 0, \quad (7)$$

This is the so-called shell with zero vertical velocity.

The streamline $\psi = 1$ delimits the region of closed circulation of the fluid, which appears in the hydrocyclone. It is impossible to calculate the fluid flow in this region in terms of the theory under consideration. The possible approaches to description of the fluid motion in the circulation region were discussed in the monograph by Gol'dshtik [3]. This circulation region has a comparatively weak effect on processes of suspension separation in the hydrocyclone. In the case when $b = 0$ ($\Gamma = w r = \text{const}$), we can eliminate parameter a from the differential equation (1) by making the substitution $F = a^{m/4}F_1$. The numerical value of this parameter is found from condition (3):

$$a = z_1^{-4} F_1(s_1)^{-4u/m}.$$

Then the formulas for calculating the axial and radial velocity components have the form

$$u = \frac{z^{m-2}F'_1}{z_1^m F_1(s_1)s},$$

$$v = \frac{z^{m-2}(F'_1 - mF_1 s^{-1})}{z_1^m F_1(s_1)}.$$

If $b \neq 0$, parameter b is eliminated from Eq. (1) by substitution $F = b^{m/2}F_2$. In this case, parameter b is found from condition (3):

$$b = z_1^{-2} F R_2(s_1)^{-2/m},$$

and the formulas for calculating the axial, radial, and tangential velocity components of the fluid are written as

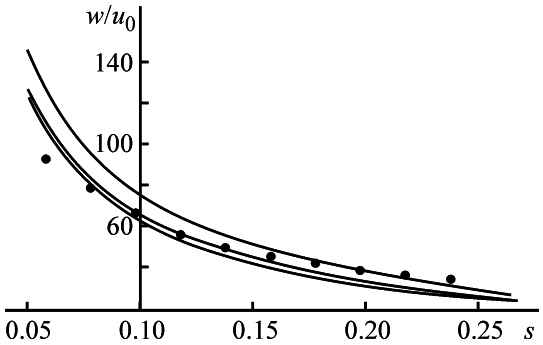

Fig. 1. Tangential velocity component w/u_0 vs. the coordinate s at varied parameter m. For comments, see text.

$$u = \frac{z^{m-2}F'_2}{z_1^m F_1(s_1)s},$$

$$v = \frac{z^{m-2}(F'_2 - mF_2 s^{-1})}{z_1^m F_2(s_1)},$$

$$w = w_0 r_0 r^{-1}\left[1 + \frac{mz^{2(m-1)}F_2^{2(m-1)/m}}{r_0^2 w_0^2 (m-1) z_1^{2m} F_2(s_1)^2}\right]^{1/2}.$$

At $b = 0$, the tangential velocity component is calculated by the formula [Eq. (6)]

$$w = w_0/r. \quad (8)$$

This dependence and the dependences obtained at $a = 0$, $b \neq 0$, and varied parameter m are shown in Fig. 1. Naturally, the theory becomes inapplicable near the apparatus axis. A comparatively thin air column is formed in this zone, and the fluid rotates in a certain vicinity of this column as a solid body. The curves were plotted at the following values of the parameters s_0, w_0, and z: $s_0 = 0.268$, $w_0 = 16.5$, $z = 1/(2s_0)$, $z_1 = 4.27$, and $s_1 = 0.0563$. The curve describing the dependence (8) is the closest to the abscissa. The two other curves were plotted for $m = 1.2$ and 2.1. The points in Fig. 1 represent the experimental data from [4]. The agreement with the experimental data is good. The most pronounced deviations are observed at small values of s, which correspond to radial coordinates comparable with the radius of the discharge pipe.

The larger the value of parameter m, the lower the run of the corresponding curve. Figure 1 shows that parameter m exerts a comparatively weak influence on the dependence of the tangential velocity component

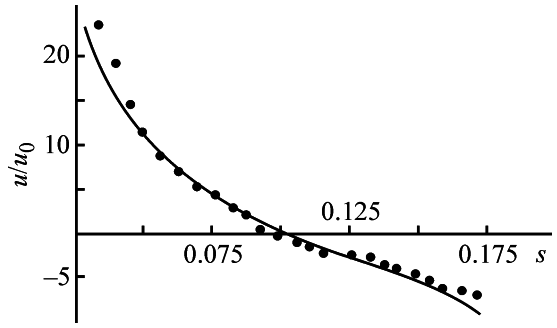

Fig. 2. Dependence of the axial velocity component u/u_0 on the coordinate s, compared with experimental data.

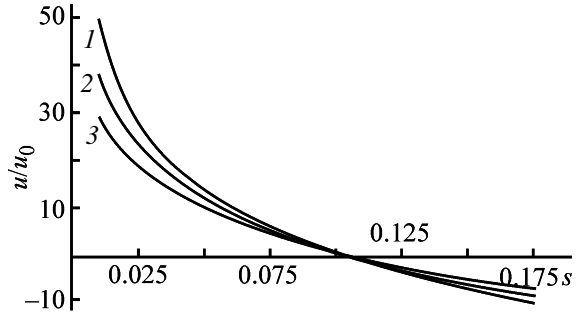

Fig. 3. Dependence of the axial velocity component u/u_0 on the coordinate s at $a = 0$ and $m = 1.8$ (*1*), 2.0 (*2*), and 2.2 (*3*).

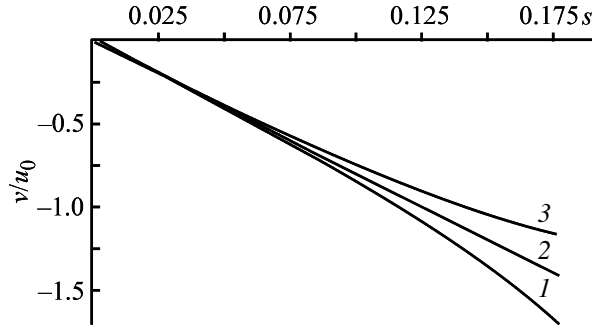

Fig. 4. Dependence of the radial velocity component v/u_0 vs. the coordinate s at $a = 0$ and $m = 1.8$ (*1*), 2.0 (*2*), and 2.2 (*3*).

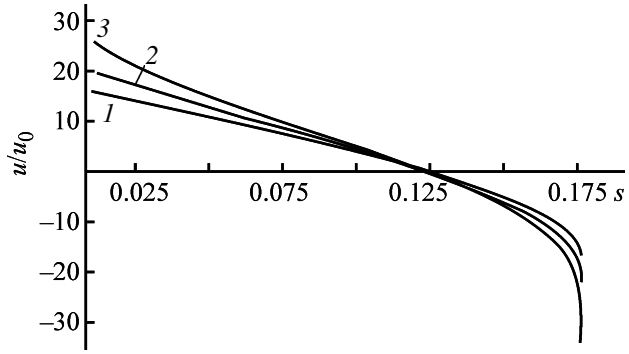

Fig. 5. Dependence of the axial velocity component u/u_0 on the coordinate s at $b = 0$ and $m = 2.6$ (*1*), 2.4 (*2*), and 2.2 (*3*).

on the distance from the apparatus axis. Also weak is the dependence of this quantity on coordinate z at a fixed value of s. The tangential velocity component differs the most strongly from the value calculated by formula (8) at such a value of s at which the second term in the radicand in the right-hand part of formula (6) reaches a maximum, i.e., at the shell of zero vertical velocity.

Parameter m exerts the strongest influence on the dependence of the axial and radial velocity components on coordinate z. The radial velocity component of the fluid in the hydrocyclone is small in magnitude. Therefore, reliable experimental data concerning the dependence of the radial component on the axial and radial coordinates are lacking. The experimental dependences of the axial velocity component on the radial coordinate at various axial coordinates have been obtained by Monderon with a laser Doppler anemometer [5]. These data make it possible to find parameter m for the hydrocyclone analyzed here. Figure 2 compares the experimental data with the calculated dependence. The following values of the parameters were taken in plotting the curves: $s_0 = 0.1763$, $z_1 = 6.338$, $s_1 = 0.05259$, $z = 4.471$, and $m = 1.2$. It is noteworthy that Monderon's experimental data confirm the self-modeling dependence of the velocity on coordinates, adopted in this study.

The dependences of the axial and radial velocity on coordinate s, plotted for the case $a = 0$ and $b \neq 0$ at varied parameter m, are shown in Figs. 3 and 4, respectively. These dependences were plotted for the following values of the parameters: $s_0 = 0.176$ ($\alpha = 10°$), $z_1 = 8.74$, $s_1 = 0.0305$, and $z = 1/s_0$. The larger the value of parameter m, the closer to the abscissa the run of the curve for the radial velocity component. As parameter m increases, the zero-vertical-velocity shell shifts toward the apparatus wall. The dependence of coordinate s_2 at which the axial velocity becomes zero on parameter m is weak. For example, $s_2/s_0 = 0.5962$ at $s_0 = 0.268$ and $m = 1.5$, $s_2/s_0 = 0.6051$ at $m = 2.0$, and $s_2/s_0 = 0.6113$ at $m = 2.5$. According to the experimental data presented in Bradley's monograph [6], s_2/s_0 is approximately 0.61, in good agreement with the values mentioned above.

The plots of the axial velocity component against coordinate s, constructed for the case $a \neq 0$ and $b = 0$ and varied parameter m, are shown in Fig. 5. The values of parameters s_0, z_1, s_1, and z were taken to be the same as those in plotting Figs. 3, 4. As m becomes higher, the magnitude of the velocity decreases. The most pronounced difference from the case $a = 0$ is in that the zero-vertical-velocity shell is situated

closer to the apparatus wall. The calculations performed at $a \neq 0$ and $b \neq 0$ show that, at a constant m and varied a/b^2, the zero-vertical-velocity shell shifts toward the hydrocyclone wall as the a/b^2 ratio increases.

Thus, parameter m exerts the strongest influence on the behavior of the axial and radial velocity components with coordinate z [formulas (4), (5)] and on the maximum value of the axial velocity component. The relation between parameters a and b has the most pronounced effect on the position of the zero-vertical-velocity shell. These conclusions can be used in determining the numerical values of these parameters from experimental data. The values of the parameters ($a = 0$, $m = 2$) accepted by Bloor and Ingham [7] correspond to the following conditions at the hydrocyclone inlet. The fluid flow arriving at the hydrocyclone at $z = z_1$ and $r_i < r < 1$ has a constant pressure p, zero radial velocity component ($v = 0$), and constant axial and tangential velocity components ($u = -u_i = \text{const}$, $w = w_i = \text{const}$). Here, the value of coordinate r_i is not known beforehand.

With the exception of two particular cases ($a = 0$, $m = 2$ and $b = 0$, $m = 4$), no analytical solution to Eq. (1) can be constructed and we are forced to use the results of a numerical solution of this equation for calculating the fluid velocity components. In calculating the process of suspension separation in a hydrocyclone, it would be convenient to have approximate analytical expressions for the fluid velocity components. To construct these expressions, we could make an attempt to use asymptotic expansions of the solution at small values of parameter s, similar to those considered in [1]. Each expansion of this kind contains an uncertain parameter that cannot be found when constructing an asymptotic expansion. We could make an attempt to retain a certain finite number of terms in the asymptotic expansion and define the uncertain constant in the resulting approximate expression so that the condition $F(s_0)$ should be satisfied. It is in this way that the approximate expression for the stream function is constructed in [8], with only the first two terms retained in this expression. However, comparison with the exact solution shows that this method fails to produce good results. The point is that the asymptotic expansion becomes inapplicable at $s = s_0$ because of the existence of the nonlinear right-hand part of the equation. We can use two expansions at s close to zero and s close to s_0. The uncertain constants in these expansions can be found from the matching condition for these expansions at intermediate values of s. However, the expressions obtained in this case are rather cumbersome and it is simpler to directly use the numerical solution.

CONCLUSION

Relations that can be used to calculate the fluid velocity components in a hydrocyclone were derived. It was shown that the results obtained are in good agreement with the experimental data. These results are necessary for developing a procedure for calculating processes of suspension separation in hydrocyclones.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis and Properties of Aliphatic Oligoamides Containing Methionine Fragment

E. V. Fomina, Yu. A. Kurskii, L. N. Beloded, and G. N. Chervyakova

Kargin Research Institute of Polymers, Federal State Unitary Enterprise, Dzerzhinsk, Nizhni Novgorod oblast, Russia

Received January 11, 2006

Abstract—Oligoamides were prepared from dimerized fatty acid, hexamethylenediamine, and an amino acid (methionine). The effect of methionine on the course of polycondensation and properties of the reaction products was examined. New thermoplastic adhesive compounds based on these products were developed.

DOI: 10.1134/S1070427206050156

Oligoamide products derived from dimerized fatty acid (DFA) and aliphatic diamines are widely used as base components of thermoplastic (hot-melt) adhesives [1–3].

The specific structural features and composition of the DFA used allow preparation of oligoamides exhibiting high adhesion to various materials, high shock resistance, flexibility, and resistance to water and oils [4, 5].

Introduction of various modifying agents (e.g., carbonyl compounds and dicarboxylic acids) into these oligoamides strongly affects the structure and properties of the products and, as a consequence, the characteristics of hot-melt adhesives based on them [6, 7].

Of particular interest in this respect is the modifying effect of methionine (α-amino-γ-methylthiobutyric acid), due to several reasons. First, a fairly bulky substituent, $CH_3SCH_2CH_2$, in the α-position of methionine should affect the physicochemical properties of the products [8–10]. At the same time, methionine plays an important role in biosynthesis processes, and introduction of its fragment into an oligoamide macromolecule may be a route to promising biodegradable materials, which would allow solution of environmental problems associated with the utilization of spent oligo- and polyamides [11, 12].

In this study we prepared a series of oligoamides differing in the content of methionine fragments and examined the specific features of polycondensation and the structure and properties of the products.

EXPERIMENTAL

As starting reagents we used methionine (Met) [GOST (State Standard) 23423–89], DFA of the PRIPOL 1017 brand (the Netherlands, CAS no. 61788-89-4), hexamethylenediamine (HMDA) [TU (Technical Specifications) 6-09-36–73), and wollastonite filler (NordKalk, Finland) FW-70, FW-325, and WIC-10 (mean particle diameter ≤90, ≤13, and ≤4.5 μm, respectively).

The procedure for preparing oligo- and polyamides derived from DFA and aliphatic diamines is described in detail in [1, 2] and involves the polycondensation in a nitrogen atmosphere at 160–240°C for 5–6 h without solvents and catalysts.

The synthesis of oligoamides modified with methionine is characterized by certain specific features associated with the fact that at 200–240°C *D*-methionine melts with decomposition; also, the tendency of α-amino acids to cyclize on heating with the formation of 2,5-diketopiperazines [13, 14] should be taken into account.

Therefore, the joint polycondensation of DFA, HMDA, and methionine was performed under milder conditions, which allowed us to minimize the formation of diketopiperazines and avoid thermal decomposition of the amino acid molecules into low-molecular-weight products.

A reactor was charged with the required amounts of DFA and HMDA. The mixture was heated to 80–100°C with stirring until a homogeneous mass was obtained. Then methionine was added, and the mix-

ture was slowly (over a period of 40 min) heated with vigorous stirring to 160–165°C, after which the water release started. Then the mixture was gradually (over a period of 7–8 h) heated to 195–200°C. The final step was performed under the conditions ensuring efficient removal of water (133.32–666.60 Pa, 1–1.5 h, 140–190°C). The product yield was 97.5–98.3%.

The modification of oligoamides with methionine can be represented by the scheme

$$(n+1)H_2N\text{–}R\text{–}NH_2 + nHOOC\text{–}R'\text{–}COOH + nHOOC\text{–}\underset{\displaystyle NH_2}{\underset{|}{CH}}\text{–}(CH_2)_2SCH_3 \longrightarrow H_2N[RNHC(O)R'C(O)NH\underset{\displaystyle (CH_2)_2SCH_3}{\underset{|}{CHC}}(O)NH]_nRNH_2 + 3nH_2O,$$

where R = $(CH_2)_6$, R' = $C_{34}H_{62}$, n = 3–5.

The structure of the compounds prepared was studied by IR and NMR spectroscopy. The IR spectra were recorded on a Specord M80 spectrometer in the range 4000–700 cm^{-1}. The NMR spectra were measured on a Bruker DPX-200 spectrometer (operating frequency 200 MHz for ^1H and 50 MHz for ^{13}C; solvent $CDCl_3$; reference tetramethylsilane).

The molecular-weight characteristics of the reaction products were studied by gel permeation chromatography (GPC) using a set of five Styrogel columns with pore diameters of 10^5, 3×10^4, 10^4, 10^3, and 250 Å (Waters). An R-403 differential refractometer (Waters) was used as detector; an LCD 2563 photometer (λ 254 nm) was additionally used; the eluent was tetrahydrofuran (THF). The chromatograph was calibrated with polystyrene references (polydispersity coefficient $\overline{M}_w/\overline{M}_n \le 1.1$, molecular weight M in the range 2000–100 000).

The amine numbers (AmN), acid numbers (AcN), and molecular weights (M) of the oligoamides were determined chemically from the amounts of terminal functional groups following the standard protocols [15]; the softening point T_s was determined by the ring-and-ball method (GOST 11506–73), and the shear strength of glue joints, according to GOST 14759–69.

The kinetics of the reaction of DFA, HMDA, and methionine was studied by measuring the amount of water distilled off during the reaction.

The kinetic curves (Fig. 1) show that the polycondensation of DFA with HMDA occurs more actively

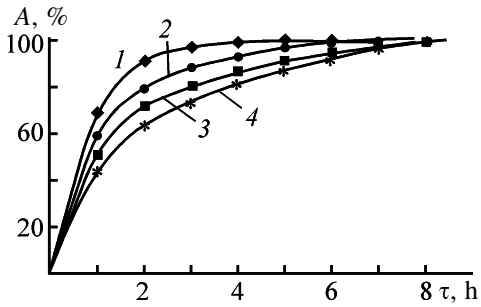

Fig. 1. Amount A of water released in the polycondensation as a function of the reaction time τ. DFA : HMDA : Met ratio: (*1*) 0.40 : 0.50 : 0, (*2*) 0.40 : 0.50 : 0.10, (*3*) 0.40 : 0.50 : 0.25, and (*4*) 0.40 : 0.50 : 0.50.

in the absence of methionine: 70% of the theoretical amount of water is released during the first hour of the reaction; ~90%, within 2 h; and ~96%, within 3 h. Then, as the concentration of the functional groups of the starting compounds decreases, the reaction decelerates; it is complete in 6 h. In the reaction of DFA with HMDA and methionine, the rate of formation of the final product noticeably decreases with an increase in the methionine content. Addition of 0.1 molar equivalent of metionine causes the amount of water released during the first hour of the reaction to decrease to 60% of the theoretical amount; with 0.25 molar equivalent of methionine, this quantity decreases to 53%, and with 0.5 molar equivalent of methionine, to 45%. The total reaction time in the presence of methionine increases to 7–8 h.

Presumably, the mutual influence of the amino and carboxy groups in the methionine molecule and the presence of a bulky substituent, $CH_3SCH_2CH_2$, in the α-position relative to these groups lead to a certain deceleration of the polycondensation in the system DFA–HMDA–Met, compared to the Met-free system.

The polycondensation products are golden-yellow solids with a weak methionine odor; their properties are given in Table 1.

With an increase in the amount of Met added, the molecular weight of the polycondensation product gradually decreases. As compared to the product prepared from DFA and HMDA without methionine, M of the oligoamides containing methionine fragments is lower by a factor of 1.2–2.3. This fact may be due to structural features of methionine and to its capability to terminate the propagating oligomer chain. Correspondingly, the softening point decreases with increasing methionine content. Apparently, incorporation of methionine makes the oligoamide structure irregular, causing an increase in the distance between

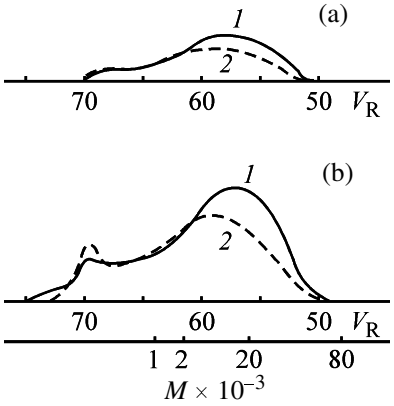
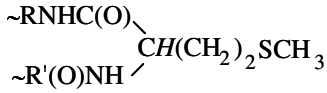
the adjacent macromolecules and hence in the number of hydrogen bonds between the adjacent oligoamide chains; as a result, the softening point decreases [16].

To confirm the incorporation of methionine into the oligomer and determine how methionine is bonded with the oligomer, we examined the chemical structure of polycondensation products formed in the system DFA–HMDA–methionine by IR and NMR spectroscopy. The expected amide structure was confirmed by the characteristic amide vibrations [1]. However, we revealed no specific shift of the absorption bands under the influence of intra- and intermolecular interactions caused by the introduction of the amino acid containing a heteroatomic substituent in the α-position. Furthermore, assignment of S–C bands is complicated by their weak intensity, and identification of this fragment by IR spectroscopy is impossible.

The NMR spectra furnish more information. They convincingly confirm the incorporation of the amino acid into the oligoamide; the methionine fragments were detected in different parts of the oligomer chain:





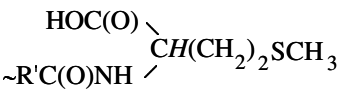


Fig. 2. Gel chromatograms [(a) refractometric and (b) UV detector] of oligoamide samples. DFA : HMDA : Met ratio in the reaction system: (*1*) 0.40 : 0.50 : 0.25 and (*2*) 0.40 : 0.50 : 0.50. (V_R) Relative retention volume and (M) molecular weight (polystyrene references).

both in the middle and on the ends. In the ^{1}H NMR spectrum, along with strong signals belonging to amide groups [1], we additionally detected signals of CH_3S protons at about 2.1 ppm, signals of the methine protons of the fragment

at 4.2 ppm, and signals at 4.6 ppm assignable to the methine protons of the fragment

.

At the same time, we detected no expected signals of the methine protons of the fragment ~RNHC(O)·$CH(NH_2)CH_2CH_2SCH_3$ at 3.1 ppm. These signals, however, may be obscured by strong signals of the $–CH_2C(O)NH–$ protons.

Examination of the molecular-weight distribution (MWD) of the compounds obtained involved certain problems due to low solubility in THF of higher-molecular-weight samples containing from 0.05 to 0.2 molar equivalent of methionine. It is known that oligo- and polyamides are resistant to the majority of solvents used and dissolve only in substances containing strongly polar groups [17]. Therefore, we determined the molecular-weight parameters only for products containing 0.25 (Table 1, sample no. 5) and 0.50 (sample no. 6) molar equivalent of methionine, which had lower molecular weight (Table 1) and higher solubility in THF. This fact confirms the previous data [17] that the solubility of oligo- and polyamides in common solvents can be increased by performing the synthesis in the presence of components containing a sulfur heteroatom.

The gel chromatograms of the reaction products obtained from DFA, HMDA, and methionine are shown in Fig. 2. It should be noted that calculation of the molecular weights from the polystyrene calibration

Table 2. Molecular parameters of sample nos. 5 and 6

Sample no.	Chemical method, M_n	GPC (refractometric detector)		
		$\overline{M}_n$	$\overline{M}_w$	$\overline{M}_w/\overline{M}_n$
5	2500	2000	7800	3.9
6	2200	1500	5400	3.6

does not give true molecular weights but allows adequate comparison of the MWDs of different samples of similar nature [18].

The chromatographic patterns show that the fractional composition of the samples obtained is nonuniform, with the prevalence of low-molecular-weight and oligomeric fractions; the MWD curves are essentially bimodal. The mean molecular weights M are $600 < M < 40\,000$ for sample no. 5 and $600 < M < 32\,000$ for sample no. 6.

The MWD data for methionine-containing oligoamides are given in Table 2.

A comparative analysis of the molecular weights of methionine-containing oligoamides shows that the number-average molecular weights obtained using various methods are in reasonable agreement. The GPC examination confirmes a decrease in M of the oligomer with an increase in the methionine content.

Methionine-modified oligoamides were used for the development of new thermoplastic adhesive formulations. Along with single-component hot-melt adhesives consisting of the base thermoplastic only, we tested a series of filled adhesives. Here we report the results obtained with wollastonite, one of the most promising fillers. Table 3 shows that introduction of wollastonite considerably expands the working temperature range of adhesive formulations, shortens the curing time, enhances the shear strength of the glue joint, and decreases the cost of the adhesive.

It should be noted that such an effect of wollastonite on the properties of adhesive formulations is determined by a characteristic needle-like shape of its crystals and by the specific chemical composition. Owing to the active surface of the particles, this filler is capable of hydrogen bonding with oligoamide molecules; an important factor is the dispersity of the wollastonite [19, 20]. Our results show that the best physicomechanical and processing characteristics are exhibited by filled hot-melt adhesives containing 20 or 50 wt % wollastonite; the strongest effect is attained with 50 wt % wollastonite WIC-10.

CONCLUSIONS

(1) Addition of methionine to the reaction mixture in the synthesis of oligoamides from dimerized fatty acid and hexamethylenediamine decelerates by a factor of 1.5, on the average, the polycondensation and formation of the final product.

(2) With an increase in the relative amount of methionine, the molecular weight of the product decreases by a factor of 1.2–2.3, and the softening point, by 5–29°C.

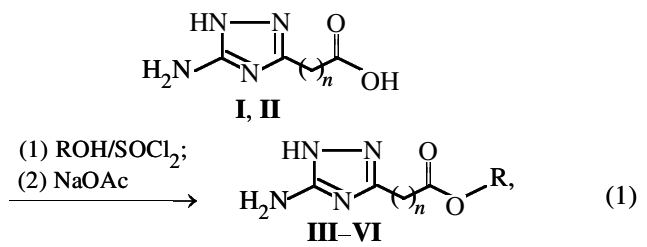
Abstract—Various synthetic routes to esters and amides of 5-amino-1,2,4-triazole-3-carboxylic and 5-amino-1,2,4-triazol-3-ylacetic acids were examined.



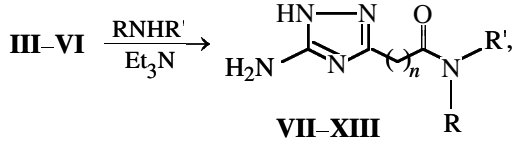
DOI: 10.1134/S1070427206050168

5-Amino-1,2,4-triazole-3-carboxylic (**I**) and 5-amino-1,2,4-triazol-3-ylacetic (**II**) acids and their esters and amides are valuable chemicals for the synthesis of drugs, herbicides [1–5], dyes [6–8], and high-energy-capacity compounds [9].

The goal of this study was the development of improved procedures for preparing esters and amides of acid **I** and **II**.

The above esters are most frequently prepared by esterification of acids **I** and **II** with alcohols in the presence of dry HCl [2, 4, 10, 11]. The reaction is reversible; therefore, its products are formed in moderate yields, and a large excess of anhydrous alcohol is required; to be reused, the alcohol should be dehydrated. The recently suggested [1] procedure for esterification of acid **I** with methanol in the presence of $SOCl_2$ (total yield of ester **III** 67%) eliminates this drawback; however, the reaction takes much time (24 h) and is performed at low temperature.

We found that methyl and ethyl esters **III**–**VI** can be prepared in good yields by esterification of acids **I** and **II** with alcohols in the presence of $SOCl_2$ with refluxing [reaction (1), see table]; in so doing, the synthesis time is as short as 4 h, and the spent alcohol can be repeatedly reused without preliminary dehydraion.



(1)

where n = 0 (**I**, **III**, **V**), 1 (**II**, **IV**, **VI**); R = Me (**III**, **IV**), Et (**V**, **VI**).

One of the simplest routes to amides of acids **I** and **II** might be the reaction of chlorides of these acids with amines. However, we failed to prepare the required acid chlorides. Refluxing of acids **I** and **II** with $SOCl_2$ or their heating with PCl_5 yielded an unseparable mixture of products, apparently because of side reactions such as self-acylation of amino group and nitrogen atoms of the triazole ring with the COCl group. Attempts to prepare the desired amides by the reaction of acids **I** and **II** with thionyl chloride and amines in pyridine at 0–100°C also failed.

The synthesis of amide of acid **I** by heating of ester **III** with aqueous ammonia was reported in [12]. However, we failed to prepare other amides by this procedure. The reactions of **III**–**VI** with amines in THF, performed by the procedure suggested previously [5] for preparing amides of 5-amino-4-alkyl-1,2,4-triazole-3-carboxylic acids, were very slow, probably because of the low solubility of the esters in THF. The best results were obtained when esters **III**–**VI** were heated with aliphatic amines in the presence of triethylamine at 85–90°C [reaction (2), see table]:

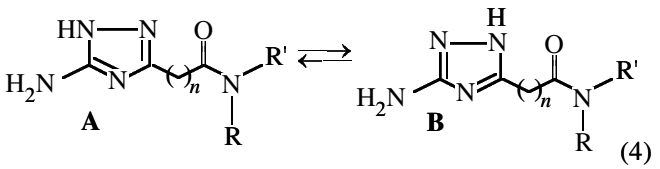
* Compounds **III** and **V** were recrystallized from H_2O; **IV**, **VI**–**X**, **XII**, **XIII**, and **XV**–**XVII**, from EtOH; and **XI**, **XIV**, and **XVIII**, from DMF.

** Published data, mp, °C: **III**, 220 [10]; **V**, 247 [11]; **VI**, 156–158 [3].

substituents in the benzene ring, the desired amides were not formed under the above conditions, and under more severe conditions (heating to 150°C without solvent or refluxing in DMF) an unseparable mixture of products was obtained.

We managed to prepare the anilides by treatment of anilines with PCl_3 followed by the reaction of the resulting organophosphorus compound, without its isolation, with acids **I** and **II**. By this procedure we prepared compounds **XIV**–**XVIII** [reaction (3), see table]:



(3)

XIV–**XVIII**

where n = 0 (**XIV**, **XVI**, **XVIII**), 1 (**XV**, **XVII**); R = Ph (**XIV**, **XV**), *p*-ClC_6H_4 (**XVI**, **XVII**), *p*-$MeOC_6H_4$ (**XVIII**).

The compositions and structures of the compounds prepared were determined by elemental analysis, ^{1}H NMR spectroscopy, and mass spectrometry; their purity was confirmed by HPLC.

The compounds obtained exhibit prototropy and can exist in the form of tautomers **A** and **B** [equilibrium (4)]. According to ^{1}H NMR spectra, in DMSO tautomer **A** prevails [δ(NH_2) 5.6–6.0 ppm, see table]. Minor amounts of tautomer **B** were detected in the spectra of amides **VII**, **IX**, **X**, **XIV**, and **XVIII** (additional broadened singlet ot the amino group at 4.8–5.1 ppm). The chemical shifts of amino group protons in tautomers **A** and **B** are consistent with published data for other 3(5)-amino-1,2,4-triazoles [13].

(4)

The mass spectra of all the compounds prepared contain a strong peak of molecular ion.

EXPERIMENTAL

The ^{1}H NMR spectra were recorded on a Varian Unity 300 spectrometer (300 MHz, DMSO-d_6, internal reference TMS). The mass spectra were taken on a Finnigan MAT-Incos 50 device with direct sample inlet (electron impact, 70 eV). The melting points were determined with a PTP device. The HPLC analysis was performed with a Milikhrom-5 chromatograph equipped with a UV detector and an 80 × 2-mm column packed with Separon C_{18}; the mobile phase was methanol (flow rate 80 μl min^{-1}). The detection was performed at λ 210 nm.

Acids **I** and **II** were predried in a vacuum at 105–110°C for 24 h.

Esters of 5-amino-1,2,4-triazole-3-carboxylic (III, V) and 5-amino-1,2,4-triazol-3-ylacetic (IV, VI) acids. A 0.047-mol portion of $SOCl_2$ was added dropwise with stirring to a mixture of 0.047 mol of acid **I** or **II** and 0.4 mol of anhydrous methanol or ethanol. The mixture was heated to boil and refluxed for 1 h, after which an additional 0.047 mol of $SOCl_2$ was added, and the refluxing was continued for 3 h more. Excess alcohol was distilled off in a water-jet-pump vacuum, and a saturated solution of sodium acetate was added with cooling to the residue to pH 5–6. The precipitate thus obtained was filtered off, washed with water, and recrystallized.

Amides of 5-amino-1,2,4-triazole-3-carboxylic (VII, IX, XI, XIII, XIV, XVI, XVIII) and 5-amino-1,2,4-triazol-3-ylacetic (VIII, X, XII, XV, XVII) acids. (a) A mixture of 0.1 mol of ester **III**–**VI**, 0.02 mol of triethylamine, and 0.012 mol of aliphatic amine was heated at 85–90°C for 3 h (synthesis of **XIII** was performed in a sealed ampule), after which triethylamine and excess aliphatic amine were distilled

off in a vacuum, 2–3 ml of water was added to the residue, and the precipitate was filtered off and recrystallized.

(b) A 0.006-mol portion of PCl_3 was added with stirring and cooling to a mixture of 0.012 mol of appropriate aniline and 4 ml of pyridine. The mixture was stirred for 10 min at room temperature, after which 0.01 mol of acid **I** or **II** was added, the mixture was stirred for an additional 10 min at room temperature, heated to 110–120°C, kept at this temperature for 45 min, and diluted with 10 ml of H_2O. The precipitate thus formed was filtered off and recrystallized.

CONCLUSIONS

(1) It is advisable to prepare methyl and ethyl esters of 5-amino-1,2,4-triazole-3-carboxylic and 5-amino-1,2,4-triazol-3-ylacetic acids by esterification of the corresponding acids with alcohols in the presence of $SOCl_2$ with refluxing (yield 55–70%).

(2) It is advisable to prepare amides of 5-amino-1,2,4-triazole-3-carboxylic and 5-amino-1,2,4-triazol-3-ylacetic acids by the reactions of aliphatic amines with methyl or ethyl esters of the corresponding acids at 85–90°C in the presence of triethylamine (yield 54–84%) or by successive treatment of aromatic amines with PCl_3 and the corresponding acids in pyridine (the second step, at 110–120°C); yield 46–74%.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Synthesis and Antioxidative Properties of Some 3,4-Dihydropyrimidin-2(1*H*)ones (-thiones)

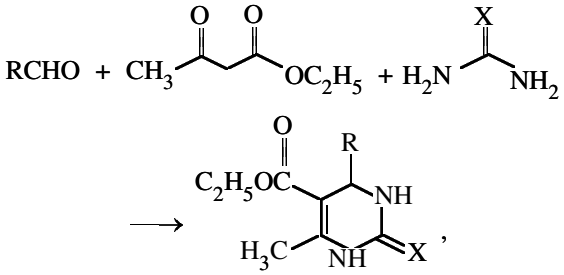
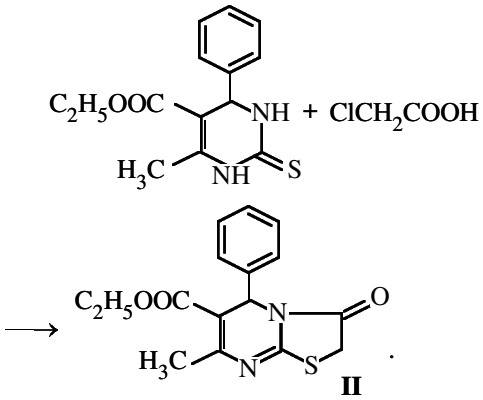
Abstract—3,4-Dihydropyrimidinones (-thiones) were prepared by ternary condensation of various aromatic aldehydes with ethyl acetoacetate and urea (thiourea) in the presence of trichloroacetic acid in ethanol.

DOI: 10.1134/S107042720605017X



Dihydropyrimidinones attract growing interest due to their therapeutical and pharmacological activity [1]. Some functional derivatives of dihydropyrimidinones exhibit a broad spectrum of biological activity, including antiviral, antitumor, and antibacterial activity. Furthermore, 4-aryldihydropyrimidinones are powerful blockators of calcium channels and antihypertonic, α-adrenergic, and neuropeptide antagonists [2].

The simplest and direct route to dihydropyrimidinones, suggested for the first time by Biginelli and involving ternary condensation of an aldehyde, a β-keto ester, and urea, often gives the desired product in a low yield, especially with aliphatic aldehydes [3]. Higher yields can be obtained by performing the reaction in several steps, but in this case the process is not so simple as the one-step Biginelli reaction. Therefore, the Biginelli reaction continues to attract the attention of researchers looking for facile and efficient procedures for preparing dihydropyrimidinones.



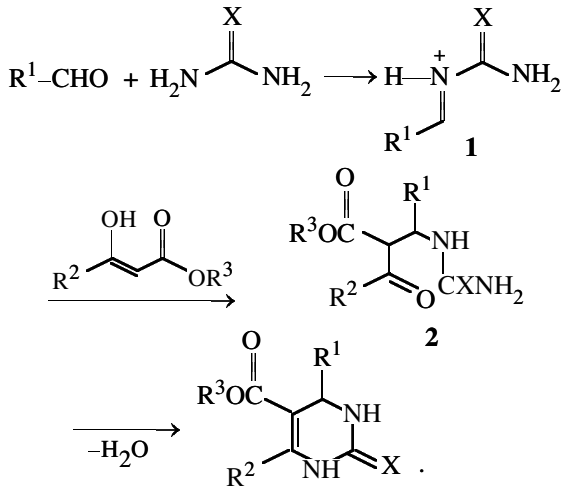
Somewhat improved procedures for preparing dihydropyrimidinones were reported in [4–6]. However, despite their potential significance, these methods are characterized by long reaction time, low selectivity, and problems with isolation of the products from the reaction mixture.

Thus, it is important to develop alternative one-pot procedures for preparing 3,4-dihydropyrimidin-2(1*H*)-ones.

Here we report on a new procedure for preparing 3,4-dihydropyrimidin-2(1*H*)-ones (-thiones) in the presence of trichloroacetic acid. We obtained 3,4-dihydropyrimidinones (-thiones) in high yield by the reaction of various aldehydes with ethyl acetoacetate and urea (thiourea) in the presence of CCl_3COOH as catalyst. The reaction required refluxing in ethanol for 2–4 h.

where X = O, R = CH_3 (**I**), 2-HO-5-BrC_6H_3 (**IV**), 1-naphthyl (**V**); X = S, R = 2-HOC_6H_4 (**III**);

II



The reaction progress was monitored by TLC on Silufol UV-254 plates.

The suggested procedure ensures higher product yields (60–80%). The product can be readily isolated from the reaction mixture by filtration and washing with ethanol and water; recrystallization or chromatographic purification is not required.

The mechanism of formation of dihydropyrimidinones (-thiones) was studied for a long time; the majority of researchers today agree with the following transformation sequence suggested by Kappe [7]:

First, protonated imine **1** is formed; it subsequently reacts with the enol form of the keto ester to give ureide **2**. This is followed by cyclization with the release of a water molecule.

The structures of the compounds were confirmed by IR, ^1H, and ^{13}C NMR spectroscopy.

The physicochemical characteristics and spectral properties of the compounds are given in Table 1.

To evaluate the antioxidative power of **I**–**V** in elementary steps of cumene oxidation, we studied the reactions of **I**–**V** with cumylperoxy radicals (CPRs) and cumyl hydroperoxide (CHP).

The capability of **I**–**V** to terminate oxidation chains by the reaction with CPRs was evaluated using as example the cumene oxidation at 60°C, initiated with azobis(isobutyronitrile) in a concentration of 2×10^{-2} M. We found that compounds **I**–**V** actively terminate oxidation chains by reacting with CPRs (Fig. 1).

From the duration of the induction period τ_{ind}, we calculated the stoichiometric coefficient of inhibition f, equal to the number of oxidation chains terminated on one inhibitor molecule and its transforma-

tion products:

$$f = \tau_{ind} W_i / [In]_0,$$

where W_i is the initiation rate and $[In]_0$ is the initial concentration of the inhibitor In.

From the kinetics of the oxygen uptake, we calculated the rate constants of the reactions of **I**–**V** with CPR, k_7 [8, 9]. To this end, the kinetic curves of the oxygen uptake $[O_2]$–τ were linearized in the coordinates $[O_2]^{-1}$–τ^{-1}, and k_7 was calculated from the line slope: $\tan\alpha = fk_7[In]_0/(k_2[RH]W_i)$ [9, 10], hence, $k_7 = (\tan\alpha)k_2[RH]W_1/(f[In]_0)$, where k_2 is the chain initiation rate [8, 9], equal to 1.51 l mol^{-1} s^{-1}, [RH] = 7.17 M.

The high antioxidative activity and the kinetic parameters of the reactions involving **I**–**V** were also confirmed in experiments on autooxidation of cumene at 110°C (Fig. 2).

Table 2 shows that the parameter f for **I**–**V** varies from 0.5 to 4.22, and the rate constants k_7 of the reactions of the inhibitors with CPR vary from 2.01×10^4 to 2.92×10^4 l mol^{-1} s^{-1}. The transformation products of **I**–**V** formed in the reactions with CPR also exhibit certain inhibiting effect; the oxidation rate after the induction period is somewhat lower than in the uninhibited oxidation (Fig. 1).

The reactions of **I**–**V** with CHP were performed in chlorobenzene in a nitrogen atmosphere at 110°C. All these compounds decompose CHP. The kinetic curves of CHP decomposition under the action of **I**–**V** (the curve obtained with **I** is shown as example in Fig. 3) are S-shaped, which is characteristic of an autocatalytic process. The reaction has a certain induction period in which the CHP consumption is insignificant; this is followed by its catalytic decomposition, and then, as the CHP is consumed, the reaction rate decreases.

Apparently, the inhibitor first reacts with CHP, and the resulting transformation product catalytically decomposes CHP. To determine the reaction stoichiometry, CHP was taken in excess.

The catalytic factor ν is the number of CHP molecules decomposed by one inhibitor molecule; it was calculated as $\nu = ([ROOH]_0 - [ROOH]_\infty)/[In]_0$, where $[ROOH]_0$ and $[ROOH]_\infty$ are, respectively, the initial and final concentrations of CHP, and $[In]_0$ is the initial inhibitor concentration.

Our experiments showed that one molecule of **I**–**V** can decompose up to several ten thousands of CHP molecules. Presumably, compounds **I**–**V** exert a combined inhibiting effect, terminating the oxidation chains in the reaction with CHP and catalytically decomposing CHP.

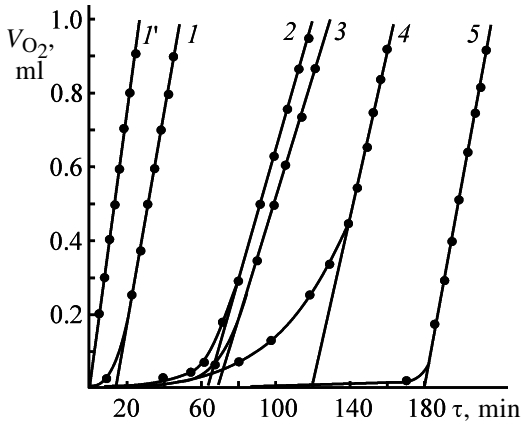

Fig. 1. Kinetic curves of initiated oxidation of cumene in the presence of **I**–**V** (curves *1*–*5*, respectively). 60°C; [AIBN] = 2×10^{-2} M. (V_{O_2}) Oxygen volume and (τ) time; the same for Fig. 2. [InH], M: (*1*') 0 and (*1*–*5*) 5×10^{-5}; the same for Fig. 2.

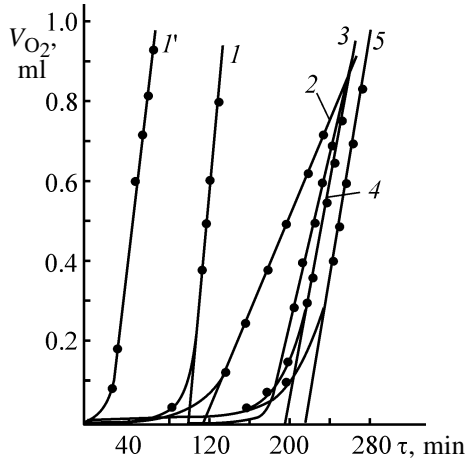

Fig. 2. Kinetic curves of cumene autooxidation in the presence of **I**–**V** (curves *1*–*5*, respectively) at 110°C.

EXPERIMENTAL

The ^{1}H and ^{13}C NMR spectra were recorded on a Bruker-300 NMR spectrometer (300 MHz for ^{1}H), and the IR spectra, on a Specord 75-R spectrometer (mulls in mineral oil). To check the purity of the compounds prepared and monitor the reaction progress, we used TLC on Silufol UV-254 plates (eluent isopropyl alcohol–hexane, 1 : 1).

3,4-Dihydropyrimidin-2(1*H*)-ones (-thiones). A round-bottomed flask equipped with a reflux condenser and a power-driven stirrer was charged with appropriate aldehyde (1.25 mol), ethyl acetoacetate (1.90 mol), urea or thiourea (1.25 mol), CCl_3COOH

Table 2. Kinetic parameters of the reactions of **I**–**V** with cumylperoxy radicals (k_7, f, 60°C, [AIBN] = 2×10^{-2} M) and of the decomposition of cumyl hydroperoxide (k, ν, 110°C)

Compound	T = 60°C		T = 110°C			
	f	$k_7 \times 10^{-4}$, l mol^{-1} s^{-1}	k, l mol^{-1} s^{-1}	ν	$[In]_0$, M	τ, min
I	0.5	2.01	11	20000	5×10^{-5}	100
II	1.54	2.3	33	27000	5×10^{-5}	120
III	1.68	2.92	18.5	22000	5×10^{-5}	180
IV	2.88	2.4	20.8	25000	5×10^{-5}	200
V	4.32	2.85	16.6	30000	5×10^{-5}	220

(25 mg), and 95% ethanol (10 ml). The mixture was stirred for 2–4 h. The reaction progress was monitored by TLC. After the reaction completion, the mixture was cooled to room temperature, and the crystalline product was filtered off, washed with ethanol, dried, and recrystallized from aqueous ethanol (1 : 3).

Cumyl hydroperoxide was purified [10] and then distilled.

Chlorobenzene and cumene were purified by a common procedure based on sulfonation of impurities with concentrated sulfuric acid [11, 12]. The CHP concentration was determined by iodometric titration [10] of samples taken at regular intervals.

Experiments on CHP decomposition were performed in chlorobenzene at 110°C in a glass bubbler in an inert gas atmosphere; the CHP concentration was varied in the range 0.16–0.64 M, and the concentrations of **I**–**V**, in the range $(1–5) \times 10^{-4}$ M.

Experiments on the initiated oxidation of cumene were performed on a manometric unit [12]. As initiator we used AIBN (initiation rate 1×10^{-5} l mol^{-1} s^{-1} at 60°C [13]; initiator concentration 2×10^{-2} M in all the experiments). The concentrations of **I**–**V** were $(1–5) \times 10^{-4}$ M.

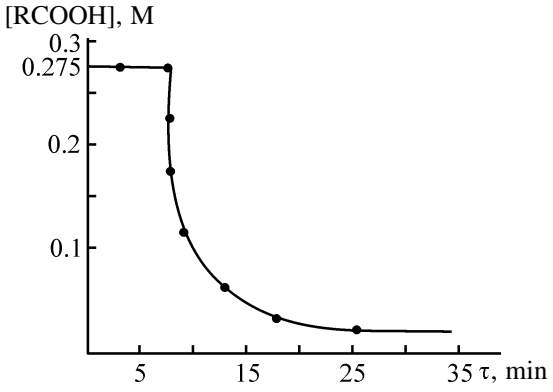

Fig. 3. Kinetic curve of CHP decomposition in the presence of **I**. 110°C; $[In]_0 = 1 \times 10^{-4}$ and $[CHP]_0 = 0.275$ M. (τ) Time.

CONCLUSION

3,4-Dihydropyrimidinones (-thiones) exhibiting high antioxidative power were prepared by ternary condensation.

Abstract—The reaction of a technical mixture of polychlorinated biphenyls with ethanol and potassium hydroxide in dimethyl sulfoxide was studied. The composition of the products formed in the process was determined by gas chromatography and gas chromatography–mass spectrometry.

DOI: 10.1134/S1070427206050181

Polychlorinated biphenyls (PCBs) are persistent global environmental pollutants [1, 2]. The search for methods of their safe destruction or conservation is under way now worldwide. Also, PCBs can be processed into useful materials [2, 3]. We showed previously [4, 5] that PCBs readily react with sodium alkoxides in polar solvents, forming a mixture of products whose composition depends on the structure of the alcohol and the reaction conditions. A possible way of utilization of PCBs is to convert them to hydroxy and alkoxy derivatives to be further introduced into polymer compounds.

In this study we examined reactions of congeners of PCBs from the Sovol technical mixture with ethanol and potassium hydroxide in a polar solvent and sought for conditions ensuring the deepest conversion. Of primary importance is identification of the reaction products, which can be done by gas chromatography–mass spectrometry (GC–MS) only. This study is also of scientific importance, since nucleophilic substitution reactions in the PCB series are virtually not studied.

EXPERIMENTAL

The reaction mixtures were analyzed on a Shimadzu GC-17A gas chromatograph with a flame-ionization detector (FID), an MDN quartz capillary column (an analog of HP-5; length 30 m, inner diameter 0.25 mm, stationary phase film thickness 0.25 μm). Carrier gas nitrogen, flow split ratio 1 : 30. Column temperature: initial 100°C (1 min isotherm), programmed heating at a rate of 10 deg min^{-1} to 200°C and further at a rate of 2 deg min^{-1} to 300°C. Vaporizer temperature 250°C; detector temperature 280°C.

The mass-spectrometric analysis was carried out on a Fisons MD 800 instrument at the electron energy of 70 eV, scanning rate of 1 spectrum per second, recording of the total ion current in the range of m/z 30–400. We used an HP-5 quartz capillary column (length 25 m, inner diameter 0.25 mm, stationary phase film thickness 0.25 μm). Carrier gas helium, flow split ratio 1:20. Column temperature: initial 60°C (3 min isotherm), programmed heating at a rate of 10 deg min^{-1} to 200°C and further at a rate of 2 deg min^{-1} to 280°C. Vaporizer temperature 250°C.

We used a Sovol technical mixture comprising ca. 20% tetrachlorobiphenyls, over 50% pentachlorobiphenyls, ca. 20% hexachlorobiphenyls, and also minor amounts of trichloro- and heptachlorobiphenyls. Previously [6], we identified the major congeners of PCBs in the mixture, which were numbered in accordance with IUPAC recommendations.

The reaction of the PCB mixture with ethanol and KOH in dimethyl sulfoxide (DMSO) was carried out as follows. A round-bottomed flask equipped with a stirrer and a thermometer was charged with a solution of 5.6 g of KOH (0.1 M) in 11.5 ml (0.2 M) of ethanol, 23 ml of DMSO, and 0.05 g of biphenyl as internal reference. The resulting mixture was heated to 130°C until the components dissolved. Then a solution of 8.2 g (0.025 M) of the PCB mixture in 13 ml in DMSO was added into the mixture. The temperature was raised to 150°C and kept constant for a certain period, whereupon the mixture was cooled. Then 50 ml of water, 2 ml of HCl(conc.), and 20 ml of

chloroform were added. The mixture was shaken and transferred into a separatory funnel. The organic layer was separated and dried over anhydrous Na_2SO_4; chloroform was distilled off. We prepared a solution of the reaction product with a concentration of 10 mg ml^{-1} in toluene with tridecane as internal reference in a concentration of 1 mg ml^{-1}, and analyzed the resulting solution by GC with FID (GC–FID).

The reaction progress was monitored in time. The samples were taken just after the PCB mixture was introduced into DMSO at 130°C, after heating to 140°C (15 min), and then every 20 min during 2 h at 150°C. The samples were treated by the following procedure: A 10-ml volumetric flask was charged with 0.5 ml of the reaction mixture, after which 1 ml of water and 5 ml of toluene with the internal reference (tridecane in a concentration of 1 mg ml^{-1}) were added. The resulting mixture was acidified with 0.1 ml of HCl(conc.) and shaken, which was followed by GC–FID analysis of the organic layer after the phase separation.

Then 1 ml of the organic layer was taken, additionally treated with 5 ml of a 1% NaOH solution, and analyzed. Upon this treatment, the hydroxy derivatives of PCBs pass into the alkaline solution, whereas the ethoxy derivatives of PCBs and the initial unchanged PCBs remain in the organic phase.

Formation of hydroxy derivatives of PCBs was additionally confirmed by acylation of the toluene solution with trifluoroacetic anhydride. To this end, 1 ml of the solution was placed into a 10-ml volumetric test tube, 0.02 ml of trifluoroacetic anhydride and 0.005 ml of pyridine were added, and the resulting mixture was kept for 20 min. Then 5 ml of saturated $NaHCO_3$ solution was added, and the mixture was shaken. After the phase separation, the organic layer was analyzed by GC–FID.

The amounts and relative contents of the reaction mixture components were determined relative to the internal reference, biphenyl, and the accuracy of preparation of the solutions analyzed and the stability of operation of the GC system were checked with tridecane as reference.

We showed previously [5] that treatment of the Sovol PCB mixture with sodium ethoxide in the presence of ethanol with DMSO yields monoethoxy derivatives of tri- and tetrachlorobiphenyls, mono- and diethoxy derivatives of pentachlorobiphenyls, and di- and triethoxy derivatives of hexachlorobiphenyls.

In this study, we used a mixture of KOH and ethanol in DMSO as reagent in order to examine the possibility of formation of ethoxy and hydroxy derivatives of PCBs. We carried out a series of experiments with varying the reactant ratio, temperature, and treatment time. The reaction products were analyzed by GC–FID. By so doing, we determined the conditions providing the maximal conversion of the initial PCBs. The molar ratio of the reactants, PCBs : KOH : ethanol, was 1 : 4 : 8; the reaction temperature, 150°C; and the treatment time, up to 120 min.

The reaction products contained certain amounts of unchanged tri- and tetrachlorobiphenyls and no penta- and hexachlorobiphenyls. The chromatographic pattern is much more complex than in the case of ethoxylation [5]. After treating the solution of the reaction products with a NaOH solution, the chromatogram gets simpler; some peaks disappear, and the chromatogram resembles that of ethoxy derivatives. Acylation also causes the chromatographic pattern to change; some peaks are shifted in time. All these facts suggest that the resulting derivatives are ethoxy and hydroxy derivatives of PCBs.

Our study followed the procedure described in Experimental, with sampling. The substitution of the chlorine atoms by ethoxy groups occurs already when the PCB mixture is introduced into a solution of ethanol and KOH in DMSO at 130°C. The chromatogram of the sample taken just after mixing the reactants substantially differs from the initial chromatogram of the PCB mixture. Peaks of tri- and tetrachlorobiphenyls are recorded; their total relative area decreased by 20% compared to that of the initial mixture. The total area of the peaks of pentachlorobiphenyls decreased by 80%, and the peaks of hexachlorobiphenyls fully disappeared.

The GC–MS data showed that, at this moment, the reaction mixture contained the following derivatives: monoethoxytrichlorobiphenyls **2**, monoethoxytetrachlorobiphenyls **4**, diethoxytrichlorobiphenyls **5**, and diethoxytetrachlorobiphenyls **8** (see table). The major transformation products that can be chromatographically detected at this moment are derivatives **4**, products of substitution of one chlorine atom in pentachlorobiphenyls. We never detected monoethoxypentachlorobiphenyls **7**. After treating the extract with a NaOH solution, the chromatographic pattern remained unchanged, all the peaks were recorded; the content of the components remained unchanged. Thus, the first stage of the reaction yields ethoxy derivatives of PCBs only.

After heating the mixture for 15 min (140°C), we obtained a different chromatogram. There were peaks of tri- (PCBs 28, 33, 22) and tetrachlorobiphenyls

Estimation of the relative content of the reaction products of PCBs with ethanol and KOH in DMSO from the base peak areas

Compound	Formula	Molecular ion	Base peaks	Content of indicated derivative	Total content of derivatives
				%	
PCB-3	$C_{12}H_7Cl_3$	256–260	256	0.3	1.2
PCB-4	$C_{12}H_6Cl_4$	290–294	220	0.9	
1	$C_{12}H_7Cl_2OC_2H_5$	266–270	238, 168	1.8	1.8
2	$C_{12}H_6Cl_3OC_2H_5$	300–304	272, 202	12.4	24.7
2-1	$C_{12}H_6Cl_3OH$	272–276	272, 202	4.4	
3	$C_{12}H_6Cl_2(OC_2H_5)_2$	310–314	254, 218	7.9	
4	$C_{12}H_5Cl_4OC_2H_5$	334–338	308, 236	1.8	61.2
4-1	$C_{12}H_5Cl_4OH$	306–310	308, 236	25.8	
5	$C_{12}H_5Cl_3(OC_2H_5)_2$	344–348	316, 288	9.2	
5-1	$C_{12}H_5Cl_3(OC_2H_5)OH$	316–320	316, 288	15.0	
6	$C_{12}H_5Cl_2(OC_2H_5)_3$	354–358	270, 234	7.1	
6-1	$C_{12}H_5Cl_2(OC_2H_5)_2OH$	326–328	270, 234	2.3	
8	$C_{12}H_4Cl_4(OC_2H_5)_2$	378–382	324	1.2	10.8

8-2	$C_{12}H_4Cl_4(OH)_2$	322–326	324	0.9	
9	$C_{12}H_4Cl_3(OC_2H_5)_3$	388–392	304	0.9	
9-1	$C_{12}H_4Cl_3(OC_2H_5)_2OH$	360–364	304	1.1	

(PCBs 52, 49, 44) only; the content of these PCBs in the reaction mixture decreased twofold. The relative area of the PCB peaks was 6%. There were no peaks corresponding to other initial PCBs.

The reaction mixture contained derivatives of tetrachlorobiphenyls (monoethoxytrichlorobiphenyls **2** and diethoxydichlorobiphenyls **3**, with **2** dominating), pentachlorobiphenyls [monoethoxytetrachlorobiphenyls **4**, diethoxytrichlorobiphenyls **5** (dominated, 25% of the total mass), and triethoxydichlorobiphenyls **6**], and hexachlorobiphenyls (diethoxytetrachlorobiphenyls **8**, triethoxytrichlorobiphenyls **9**). Hydroxy derivatives of PCBs were manifested both as individual, fairly intense, peaks, and in the peaks of coeluted compounds. This is suggested by the results obtained after treating the reaction mixture with a NaOH solution. In the GC–FID pattern of the toluene extract, some peaks disappear, and some of them decrease in intensity. The relative decrease in intensity of the sum of the PCBs and derivatives was estimated at 25%.

The chromatogram recorded 35 min after the beginning of the reaction (150°C) also substantially differs from that of the previous one. There are peaks that can be assigned to monoethoxydichlorobiphenyls **1**, derivatives of trichlorobiphenyls. Peaks **2**, which are preserved until the end of the experiment, increased in intensity, as well as a number of peaks of compounds **5** and **8** and peaks of monohydroxytetrachlorobiphenyls **4-1**. Thus, the chromatographic pattern suggests that transformations of less reactive tri- and tetrachlorobiphenyls are still under way and the initially formed derivatives undergo further transformations (both alcoholysis and elimination of the ethyl cation).

The chromatogram of the reaction mixture recorded 55 min after the beginning of the reaction also differs from those observed for the previous samples, but many peaks with identical retention times are preserved. The chromatogram is very complex; there is a large number of overlapping weak peaks. It should be noted that, since this moment, the general chromatographic pattern of the reaction mixture samples remains unchanged until the end of the experiment, with only the relative intensity of the peaks changing.

We gave special attention to studying the composition of the reaction mixture at the end of the process (125 min after the beginning of the reaction). A GC–FID analysis revealed the presence of <2% trichlorobiphenyls and tetrachlorobiphenyls in total. Treatment of the mixture with a NaOH solution showed that the content of the hydroxy derivatives exceeded that of the ethoxy derivatives in the mixture. In this case, we determined the composition of the reaction mixture by GC–MS. It should be noted that the chromatograms obtained on different instruments were not identical, with a better peak resolution characteristic of the GC–FID method. However, processing of the chro-

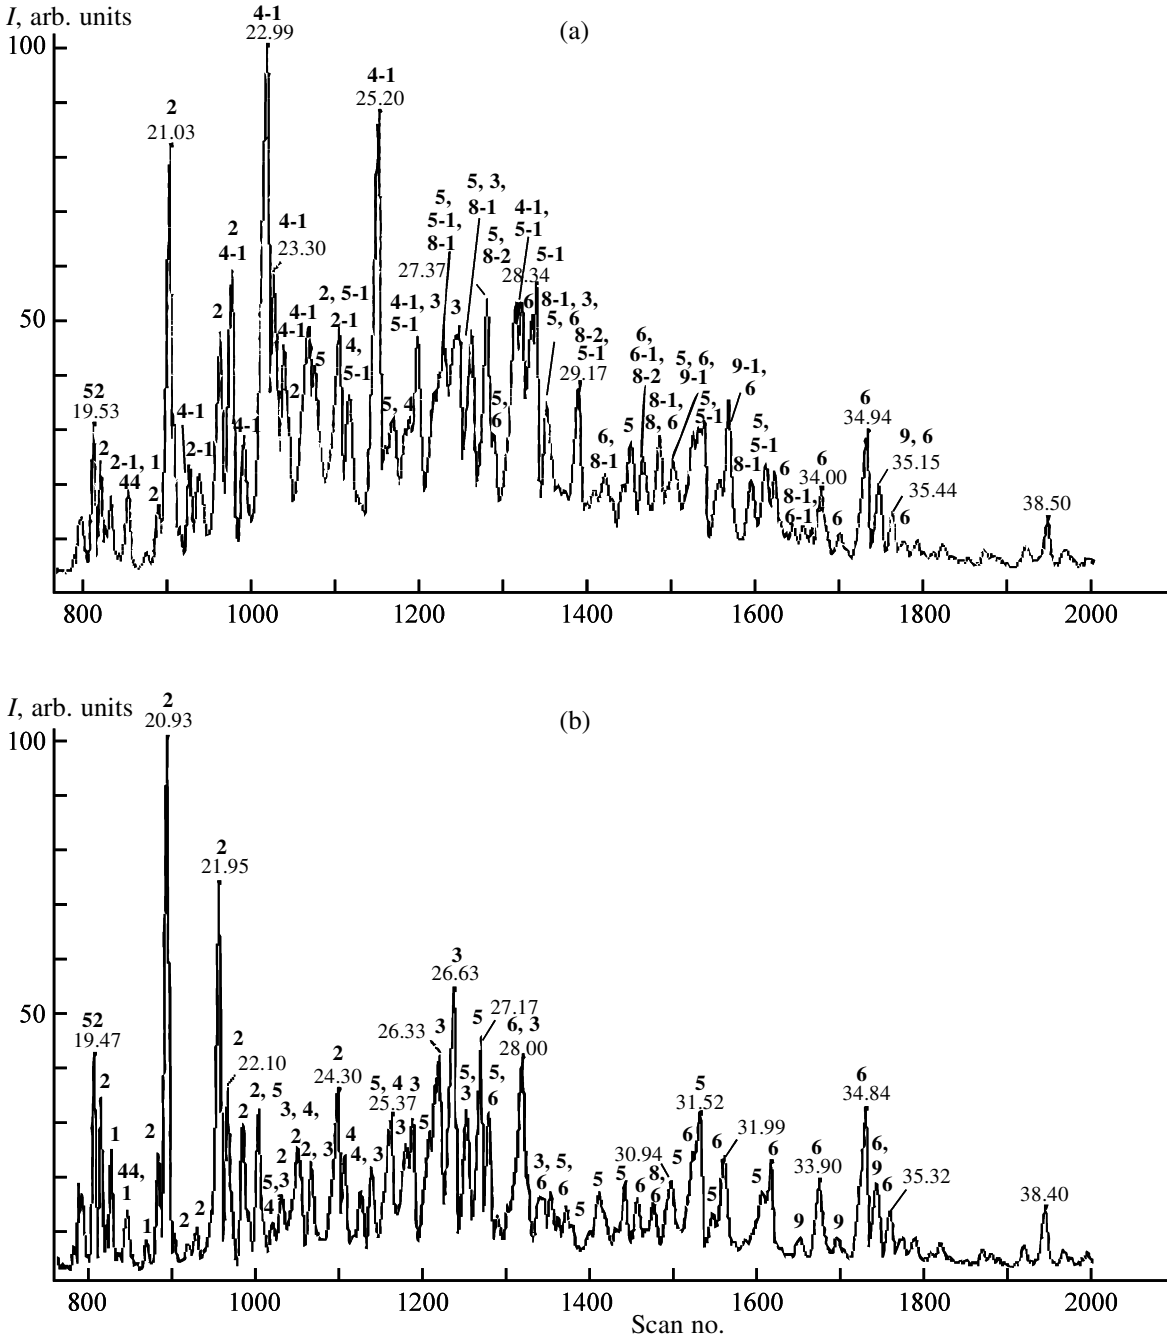

Fig. 1. GC–MS patterns of the products of alcoholysis of the PCB mixture with alcoholic alkali in DMSO. Reaction product (a) untreated and (b) treated with a NaOH solution.

matograms obtained by GC–MS involved reconstruction based on selective ions corresponding to certain types of derivatives, which enabled identification of individual compounds in coelution. We studied the compositions of the reaction mixture extract and the extract after treatment with a NaOH solution. Figures 1a and 1b show the chromatograms of the PCB reaction products. In the latter case, the chromatograms become somewhat simpler; only peaks of the initial PCBs and ethoxy derivatives of PCBs are recorded.

We identified five monoethoxydichlorobiphenyls **1**, whose relative content slowly grew throughout the keeping time.

We identified 14 monoethoxytrichlorobiphenyls **2**; two peaks have a high intensity and individual composition. They are prominent even in the first sample

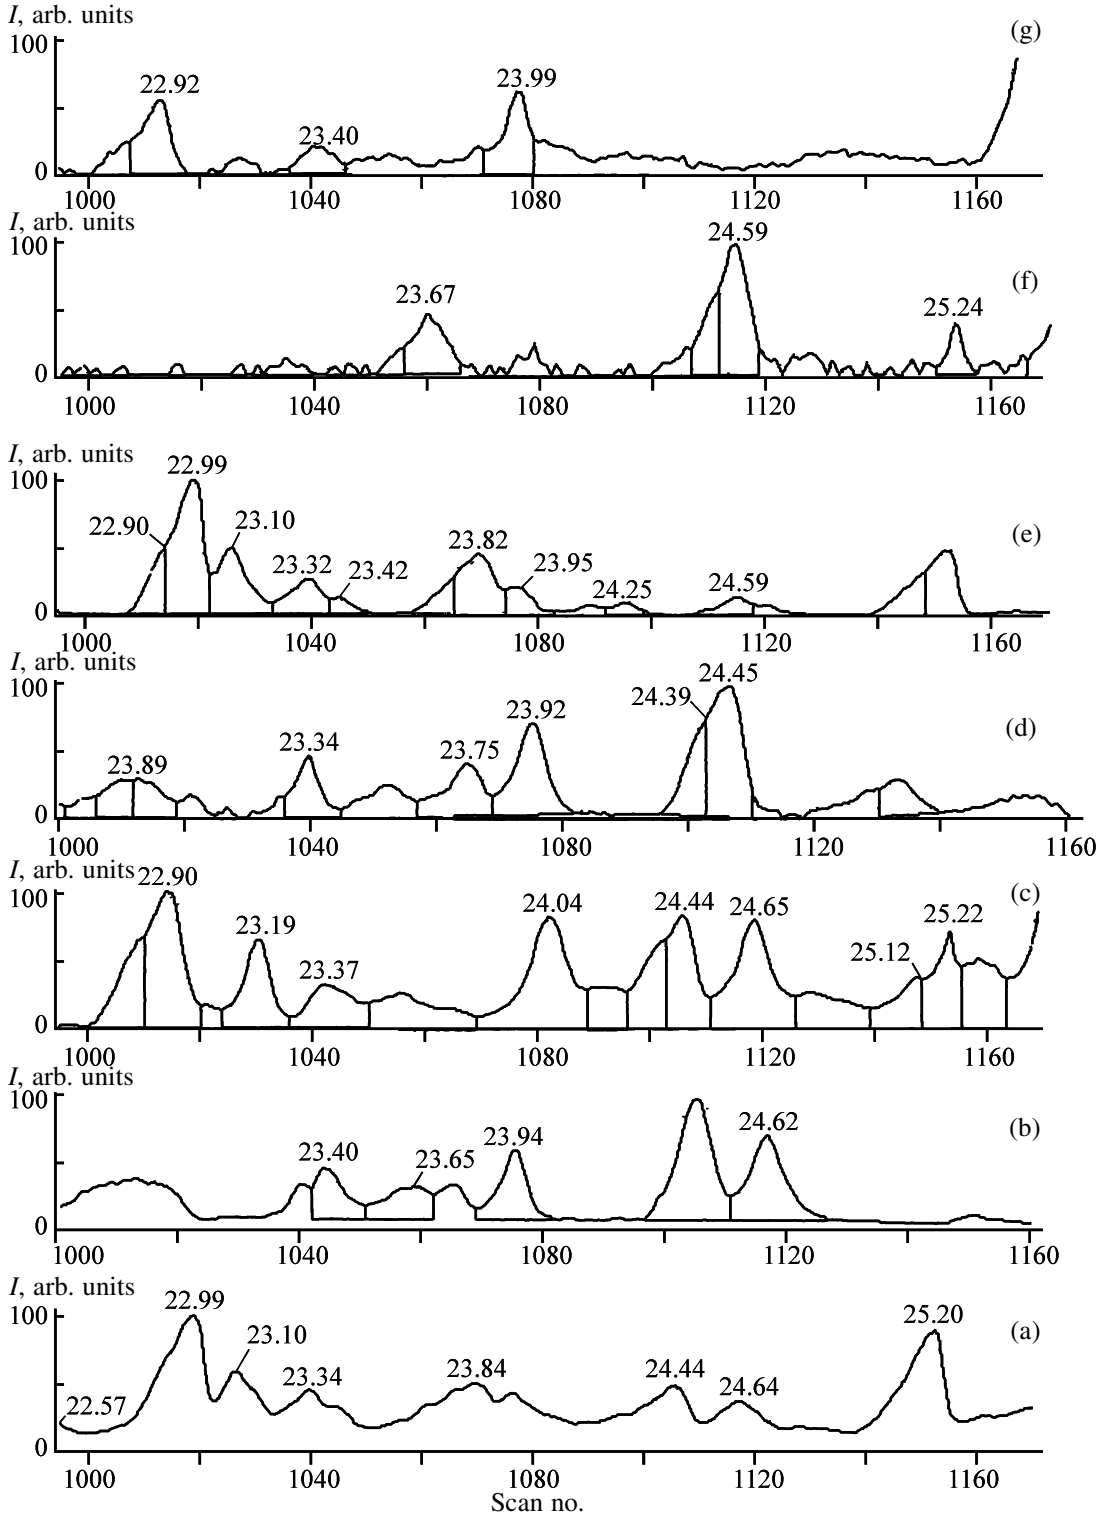

Fig. 2. Processing of the chromatogram of the reaction products: (a) total ion current; *m*/*z*: (b) 202 (**2, 2-1**), (c) 288 (**5, 5-1**), (d) 300 (**2**), (e) 308 (**4, 4-1**), (f) 336 (**4**), and (g) 344 (**5**).

and grow in intensity as the reaction goes; seven medium-intensity peaks are clearly recorded, of which four are individual peaks. We identified 16 diethoxydichlorobiphenyls **3**; six peaks among those corresponding to these compounds are attributed to individual compounds. Comparison of the total areas of the peaks belonging to molecular or base ions of mono- and diethoxy derivatives obtained from tetrachlorobi-

phenyls suggests that the amount of diethoxydichlorobiphenyls **3** is approximately half that of monoethoxytrichlorobiphenyls **2**. In the GC–MS pattern of the reaction mixture extract, many peaks are obscured by intense peaks of hydroxy derivatives of PCBs.

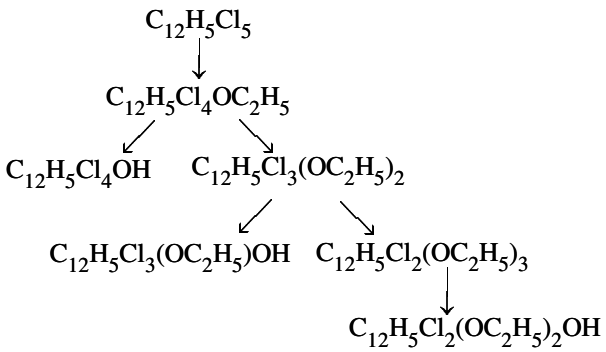
The mixture contains only trace amounts of ethoxytetrachlorobiphenyls **4** (no more than five compounds), and only one peak corresponds to an individual derivative. As already mentioned, these products were recorded just after mixing the reactants, whereupon they rapidly underwent further transformations.

Diethoxytrichlorobiphenyls **5** and triethoxydichlorobiphenyls **6** are present in the mixture in almost identical amounts. The chromatogram contains 17 and 13 low- and medium-intensity peaks belonging to such derivatives, respectively. About one-third of the peaks belong to individual compounds, and the remaining peaks, to mixtures. The relative content of the ethoxy derivatives of pentachlorobiphenyls is slightly lower than that of the derivatives of tetrachlorobiphenyls. More reactive diethoxytrichlorobiphenyls **5** underwent further transformations.

In the reaction mixture analyzed we detected only minimal amounts of diethoxytetrachloro- (**8**, six compounds) and triethoxytrichlorobiphenyls (**9**, three compounds) derivatives of hexachlorobiphenyls.

As already mentioned, the chromatogram of the reaction mixture extract is much more complex, with most peaks belonging to mixtures of products (Fig. 1a). We considered the mass spectrum of each peak, and the chromatograms were reconstructed using molecular ions and ions characteristic for a certain type of products. The relative content was estimated from the areas of the peaks of the base ions. For each compound we took only one base ion. Figure 2 shows as example the processing of a part of the chromatogram. Table presents the structures of the compounds considered, the characteristic ions, and the results of the calculations.

We identified at least seven peaks (three with a noticeable intensity) whose spectra corresponded to hydroxytrichlorobiphenyls **2-1**; their content was 30% of that of compounds **2**.



Derivatives **3** are stable under the reaction conditions; we recorded no compounds with the structure $C_{12}H_6Cl_2(OC_2H_5)OH$.

The products were the most abundant in the case of the reaction of pentachlorobiphenyls; they initially gave very rapidly ethoxytetrachlorobiphenyls **4**, which further transformed into hydroxy derivatives. Hydroxytetrachlorobiphenyls **4-1** (a total of 16 compounds) had the maximal content in the reaction mixture.

In this study, we observed for the first time formation of hydroxyethoxytrichlorobiphenyls **5-1** (15 compounds) and hydroxydiethoxydichlorobiphenyls **6-1** (4 compounds). As suggested by redistribution of the peak intensities, derivatives **5-1** are formed from diethoxytrichlorobiphenyls, and derivatives **6-1**, from triethoxydichlorobiphenyls. It should be noted that the content of compounds **5-1** exceeds that of **5**, and the content of compounds **6-1** was estimated at ca. 30% of that of **6**. Thus, the three chlorine atoms in the molecule of **5** favor substitution, and two chlorine atoms are insufficient for such a reaction. Moreover, ethoxy groups themselves exhibit an electron-donating power.

As to derivatives of hexachlorobiphenyls, the content of individual components in the reaction mixture is fairly low. We detected only three peaks corresponding to derivative **8-1** as the main component. Reconstruction of the mass chromatograms based on the characteristic ions revealed a total of 14 peaks corresponding to the structure of **8-1** and three peaks corresponding to the structure of **8-2** at trace level. Also, we identified six compounds with the structure of **9-1** in low concentrations.

Our data suggest the occurrence of a series of successive reactions proceeding at different rates and yielding different sets of final products, depending on the structure of the initial PCB congener. The first stage of the reaction consists in substitution of a chlorine atom by an ethoxy group, and hydroxy derivatives are formed specifically from ethoxy derivatives of PCBs. Given below is an example of transformations for pentachlorobiphenyls:

These conclusions are consistent with the results obtained by Shein and Ignatov [7, 8] in studies of the reaction of 1,2,4,5-tetrachlorobenzene with sodium methylate in anhydrous or aqueous methanol. A kinetic study showed that 2,4,5-trichloroanisole is initially formed; it further reacts with sodium methylate or NaOH to form 2,4,5-trichlorophenol.

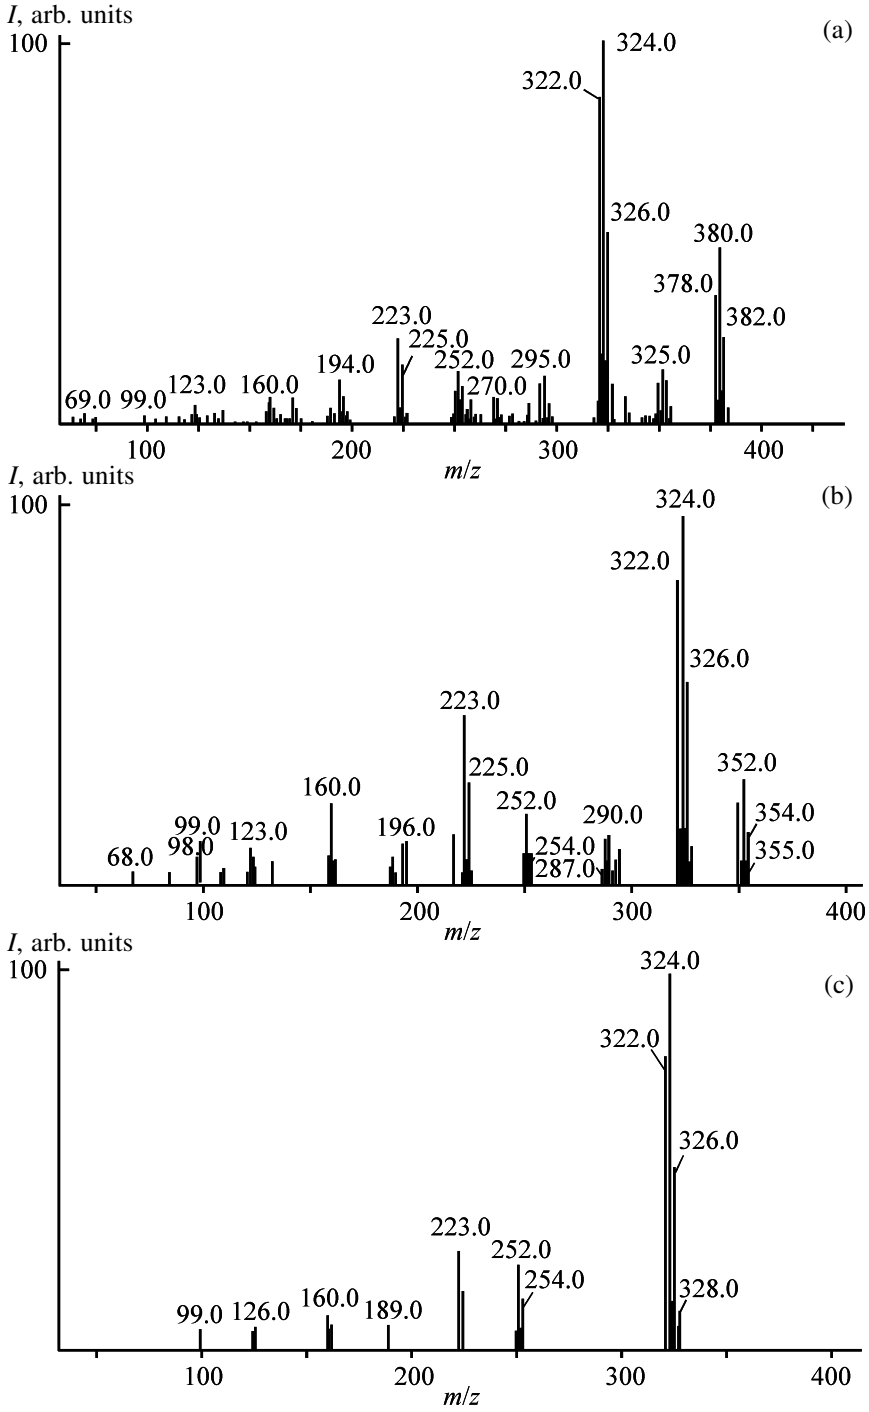


Fig. 3. The mass spectra of compounds **8** (a), **8-1** (b), and **8-2** (c).

We studied the composition of the products of the reaction of the PCB mixture with ethanol and KOH in sulfolane under identical conditions. In this case, only ethoxy derivatives of PCBs are formed, whose composition is similar to that of the ethoxy derivatives formed in DMSO. Alcoholysis is slower; the final mixture contains ca. 10% partially reacted tri- and tetrachlorobiphenyls, as well as pentachlorobiphenyls (PCBs 66, 95, 110).

We studied in detail the mass spectra of the PCB derivatives containing an ethoxy group and a hydroxy group. Previously [5] we discussed the mass spectra of the ethoxy derivatives of PCBs. We showed that all the mass spectra contain peaks corresponding to suc-

cessive loss of ethylene molecules. In most cases, specifically the peak of the radical ion corresponding to the hydroxypolychlorobiphenyl thus formed is the most intense.

The mass spectra of derivatives **5-1** contain molecular ions that are not the base ions. Initially, an ethylene molecule is lost, and the mass spectrum contains a base peak of the $[C_{12}H_5Cl_3(OH)]^+$ ion with *m*/*z* 288. Then Cl or HCl is lost, with the formation of characteristic ions with *m*/*z* 253 (252). After the loss of the second chlorine atom, the ion with *m*/*z* 218 is formed, which is the most intense for the majority of the mass spectra. The next step involves successive loss of two CHO groups, and the mass spectra contain characteristic peaks of the $[C_{11}H_5ClOH]^+$ ion at *m*/*z* 189 and the $[C_{10}H_5Cl]^+$ ion at *m*/*z* 160. Eventually, the remaining chlorine atom is lost with the formation of the $[C_{10}H_5]^+$ ion.

The mass spectra of derivatives **6-1** containing two ethoxy and one hydroxy groups exhibit medium-intensity peaks of molecular ions. Similar to fragmentation of diethoxytrichlorobiphenyls, ethylene molecules are successively lost; the peak at *m*/*z* 270 ($M - 2C_2H_4$) has the highest intensity. The characteristic peaks are those at *m*/*z* 234, corresponding to the subsequent loss of HCl, and at *m*/*z* 200 ($M - 2C_2H_4 - 2Cl$); both peaks have medium intensities. A CHO group is lost from the $[C_{12}H_4Cl(OH)_3]^+$ ion, with the formation of an ion with *m*/*z* 205. Further fragmentation corresponds to the successive loss of two CHO groups.

We have not observed the patterns assignable to ethoxy- (**7**) and hydroxypentachlorobiphenyls (**7-1**).

The mass spectra of ethoxyhydroxytetrachlorobiphenyls **8-1** contain peaks corresponding to molecular ions. The base ion is that formed by the loss of an ethylene molecule from M^+. Then two chlorine atoms are successively lost. The characteristic ion is that with *m*/*z* 223 ($M - C_2H_4 - 2Cl - CHO$). This is followed by the loss of a second CHO group and successive loss of the remaining chlorine atoms.

It is difficult to follow the fragmentation pattern of derivatives **9-1**, since we have not obtained the individual mass spectra. The mass spectra contain peaks of a molecular ion which successively loses ethylene molecules, yielding the characteristic ion with *m*/*z* 304. Then Cl or HCl is lost.

Comparison of the mass spectra that we recorded with those of the related ethoxy derivatives of PCBs [5] suggests that the fragmentation patterns of the PCB derivatives containing ethoxy and hydroxy groups are, on the whole, similar. Figure 3 compares the mass spectra of compounds **8**, **8-1**, and **8-2**.

Thus, a GC–MS study of the reaction mixture suggests the presence of over 150 derivatives of polychlorinated biphenyls belonging to 15 types of compounds. The total content of hydroxy and hydroxyethoxy derivatives of PCBs among the products was estimated at ca. 56%, and that of ethoxy derivatives of PCBs, at 42%.

CONCLUSIONS

(1) Reaction of a mixture of polychlorinated biphenyls with ethanol and potassium hydroxide in dimethyl sulfoxide yields a complex mixture of products; its components were identified.

(2) The reaction proceeds in two steps: Initially, ethoxy derivatives of polychlorinated biphenyls are formed, which are converted to hydroxy derivatives in the course of the process.

(3) Under the optimal conditions, trichlorobiphenyls form only ethoxydichlorobiphenyls, and tetrachlorobiphenyls form ethoxytrichloro-, diethoxydichloro-, and hydroxytrichlorobiphenyls. The reaction products formed from pentachlorobiphenyls are mono-, di-, and triethoxy derivatives and monohydroxy, hydroxyethoxy, and hydroxydiethoxy derivatives. The reaction products formed from hexachlorobiphenyls are predominantly hydroxyethoxy, diethoxy, and hydroxydiethoxy derivatives. Tri- and tetrachlorobiphenyls are not completely converted to the reaction products.

(4) The mass spectra of the obtained derivatives of polychlorinated biphenyls suggest similar fragmentation patterns of the ethoxy and hydroxy derivatives.

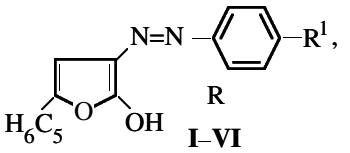
ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Lightfast Filter Dyes Derived from Five-Membered Heterocycles

N. B. Sokolova, I. V. Bezova, and O. I. Nastoyashchaya

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received November 7, 2005

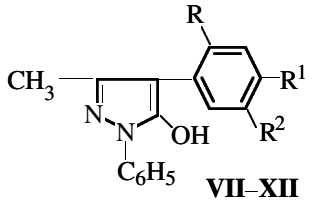


Abstract—The lightfastness of new potential filter dyes derived from furan and pyrazole in three polymer matrices, cellulose acetobutyrate, poly(methyl methacrylate), and styrene–acrylonitrile copolymer, was studied.

DOI: 10.1134/S1070427206050193

Development and improvement of polymeric optical filters is impossible without development of new dyes with specific spectral characteristics, extending the possibilities of available dyes. The technical class of dyes used in the development of color filters is determined by the structure of the polymer used. For example, with cellulose esters such dyes can be used as fat-, alcohol-, and acetone-soluble and dispersible dyes produced in Russia, and also Sudans, Cellitons, Zapons, and other dyes produced in the world. However, not all hydrophobic dyes are suitable as filter dyes. Along with the solubility in organic solvents, they should exhibit a set of properties: high saturation limit both in the solvent and in the polymer, chemical inertness toward the polymer, thermal stability, and lightfastness.

New filter dyes were searched for previously among azo dyes derived from five-membered heterorings such as furan, thiophene, and pyrazole [1, 2]. These dyes have yellow-orange color with narrow absorption bands in the electronic spectra. Thanks to the fact that the absorption ranges of these dyes vary in succession (pyrazole dyes, 380–420 nm; furan dyes, 410–450 nm; thiophene dyes, 460–480 nm), it becomes possible to cover a large wavelength range depending on specific task. Our studies showed that, by varying substituents in the dye molecule, it is possible to obtain dyes that have with similar absorption maxima but differ in the solubility and lightfastness. Furthermore, the lightfastness largely depends on particular polymer matrix [1, 2].



To choose the most lightfast dyes, we prepared and studied new azo dyes derived from 2-phenyl-5-furanone and 1-phenyl-3-methyl-5-pyrazolone. Furan dyes were described previously [3], but their properties were not studied. By the procedure described in [3] we prepared six dyes of the general formula

I–VI

where R = CH_3, R^1 = H (**I**); R = H, R^1 = CH_3 (**II**); R = H, R^1 = OC_2H_5 (**III**); R = Cl, R^1 = H (**IV**); R = OCH_3, R^1 = H (**V**); R = H, R^1 = OCH_3 (**VI**).

Six pyrazolone dyes **VII**–**XII** of the general formula

VII–XII

were prepared by the standard procedure [1]; their properties are given in Table 1.

With dyes **I**–**XII**, we prepared 36 colored polymer films from cellulose acetobutyrate (CAB), poly(methyl methacrylate) (PMMA), and styrene–acrylonitrile copolymer (SAN-25). In all the cases, the spectral characteristic of the dye in the polymer coincided with that in chloroform, i.e., there was no specific interaction of dyes with the polymer. The lightfastness of the dyes in the polymer matrix was studied on a Xenon Long Life Fade Meter XFL-1 accelerated aging installation by the procedure described previously [4, 5]. Under similar conditions we irradiated colorless films of the corresponding polymers containing no dyes; these samples were used as references when measuring the electronic absorption spectra of the insolated

irradiated films. As analytical wavelength we chose λ_{max} of the dyes. The degree of photochemical degradation Φ_d (%) was calculated by the formula

$$\Phi_d = (\Phi_0 - \Phi_i/\Phi_0) \times 100.$$

The time of accelerated photochemical aging of the films was usually 10 h, which corresponds to the service time of filters under usual conditions; however, the insolation of pyrazolone dyes in the chosen polymer matrices for 10 h did not lead to any photochemical degradation in most cases. That is, pyrazolone dyes exhibit extremely high lighthfastness; however, the effect of substituents in the phenyl moiety on the lightfastness cannot be revealed. Therefore, we performed longer insolation (20 h) of films with pyrazolone dyes; however, even under these, more severe, conditions some of the dyes showed no degradation. The results are listed in Table 2.

These data show that pyrazolone dyes surpass the majority of the known dyes in the lightfastness but absorb the light only in the near-UV range and at the violet edge of the visible range (380–410 nm). The most resistant to photochemical degradation are *o*- and *p*-nitro-substituted dyes, and specifically these dyes can be recommended as filter dyes providing the absorption at 400–410 nm.

The lightfast dye with λ_{max} = 390 nm was described previously [1]. This is fat-soluble Yellow 3Zh dye containing no substituents in the phenyl moiety. *o*-COOH-substituted dye **VIII** prepared in this study is not inferior to Yellow 3Zh in the lightfastness. A pyrazolone dye with λ_{max} = 380 nm, *o*-OCH_3-substituted dye **IX**, was prepared in this study. This dye is the least stable among the pyrazolone dyes; nevertheless, it is considerably more stable than furan and thiophene dyes: The degree of its photochemical degradation in 20 h in the CAB matrix, in which it is the least stable, is 25.4%.

Furan dyes are appreciably less lightfast than pyrazolone dyes, but they are unique in that they absorb at λ_{max} = 415–450 nm with very steep wings of the absorption curve.

Dyes absorbing at λ_{max} = 415–420 nm were not studied previously. Such dyes are **I**, **III**, and **IV**. In the CAB matrix, the most lightfast among them is dye **IV** containing *o*-Cl substituent; dyes **I** (*o*-CH_3) and **III** (*p*-OC_2H_5) are considerably more lightfast in SAN-25, approaching in this characteristic the pyrazolone dyes.

In this study we failed to obtain furan dyes with λ_{max} = 430 nm, but two dyes with such absorption were studied previously [1]: the dye unsubstituted in the phenyl moiety and the dye with the *p*-Cl substituent. Among them, the unsubstituted dye is more lightfast, and it is recommended as filter dye.

Finally, dyes with λ_{max} = 440 nm (**II**, *p*-CH_3) and 450 nm (*p*-NO_2 [1]) show satisfactory lightfastness only in SAN-25. With the other polymers, special photostabilization of these dyes is required.

EXPERIMENTAL

Dyes **I**–**VI** were prepared by the procedure described in [3]. They were purified by column chromatography on silica gel (eluent $CHCl_3$) followed by recrystallization from appropriate solvent until the melting points agreeing with the published data [3] were obtained.

Dyes **VII**–**XII** were prepared as described in [1] and purified by the same procedure as dyes **I**–**VI**. The characteristics of the dyes are given in Table 1.

The colored films were prepared in the laboratory by casting of a solution of a dyed polymer formulation onto polished glass with a bounding frame of a definite size, followed by drying according to the prescribed schedule [4, 5].

The films were insolated on a Suga Standard Xenon Long Life Fade Meter, model XFL-1, equipped with a 1-kW xenon lamp. The insolation was performed in the automatic mode at 30°C and 65% air humidity, in 15-min periods until the 1-h exposure was accumulated and then in 1-h periods to a total exposure of 20 h. After the completion of each irradiation cycle, the films were kept in the dark for 24 h at room temperature, after which the electronic absorption spectra were recorded on an SF-16 spectrophotometer.

CONCLUSIONS

(1) The furan and pyrazolone dyes synthesized can be used as filter dyes.

(2) Azo dyes derived from 1-phenyl-3-methyl-5-pyrazolones surpass in the lightfastness all the heterocyclic azo dyes studied.

(3) Dyes derived from 2-phenyl-5-furanone exhibit high lightfastness only in SAN-25; in the other polymers, these dyes can be used only in the presence of photostabilizers.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Sorption of Trypsin on the Polysiloxane Rubber Surface

G. U. Ostrovidova and E. V. Zamyslov

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received February 1, 2006

Abstract—The sorption kinetics of trypsin on medical polysiloxane rubber and polysiloxane rubber modified with graphite was studied. The effect of the nonuniformity and hydrophilicity of the rubber surface on the trypsin immobilization rate was analyzed.

DOI: 10.1134/S107042720605020X

In contact of protein-containing biological solutions with foreign solids, the process occurring first is the sorption of protein. This process is mainly responsible for biocompatibility of medical materials [1]. In this study we examined the interaction of proteolytic enzyme trypsin with the polysiloxane rubber surface. The positive effect of trypsin on the hemocompatibility of medical materials was reported in [2, 3].

EXPERIMENTAL

The initial polysiloxane rubber of medical purity grade $SKTV_{med}$ (M = 60 000) and polysiloxane rubber modified in the bulk with graphite [20–50 wt % relative to rubber, $SKTV_{med}$ composite material (CM)] [4] were used as sorbents. Trypsin (proteolytic enzyme) was purchased from Spofa (Czechia). Other chemicals were of ultrapure, analytically pure, and chemically pure grade.

The surface trypsin concentration was determined spectrophotometrically (λ = 280 nm) [5]. The proteolytic activity was determined with casein as a substrate. The contact angles were measured with a horizontal microscope. The free surface energy was calculated by the equation [6]

$$\sigma = \sigma_1(1 + \cos\theta)^2/4,$$

where σ_1 = 72.5 mJ m^{-2} is the water surface tension.

The X-ray photoelectron spectra of trypsin immobilized on both the initial and modified polysiloxane rubber were recorded on a PH1 5400 spectrophotometer (Perkin–Elmer, the United States) using MgK_α radiation (1253.6 eV) at a pressure in the spectrophotometer chamber of 1.3×10^{-6} Pa. The binding energy was measured with an accuracy of ±0.1 eV. The trypsin determination error was 10 rel. %. The spectrophotometer was calibrated relative to the C1s line of residual hydrocarbons (electron binding energy 285.0 eV) taking into account the sample charging. The X-ray photoelectron spectra were processed with the Perkin–Elmer program.

Figure 1 shows the kinetic curves of trypsin sorption on the initial polysiloxane rubber and composite material with varied graphite content. It is seen that, for all the materials tested, the sorption saturation is attained within 30–60 min. At high graphite content in the modified rubber, its surface becomes mosaic and acquires a negative charge. Owing to the presence of graphite, the modified rubber surface contains specific sorbing groups influencing the trypsin immobilization. The shape of the kinetic curves (Fig. 1) shows that the sorption of trypsin on the initial rubber

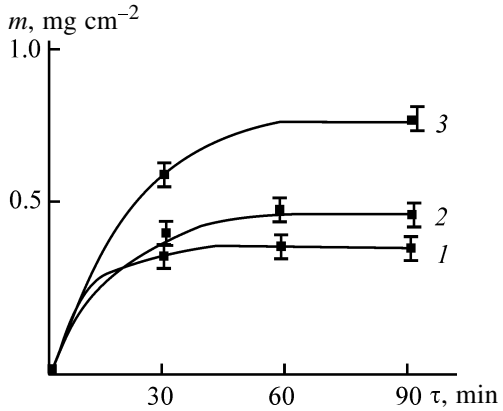

Fig. 1. Kinetic curves of trypsin sorption on polysiloxane rubber. (m) Trypsin surface concentration and (τ) time. (*1*) Initial polysiloxane rubber ($SKTV_{med}$); graphite content in composite material, wt % relative to rubber: (*2*) 20 and (*3*) 50.

Table 1. Physicochemical and sorption characteristics of the initial and modified polysiloxane rubber

Support	Contact angle, deg	Surface energy, mJ m^{-2}	Sorbed trypsin fraction, %	Trypsin enzymatic activity, % of native
$SKTV_{med}$	90–107	18.2–20	11	52
CM, 50 wt % graphite	72	31.2	25	76

reaches saturation in a shorter time than on the modified rubber. For the initial rubber $SKTV_{med}$, the saturation in the trypsin sorption is attained within 30–40 min. However, this does not mean that within this time the true sorption equilibrium is reached. Actually, only a steady state is attained within 20–120 min and even in longer time [7]. Thus, the short-time sorption experiments reflect the nonequilibrium protein immobilization depending on particular experimental conditions [7].

The increased sorption capacity of the modified rubber for trypsin is caused by enhanced hydrophilicity of this material, which is manifested as a decrease in the contact angle (Table 1). It is believed that the free surface energy of solid medical materials (in the range 20–50 mJ m^{-2}) correlates with their biocompatibility [9]. The surface defects of medical materials sharply increase their surface energy and, as a result, increase a risk for thrombosis. To evaluate the suitability of any material for medical use, its roughness is monitored profilographically, and the roughness height is determined [8]. The modified medical rubber under consideration had roughness height of about 2.66 μm, which is too small to promote thrombosis.

With increasing the graphite content in the modified rubber, its surface electrical charge increases and the electrostatic attraction between trypsin and rubber surface is strengthened. As a result, the sorption of trypsin increases. In spite of stronger binding to modified rubber surface, immobilized trypsin exhibits high enzymatic activity. Figure 2 shows that the trypsin sorption increases with increasing surface energy of the modified rubber. The trypsin sorbability correlates also with the wettability of the modified rubber. In going from the initial rubber to the composite material containing 50 wt % graphite relative to the rubber, the contact angle decreases from 90°–107° to 72°. It should be noted that the surface energy of medical rubber under consideration was within 20–50 mJ m^{-2}; this range is typical of materials preventing thrombosis [6, 9].

The X-ray photoelectron spectra of all the rubber samples under consideration show that the new N1*s* and S2*p* bands appear after sorption of trypsin. In addition, the carbon band becomes broadened from the high-binding-energy side suggesting the appearance of organic carbon. The complicated N1*s* band of immobilized trypsin can be resolved into two separate bands. One of them (E = 399.7 eV) belongs to nitrogen atoms of the NH_2 groups bound by hydrogen bonds and other (E = 401.6 eV), to the NH_2 groups free of hydrogen bonds. Based on trypsin molecular structure, the high-energy band (E = 401.6 eV) can be assigned to nitrogen atoms of the side functional groups:

The low-energy band (E = 399.7 eV) belongs to the nitrogen atoms of the main polypeptide chain of the trypsin molecule.

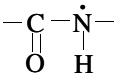

Table 2 shows that the ratio of the areas of nitrogen bands of trypsin immobilized on the modified rubber (401.6 and 399.7 eV) depends on the incidence angle

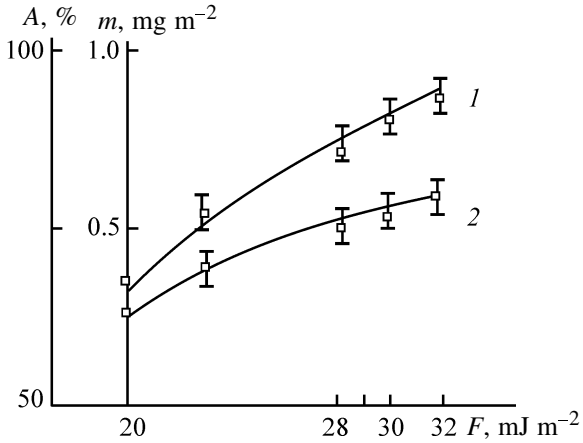

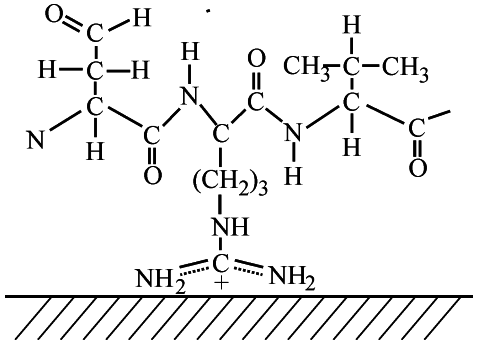

Fig. 2. (*1*) Surface concentration m and (*2*) enzymatic activity A of trypsin vs. free surface energy F of rubber. Initial polysiloxane rubber $SKTV_{med}$, F = 20 mJ m^{-2}; composite material [graphite content (wt %), surface energy (mJ m^{-2})]: 40, F = 28 mJ m^{-2}; 50, F = 32 mJ m^{-2}.

Table 2. Dependence of the intensity of the photoelectron bands of trypsin immobilized on modified rubber (50 wt % graphite) on incidence angle of X-ray radiation relative to the rubber surface

Sample no.	Incidence angle, deg	E_b N1*s*, eV	Peak area, %
no. 1	15	403.77	25.17
		401.6	64.82
		399.7	10.01
no. 2	60	403.77	39.26
		401.6	46.94
		399.7	13.8

of X-ray radiation relative to the rubber surface. The tertiary protein structure is mainly formed by hydrophobic interactions between side functional groups of polypeptide chains. The intermolecular hydrogen bonding between side functional groups and intramolecular hydrogen bonding between the NH and CO groups of polypeptide chain also contribute to this process. For trypsin sorbed on the modified rubber, the ratio of the 401.6- and 399.7-eV peak areas shows that this enzyme is predominantly fixed on the rubber surface with the side NH_2 groups. We believe that trypsin is immobilized due to electrostatic attraction between the positively charged $NH_2 \cdots C^+ \cdots NH_2$ groups and negatively charged graphite-containing sites of the composite material (see scheme).

Scheme of trypsin immobilization on composite material

In going to the initial (unmodified) polysiloxane rubber whose surface has lower surface energy and contains no specifically sorbing functional groups, the sorption of trypsin decreases. In this case, the intermolecular interactions between trypsin molecules prevail and their denaturation occurs. Table 1 shows that, under these conditions, the trypsin proteolytic activity decreases [11]. The maximal surface concentration of trypsin is reached within 60 min (Fig. 1).

It is known that the enzyme–support interactions affect the enzymatic activity. It is believed that, in enzyme immobilization by sorption on a solid support or by any other method, the first stage is the protein concentration at the surface. This "primary adsorption" is accompanied by formation of a small number of bonds between trypsin and specific surface sorbing sites. With increasing surface concentration of protein, weak nonspecific contacts appear along with these specific bonds [11]. In the case of mosaic surface structure containing, for example, polysiloxane and graphite sites, the protein immobilization occurs through its binding with different surface sites. Owing to this multimode sorption, immobilized trypsin preserves its enzymatic activity (see scheme).

CONCLUSIONS

(1) The kinetics of sorption of trypsin on polysiloxane rubber, initial and modified in the bulk with graphite, was studied.

(2) The surface of modified polysiloxane rubber is more nonuniform and hydrophilic than that of the initial rubber. The modified polysiloxane rubber sorbs 2.5 times larger amount of trypsin than does the initial polymer.

(3) Trypsin molecules are immobilized on the modified rubber surface by attraction of their positively charged NH_2-containing side groups to negatively charged sorbing sites.

Received January 17, 2006

Abstract—The physicomechanical properties and thermal stability of films prepared from solutions of fibroin–cellulose blends in *N*-methylmorpholine *N*-oxide were studied.

DOI: 10.1134/S1070427206050211

The unique physicomechanical properties of fibroin, a natural polymer, are well known [1]. This polypeptide is the main component of silk threads and cobweb and consists to more than 80% of the simplest amino acids (glycine, alanine, serine). The content of crystalline fraction of the polymer can be as high as 70%. In this fraction, the macromolecules form antiparallel β-folded structure and α-spiral secondary structure.

The possibility of using fibroin in the form of powders, gels, and films for biotechnological and biomedical purposes was studied in [2–4]. Fibroin membranes can be used to separate aqueous alcoholic solutions and to immobilize enzymes. Fibroin is a biocompatible compound suitable for preparing contact lenses.

The main disadvantage of films prepared from fibroin solutions is their high brittleness. Dry films are virtually unsuitable for practical purposes. Fibroin in natural silk threads is plasticized with natural sericin, which imparts strength and elasticity to silk. Therefore, we studied blends of fibroin with other polymers [5, 6] with the aim to improve the film properties. Taking into account the possible applications of the films, we used natural and biodegradable polymers as the second component.

In this study we examined properties of films prepared from solutions of fibroin–cellulose blends. *N*-Methylmorpholine *N*-oxide (NMMO) readily dissolving cellulose [7] and fibroin [8] was used as the solvent.

EXPERIMENTAL

We used the following polymers: fibroin of *Bombyx mori* silk (washed to remove fat, wax, and mineral compounds) and wood sulfite pulp with the degree of polymerization of 495. The polymers were dissolved in NMMO at 95°C for 2–5 h. The resulting solutions with the polymer concentration of 4% were mixed to obtain solutions with the fibroin/cellulose ratios of 90/10, 50/50, 30/70, and 10/90. The films were prepared by application of these solutions to glass plates with subsequent coagulation with aqueous alcohol. After coagulation, the films were washed with distilled water to completely remove the solvent and were dried in air. The film thickness was 10–30 μm.

The physicomechanical properties of the films were studied on an Instron tensile-testing machine in accordance with DIN EN ISO 527-3. The IR spectra were recorded on a IFS25 IR spectrometer. Thermal gravimetric analysis was performed in air on a MOM Q-1500D derivatograph (Hungary) in the temperature range 23–500°C. The heating rate was 2.5 deg min^{-1}.

The IR spectra of recovered fibroin, cellulose, and their blends with different ratios of the components are shown in Fig. 1. The band assignment is given in Table 1. According to the published IR data, the crystalline fraction with the β-structure has particular spectrum, whereas the IR spectra of the α-spiral crystal structure are similar to those of the amorphous random globules [9–13]. Therefore, we could not distinguish the α-structure and the amorphous fraction by IR spectroscopy. The bands at 1624 (Amide I), 1521 (Amide II), and 671 cm^{-1} (Amide V) in the spectrum of fibroin (curve *6*) can be assigned to the crystalline β-structure. The band at 1230 cm^{-1} (Amide III) in the spectrum of pure fibroin suggests that a part of the macrololecues has the α-spiral or random globule conformation. The cellulose spectrum (curve *1*) is typical of cellulose II [14].

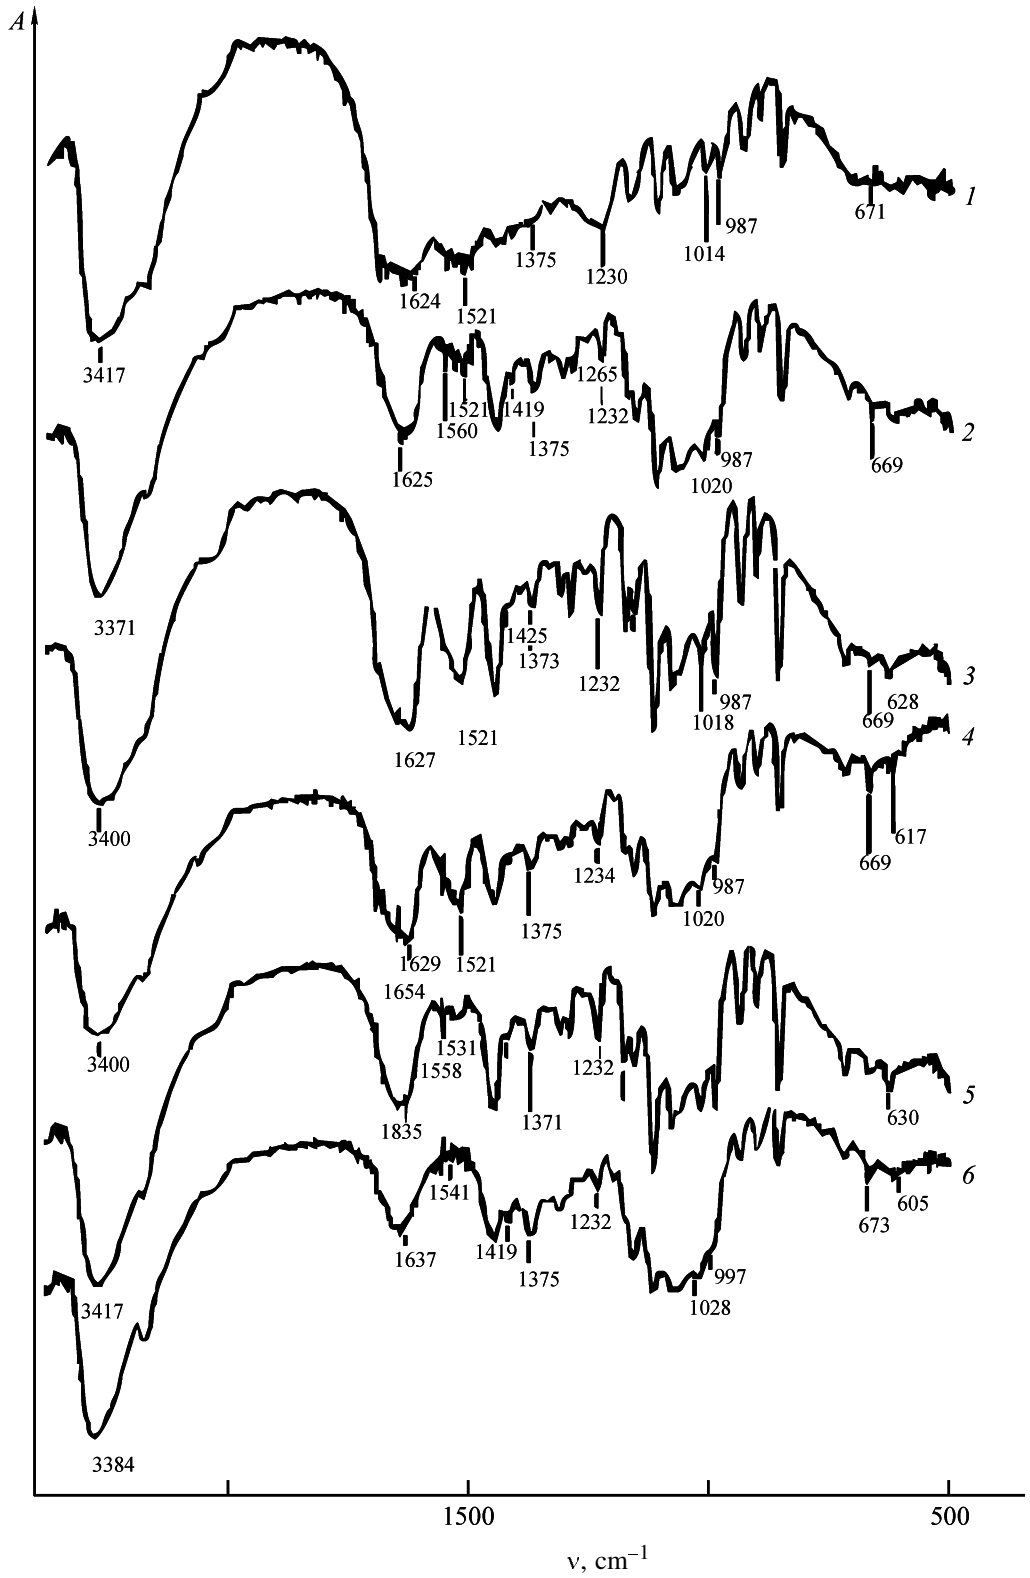

Fig. 1. IR spectra of the films of (*1*) 100% cellulose, fibroin–cellulose [component ratio: (*2*) 10/90, (*3*) 30/70, (*4*) 50/50, (*5*) 90/10], and (*6*) 100% fibroin; the same for Fig. 2. (*A*) absorption and (ν) wavenumber. The same for Fig. 2.

Table 1. Assignment of the absorption bands in the IR spectra of the films of fibroin–cellulose blends to various fibroin conformations

Absorption band	Frequency, cm^{-1}					
	100% fibroin	90 : 10	50 : 50	30 : 70	10 : 90	100% cellulose
Characteristic fibroin bands						
Amid I (C=O)	1624 (β)	*1652* (α)	1627 (β)	*1654* (α), 1629 (β)	1635 (β)	1637
Amid II (N–H bound, C–N)	1521 (β)	*1560* (α), 1521 (β)	1521 (β)	1521 (β)	*1558* (α), 1531 (β)	1541
Amid III (C–N, N–H bound)	1230 (α)	*1265* (β), 1232 (α)	1232 (α)	1234 (α)	1232	1232
Amid V	671 (β)	669 (β)	669 (β), *628* (α)	669 (β), *617* (α)	667 (β), *630* (α)	673, 605
Gly–Gly	1014	1020	1018	1020	1020	1028
Gly–Ala	987	987	987	987	987	997
Characteristic cellulose bands						
O···H	3417	3371	3400	3400	3417	3384
OH	–	1419	1425	1423	1423	1419
CH_2	1375	1375	1373	1375	1371	1375
OH	671	669	669	669	667	673

The IR spectra of the films of fibroin–cellulose blends (curves *2*–*5*) contain the typical bands of the components and new bands assigned to the spiral and random conformations of fibroin macromolecules (printed italic in Table 1). The spectrum in the range 1250–800 cm^{-1} characterizing the primary polypeptide structure changes. The bands of the Gly–Gly units at 1014 cm^{-1} change to the greatest extent. The frequency and the intensity of the bands of H-bonded hydroxy groups of cellulose at 3384, 1419, and 673 cm^{-1} change in the spectra of the films of the blends.

These data suggest that the hydroxy groups of cellulose macromolecules form intermolecular hydrogen bonds with the amide groups of fibroin and prevent β-folding of the polypeptide macromolecules.

Table 2. Physicomechanical properties of films of fibroin–cellulose blends

Fibroin content in the blend, %	Tensile strength, N mm^{-2}	Elongation at break, %
100	31.1	2.9
90	31.2	3.1
50	35.0	9.5
30	47.5	10.4
10	45.3	10.3
–	50.1	10.4

The TG curves of the films are shown in Fig. 2. The samples undergo stepwise thermal oxidative degradation accompanied by weight loss. The weight loss of the fibroin in air at 130°C (curve *6*) is due to vaporization of adsorbed water. On further heating, gradual weight loss owing to transformations of the amorphous fractions is observed. The thermolysis rate increases at 250°C and reaches a maximum at 278°C. At this temperature, the H bonds of nonoriented β-crystalline fractions of the polymer start to rupture [15–18]. The weight loss at 500°C is 77%.

The TG curve of the cellulose film (curve *1*) contains a step at 105°C with a weight loss of 11.2%, caused by vaporization of adsorbed water. The thermolysis sharply accelerates on heating above 157°C. The maximal rate of the weight loss is observed at 190°C. The total weight loss at this temperature is 43%. On further heating, the thermolysis rate decreases and then increases again, reaching a maximum at 349°C (weight loss 73.5%). This can be due to dehydroxylation of cellulose units mainly in the amorphous fractions and then, at higher temperatures, to depolymerization of the crystalline fraction of the polymer [19, 20]. The weight loss at 500°C is 96%, owing to liberation of volatile thermolysis products.

The temperature of the intense weight loss of the cellulose film containing 10% fibroin (curve *2*) is 10°C higher than that of the pure cellulose film. With increasing fibroin concentration, this temperature in-

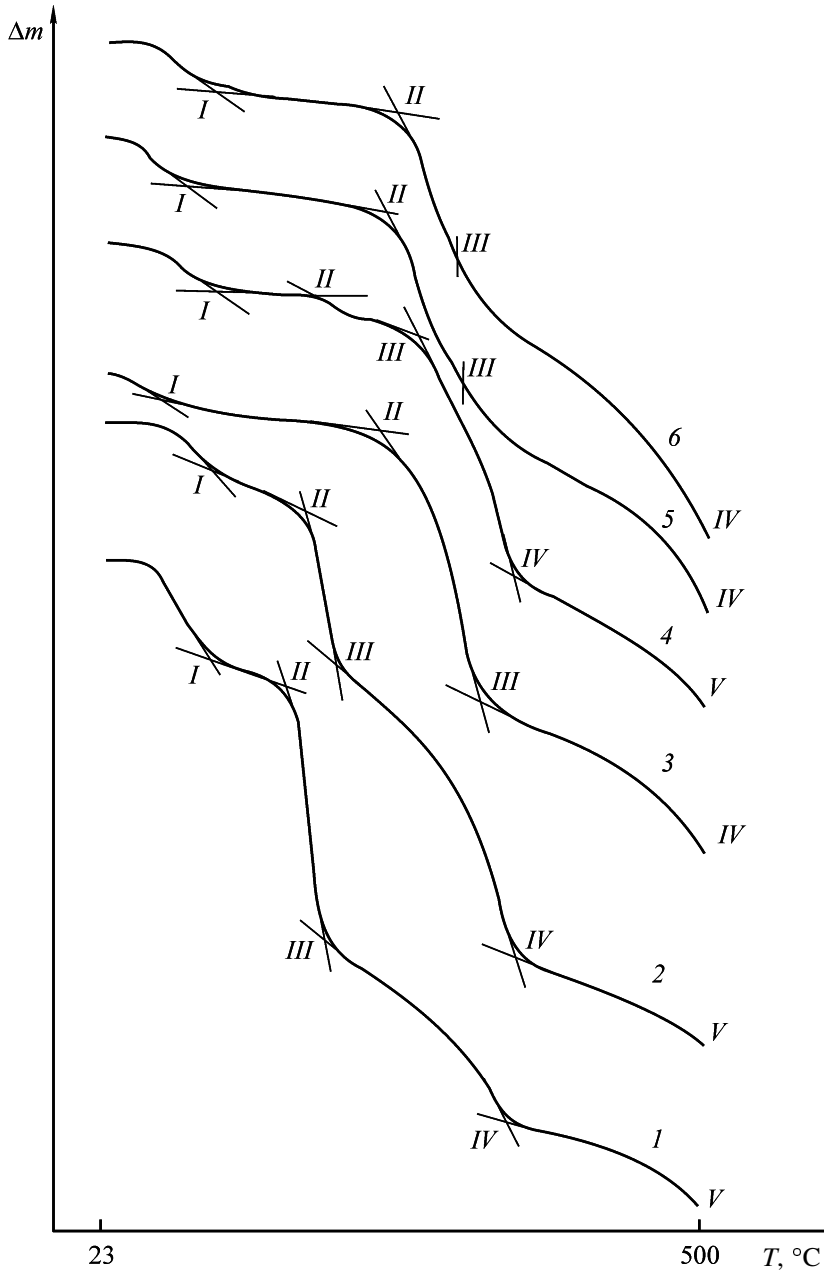

Fig. 2. TG curves of the films (Δ*m*) Weight loss and (*T*) heating temperature. Heating temperature (°C), weight loss (%): (*1*) (*I*) 105, 11.2; (*II*) 157, 17; (*III*) 197.5, 47.5; (*IV*) 349, 73.5; (*V*) 500, 96; (*2*) (*I*) 120, 6; (*II*) 167, 12; (*III*) 192, 28.5; (*IV*) 347, 71; (*V*) 500, 95; (*3*) (*I*) 81, 3; (*II*) 252, 9; (*III*) 345, 22.5; (*IV*) 500, 67.5; (*4*) (*I*) 105, 4.8; (*II*) 180, 6; (*III*) 254, 11; (*IV*) 350, 40; (*V*) 500, 74.2; (*5*) (*I*) 100, 6, 245, 12; (*III*) 280, 26; (*IV*) 500, 70; (*6*) (*I*) 130, 6; (*II*) 250, 11; (*III*) 278, 26; (*IV*) 500, 77.

creases, approaching the thermolysis temperature of fibroin (curves *3–5*). The weight loss of these samples at 500°C decreases to 70–74%. The film with a fibroin–cellulose ratio of 30/70 is the most stable at temperatures of up to 500°C. Thus, addition of fibroin increases the heat resistance of cellulose. Nishioka et al. [21] showed that the heat resistance of cellulose in blends with synthetic polymers decreases or remains virtually the same depending on the type of the synthetic polymer.

The tensile strength and elongation at break of the films with different component ratios are presented in Table 2. As seen from Table 2, the sample containing 30% fibroin and 70% cellulose has the best combination of the tensile strength and elongation.

CONCLUSIONS

(1) An IR study of the films of fibroin–cellulose blends revealed intermolecular interaction between the components.

(2) The fibroin–cellulose films are characterized by good physicomechanical properties and high heat resistance.

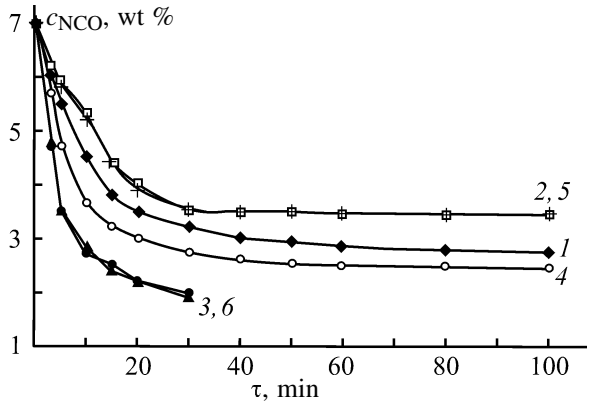
Abstract—The effect of acetylacetone on the reaction of polyethylene glycol adipate with diisocyanate in the presence of catalytic amounts of Mannich bases was examined.

DOI: 10.1134/S1070427206050223

Polyestes (PEs) stabilized with acetylacetone (AcA) are used as raw material in synthesis of castable monolythic polyurethanes (PUs) via prepolymers [1]. Addition of AcA to a PE allows preparation on its basis of linear prepolymers with terminal isocyanate groups. The role of AcA consists in conversion of metal impurities in PEs into acetylacetonate complexes. These complexes accelerate exclusively the formation of urethanes and prevent the formation of allophanates and triisocyanurates causing branching of the prepolymer [1, 2].

In the synthesis of PUs of the SKU-OM type [3], formed by the reactions of PEs with diisocyanate in the presence of catalytic amounts of (dimethylaminomethyl)phenol derivatives (phenolic Mannich bases, MBs), it was noted that the use of stabilized PEs requires increased catalyst dosage. Otherwise the PUs are not hardened. In this connection, it was interesting to examine the effect of AcA on the reaction of a PE with diisocyanate in the presence of catalytic amounts of MBs and on the properties of PUs of the SKU-OM type.

EXPERIMENTAL



For the kinetic study of the reaction of diisocyanate with PE, we chose 2,4-toluene diisocyanate (TDI) and nonstabilized polyethylene glycol adipate (PEGA) with the number-average molecular weight of 2040, into which we introduced in advance AcA, 2,4,6-tris-(dimethylaminomethyl)phenol (MB), or their mixture. The AcA dosage in PEGA corresponded to its content commonly used in the commercial production of stabilized PEs. The reaction was performed at an NCO : OH molar ratio of 2 : 1 and 80°C. The content of free NCO groups was determined chemically. The apparent reaction rate was evaluated from the content of free NCO groups after heating at 80°C for 30 min, $c_{NCO,\,30}$. The rates of the reaction of PEGA with TDI in the presence of the above additives were compared using as criterion the difference Δc_{NCO} between the "ideal" content of free NCO groups $c_{NCO,\,id}$ (3.52 wt % if the only reaction pathway is the urethane formation) and $c_{NCO,\,30}$.

The SKU-OM was prepared from TDI and PEGA containing various amounts of AcA and MB, at NCO : OH = 2 : 1. The physicomechanical tests of PUs were performed according to GOSTs (State Standards) 270–75, 6950–73, and 263–75.

Table 1 and the figure show that the shapes of the

Kinetic curves of consumption of NCO groups in the course of the reaction of PEGA with TDI at 80°C in the presence of AcA, MB, or their mixture. (c_{NCO}) Content of NCO groups and (τ) time. Curve numbers are system numbers in Table 1.

kinetic curves and the rates of the reaction of PEGA with TDI are different in the absence and in the presence of the above additives.

Kinetic curve *1* (see figure), indicating that the concentration of the isocyanate groups monotonically decreases during a long period, and the numerical value of $c_{NCO, 30}$, which is lower than $c_{NCO, id}$, show that the starting PEGA is a relatively active PE. A sharp decrease in c_{NCO} within the first ~30 min is mainly due to the formation of urethanes [reaction (1)] and insignificant amount of allophanates [by the reaction of unchanged TDI with a urethane group of the prepolymer, reaction (2)]. The further decrease in the content of the isocyanate groups in the system is mainly due to the continuing formation of allophanate structures from the NCO groups of both TDI and the prepolymer [reactions (2), (3)]. The presence of allophanates in the prepolymers prepared from active batches of PEGA was proved in [2], where it was suggested that the allophanate formation is promoted by complexes of crown ethers with metal compounds (salts, oxides, hydroxides, etc.), present as impurities in the starting PE.

Addition of AcA to PEGA decreases the rate of the reaction of the PE with TDI (see figure, curve *3*) to the value corresponding to the "ideal" content of NCO groups ($c_{NCO, 30} = c_{NCO, id} = 3.52$ wt %, $\Delta c_{NCO} = 0$), after which this parameter varies insignificantly. This fact is due to the reaction of AcA with metal compounds, including unstable complexes of crown ethers with metal complexes, yielding metal acetylacetonates [4], which catalyze only the urethane formation [reaction (1)] and do not promote secondary reactions [5].

In the presence of MBs, the reaction of PEGA with TDI is considerably accelerated (see figure, curve *2*) and is virtually complete in 40 min. Such a rapid reaction is due not only to the catalysis of urethane formation, but also to the formation of allophanate and triisocyanurate structures [reactions (1)–(5)] whose presence was proved previously [6]:

where HO^^OH is a polyester and $R(NCO)_2$ is a diisocyanate.

When equimolar amounts of MB and AcA are added simultaneously, the rate of the reaction of PEGA with TDI (Table 1, system no. 4) differs insignificantly from that without additives (Table 1, system no. 1). However, the reaction is considerably slower than that of PEGA with TDI catalyzed by MB (Table 1, system no. 3). Apparently, AcA not only

3	PEGA + 2TDI + 0.024MB + 0.048AcA	No curing						
4	PEGA + 2TDI + 0.048MB + 0.024AcA	3.4	7.1	25.9	380	0	35	61

* (f_{100}, f_{300}) Nominal strain at 100 and 300% elongation, respectively; (f_t) nominal tensile strength; (ε) relative break elongation; (Δε) relative elongation set; (E) rebound elasticity; and (H_{TM-2}) hardness evaluated with TM-2 device.

reacts with metal impurities in PE but also forms a complex with MB, thus decreasing the concentration of free MB in the system and hence its catalytic effect.

At a higher AcA content, when its amount is sufficient not only for the formation of metal acetylacetonates but also for complete suppression of the catalytic effect of MB, the shape of the kinetic curve of the reaction of PEGA with TDI (see figure, curve *5*) is identical to that obtained for the reaction of PE with diisocyanate in the presence of AcA only (see figure, curve *2*). Therefore, $\Delta c_{NCO} = 0$, and only reaction (1) occurs in the system. On the contrary, when the MB content is higher compared to AcA and is sufficient not only for suppressing the negative effect of AcA but also for catalyzing the reactions of PEGA with TDI [reactions (1)–(5)], variation of the concentration of the NCO groups is virtually similar to variation of c_{NCO} in the reaction of PEGA with TDI in the presence of the MB only (see figure, curve *3*).

The influence of the AcA concentration on the physicomechanical characteristics of SKU-OM is illustrated by Table 2. It should be noted that, for the faster curing of PU, the amount of MB and, correspondingly, that of AcA were increased relative to their amounts in the kinetic experiments, with their molar ratio being preserved. Table 2 shows that AcA (formulation no. 2) decreases the strength of the elastomer, and at a large excess of AcA the polymer is not cured at all (formulation no. 3). This fact is caused by the fact that the catalytic formation of allophanate and triisocyanurate groups, acting as cross-links in the network PU structure, does not occur in the system. An increase in the content of MB relative to AcA eliminates the negative effects of AcA and allows preparation of the polymer whose properties are similar to those of the SKU-OM derived from the nonstabilized PE (formulation no. 4).

Similar trends were observed upon introduction of AcA into other PEs differing in the structure and activity in the reaction with the diisocyanate, and also with various commercial stabilized PEs.

CONCLUSIONS

(1) Acetylacetone inhibits the reaction of polyethylene glycol adipate with diisocyanate in the presence of catalytic amounts of phenolic Mannich bases, which is due to a decrease in the catalyst concentration in the system as a result of its consumption for the formation of the acetylacetonate complex.

(2) Synthesis of castable polyurethanes of the SKU-OM brand from stabilized polyesters should be performed at increased dosage of the Mannich base, eliminating the negative effect of acetylacetone.

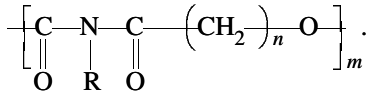
Abstract—Chemical modification of polyolefins (polypropylene, high-density polyethylene) with mixtures of isocyanates and ε-caprolactone was studied. Chemical transformations occurring in the course of modification of polyolefins with a binary modifying system containing 2,4-toluene diisocyanate and ε-caprolactone in the presence of sodium caprolactamate catalyst were studied using model systems based on α-olefins.



DOI: 10.1134/S1070427206050235

Modification with various reactive compounds is widely used for improving properties of commercial polyolefins (POs). One of the promising procedures for preparing polymeric materials with a required set of properties is their modification with binary mixtures of chemically active compounds able to react under the conditions of PO processing to form copolymer products. It was found [1–3] that binary mixtures of isocyanates (ICs) with a series of heterocyclic compounds (in particular, epoxides and lactames) exert a synergistic effect on the thermal stability and physicochemical properties, which is due to the formation of copolyamide and copoly(amide–ester) fragments grafted to PO unsaturated bonds.

As shown in [1], IC and epoxides added simultaneously in concentrations of up to 3 wt % in the presence of catalytic amounts (with respect to the components of the modifying system) of tertiary amines exert a synergistic effect on the thermal stability and physicochemical properties. This is due to chemical reactions of the additives with each other and with residual unsaturated bonds of polyolefins, which act as potential active centers of degradation.

The mixtures based on 2,4-toluene diisocyanate (TDI) and lactames (LCs) of various structure are also characterized by significant modifying affect in a wide concentration range (1–12 wt %) [2, 3]. These effects are due to decreasing defectiveness of the supramolecular aggregates [4] and to copolymerization of the modifying agents under the conditions of anionic initiation, in particular, in the presence of alkali metal caprolactamates [5, 6]. For example [2], two local optima with respect to relative elongation were determined in the course of PO modification at simultaneous addition of TDI and ω-dodecalactam (ω-DL). In this case, at low concentrations (up to 3 wt %), the optimum is due to deactivation of unsaturated PO bonds and formation of the grafted copolyamide fragments, whereas at high concentrations certain increase in the relative elongation is due to phase segregation of the resulting composites as the products of LC and IC copolymerization form a separate phase [2].

Similar results are obtained with the system based on TDI and ε-caprolactone (cyclic ester, ε-CLN). It was found [7] that, at temperatures close to those of PO processing, in the presence of sodium caprolactamate (Na-LC) catalyst, ICs and CLNs can form copoly(amide–esters) (CPAEs) of the following structure:

Macro- and supramolecular properties and processing and service characteristics of the resulting copolymer products can vary within wide ranges depending on the ratio of the initial monomers.

In this study we examined modification of crystalline POs [polypropylene (PP), high-density polyethylene (HDPE)] with binary mixtures based on TDI and ε-CLN in the presence of Na-CL catalyst; chemical transformations occurring in the course of the modi-

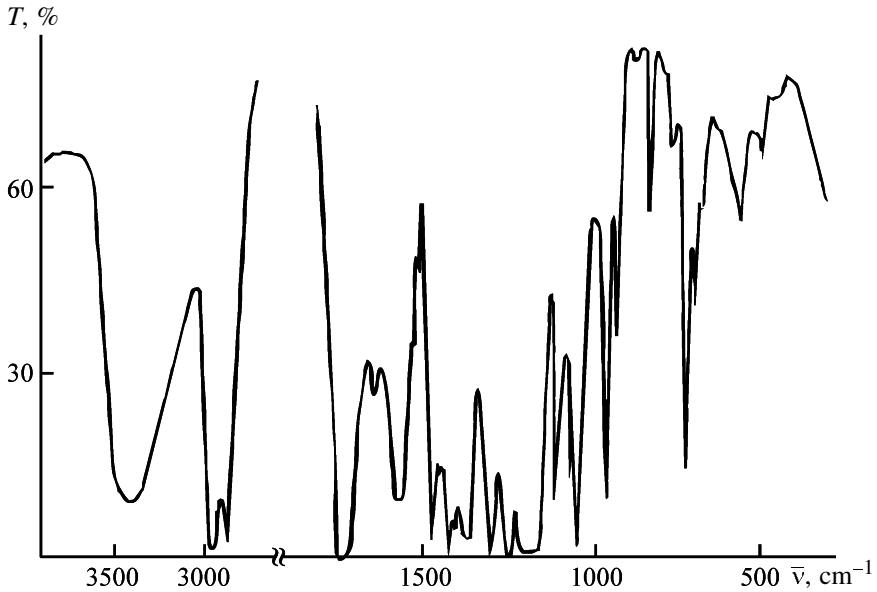


Fig. 1. IR spectra of the product of reaction of heptene and ε-CLN (molar ratio of the initial components 1 : 3). (*T*) Transmission and ($\bar{\nu}$) wavenumber; the same for Fig. 2.

fication were analyzed using real and model systems containing α-olefins.

EXPERIMENTAL

The chemical reaction of α-olefins (hexene, octene, and decene) with ε-CLN and TDI was carried out in a three-necked flask equipped with a reflux condenser and a magnetic stirrer under an inert gas (argon) flow. The required amounts of the monomers and catalyst (Na-CL) were melted at 100°C and then the temperature was increased stepwise to 180°C. The reaction was performed to the formation of the viscous product, and then the reaction mixture was depolymerized in 120 min.

The unchanged reagents were separated from the products of the model reactions by refluxing with acetone in a Soxhlet apparatus for 8 h. The IR spectra of the products of the model reactions were recorded on a PC-16 Perkin–Elmer Fourier IR spectrometer. The IR spectra were analyzed using an internal reference [8].

In our study we used a Balen brand polypropylene (Polipropilen Private Company, Ufa, Russia) and 273–77 brand high-density polyethylene (Kazan'orgsintez Joint-Stock Company, Kazan, Tatarstan, Russia). PO modification was performed in a melt on the rolls at 185 and 165°C for PP and HDPE, respectively. The rolling time was 5 min; the components of the modifying system were added simultaneously with the catalyst.

The samples were cut out from the plates prepared by the direct pressing in accordance with GOST (State Standard) 12019–66 at 210 and 185°C for PP and HDPE, respectively. The specific pressure of the pressing was 7–10 MPa, the heating time was 10 min, the pressing time was 5 min per 1 mm thickness, and the cooling time was 4 min. The thickness of the samples used to determine physicomechanical properties was 0.1 ± 0.01 and 0.2 ± 0.02 cm for PP and HDPE, respectively. We studied the samples with smooth surface without swellings, cracks, and other defects.

The physicomechanical properties (ultimate tensile stress σ_t and relative elongation ε) were determined on an RM 500-T relaxometer in accordance with GOST (State Standard) 11262–80; the velocity of the shifting clamp was 100 mm min^{-1}. The samples were tested for no less than 24 h after the preparation and were preliminarily stored at the test temperature for 4 h.

The melt flow index (MFI) was determined using an IIRT-type capillary viscometer with a capillary diameter of 0.095 ± 0.005 cm. The test temperature and load were 300°C and 5 kg, and 190°C and 2.16 kg for PP and HDPE, respectively. The search for efficient mixtures of the modifying agents was optimized by the simplex–grid method of the experiment design using the Scheffe model of the third and fourth order as a polynomial approximant [9].

To understand the origin of chemical transformations probably occurring at PO modification with

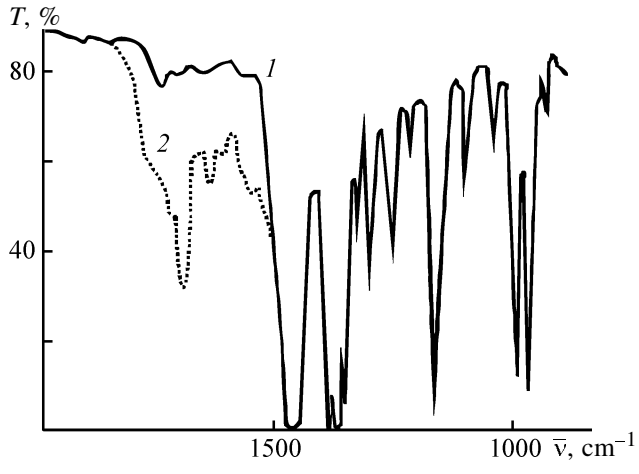

Fig. 2. IR spectra of the (*1*) initial PP and (*2*) PP modified with the ε-CLN + TDI system; weight ratio of the modifying agents 1 : 1, concentration 12 wt %.

the binary system based on TDI and ε-CLN, we should take into account the possibilities of their reaction both with each other and with terminal unsaturated groups of the modified monomers. Therefore, we studied the reactions occurring in binary (ε-CLN + α-olefin) and ternary (ε-CLN + TDI + α-olefin) systems under the conditions of anionic initiation. In the presence of Na-CL the reaction of α-olefins with ε-CLN yield only the ε-CLN homopolymer, and no copolymerization with unsaturated compound was observed. The IR spectrum of the product after removal of the unchanged components (Fig. 1) contains the bands at 2920 (stretching vibrations of the C–H bond in the methylene group), 1730 (vibrations of the carbonyl ester groups), 1472 (bending vibrations of the C–H bond in the methylene group), and 1172 cm^{-1} (stretching vibrations of the C–O bond).

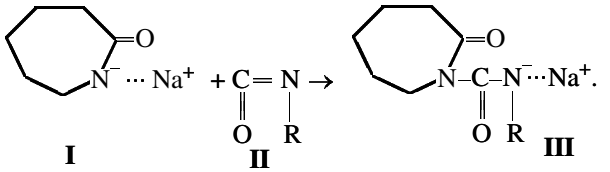
Table 1. Variation in the content of vinylidene bonds in PP modified with the TDI + ε-CLN system

System composition, wt %			$\log(I_{888}/I_{1380})$
PP	TDI	ε-CLN	
100	–	–	0.92
94	–	6	0.91
94	6	–	0.79
88	6	6	0.84

Note: I_{888} and I_{1380} are the intensities of the absorption bands at 888 and 1380 cm^{-1}, belonging to out-of-plane bending vibrations of the terminal vinylidene groups and symmetrical bending vibrations of the methylene groups, respectively.

Formation of the ε-CLN copolymer as the only product was confirmed by the ^1H NMR spectra, which contained signals at 4.1–3.9 and 2.3–2.1 ppm belonging to the protons of the CH_2–O and CH_2–C(O) groups in poly-ε-CLN, respectively. No signals of the methylene and methine groups were found, which suggests the absence of the olefin component.

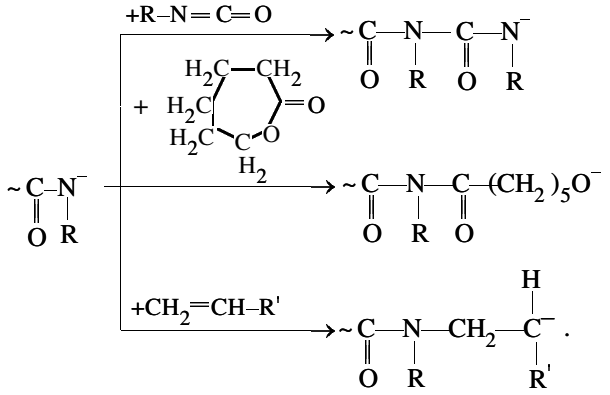
Previous studies of chemical transformations in the reaction of TDI with α-olefins in the presence of Na-CL showed that their copolymerization proceeded at a high rate and the yield of the final product was as high as 97% [2]. An IR study of the chemical structure of TDI copolymers with various α-olefins showed that the isocyanate reacted with unsaturated bond of the α-olefin through opening of the N=C=O group.



Based on the above facts, we assumed that only the isocyanate component of the TDI + ε-CLN system is chemically active with respect to PO macromolecule; however, formation of more complex copolymers is also possible.

The data on chemical transformations in the ternary α-olefin + ε-CLN + TDI systems showed that, under the given experimental conditions, isocyanate copolymerizes with both CLN and olefin. The resulting products are transparent yellowish solids soluble in strongly polar solvents (such as DMSO, DMF) at elevated temperatures. The yield of the products of reaction of TDI and ε-CLN with various α-olefins depends on both the monomer ratio and the chemical nature of the unsaturated compound and varies from 24 to 89%. These results are confirmed by the IR spectra of PP modified with ε-CLN + TDI. For example, the IR spectrum (Fig. 2) contains the bands at 1720 and 1710 cm^{-1} belonging to the stretching vibrations of the carbonyl group in esters and tertiary amides, respectively.

The decreased intensity of the band at 888 cm^{-1} confirms the reaction of isocyanate with terminal unsaturated bonds in PP (Table 1).



Thus, the data on the model reactions and on the chemical structure of the PO compositions suggest that both copolymerization of the system components and reaction of isocyanates with unsaturated terminal groups of PO occur in the course of modification of PO with TDI + ε-CLN systems under the conditions of anionic initiation. In this case, the ester fragments can be grafted to the PO macromolecule owing to high chemical activity of the isocyanate anion. The main chemical transformations in the tertiary α-olefin + TDI + ε-CLN systems are probably as follows. In the first stage, the catalyst dissociates to form the lactam

anion and alkali metal cation, and this anion reacts with unsaturated N=C bond:

I **II** **III**

In the second stage, anion **III** arising in the α-olefin + TDI + ε-CLN system reacts with the corresponding monomers:

The resulting chain is terminated by the reaction of the anion of the propagating chain with compounds containing labile hydrogen atoms to form terminal hydroxy and amino groups. The data on copolymerization of ε-CLN with diisocyanates [7] showed that either branched or cross-linked structures are formed depending on the content of the initial components.

Similar processes occur in the systems studied. For example, the solubility of the products strongly decreases with increasing concentration of isocyanate component in the monomer system. The data on the service and processing properties of the modified POs showed that the relative elongation ε of the HDPE formulations strongly increases with addition of both individual ε-CLN and its mixtures with the other modifying agents in concentrations of up to 3 wt % (Fig. 3a). Similar results are observed with PP (Fig. 3b). It should be noted that in this case the σ_t values remain virtually constant (Table 2). In the case of the mixtures, the viscosity of the molten PO formulations decreases (Fig. 3c). Such simultaneous changes in the viscosity and elasticity characteristics are probably due to both plasticizing effect of the copoly(amide–ester) formed in the PO matrix and deactivation of the terminal unsaturated bonds.

No effect on the relative elongation ε of PO of the second concentration optimum was observed in modification of polyolefins with systems based on TDI and

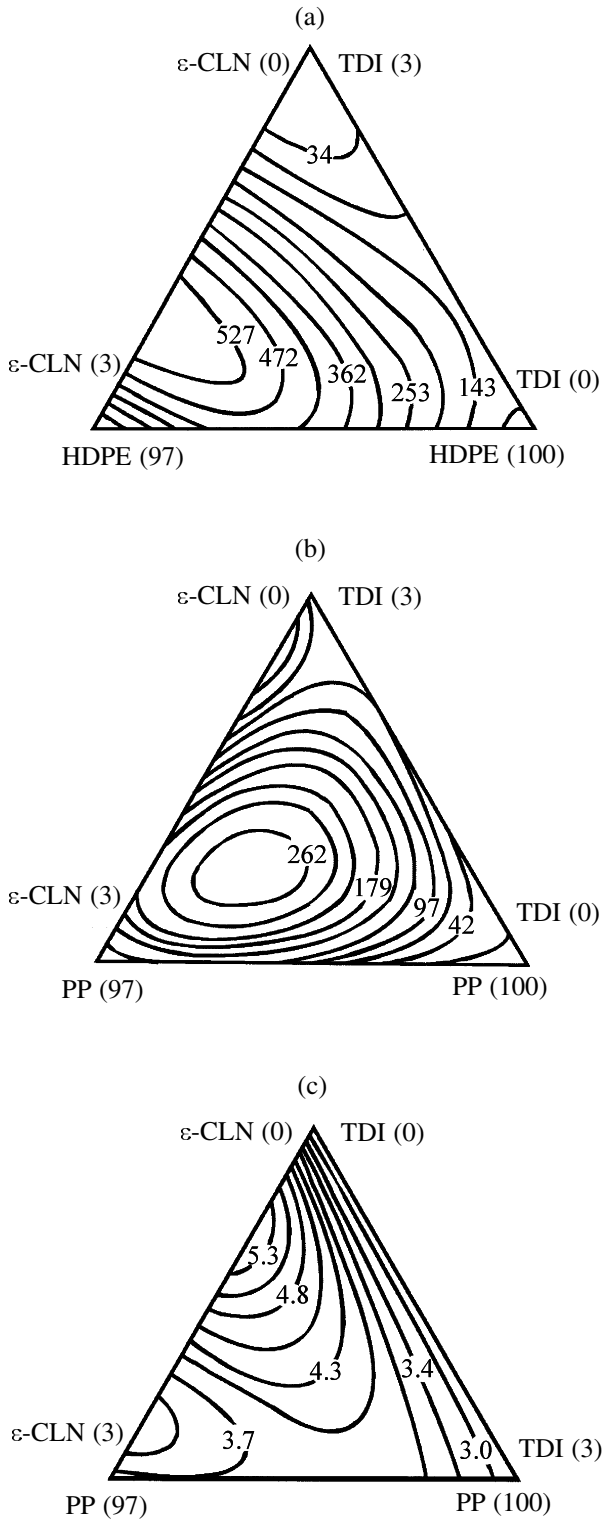


Fig. 3. Diagrams of the relative elongation of the (a) HDPE + TDI + ε-CLN and (b) PP + TDI + ε-CLN, and (c) PP + TDI + ε-CLN systems; figures in parentheses indicate the content of corresponding compound (wt %); the same for Fig. 4.

98	1	1	30.4	34.2
97	1	2	29.2	33.7

ω-DL. This is obviously due to the fact that in the case of 13-membered LC the separate phase appears only at concentration of the modifying system of more than 6%, whereas with mixtures based on CLN it is formed at concentrations as low as 2–3%. This is confirmed by increasing optical density of PP in this concentration range (Fig. 4). These results can be probably explained as follows: opening of the ε-CLN ring yields an aliphatic radical of smaller length (as compared to ω-DL) and, as a result, the copolymer products formed in the course of modification are characterized by lower compatibility with PO.

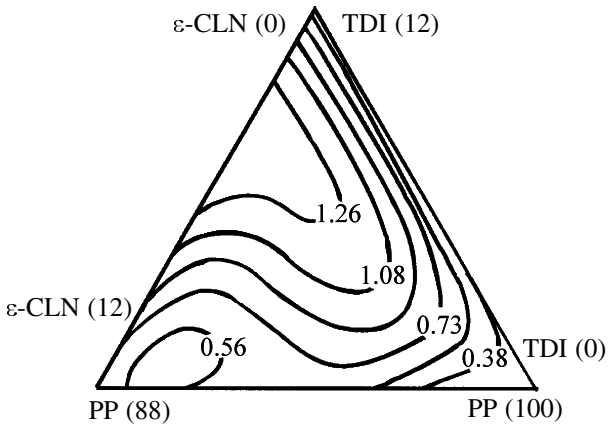

Fig. 4. Diagram of the optical density of the PP + TDI + ε-CLN system (λ 1000 nm).

CONCLUSIONS

(1) Modification of polyolefins with a binary system consisting of 2,4-toluene diisocyanate and ε-caprolactone improves the physicomechanical characteristics of the resulting composites by up to 8–10%.

(2) Isocyanate groups react with the terminal vinyl groups of polyolefins, providing grafting of the polymer matrix with copoly(amide–ester) fragments.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Boric Acid Esters as Thermal Stabilizers and Fungicidal Additives for Elastomers from Natural Rubber

V. I. Grachek and A. N. Lukashik

Institute of Physical Organic Chemistry, National Academy of Sciences of Belarus, Minsk, Belarus

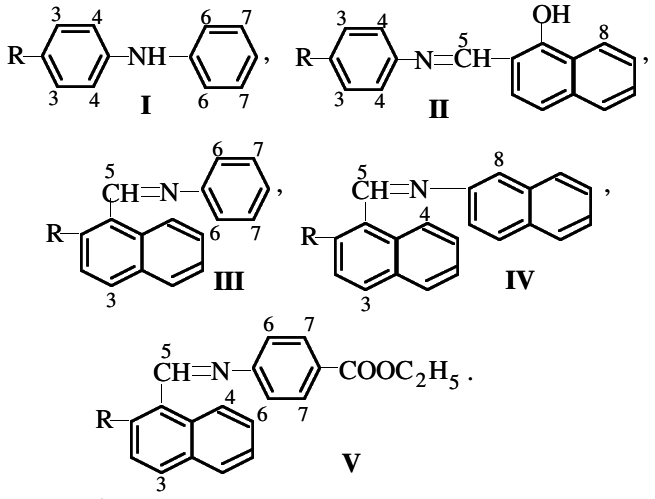
Received November 14, 2005

Abstract—New and previously synthesized boric acid esters were studied as thermal stabilizing and fungicidal additives to elastomers based on natural rubbers.

DOI: 10.1134/S1070427206050247

The world's consumption of natural rubber, mainly used in tire and car industry, steadily increases. Natural rubber, having a unique set of characteristics and being a standard of general-purpose rubber, also has a number of drawbacks hampering its processing and application, such as low fungus resistance [1] and susceptibility to heat aging. The fungus and heat resistance of a material can be enhanced by modification of the rubber, i.e., by purposeful variation of its characteristics using appropriate additives. Proceeding with studies on modification of elastomers [2], we attempted to improve the fungus and heat resistance of natural rubber by introduction of boric acid esters.

The use of organoboron compounds as additives improving the quality of polymer materials is well known [3–5]. With the aim to synthesize promising thermal stabilizing and fungicidal additives for natural rubber, we studied new boric acid esters and those described previously [2].



EXPERIMENTAL

The ^{1}H NMR spectra of solutions in $CDCl_3$ were recorded on a Tesla BS-567 spectrometer (100 MHz), hexamethyldisiloxane was used as internal reference. The IR spectra were recorded on a UR-20 spectrophotometer in KBr pellets. The melting points of the compounds were determined on a Köfler unit.

Borates were prepared by heating of a mixture of boric acid with pyrocatechol and hydroxo compounds at 70–100°C in toluene or benzene with simultaneous removal of the released water as a heteroazeotrope. The structure of the resulting compounds was proved by IR spectroscopy, ^{1}H NMR, mass spectrometry, and elemental analysis.

The absorption bands in the ranges 1350 ± 10 and 1040 ± 10 cm^{-1} are assigned to the symmetric and asymmetric vibrations of the B–O group, and those in the ranges 1240 ± 5 and 1090 ± 10 cm^{-1}, to the symmetric and asymmetric vibrations of the C–O group. The bands at 1640 ± 5 cm^{-1} are assigned to vibrations of the CH=N group. The absorption at 1754 ± 10 cm^{-1} corresponds to the stretching mode of the ester group.

The ^{1}H NMR spectra of previously unknown compounds **I**–**V** are presented in Table 1:

The ^{1}H NMR spectra of **VI**–**IX** were described in [2]:

* Compounds **VI–IX** were described in [2].

IX

where R =  (**I–IX**).

As seen from Table 1, protons of the pyrocatechol ring give signals at 6.18 ± 0.06 and 5.60 ± 0.03 ppm. The proton of the azomethine group gives a signal at 8.12 ± 0.05 ppm. The chemical shifts of substituent proton signals in the spectra of **I–V** are given in Table 1.

The mass spectra of boric acid esters contain weak peaks of molecular ions (Table 1). The molecular peaks have approximately the same intensity for all the compounds. Hence, the degree and features of electron delocalization in the substituents, affecting the resistance to electron impact, the yield of molecular ions, and formation of stable radicals, are similar.

The physicochemical characteristics of the newly synthesized compounds are given in Table 2.

Boric acid esters were incorporated into formulations based on natural rubber. The rubber stocks were prepared on 320/320 laboratory rolls. We used the following formulas (wt proportion): plasticized natural rubber, thick "light crepe," sort 1, 100; stearin, 0.5; Captax, 0.7; zinc oxide, 5.0; sulfur, 3.0; and boric acid ester, 0.5 or 1.0 (a total of 160 samples). The temperature of rolls was 55–60°C; clearance, 0.4 mm; and mixing duration, 3 min. Standard plates 2 mm thick were vulcanized on a 300 × 400 hydraulic press at 140°C for the time corresponding to the optimum of vulcanization determined from the physicomechanical characteristics of rubber and equal to 22–25 min.

Thermal oxidative aging of vulcanized rubbers was examined using samples in the form of blades in a thermostat with air circulation at 100°C for 37 h.

The fungicidal resistance of vulcanized rubbers was evaluated according to requirements of GOST (State Standard) 9048–75. The degree of fungus development on the samples of vulcanized rubber was evaluated on the six-point scale.

Aging of elastomers is one of the main causes of decreasing working capacity and service life of items made of them. The resistance of rubbers to thermal action is appreciably governed by the rubber structure. The unique characteristics of natural rubber are due to strict and fine adjustment of the composition, structure, and length of macromolecules, realized in biosynthesis in plant cells [6]; therefore, not all additives

are compatible with natural rubber. In aging, the bonds are ruptured and rearranged, which can also initiate thermal oxidative degradation of the chains. Boric acid esters containing an electron-seeking boron atom able to accept electrons on the vacant orbitals can block the radicals formed in aging of elastomers. In addition, borates contain a nitrogen atom able to terminate the chains.

The thermal stability of rubbers with borates added was compared to that of the rubber without additives and with the rubber containing a commercial stabilizing agent, Neozon D (Table 3). Organoboron compounds are uniformly distributed in the natural rubber, do not affect vulcanization of the rubbers, do not deteriorate the initial physicochemical characteristics, and do not color the rubber items. In thermal aging (100°C, 37 h), the rubbers containing boric acid esters have higher physicochemical characteristics than the rubbers without additives, i.e., all the compounds studied thermally stabilize vulcanized rubbers. Compound **I** containing no azomethine group is less efficient as stabilizing agent. All boric acid esters contain a common phenylene borate group bonded by a bridging oxygen atom with an aromatic radical. In this case, the presence of substituents in the *o*- or *p*-position of the aromatic radical does not noticeably affect the thermal stabilizing characteristics of borates. For example, compounds **VII** and **VIII** differing only in the substituent position have the same stabilizing activity. Borates containing, along with azomethine group, hydroxy or ester group (**II, V, IX**) have a high thermal stabilizing effect. A comparison with Neozon D shows that the boric acid esters containing azomethine group have approximately the same thermal stabilizing activity as Neozon, but, contrary to Neozon, do not color rubber items. Compound **VI** in an amount of 1.0 wt % relative to rubber is the most efficient thermal stabilizing agent for natural rubber and is somewhat more active than Neozon D. The strength of vulcanized rubber containing this compound varies in aging by a factor of 2.5, and the elasticity of this rubber is 15% lower than that of the rubber without an additive. The high thermal stabilizing effect of this borate is caused by the presence of a boron atom, an azomethine group, and also, contrary to the other esters, an ester group in a combination with hydroxy group.

Natural rubber is not fungus-resistant and is very easily overgrown with fungi at high relative humidity (approximately 85%), elevated temperature (20–30°C), and in stagnant air, which accelerates degradation of the material. Various compounds, among them polyalkyleneguanidine salts, are used as disinfectants for natural rubber [7]. Since organoboron compounds have a fungicidal effect on polymer materials [8, 9], we studied the effect of boric acid esters on biofouling of vulcanized rubbers with fungi. The results are listed in Table 4.

Table 4 shows that biofouling of rubbers with fungi is significantly weaker in the presence of borates than without additives. The results obtained show

Table 4. Estimation of fungus development on vulcanized rubbers according to six-point scale

Compound	Amount added, wt %	Estimation of fungus development, points, in indicated period, days			
		28	56	84	120
I	0.5	2	3	3–4	4
II	0.5	0–1	0–1	1–2	2
	1.0	0	0	0–1	1–2
III	0.5	2	3	3	3–4
IV	0.5	1–2	2	2–3	3–4
V	0.5	0	1–2	2–3	3
	1.0	0	0–1	1–2	2–3
VI	0.5	0	0–1	1	1–2
	1.0	0	0	0–1	0–1
VII	0.5	0–1	0–1	1–2	2
VIII	0.5	1–2	2	2–3	3–4
IX	0.5	0	1–2	1–2	2
No additive	–	4	4–5	5	5

that esters of different structures differently affect the resistance of rubbers to biofouling with fungi. The most efficient additives are the compounds containing a *p*-substituted phenylene group bonded to the boron atom through the oxygen bridge. In particular, compounds **VII** and **VIII** have similar thermal stabilizing activity, but the fungicidal effect of **VII** is stronger. Addition of the substituted azomethine group to phenyl ring in the *p*-position makes the borate molecule more mobile, and this molecule more readily diffuses in the material bulk to the surface; to suppress development of microorganisms at the surface, the fungicide concentration at the surface should be sufficiently high [10]. Therefore, compounds **III**–**V** and **VIII** containing bulky substituents in the *o*-position of the phenyl ring or in the α-position of the naphthalene ring show lower fungicidal activity than **VII**.

Compound **VI** has the highest fungicidal activity with respect to vulcanized natural rubber, and, as we showed, this compound is the most efficient thermal stabilizing agent. The compounds synthesized meet the requirements imposed on fungicidal additives: they have a high toxicity for fungi but are virtually nontoxic for humans (LD_{50} = 580–670 mg kg^{-1}), are well compatible with natural rubber, and do not prevent vulcanization.

The studies showed that boric acid esters are multitarget process additives whose introduction enhances the resistance of rubbers to thermal aging and fungi.

CONCLUSIONS

(1) Boric acid esters were synthesized. They are thermal stabilizing agents for vulcanized rubbers and protect them from biofouling with fungi.

(2) Boric acid ester containing azomethine, hydroxy, and ester groups exhibit the strongest thermal stabilizing and fungicidal effects.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Initiation of Radical-Chain Processes with Mixtures of Benzoyl Peroxide and Azobis(isobutyronitrile)

Abstract—The initiating power of binary mixture of initiators, benzoyl peroxide and azobis(isobutyronitrile), in polymerization of methyl methacrylate and in liquid-phase oxidation of cumene in acetonitrile at 339 K was studied.

DOI: 10.1134/S1070427206030259

Initiation of radical-chain polymerization reactions with mixtures of initiators attracts steady researchers' attention [1–4]. These studies are aimed to choose the optimal conditions for preparing polymers with desired physicochemical characteristics. When the reaction mixture contains initiators or catalysts promoting low-temperature homolytic decomposition of the arising hydroperoxides, the liquid-phase radical-chain oxidation proceeds in the mixed initiation mode [5].

Mixtures of initiators of different chemical natures are of particular interest. Among these initiators are benzoyl peroxide and azobis(isobutyronitrile), which are widely used in polymerization reactions, in particular, as components of binary mixtures when it is necessary to provide a high efficiency of initiation with variation of the process temperature [1, 6]. Azobis(isobutyronitrile) is also used for acceleration of radical-chain oxidation of alkylaromatic hydrocarbons at a temperature below 360 K. The initiating power of each of these initiators was studied, and the kinetic parameters of their decomposition and the initiation efficiencies are well known [5].

In this study we examined the combined action of benzoyl peroxide and azobis(isobutyronitrile) in the radical-chain reactions of cumene oxidation and methyl methacrylate polymerization.

EXPERIMENTAL

Cumene (Cum), acetonitrile used as a solvent, benzoyl peroxide (BPO), and azobis(isobutyronitrile) (AIBN) were purified by standard procedures [7, 8]. Commercial methyl methacrylate (MMA) was washed 2–3 times with 10–15% aqueous alkali to remove completely the inhibitor. Then, MMA was washed 2–3 times with distilled water, dried over anhydrous calcium chloride, and distilled in a nitrogen atmosphere at reduced pressure; the fraction boiling at 22 ± 0.2°C/25 mm Hg was collected. Freshly distilled MMA was used. The kinetics of MMA polymerization was studied dilatometrically to a monomer conversion of 10%. The monomer content in the reaction mixture was 25 vol %. Polymerization of MMA in the presence of BPO and AIBN was performed in acetonitrile at 339 K. The concentrations of peroxide and azobis(isobutyronitrile) in the initiation systems were 1×10^{-2} and 5×10^{-3} M, respectively.

The oxidation rate W was determined volumetrically from the amount of oxygen taken up at a constant oxygen pressure; the reaction mixture was stirred sufficiently intensely to provide the kinetic control of the reaction.

Polymerization initiated by benzoyl peroxide can be described by the following scheme:

$$\mathrm{BPO} \longrightarrow \mathrm{R}^{\bullet},$$

$$\mathrm{R}^{\bullet} + \mathrm{M} \longrightarrow \mathrm{M}^{\bullet},$$

$$\mathrm{M}^{\bullet} + \mathrm{M} \longrightarrow \mathrm{M}_n^{\bullet},$$

$$2\mathrm{M}^{\bullet} \longrightarrow \text{Products}.$$

In the case of the polymerization initiation with a mixture of benzoyl peroxide and azobis(isobutyro-

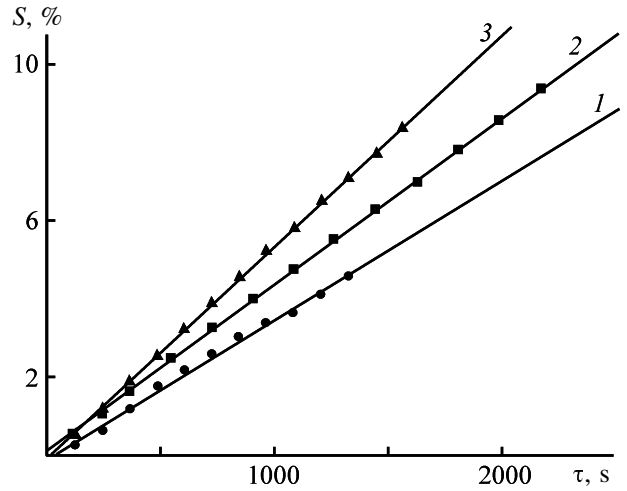

Fig. 1. Kinetic curves of polymerization S of methyl methacrylate ($[MMA]_0$ = 25 vol %) in acetonitrile in the presence of benzoyl peroxide and azobis(isobutyronitrile) at 339 K. (τ) Time. Initial concentration, M: (*1*) $[BPO]_0$ = 0.01, (*2*) $[AIBN]_0$ = 0.005, and (*3*) $[BPO]_0$ = 0.01 and $[AIBN]_0$ = 0.005.

nitrile), the above scheme is supplemented with the following reactions:

$$AIBN \longrightarrow r^{\bullet},$$

$$r^{\bullet} + M \longrightarrow M^{\bullet}.$$

For the initial steady-state stage of the polymerization, the polymerization rate is described by the equation [9]

$$W_{pol} = k_p(2k_t)^{-1/2}[M]W_i^{1/2}, \quad (1)$$

where k_p and k_t are the rate constants for chain propagation and termination, respectively; [M] is the monomer concentration; and W_i is the initiation rate.

In the absence of induced decomposition of the initiator, the initiation rate can be presented as follows:

$$W_i = 2fk_d[I][M]^m, \quad (2)$$

Rates of initiated polymerization of methyl methacrylate W_{pol} at 339 K. $[MMA]_0$ = 25 vol %, solvent acetonitrile

$[BPO]_0$	$[AIBN]_0$	$W_{pol} \times 10^5$, mol l^{-1} s^{-1}
M		
–	0.005	9.83 ± 0.05
0.01	–	8.14 ± 0.18
0.01	0.005	12.29 ± 0.05
0.04	–	14.58 ± 0.50
0.04	0.005	18.17 ± 0.11

where the coefficient 2 is the number of radicals formed by the initiator decomposition; f, initiation efficiency; k_d, rate constant of the initiator decomposition; and [I], initiator concentration.

It is well known [9] that the initiation rate of MMA polymerization at a monomer concentration above 2 M is independent of the monomer concentration. Under the experimental conditions, the MMA concentration was 2.24 M, i.e., the experiment was performed under conditions when the monomer concentration did not affect the polymerization rate. Thus, the rate of initiated MMA polymerization is

$$W_{pol} = a(fk_d[I])^{1/2}, \quad (3)$$

where $a = k_p(2k_t)^{-1/2}[M]$.

The total polymerization rate is

$$W_{pol\Sigma} = a(f_{BPO}k_{dBPO}[BPO] + f_{AIBN}k_{dAIBN}[AIBN])^{1/2} = (W_{polBPO}^2 + W_{polAIBN}^2)^{1/2}. \quad (4)$$

The amount of the polymerized monomer as a function of the duration of methyl methacrylate polymerization initiated by the system BPO–AIBN at 339 K is plotted in Fig. 1. The polymerization rates were determined from the slopes of the straight lines.

The kinetic parameters of methyl methacrylate polymerization in the presence of benzoyl peroxide and azobis(isobutyronitrile) separately and in a mixture are presented in the table.

As seen from the table, the calculated polymerization rate with the combined action of the initiators is $(12.7 \pm 0.19) \times 10^{-5}$ mol l^{-1} s^{-1}, and the experimental value is $W_{pol\Sigma} = (12.29 \pm 0.05) \times 10^{-5}$ mol l^{-1} s^{-1}. Thus, the effect of a mixture of initiators is additive, i.e., the initiators do not affect the initiating power of each other.

It can be assumed that the rate equation for the liquid-phase oxidation of cumene in the presence of binary mixture BPO–AIBN, which proceeds by the same nonbranched radical-chain mechanism, will be similar to the rate equation for the polymerization of methyl methacrylate in the presence of BPO and AIBN. The kinetic scheme of oxidation of hydrocarbons is well known [5]. The initiation and oxidation rates can be presented by the equations

$$W_{iBPO} = k_i[I], \quad (5)$$

$$W_{oBPO} = a(k_i[I])^{1/2}. \quad (6)$$

The total rate of oxidation in the presence of two

initiators is

$$W_{o\Sigma} = a(k_{iBPO}[BPO] + k_{iAIBN}[AIBN])^{1/2} = (W_{oBPO}^2 + W_{oAIBN}^2)^{1/2}. \quad (7)$$

However, the experimental oxidation rates in initiation with individual initiators and their mixtures do not confirm this assumption.

The examples of the kinetic curves of oxygen uptake in cumene oxidation are presented in Fig. 2. They show that the reaction rate remains practically constant during the experiments. It follows from Fig. 2 that at a fixed concentration of benzoyl peroxide addition of AIBN into the reaction mixture increases the oxidation rate.

If we substitute the rate of cumene oxidation in the presence of only AIBN (1.71×10^{-5} mol l^{-1} s^{-1}) or BPO (0.74×10^{-5} mol l^{-1} s^{-1}) in Eq. (7), the calculated oxidation rate at the combined action of the initiators should be equal to 1.86×10^{-5} mol l^{-1} s^{-1}, whereas the experimental value is $W_{o\Sigma} = 1.23 \times 10^{-5}$ mol l^{-1} s^{-1}.

To check whether the initiation efficiency varies in this case, we used the method of inhibitors. The experiments were performed as follows: cumene was oxidized in the presence of BPO and AIBN individually and in a mixture at the ratio cumene : acetonitrile = 1 : 1 at 339 K with addition of 3×10^{-4} M Ionol as an inhibitor.

The equation for the induction period τ in the case of a single initiator is in the form

$$\tau_I = [In]/(k_i[I]). \quad (8)$$

For a mixture of the initiators, the total induction period is

$$\tau_\Sigma = [In]/(k_{iBPO}[BPO] + k_{iAIBN}[AIBN]). \quad (9)$$

If Eq. (8) is substituted in Eq. (9), we obtain the total induction period:

$$\tau_\Sigma = [In]/([In]/\tau_{BPO} + [In]/\tau_{AIBN}) = 1/(1/\tau_{BPO} + 1/\tau_{AIBN}) = \tau_{BPO}\tau_{AIBN}/(\tau_{BPO} + \tau_{AIBN}). \quad (10)$$

If we substitute the induction period in the presence of only AIBN (540 s) or BPO (480 s) in Eq. (10), the calculated total induction period is 254 s, whereas the experimental value is τ_Σ = 360 s.

Thus, the effective initiation rate is significantly lower than the additive value, i.e., the two-component initiating mixture BPO–AIBN exhibits lower initiating power in comparison with the individual effect of

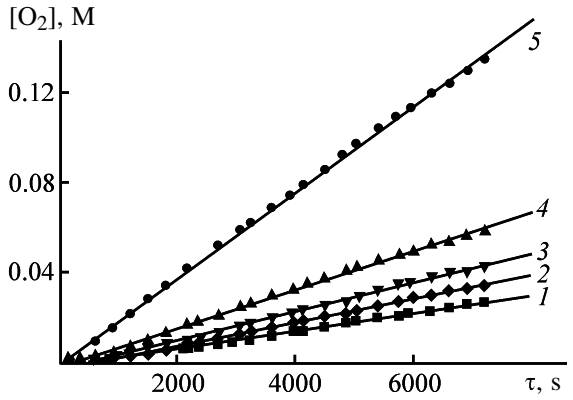

Fig. 2. Kinetic curves of cumene oxidation ([Cum]$_0$ = 3.58 M) in acetonitrile in the presence of benzoyl peroxide and azobis(isobutyronitrile) at 339 K. [BPO]$_0$ = 0.15 M. ([O_2]) Oxygen uptake and (τ) time. [AIBN]$_0$, M: (*1*) 0, (*2*) 0.005, (*3*) 0.01, (*4*) 0.02, and (*5*) 0.06.

AIBN in low-temperature oxidation of cumene. The decrease in the total rate of oxidation can be explained by the reactions of initiator molecules or radicals formed by the decomposition of BPO and AIBN, e.g., by the reaction of 2-cyano-2-propyl radical formed by AIBN decomposition with a BPO molecule:

$$r^\bullet + BPO \longrightarrow r_1^\bullet + P. \quad (11)$$

The reactions of peroxy radicals with peroxide molecule or benzoate radical

$$rO_2^\bullet + BPO \longrightarrow R^\bullet + P_1, \quad (12)$$

$$rO_2^\bullet + R^\bullet \longrightarrow P_2. \quad (13)$$

are also possible.

However, a study of the thermal decomposition of benzoyl peroxide ([BPO]$_0$ = 0.06 M) taken alone and in a mixture with azobis(isobutyronitrile) ([AIBN] = 0.06 M) in ethylbenzene and acetonitrile (1 : 1) does not confirm the occurrence of reaction (11). The experiments were performed as follows. Ampules filled with the reaction mixture were purged with argon for 3 min and heated at 339 K for 12 h. The concentration of benzoyl peroxide was monitored by iodometric titration. In both cases, approximately 17% of the benzoyl peroxide decomposed in 12 h ([BPO] is concentration of benzoyl peroxide after thermal decomposition for 12 h; solvent acetonitrile):

[AIBN]$_0 \times 10^2$, M	[BPO]$_0 \times 10^2$, M	[BPO] $\times 10^2$ M
–	5.97	4.93
6.00	5.85	5.05

The above data show that the presence of AIBN, which decomposes under these conditions with the formation of C-centered radicals, does not accelerate thermal decomposition of benzoyl peroxide. Therefore, reactions (12) and (13) decreasing the total oxidation rate in the presence of a mixture of initiators BPO and AIBN should be included in the scheme of cumene oxidation.

CONCLUSIONS

Initiation of methyl methacrylate polymerization with a mixture of initiators, peroxide and azo compound, occurs by the additive scheme without a reaction between the initiator radicals. In the liquid-phase oxidation of cumene with the same initiators and in the same temperature range, a significant antagonistic effect is observed.

Abstract—α-Galactosidase was encapsulated into sol–gel derived hybrid polysaccharide–silica nanocomposites. The main properties of the immobilized enzyme were studied.

DOI: 10.1134/S1070427206030260

Immobilization has long been successfully used for storage and prolongation of action of enzymes, as well as for development of artificial biocatalysts [1, 2]. Encapsulation into a matrix or immobilization on a support allows repeated use of enzymes and facilitates isolation of products of enzymatic reaction, which is essential for development of biotechnological processes. An important advantage of immobilization is the stabilization effect, i.e., significant prolongation of the lifetime and enhancement of the stability of enzymes. Therefore, new efficient supports and matrices for encapsulation of enzymes are constantly sought for.

α-Galactosidase (α-*D*-galactoside galactohydrolase, EC 3.2.1.22) is a promising biochemical tool for studying the antigene structure of various biological objects, in particular, blood cells. Immobilization of α-galactosidase was repeatedly attempted. For example, enzyme from coffee beans was covalently bound to dextran activated with cyanogen bromide [3].

α-Galactosidase from *Pycnoporus cinnabarinus* was immobilized on chitin dispersions with glutaric dialdehyde [4]. Enzyme from *Aspergillus oryzae* was immobilized on Eupergit C containing epoxy groups, which provided covalent bonding of the protein by amino, SH, and carboxy groups [5]. α-Galactosidase from the same source was placed into calcium alginate gel, in which it was additionally immobilized with glutaric dialdehyde [6]. Also, this enzyme was immobilized with polyacrylamide gel [7].

It should be noted that, in the cited studies, the enzyme was encapsulated via cross-linking. Immobilization inside a matrix or on a support by covalent bonding can adversely affect the enzyme through disturbing the conformation of the protein macromolecule. In some cases this is the main reason for partial or complete denaturation of not very stable enzymes [8, 9]. In the case of sol–gel technology, immobilization involves no cross-linking agents. The protein macromolecules are encapsulated into the inorganic matrix formed in situ by polycondensation reactions. The macromolecules undergo minimal structural changes, and the enzymes can preserve their activity [1–3]. α-Galactosidase from *Pseudoalteromonas sp*. KMM 701 sea bacterium can eliminate α-1,3-bound galactose residues from the nonreducing end of glucoconjugates, blood group substances, and antigene determinants for erythrocytes in B(III) blood group via suppressing their serologic activity [10]. α-Galactosidase is a thermally labile enzyme. In concentrated solutions at 20°C α-galactosidase remained active for 1 week, and at 30°C lost 50% activity within 10 min [10]. Dilution of concentrated solutions of the enzyme accelerated its inactivation. A low thermal stability and short lifetime of α-galactosidase in solution hinder its biotechnological application.

Our preliminary studies showed that encapsulation of α-galactosidase into polysaccharide–silica matrices obtained by the method we suggested previously [11, 12] significantly prolonged the lifetime of the enzyme. In this study we examined in more detail the conditions for α-galactosidase immobilization inside new hybrid nanocomposites and the properties of immobilized α-galactosidase in order to select candidate nanocomposites for development of biocatalysts suitable for biotechnological and biosensing applications.

EXPERIMENTAL

Tetrakis(2-hydroxyethyl) orthosilicate (THEOS) was synthesized from tetraethoxysilane (ABCR, Germany) as described in [13]. Polysaccharides xanthan and galactomannan (locust bean gum, from here on, LBG) (Fluka) was used without additional purification. Laminaran (β-1,3-glucan) was isolated from *Laminaria cichorioides* brown alga [14], and α-galactosidase, from biomass of *Pseudoalteromonas sp.* KMM 701 sea bacterium, cultivated at the Laboratory of Microbiology, Pacific Ocean Institute of Bioorganic Chemistry, Far-East Division, Russian Academy of Sciences, by the procedure from [10].

α-Galoactosidase was encapsulated into hybrid polysaccharide–silica nanocomposites by the procedure described in our previous paper [12]. First, 1.9 ml of solution containing 10 or 30 wt % precursor, different concentrations (0.25, 0.35, 0.75, and 1.5 wt %) of one of the three polysaccharides, and 0.1 M sodium phosphate buffer solution (to adjust pH) was prepared. It was kept for some time, determined in previous experiments and required for its conversion into a pregel state by partial polymerization of silicic acids formed from hydrolysis of THEOS. Then, 0.1 ml of the enzyme solution with an activity of 10 units ml^{-1} was added. All the solutions were precooled to 3–5°C in a refrigerator. After mixing and thorough stirring, they once again were placed into the refrigerator in order to minimize denaturation of the enzyme during immobilization.

The activity of immobilized α-galactosidase was determined with *p*-nitrophenyl-α-*D*-galactopyranoside (Sigma) as substrate. The reaction mixture was prepared by mixing 0.35 ml of a 3.3×10^{-3} M solution of substrate in the buffer solution (10^{-1} M sodium phosphate, pH 7.2) and 0.05 ml of solution of free α-galactosidase, or 0.05 g of the gel with the enzyme immobilized, and incubated at 20°C. The reaction was terminated by adding 0.6 ml of an aqueous solution of 1 M sodium carbonate, whereupon the gel was separated by centrifugation. The amount of *p*-nitrophenol yielded by the enzymatic reaction was determined spectrophotometrically at 400 nm (ε = 18 300 l mol^{-1} cm^{-1}). The enzyme activity unit *U* was taken equal to the amount of the enzyme in 1 ml of solution (free enzyme) or 1 g of gel (immobilized enzyme) with which 10^{-6} mol of *p*-nitrophenol was formed per minute. The control was a solution of the enzyme (free enzyme) prepared by 20-fold dilution of the initial solution of α-galactosidase with 0.1 M sodium phosphate buffer solution (pH 7.2). It was free from additions of the precursor and polysaccharide used for immobilization.

α-Galactosidase from *Pseudoalteromonas sp.* KMM 701 sea bacterium was immobilized inside hybrid polysaccharide–silica nanocomposites synthesized using a new precursor, THEOS. It is distinguished by complete solubility in water and compatibility with biopolymers. Polysaccharides were used because they catalyze sol–gel processes [15, 16]. In their presence gelation proceeds at any pH, as well as at low temperatures, which is essential for thermolabile enzymes. In particular, to minimize denaturation of α-galactosidase exhibiting a low thermal stability during encapsulation into silica matrix, immobilization was carried out at a temperature close to 0°C and pH 7.2. Commonly used precursors, such as tetramethoxy- and tetraethoxysilanes, do not form gels under such conditions [8, 9, 17, 18].

To elucidate how the structure of the polysaccharide and its charge affect the catalytic properties of α-galactosidase, we tested negatively charged xanthan and neutral LBG and laminaran. Previously we studied the possibility of immobilization of endo-1 → 3-β-*D*-glucanase L_{IV} from *Spisula sacchalinensis* and α-galactosidase in hybrid polysaccharide–silica nanocomposites [12]. The immobilized proteins remained functionally active for 165 days. The activity of the proteins varied with the formulation of the nanocomposite and structure of the polysaccharide, but these aspects were not studied in detail.

Table 1 lists the activities of α-galactosidase immobilized inside hybrid polysaccharide–silica nanocomposites with various formulations, synthesized in this study. It was tested for 16 months after matrix immobilization of the enzyme. It is seen that the enzyme remained active by the end of the test in selected cases only. To elucidate how the catalytic properties of α-galactosidase are influenced by the structure and concentration of the polysaccharide, as well as by the silica concentration in the matrix, we will consider the activities determined just after gel formation.

Table 1 shows that the highest activity was exhibited by sample no. 5 prepared by mixing 0.25 wt % solution of xanthan and 10 wt% solution of THEOS. It was nearly two times that of the free enzyme. Also, it exceeded the activity of galactosidase in a matrix with identical formulation that we examined previously [12], but in that study the content of the enzyme was by an order of magnitude lower.

The enzymatic activity of sample nos. 2 and 3, containing 0.25 and 0.75 wt % LBG, respectively,

Table 1. Activity of α-galactosidase in relation to the immobilization conditions and storage time

just after immobilization was comparable to that of the enzyme in solution. With increasing amount of LBG in the silica matrix to 1.5 wt % (sample no. 4), the activity decreased almost threefold. This suggests that the activity depends on the concentration of the polysaccharide in the hybrid nanocomposite. As shown in [15, 16], this can be due to the fact that the network structure of the nanocomponent becomes thicker, which can hinder diffusion of the substrate and the enzymatic reaction products.

Most probably, a similar factor also operates when the content of silica in the nanocomposite is increased. Comparison of the data for sample nos. 4 and 5 (Table 1), containing identical amounts of xanthan and different amounts of THEOS (10 and 30 wt %, respectively), shows that the activities of the enzyme immobilized differed for them by a factor of nearly 5. Among the polysaccharides that we studied only laminaran in the gel did not exert a stabilizing effect on the immobilized α-galactosidase. This follows from the fact that the enzymatic activity of control sample no. 1 was 1.5 times that of sample no. 7 (see Table 1).

A 16-month testing of the samples showed that, by the end of this time, α-galactosidase lost its enzymatic activity in most cases (Table 1). The situation with the free enzyme was similar. The activity was preserved by sample nos. 2–4 only: By the end of the test period it was virtually identical to that in the beginning of the experiment. However, the activity of the biocatalysts varied during the tests. For sample nos. 2 and 3 it increased more than twofold within the first 19 days and then tended to decrease. The activity of sample no. 4 significantly varied in the beginning of the experiment, whereupon it remained virtually unchanged throughout the test period.

Tests of xanthan- (nos. 5 and 6) and laminaran-containing (no. 7) samples showed that the activity of the immobilized enzyme decreased with time. Also, the lifetime of α-galactosidase in matrices containing these polysaccharides was shorter than that in the previously discussed samples with LBG.

The retention of the immobilized enzymes in(on) the support is of practical importance. To estimate the strength of immobilization of α-galactosidase in the polysaccharide–silica matrices, we tested sample nos. 2–4 in which the enzyme was best preserved. To 0.1 g of gels, 0.4 ml of 10^{-1} M buffer sodium phosphate solution (pH 7.2) was added. After 2-day keeping in a refrigerator at 4°C with intermittent stirring, the samples were centrifuged at 10000 rpm. The activity was determined in both supernatants and gels by the above-described procedure.

The solutions in which the biocatalysts were kept and separated by centrifugation virtually lack enzymatic activity (Table. 2). This suggests a fairly strong immobilization of the enzyme macromolecules in the gel matrix, when only insignificant number, if any, of them can liberate. However, the activity in gel nos. 2 and 3 proper proved to be significantly lower than the initial activity (Table 2). Probably, centrifugation was responsible for compaction of gels, which do not exhibit high mechanical strength, and

Table 2. Retention of α-galactosidase in the silica nanocomposite (10 wt %) containing different amounts of LBG

Sample no.	LBG, wt %	$U \times 10^3$, g^{-1}	$U \times 10^3$	
			in 1 ml of supernatant	in 1 g of gel
2	0.25	34.6	0.076	3.7
3	0.75	32.8	0.018	12.5

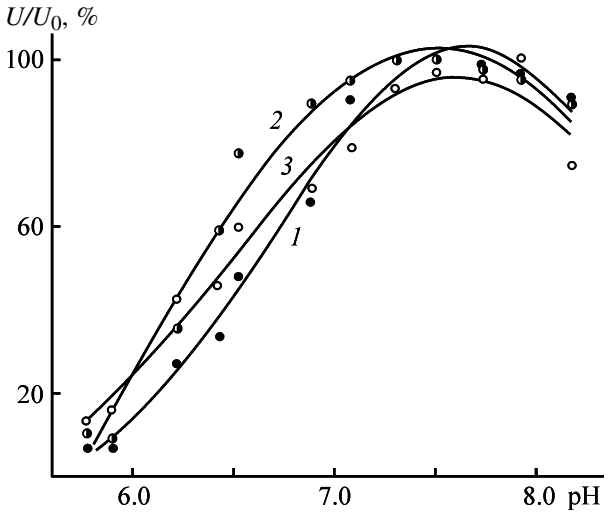

Fig. 1. pH dependence of the residual activity U of (*1*) free and (*2, 3*) immobilized α-galactosidase in gel nos. 4 (*2*) and (*3*) 5. 0.1 M sodium phosphate buffer solution.

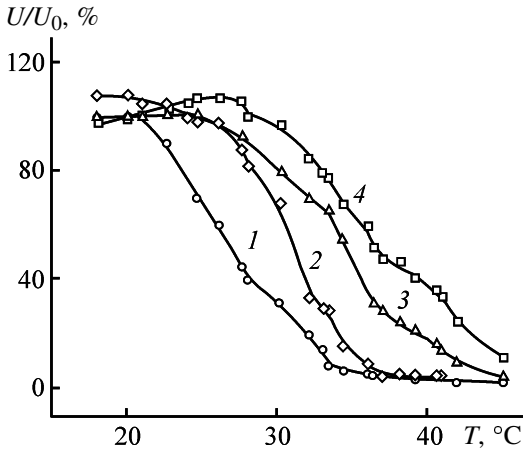

Fig. 2. Temperature dependence of the residual activity U of (*1, 2*) free and (*3, 4*) immobilized α-galactosidase in sample nos. (*3*) 4 and (*4*) 5. 0.1 M sodium phosphate buffer solution, pH 7.3. Time of keeping at the required temperature, min: (*1, 3*) 30 and (*2, 4*) 10.

this either hindered the accessibility of the enzyme for the substrate, or inactivated the enzyme immobilized. When the LBG concentration in the gel (sample no. 4) was increased, the mechanical exposure affected the enzyme activity to a significantly lesser extent.

We determined the pH corresponding to the optimal activity of immobilized α-galactosidase. To 0.05 ml of free enzyme preparation, or 0.05 g of gel, 0.25 ml of 0.1 M sodium phosphate buffer solution with pH under study and 0.1 ml of 10^{-2} M aqueous solution of the substrate were added. The activity of the enzyme was determined by the above-described procedure. The residual activity was calculated as the ratio, %, of the activity U at various pH values to that of the enzyme at optimal pH values, U_0. Figure 1 presents the pH dependences of the residual activity of the enzyme for free (curve *1*) and immobilized α-galactosidase in gels with LBG (sample no. 2) and xanthan (sample no. 3) (curves *2* and *3*, respectively). It is seen that encapsulation into a silica matrix caused the pH range to broaden to a certain extent, but left the pH corresponding to the optimal activity of the enzyme virtually unaffected.

As shown by analysis of published data, immobilization by cross-linking noticeably shifted the pH corresponding to the highest activity of α-galactosidases. For example, for enzyme isolated from *A. oryzae*, immobilized inside an alginate matrix with glutaric dialdehyde, this pH shifted to the acid region by 0.3 pH unit [6], and for α-galactosidases from *Gibberella fujikuroi* in polyacrylamide gel and from green coffee beans in dextran, by 0.4 pH unit [3, 7]. In the case of sepharose-immobilized enzyme isolated from fig, the pH corresponding to the best activity shifted by 1 pH unit [19]. These published data suggest that the properties of α-galactosidase changed more substantially in the case of immobilization by cross-linking than in the case of the sol–gel technology that we applied here.

Another problem addressed by this study is the thermal stability of α-galactosidase. Gel (0.05 g) with the enzyme immobilized was placed into a thermostat, kept at the required temperature for 10 or 30 min, and cooled to room temperature, whereupon the residual activity was estimated as described above. The control sample was subjected to analogous manipulations.

Figure 2 shows the temperature dependences of the residual activity for free (curves *1* and *2*) and immobilized α-galactosidase in gels with LBG (sample no. 3) and xanthan (sample no. 5) (curves *3* and *4*, respectively). The keeping time was 10 min (curves *2* and *4*) and 30 min (curves *1* and *3*). Analysis of these dependences showed that, after 10-min keeping, free α-galactosidase lost its activity at 37°C (curve *2*), and after 30-min keeping, at 32°C (curve *1*). Under identical conditions, the immobilized enzyme preserved from 50 to 70% of its activity (curves *3* and *4*). Major shift of curves *3* and *4* to higher temperatures relative to curves *1* and *2* suggests that encapsulation into the polysaccharide–silica gel causes the thermal stability of α-galactosidase to increase. This can be due to a stabilizing effect of the inorganic matrix, hindering temperature-induced conformational transitions of the protein molecule. This effect was observed, for example, in the case of proteins immobilized inside

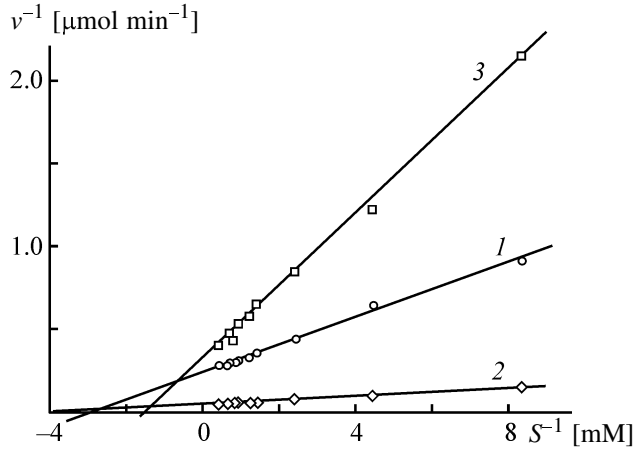

Fig. 3. Reciprocal rate of accumulation of *p*-nitrophenol v^{-1} vs. the reciprocal concentration of *p*-nitrophenyl galactoside S^{-1} for α-galactosidase (*1*) in solution and (*2*, *3*) in immobilized state in sample nos. (*2*) 2 and (*3*) 5.

silica hydrogel [20–23]. Immobilization typically increases the thermal stability of enzymes. In the majority of studies with α-galactosidase it increased by several degrees [3, 5–7, 19]. At the same time, Mitsutomi [4] reported that the thermal stability of α-galactosidase from *P. cinnabarinus*, immobilized in chitin, did not change relative to free α-galactosidase [4].

To compare the catalytic properties of free and gel-immobilized α-galactosidase, we determined the corresponding Michaelis constants K_m. We tested gels containing 0.75 wt % LBG (sample no. 2) and 0.25 wt % xanthan (sample no. 5) at 20°C in 0.1 M sodium phosphate buffer solution, pH 7.7, at a time when the free and immobilized gels still exhibited the maximal activity. The concentration of the substrate, *p*-nitrophenyl galactopyranoside, was varied from 0.12×10^{-3} to 2.49×10^{-3} M. To 0.05 ml of dilute enzyme, or to 0.05 g of gel, 0.350 ml of the buffer solution of the substrate was added. The reaction was terminated by introducing 0.6 ml of aqueous solution of 1 M sodium carbonate. The samples with the gels immobilized were centrifuged at 10000 rpm, whereupon the concentration of *p*-nitrophenol in the supernatant was determined by the above-described procedure. The K_m constant was calculated by the standard Lineweaver–Berk method.

Figure 3 presents the plots of the reciprocal enzymatic reaction rate vs. the reciprocal substrate concentration for α-galactosidase in solution (curve *1*) and in the immobilized state in gel nos. 2 (curve *2*) and 5 (curve *3*), containing LBG and xanthan, respectively. It is seen that immobilization did not substantially affect the catalytic properties of the enzyme. A minor and a twofold increase in K_m, respectively, for the enzyme in gel nos. 2 (0.42×10^{-3} M) and 5 (0.72×10^{-3} M) compared to that for free α-galactosidase (0.36×10^{-3}) can be due to hindered diffusion of the substrate and reaction products in the silica matrix pores. A similar increase in K_m was observed, e.g., for α- and β-galactosidases immobilized in polyacrylamide and alginate gels using cross-linking agents [5, 6, 15].

CONCLUSIONS

(1) α-Galactosidase was immobilized inside sol–gel derived hybrid polysaccharide–silica nanocomposites with different formulations.

(2) The catalytic activity of α-galactosidase varies with the formulation of the silica–polysaccharide matrix. The enzymatic activity tends to decrease with increasing content of the inorganic component. The activity and stability of the enzyme are also influenced by the structure of the polysaccharide and its concentration in the matrix.

(3) α-Galactosidase immobilized inside a tetrakis-(2-hydroxyethyl) orthosilicate (10 wt %) matrix containing galactomannan (0.25 and 0.75%) preserved the catalytic activity for a long time; its thermal stability increased by 10°C. The immobilized α-galactosidase exhibited the maximal activity at the same pH values as the free enzyme; the Michaelis constant K_m did not substantially change.

Abstract—The composition and structure of low-molecular-weight products of thermal oxidative degradation of atactic polypropylene were studied.

DOI: 10.1134/S1070427205030272

In this study we examine the composition and structure of low-molecular-weight products of thermal oxidative degradation (TOD) of atactic polypropylene (APP) and discuss the most probable pathways of formation of oxidized atactic polypropylene (OAPP) and low-molecular-weight by-products of TOD.

EXPERIMENTAL

The mixture of low-molecular-weight organic compounds formed by oxidation of APP melt at 180°C was separated on a silica gel column (eluents hexane and chloroform); the solvent was distilled off in a vacuum. The yield of the hexane fraction of the concentrate of low-molecular-weight compounds was 63.8, and that of the chloroform fraction, 34.4 wt %. The ^{1}H NMR spectra were recorded at 27°C on a Tesla BS 497 spectrometer (100 MHz; solvent CCl_4; reference HMDS). A shift reagent, tris(6,6,7,7,8,8,8-heptafluoro-2,2-dimethyloctane-4,6-dionato)europium(III), was used:

The measurement error did not exceed 3%.

The GC–MS analysis was performed on a Nermag R10-10C device (France). The mixture was separated on a quartz capillary column (length 30 m, internal diameter 0.32 mm) under the following conditions: stationary phase SE-54, carrier gas He, inlet carrier gas pressure 0.45 atm, vaporizer and interface temperature 250°C; column temperature schedule: 65°C, 2 min; heating to 280°C at a rate of 5 deg min^{-1}; 280°C, 60 min; sample inlet with a flow splitting ratio of 1 : 40; sample volume 1 μl; mass-selective quadrupole detector; electron impact, 70 eV; scanning range 33–330 amu; scan time 0.4 s; Wiley138 library of mass spectra; software: Technivent-1 for data collection and HP Chemstation for data processing. The relative measurement error did not exceed 5%.

The compositions and structures of low-molecular-weight condensable compounds formed by TOD of APP at 180°C furnish information on the radical mechanism of degradation and on the structure of OAPP. The IR spectrum of the low-molecular-weight compounds (Fig. 1) shows that they contain hydrocarbons and ketones with various degrees of unsaturation. In the range 3400–3200 cm^{-1}, there is a characteristic broad absorption band of stretching vibrations of hydrogen-bonded hydroxy groups (probably those of the enol form of unsaturated ketones); this is confirmed by the presence of the ⩾C–O–H band at 1125–1030 cm^{-1}. The medium-intensity band at 1720 cm^{-1} is characteristic of carbonyl stretching vibrations. It has a complex shape suggesting the presence of ketones of different structures; in particular, the shoulder at 1774 cm^{-1} may be assigned to the stretching vibrations of the carbonyl group in cyclic ketones, and the shoulder at 1700 cm^{-1} is characteristic of a >C=O group conjugated with a C=C bond. The presence of large amounts of aliphatic compounds is confirmed

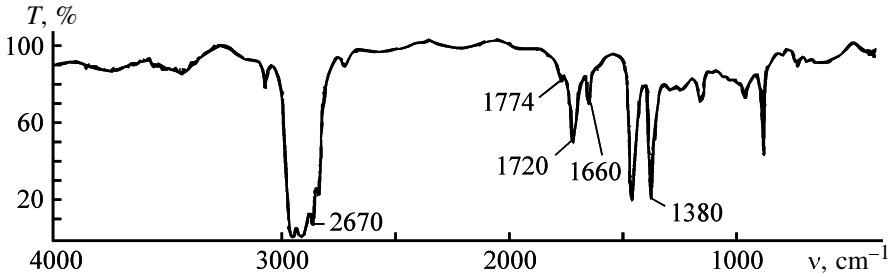

Fig. 1. IR spectrum of the low-molecular-weight products of TOD of APP. (*T*) Transmission and (ν) wave number; the same for Fig. 2.

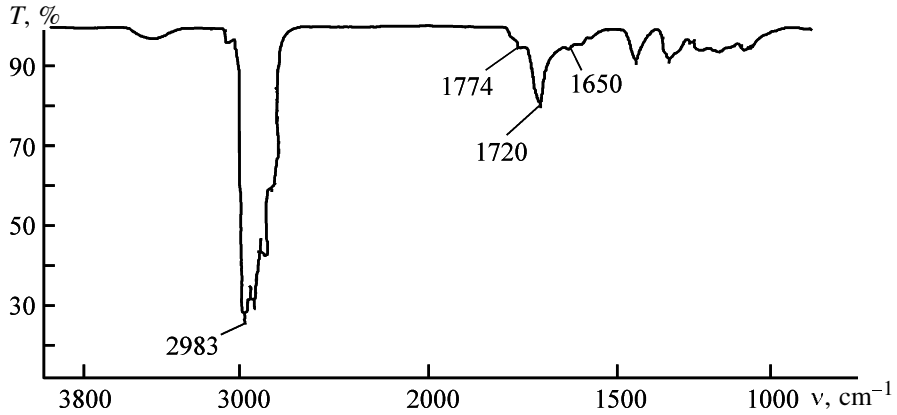

Fig. 2. IR spectrum of the chloroform fraction of the low-molecular-weight products of TOD of APP.

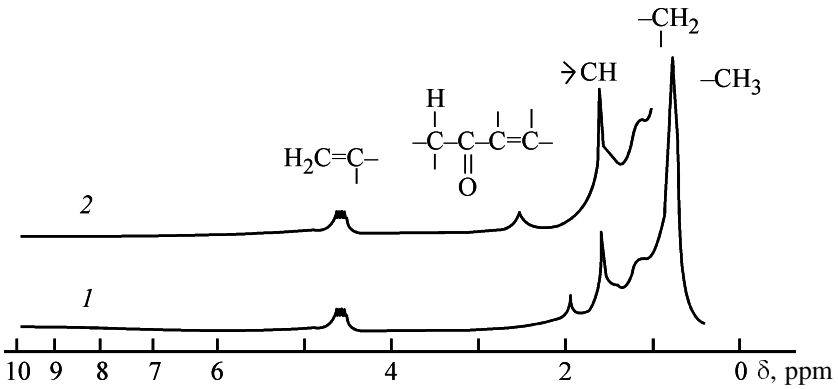

Fig. 3. ^{1}H NMR spectrum of the chloroform fraction of the low-molecular-weight products of TOD of APP. (δ) Chemical shift. (*1*) Initial spectrum and (*2*) spectrum recorded in the presence of $Eu(FOD)_3$ shift reagent.

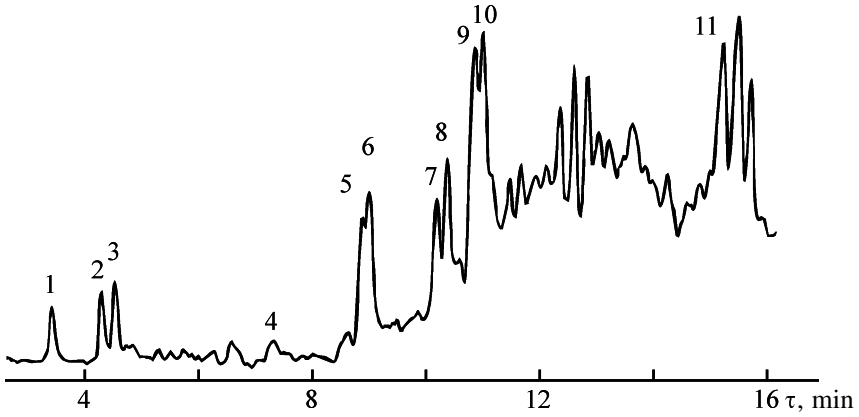
by strong bands of C–H stretching vibrations in $>CH_2$ and CH_3 groups (2900–2800 cm^{-1}), 1415–1465, 1380, and 720–723 cm^{-1}. The absorption bands at 1660–1580 cm^{-1} can be assigned to vibrations of the >C=C< bonds, possibly conjugated with the carbonyl group [1, 2]. For more detailed analysis we took the chloroform and hexane fractions obtained by separation of the starting mixture of low-molecular-weight compounds by column chromatography. The IR spectrum of the chloroform fraction containing polar compounds (Fig. 2) was indicative of the following structural features. The absorption at 3400–3200 and 1125–1030 cm^{-1} confirms the presence of the hydroxy group in the enol form of unsaturated ketones; these bands are also present in the spectra of other α,β-unsaturated ketones, e.g., of mesityl oxide. At 1720, 1660–1580, and 980–950 cm^{-1}, there are characteristic absorption bands of the carbonyl group and >C=C< bond [1, 2].

The ^{1}H NMR spectrum of the chloroform fraction (Fig. 3) contains signals from vinyl and alkyl protons. The ratio of their integral intensities is as follows: alkyl protons : protons at the α-C atom relative to carbonyl group : vinyl protons = 20 : 1 : 2. The empirical formula of the ketone is $C_{13}H_{22}O$.



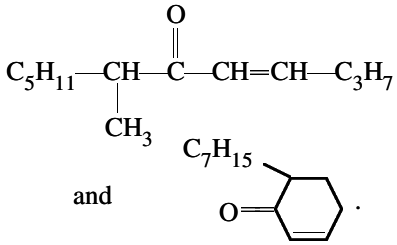


Fig. 4. Fragment of the chromatogram of the chloroform fraction of ketones. (τ) Time; the same for Fig. 5. The peak assignment is given in the text (parent compounds in the corresponding reactions); the same for Fig. 5.

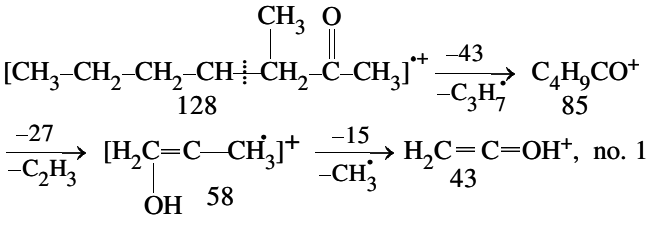
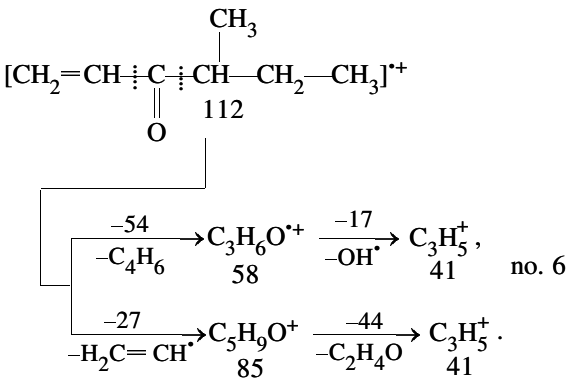
The relatively high content of vinyl protons suggests the presence of C=C bonds, possibly conjugated with a carbonyl group, e.g.,

The IR spectrum of the hexane fraction differs from that of the chloroform fraction by the absence of absorption bands of oxygen-containing groups. The absorption bands at 2900–2800 cm^{-1} belong to the stretching vibrations of the C–H bonds in $–CH_2–$ and $–CH_3$ groups; the presence of a large amount of aliphatic structures is confirmed by strong absorption at 1465–1415 and 1380 cm^{-1}; the absorption bands at 723–720 cm^{-1} are assigned to the rocking vibrations of the CH_2 groups in polymethylene chains; the bands at 1070–650 cm^{-1} are characteristic of bending vibrations of C–H and C–C bonds; the bands at 980–950, 1640, and 1660 cm^{-1} are indicative of the presence of unsaturated structures.

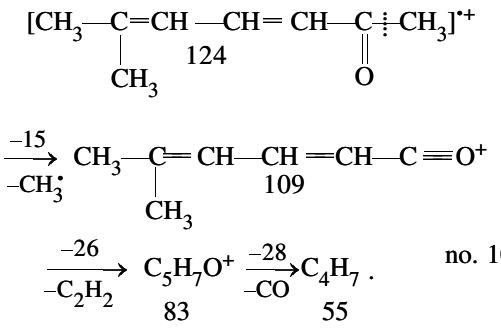


The fractions obtained were subjected to GC–MS analysis. A fragment of the chromatogram of the chloroform fraction is shown in Fig. 4. The group identification by characteristic ions showed that the chloroform fraction contained a large set of ketones, both saturated and unsaturated. The mass spectra were interpreted only for the peaks numbered in the initial part of the chromatogram, because the stability of molecular ions drastically decreases with an increase in the molecular weight and with branching. The mass spectra of the other homologous compounds in the chloroform fraction contain no molecular ion peaks, which does not allow complete elucidation of their structures. The fragment peaks confirm the presence of saturated and unsaturated ketones and of alkylcyclohexenones.



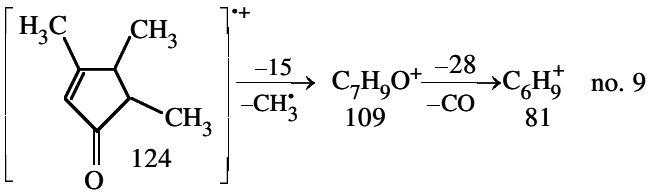
The most characteristic fragmentation pattern of molecular radical cations of ketones under electron impact involves formation of acyl ions and their subsequent decarbonylation to alkyl cations. Other fragmentation pathways of ketones involve the McLafferty rearrangement which occurs if at least one of the alkyl groups contains no less than three carbon atoms and a γ-H atom [3].

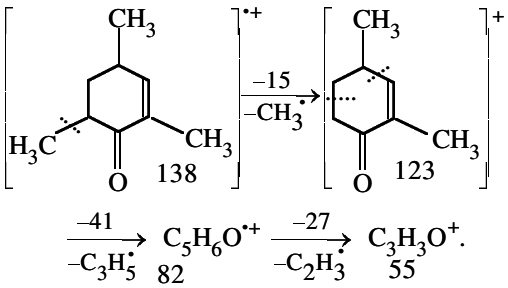
For α,β-unsaturated ketones, there are two characteristic fragmentation pathways. One of them involves the loss of the ketene molecule formed from the carbonyl group and adjacent saturated carbon atom. The formation of $R–CH_2CO^+$ ions is particularly facilitated in ketones containing alkyl substituents in the γ-position relative to the CO group. The other fragmentation pathway noted for 2-cyclohexenones involves the retro-diene cleavage competing with the previous pathway [4]. In the chloroform fraction, we identified by GC–MS the following compounds: 4-methyl-2-heptanone, 3,5-dimethyl-1-hepten-4-one, 4,6-dimethyl-4-hepten-2-one, 3,5-dimethyl-2-cyclohexen-1-one, 1-hepten-3-one, 4-methyl-1-hexen-3-one, 1-hepten-3-one, 4-methyl-1-hexen-3-one, 2,4-dimethyl-1-hexen-3-one, 2,5-dimethyl-1-hexen-3-one, 3,4,5-trimethyl-2-cyclopenten-1-one, 6-methyl-3,5-heptadien-2-one, and 2,4,6-trimethyl-2-cyclohexen-1-one.



The mass spectra of the majority of these compounds well coincide with those of the same compounds from the library. The fragmentation patterns of other isomers differ from those described above, but the main genetic evidences are preserved. For

example, the presence of a strong peak with *m/z* 58, corresponding to the rearranged radical cation $[CH_2=C(OH)–CH_3]^+$, suggests the occurrence of the McLafferty rearrangement characteristic of some aliphatic and α,β-unsaturated ketones:





Ketones that contain less than three C atoms in the carbon chain or do not contain a γ-H atom do not undergo the McLafferty rearrangement:

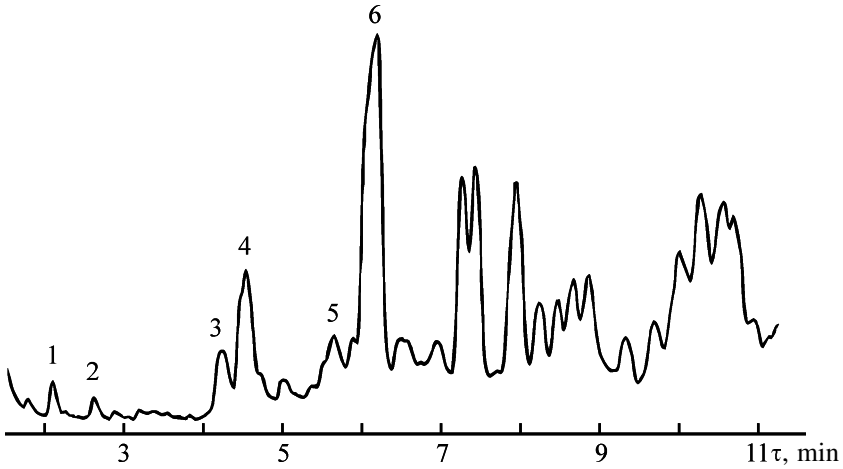
The mass spectra of cyclic unsaturated ketones differ from those of all the other ketones by the considerably smaller number of peaks, which is due to limited number of possible fragmentation pathways of the molecular ion:

The GC–MS study of the hexane fraction of the low-molecular-weight products of TOD of APP showed that this fraction contained a mixture of hydrocarbons differing from each other in the number and position of C=C bonds and in the extent of branching of the carbon skeleton.

The group identification based on the characteristic ions suggests that the compounds formed are homologs differing in the amount and position of multiple bonds and in the extent of branching of the carbon skeleton.

Thus, the hexane fraction consists of isoparaffins (with regularly repeating structural fragments) and hydrocarbons with one, two, or three double bonds. The presence of cyclic structures with double bonds in the ring (of the alkylcyclohexene type) is not improbable, but these compounds are difficult to identify reliably because of the similarity of their mass spectra to those of open-chain dienes. All the four groups of hydrocarbons (alkanes, alkenes, dienes, trienes) present in the hexane fraction of low-molecular-weight products of APP oxidation are characterized by the branched structure and high molecular weights, which severely complicates their identification. In the mass spectra of components of the hexane fraction, only one alkene with MW = 126 (2,4-dimethyl-1-heptene) contains a fairly strong peak of molecular ion (Fig. 5, peak *1*); in the mass spectra of the other hydrocarbons, the peak of the molecular ion is lacking because of its low stability. The group composition of the identified low-molecular-weight compounds is given in the table.

The structure of low-molecular-weight TOD products explains the kinetic features of the accumulation of oxygen-containing groups in TOD of APP and confirms the OAPP structure. Unsaturated ketones present among low-molecular-weight products may be of practical interest, e.g., as metal extractants. Up to now, these compounds and their properties remained poorly studied, because their purposeful synthesis was difficult. Possible pathways of reactions yielding low-molecular-weight products are of scientific interest, because they are associated with the mechanism of



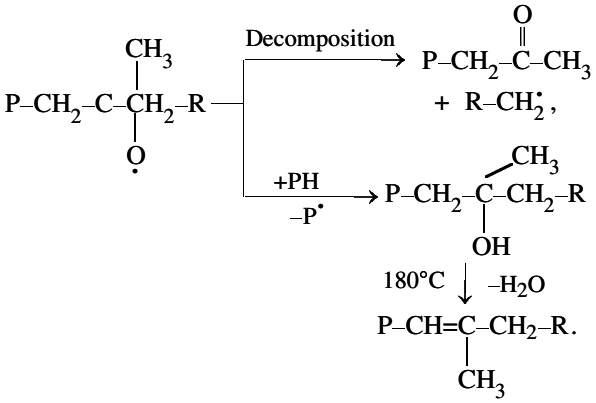


Fig. 5. Fragment of the chromatogram of the hexane fraction of low-molecular-weight APP TOD products.

TOD of APP at temperatures above 150°C:

$$PH + O_2 \xrightarrow[-{}^{\bullet}OOH]{} P^{\bullet} \xrightarrow{+O_2} POO^{\bullet} \xrightarrow[-P^{\bullet}]{+PH} POOH \rightarrow PO^{\bullet} + {}^{\bullet}OH,$$

where $P^{\bullet}$ is the radical of heterotactic polypropylene.

Tertiary alkoxyl radicals tend to decompose with the formation of primary alkyl radicals $R–CH_2^{\bullet}$ exhibiting low regioselectivity in hydrogen abstraction [5]:

$$R–\dot{C}H_2 + P–CH_2–\underset{\displaystyle CH_3}{\underset{|}{CH}}–P \xrightarrow[-R–CH_3]{} P–\dot{C}H–\underset{\displaystyle CH_3}{\underset{|}{CH}}–P$$

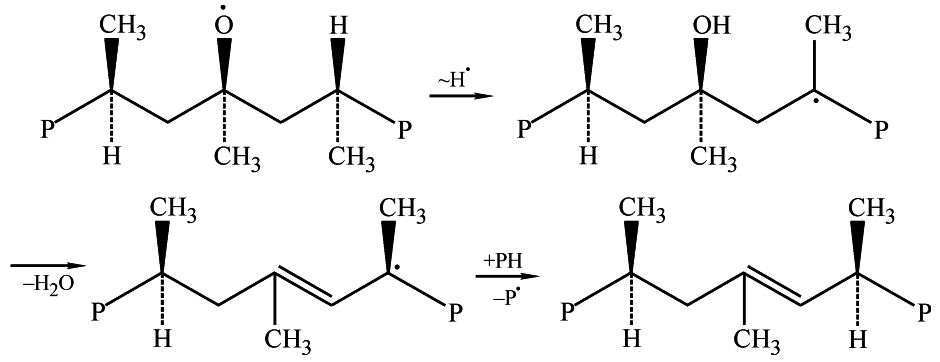
$$\xrightarrow[-\dot{O}H,\ -P^{\bullet}]{+O_2,\ +PH} P–\underset{\displaystyle OH}{\underset{|}{CH}}–\underset{\displaystyle CH_3}{\underset{|}{CH}}–P \xrightarrow[-H_2O_2]{+O_2} P–\underset{\displaystyle O}{\underset{\|}{C}}–\underset{\displaystyle CH_3}{\underset{|}{CH}}–P.$$

Secondary alkoxyl radicals are apparently oxidized to keto groups by the reaction with alkyl radicals $R^{\bullet}$:

$$P–\underset{\displaystyle O^{\bullet}}{\underset{|}{CH}}–P + R^{\bullet} \xrightarrow[-RH]{} P–\underset{\displaystyle O}{\underset{\|}{C}}–P.$$

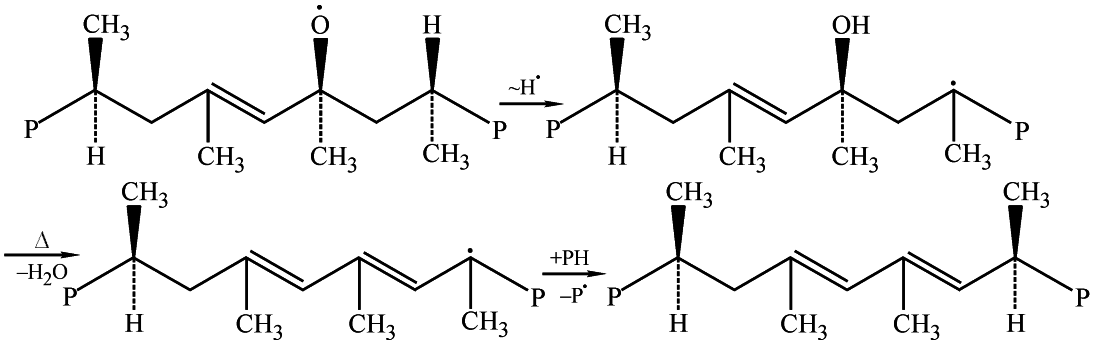
The APP chain is ruptured randomly, which accounts for the formation of homologous series of all the four types of hydrocarbons. The formation of alkenes, dienes, and trienes is characterized by the following features.

(1) The thermal oxidative degradation is controlled by the diffusion of the oxygen molecule to the reactive center; therefore, because of the low kinetic mobility of the polymeric chains, the unstable tertiary alkyl radicals can decompose:



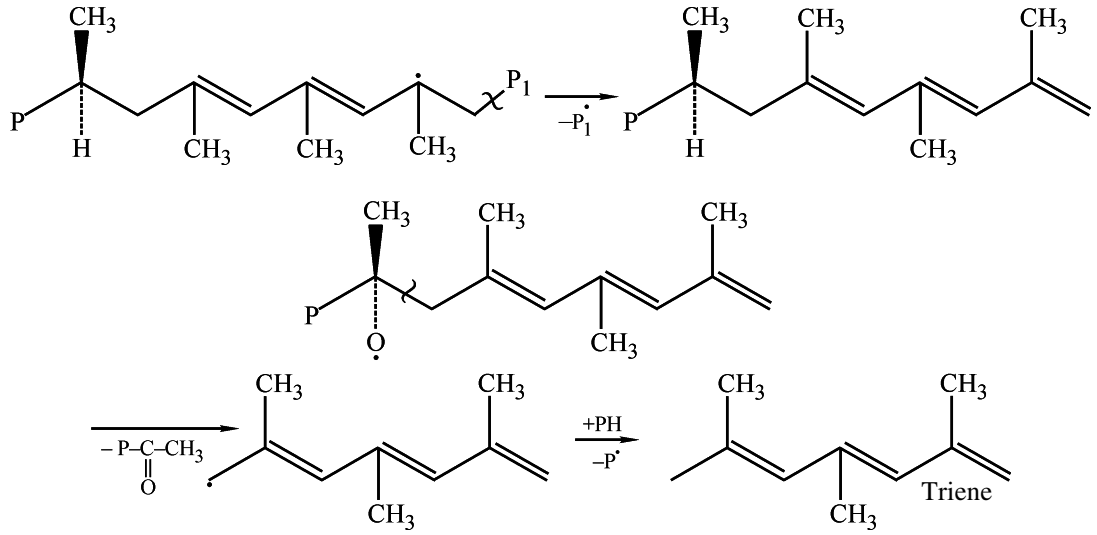
$$P–CH_2–\underset{\displaystyle CH_3}{\underset{|}{\dot{C}}}–CH_2–\vdots–P_1 \longrightarrow P–CH_2–\underset{\displaystyle CH_3}{\underset{|}{C}}=CH_2 + P_1^{\bullet},$$

where the MW of P is higher than that of P_1.



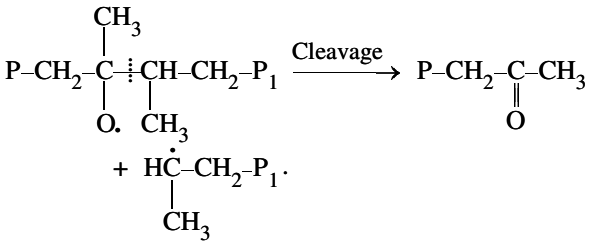
(2) The presence of dienes and trienes in the low-molecular-weight APP oxidation products suggests formation of several hydroperoxy groups in the polymer macromolecule and prevailing intramolecular abstraction of the hydrogen atom by the alkoxy radical:

Composition of the organic phase of the condensate, according to GC–MS analysis

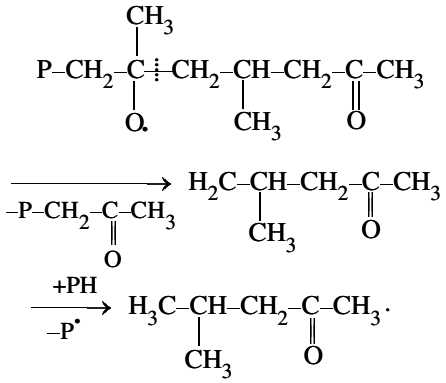


Parameter	Fraction	
	hexane	chloroform
Yield, wt %	63.75	34.40
MW range	126–238	128–286
Relative content, %:		
saturated hydrocarbons	<5.0	0.0
unsaturated hydrocarbons	88.7	13.0
unsaturated ketones of various structures	0.0	71.6
unidentified compounds	6.3	15.4

In this case, the carbon atoms undergo rehybridization, and the most stable tertiary allyl-type radical is formed; this radical can react with the oxygen molecule, with propagation of the oxidation chain [6]:

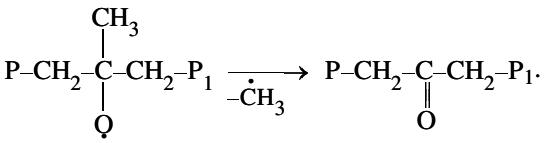


(3) Conjugated trienes are formed by the similar reaction. Low-molecular-weight alkenes and trienes are eliminated upon cleavage of tertiary alkyl and alkoxyl radicals, e.g., by the scheme



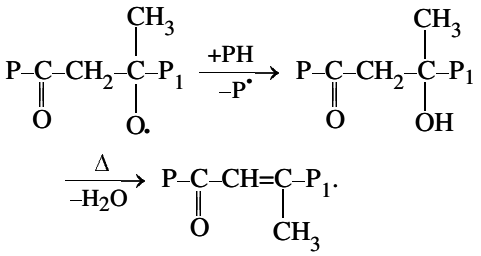
At intermolecular hydrogen abstraction by the alkoxyl radical, the forming alkyldienes and trienes should contain nonconjugated double bonds. Alkyltetraenes were not detected in the examined hexane

fraction of the low-molecular-weight products of APP oxidation.

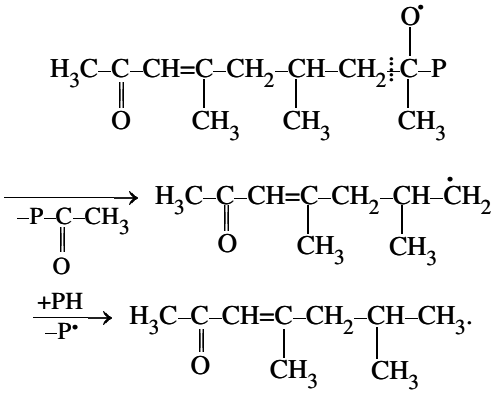


The formation and decomposition of tertiary alkoxyl radicals do not follow any regular trends, i.e., occur at the sites of an APP macromolecule that are the most accessible to reagents (hydroxy, methyl, alkyl radicals). As a result, homologous saturated ketones with different structures of alkyl chains are formed [5]. The structure of alkyl chains in ketones undoubtedly depends on the presence in APP macromolecule of units originating from anomalous tail-to-tail addition and of backbone branchings. Such sections of the macromolecular chain are particularly reactive in oxidation and degradation, e.g.,

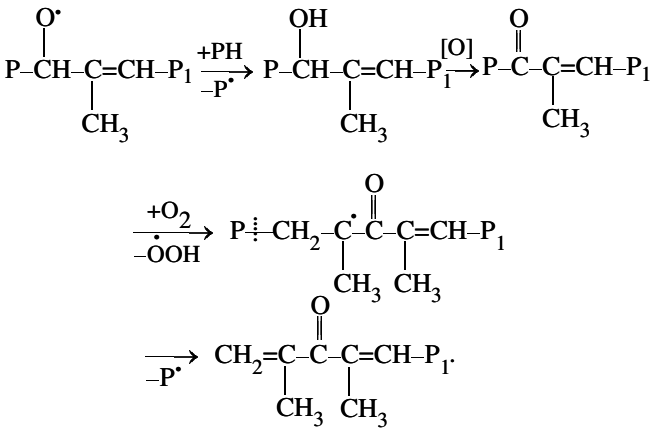
Low-molecular-weight saturated ketones are formed by successive formation and degradation of tertiary alkoxyl radicals:



In the process, alkoxyl radicals can decompose with the elimination of the methyl group, which appreciably affects the structure of the forming ketone, e.g.,

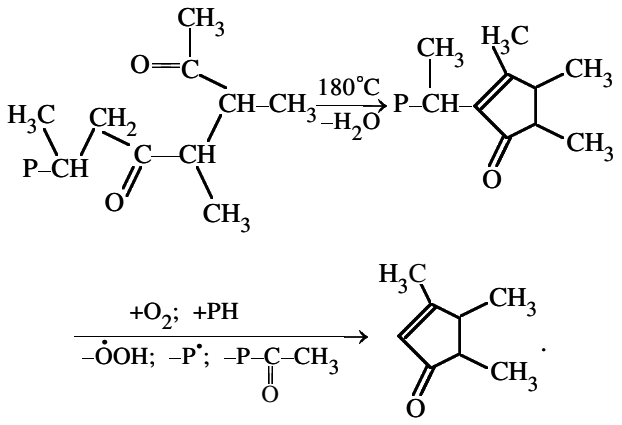


Unsaturated ketones of various structures are the major components in the mixture of condensable low-molecular-weight APP oxidation products. The majority of them are conjugated α,β-unsaturated ketones with an impurity of nonconjugated unsaturated ketones and of ketones containing two double bonds.



In the course of the APP oxidation, several reactions yielding low-molecular-weight unsaturated ketones occur simultaneously, e.g., dehydration and oxidation of hydroxy groups in the polymer and decomposition of polymeric alkoxyl radicals:

The subsequent oxidation of the polymer occurs via formation of intermediate alkoxyl radicals, which results in the elimination of unsaturated ketones:



Allyl-type radicals exhibit increased stability, which enhances the reactivity of the α-C atom adjacent to the double bond:

The identification of cyclic six- and five-membered conjugated unsaturated ketones in the mixture of low-molecular-weight APP oxidation products is rather unexpected and difficult to explain. Possible pathways of their formation involve aldol and crotonic condensation, diene synthesis, and intramolecular cyclization

of biradical products formed in the course of the oxidation. Owing to the minimal distortions of the bond angles and minimal ring strain, five- and six-membered rings and the transition states preceding their formation are energetically the most favorable among cyclic systems. Rings of this size are formed almost spontaneously if this is possible, and competing reactions are excluded in this case.

The diene synthesis can be a route to cyclic ketones only if ketene or its derivatives R–CH=C=O are used as dienophiles. Ketene and its derivatives were not detected in a mixture of low-molecular-weight ketones; their formation as reaction intermediates is also improbable, because their generation methods are rather specific. Therefore, the occurrence of the diene synthesis in the course of the APP oxidation is improbable. The intramolecular cyclization by the radical mechanism is possible in the case of formation of biradical intermediates, with simultaneous abstraction of hydrogen atoms from tertiary carbon atoms. The intramolecular cyclocondensation should involve units originating from anomalous tail-to-tail addition, which apparently affects the most energetically favorable cyclic conformation of carbon chains in oxidized APP [7]:

Six-membered alkyl-substituted cyclohexenones are formed similarly.

CONCLUSIONS

(1) Examination of the structure of low-molecular-weight by-products of thermal oxidative degradation of atactic polypropylene at 180°C showed that these products consist of unsaturated hydrocarbons and ketones of various structures.

(2) Reaction schemes describing the formation of oxidized atactic polypropylene and low-molecular-weight thermal oxidative degradation products were suggested.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Effect of Mixture Components on the Rheological Characteristics of the Composite

V. I. Chursin

Central Research Institute of Leather-Shoe Industry, Joint-Stock Company, Moscow, Russia

Received January 24, 2006

Abstract—Rheological characteristics and properties of composites prepared from tanning industry wastes were studied in relation to the ratio and composition of components in the mixture.

DOI: 10.1134/S1070427206050284

Any production involves formation of wastes whose certain fraction is recycled, whereas the other fraction is dumped, polluting the environment. Therefore, utilization of collagen-containing wastes (chrome leather chips, hide crops, etc.) formed in significant amounts in the course of the rawstock treatment is an urgent problem from both commercial and environmental viewpoints.

An alternative solution of the problem of utilizing collagen-containing wastes can be based on modern procedures developed for processing of polymeric and biopolymeric systems [1, 2]. New polymeric materials with a wide range of service properties can be prepared from compounds of various chemical nature, including wastes from the tanning industry. These materials can be most efficiently used in production of insole and support materials, especially for sports, childhood, and orthopedic footwear.

Elucidation of the relationship between the composition and structural and mechanical properties of the composites is one of the main problems in production of composite materials with required characteristics [3]. However, data on the rheological properties of mixtures for preparing composites based on the protein–polymer matrix and collagen-containing filler are scarce.

In this study we examined the elastoplastic and heat-protecting properties of composites prepared from disperse systems containing latexes, products of collagen dissolution (PCD), products of collagen hydrolysis (PCH), and polyethylene glycol oleate (PEGO) plasticizer. The following latexes were used: Lenteks A5 (acrylate–styrene), Lenteks AN7 (terpolymer of acrylate with styrene and acrylonitrile), BS-50 (butadiene–styrene), and BN3 (copolymer of acrylate with acrylonitrile). As a filler, we used chrome leather chips, wastes from shaving of the chroming half-finished product, preliminarily ground to 1.0–1.5 mm size, with water and chromium oxide contents of ≥30 and ≥3.8–4.3%, respectively. The dry residues of PCD and PCH were 2.81 and 8.57%, respectively.

The rheological properties of the mixtures were determined on a DV-II Brookfield viscometer at a shear rate of 30 s^{-1}. First, we studied the rheological properties of mixtures of the initial components. The viscosity of the protein-containing solutions is plotted in Fig. 1 vs. the content of chrome leather chips. As seen, with increasing content of the chips in the mixture its viscosity increases. The strongest increase in the viscosity of the PCH- and PCD-containing systems is observed at the chip content of 20–25 and 10–20 wt %, respectively. Probably, at these compositions fine chips are saturated with macromolecules of hydrolyzate and PCD, whereas further linear increase in the viscosity is due to the system thickening. At the viscosity of the chrome leather chips–PCD system higher than 8000 mPa s, casting of the resulting mixture to prepare the composite material is complicated by its poor distribution in the mold.

Changes in the viscosity of the chrome leather chips– PCD system also depend on the content of PCD (Fig. 2).

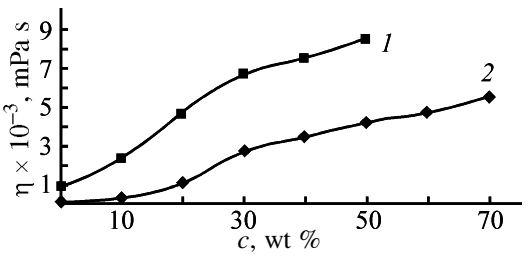

Fig. 1. Viscosity η of (*1*) PCD and (*2*) PCH systems as a function of the chip content *c*.

Table 1. Properties of composites in relation to the ratio of the initial components

Sample no.	Chips : PCD : AN7 latex ratio	Volume, cm^3	Thickness, cm	Weight, g	Specific density, g cm^{-3}	Heat conductivity, W m^{-1} deg^{-1}
1	1 : 1 : 0.1	16.06	0.3	6.8	0.42	0.059
2	1 : 1 : 0.5	23.59	0.4	11.4	0.48	0.047
3	1 : 1 : 1.3	46.07	1.0	23.2	0.50	0.168
4	1 : 0.5 : 0.1	18.28	0.3	6.4	0.35	0.079
5	1 : 0.5 : 0.2	20.90	0.4	8.2	0.39	0.086
6	1 : 0.5 : 0.5	26.12	0.4	12.0	0.42	0.104
7	1 : 0.5 : 1	37.21	0.7	16.6	0.45	0.138

For example, the viscosity strongly decreases with adding AN7 latex at a small content of PCD. This suggests that, under the given experimental conditions, the system viscosity decreases due to the plasticization of the chrome leather chips with the polymer. With increasing PCD content in the system, the dependence becomes more complex, probably due to the interaction between PCD and latex (solutions of protein and acrylonitrile polymer), and this interaction determines the viscosity of the system. First, the polymeric complexes exhibiting no plasticizing effect are formed, and, as a result, the viscosity increases. Then, due to the affinity for the chromic collagen, certain fraction of the hydrolyzate is adsorbed on the chip surface, plasticizing the system and decreasing its viscosity. The system stabilizes at a PCD : latex ratio of 1 : 1, and its viscosity decreases with further addition of the polymer. In excess PCD, the maximal viscosity is observed at the polymer content of 5 wt %.

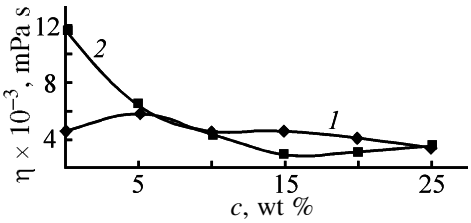

Fig. 2. Viscosity η of the system as a function of the AN7 latex content *c*. PCD content, wt %: (*1*) 12.8 and (*2*) 6.4.

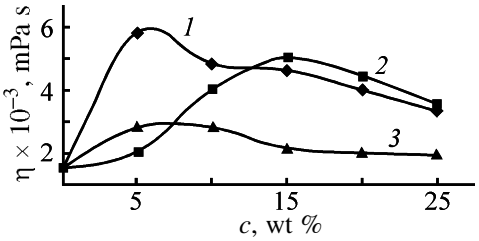

Fig. 3. Viscosity η of the system as a function of the latex content *c*. Latex: (*1*) AN7, (*2*) BN3, and (*3*) BS-50.

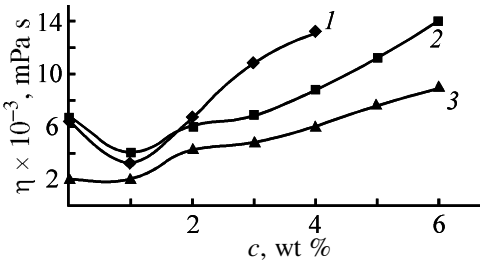

Fig. 4. Viscosity η of the system as a function of the plasticizer content *c*. PCD content, wt %: (*1*) 3.2, (*2*) 6.4, and (*3*) 12.8.

The effect of various latexes on the rheological properties of the system is illustrated in Fig. 3. In all the systems, the viscosity passes through a maximum, though at different polymer concentrations. The best structuring effect is observed for AN7 latex exhibiting the maximal viscosity of 6000 mPa s at its content in the system of 5 wt %. Slightly lower viscosities are typical of the mixtures with BN3 latex at its content of 15 wt %. BS-50 latex is efficient in the concentration range 5–10%, but the system viscosity does not exceed 3000 mPa s, i.e., it is lower by a factor of 2 as compared to the system with AN7 latex. These data suggest intermolecular interactions between the protein functional groups and polar groups of the latexes in the systems studied.

Study of the rheological characteristics of the system in the presence of PEGO (Fig. 4) showed that the viscosity of the system first decreases and then increases upon addition of the plasticizer, and the system becomes thickened. Since the viscosity range is limited, 2 wt % plasticizer content was suggested.

As seen from Table 1, sample nos. 4 and 5 have the smallest density, and sample nos. 1 and 2, the lowest heat conductivity. The use of these materials as insoles would provide the comfortable conditions of shoe wearing [4].

The elastoplastic characteristics of the resulting composites were studied on a Relaks apparatus [5]. It is known that comparison of the deformation and

Table 2. Elastoplastic properties of the composites

strength properties of the composites allows evaluation of the contribution of one or another component to formation of the structure and properties of the materials. The relaxation spectra of the composites prepared using AN7 latex with various ratios of the initial components are shown in Fig. 5. The elastoplastic characteristics of the composites are listed in Table 2. Figure 5 shows a strong effect of the latex content on the composite properties. At a small latex content, the relaxation spectra have two maxima characterizing various structural levels, which indicates that the composite structure in this case most strongly resembles natural leather. These relaxation maxima suggest formation of the developed inner surface of the composite and high porosity, which is confirmed by the data on air permeability (maximal value 36000 ml cm^{-2} h^{-1}) and density of the samples (minimal value, Table 1).

Comparison of these results with the rheological characteristics of the mixtures suggests that, to prepare composites with high molding properties, low heat conductivities, and small densities, the composition viscosity should vary within the 3000–4500 mPa s range.

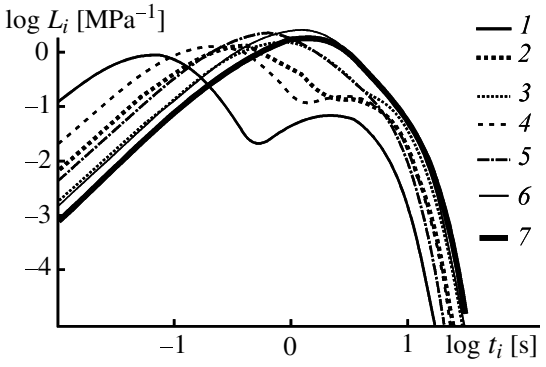

Fig. 5. Relaxation spectra of the composite samples in $\log t_i$–$\log L_i$ coordinates. (t_i) Relaxation time and (L_i) ductility. Numbers at the curves correspond to the sample nos. in Table 1.

As seen, with increasing content of AN7 latex (sample nos. 1–3), the viscosity coefficient of the rapid relaxation processes N_1 increases, and at a latex content of 25 wt %, N_1 increases by an order of magnitude. The elasticity characteristics also sharply increase. In the systems with smaller content of PCD (sample nos. 4–7), with increasing content of the latex from 6 to 25 wt %, the moduli of Hookean elasticity and hyperelasticity first decrease and then increase. As shown previously, these trends are due to the interaction of the protein and acrylonitrile polymer in solutions. The moduli of Hookean elasticity and hyperelasticity are the most informative in evaluation of the effect of the polymer content on the composite properties.

Using the rheological characteristics of the systems studied, we determined the optimal ratios of the initial components to prepare the mixtures with high moldability. Variation of the chrome leather chips : PCD : latex ratio allows control of the properties of the composite materials. The composites prepared from the tanning industry wastes show promise for the development of the modern footwear design and production of building and decorative panels with high heat-protection properties.

CONCLUSIONS

(1) Viscosity of the mixtures is determined by both the ratio of the initial components and their chemical nature. Styrene and acrylate latexes exhibit different structuring effect. The optimal viscosity of the system studied varies within 3000–4500 mPa s.

(2) The heat conductivity of the composite increases with increasing latex content in the mixture.

(3) Moduli of Hookean elasticity and hyperelasticity strongly increase and the heat-protection properties decrease with increasing latex content in the mixture over 25 wt %.

Abstract—Degradation of chitosan in solution under the action of redox radical initiators was studied with the aim to prepare chemically oligomers of natural polysaccharides. The influence of temperature on the rate and extent of the process was examined. The optimal ratios of the substrate to initiator and of the reductant to oxidant in the initiating system were determined.

DOI: 10.1134/S1070427206050296

Chitosan (β-1,4-bonded 2-deoxy-2-amino-*D*-glucopyranose) is the deacetylation product of chitin, a natural polysaccharide. Chitosan is a structural analog of cellulose; it has unique properties. In contrast to cellulose, chitosan is soluble in dilute aqueous solutions of some mineral and organic acids. Chitosan is widely used today in biology, cosmetics, paper production, and treatment of wastewater containing heavy metals [1]. The application fields of chitosan and its derivatives will expand because, firstly, chitin, which is the natural source of chitosan, is a renewable raw material. Chitin is present in crustacean processing wastes; it can also be recovered from insects (dead bees, mulberry silkworm, etc.), mushrooms, segmented worms, and mollusks [2, 3]. Secondly, chitosan is biodegradable, i.e., it can be utilized without environmental pollution. The molecular weight of chitosan recovered from various natural sources is usually in the range 10^5–10^6. A decrease in the molecular weight of chitosan to values typical of oligomers would expand its application field, because chitosan oligomers exhibit certain specific properties untypical of high-molecular-weight products [4]. Chitosan oligomers dissolve in water at neutral pH values.

To obtain a low-molecular-weight product, the starting chitosan is subjected either to chemical hydrolysis or to enzymatic degradation [5–8]. However, the enzymatic degradation requires thorough purification of the raw material to remove impurities that diminish the activity of enzymes (in particular, calcium) and of the final product to remove the enzymes. Chemical hydrolysis is most frequently performed with aqueous solutions of hydrogen peroxide of various concentrations. Other reagents such as potassium persulfate [8] or ozone [5] are also used; however, in this case the purification of the oligochitosan obtained may be labor-consuming. Hydrogen peroxide seems to be preferable as degradation agent, because products of its decomposition are nontoxic and excess reagent can be readily removed from the reaction medium. However, low-molecular-weight chitosan and its oligomers are prepared with these reagents, as a rule, at elevated temperatures (50–70°C). Under these conditions, the chemical composition of the polysaccharide may change. In particular, Galiaskarova [5] observed deamination of chitosan and oxidation of hydroxy groups to carboxy groups. At lower temperatures and reagent concentrations, water-soluble chitosan is not formed.

Hsu et al. [8] proved the radical mechanism of the chemical degradation of chitosan chains under the action of reagents capable of radical generation under various conditions. The radical mechanism of the degradation in the presence of free radical initiators suggests the suitability of redox initiators. Such initiators allow the reactions to be performed at lower temperatures; the probability of undesirable transformations of chitosan functional groups can be thus decreased. It is known [9] that the hydrogen peroxide–ascorbic acid redox system efficiently initiates reactions performed at room or even lower temperature.

The goal of this study was the preparation of chitosan oligomers at low temperatures by the degradation of chitosan under the action of the hydrogen peroxide–ascorbic acid redox system. The choice of ascorbic

acid is governed by its efficiency as reductant [9] and by the nontoxicity of ascorbic acid and its oxidation products [10].

EXPERIMENTAL

Chitosan samples with M 8.0×10^4 and 9.6×10^4 (Sonat, Moscow) were used without additional purification (degree of deacetylation 82%, weight fraction of insoluble substances 0.25%, weight fraction of dry residue after calcination 0.3%). Ascorbic acid was of chemically pure grade, and hydrogen peroxide (30% aqueous solution), of analytically pure grade; 0.1 N HCl solution was prepared from the titrimetric standard. The solvent was prepared using chemically pure grade glacial acetic acid.

The molecular weight of samples of chitosan and its oligomers was determined viscometrically with an Ubbelohde viscometer at 21°C in an aqueous solution containing 0.33 M acetic acid and 0.3 M NaCl. The viscosity-average molecular weight was calculated by the Mark–Houwink equation $[\eta] = k\overline{M}_\eta^\alpha$, $k = 3.41 \times 10^{-5}$, $\alpha = 1.01$ [11].

The degree of deacetylation of chitosan was determined by potentiometric titration of its solutions in 0.1 N HCl with a 0.1 N solution of KOH, using an EV-74 pH meter.

The initial concentration of the hydrogen peroxide solution was determined by volumetric titration with a potassium permanganate solution in the presence of sulfuric acid [12].

To perform the chitosan degradation under the action of the redox system, we added the required weighed portion of ascorbic acid to a chitosan solution of the required concentration. After the acid dissolved, the required amount of a hydrogen peroxide solution in distilled water was added. The reaction progress was monitored by measuring the viscosity of chitosan solutions with an Ubbelohde (for dilute solutions) or Hoeppler (for moderately concentrated solutions) viscometer. The total extent of degradation was evaluated from the change in the molecular weight of chitosan after performing the reaction for 24 h.

The chemical composition of chitosan was determined by Fourier IR spectroscopy, potentiometric titration, and analysis for nitrogen (Kjeldahl method).

In this study we examined the performance of redox systems in the degradation of the chitosan backbone in solutions with pH 4.5–5.5 and the influence of the temperature and component ratio on the rate and extent of the process.

Figure 1 shows how the viscosity of chitosan solutions of different concentrations varies with time in the presence of the hydrogen peroxide–ascorbic acid redox system. The relative and dynamic viscosities of solutions (Fig. 1) and the molecular weight of chitosan (Fig. 2) sharply decrease in the first 10 min; within 15–20 min, the curves flatten out. Thus, the chosen redox system efficiently breaks the chitosan chains. Measurements of the molecular weight of chitosan as a function of the reaction time (a typical curve is shown in Fig. 2) demonstrate that the kinetic curves for the viscosity and molecular weight fully correlate

with each other, i.e., a decrease in the solution viscosity is due to a decrease in the molecular weight of the starting chitosan.

The nitrogen content in the initial and final products, determined by the Kjeldahl method, is the same (8%), which shows that the reaction does not involve chitosan amino groups. This conclusion is also confirmed by the titration results. The degree of deacetylation was 82% for all the samples.

The Fourier IR spectra of chitosan before and after the reaction are somewhat different. A new band at 1667 cm^{-1}, assigned to the stretching vibrations of the ketone carbonyl group, appears in the absorption spectrum of the low-molecular-weight product.

To determine how the extent of the decrease in the molecular weight of chitosan depends on the ratio of the redox system components, we varied the amount of ascorbic acid relative to hydrogen peroxide at a fixed ratio of the other components. Figure 2 shows that it is most appropriate to take the redox system components in an equimolar ratio. Excess ascorbic acid relative to hydrogen peroxide does not cause further changes in the molecular weight of chitosan relative to the equimolar ratio. Thus, in our further experiments we chose the equimolar ratio of H_2O_2 to ascorbic acid as the optimum.

There is also a certain limiting ratio between the substrate and initiating system (with equimolar ratio of the components) (Fig. 4). It could be expected that the degree of polymerization of chitosan would gradually decrease with an increase in the amount of hydrogen peroxide per chitosan molecule in solution; however, this is not the case. Figure 4 shows that there is a saturation plateau whose onset corresponds to approximately 0.1 mol of hydrogen peroxide per mole of the glucosamine units. Further addition of hydrogen peroxide (and, correspondingly, ascorbic acid) is virtually inefficient. Theoretically, this amount of H_2O_2 should lead to the formation of an oligomer with the degree of polymerization of 10–11. The calculated curve (Fig. 4, curve *2*) shows that actually the efficiency of utilization of hydrogen peroxide as a source of radicals breaking the chitosan backbones is appreciably less than unity (about 50%), i.e., H_2O_2 is also consumed in side reactions.

The decreased efficiency of radical initiation was also observed by Hsu et al. [8], who performed radical degradation of chitosan under the action of potassium persulfate. They considered as one of the possible reasons the deactivation of the generated free radicals in their reaction with the carbonyl groups of the arising terminal units of the oligomer. Hsu et al. believe that this reaction is responsible for the rapid reaction completion (within 1 h), compared to the half-life of the initiator at the reaction temperature (20.9 h).

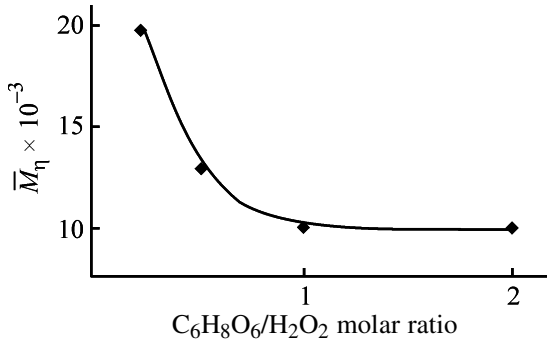

Fig. 3. Molecular weight of chitosan $\overline{M}_\eta$ measured 24 h after adding the redox system as a function of the molar ratio of ascorbic acid to hydrogen peroxide. Concentrations, wt %: chitosan 3 and acetic acid 2; molar ratio chitosan : H_2O_2 10; 21°C.

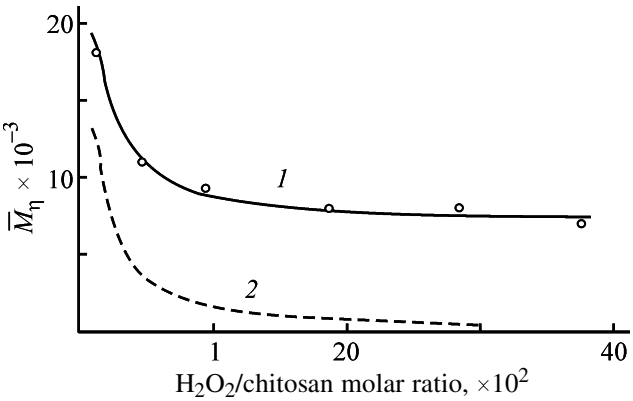

Fig. 4. Molecular weight of chitosan $\overline{M}_\eta$ measured 24 h after adding the redox system as a function of the molar ratio of hydrogen peroxide to chitosan. Concentrations, wt %: chitosan 3 and acetic acid 2; molar ratio H_2O_2 : ascorbic acid 1; 21°C. (*1*) Experimental curve and (*2*) theoretical dependence.

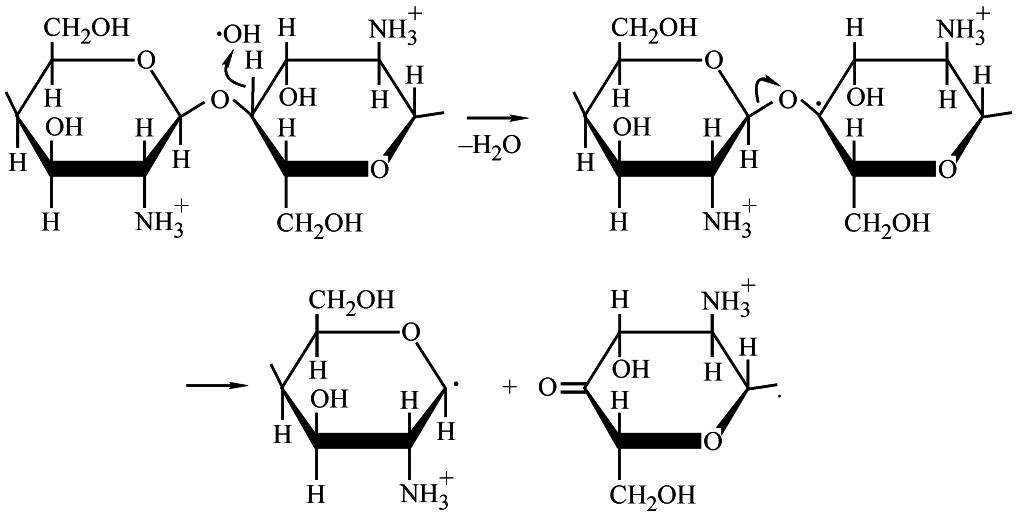
Presumably, under the conditions of radical degradation in the presence of redox system, the degradation reactions yielding low-molecular-weight chitosan compete with other reactions involving free radicals. In particular, radicals can decay in the reactions with ascorbic acid [9]. In this case, an increase in the ascorbic acid concentration at a constant substrate concentration may increase the relative rate of reactions leading to the decay of radicals. Furthermore, low-molecular-weight chains also participate in the decay of radicals. We suggest the following reaction scheme.



Generation of radicals by the reaction of hydrogen

peroxide with ascorbic acid (AAH_2 is ascorbic acid and AA, dehydroascorbic acid):

$$AAH_2 \rightleftarrows AAH^{\bullet} + H_2O + OH^{\bullet},$$

$$AAH^{\bullet} + H_2O_2 \rightarrow AA + H_2O + OH^{\bullet}.$$

Cleavage of the chitosan backbone with the formation of low-molecular-weight products:

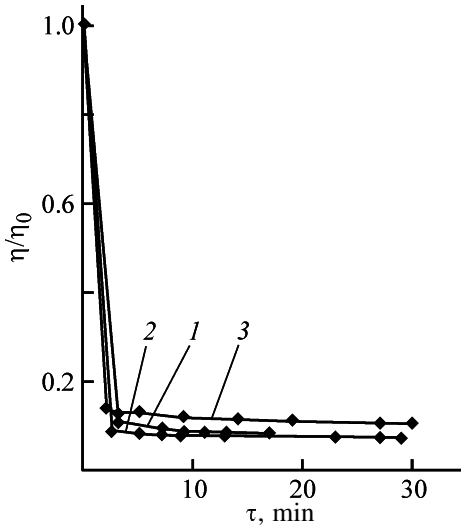
Deactivation of radicals:

$$AA^{-} + OH^{\bullet} \rightarrow AA + OH^{-},$$

$$AAH^{\bullet} + OH^{\bullet} \rightarrow AA + H_2O,$$

$$OH^{\bullet} + AAH^{-} \rightarrow AAH^{\bullet} + OH^{-},$$

$$OH^{\bullet} + AAH_2 \rightarrow AAH^{\bullet} + H_2O,$$



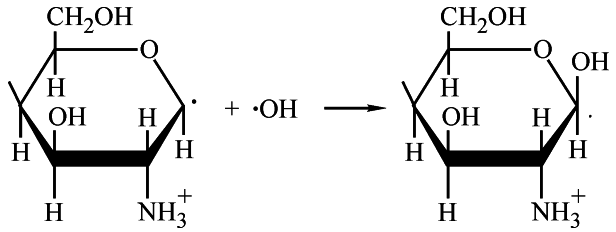


Fig. 5. Variation of the viscosity η/η_0 of chitosan solutions with time τ at (*1*) 24, (*2*) 40, and (*3*) 60°C. Concentrations in solution, wt %: chitosan 2 and acetic acid 1.5; molar ratios: chitosan : H_2O_2 40 and H_2O_2 : ascorbic acid 2.

The rate of the latter reaction should sharply increase as the low-molecular-weight chitosan is accumulated in the reaction mixture with an increase in the concentration of the initiating system.

The influence of temperature on the degradation of chitosan chains was examined by comparing the initial reaction rates and molecular weights of products in the range 0–60°C. We found that raising the temperature only slightly affects the rate at which the viscosity of chitosan solutions decreases (Fig. 5). Such a behavior is consistent with the general concept that processes occurring by the redox mechanism have a low activation energy. The activation energy calculated from data in Fig. 5 is 5 kJ.

The molecular weight of chitosan after the degradation at 0°C was 8.5×10^3, against 9.5×10^3 at 21°C and equal other conditions.

CONCLUSIONS

(1) Chitosan with a degree of polymerization of 10–40 can be prepared by low-temperature chemical

degradation of high-molecular-weight natural chitosan using the hydrogen peroxide–ascorbic acid redox system.

(2) It is the most appropriate to perform the process at molar ratios H_2O_2 : substrate 0.1 and H_2O_2 : ascorbic acid 1 : 1.

(3) The chitosan degradation rate weakly depends on temperature (activation energy 5 kJ).

BRIEF COMMUNICATIONS

Extraction Recovery of Vanadium(V) from Sulfuric Acid Solutions

L. D. Kurbatova and D. I. Kurbatov

Institute of Solid State Chemistry, Ural Division, Russian Academy of Sciences, Yekaterinburg, Russia

Received December 21, 2005

Abstract—The IR and electronic absorption spectra of di-2-ethylhexyl hydrogen phosphate (HDEHP) extracts of vanadium(V) and sulfuric acid and of vanadium(V) solutions in sulfuric acid were studied. The composition of the extractable complex was determined, and the equation of vanadium(V) extraction with HDEHP was suggested. The equilibrium constant of vanadium(V) extraction from concentrated sulfuric acid solutions was found.

DOI: 10.1134/S1070427206050302

Vanadium is a polyvalent element forming a variety of ionic species; it is susceptible to hydrolysis, polymerization, and reduction. Therefore, search for new efficient methods of its recovery is an urgent problem. This particularly concerns vanadium extraction recovery from sulfuric acid solutions, which are widely used in vanadium analytical chemistry and technology, because in sulfuric acid solutions vanadium(V) is not reduced and HDEHP does not noticeably extract sulfuric acid [1].

We showed previously [2] that HDEHP can effectively recover vanadium(V) from weakly acidic solutions. In this study we examined vanadium(V) extraction from concentrated sulfuric acid solutions.

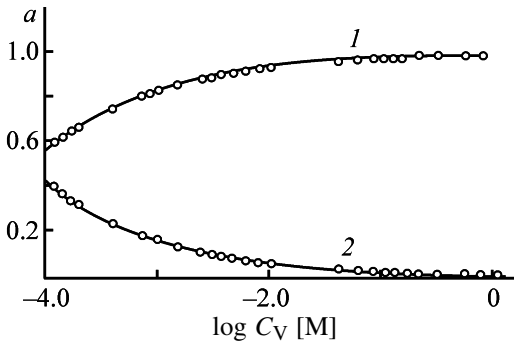
EXPERIMENTAL

Vanadium(V) extraction and spectroscopic measurements were performed at 25 ± 0.5°C. HDEHP was preliminarily purified to remove an impurity of 2-ethylhexyl dihydrogen phosphate. Vanadium(V) was extracted with neat HDEHP at the ratio of the organic to aqueous phases $V_o : V_{aq} = 1$ and repeated phase contact (~4 min). Vanadium(V) solutions were prepared from chemically pure grade sodium metavanadate. Vanadium(V) concentration in aqueous solutions was determined by atomic absorption spectroscopy and titration [3]. The vanadium content in the organic phase was calculated as the difference of the concentrations in the aqueous phase before and after extraction. The IR spectra were recorded on a Specord 75IR spectrometer within the 400–4000 cm^{-1} range. KRS-6 optical windows were used.

In the IR spectra of the vanadium(V) extracts with HDEHP, the ν(P–OH) band, observed in the spectrum of the HDEHP extract of sulfuric acid at 1680 cm^{-1}, shifts to 1630 cm^{-1}. The components at 2260 and 2660 cm^{-1} of the ν(P–OH) band are absent. This pattern shows that deprotonated P–OH groups coordinate to V(V) [4]. Probably, protons of the extractant are substituted by vanadium(V) cations existing in the concentrated sulfuric acid solutions [5]. In addition, the spectra of the vanadium(V) extracts with HDEHP from concentrated sulfuric acid solutions contain the bands at 1070 and 1170 cm^{-1} assigned to ν_s(POO) and ν_{as}(POO), respectively [4]. The shift of the ν_{as}(POO) band to lower frequencies in the spectrum of the V(V) extract relative to the sulfuric acid extract shows that POO groups participate in coordination to vanadium(V). In accordance with published data [6], the extractable vanadium(V) complex with HDEHP is characterized by γ coordination, because $\Delta = \nu_{as}(POO) - \nu_s(POO) = 1170 - 1070 = 100$ cm^{-1}.

The other types of coordination, α, β, and γ', are characterized by higher ν_s(POO) 1085–1100 cm^{-1}, and δ coordination, by large Δ and lower ν_s(POO), <1070 cm^{-1} [6].

The comparison of the IR spectra of the vanadium(V) extract with HDEHP and vanadium(V) solution in 12 M sulfuric acid allowed identification of the vanadium(V) extractable complex. It was shown in [5] that in concentrated sulfuric acid solutions vanadium(V) exists as a dimeric oxovanadium(V) cation. Compensation of sulfuric acid absorption reveals bands at 988 and 750 cm^{-1} (shoulder) in the IR spec-



trum of vanadium(V) in sulfuric acid (12 M). In the spectrum of the HDEHP extract, we found a 970, 990 cm^{-1} doublet, which transforms into a strong band at 985 cm^{-1} after compensation of the HDEHP absorption. By the analogy with [7], we assigned this band to ν_1 of the dimeric oxovanadium(V) cation. The band at 750 cm^{-1} was not revealed, since it is probably obscured by the strong HDEHP band. All these facts show that HDEHP recovers vanadium(V) from sulfuric acid solutions as a complex of dimeric vanadium(V) oxocation. To determine the composition of the extractable complex, we studied the reaction of vanadium(V) with HDEHP by the molar ratio method, which showed that the stoichiometry of the vanadium(V) reaction with HDEHP, $V_{aq} : R_o$, is 1 : 2. In the spectrum of the complex formed, the band of sulfate anion splits into two bands at 570 and 600 cm^{-1} (shoulder), suggesting sulfate coordination to vanadium(V) [8]. The presence of the band at 3450 cm^{-1} in the IR spectrum of the extract shows that the vanadium extractable complex contains water molecules [8]. All these facts suggest the following composition of the extractable complex: $V_2O_3(H_2O)_{6-n}(HSO_4)_n \cdot (HR_2)_2$. Formation of the mixed-ligand complex of dimeric oxovanadium(V) with anions of sulfuric acid and HDEHP is confirmed by the electronic spectrum of the vanadium(V) extract, in which the band at 29000 cm^{-1} is shifted to lower frequencies [5]. Thus, vanadium(V) extraction with HDEHP can be described by the following equation:

$$V_2O_3(H_2O)_{8-n}(HSO_4)_n^{(4-n)+} + 2H_2R_2 \rightleftarrows V_2O_3(H_2O)_{6-n}(HSO_4)_n(HR_2)_2^{(2-n)+} + H_3O^+. \quad (1)$$

The equilibrium constant of this reaction was determined with regard to the composition of the extractable complex and vanadium(V) ionic state in 12 M H_2SO_4. Preliminarily, we found the optimal conditions of the extraction and the lower limit of the vanadium(V) concentration at which the extraction with HDEHP is still detectable. For this purpose, we studied the formation of the complex of the dimeric vanadium(V) oxocation in 12 M H_2SO_4 by electronic absorption spectroscopy. We found previously that at $C_{H_2SO_4} \geq 9.0$ M vanadium(V) transforms into a complex of dimeric oxovanadium in accordance with the equation

$$2VO_2(H_2O)_4^+ + 3H_3O^+ \rightleftarrows V_2O_3(H_2O)_8^{4+} + 3H_2O. \quad (2)$$

The following equilibrium constant of vanadium(V) dimerization in 12 M H_2SO_4 was found at three wavenumbers, 30000, 26000, and 23000 cm^{-1}:

Relative content α of vanadium(V) complexes in 12 M sulfuric acid. (C_V) Vanadium concentration. (*1*) $V_2O_3(H_2O)_8^{4+}$ and (*2*) $VO_2(H_2O)_4^+$.

$K = (1.57 \pm 0.01) \times 10^4$ l mol^{-1}. The optical densities of vanadium(V) solutions in sulfuric acid, calculated with this K, reasonably agree with the experimental values.

The figure shows the fractions of the monomeric and dimeric vanadium(V) species in 12 M H_2SO_4 as functions of the vanadium concentration. As seen, the higher the vanadium(V) concentration, the higher is the concentration of the dimer. At vanadium(V) concentration of 1×10^{-4} M, ~60% of vanadium is bound in a dimer, whereas at $C_V \geq 1 \times 10^{-3}$ M, the dimer fraction exceeds 80%.

To determine the equilibrium constant of extraction reaction (1) at $C_{H_2SO_4}$ 12 M, we used a series of vanadium(V) solutions with concentrations from 1×10^{-3} to 5×10^{-3} M. We determined the equilibrium concentration of the complex of dimeric oxovanadium(V) $V_2O_3(H_2O)_{8-n}(HSO_4)_n^{(2-n)+}$ using the above equilibrium constant of vanadium(V) dimerization in 12 M H_2SO_4.

The extraction constant calculated assuming $\alpha = 0.95$ is independent of the V concentration in the examined range and equal to $(2.51 \pm 0.03) \times 10^{-1}$, which confirms the adequacy of the suggested scheme of vanadium(V) extraction with HDEHP from concentrated sulfuric acid.

The constant obtained is consistent with the constants of vanadium(IV) extraction with HDEHP from perchloric and sulfuric acid solutions [9, 10], which also occurs by the cation-exchange mechanism.

CONCLUSION

A study of the IR and electronic spectra of vanadium(V) extracts showed that extraction of vanadium(V) with HDEHP from concentrated sulfuric acid

solutions (12 M) occurs by the cation-exchange mechanism. The composition of the extractable complex was determined, and an equation of the extraction reaction was suggested. The equilibrium constant of vanadium(V) extraction was determined.

Abstract—A procedure was developed for preparing weakly acidic cation exchanger from polypropylene fiber wastes by grafting of acrylic acid to the preoxidized surface of the fiber in an aqueous solution.

DOI: 10.1134/S1070427206050314

Polypropylene (PP) articles find wide application owing to their good consumer properties, low cost of the monomer, and minimal consumption of the polymer per unit of the product. Approximately 30% of the produced PP is processed into the fiber. The annual demand of the Russian market for woven polypropylene fiber bags is 1.5 billion pieces [1]. Therefore, utilization of PP waste becomes an urgent problem. PP fiber can be used for preparing ion-exchange fibrous materials [2, 3]. One of the procedures for preparing fibrous polyolefin ion exchangers is grafting of macromolecular electrolytes (e.g., polyacrylic acid) to the fiber surface. This process is performed, as a rule, in organic solvent in the presence of radical initiators [3]. It involves expensive and power- and labor-consuming step of solvent regeneration and results in pollution of the environment with vapors of organic solvents. Therefore, development of a procedure for preparing weakly acidic anion exchanger by oxidation of PP fiber waste and grafting of acrylic acid to the oxidized surface in aqueous solution is an urgent problem.

EXPERIMENTAL

In this study we used PP fiber waste. To graft acrylic acid to the fiber surface, reactive surface centers capable of initiating growth of grafted macromolecules should be produced [4]. The surface of PP fiber was preactivated by initiated oxidation to form hydroperoxy (HP) groups. Thermolysis of these groups yields surface free radicals which initiate growth of the grafted macromolecules.

Novoselova [5] studied oxidation of PP fiber with atmospheric oxygen in toluene in the presence and in the absence of radical initiators at 120°C for 0.5–180 h. A procedure was developed for oxidizing PP wastes with atmospheric oxygen in aqueous solutions in the presence of H_2O_2/Fe^{2+} initiating system.

The IR spectra of oxidized PP waste contain the C–O stretching band at 1160 and the OH stretching bands at 3300–3500 cm^{-1}. Thus, the IR data and the results of iodometric titration confirm the presence of HP groups in the macromolecules.

As seen from Table 1, the material with the maximal content of the HP groups [3.3×10^{-4} mol (0.1 g of PP)$^{-1}$] was prepared by oxidation at 80–85°C for 13 h in the presence of 2.7 M H_2O_2.

The content of the HP groups does not increase in the course of longer oxidation. The hydroxyperoxy groups of oxidized PP are fairly stable. When the material is stored at room temperature or in the cold for 7 days, the concentration of HP groups decreases by 30 and 10%, respectively.

The degradation rate of a polymerization initiator at the reaction temperature is characterized by its half-life [6]. The half-life of HP groups determined from the kinetic curve of their thermolysis at 80°C (see figure) is $\tau_{1/2}$ 102 min. The half-life of HP in oxidized PP is comparable with that of the well-known radical initiator (at indicated temperature).

The ionic monomer grafted to the surface was acrylic acid (AA). The acid was grafted to oxidized PP fiber with the HP content of 2.70×10^{-4} mol (0.1 g of PP)$^{-1}$. The grafting was performed in an aqueous

Table 1. Oxidation conditions of PP

T, °C	AA concentration, %	*t*, h	Concentration, M		SEC, mg-equiv g^{-1}
			$[FeSO_4 \cdot 7H_2O]$	$[H_2O_2]$	
80	20	5.5	–	–	1.6
80	20	5.0	1.0×10^{-4}	6.7×10^{-2}	3.4
85–87	20	7.0	1.0×10^{-4}	2.2×10^{-3}	1.7
85–95	20	6.0	1.0×10^{-4}	1.7×10^{-2}	3.1
80–85	20	13.5	1.0×10^{-4}	–	2.9
75–80	20	7.0	9.0×10^{-4}	9.0×10^{-3}	2.3
70–75	20	12.0	2.7×10^{-4}	–	1.3

* For comparison: the SEC of commercial weakly acidic ion-exchange fiber KN-2 is 4.5–6.0 mg-equiv g^{-1}.

solution under inert atmosphere both in the absence and in the presence of a water-soluble initiator, hydrogen peroxide. An iron(II) salt was added to prevent formation of homopolymer of polyacrylic acid (PAA) [4]. The resulting material was thoroughly washed with distilled water to remove the homopolymer and dried. To recover PAA homopolymer, the wash waters were evaporated.

Concentration of HP groups in oxidized PP at 353 K as a function of time *t*.

The content of grafted PAA was determined by the weight gain ΔP of the grafted fiber

$$\Delta P = \frac{m_1 - m_0}{m_0} \times 100,$$

where m_0 and m_1 are the sample weight before and after grafting. The grafting degree ΔP of the samples ranged from 10 to 45%.

The presence of carboxy groups in PP samples with grafted PAA was confirmed by IR spectroscopy. The IR spectra of the samples contain the band of carboxy group at 1700 cm^{-1} and broad bands of OH groups in the range 3000–3400 cm^{-1}. The static exchange capacity (SEC) of the samples was determined in accordance with GOST (State Standard) 20255.1–89.

The conditions of grafting of AA to oxidized PP fiber and the exchange capacity of the resulting samples are summarized in Table 2. As seen from Table 2, SEC of the ion-exchange fibers prepared by grafting of AA to the surface of oxidized PP fiber is not higher

than 2.9 mg-equiv g^{-1}. The samples prepared in the presence of hydrogen peroxide initiator have the highest exchange capacity (3.4 mg-equiv g^{-1}). Probably, in this case the grafting becomes more efficient: the monomer is grafted owing to both degradation of HP and the chain-transfer reactions.

CONCLUSIONS

(1) Weakly acidic cation exchanger was prepared by grafting of acrylic acid in an aqueous solution in the presence of H_2O_2/Fe^{2+} initiating system to the surface of PP fiber waste preoxidized with atmospheric oxygen.

(2) This procedure has the following advantages: It allows utilization of polypropylene waste, thus decreasing the environment pollution with solid organic waste; hazardous, toxic, and expensive organic solvents and radical initiators are not used; the resulting material has the fibrous structure.

(3) The suggested process is virtually waste-free.

Abstract—The ternary system cyclohexane–*n*-hexadecane–*n*-docosane was studied by low-temperature differential thermal analysis.

DOI: 10.1134/S1070427206050326

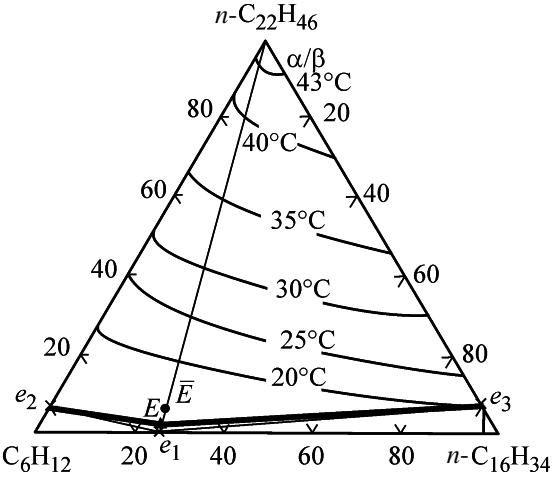
Systems based on paraffin hydrocarbons are of interest for petroleum chemistry and oil refining. These hydrocarbons are characterized by chemical inertness, high stability, and high heats of phase transitions. However, their studies involve certain problems. First, the temperature interval of interest is inconvenient for studies. Second, the phase diagrams in this case are extremely complex, despite the fact that the substances constituting the systems do not react chemically with each other, because in some cases the systems involve all the existing types of nonchemical phase equilibria: eutectics, peritectics, and formation of solid solutions with and without extrema. Interpretation of the diagrams in the course of construction is very sophisticated and requires high skill.

In this study we examined the ternary system cyclohexane–*n*-hexadecane–*n*-docosane by low-temperature differential thermal analysis (LTDTA) [1–3]. This method allows determination of the melting points for compositions of the system studied and enables construction of its melting diagram.

The cyclohexane–*n*-hexadecane–*n*-docosane (C_6H_{12}–*n*-$C_{16}H_{34}$–*n*-$C_{22}H_{46}$) system forms three binary subsystems (cyclohexane–*n*-hexadecane, cyclohexane–*n*-decosane, and *n*-hexadecane–*n*-docosane). The characteristics of these subsystems are given in Table 1.

The available data on the binary systems suggest that the ternary system C_6H_{12}–*n*-$C_{16}H_{34}$–*n*-$C_{22}H_{46}$ is eutectic; this assumption was confirmed experimentally.

The polythermal section e_2–e_3 in the crystallization field of *n*-$C_{22}H_{46}$ was chosen in the phase diagram of the ternary system (see figure). The phase diagram of this section was constructed from the LTDTA data and was used for determining the ratio of C_6H_{12} to *n*-$C_{16}H_{34}$ in the ternary eutectic *E*. The eutectic composition of the ternary system determined from the *n*-$C_{22}H_{46}$–$\bar{E}\rightarrow E$ section (see figure) is as follows (wt %): C_6H_{12} 79.9, *n*-$C_{16}H_{34}$ 19.1, and *n*-$C_{22}H_{46}$ 1.0. The phase diagram of the ternary system cyclohexane–*n*-hexadecane–*n*-docosane is characterized in Table 2.



The specific enthalpy of melting for the eutectic composition of the ternary system (80 J g^{-1}) was determined by quantitative low-temperature differential thermal analysis.

Table 1. Characteristics of binary subsystems of eutectic type

System	T_m, °C	Content in eutectic, wt %		
		cyclohexane	*n*-hexadecane	*n*-docosane
Cyclohexane–hexadecane [4]	12.7	80.77	19.23	–
Cyclohexane–docosane [4]	4.6	83.8	–	16.2
n-Hexadecane–docosane [5]	16.2	–	94.3	5.7

Table 2. Characterization of the phase diagram of the ternary system C_6H_{12}–*n*-$C_{16}H_{34}$–*n*-$C_{22}H_{46}$

Element of phase diagram	Equilibrium	
	nonvariant	monovariant
Eutectic E; T_m = –17.9°C	l $\rightleftarrows$ C_6H_{12}–*n*-$C_{16}H_{34}$–β-*n*-$C_{22}H_{46}$	
e_1E		l $\rightleftarrows$ C_6H_{12}–β-*n*-$C_{22}H_{46}$
e_2E		l $\rightleftarrows$ *n*-$C_{16}H_{34}$–β-*n*-$C_{22}H_{46}$
e_3E		l $\rightleftarrows$ C_6H_{12}–*n*-$C_{16}H_{34}$

Projection of the phase diagram of the C_6H_{12}–*n*-$C_{16}H_{34}$–*n*-$C_{22}H_{46}$ system (wt %). (e_1, e_2, e_3) Binary and (E) ternary eutectics.

CONCLUSIONS

The ternary system cyclohexane–*n*-hexadecane–*n*-docosane is eutectic, the melting point of the eutectic is –17.9°C, and the specific enthalpy of melting is 80 J g^{-1}. The eutectic composition is as follows (wt %): C_6H_{12} 79.9, *n*-$C_{16}H_{34}$ 19.1, and *n*-$C_{22}H_{46}$ 1.0.

Abstract—Preparation conditions of composites of vinylmethyltetrazole–acrylate copolymers with fullerene were studied. The sorption properties of the composites were studied in relation to the C_{60} content.

DOI: 10.1134/S1070427206050338

Fullerene-containing polymers and composites are promising materials for medicine, biology, building, and optics [1–3]. Materials with required particular properties can be prepared by modification of the initial polymer matrix with fillers. Introduction of fullerenes (F) into atactic PMMA affects the thermal oxidative degradation of the polymer matrix [4].

Previously we showed that introduction of fullerene into acrylate formulations slightly decreases the tensile strength of the films but substantially increases their relative elongation (ε ~1100%). Data on the preparation and properties of composites of vinylmethyltetrazole–acrylate copolymers with fullerene are scarce. The aim of this study was to prepare fullerene-containing acrylate composites and to examine their sorption properties.

EXPERIMENTAL

Films of composites of vinylmethyltetrazole–acrylate copolymers with fullerene were prepared by radical polymerization in aqueous solutions at 10–60°C in the presence of the ammonium persulfate (APS)–tetramethylethylenediamine initiating system. *N,N'*-Methylenebisacrylamide (MBAA) was used as the cross-linking agent. The degree of neutralization of acrylic acid α ranged from 0.1 to 0.9. The polymerization was performed at the initial monomer concentration of 10–57%, the concentration of 2-methyl-5-vinyltetrazole (MVT) of 0–65 wt % of the weight of acrylic acid (AA), and the concentration of the cross-linking agent of 0–0.9 wt % of the total monomer weight. The properties and purification procedures of other chemicals and the procedures for preparing composites and studying their sorption properties were reported previously [6]. The composites were prepared in aqueous solutions in 8–15 h.

Solid fullerene (C_{60}) was introduced with stirring in the first polymerization step. Since the composite is heterogeneous, the fraction of the unchanged modifier was determined gravimetrically after swelling of the composite in distilled water for 5–7 days.

The preparation conditions and some properties of composites of new vinylmethyltetrazole–acrylate copolymer with fullerene are presented in the table. It is seen that the copolymer yield decreases and the gelation onset time increases with increasing the fullerene concentration in the reaction mixture. This fact suggests that fullerene inhibits the initiation of the free-radical copolymerization [7]. It should be noted that the copolymer yield increases with increasing the AA concentration in the initial monomer mixture.

The kinetic curves of swelling of composites of vinylmethyltetrazole–acrylate copolymers with fullerene, prepared at different concentration of the cross-linking agent, are shown in Fig. 1a. The equilibrium swelling of these composites with different fullerene content is attained within 5–10 h, which is significantly faster than the time required for equilibrium swelling of vinylmethyltetrazole–acrylate hydrogels without the modifier.

As seen from Fig. 1a, the equilibrium swelling of the absorbing composites decreases with increasing the concentration of the cross-linking agent. This is due to shortening of the polymer segment between the cross-links of the polymeric network.

The kinetic curves of swelling of the fullerene-containing acrylate composites with different modifier content are shown in Fig. 1b. As seen from Fig. 1b,

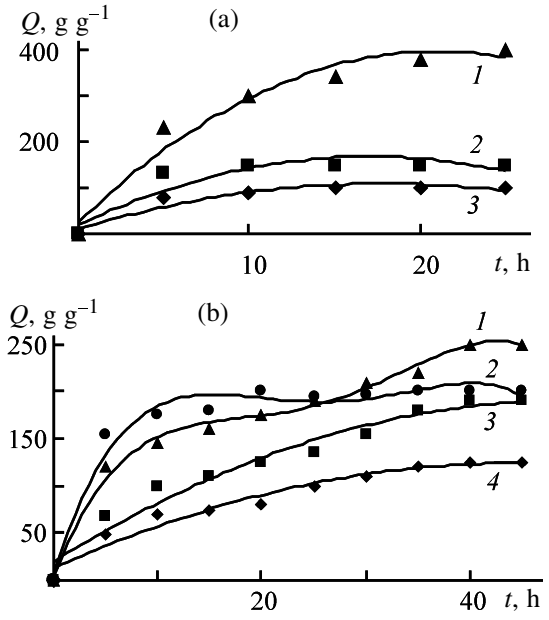

Fig. 1. Equilibrium degree of swelling *Q* of (a) vinylmethyltetrazole–acrylate copolymer and (b) fullerene-containing polymer composites in distilled water at 15°C as a function of time *t*. (a) Concentrations of fullerene and APS 0.1 and 0.6 wt %, respectively; α = 0.4. MBAA concentration, wt %: (*1*) 0.1, (*2*) 0.15, and (*3*) 0.2. (b) Concentrations of APS and MMBA 1 and 0.15 wt %, respectively; α = 0.3. Fullerene concentration, wt %: (*1*) 0.03, (*2*) 0.1, (*3*) 0.01, and (*4*) 0.

the initial swelling is accelerated as the fullerene content in the composite increases. The dependence of the equilibrium swelling passes through a maximum at the fullerene C_{60} concentration of 0.03 wt %. Ginzburg et al. showed [4] that aggregation of C_{60} molecules at their definite concentrations decreases the effect of the fullerene on the properties of PMMA films.

Fullerene C_{60} is insoluble in water but is a component of partially water-soluble material. The fullerene can be removed from the condensed phase during dissolution of the polymer. This is the case in prolonged swelling of the composites with the fullerene content higher than 0.7 wt %.

It should also be noted that the equilibrium degree of swelling of the vinylmethyltetrazole–acrylate copolymer prepared under the similar conditions but without the modifier is smaller that that of the copolymer modified with C_{60}. This can be due to fullerene–copolymer intermolecular interactions affecting the absorption properties of the acrylate composites. Stabilization of monomolecular layers of C_{60} by aqua aggregation was demonstrated in [8].

The fact that swollen fullerene-containing composite holds its shape allows preparation of articles with required geometrical parameters.

CONCLUSIONS

(1) Absorbing composites of vinylmethyltetrazole–acrylate copolymer with fullerene were prepared.

(2) The influence of the modifier on the absorption properties of the composites was demonstrated. The dependence of the equilibrium degree of swelling of the composites on the fullerene content passes through a maximum. These dependences allow prediction of the properties of composites with different modifier content.

(3) The rate of the swelling of the composites in distilled water depends on the fullerene content in the sample.

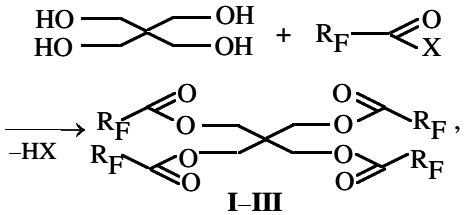
Abstract—Wetting angles and limits of thermal stability of esters derived from pentaerythritol and perfluoro-, ω-chloropolyfluoro-, and perfluoropolyethercarboxylic acids were studied.

DOI: 10.1134/S107042720605034X

Esters derived from polyhydric alcohols and carboxylic acids occupy leading positions on the market of lubricants thanks to their high resistance to heat and oxidation, good lubricating characteristics, and favorable viscosity–temperature parameters [1]. Depending on the demands, these esters are used as working bodies or as additives to other commercial oils. The field of application of lubricants based on esters derived from polyhydric alcohols and carboxylic acids ranges from the production of consumer goods to operation of jet and high-temperature gas turbines.

A particular place among such lubricants is occupied by pentaerythritol (PE) esters. An advantage of PE esters is the presence of a quaternary carbon atom in the β-position to the ester group [2], which enhances their thermal stability.

Much attention is given to synthesis procedures and physicochemical properties of esters derived from PE and alkylcarboxylic acids. Halogenated PE esters have been studied insufficiently.



Synthetic lubricating oils derived from alcohols and perfluoro acids exhibit chemical inertness, high stability, and inflammation resistance [2].

In this study we examined the hydrophobicity and thermal stability of new fluorinated PE tetraesters. Among the most studied analogs of fluorinated PE esters are perfluoro polyesters prepared by reactions of PE with perfluoropolyetheracids [3]. These compounds were recommended as lubricants and hydraulic fluids.

Commercial procedures for preparing carboxylic acid esters involve direct esterification of alcohols with fatty acids or ester interchange of esters (e.g., methyl esters) with appropriate alcohol in a solvent in the presence of a catalyst.

Application of these methods to the synthesis of esters from PE and perfluorocarboxylic acids does not ensure high yields of the target products. Since PE contains four OH groups, esterification by the classical procedure in the presence of a catalyst (H_2SO_4, KU-2 cation-exchange resin, etc.) yields a mixture of four compounds (from mono- to tetraesters).

Therefore, we attempted to use as acylating agents halides of fluorocarboxylic acids:

I–III

(41–53%)

where $R_F = C_6H_{13}$, X = F (**I**); $R_F = Cl(CF_2)_8$, X = Cl (**II**); $R_F = C_3F_7OCF(CF_3)CF_2OCF(CF_3)$, X = F (**III**).

The process occurs without catalyst. The reaction medium is excess acyl halide; after the reaction completion, it is removed from the reaction mixture.

Compounds **I**–**III** are insoluble in common solvents but readily soluble in fluorinated liquids (hexafluorobenzene, Freons, etc.).

The structures of **I**–**III** were determined by elemental analysis and IR spectroscopy, and also from the saponification numbers [4] (see Experimental).

Different structures of acid residues in **I**–**III** suggest their different physicochemical properties; in-

deed, these compounds differ in the hydrophobicity and thermal stability.

Introduction of fluorinated acid residues into PE by esterification should enhance the hydrophobicity as compared to esters of PE with common carboxylic acids, because of weakness of the intermolecular interaction on the water–organofluorine compound phase boundary [5].

The hydrophobic properties of tetraesters **I**–**III** were evaluated by measuring the wetting angle by the stagnant drop method [6]. To obtain surface layers of **I**–**III**, we used their 2 and 4% solutions in hexafluorobenzene; aluminum foil was used as support. The conditions for determining the wetting angle are given in the Experimental.

As reference compounds for studying the hydrophobicity of **I**–**III** we used commercially available PE tetrabutyrate and PE tetrabenzoate.

The wetting angles we obtained show that compound **I** containing four perfluoroalkyl groups is the most hydrophobic. Tetraester **II** with four ω-chloroperfluoroalkyl groups is less hydrophobic, and compound **III** is the least hydrophobic, which agrees with the data from [5].

Parallel determination of the wetting angle with the reference compounds showed that PE tetrabutyrate and tetrabenzoate are wetted well, which is due to their low hydrophobicity.

Fluorinated esters are used as synthetic lubricating oils and as additives to commercial lubricating materials [2]. The thermal stability of synthetic ester oils and additives is largely determined by the steric structure of the acid or alcohol residues. However, the service temperatures of esters derived from PE and alkylcarboxylic acids do not exceed 175–200°C.

To evalulate the thermal stability of the new tetraesters and the possibility of using them as additives, we studied both neat compounds **I**–**III** and their 0.2% solutions (prepared by ultrasonic dispersion) in I-12A industrial oil [GOST (State Standard) 20799–88] by derivatographic thermal gravimetric analysis (see table). Our results show that ester **II** considerably surpasses in the thermal stability compounds **I** and **III**, which is apparently associated with the structure of fluoroalkyl radicals.

Similar trends are observed when studying the thermal stability of I-12A industrial oil with additions of **I**–**III**. The most thermostable is a solution of **II** in I-12A; esters **I** and **III** enhance the thermal stability of I-12A to a lesser extent, giving similar results.

EXPERIMENTAL

The IR spectra were recorded on a Spectrum One Perkin–Elmer Fourier spectrophotometer. Compounds **I** and **III** were taken as thin layers, and for **II** the diffuse reflection mode (DRA) was used. Derivatographic thermogravimetric analysis was performed with a Ditector-MOM device with programmed heating at a rate of 5 deg min^{-1}; the sample weight was 100 mg. Elemental analysis was performed with an EA1108 CHN analyzer (Carlo Erba, Italy).

Ester of PE and perfluoroenanthic acid (I). To 0.1 mol of PE, 0.6 mol of perfluoroenanthic acid fluoride was added dropwise at a rate allowing the reaction mixture temperature to be maintained within 55°C. After adding the whole amount of the acid fluoride, the mixture was heated at 140°C for 30 h. Excess acid fluoride was distilled off, and the residue was distilled in an oil-pump vacuum. Yield of ester **I** 76 g (50%), bp 280–282°C (60 mm Hg). IR spectrum

(ν, cm^{-1}): 1797 (–O–C=O).

Found, %: C 26.10, H 0.46, F 65.05.
$C_{33}H_8F_{52}O_8$.
Calculated, %: C 26.07, H 0.53, F 64.98.

Saponification number, found: 155.

Ester **II** of PE and ω-chloroperfluoropelargonic acid was prepared similarly; yield 41%, mp 92°C. IR spectrum, ν, cm^{-1}: 1789 (–O–C=O).

Found, %: C 25.01, H 0.38, F 61.77.
$C_{41}H_8Cl_4F_{64}O_8$.
Calculated, %: C 24.79, H 0.41, F 61.22.

Saponification number, found: 117.

Ester **III** of PE and perfluoro-3,6-dioxa-2,5-dimethylnonanoic acid was prepared similarly; yield 53 %, bp 225–228°C (60 mm Hg). IR spectrum (ν, cm^{-1}): 1795 (–O–C=O).

Found, %: C 24.28, H 0.48, F 62.70.
$C_{41}H_8F_{68}O_{16}$.
Calculated, %: C 24.04, H 0.39, F 63.07.

Saponification number, found: 116.

Determination of the wetting angle. Two stands were arranged on an antivibration table. The stands were equipped with levels with which the stands were aligned relative to the table surface. A Nikon Coolpix 5200 digital camera was arranged on one of the stands. A thin rigid plate acting as a microscopic stage was arranged on the other stand. On this plate we arranged on aluminum foil treated with solutions of tetraesters **I**–**III** in hexafluorobenzene as described in [6]. The Macro mode of the camera was set. A 50-μl water drop was applied with a pipet to the foil surface treated with solutions of **I**–**III**, the camera lens was focused on the drop surface, and the image was taken. The images were treated with a computer using ACDSee 6.0 program and various program filters. The inital image of a water drop (before using filters) is shown in Fig. 1a. Figure 1b shows the same water drop after application of the program filters. The borders of the water drop, required for the mathematical calculation of the wetting angle (line width 1 pix) are clearly seen in Fig. 1b.

The mathematical treatment of the images was performed using data of [7], according to which the wetting angle is calculated from the length of the drop base ($d = 2r$) and the drop height (h). For wetting angles $\theta > 90°$, when the surface is hydrophobic, the following expressions are valid:

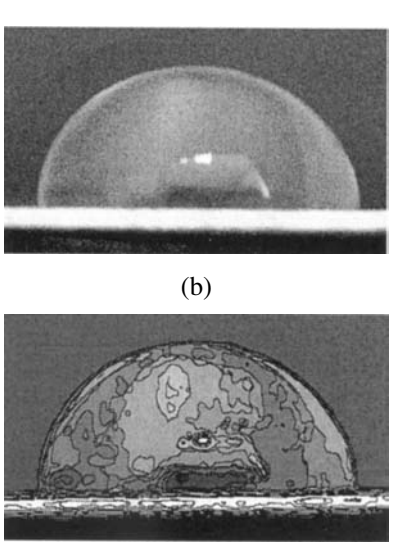

Fig. 1. Photograph of a water drop on films of **I**–**III**: (a) before and (b) after computer treatment of the image.

$$\tan\alpha = (2hr - h^3)^{1/2}(r - h)^{-1}, \qquad \alpha = \pi - \theta.$$

The angle α was found from tables [8]. For wetting angles $\theta < 90°$, the use of this expression is unnecessary.

The witting angles on films of **I**–**III** (deg) are as follows. Films prepared from 2% solutions: **I**, 100; **II**, 91; **III**, 67. Films prepared from 4% solutions: **I**, 103; **II**, 93; **III**, 71.

CONCLUSION

The synthesized esters of pentaerythritol and fluorinated acids show high hydrophobicity and thermal stability.

ACKNOWLEDGMENTS

The study was financially supported by the Russian Foundation for Basic Research (project no. 04-03-96 109).

BOOK REVIEWS

Meretukov, M.A., Tsepin, M.A., Vorob'ev, S.A., and Syrkov, A.G., *Klastery, struktury i materially nanorazmera: innovatsionnye i tekhnicheskie perspektivy* (Nanosize Clusters, Structures, and Materials: Innovational and Technological Prospects),

Moscow: Ruda i Metally, 2005, 128 pp.

DOI: 10.1134/S1070427206050351

A strong interest in nanostructures composed of various substances has been expressed in recent 15–20 years, and quite a number of domestic and translated monographs of varied scientific level on nanotechnologies and nanochemistry have been published. On passing to the nanometer range (to objects of size less than 10 nm), quite a number of the most important parameters of substances change fundamentally. The small-volume book by M.A. Meretukov and coauthors presents in form understandable for a wide audience of readers modern concepts of high nanometer technologies, nanoobjects, and areas of their application. The principal feature of the book, which distinguishes it from other publication devoted to similar topics, is that gold is chosen as the object metal illustrating the advances in nanotechnology and new properties of gold are clearly shown for the example of its nanoparticles.

The book comprises an introduction and eight chapters, with each section provided with its own list of references and recommended literature. The introduction (pp. 6–17) gives a general notion of nanostructured materials and the extent to which nanotechnologies are developed and applied in a number of countries, including Russia, and discusses prognoses of development of nanotechnologies and their potentialities that can be implemented in the nearest five years and in 50–60 years. The concluding part of the introduction considers the potentialities of nanotechnologies as applied to some metallurgical processes.

Chapter 1 (pp. 18–29) presents the general concepts concerning the nature of nanostructures, by which are understood formations with at least one dimension of several nanometers. The authors give notion of the tunneling effect and scanning probe microscopy. Chapter 2 (pp. 30–43) gives notion of physical and chemical methods for production of nanostructured metals. Chapter 3 (pp. 44–53) presents the concepts of clusters and the cluster state of metals. Chapter 4 (pp. 54–69) presents evidence about fullerenes, their structure, properties, synthesis, and possible application areas. Chapter 5 (pp. 70–87) continues with this subject and presents various data on carbon nanotubes.

As already noted, the book is made original by Chapters 6 (pp. 88–98), 7 (pp. 99–111), and 8 (pp. 112–125) considering gold-based nanomaterials. Chapter 6 notes that nanosize particles of gold are used as biosensors and in chemical catalysis, with an important role assigned to these nanoparticles in the development of new generations of nanosize optical and electronic devices. Gold clusters, specific features of their structure, geometrical dimensions, and synthesis methods are described in detail. Of interest is the evidence presented in the book (Chapter 7) about natural nanosize particles of gold. The development of analytical methods using various kinds of microprobes in the last 20 years has revealed in ores invisible gold localized on the surface and in the bulk of sulfide and other minerals. The final Chapter 8 is devoted to synthesis and application of gold nanostructures. The authors, in particular, note that of special interest is the possibility of obtaining ordered (regular) structures that can be deposited in the form of films on specialized substrates, mostly those composed of metal oxides. Use of gold nanomaterials in electronics, as catalysts in chemical industry, and in solution of certain environmental problems is considered.

Owing to the well-understandable manner of presentation, the book by Meretukov and co-authors is of interest not only to specialists in nanotechnology, but also to the widest audience of students and teachers at higher-school and secondary educational institutions. The book is very well published and contains a large number of illustrative schemes and figures, which improves its cognitive value.

BOOK REVIEWS

Kazantsev, G.F., Barbin, N.M., Brodova, I.G., Vatolin, N.A., Moiseev, G.K., and Bashlykov, D.V., *Pererabotka loma i otkhodov tsvetnykh metallov v ionnykh rasplavakh* (Processing of Scrap and Waste Nonferrous Metals in Ionic Melts),

Yekaterinburg: Ural'sk. Otd. Ross. Akad. Nauk, 2005, 210 pp.

DOI: 10.1134/S1070427206050363

The monograph devoted to a rather topical subject was prepared by a group of specialists from institutes affiliated with the Ural Division of the Russian Academy of Sciences: Institute of Metallurgy, Institute of High-Temperature Electrochemistry, and Institute of Metal Physics. The authors summarized the results of mostly their own studies in the field of theoretical foundations and technology of processing of nonferrous-metal secondary raw materials.

The book comprises an introduction, seven chapters, and reference lists for each chapter separately. The brief introduction (pp. 3, 4) notes that the many years' studies carried out at the institutes of the Ural Division demonstrated the possibility and advisability of processing of secondary raw materials (scrap aluminum and aluminum alloys, copper, zinc, and tin) in ionic melts and, in particular, in molten halides of alkali and alkaline-earth metals. The authors considered it appropriate to include into the monograph evidence concerning use of light metals and their alloys in various fields of technology and to present data on selected physicochemical properties of nonferrous metals.

Chapter 1 (pp. 5–43) is mostly devoted to application of aluminum alloys. Also presented is evidence concerning the composition of certain aluminum alloys, both cast and wrought. There is no escape from mentioning that a considerable part of the material presented in Chapter 1 bears no direct relation to the problem under discussion. Chapter 2 (pp. 44–81) considers the equipment used in processing of various kinds of secondary raw materials containing nonferrous metals. Unfortunately, the companies manufacturing such equipment in Russia or CIS countries are not named by the authors.

Chapter 3 (pp. 82–103) briefly discusses the properties of molten electerolytes and presents a number of tables with data on the physicochemical properties of individual molten compounds and mixtures of these. Among issues related to refinable metals, only melting of scrap aluminum under a layer of molten salts is very briefly considered. Chapter 4 (pp. 104–150) mainly includes results obtained when studying the remelting of aluminum alloy shavings under a layer of flux composed of molten salts. Chapter 5 (pp. 151–167) considers remelting, under a layer of halide fluxes, of a complex scrap constituted by various cables, bimetals, and oxidized secondary aluminum. The brief Chapter 6 (pp. 168–184) describes application of fluxes composed of molten salts in modification of certain aluminum alloys. The final Chapter 7 (pp. 185–199) discusses remelting of wastes containing copper, zinc, tin, and titanium.

On the whole, the book by G.F. Kazantsev and co-authors contains useful recommendations concerning use of molten salts as fluxes in processing of secondary raw materials containing, primarily, aluminum and, to a lesser extent, other nonferrous metals. Despite the positive assessment of the monograph written by the group of authors, there is no escape from mentioning the certain incoherence of the structure of the book, its narrowly applied nature, and its overloading with reference data and other materials that bear no direct relation to the technologies discussed. Probably, the authors should have more clearly formulated the subject of the monograph in the introductory part. In fact, the book is only devoted to remelting of secondary raw materials containing nonferrous metals and, primarily, aluminum. Separation or reduction processes occur in remelting only in some cases. The term "processing of scrap and wastes" presumes, in its modern understanding, a deeper processing of the starting secondary raw ma-

terials, with not only remelting, but also the subsequent separation of components. It seems that, in compiling the reference tables, primarily for individual metals and salts, the authors did not always select the best source of these data.

The monograph by Kazantsev and co-authors is of interest for engineers and technicians working in the field of utilization of secondary aluminum-containing raw materials and is also of use for specialists in processing of various secondary raw materials in nonferrous metallurgy.

Abstract—The solubility of silk fibroin in aqueous-salt, aqueous-organic, and organic media is analyzed. Factors affecting the formation of the secondary structural organization of fibroin in solutions and in the solid state after the recovery from solutions are analyzed.

DOI: 10.1134/S1070427206060012

Of particular importance among natural polymers widely used in various spheres of human activity are polysaccharides (cellulose, chitin, their derivatives, starch, etc.) and proteins (primarily silk fibroin).

Articles made of silk fibers exhibit high wear resistance and physicomechanical properties making their wearing comfortable: good capability of silk fibers for moisture absorption, air permeability, and low electrifiableness. Processing of fibers produced by cultivated *Bombyx mori* mulberry silkworm involves formation of large amounts of wastes (fibers that are difficult to take out from cocoons), which are potentially valuable and can be processed into films, artificial fibers, or nonwoven materials by dissolution of silk fibroin, followed by its recovery. The silk fibroin dissolution is affected by the nonuniformity of fibroin in the chemical composition, by the system of hydrogen bonds existing in the polymer, by its supramolecular structure, and by the morphological features of natural fibers. The solubility of silk and web thread fibroin in aqueous and organic salt-containing systems and in certain salt-free organic solvents has been studied in recent years. It seems appropriate to summarize papers that deal with the factors affecting the solubility of silk fibroin in aqueous and nonaqueous solvent systems, with the properties of the solutions obtained, and with conformational changes of silk fibroin macromolecules in the course of recovery of the polymer from solutions.

1. STRUCTURE OF NATURAL SILK FIBROIN

Silk fibroin, like creatine and collagen, belongs to fibrillar proteins [1]. The elements of the supramolecular structure of silk fibers are macrofibrils with a width of up to 6.5×10^5 nm, which, in turn, consist of helically packed nanofibrils 90–170 nm in diameter [2, 3]. Nanofibrils may play an important role in imparting enhanced strength to silks. The molecular weight of natural silk fibroin reaches 370000 Da; fibroin macrochain length, 150 nm; and macrochain diameter, 0.45 nm [4, 5].

Silk fibers produced by cultivated *Bombyx mori* mulberry silkworm mainly consist of two proteins, sericin and fibroin; they also contain minor amounts of residues of other amino acids and various impurities: fats, waxes, dyes, and mineral salts. Depending on the cocoon strain, the fibroin content is 66.5–73.5, and the sericin content, 26.5–33.5 wt % [6].

As for the chemical composition, *Bombyx mori* fibers consist of residues of no less than 16 amino acids whose ratio varies between different areas of the supramolecular structure of fibroin (Table 1). "Heavy" areas of the polymer, with a mean molecular weight of up

Table 1. Amino acid composition of *Bombyx mori* fibroin [7]

Amino acid	Composition, mol %		
	total	heavy areas	light areas
Glycine	42.9	49.4	10.0

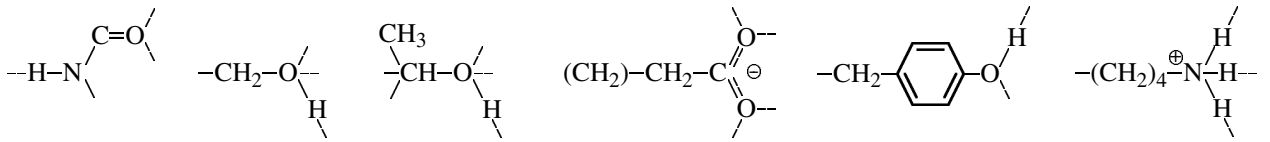
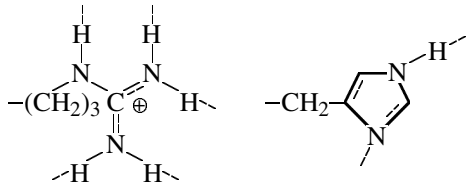
Threonine	0.92	0.45	2.8
Phenylalanine	0.67	0.39	2.7
Methionine	0.37	–	0.37
Isoleucine	0.64	0.14	7.3
Leucine	0.55	0.09	7.2
Proline	0.45	0.31	3.0
Arginine	0.51	0.18	3.8
Histidine	0.19	0.09	1.6
Lysine	0.38	0.06	1.5



to 350000–370000, mainly consist of highly ordered hydrophobic macromolecules, and in looser "light" areas with a mean molecular weight of about 25000 the major components are polar amino acid residues [7].

The mole fraction of glycine, alanine, serine, and tyrosine residues combined is 90%; their sequence is represented by the general formula [8, 9]



$$-Gly-Ala-Gly-Ala-Gly-Ser-Gly-Ala-Ala-Gly-[-Ser-Gly-(Ala-Gly)_n-]_8-Tyr-$$

The pendant fragments of fibroin macromolecules are nonpolar hydrophobic aliphatic hydrocarbon (alanine, leucine, isoleucine, valine, proline) and aromatic (phenylalanine) substituents, polar hydrophilic hydroxyl-containing residues of serine, threonine, and tyrosine, carboxy groups of aspartic and glutamic acids, amino groups of lysine, and guanidine groups of arginine.

The secondary structure of fibroin is stabilized by various kinds of interactions. Hydrogen bonds arise between functional groups of peptide macrochains and between side fragments of macromolecules [10]:

Peptide Ser Thr Gly, Asp Tyr Lys

Arg His

The polar carboxy and amino groups in fibroin can also be involved in dipole interactions, and in the case of proton transfer, also in electrostatic interactions [11]. As the content of acid and base groups in fibroin is low, the electrostatic factor is not decisive in the formation of the secondary structure; it, however, may become decisive in the fibroin dissolution.

Since fibroin consists to 3/4 of nonpolar hydrophobic amino acids, it is necessary to take into account also hydrophobic (dispersion) interactions making fibroin resistant to the majority of solvents.

Three main kinds of secondary structures of natural silk fibroin are distinguished today: in crystalline areas, α-helical and β-folded structures (silk I and silk II, respectively), and in amorphous areas, disordered conformation of random globules. Liquid silk synthesized by the silkworm gland is a 26.0 vol % aqueous solution of fibroin in which the macromolecules have the conformation of globule or α-helix. Fibroin of natural *Bombyx mori* fibers contains 56 ± 5% macromolecules in the β-folded form and 13 ± 5% macromolecules in the α-helical form [12]. Thus, the fraction of highly ordered (crystalline) areas of the polymer reaches 60–70%.

Figures 1 and 2 show the projections of macrmolecule segments forming the α-helical and β-folded structures. The α-helical structure is formed by intramolecular hydrogen bonds, with the hydrophobic fragments displaced to the periphery [13]. In the β-folded structure, the macromolecules are arranged in the parallel or antiparallel mode, forming a folded sheet or layer (β-sheet). Antiparallel β-sheets of silk fibroin are packed in the face-to-face, back-to-back mode: double layer of glycine residues (interplanar spacing 3.5 Å)–double layer of alanine/serine residues (interplanar spacing 5.7 Å)–double layer of glycine residues, etc. [1]. For the hydrophobic fragments of macromolecules, this structure is the most favorable energetically [14, 15].

Okuyama et al. [17] reported the interatomic distances and bond angles for various conformations of

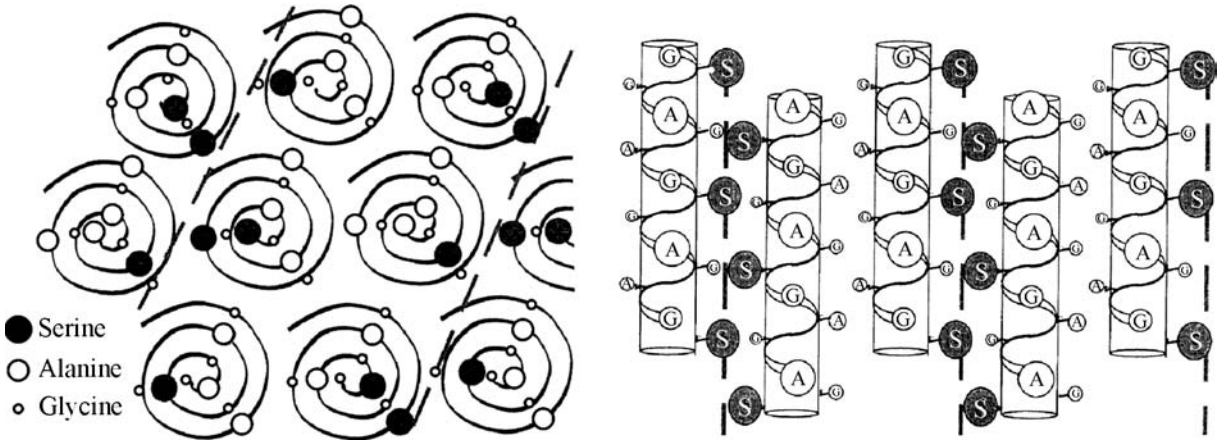


Fig. 1. α-Helical structure of fibroin macromolecules in two projections [9].

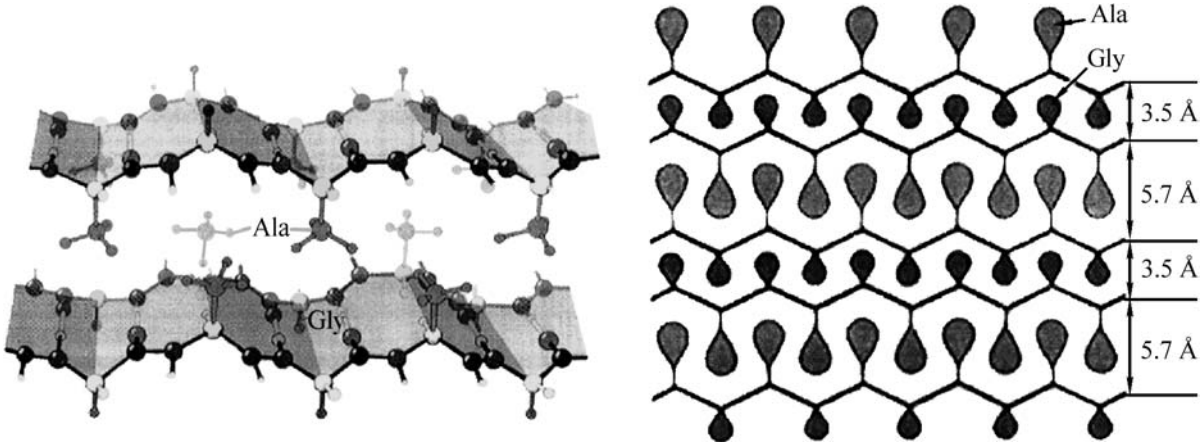

Fig. 2. β-Folded structure of fibroin [16].

protein chains, calculated from the X-ray scattering data. The most energetically favorable model was that with the antiparallel arrangement of the macrochains, in which the alanine–glycine diads (Ala–Gly) form two intramolecular and one intermolecular hydrogen bonds, and the $(Ala–Gly)_2$–Ser–Gly fragments form three intra- and one intermolecular hydrogen bonds (Table 2).

Table 2. Interatomic distances and angles in hydrogen bonds in the most stable models of crystalline areas of fibroin [17]

Fibroin structure model	Intermolecular hydrogen bonds			Intramolecular hydrogen bonds		
	bond	interatomic distance, Å	angle, deg	bond	interatomic distance, Å	angle, deg
Ala–Gly	N(Ala)...O(Gly)	2.87	77.7	N(Gly)...O(Ala)	3.02	123.7
				N(Ala)...O(Ala)	2.84	83.6
$(Ala–Gly)_2$–Ser–Gly	N(Ala)...O(Gly)	2.98	76.9	N(Gly)...O(Ala)	3.13	125.6
				N(Ala)...O(Ala)	2.88	86.4
				O(Ser)...O(Ala)	2.65	88.5

2. SOLUTIONS OF SILK FIBROIN IN SALT-CONTAINING AQUEOUS AND NONAQUEOUS SOLVENT SYSTEMS

Natural silk fibers dissolve only in a limited number of solvents, compared to globular proteins, because of the presence in fibroin of a large amount of intra- and intermolecular hydrogen bonds and its high crystallinity and specific physicochemical properties (wetting angle of silk fibroin 69° ±3° [18]). Sadov et al. [19] estimate the Kuhn segment of fibroin macromolecules at 40 Å, and the solubility parameter δ, at 24.3 $(mJ\ m^{-3})^{0.5}$. Fibroin does not dissolve in water and in the majority of organic solvents, but only swells to 30.0–40.0%; 2/3 of the absorbed solvent is retained by the amorphous fraction of the polymer [20]. The isoelectric point of fibroin varies in the range pH 3.6–5.2, depending on the conditions of solution preparation [21, 22].

Fibroin dissolves in concentrated aqueous solutions of acids (phosphoric, formic, sulfuric, hydrochloric) and in concentrated aqueous, organic, and aqueous-organic solutions of salts [LiCNS, LiBr, $CaCl_2$, $Ca(CNS)_2$, $ZnCl_2$, NH_4CNS, $CuSO_4$ + NH_4OH, $Ca(NO_3)_2$]. The main disadvantages of salt-containing aqueous, aqueous-organic, and organic solutions of fibroin are the long preparation time (aqueous solutions of fibroin should be dialyzed for several days) and large power consumption for the regeneration of the solvents for their reuse. It should be noted that the concentrations of salts in such solutions reach the saturation limit.

The solvency of aqueous salt systems depends on the salt concentration and increases in the following order: for anions, sulfate < citrate < tartrate < acetate < chloride < nitrite < bromide < iodide < thiocyanate < dichloroacetate; for cations, $Ca^{2+} < Sr^{2+} < Ba^{2+} < Li^+ < Zn^{2+}$ [1, 8, 20]. In some one-component organic solvents (hexafluoroisopropanol [23], hexafluoroacetone [24]), fibroin can be dissolved only after its preliminary activation. The fibroin activation consists in the preliminary dissolution of the protein in an aqueous salt solution followed by dialysis of the solution and recovery of the polymer as a film from aqueous solution by dry forming.

High solvency is exhibited by solutions of lithium halides in organic solvents: dimethylacetamide (DMAA) and dimethylformamide (DMF). For example, a 10.0% solution of fibroin can be obtained at 50°C in a 2–3 M solution of LiBr in DMAA or DMF and in 9.5–10 M solution of LiBr in water [25]. Thus, an important characteristic of a complex solvent is the nucleophilicity of the anion, which attacks the electrophilic centers (hydroxy, amide, amino groups) of fibroin macromolecules. In aprotic solvents, anions are not solvated; therefore, their nucleophilicity can be even higher than in aqueous solutions [26]. Indeed, the solvency of organic salt solutions decreases, depending on an anion, in the following order: $Cl^- > Br^- > SCN^-$, correlating with decrease in the nucleophilicity of the anion. In aqueous solutions, the trend is opposite, because water molecules compete with the electrophilic centers of fibroin, and more nucleophilic anions interact with water more strongly than with the polymer. Solutions of thiocyanates in organic solvents proved to be inefficient, despite that an aqueous solution of LiSCN readily dissolves the polymer. As for the activity of cations, the aqueous and organic systems also differ in this respect. Aqueous solutions of $ZnCl_2$ are the most effective solvents, whereas in solutions of $ZnCl_2$ in DMAA, DMF, and *N*-methyl-2-pyrrolidone, fibroin dissolves only at 155°C to form relatively dilute solutions (1.0–2.0 wt %).

The specific features of fibroin dissolution in various systems are associated with its molecular structure. In concentrated solutions of acids, the fibroin macromolecules are solvated owing to strong ion–ion interaction, which becomes possible upon protonation of the amino and amide groups of the polymer. Dissolution in salt systems is due to interaction of solvent ions with functional groups of the fibroin macromolecules. By analogy with dissolution of cellulose in the DMAA–LiCl system, it can be assumed that the intra- and intermolecular hydrogen bonds in the fibroin structure are ruptured as a result of the nucleophilic attack by the anion [27]. The solvent ions interact with polar and charged groups of pendant chains of fibroin, breaking the hydrogen bonds between the macromolecules.

In the course of dissolution, fibroin from the amorphous areas characterized by a high content of amino acid residues with bulky and polar groups dissolves first. The amino acid composition of fibroin precipitated from various solutions differs from that of the initial fibers. Tsukada et al. [28, 29] reported how the amino acid composition of *Bombyx mori* fibroin changed after its recovery from aqueous LiBr and LiSCN solutions. They found that, irrespective of the dissolution temperature, the relative content of glycine and alanine residues characteristic of the hydrophobic areas increased and the content of amino acid residues forming the amorphous areas decreased after the precipitation of the polymer. In organic salt solutions (LiCl in DMAA), the amorphous fraction also dissolves first [25].

Table 3. Molecular characteristics of fibroin in solutions [34]

Characteristic	Aqueous solution of fibroin after dialysis	Fibroin in methanol–water system (20 : 80)
Molecular weight, Da	188000	302000
Hydrodynamic length L_H, Å	8563	13800
Rotation radius R, Å	81.5	121.2
Cross section rotation radius R_c, Å	43.0	45.4
Persistent length a^*, Å	37.3	32.7
Volume $V \times 10^{-6}$, Å^3	2.30	4.85
Cross section area A, Å^2	7.9	9.6

As the dissolution temperature is raised over 70°C, the macromolecules undergo degradation [25]. As shown in [20, 28, 30], the molecular weight of natural silk fibroin is 370000, and that of the fibroin dissolved in aqueous LiBr, 30000 to 200000.

The fibroin macromolecules strongly differ in size in aqueous and organic solvents, as indicated by the intrinsic viscosity [η] of fibroin in 7.7 M aqueous NaCNS and a 2.5 M solution of LiCl in DMF (0.46 and 1.30 dl g^{-1}, respectively) [31]. In a salt-containing aprotic organic solvent, the polymer macromolecules exist in a more unrolled conformation as compared to the aqueous salt solution, because, under equal other conditions, [η] is proportional to the cube of the rms radius of particles [32].

Mathur et al. [33] showed that, in solutions of fibroin in the $Ca(NO_3)_2$–methanol system (salt concentration 60–75 wt %), [η] is a nonlinear function of temperature (8.71, 10.41, and 8.94 at 25, 30, and 40°C, respectively). The activation energy of viscous flow of a 0.1% fibroin solution in this solvent increases by 30.0%, compared to the straight solvent (9.03 and 7.01 kcal mol^{-1}, respectively).

Canetti et al. [34] studied by the methods of circular dichroism and small-angle X-ray scattering how addition of organic solvents to an aqueous solution of fibroin (dissolution in aqueous LiBr, followed by dialysis) affects the secondary (supramolecular) structure of the protein. They showed that, after the dialysis, the dilute aqueous solution of silk fibroin contains associates of two and more solvated macrochains, mainly rolled up in globules. Addition of methanol or dioxane increases the degree of association, and a β-folded structure is formed. On adding trifluoroethanol, a labile equilibrium is observed between the disordered globule and β-folded structures. Proceeding from the length of the monomeric unit of 6.95 Å (two amino acid residues), they calculated the geometric characteristics of macromolecules in aqueous and mixed aqueous–organic solvent systems (Table 3).

Aqueous and aqueous-organic solutions of LiCl, LiBr, NaSCN, and KSCN dissolve up to 20 wt % fibroin; the solvency of mixtures increases with a decrease in the relative content of water in the solvent [35]. The intrinsic viscosity of solutions [η] is inversely proportional to the water content of the mixtures and amounts to 0.3–0.7 dl g^{-1} at 30°C. The Huggins constant k_H is 0.5–1.0, with a minimum observed at 10% water content. An increase in the LiBr concentration, at equal other conditions, affects k_H insignificantly; the salt effect consists in unrolling of fibroin macromolecules. By contrast, in the NaSCN–water–isopropanol system, the effective viscosity and surface tension of the fibroin solution decrease as the isopropanol content is raised from 2 to 20% [36]. Thus, due to differences in the solvation of ions in aqueous and nonaqueous solutions, the properties of fibroin solutions vary with the water : organic solvent ratio differently, depending on a particular salt.

The interaction with the solvent necessarily leads to a change in the conformation of fibroin macromolecules and their secondary structure. Addition of polar solvents (alcohols, acetone, acetic acid) to water-soluble silk I initiates formation of the β-folded conformation of the macromolecules in solution [37]. The same trend is observed in treatment of fibroin films. Apparently, nonpolar solvents solvate hydrophobic fragments of fibroin; as a result, the amide, hydroxy, and other polar groups interact with each other through H bonds and thus fix the α-helix structure. In polar solvents, the existing H bonds are broken, which promotes transition to the β-structure; in the process, the macromolecules are arranged in the same plane, the hydrophobic groups of adjacent macromolecules interact with each other within the planes, and the polar groups outside the macromolecule plane form intra- and intermolecular H bonds.

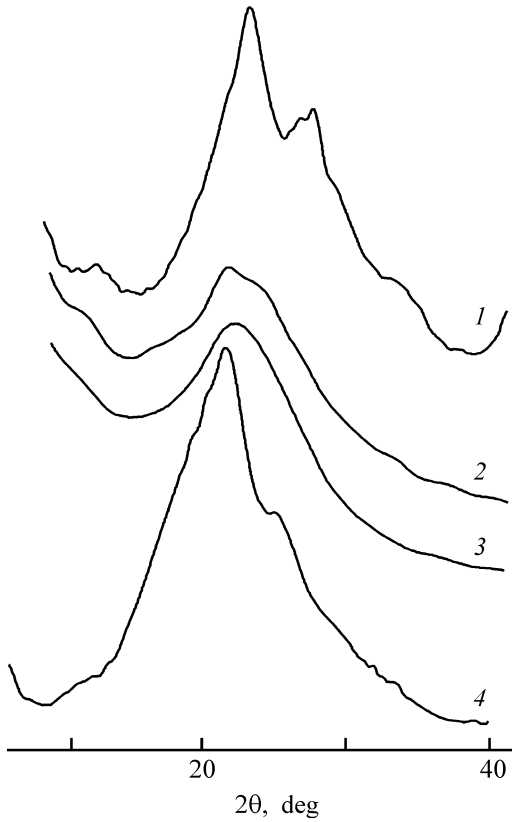

Fig. 3. X-ray diffraction pattern of (*1*) natural fibroin and of fibroin films recovered from solutions in (*2*) aqueous LiBr after dialysis, (*3*) hexafluoroisopropanol, and (*4*) NMMO [41]. (2θ) Bragg angle.

The fibroin recovered from dialyzed solutions in LiBr–H_2O has a disordered structure [34, 38–40], whereas the silk fibroin in a film cast from a solution in LiBr–ethanol has a lamellar β-sheet secondary structure. Thus, by choosing a solvent system, it is possible to control the formation of the secondary structure in solutions and, correspondingly, in the precipitated polymer [40].

3. SOLUTIONS OF FIBROIN IN ORGANIC SOLVENTS

Fibroin dissolves in hexafluoroisopropanol [23] and hexafluoroacetone [24], but this only occurs after its preliminary activation by dissolution in aqueous-salt systems followed by the recovery. In hexafluoroisopropanol, fibroin has mainly the α-helical structure with a small content of the β-folded structure [41, 42]. These data are well consistent with the data of Kimura et al. [43], who showed that macromolecules of proteins consisting of alanine residues form predominantly α-helical structures in hexafluoroisopropanol.

A procedure for fibroin dissolution without preliminary activation was suggested in [44, 45], and solutions containing more than 10 wt % fibroin in *N*-methylmorpholine *N*-oxide (NMMO) were obtained. The dissolution occurs in the hydrated form of the amine oxide at a water content of no more than 0.8 mol per mole of NMMO. NMMO monohydrate melts at 78°C, and, with a decrease in the water content, the melting point increases to 100°C and over. To lower the melting point of the hydrated amine oxide, it was suggested to add organic diluentes; DMSO appeared to be the most effective [46]. The addition of DMSO in an amount of 2–3 mol per mole of NMMO does not deteriorate the system solvency.

As expected, with an increase in the temperature, the intrinsic viscosity of the solutions decreases and the Huggins constant increases. The intrinsic viscosity of fibroin solutions in NMMO–H_2O–DMSO (molar ratio 1 : 0.3 : 1.8) at 95 and 115°C is 0.86 and 0.60 dl g^{-1}, and the Huggins constant, 0.41 and 0.71, respectively [47].

The structural organization of fibroin after its recovery from an aqueous-salt solution (LiBr–water) and salt-free organic solvents (hexafluoroisopropanol, NMMO) was studied by X-ray diffraction, IR spectroscopy, and DSC [41]. Figure 3 shows the X-ray diffraction patterns of natural fibroin (*Bombyx mori* silk) and fibroin recovered as films from solutions in LiBr–water, hexafluoroisopropanol, and NMMO. The diffraction pattern of natural fibroin (curve *1*) contains a pronounced peak at 2θ = 20.6° and well-defined reflections at 2θ 9.5°, 24.6°, and 25.3°, indicative of the β-folded structure of fibroin [48–53]. The fibroin recovered as a film from an aqueous-salt solution shows a diffuse halo with a maximum at 2θ = 20.5°, characteristic of amorphous or disordered fibroin (curve *2*). The presence of a small amount of fibroin forming an α-helical or β-folded structure is indicated by weak reflections at 2θ 9.50° and 22.0°. The diffraction pattern of the fibroin sample obtained from hexafluoroisopropanol (curve *3*) is virtually identical to that of the sample obtained from the aqueous-salt solution.

The fibroin recovered from the solution in NMMO (curve *4*) has the most ordered structure, approaching natural fibroin in the degree of ordering. This is indicated by peaks at 2θ 20.5° and 24.7°, characteristic of the β-folded ordered structure.

CONCLUSIONS

(1) The conformational state of fibroin macromolecules in solutions depends on the solvent. Fibroin

macromolecules in solution undergo association to an extent that increases in going from aqueous to organic solvents. In aqueous salt systems, the macromolecules mainly exist in the form of random globules, and a disordered secondary structure is observed. In organic and mixed aqueous-organic salt systems, the α-helical and β-folded structures are formed. The prevalence of one or another structure of fibroin depends on a particular organic solvent.

(2) Fibers and films with the prescribed supramolecular organization can be prepared by properly choosing the solvent systems and conditions of the fibroin recovery from the solution.

(3) *N*-Methylmorpholine *N*-oxide is the most promising for development of a technology for fibroin processing into fibers and films, because the step of salt removal, required with salt-containing aqueous, aqueous-organic, and organic solvents, is thus eliminated.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Development of a Technology for Sulfuric Acid Breakdown of a Bertrandite–Phenacite–Fluorite Flotation Concentrate

V. I. Samoilov

Ulba Metal Works AO, Ust Kamenogorsk, East-Kazakhstan oblast, Kazakhstan

Received March 14, 2006

Abstract—The possibility of direct sulfuric acid breakdown of the bertrandite–phenacite–fluorite concentrate from the Ermakovskoe deposit was studied experimentally using samples taken from 23 different batches of the concentrate over the period from 1997 to 2004.

DOI: 10.1134/S1070427206060024

The bertrandite–phenacite–fluorite concentrate manufactured by the Zabaikal'skii mining and ore-dressing plant, which contains 4 wt % beryllium, is a rather new promising type of raw materials for beryllium chemical-metallurgical plants [1]. The industrial use of this concentrate was commenced at the end of the XX century at Ulba Metal Works joint-stock company. The existing technology for processing of the concentrate [2] involves a large number of stages and requires an expensive activating preparation of raw materials for sulfuric acid breakdown, including high-temperature smelting of a mixture of a high-grade bertrandite–phenacite–fluorite concentrate and a low-grade beryl concentrate (containing 2 wt % beryllium) with soda ash and limestone in an ore-smelting furnace (the temperature and duration of the smelting are approximately 1500°C and 4 h). The fusion cake obtained by smelting of the above-mentioned stock in this furnace is granulated in cold water and then is subjected to wet crushing and classification. The thus prepared water pulp of the crushed granulate is condensed and treated with 93% H_2SO_4 (sulfation of the granulate at a temperature of about 100°C in the course of 2 min). After the sulfation, the granulate is leached in water to obtain a beryllium sulfate solution and a poorly soluble silica- and gypsum-containing waste cake. The sulfate solution is neutralized with ammonium hydroxide, which results in the precipitation of the poorly soluble $Be(OH)_2$. The process is characterized by large volumes of ecologically harmful unutilizable beryllium-, silica-, and gypsum-containing cake formed in the stage of sulfuric acid breakdown of granulated fusion cake, by significant loss of beryllium with the cake, and by the formation of a waste mother liquor in the stage of $Be(OH)_2$ precipitation [1–3]. The considerable loss of beryllium with the cake (about 2.5 wt %) is due to use of limestone in the smelting of the concentrates, which leads to formation of gypsum in the sulfation stage and leads to a significant increase in the mass of the waste cake. The considerable loss of beryllium with the mother liquor (approximately 2.5 wt %) is caused by the high content of fluorine in the bertrandite–phenacite–fluorite concentrate (and, as a consequence, in the stock mixture). Further, the main part of fluorine passes into a beryllium sulfate solution and then binds beryllium into stable water-soluble complexes in the stage of $Be(OH)_2$ precipitation. For comparison, less than 1 wt % of beryllium is lost with the mother liquor when a preliminarily defluorinated concentrate (washed with an aluminum nitrate solution to remove fluorite) is used [2]. However, this washing procedure is ineffective because it leads to a considerable loss of beryllium with the nitric acid solution.

A study of the mineralogical composition of the concentrate demonstrated (Table 1) that the content of fluorite, bertrandite, and phenacite varies. A study of the granulometric composition of nine samples of the concentrate (Table 1) showed that the concentrate is composed only of particles with size of 0.12 mm and less (most of particles belong to the –0.064-mm fraction). These particles form unstable conglomerates approximately 1–4 mm in size (about 50 wt % of the concentrate is represented by

the conglomerates). Data on the chemical composition of 19 batches of the concentrate are listed in Table 2.

Research experiments on direct sulfation of 12 batches of the Ermakovskoe concentrate were carried out using a 2.5-l glassy graphite cup covered with a fluoroplastic lid. The concentrate (–0.045 mm fraction or no preliminary sieving into fractions) was mixed with a prescribed amount of 93% H_2SO_4 in the glassy graphite cup placed on an electric heater (the reaction mixture was a jelly-like product). The reaction mass was kept at a prescribed temperature for a prescribed sulfation time. The reaction mixture was periodically agitated with a putty knife. After the sulfation was complete, the sulfated concentrate, which had the form of a semidry mass with lumps, was treated with water (leaching-out of soluble sulfates), the leaching pulp was neutralized with ammonium

Table 3. Results of research experiments on direct sulfuric acid breakdown of the Ermakovskoe concentrate with 93% H_2SO_4; sulfation: 100-g portion of the concentrate; leaching: s : l = 1 : (4–6) (in terms of the starting concentrate), τ = 20 min, T = 95°C, V = const; pulp neutralization to pH 3.0–3.5 (with a 8–10% NH_3 solution); first cake washing with 5% $(NH_4)_2SO_4$ solution acidified with H_2SO_4 to pH 3.0–3.5: s : l = 1 : 7 (in terms of the initial concentrate), τ = 15 min, T = 95°C, V = const; second washing of the cake with 5% $(NH_4)_2SO_4$ solution acidified with H_2SO_4 to pH 3.0–3.5: (see first washing)

hydroxide and filtered, and the silicon-sulfate cake was washed with water to remove the water-soluble beryllium in the standard mode (Table 3).

It follows from the research experiments on direct sulfuric acid breakdown of the Ermakovskoe concentrate (Tables 3 and 4) that the technology tested provides a statistical-average recovery of beryllium from the concentrate into a sulfate solution equal to about 92.4%.

The completeness of beryllium precipitation from the thus prepared sulfate solutions approaches 100%, because an industrially acceptable defluorination of the concentrate (94.8% on the average) is achieved in our experiments (Table 4). Nevertheless, the recovery of beryllium from the raw material into beryllium hydroxide is insufficiently high (about 92%), although a significant reduction in the number of expensive technological operations for recovery of $Be(OH)_2$ from mineral raw materials is achieved.

The reaction of bertrandite and phenacite with H_2SO_4 at the optimal process temperature presumably occurs in accordance with the reaction equations (1) and (2).

$$4BeO \cdot 2SiO_2 \cdot H_2O + 4H_2SO_4 \xrightarrow{550–300°C} 4BeSO_4 + 2SiO_2 + 5H_2O\uparrow, \quad (1)$$

$$2BeO \cdot SiO_2 + 2H_2SO_4 \xrightarrow{250–300°C} 2BeSO_4 + SiO_2 + 2H_2O\uparrow. \quad (2)$$

The mechanism of defluorination of the Ermakovskoe concentrate is based on the reaction of sulfation of its fluorite component:

$$CaF_2 + H_2SO_4 \xrightarrow{250–300°C} CaSO_4 + 2HF\uparrow. \quad (3)$$

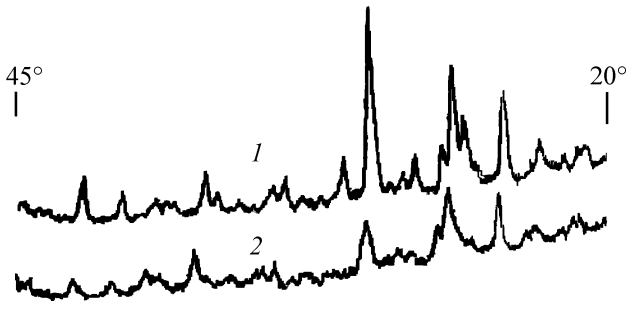
The evolving gaseous hydrogen fluoride intensifies the breakdown of the phenacite–bertrandite component of the concentrate, presumably by reactions (4)–(6).

$$4BeO \cdot 2SiO_2 \cdot H_2O + 16HF \xrightarrow{250–300°C} 4BeF_2 + 2SiF_4\uparrow + 9H_2O\uparrow, \quad (4)$$

$$2BeO \cdot SiO_2 + 8HF \xrightarrow{250–300°C} 2BeF_2 + SiF_4\uparrow + 4H_2O\uparrow, \quad (5)$$

$$BeF_2 + H_2SO_4 \xrightarrow{250–300°C} BeSO_4 + 2HF\uparrow. \quad (6)$$

Thus it may be assumed that the presence of fluorite in the concentrate tested in this study positively affects the recovery of beryllium from the concentrate into a water-soluble sulfate.



To additionally raise the recovery of beryllium from the concentrate, the influence exerted by mechanical activation of this type of beryllium raw materials on the completeness of its breakdown by

* The content of F in combined washing waters 1 and 2 did not exceed hundredths of a gram per liter; recovery of F from the concentrate into combined washing waters 1 and 2 did not exceed 1%.

sulfuric acid was studied. Experiments on crushing of the Ermakovskoe bertrandite–phenacite–fluorite flotation concentrate in the beaker of a laboratory vibrating grinder to –45 μm with the subsequent sulfation of the activated material were carried out (see figure and Table 5).

Results of X-ray structural analysis of the starting and crushed concentrate at reflection angles of 20° to 45°. (*1*) Starting concentrate; (*2*) concentrate (100 g) crushed on a vibrating grinder (τ_{cr} = 40 min).

An X-ray structural analysis of the concentrate demonstrated (see figure) that crushing of the concentrate on a vibrating grinder leads to partial destruction of the crystal lattices of the minerals contained in the concentrate.

As follows from Table 5, crushing of the Ermakovskoe concentrate on a vibrating grinder provides a high recovery of beryllium into a sulfate solution (at a level of 96.7%) with a simultaneous (~96%) defluorination of the concentrate, which results in that beryllium is almost completely (99.9 % [2]) recovered from the sulfate solution into $Be(OH)_2$ in the following stage. The recovery of beryllium from the raw material into beryllium hydroxide is 96.6%.

Comparative analysis of the data in Tables 4 and 5 shows that preliminary crushing of the Ermakovskoe concentrate makes it possible to raise the completeness of its breakdown with sulfuric acid from 92.4% (completeness of breakdown of a nonactivated concen-

trate) to 96.7%. Dry-grinding ball mills can be recommended for the industrial implementation of the process for crushing of the Ermakovskoe concentrate. The experience of the Brash Wellman plant, which employs dry crushing of thermally activated beryl in ball mills prior to sulfation [2, 3], can be used in this case.

CONCLUSIONS

(1) Application of a mechanical activation of the bertrandite–phenacite–fluorite concentrate makes it possible to reduce the number of preparatory operations before its sulfation from six to one and to rule out use of expensive fluxes, stock smelting, and granulate crushing.

(2) The presented technology of sulfation of a mechanically activated concentrate makes it possible to raise the recovery of beryllium from raw materials into $Be(OH)_2$ approximately from 95 to 96.5% and to reduce the volumes of both the ecologically harmful waste cake and the mother liquor.

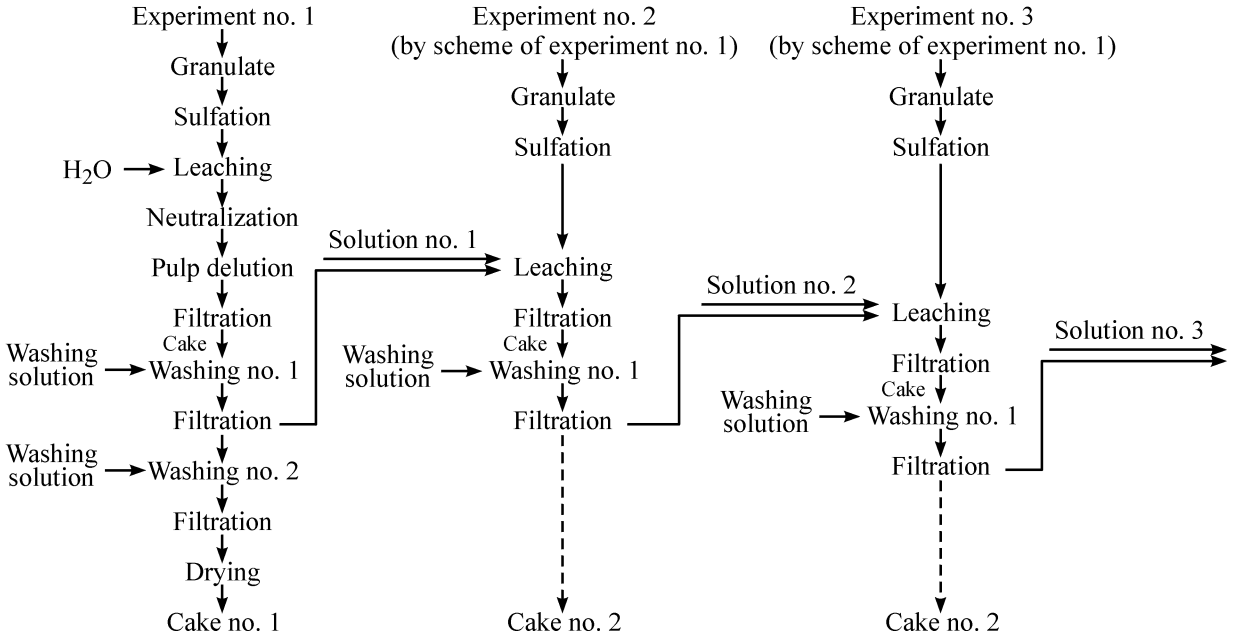
Received March 14, 2006



Abstract—The possibility of purifying a sulfate solution to remove silicon and calcium by concentrating beryllium in this solution was studied.

DOI: 10.1134/S1070427206060036

The classical sulfuric acid technology of beryllium recovery from low-grade ores has essential drawbacks. These are the low beryllium content in the sulfate solution formed in the stage of sulfuric acid breakdown of granulated fusion cakes produced from the stock composed of beryllium ore concentrates, soda ash, and limestone (approximately 1–2 g l^{-1}), and the high content of silicon and calcium in this solution (about several tens of percent relative to beryllium) [1–4].

In this study, we tested three procedures for concentration of beryllium in a sulfate solution. According to the first procedure, the granulate from the Ulba Metal Works joint-stock company was decomposed by the scheme presented below. (The shop granulate, obtained by fusion of beryl and bertrandite–phenacite–fluorite concentrates with soda and limestone, contained (wt %): Be 2.21, Al 6.99, Fe 2.28, Ca 10.48, Si 19.03, Mn 0.40, and Cr 0.015.)

In the breakdown of the shop granulate, it was sulfated by mixing a weighed portion of the granulate (25 g) with water at a rate of 0.8 ml per 1 g of the granulate (see scheme). The thus obtained water-granulate pulp was treated with 93% sulfuric acid (0.8 ml per 1 g of the granulate). In the first run,

Technological scheme of beryllium concentration in sulfate solutions.

* Content of H_2SO_4 in a sulfate solution at the instant of termination of leaching of sulfates was 29.4–37.2 g l^{-1} (run nos. 1–4, series 4).

the sulfates obtained by sulfation of the granulate were leached with water for 20 min at 80–95°C and s : l = 1 : 5 (in terms of the granulate) with stirring. In the following runs, the leaching was done with stock sulfate solutions (with addition of the first washing water in required amounts) obtained in the preceding run. In this case, water-soluble beryllium, aluminum, and iron sulfates and other admixtures pass into solution. The insoluble residue mostly consists of gel-like silicic acid $SiO_2 \cdot nH_2O$ and hydrated gypsum $CaSO_4 \cdot 2H_2O$. The resulting pulp was neutralized with 8–10% ammonium hydroxide to pH 3.0–3.5 and diluted with hot water to s : l = 1 : 10 (in terms of the granulate) (see scheme).

Then the pulp was delivered to filtration to be separated into a liquid phase (stock solution of sulfates) and cake. The filtered sulfate solution was analyzed for the content of beryllium and limited impurities and delivered to the following stage of leaching-out of sulfates (see scheme). The filtered-off cake was washed to remove water-soluble beryllium with an ammonium sulfate solution (concentration 50 g l^{-1}) acidified with sulfuric acid to pH 3.0–3.5 for 15 min at s : l = 1 : 7 (in terms of the granulate) and temperature of 80–95°C. Then the resulting pulp was filtered, and the filtered-off cake was again washed to remove water-soluble beryllium. In this case, the filtrate from the stage of the first cake washing was used to compensate for the deficiency of the main solution to be used for leaching a next portion of a sulfated granulate (see scheme). The mode of repeated cake washing is similar to that of its first washing. The cake filtered-off after the repeated washing was dried to constant weight and analyzed for the content of beryllium.

The results of experiments on concentration of beryllium and impurities in a sulfate solution are listed in Table 1.

* Content of H_2SO_4 in solution at the instant of termination of leaching of sulfates was 24.5–36.8 g l^{-1} in run nos. 1 of series 5–8 and 63.7–90.7 g l^{-1} in final runs of series 5–8.

It is seen from Table 1 that three to four turnovers of the stock sulfate solution, with its recycling to the "head" of the process, resulted in that the beryllium content increased, on average, from 2.25 (run nos. 1, series 1–4) to 4.57 g l^{-1} (run no. 4, series 1; run no. 5, series 2 and 3; run no. 4, series 4). In this case, the beryllium content in the cake did not exceed the admissible value of 0.15 wt %. Further increase in the number of solution turnovers in series 1–4 does not raise the beryllium content in them, presumably, because of the supersaturation of the solutions with sulfates of ammonium, aluminum, iron, etc. After five to six cycles of series 1–4, the solutions became viscous and the rate of their filtration decreased. A large amount of ammonium alum crystallized from the thus obtained solutions upon their cooling.

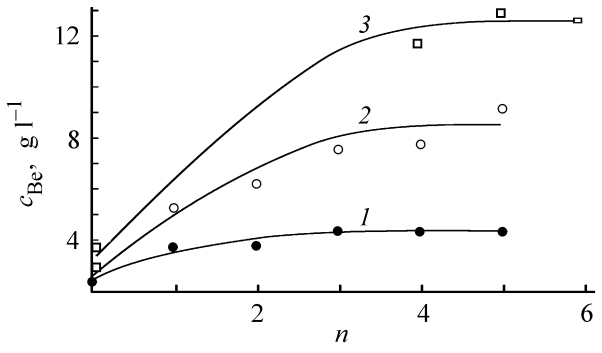
The degrees of purification of the sulfate solution to remove impurities are listed in Table 1. It can be seen 1 that the concentration of beryllium in the sulfate solution resulted in its deep purification to remove silicon (whose content decreased by a factor of 5) and noticeable purification to remove calcium (by approximately a factor of 1.6).

The second technological scheme of beryllium concentration in sulfate solutions was studied on an enlarged laboratory scale. Similarly to the preceding runs (see scheme and Table 1), the breakdown of a 25-g portion of a shop granulate (the same granulate as that in the first scheme) was performed by its sulfation. In the first run, the sulfates obtained in the sulfation of the granulate were leached with water for 20 min at s : l = 1 : 5 (in terms of the granulate) and 80–95 °C with stirring. In the subsequent runs, this was done using stock sulfate solutions (mixed with the first washing water in the case of their deficiency) obtained in the preceding run. Unlike the first scheme, the resulting pulp was delivered to filtration without neutralization and dilution to be separated into a liquid phase (stock solution of sulfates) and a cake. The filtered sulfate solution was analyzed for the content of beryllium and limited impurities and delivered to the following stage of leaching of sulfates. The filtered-off cake was washed to remove water-soluble beryllium with an acidified solution of ammonium sulfate. The filtrate from the stage of the first cake washing was used to compensate for the deficiency of the stock solution for leaching of the next portion of a sulfated granulate (see scheme).

The results of the experiments on concentration of beryllium in a sulfate solution are listed in Table 2. It can be seen that the content of beryllium in solution after 3–5 turnovers of the stock sulfate solution increased, on average, from 2.94 (run nos. 1, series 5–8) to 8.74 g l^{-1} (run no. 4, series 5; run no. 5, series 6 and 7; run no. 6, series 8). In this case, the content of beryllium in the cake did not exceed the admissible value of 0.15 wt %. It follows from the data in Table 2 that further increase in the number of turnovers does not provide an additional rise in the beryllium content in the stock solution because of the formation of solutions saturated with sulfuric acid and sulfates of aluminum, iron, beryllium, etc. In the course of the experiment, we estimated the completeness of purification of the sulfate solution to remove impurities (Table 2). It follows from Table 2 that a deep purification of this solution to remove silicon (by approximately a factor of 41) and calcium (by approximately a factor of 5) was achieved in the course of concentration of beryllium in the sulfate solution.

According to the third technological scheme, the breakdown of the shop granulate and concentration of beryllium in a sulfate solution were carried out as follows [shop granulate contained (wt %): Be 2.34, Al 2.65, Fe 2.28, Ca 10.10, Si 19.09, Mn 0.49, and Cr 0.034; the granulate was produced by fusion of beryl and bertrandite–phenacite–fluorite concentrates with soda and limestone]. As in the preceding series of experiments, the breakdown of 25-g weighed portions of the shop granulate was performed by its sulfation in the standard mode. In the first run, sulfates obtained by the sulfation of the granulate were leached with water, and in the following runs, this was done with stock sulfate solutions mixed with the first washing water obtained in the preceding run. The pulp obtained in leaching was delivered to filtering without neutralization and dilution. The filtered sulfate solution was analyzed for the content of beryllium and the main impurities and delivered to the following stage of leaching of the sulfates. In the first run, the filtered-off cake was washed to remove water-soluble beryllium with a solution of ammonium sulfate at pH 3.0–3.5. In the following runs, the cake was washed with the first washing water obtained in the preceding run via filtration of the pulp after the first washing of the cake. If the amount of the first washing water was insufficient, it was mixed with the second washing water. Then the resulting pulp was filtered and the filtered-off cake was repeatedly washed to remove watersoluble beryllium. The mode of the repeated washing of the cake was similar to that of the first washing: in the first run, an ammonium sulfate solution with pH 3.0–3.5 was used, and in the following runs, the second washing water from the preceding run, whose deficiency was compensated for by adding a fresh washing solution. The cake filtered-off after the repeated washing was dried to constant weight and analyzed for the beryllium content.

The results of the experiments on concentration of beryllium in a sulfate solution by the third technological scheme are listed in Table 3. It can be seen that the technological variant we tested provides, after five to six turnovers of the stock sulfate solution, an average increase in the beryllium content from 3.78 (run nos. 1 of series 9–11) to 13.30 g l^{-1} (run no. 6 of series 9; run no. 6 of series 10; run no. 7 of series 11). In this case, the content of beryllium in the cake did not exceed the admissible value of 0.15 wt %. Further increase in the number of turnovers of the solutions (Table 3) does not provide any additional rise in the beryllium content in the sulfate solution because of the formation of solutions saturated with sulfuric acid and sulfates of aluminum, iron, beryllium, etc.



In the course of the experiment, we estimated the completeness of purification of the stock sulfate solution to remove impurities (Table 3). It follows

Table 3. Results of experiments on concentration of beryllium in a sulfate solution*

* Content of H_2SO_4 in solution at the instant of termination of leaching of sulfates was 39.2–44.1 g l^{-1} in run nos. 1 of series 9–11 and 124.0–128.9 g l^{-1} in the final runs of series 9–11.

from the data in Table 3 that a deep purification of the sulfate solution to remove silicon (by approximately a factor of 372) and calcium (by approximately a factor of 6) is achieved in the process of beryllium concentration.

Dependence of the beryllium contents c_{Be} in a sulfate solution on the number of its recyclings to the "head" of the process. Technological scheme: (*1*) first (Table 1), (*2*) second (Table 2), and (*3*) third (Table 3).

Comparison of the three variants of the technological scheme we tested shows that the last of these is the most efficient in concentration of beryllium in a sulfate solution (see figure) and in purification of this solution to remove calcium and silicon impurities (Tables 1–3).

As follows from the figure (curve *3*), the process we developed can significantly raise the content of beryllium in a sulfate solution. This can, accordingly, diminish the energy consumption in the production process and the volumes of ecologically harmful unutilizable mother liquor formed in the stage of $Be(OH)_2$ precipitation from the sulfate solution with ammonia [4]. As for removal of silicon and calcium from the sulfate solution, the process we developed (Table 3) makes it possible to reduce the content of

these impurities in solution by approximately factors of 372 and 6, respectively.

CONCLUSIONS

(1) The technological process developed for processing of a beryllium sulfate solution formed in the stage of sulfuric acid breakdown of mineral raw materials makes it possible to raise many-fold the content of beryllium and drastically reduce the content of silicon and calcium in this solution.

(2) The technology developed provides a significant increase in the economic efficiency of the beryllium chemical-metallurgical process and in its ecological safety.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Leaching-out of Scandium(III) in Processing of a Fluoride Concentrate

Yu. V. Sokolova and R. N. Cherepanin

Moscow Institute of Steel and Alloys, Moscow, Russia

Received February 17, 2005; in final form, January 2006

Abstract—Leaching-out of scandium(III) from a fluoride concentrate with a solution of ammonium hydrofluoride is analyzed. Results of a kinetic experiment on leaching-out of scandium(III) at various temperatures and reagent concentrations are presented. The basic characteristics of the process are calculated: activation energy, reaction order with respect to the reagent, and rate constant. Specific features of the process of leaching-out of scandium(III) from a fluoride concentrate are demonstrated.

DOI: 10.1134/S1070427206060048

Recovery of scandium(III) in processing of a uranium ore, zircon, ilmenite [1], and silicate-carbonate ore [2] yields fluoride concentrates with varied content of scandium(III). The conventional methods for decomposition of fluoride concentrates are leaching with a 15–20% NaOH solution at 75–90°C (or fusion with the alkali) and dissolution in concentrated sulfuric acid at the boiling point of the solution [1, 3]. In [1], in processing of thortveitite, a mixture of metal compounds was isolated from the resulting fluoride concentrate of scandium(III); further, this mixture was dissolved in hydrochloric acid and impurities were separated.

This study is concerned with the kinetics of leaching-out of scandium(III) with an ammonium hydrofluoride solution from a fluoride concentrate produced in utilization of wastes that are formed in manufacture of Al + 2% Sc alloy by aluminothermy and contain 1.5–1.7% Sc.

EXPERIMENTAL

The leaching was performed in a thermostated fluoroplastic reactor equipped with a stirrer at solution volume to concentrate mass ratio of 10. The insoluble residue was separated by filtration through a "wide-band" filter.

For analytical purposes, a weighed portion of the fluoride concentrate was fused with potassium hydroxide at a temperature of 500°C in the course of 15 min, and the fusion cake was dissolved in hydrochloric acid. The concentration of Sc(III) in solution was determined by emission spectroscopy with inductively coupled plasma on a Labtam V-310 Plasma Spectrometer and Perkin Elmer Model 300 AA Spectrometer. The lower determination limit of Sc(III) was 10^{-6}%.

The phase composition of the concentrate was studied by means of X-ray phase analysis on a DRON-1 instrument with Fe_{K_α} radiation. The determination accuracy of interplanar spacings was 5×10^{-3} Å, the lower determination limit of phases in multiple-phase and discrete systems was 1%.

The degree of leaching-out, α, was calculated as the ratio of the Sc(III) mass in solution to that in the concentrate. All the procedures involving fluoride salts were performed in fluoroplastic or polyethylene vessels. Nickel crucibles were used in fusion.

The fluoride concentrate of scandium(III), used in the study, was produced by grinding and water-leaching of a salt flux formed in manufacture of the Al + 2% Sc alloy. According to the results of a microscopic study, particles of the concentrate have the shape of prisms of size 10 to 200 μm (predominantly 10–60 μm), i.e., the concentrate is a polydisperse material composed of isometric particles.

According to X-ray phase analysis, the fluoride concentrate of scandium(III) (FC) contains hexafluoroaluminate of potassium and sodium, K_2NaAlF_6, as the main substance. Scandium is represented by several phases: scandium(III) oxide; mixed oxide of scandium and aluminum, $(Al, Sc)_2O_3$; and a minor amount of an intermetallic compound Al_3Sc and a complex salt Na_3ScF_6 [4]. Therefore, it should be

kept in mind when discussing the kinetics of Sc(III) leaching-out from FC that the process includes several concurrent reactions, the main of which can be expressed by the equations

$$Sc_2O_{3(cake)} + 6NH_4HF_{2(sol)} \rightarrow 2(NH_4)_3ScF_{6(sol)} + 3H_2O_{(l)}, \quad (1)$$

$$(Al, Sc)_2O_{3(cake)} + 6NH_4HF_{2(sol)} \rightarrow (NH_4)_3AlF_{6(sol)} + (NH_4)_3ScF_{6(sol)} + 3H_2O_{(l)}. \quad (2)$$

The kinetics of scandium(III) leaching-out from FC was studied at NH_4HF_2 concentrations in the range 0.8–2.8 M at 20–90°C. According to the results obtained, the process rate is independent of the agitation intensity in a wide range of variation of the rotation speed of the stirrer. As specific features of the process should be mentioned the small change in the NH_4HF_2 concentration under conditions of a manyfold excess of the reagent and the insignificant loss of mass (7–8%).

The kinetic curves of leaching-out of scandium(III) at various NH_4HF_2 concentrations are shown in Fig. 1. The degree of leaching-out of scandium(III) markedly increases on passing from a 4% to a 10% solution of the reagent, but grows only slightly as the NH_4HF_2 concentration is raised further. The rate of the process substantially increases with the NH_4HF_2 concentration and decreases in the course of leaching. In this case, the Van't Hoff method [5] can be used to determine the process order with respect to the reagent. Figure 2 shows the data in the $\log v$–$\log c$ coordinates, where the reaction rate v is calculated as the ratio $\Delta\alpha/\Delta\tau$ (τ is time) for a degree of leaching equal to 0.6. The linear run of the dependence makes it possible to determine the process order with respect to the reagent as the slope of the straight line in the chosen coordinates. In the case in question, the reaction order is 0.54 ± 0.01.

The data obtained enable calculation of the rate constant at T = 90°C as the intercept on the abscissa axis for a reagent concentration of 1 M. The rate constant is $(10.2 \pm 0.2) \times 10^{-3}$ mol s^{-1}. The equation for calculating the rate of scandium(III) leaching-out of from FC for a temperature of 90°C has the form

$$\log v = -10.2 \times 10^{-3} - 0.54 \log c, \quad (3)$$

where c is the NH_4HF_2 concentration (M).

The kinetic curves of scandium(III) leaching-out of from FC with a 15% solution of NH_4HF_2 at 20–90°C are shown in Fig. 3. The data obtained point to a strong dependence of the degree of leaching and process rate on temperature. The highest values of α were obtained at 90°C, with the equilibrium attained in 2 h.

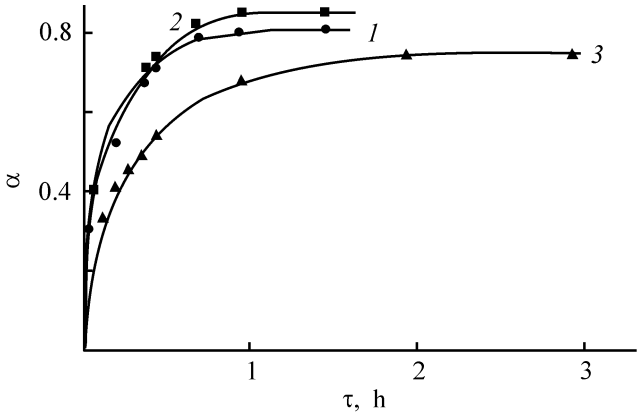

Fig. 1. Kinetics of leaching-out of scandium(III) from FC with an NH_4HF_2 solution at 90°C. (α) Degree of leaching-out of scandium and (τ) time; the same for Fig. 3. $c_{NH_4HF_2}$ (wt %): (*1*) 15, (*2*) 10, and (*3*) 4.

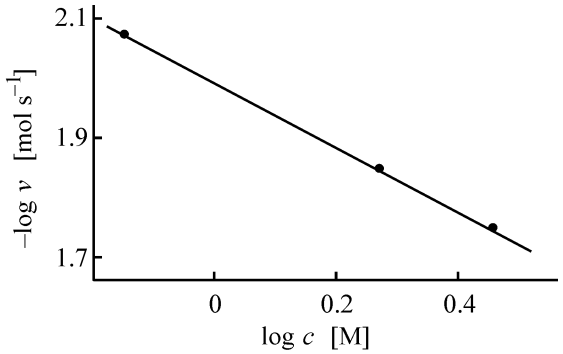

Fig. 2. Rate v of leaching-out of scandium(III) from FC vs. the NH_4HF_2 concentration c (T = 90°C).

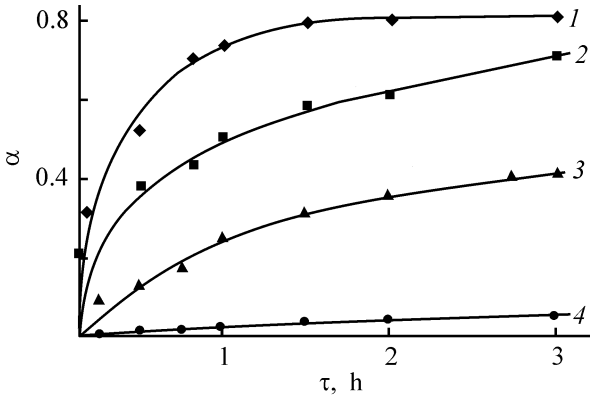

Fig. 3. Kinetics of leaching-out of scandium(III) from FC with a 15% NH_4HF_2 solution. Temperature (°C): (*1*) 90, (*2*) 70, (*3*) 50, and (*4*) 20.

In order to determine the activation energy of the process, the experimental data are plotted in

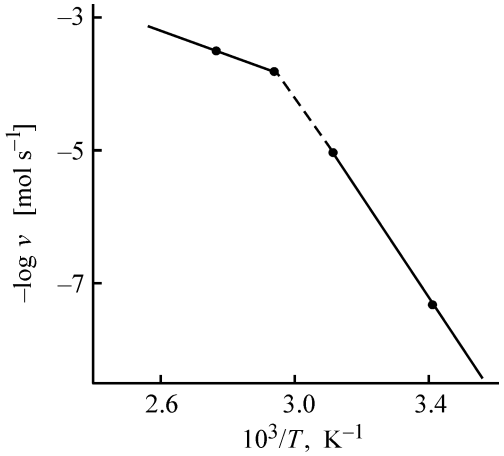

Fig. 4. Rate v of leaching-out of scandium(III) vs. temperature T.

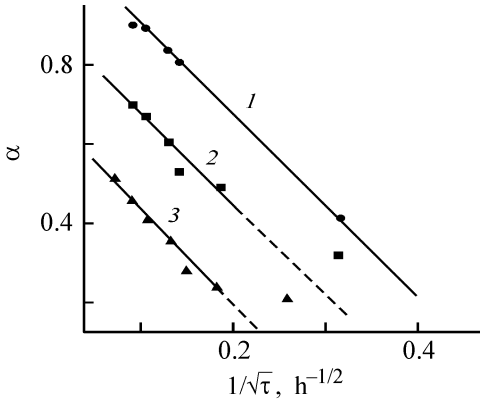

Fig. 5. Degree α of leaching-out of scandium(III) from FC with a 15% NH_4HF_2 solution vs. time τ. Temperature (°C): (*1*) 90, (*2*) 70, and (*3*) 50.

Fig. 4 in the $\ln v$–$1/T$ coordinates. The absence of a linear dependence in this case may be due to simultaneous occurrence of two reactions with different activation energies [6] or to a change of the rate-determining stage of the process with increasing temperature. In the temperature range 20–50°C, the apparent activation energy is 64.7 ± 1.5 kJ mol^{-1}, which indicates that the process occurs in the kinetic mode. In the range 70–90°C, the apparent activation energy is 19.4 ± 0.5 kJ mol^{-1}, which is a characteristic indication that the process occurs in the inner-diffusion region. As the temperature and the degree of leaching increase, the thickness of a layer of waste (leached) rock grows, i.e., the diffusion path for the reagent or leaching product becomes longer and, therefore the diffusion resistance grows. In this case, the amount of diffused substance (and, in the case of diffusion hindrance, the degree of leaching, as well) is proportional to $\sqrt{\tau}$ (τ is time), provided that the reagent concentration and the surface area of the material change only slightly [6]. Figure 5 shows the dependence of the degree of leaching on $1/\sqrt{\tau}$ for the temperature range under study. The dependence is linear only at 90°C, which is evidence that the rate-determining stage changes on passing to the diffusion mode. Therefore, the existence of a break in the given case suggests that the rate-determining stage of the process changes: the process occurs in the kinetic region at temperatures below 70°C, and inner diffusion is the rate-determining stage at above 70°C.

The data obtained make it possible to optimize the conditions of leaching-out of scandium(III) from FC and to suggest ways to intensify the process under study.

CONCLUSIONS

(1) The kinetics of leaching-out of scandium(III) from a fluoride concentrate with a solution of ammonium hydrofluoride was studied. It was shown that the process rate increases with temperature and reagent concentration.

(2) It was found that the process order with respect to the reagent is 0.54 ± 0.01. At temperatures below 70°C, the process occurs in the kinetic mode (apparent activation energy $E_a = 64.7 \pm 1.5$ kJ mol^{-1}), and at temperature of 70°C and more, in the diffusion mode ($E_a = 19.4 \pm 0.5$ kJ mol^{-1}).

(3) It was shown that the dependence of the rate of leaching-out of scandium(III) on the reagent concentration at a temperature of 90°C is described by Eq. (3).

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Synthesis of Zinc and Copper Borates in a Single Technological Cycle

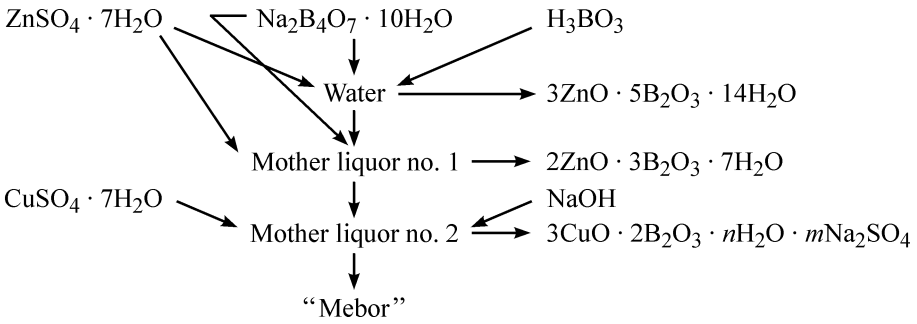
E. M. Shvarts and R. G. Belousova

Institute of Inorganic Chemistry, Riga Technical University, Salaspils, Latvia

Received December 21, 2005

Abstract—A zero-waste technology was developed for obtaining in a single technological cycle four valuable products: combustion retarder $Zn_3B_{10}O_{18} \cdot 14H_2O$, microfertilizer $2ZnO \cdot 3B_2O_3 \cdot 7H_2O$, copper borate $3CuO \cdot 2B_2O_3 \cdot nH_2O \cdot mNa_2SO_4$, and wood antiseptic "Mebor."

DOI: 10.1134/S107042720606005X



Many zinc borates are known. Among them are various hydrates $2ZnO \cdot 3B_2O_3 \cdot nH_2O$ (n 7.5, 7, 5, 4, 3.2–3.7) [1]. Most of them are obtained from zinc sulfate, sodium tetraborate, zinc carbonate, zinc oxide or hydroxide, and boric acid under various conditions. The hydrate containing 3.2–3.7 molecules of crystallization water, obtained from zinc chloride, sodium tetraborate, and sodium hydroxide on heating [2], is the most important. Zinc borate $2ZnO \cdot 3B_2O_3 \cdot (3.2–3.7)H_2O$ is widely used under the brand name "Firebrake" as a synergetic additive to halogen-containing antipyrenes and antimony oxides to protect polyvinyl chloride, polyesters, polyolefines, and rigid polyurethanes against fire.

In 1993, zinc borates, $4ZnO \cdot B_2O_3 \cdot H_2O$ and $4ZnO \cdot B_2O_3$, were obtained by the reaction of zinc oxide or its corresponding salt with boric acid or with its salts in water at high temperature. It was also suggested to use these borates as fire retarding and smoke suppressing additives to organic polymers [3]. Also, a borate $Zn_3 \cdot B_{10}O_{18} \cdot 14H_2O$ (3-5-14) is known. It was first synthesized by Putnin' and Jevin'sh [4] but failed to find application in industry because of the low yield. The authors of [5] developed a method for synthesizing zinc borate $Zn_3 \cdot B_{10}O_{18} \cdot 14H_2O$ in a 80–94% yield.

As for copper borates, their amorphous {$2CuO \cdot B_2O_3 \cdot H_2O$ and $3CuO \cdot 2B_2O_3 \cdot nH_2O$ (n 1, 2, 4, 5) [6]}, crystalline {bandylite $CuB(OH)_4Cl$ [7] and henmilite $[Ca_2Cu(OH)_4B(OH)_4]_2$ [8]} minerals, and synthetic borates {$Na_6Cu_2[B_{16}O_{24}(OH)_{10}] \cdot 12H_2O$ [9], $K_5HCu_4O[B_{20}O_{32}(OH)_8] \cdot 32H_2O$ [10], and $Cu(NH_3)_4B_4O_7 \cdot 6H_2O$ [11]} are known.

Synthesis of $Zn_3 \cdot B_{10}O_{18} \cdot 14H_2O$ yields a mother liquor containing (g l^{-1}): B(III) ~10 and Zn(II) 4.22.

The goal of our study was to develop methods that involve utilization of the forming wastewater. We achieved this by developing a zero-waste cycle that simultaneously yielded four valuable products: $Zn_3 \cdot B_{10}O_{18} \cdot 14H_2O$ ("Pyroteran"), dizinc hexaborate heptahydrate $2ZnO \cdot 3B_2O_3 \cdot 7H_2O$ (2-3-7) (BZn), copper borate $3CuO \cdot 2B_2O_3 \cdot nH_2O \cdot mNa_2SO_4$ (BCu), and wood antiseptic "Mebor." An example of a zero-waste cycle for joint synthesis of 3-5-14, 2-3-7 zinc borates and copper borate is presented in the scheme.

Scheme for synthesis of zinc and copper borates in a single cycle.

Results of analyses of zinc and copper borates

Borate	Main components	Composition, wt %		X-ray diffraction patterns	
		found	calculated	D, Å	Intensity, %
$3ZnO \cdot 5B_2O_3 \cdot 14H_2O$	ZnO	29.30	29.91	9.591	100
	B_2O_3	40.82	41.21	6.689	100
	H_2O	30.58	29.88	2.935	80
$2ZnO \cdot 3B_2O_3 \cdot 7H_2O$	ZnO	32.66	32.70	6.79	100
	B_2O_3	41.60	41.98	3.36	80
	H_2O	25.65	25.35	3.02	80
$3CuO \cdot 2B_2O_3 \cdot nH_2O \cdot mNa_2SO_4$	CuO	39.90			
	B_2O_3	26.60			
	Na_2SO_4	10.30			
	H_2O	21.30			
	ZnO	2.50			

The 3-5-14 zinc borate was obtained by reacting zinc sulfate solutions and a solution containing borax and boric acid under heating, with stirring of the reaction mixture and isolation of a crystalline 3-5-14 zinc borate from mother liquor no. 1 by filtration. Mother liquor no. 1 was used to obtain a 2-3-7 zinc borate. To mother liquor no. 1 we added calculated amounts of borax and zinc sulfate (both dry). After the reaction mixture was heated and stirred, crystalline zinc borate was filtered off. The remaining mother liquor no. 2 was used to synthesize copper borate.

Copper borate was obtained by addition of calculated amounts of copper sulfate and sodium hydroxide. Mother liquor no. 3, obtained upon separation of copper borate, corresponds in composition to the known wood preservative "Mebor."

The 3-5-14 zinc borate can be used as nontoxic fire-retarding additive to lacquers, paints, and polymer materials, and as a constituent of fireproofing formulations for impregnation of wood. It is effective even in the absence of antimony halides and oxides [12]. The 2-3-7 zinc borate and copper borate can be used as microfertilizers for a presowing seed treatment of vegetables, flax, sugar beet, and other cultures [13].

EXPERIMENTAL

Trizinc decaborate tetradecahydrate $Zn_3 \cdot B_{10}O_{18} \cdot 14H_2O$. Borax $Na_2B_4O_7 \cdot 10H_2O$ (38.1 g) and boric acid (61.8 g) were dissolved in 800 ml of distilled water, and zinc sulfate $ZnSO_4 \cdot 7H_2O$ (28.8 g), in 200 ml. Both solutions were poured into a 2-l flask and heated to 30–40°C under mechanical agitation to complete crystallization of amorphous precipitate (~6 h).

The crystalline precipitate was filtered off, washed with 100 ml of warm water, and dried in air to give 26.5 g of 3-5-14 zinc borate (in 94% yield), identified by X-ray analysis. This is a white crystalline substance in the form of very fine needles. The results of the analysis are listed in the table.

Dizinc hexaborate heptahydrate $Zn_2 \cdot B_6O_{11} \cdot 7H_2O$. After separation of 3-5-14 zinc borate, mother liquor no. 1 contains 4.22 g l^{-1} Zn(II) and 10.03 g l^{-1} B(III). The mother liquor was heated in a 2-l round-bottomed flask to 50–60°C, and then 39.45 g zinc sulfate was dissolved in it. After that, 78.48 g of borax was added and agitation was continued until an amorphous precipitate was formed. The precipitate crystallized in 4 h under heating and stirring. The crystals were filtered off, washed with warm water (50 ml), and dried in air. The 2-3-7 zinc borate (49.28 g) was obtained in 96% yield, identified by chemical analysis (see table).

Copper borate. Mother liquor no. 2, containing Zn(II) (2.27 g l^{-1}) and B(III) (11.62 g l^{-1}), was used to obtain copper borate. Copper sulfate $CuSO_4 \cdot 5H_2O$ (88.73 g) was dissolved in 140 ml of distilled water under heating, and 42 g of NaOH was dissolved in 72 ml of distilled water. A copper sulfate solution was added to mother liquor no. 2, placed in a 2-l round-bottomed flask and agitated with a mechanical stirrer. A NaOH solution was added in small portions under agitation, the temperature was raised to 80°C, and the solution was stirred for 4 h. The resulting

blue precipitate was filtered off from a hot solution, washed with 100 ml of warm 1% boric acid, and dried in air to give the product (75.6 g) in 96.5% yield. The composition of the product is listed in the table.

Copper borate is a blue finely dispersed amorphous powder with admixture of sodium sulfate, whose content depends on its concentration in mother liquor no. 2. The product has the formula $3CuO \cdot 2B_2O_3 \cdot nH_2O \cdot mNa_2SO_4$. In this case, the ZnO content can be disregarded. The product is insoluble in water.

Precipitation of zinc and copper borates in a common process yields mother liquor no. 3. It contains (wt %): 0.002 CuO, 1.77 B_2O_3, and 5.75 Na_2SO_4 and can be used as a preservative for plywood and lumber.

CONCLUSIONS

(1) Zinc and copper borates, $3ZnO \cdot 5B_2O_3 \cdot 14H_2O$, $2ZnO \cdot 3B_2O_3 \cdot 7H_2O$, and $3CuO \cdot 2B_2O_3 \cdot nH_2O \cdot mNa_2SO_4$, were obtained by the reaction of the corresponding sulfates and borax in the presence of boric acid or sodium hydroxide in a single technological cycle.

(2) The mother liquors obtained, which are saturated solutions of boric acid, are used for further synthesis of zinc borates.

(3) The borates obtained can be used as a fire-retarding and smoke-suppressing additives and a microfertilizers for presowing seed treatment of vegetable cultures and flax.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

High-Temperature Oxidation of Titanium, Zirconium, and Hafniyum in Steam

V. I. D'yachkov

St. Petersburg State University, St. Petersburg, Russia

Received February 1, 2006

Abstract—The influence exerted by the nature of titanium, zirconium, and hafnium on the kinetic parameters of oxidation and on the diffusion mechanism of scale formation in steam at 973–1473 K is analyzed. The results obtained are compared with the data for the air medium.

DOI: 10.1134/S1070427206060061

In the preceding paper [1], the results obtained in systematic studies of the influence exerted by the physical and chemical properties of Ti, Zr, and Hf on their behavior in oxidation in air at 973–1473 K were reported. The present study was undertaken with a similar purpose to examine a technologically important medium of steam in the same temperature interval. The main goal was to reveal how specific features of the nature of these elements and their dioxides affect the oxidation rate and the type of the oxidation law, the temperature dependence of the rate constants and activation energy of this process, diffusion mechanism of scale formation, and properties of scale.

The tests were performed in a dynamic medium of steam at a pressure of 101.3 kPa and flow velocity of 0.06 m s^{-1}. The procedure used to prepare samples of refined Ti, Zr, and Hf of high purity (99.93 Ti, 99.80 Zr, 99.70 Hf) remelted in an electromagnetic crucible in the atmosphere of purified argon and the experimental procedures employed were described in [1–5]. In particular, metals were analyzed for the content of hydrogen by the spectral-isotopic method with an accuracy of ±(5–7)% [5].

According to [1–4, 6–9] and to the summary in Table 1, the oxidation rate of Ti in steam at 973–1473 K markedly exceeds that of Zr and, especially, Hf. In contrast to Ti, for which replacement of air with steam leads to a dramatic increase in the overall oxidation rate, the opposite is observed for Zr and Hf, which was previously found for Zr in [10]. This means that the mechanism responsible for the increase in the oxidation rate of Ti in the case when hydrogen from steam is involved [6, 7] is not operative for Zr and Hf.

A processing of the oxidation curves revealed the applicability of the Evans equation [11]:

$$K_{lin}q^2 + K_p q = K_{lin}K_p\tau + C, \quad (1)$$

and parabolic

$$q^2 = K_p\tau + C, \quad (2)$$

and cubic laws

$$q^3 = K_c\tau + C. \quad (3)$$

Here, q is mass; τ, time; C, constant; and K_{lin}, K_p, and K_c oxidation rate constants by the linear, parabolic, and cubic laws, respectively.

In contrast to the air medium [1], no linear oxidation law was revealed in the case of steam, whereas it is obeyed in the initial stage of Ti oxidation at 923–1123 K and then gives way to the parabolic behavior. In the case of strong deviations of the oxidation rate in steam from the laws (2), (3), which are observed more frequently as compared with air, the results can be formally represented by the expression

$$q^n = K\tau + C \quad (4)$$

at different values of the exponent n.

The results concerning the type of the kinetic laws of oxidation of Ti, Zr, and Hf are summarized in Table 2, in which the temperature range and duration of their action are given in parentheses, together with the value of n in expression (4). It can be seen that, at least during 3 h at 973–1423 K and 2 h at 1473 K, the oxidation rate of Ti is totally governed by the Evans equation (Fig. 1). This indicates that the oxida-

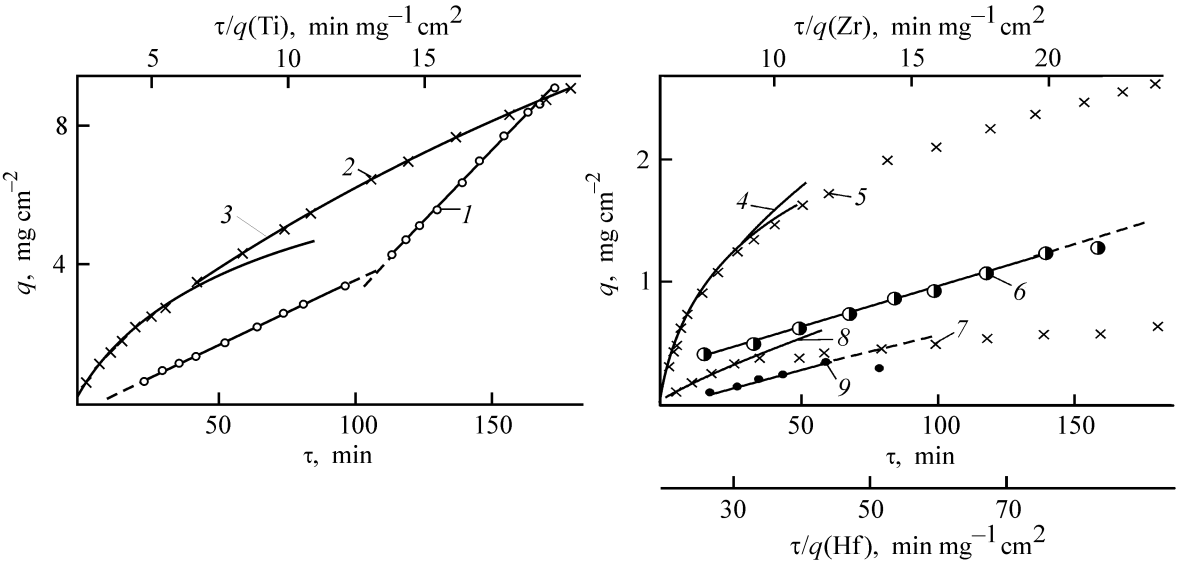

Fig. 1. (*1*, *6*, *9*) Data on oxidation of (*1–3*) titanium, (*4–6*) zirconium, and (*7–9*) hafnium in steam, plotted in the coordinates of the Evans equation, and (*2*, *5*, *7*) positions of the experimental points with respect to (*3*, *4*, *8*) curves described by the Evans equation, plotted with the use of the K_{lin} and K_p values obtained. (*q*) Mass and (τ) time. Temperature (K): (*1–3*, *7–9*) 1073 and (*4–6*) 1023; the same for Figs. 2, 3.

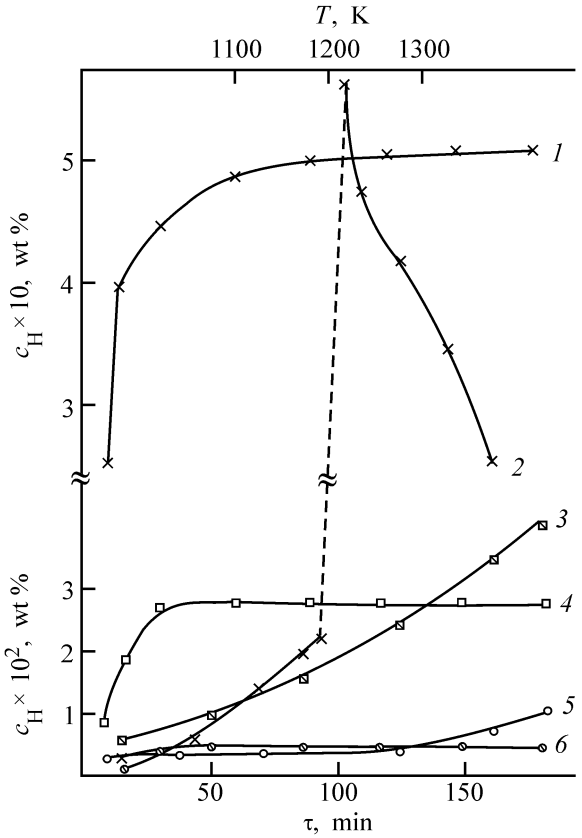

Fig. 2. Content of hydrogen in a metal vs. (*2*, *3*, *5*) temperature T and (*1*, *4*, *6*) duration of oxidation at 1273 K of (*1*, *2*) titanium, (*3*, *4*) zirconium, and (*5*, *6*) hafnium. (c_H) Content of hydrogen and (τ) time.

tion is nonstationary and, consequently, it is governed to comparable extents by diffusion and interphase processes [11, 13]. By contrast, the Evans equation is obeyed in the case of Zr and Hf only at the very beginning of tests, during $\tau \leq 40$ and $\tau \leq 15$ min, respectively (Fig. 1), and later gives way to laws close to the parabolic (2) and then cubic (3) types of behavior, which largely determine the overall rate of the process (3 h).

It can be concluded, with account of the data of [1], that replacement of air with steam leads to a certain stabilization of the Evans equation (1) in oxidation of Ti and, in part, Zr, and to a dramatic shortening of the duration of its action in the case of Hf.

The absorption of hydrogen by titanium at $T \leq (1218 \pm 5)$ K also obeys the Evans law [6, 7]. As, however, the temperature increases to (1273 ± 5) K, the absorption isotherms take a shape of an asymptote when a curve levels-off to become a nearly horizontal straight line after 20–30 min of oxidation for Zr and Hf and 120 min for Ti (Fig. 2). In this case, the rate of hydrogen absorption by titanium is many times that for Zr and Hf.

As can be seen in Fig. 2, the concentration of hydrogen in Zr and Hf steadily increases with temperature, whereas for Ti, it shows a steep rise on going from (1218 ± 5) to (1233 ± 5) K and a nearly equally steep fall at $T > (1233 \pm 5)$ K. This curve reflects the change with temperature of the degree and mechanism of involvement of hydrogen in the Ti oxidation process [6, 7]. Because, according to these reports, the oxidation kinetics is mostly controlled by the cubic law below 810 K, no accelerating effect of hydrogen on this process is observed. Above 810 K and up to (1218 ± 5) K, the noticeable increase in the rate of hydrogen absorption leads to a higher, compared with oxygen and air, oxidation intensity (Table 1), to a more important role of the cation diffusion in scale formation, and to a larger degree of deviation of its composition from stoichiometry. This is mainly due to a rise in the concentration of cation defects in the lattice of rutile upon its partial reduction by hydrogen, e.g., by the following reaction (in the Kroger–Vink notation [14])

$$4Ti_{Ti} + O_O + H_2 = 3Ti^{\bullet}_{Ti} + Ti^{\bullet\bullet\bullet\bullet}_{Ti} + H_2O.$$

On passing to temperatures exceeding $(1218–1233) \pm 5$ K, there occurs a dramatic increase in the overall oxidation rate of titanium (Table 1) and in the porosity of scale, with the mechanism of its formation changing and the decree of nonstoichiometry of rutile decreasing. This is, in particular, due to an increase in the volume of the metal upon its fast saturation with hydrogen. Such a behavior is also favored by accumulation of molecular hydrogen at the metal–scale interface via the reaction of OH^- with Ti:

$$Ti + 2OH^{\bullet}_O = Ti_{Ti} + xO^{(Ti)} + (2 - x)O_O + 2V^{\bullet\bullet}_O + yH^{(Ti)} + [(2 - y)/2]H_2 + 2e,$$

where $xO^{(Ti)}$ and $yH^{(Ti)}$ are oxygen and hydrogen absorbed by the metal, respectively. In this case, the OH^- ($OH^{\bullet}_O$) ions at anion sites of the rutile lattice are generated at the outer surface of the oxide film by the reaction

$$H_2O_{chem.bound} + VO^{\bullet\bullet}_O + e = OH^{\bullet}_O + 1/2H_2$$

and diffuse toward the metal–scale interface because of the smaller radius of OH^- ions (r = 95 pm), compared with O^{2-} (r = 136 pm). As the temperature is elevated, the considerable increase in the rate of oxy-

		z, %	–	69	71	61	60	24	18

gen dissolution in the metal leads to a decrease in the intensity of hydrogen absorption, which diminishes its destructive action on scale. In addition, the density of scale also grows because of an increase in its plasticity and sinterability. By contrast, only minor changes in the color of scale and, consequently, in the degree of its nonstoichiometry are observed for Zr and Hf as temperature increases.

According to the data in Table 3, the growth rate of the diffusion layer of oxygen (DLO) in steam at 1073–1473 K on Ti strongly exceeds that on Hf. At the same time, as the temperature and duration of oxidation (at 1273 K) become higher, the fraction of oxygen in the DLO on Ti decreases, whereas that on Hf, contrastingly, increases, which is due to differences in the law governing the growth of DLO (quadratic parabola) and scale for Ti (Evans equation) and Hf (cubic parabola).

The composition of the gas phase also affects the growth rate of DLO. For example, replacement of air with steam in the case of Ti leads to an increase in the growth rate of DLO up to 1273 K, but causes its decrease at 1373–1473 K. At the same time, the opposite behavior is observed in oxidation of Hf.

It can be seen in Fig. 3, in which $K_{lin}^{(1)}$ and $K_p^{(1)}$ characterize the nonstationary stage of oxidation (in accordance with the Evans equation), and $K_p^{(2)}$, that by the parabolic law (2), that, as a rule, the temperature dependences of these constants for Ti, Zr, and Hf show inflections and a certain difference between the slopes and lengths of the corresponding linear portions. The possible reasons for the occurrence of these inflections were described in the preceding paper [1].

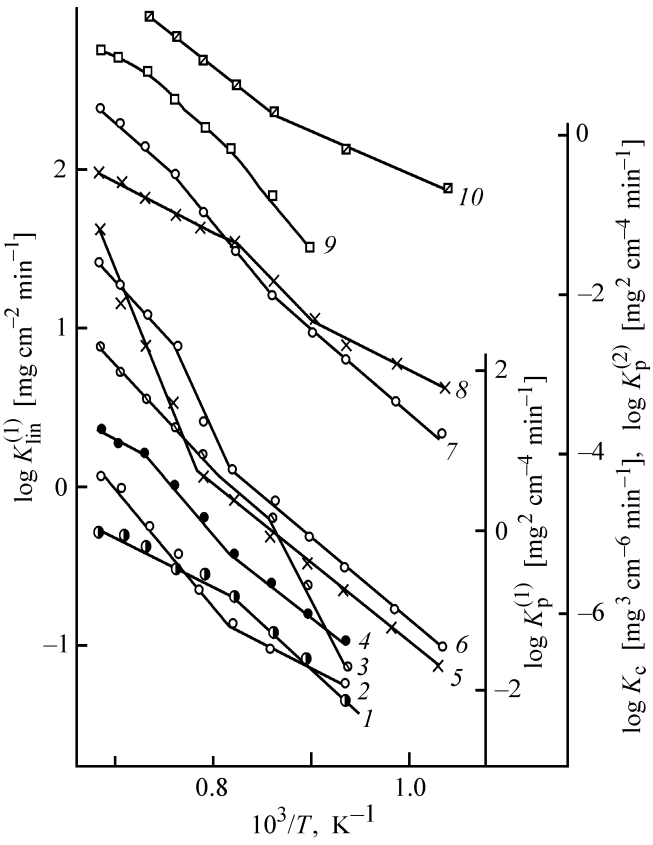

Fig. 3. Oxidation rate constants (*2*, *3*, *5*) $K_{lin}^{(1)}$, (*1*, *4*, *6*) $K_p^{(1)}$, (*8*, *9*) $K_p^{(2)}$, and (*7*, *10*) K_c in oxidation of (*5*, *6*) titanium, (*3*, *4*, *9*, *10*) zirconium, and (*1*, *2*, *7*, *8*) hafnium vs. temperature T.

Table 5. Effect of the nature of a metal, temperature, and composition of the gas phase on the $K_{lin}^{(1)}/K_p^{(1)}$ ratio at the initial stage of oxidation

Medium	Metal	Values of $K_{lin}^{(1)}/K_p^{(1)}$, mg cm^{-2}, at indicated temperature, K						
		1073	1123	1173	1223	1273	1373	1423
Steam	Ti	0.7	0.4	0.3	0.2	0.04	0.02	0.02
	Zr	3.4	2.9	2.6	2.0	1.40	0.40	0.50
	Hf	6.8	5.0	3.4	1.1	0.80	1.70	1.40
Air	Ti	3.1	1.7	0.2	0.05	0.07	0.10	0.14
	Hf	5.7	2.2	2.0	2.0	0.40	0.20	0.21

The values of the apparent activation energies E of oxidation by the corresponding laws (Table 4) are, for the most part, determined with an error of ± (3–5)%. The temperature ranges of their action are given in parentheses. It can be seen that, in the case of nonstationary oxidation, the energy of the diffusion processes ($E_p^{(1)}$) increases on passing from Ti to Zr and Hf in the temperature range 973–1218 K, and, contrariwise, noticeably decreases in the same direction at higher temperatures. The values of $E_{lin}^{(1)}$ for Ti and its analogues also noticeably differ, as also do $E_p^{(2)}$ and E_c for Zr and Hf.

The data of Table 5 suggest that the $K_{lin}^{(1)}/K_p^{(1)}$ ratio markedly increases on going from Ti to Zr and Hf and its variation is to a certain extent nonmonotonic in the range 1223–1273 K. This indicates that the role of diffusion in the control over the rate of nonstationary oxidation grows in the same order. As, however, the temperature increases to 1323 K for Ti and 1273 K for Hf, the $K_{lin}^{(1)}/K_p^{(1)}$ ratio decreases, with this decrease particularly pronounced in oxidation of Ti. For Zr, such a behavior is observed in the entire interval 1073–1423 K. This result demonstrates that the role of interphase processes in determining the overall oxidation rate becomes more important, in agreement with the existing concepts concerning this issue [15]. The increase in $K_{lin}^{(1)}/K_p^{(1)}$ at $T > 1323(1373)$ K for Hf and Ti is presumably due, as in the case of the air medium [1], to specific features of the temperature dependence of $K_{lin}^{(1)}$ and $K_p^{(1)}$ (Fig. 3) and to a change of the mechanism of nonstationary oxidation. With account of the data for air, it can also be concluded that its replacement with steam in tests with Ti leads (except at 1173, 1223 K) to a decrease in $K_{lin}^{(1)}/K_p^{(1)}$ and, consequently, makes more important the role of interphase reactions in the control over the oxidation rate. By contrast, an increase in $K_{lin}^{(1)}/K_p^{(1)}$ on passing from air to steam is observed for Hf, and the control over the oxidation rate goes to diffusion processes.

In tests of Ti, Zr, and Hf in steam, the parts played by the cation and anion diffusion in scale formation

also strongly differ. Indeed, in oxidation of Zr and Hf at temperatures of up to 1473 K, the scale thickness grows, as it also does in air, via the anion diffusion. In the case of Ti, however, the role of the cation diffusion in this process markedly grows as the temperature increases to (1218 ± 5) K. According to the data furnished by the method of "inert" tracers, it governs at this temperature the growth of no less than 80% of the whole amount of scale [6]. At the same time, the role of cation diffusion falls dramatically at $T > (1218 \pm 5)$ K and the growth of the oxide film is mostly governed by the diffusion of oxygen.

The scale formed in tests in steam is composed, mostly for Ti and completely for Zr and Hf, of their nonstoichiometric oxides if $T \leq 1218$, $T < 1223$, and $T \leq 1473$ K, respectively. As the temperature increases, the degree of nonstoichiometry of the scale composition markedly decreases, and this decrease is the most pronounced for Ti. In contrast to the case of an air medium, not only rutile, but also Ti_3O_5 and, occasionally, also Ti_4O_7 are found in scale upon oxidation of Ti in steam. TiO is found at the interface between the scale and the metal (T = 1373 K), and Ti_2O, in the surface layer of scale.

A porous, but denser than that produced in air, oxide film is formed in oxidation of the metals under consideration in steam [at $T \leq (1218 \pm 5)$ K for Ti]. This film shows no microlamination and high adhesion to the matrix surface, which increases on passing from Ti to Zr and Hf. In addition, the thickness of scale formed at sample edges in tests of Ti in steam markedly exceeds that at the matrix faces, in contrast to tests in air. In the case of Zr and Hf, replacement of air with steam does not lead to any noticeable changes in scale morphology, both in this zone and in the whole volume. This indicates that, in contrast to the case of Ti, the mechanisms of scale formation on Zr and Hf in both media are similar.

The revealed differences in the behavior of Ti, Zr, and Hf in oxidation in steam are undoubtedly associated with specific features of their physical and chemical properties, reported in [1]. Here, mention should be primarily made of the decreasing influence of the unfilled state of the outer *d*-shells on the properties of these elements in passing from Ti to Zr and Hf, which is due to the screening of the 4*d* and 5*d* shells of Zr and Hf from the nucleus by the filled, in contrast to Ti, 3*d* shell. This results in that their electronegativity decreases in the same direction, as also, accordingly, do the acceptor capacity and oxygen solubility in the metal lattice. Therefore, a decrease in the growth rate of DLO should be observed on going from Ti to Zr and Hf, which is confirmed experimentally (Table 3). In addition, the metallic chemical bonding in the suboxides Ti_6O and Ti_3O becomes mostly covalent for Zr_6O and Zr_3O. In this case, the oxidation rate decreases as the concentration of oxygen in the metal becomes higher for Ti, but increases for Zr [16, 17]. The departure from this behavior in the case of tests in steam (Table 1) is due to specific features of the mechanism and degree of involvement of hydrogen in the oxidation of Ti and its analogues. The differences in the diffusion mechanisms of scale formation on Ti, Zr, and Hf are mostly due to specific features of the defective structure of their dioxides [14]: $V_O^{\cdot\cdot}$ vacancies are dominant in Zr and Hf dioxides, whereas rutile additionally contains interstitial cations $Ti_{Ti}^{\cdot\cdot\cdot\cdot}$.

Analysis of the results obtained, with account of the phenomenological scheme of oxidation of the metals in the nonstationary (transition) region [13], suggests that the reason why this process is nonstationary in the case of steam is, mostly, the lower, compared with that in equilibrium, activity of oxygen in scale at its interface with the gas medium (steam). At the same time, in tests of Ti in oxygen or air, the nonequilibrium oxidation conditions are mostly confined to the scale–metal interface [18]. However, a more precise solution of these questions in the case of oxidation of the metals under consideration in a steam-and-water medium, and for Hf also in air, requires a special study.

CONCLUSIONS

(1) On passing from Ti to its chemical analogues (Zr, Hf), the overall oxidation rate and the role of interphase processes in the control over this rate markedly decrease, the period of nonstationary oxidation (Hf) becomes shorter, the type of the rate-determining oxidation law is altered, the position and extent of separate zones in the temperature dependence of the rate constants and the activation energy of oxidation change, the growth rate of DLO and rate of hydrogen absorption by a metal decrease at an increasing fraction of oxygen in it, and the contribution of anion diffusion to scale formation becomes more important.

(2) The closeness of many properties of Zr and Hf and of their dioxides predetermines the similarity in the kinetics of their oxidation, diffusion mechanism of scale formation, and scale morphology. As regards the duration of the nonstationary stage of oxidation, Zr is more similar to Ti, than Hf.

(3) The considerable changes in the oxidation rate and, for Ti, in contrast to Zr and Hf, also in the diffusion mechanism of scale formation upon replacement of air with steam are due to the involvement of hydrogen in this process, with the mechanism of this involvement determined by the temperature and duration of tests. The difference between the behavior of Ti and that of Zr and Hf in oxidation with steam is more substantial than that in the air medium.

Abstract—The nature and mechanism of dissolution of single crystals of a $Cd_{0.21}Hg_{0.79}Te$ solid solution in H_2O_2–HBr–solvent bromine-releasing aqueous solutions were determined, with water, ethylene glycol, and tartaric, citric, and lactic acids used as solvents. Projections of the surfaces of equal etching rates were constructed and the concentration limits were found for solutions that can be used for chemical-dynamical polishing of the surface of $Cd_{0.21}Hg_{0.79}Te$ single crystals.

DOI: 10.1134/S1070427206060073

$Cd_xHg_{1-x}Te$ solid solutions are the main material for fabrication of IR photodetectors, including multiple-element linear and matrix arrays. Despite the wide practical use of this semiconducting material, there exist severe difficulties associated with the technology of its processing, which includes chemical etching as one of stages.

Most frequently, Br_2–CH_3OH etchants are used for chemical treatment of the surface of $Cd_xHg_{1-x}Te$ single crystals [1]. A study of the process of chemical etching of $Cd_{0.21}Hg_{0.79}Te$ in bromine-releasing etching formulations of the system HBr–HNO_3–H_2O was reported in [2]. In [3], the possibility that etchants containing hydrogen peroxide as an oxidizing agent can be used for chemical treatment of $Cd_xHg_{1-x}Te$ single crystals was mentioned. The kinetics and mechanism of dissolution in aqueous solutions containing H_2O_2 and a mineral acid (nitric, sulfuric, phosphoric, and hydrochloric) were analyzed. The experimental results obtained demonstrated that regions of polishing solutions exist in virtually all of the systems studied.

The authors of [4] examined the nature of chemical dissolution of CdTe and $Cd_xHg_{1-x}Te$ in aqueous solutions of H_2O_2–HI. The dependence of the dissolution rate of these materials on the concentration of the starting etching formulations and on the composition of the solid solutions. The concentration limits of solutions that can be used for chemical-dynamical polishing (CDP) of CdTe and $Cd_xHg_{1-x}Te$ were determined.

The ellipsometric method has been applied to analyze the composition of films formed on the surface of $Cd_{0.21}Hg_{0.79}Te$ treated with H_2O_2-containing solutions [5].

No evidence concerning application of bromine-releasing solutions based on the H_2O_2–HBr system for CDP of the surface of single-crystal wafers of $Cd_xHg_{1-x}Te$ solid solutions could be found in the literature, despite that preliminary experiments revealed their real promise.

The aim of this study was (i) to analyze the nature of the physicochemical interaction between single crystals of $Cd_xHg_{1-x}Te$ solid solutions and H_2O_2–HBr–solvent etching formulations containing water, ethylene glycol, and tartaric, citric, and lactic acids as solvents; (ii) construct the corresponding diagrams of etchant composition versus etching rate; (iii) establish concentration boundaries for the solutions with respect to the type of action of these solutions on the surface; (iv) reveal the rate-determining stages of the dissolution process; and (v) optimize the compositions of polishing etching mixtures and the processing modes of the materials.

EXPERIMENTAL

The chemical dissolution of single-crystal wafers was performed on an installation for CDP, with the rotating-disc method employed. $Cd_{0.21}Hg_{0.79}Te$ single crystals *n*-type, grown by the Bridgman technique, were used. The samples under study had a surface area

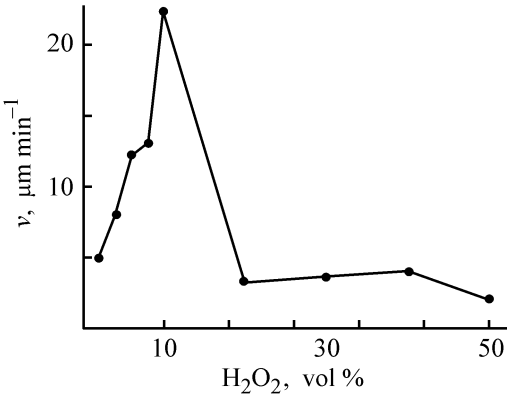

Fig. 1. Concentration dependence of the etching rate ν of $Cd_{0.21}Hg_{0.79}Te$ in aqueous solutions of H_2O_2–HBr. T = 291 K, γ = 86 rpm. (H_2O_2) Content.

of approximately 0.5 cm^2 and thickness of 1.5–2 mm. Prior to being etched, they were mechanically ground with abrasive dusts of M5 and M1 brands, polished with diamond pastes, and degreased with acetone and ethanol. After that, a 50–100-μm-thick layer distorted by the preceding treatments was removed from the sample surface by an etchant of the composition that was used in further measurements. Then, the samples were glued with picein, with nonworking surface down, onto glass substrates and placed in a holder that enabled dissolution in the rotating-disc mode (with the rate of rotation varied in the range 36–120 rpm).

The dissolution rate of the samples was determined from the decrease in their thickness, measured with an ICh-1 watch indicator to within ±0.5 μm. Two or three samples were dissolved simultaneously, with the scatter of the thickness measured not exceeding 5%. The microstructure of the surfaces obtained upon etching was studied with a Zeiss Jenatech Inspection versatile control microscope equipped with a digital camera, at magnifications of 25 to 1600. The microprofile and structure of the etched wafer surfaces were studied using the mechanical-contact method intended for determining the surface roughness. The measurements were done with a Dectac 3030 Auto II profilograph, which can precisely determine vertical deviations from the mean line: microirregularities with heights of 50 Å to 100 μm.

The etching mixtures were prepared using 40% hydrobromic acid of special-purity grade, 35% aqueous solution of chemically pure H_2O_2, 80% aqueous solution of lactic acid ($C_3H_6O_3$) of analytically pure grade, 27% aqueous solution of tartaric acid ($C_4H_6O_6$), and 20% aqueous solution of citric acid ($C_6H_8O_7$) (the last two of chemically pure grade). These components were mixed in amounts corresponding to their volume ratio in the etching formulation (i.e., the composition of the etchant was expressed in volume percent). The etchant components were mixed in a vessel placed in water with ice for cooling in order to preclude overheating of the mixture. The solutions studied were prepared immediately before etching and kept for 2 h for equilibrium to be attained by the chemical reaction that occurs in aqueous solutions between the starting components of the etchant:

$$H_2O_2 + 2HBr = Br_2 + 2H_2O. \quad (1)$$

Depending on the $[H_2O_2]$: [HBr] ratio, the forming bromine can either dissolve in the excess amount of HBr to give etching mixtures similar in properties and composition to Br_2–HBr solutions or be in the free state together with an excess amount of H_2O_2. At a H_2O_2 content in the mixture equal to 22.6 vol %, reaction (1) between the starting components proceeds virtually to completion. After the end of the etching process, the samples were first washed in a 0.01 M solution of sodium thiosulfate for complete removal of the remaining etchant and then rinsed several times with plentiful of distilled water and dried in air.

The concentration dependence of the rate of $Cd_{0.21}Hg_{0.79}Te$ dissolution in aqueous solutions of H_2O_2–HBr is shown in Fig. 1. The study was performed at a H_2O_2 content in the mixture in the range 2–50 vol %, disc rotation rate of 86 rpm, and temperatures of 291–293 K. It can be seen that this dependence shows a maximum at 10 vol % H_2O_2 in the mixture. At this point the molar ratio of the reacting components of the etchant is $[H_2O_2]$: [HBr] = 1 : 5. Possibly, the maximum occurs because the largest amount of bromine, which can dissolve in the excess amount of hydrobromic acid, is released at this ratio of the starting components.

Raising the H_2O_2 content in the mixture from 2 to 10 vol % leads to a gradual increase in the dissolution rate from 5.3 to 22.3 μm min^{-1}, and treatment of samples in solutions of this kind favors formation of a lustrous surface. Further increase in the H_2O_2 content in the etching mixture from 10 to 50 vol % leads to a decrease in the etching rate to 6 μm min^{-1}, with a deteriorated quality of the surface being treated. After treatment in etching mixtures belonging to this range, $Cd_{0.21}Hg_{0.79}Te$ samples are covered with a film and yellow, green, or gray spots appear, depending on the H_2O_2 content. Possibly, at H_2O_2 content in the etchant exceeding 10 vol %, bromine starts to be removed from solution, which depletes the solutions of the active components and impairs the quality of a surface being treated.

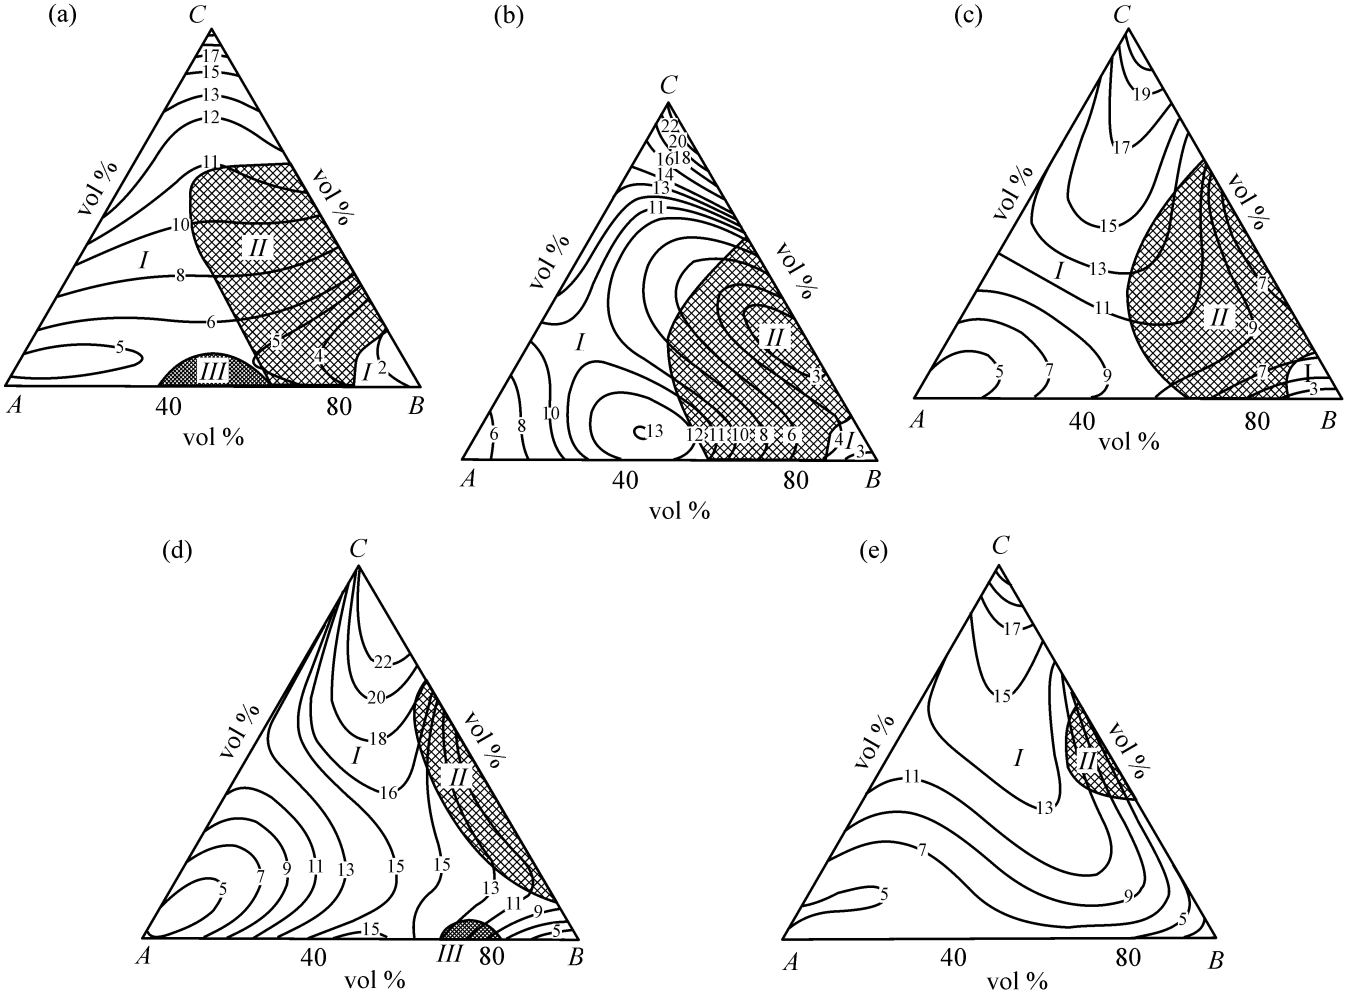

Fig. 2. Concentration dependences of the etching rate ν of $Cd_{0.21}Hg_{0.79}Te$ in aqueous H_2O_2–HBr–solvent solutions at a volume ratio H_2O_2 : HBr : solvent at vertices *A*, *B*, and *C* (vol %): *A*, 2 : 98 : 0; *B*, 10 : 10 : 80; and *C*, 10 : 90 : 0. Region of solutions: (*I*) polishing, (*II*) nonpolishing, and (*III*) selective. Solvent: (a) ethylene glycol, (b) water, (c) tartaric acid, (d) citric acid, and (e) lactic acid.

The results obtained suggest that a third component is to be used to improve the quality of the etching formulations with H_2O_2–HBr. This component could partly control the interaction between H_2O_2 and HBr, favor dissolution of the forming bromine, and convert interaction products into the soluble form. To study the dissolution of single-crystal $Cd_{0.21}Hg_{0.79}Te$ samples in solutions of the system H_2O_2-HBr–solvent, the interval delimited by the triangle ABS was chosen. At vertices *A*, *B*, and *C* of this triangle, the volume ratio H_2O_2 : HBr : solvent was (vol %) 2 : 98 : 0, 10 : 10 : 80, and 10 : 90 : 0, respectively. This approach makes it possible to exclude from consideration passivation regions and regions of strong fluctuations of the etching rate. This is necessary because addition of a minor amount of one component to another may drastically change the mechanism of the heterogeneous chemical reaction occurring in etching.

The experimental results obtained were used to construct, with mathematical simplex design of the experiment [8] for 291 K and disc rotation rate γ = 86 rpm, projections of the surfaces of equal dissolution rates (Gibbs diagrams) for $Cd_{0.21}Hg_{0.79}Te$ in solutions of the system H_2O_2–HBr–solvent, in which water, ethylene glycol, and tartaric, citric, and lactic acids served as solvents.

As can be seen in Fig. 2a, the etching rate of $Cd_{0.21}Hg_{0.79}Te$ samples in aqueous solutions composed of H_2O_2, HBr, and ethylene glycol is comparatively low and falls within the range 1.5–22.3 μm min^{-1}. It is at a maximum in solutions enriched in HBr and has the minimum value in solutions containing the

largest amount of ethylene glycol. Polishing etching formulations are constituted by solutions in two concentration ranges. The first of these, with the minimum content of ethylene glycol, falls within the limits (vol %) (2–10) H_2O_2, (55–98) HBr, and (0–38) ethylene glycol, and the second, with the maximum content of ethylene glycol, within the limits (8–10) H_2O_2, (10–21) HBr, and (69–80) ethylene glycol. The CDP rates in these ranges are 5.3–22.3 and 1.5–3.0 μm min^{-1}, respectively. The region of selective etchants (range *III*) falls within the interval (5–7) H_2O_2 : (44–65) HBr : (30–50) ethylene glycol and occupies about 5% of the whole concentration range studied.

Comparison of the concentration dependences of the etching rates of $Cd_{0.21}Hg_{0.79}Te$ in H_2O_2–HBr–H_2O and H_2O_2–HBr–$C_4H_6O_6$ etching mixtures shows their similarity. This suggests that the mechanisms of dissolution of these materials in the etchants under study are of the same type (Figs. 2b, 2c). Polishing etching formulations are formed in these systems by solutions containing the minimum and maximum amounts of the solvent and are virtually similar in the size and position of the corresponding regions in the concentration triangle. The etching rates of $Cd_{0.21}Hg_{0.79}Te$ samples in etchants of these systems are comparatively low and fall within the ranges 2.1–22.3 and 0.5–22.3 μm min^{-1}, respectively. Their maximum values are observed in solutions enriched in HBr, and the minimum values, in those containing the largest amount of water or tartaric acid. As can be seen in Fig. 2, the regions of polishing etchants are virtually the same and are delimited by the contents (vol %): (2–10) H_2O_2 : (49–98) HBr : (0–65) water, $C_4H_6O_6$ and (9–10) H_2O_2 : (10–16) HBr : (74–80) water, $C_4H_6O_6$.

In the case when citric acid is used as a solvent (H_2O_2–HBr–$C_6H_8O_7$), the etching rate of $Cd_{0.21}Hg_{0.79}Te$ samples is, as in the preceding systems, within the range 2.4–22.3 μm min^{-1}, but the boundaries of the polishing region change significantly (Fig. 2d). The maximum etching rate is observed in solutions enriched in HBr, and the minimum etching rate in those containing the largest amount of citric acid. The larger part of the concentration range of the solutions under study is occupied by the region of polishing compositions (Fig. 2d, region *I*). This region covers about 80% of the whole concentration range studied and is limited to (vol %): (2–10) H_2O_2, (10–98) HBr, and (0–80) $C_6H_8O_7$. The region of selective etchants (region *III*) is limited to (vol %) H_2O_2 : (27–37) HBr : (55–65) $C_6H_8O_7$ and occupies about 5% of the entire concentration range.

With lactic acid ($C_3H_6O_3$) used as a solvent, the etching rate of $Cd_{0.21}Hg_{0.79}Te$ samples somewhat decreases, from 0.8 to 22.3 μm min^{-1} (Fig. 2e). The minimum dissolution rate is observed for all the samples in mixtures with the highest content of lactic acid at a volume ratio H_2O_2 : HBr : $C_3H_6O_3$ = 10 : 10 : 80, and the minimum rate, in mixtures enriched in hydrobromic acid at a ratio H_2O_2 : HBr : $C_3H_6O_3$ = 10 : 90 : 0. Nearly the entire concentration range of the solutions under study is occupied by the region of polishing compositions (Fig. 2e, region *I*). This region, limited to (vol %): (2–10) H_2O_2 : (10–98) HBr : (0–80) $C_3H_6O_3$, is the largest among those for all of the solutions studied and occupies about 95% of the entire concentration range studied.

To study the nature of processes occurring in dissolution of $Cd_{0.21}Hg_{0.79}Te$, kinetic experiments were carried out and dependences of the dissolution rate ν of these materials on the disc rotation rate γ and temperature were constructed. Dependences of this kind make it possible to determine which stage, diffusion-related or kinetic, is rate-determining and to exclude from consideration the influence exerted by some side effects occurring in dissolution of a semiconductor on the chemical etching rate [9]. If the diffusion stage of the dissolution process is rate-determining, dependences of this kind can be extrapolated to the origin of coordinates. If, however, the importance of the surface (chemical) reaction in the overall dissolution process increases and it becomes rate-determining, then the corresponding straight line runs parallel to the abscissa axis. In the case of dissolution of the semiconductor by a mixed mechanism, the straight line or its extension intersects the ordinate axis and the length of the intercept can be used to calculate the rate constant of the overall chemical reaction.

The study was performed in the temperature range 285–310 K at a disc rotation rate of 36–120 rpm, with the dependences of the etching rate on the disc rotation rate plotted in the coordinates ν–$\gamma^{-1/2}$, and the temperature dependences of the etching rate, in the coordinates $\ln \nu$–$10^3/T$.

Figure 3a shows the dependences of the dissolution rate of $Cd_{0.21}Hg_{0.79}Te$ on the disc rotation rate for several aqueous H_2O_2–HBr–solvent solutions. It can be seen that these dependences can be extrapolated to the origin of coordinates for all the etching

mixtures studied. The data obtained indicate that the dissolution of $Cd_{0.21}Hg_{0.79}Te$ samples is limited by the diffusion stage in all of the solutions mentioned above. Analysis of the temperature dependences in Fig. 3b confirms the conclusion that the dissolution process is limited by the diffusion stages, because the apparent activation energies E_a, found from the temperature dependences in the range 285–310 K, do not exceed 35 kJ mol^{-1}, which is characteristic of diffusion processes.

Thus, the experimental study revealed the main specific features of the dissolution of $Cd_{0.21}Hg_{0.79}Te$ in bromine-releasing etching formulations H_2O_2–HBr–solvent. It was shown that, in the solution concentration ranges studied, a difference both in the rates of chemical etching and in the size of the concentration ranges corresponding to polishing solutions is observed upon replacement of one solvent with another. On changing the solvent in the H_2O_2–HBr–solvent system, the region of polishing solution increases in size in the order ethylene glycol → water, tartaric acid → citric acid → lactic acid.

The experimental data obtained made it possible to develop and optimize, for the first time, a set of bromine-releasing etching formulations, which were found to be promising for various technological treatments of single crystals of $Cd_{0.21}Hg_{0.79}Te$ solid solutions. The etchant compositions were optimized with respect to the etching rate, surface roughness, and contamination of the surface with etchant components, using data derived from the concentration dependences of the dissolution rate and results of metallographic and profilographic analyses. The technological modes of CDP and other kinds of treatment (wafer thinning, selective etching) were optimized for the etching mixtures selected with the use of the data on the dissolution kinetics of the semiconductors specified in relation to temperature, velocity at which the etchant flows around wafers, etc. A sequence of procedures for chemical treatment of the surface was developed. This sequence includes cleaning of the wafers with organic solvents, etching, and finishing washing in solutions of reagents that well dissolve both the remaining etching formulations and some products formed in the chemical interaction. It was shown that, to obtain a polished surface by the CDP method, it is necessary to use etchants from the polishing regions in the diagrams (region *I*) and to perform the CDP process at 295–298 K at a disc rotation rate of 86 rpm, with the subsequent washing of the samples with a 0.01 M solution of sodium thiosulfate and with distilled water.

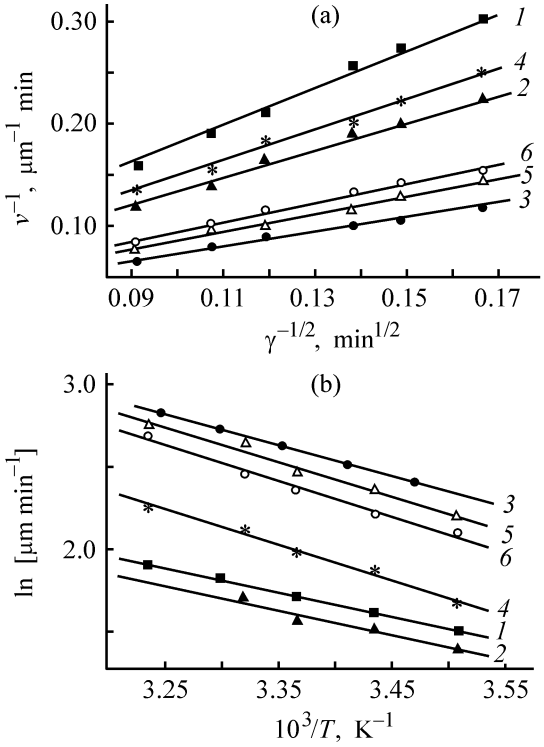

Fig. 3. Dissolution rate ν of $Cd_{0.21}Hg_{0.79}Te$ vs. (a) disc rotation rate γ and (b) temperature *T*. (a) *T* = 291 K and (b) γ = 86 rpm. Solution (vol %): (*1*) $2H_2O_2$ + 98HBr, (*2*–*4*) $4H_2O_2$ + 76HBr + 20 [(*2*) ethylene glycol, (*3*) H_2O, and (*4*) tartaric acid], and (*5*–*6*) $6H_2O_2$ + 74HBr + 20 [(*5*) citric acid and (*6*) lactic acid].

CONCLUSIONS

(1) A study of the physicochemical interaction of single crystals of $Cd_{0.21}Hg_{0.79}Te$ solid solutions with H_2O_2–HBr–solvent etching formulations, with ethylene glycol, water, and tartaric, citric, and lactic acids used as solvents, made it possible to construct surfaces of equal etching rates and determine the boundaries of the existence regions of polishing, nonpolishing, and etching-pit-forming solutions. It was shown that introduction of the above-mentioned solvents into the etching mixtures based on H_2O_2–HBr–solvent affects the nature of the dissolution process, rate of chemical etching of $Cd_{0.21}Hg_{0.79}Te$, and concentration limits of polishing solutions, with the dissolution in polishing solutions of the system H_2O_2–HBr–solvent system limited by diffusion stages.

(2) It was suggested to use, for chemical treatment of $Cd_{0.21}Hg_{0.79}Te$, bromine-releasing formulations based on an aqueous solution of H_2O_2 and hydrobromic acid. With these formulations, the etching rates are low (1–23 μm min^{-1}) and the amount of

bromine released can be to a certain extent controlled by introduction of a solvent. A set of etching formulations for various technological treatments (chemical-dynamical polishing, selective etching) was suggested. The etchant compositions and the technological modes of chemical treatment of the material were optimized.

Abstract—Extraction of rhenium(VII) and molybdenum(VI) from sulfuric, hydrochloric, and nitric acid solutions with hexabutyltriamide of phosphoric acid was studied. The influence exerted on the extraction of Re(VII) and Mo(VI) by the nature and concentration of an acid in the aqueous phase, temperature, time of contact between phases, and concentration of the extracting agent in the organic phase was analyzed. Isotherms of extraction of rhenium(VII) and molybdenum(VI) with solutions of hexabutyltriamide phosphoric acid in kerosene were obtained, the composition of the complexes being extracted was determined, the enthalpies and entropies were evaluated, and the concentration constants of extraction of the metals were found.

DOI: 10.1134/S1070427206060085

A promising way to effectively solve the problem of separation of rhenium(VII) and molybdenum(VI) is application of sorption and extraction methods. At present, the extraction recovery of rhenium(VII) and molybdenum(VI) from solutions of complex salt composition is the most widely used in technological practice [1–4].

Rhenium(VII) is, as a rule, present in real technological solutions containing a rather high concentration of sulfuric acid in the form of the perrhenate ion ReO_4^-. Rhenium(VII) is recovered from solutions of this kind with anion-exchange extracting agents (aliphatic amines and their salts) or neutral reagents [5, 6]. The most effective among the latter are neutral organophosphorus extracting agents and especially trialkylphosphine oxides [7, 8].

Molybdenum(VI) is known to be a frequent accessory of rhenium(VII). Compounds of molybdenum(VI) are strongly different in neutral, weakly acidic, and strongly acidic solutions. For example, molybdenum(VI) is present in solutions with pH ~2–3 as paramolybdate ($Mo_7O_{24}^{6-}$) and metamolybdate ($Mo_8O_{26}^{4-}$) ions. In strongly acidic solutions, molybdenum(VI) forms oxycations MoO_2^{2+}, which tend to polymerize to give polynuclear ($Mo_xO_{x-1}^{2+}$) ions [9]. Apparently, these polyions will markedly differ, when being extracted with anion-exchange and neutral extracting agents, from the monomeric perrhenate ion. This enables extractive separation of rhenium(VII) and molybdenum(VI).

It is of interest to study the possibility of extraction of simultaneously present rhenium(VII) and molybdenum(VI) with organic reagents close in their properties to trialkylphosphine oxide and possessing electron-donor substituents in the form of alkyl-substituted amino groups at the phosphoryl group.

This communication presents data on extraction of rhenium(VII) and molybdenum(VI) from acid solutions with hexabutyltriamide of phosphoric acid, $[(C_4H_9)_2N]_3PO$ (HBTA).

EXPERIMENTAL

The starting aqueous solution was prepared by dissolving a known amount of metal salts, potassium perrhenate ($KReO_4$) and sodium molybdate deca-

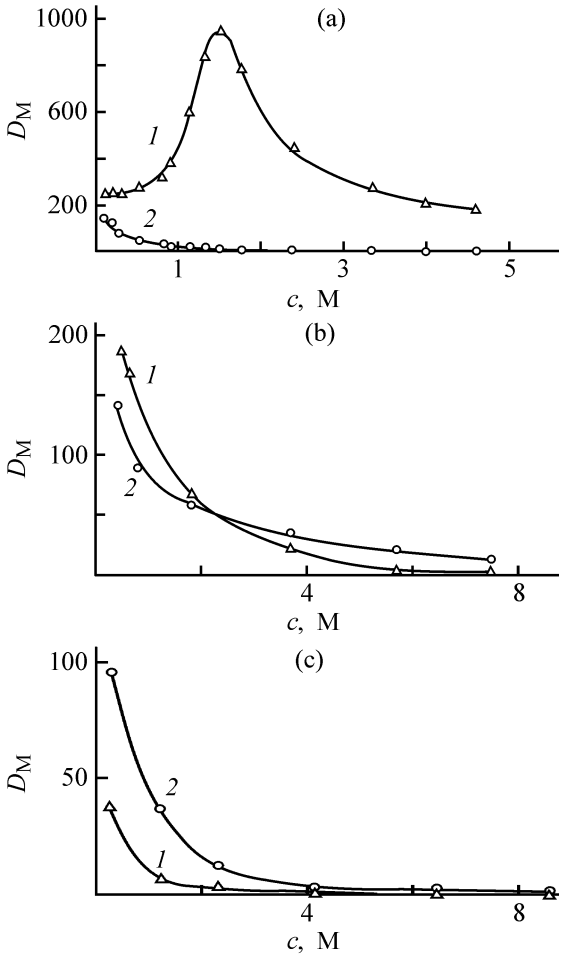

Fig. 1. Effect of the concentration c of (a) sulfuric, (b) hydrochloric, and (c) nitric acids on the extraction of (*1*) rhenium(VII) and (*2*) molybdenum(VI). Initial concentration (M): Re(VII) 5.4×10^{-3} and Mo(VI) 20.8×10^{-3}. Time of contact τ = 5 min, $V_{org} : V_{aq}$ = 1 : 1, 0.3 M solution of HBTA in kerosene; the same for Figs. 2–4. (D_M) Distribution coefficient; the same for Fig. 4.

hydrate ($Na_2MoO_4 \cdot 10H_2O$), both of analytically pure grade, in distilled water. The concentrations of the metals in the solutions did not exceed 5.4×10^{-3} for Re(VII) and 20.8×10^{-3} for Mo(VI). The necessary concentrations of sulfuric, nitric, and hydrochloric acids in the solution prepared were created with the corresponding concentrated acid of analytically pure grade.

Organic solutions of the extracting agent were prepared by diluting concentrated HBTA containing no less than 96–98 wt % main substance with kerosene with a flash point of more than 60°C. All the experiments were performed at 20–25°C with the use of separation funnels.

The number of HBTA molecules contained in the compounds being extracted was found from the logarithmic dependence of the distribution coefficient D_M on $[HBTA]_0$, processed using the least-squares method. In a similar way were found the extraction constants, enthalpies, and entropies. The equilibrium concentrations of the metals were determined by atomic-emission spectroscopy with inductively coupled plasma. The equilibrium concentrations of the acids were found by titration with a standard KOH solution. IR spectra of organic extracts were measured in a KBr cuvette (d = 0.1 mm) at 4000 – 400 cm^{-1} with an Infralyum FT-02 Fourier spectrometer with a resolution of 1 cm^{-1}, manufactured by Lyumeks NPF AP.

This study was concerned with the influence exerted by the concentration of sulfuric, nitric, and hydrochloric acids in the aqueous phase on the extraction of rhenium(VII) and molybdenum(VI) with HBTA (Figs. 1a–1c). Noteworthy are the different ways in which the extractability of rhenium(VII) and molybdenum(VI) vary with the nature and concentration of the acids. The difference observed is presumably due to the dissimilar states of Re(VII) and Mo(VI) in the equilibrium phases and to the extraction of mineral acids at their various concentrations. The extremal distribution of rhenium(VII) and molybdenum(VI) is typically observed in extraction from aqueous solutions of sulfuric, hydrochloric, and nitric acids. The distribution coefficient D for rhenium(VII) at a maximum in the case of extraction from a sulfuric acid solution at its concentration of about 1.5 M. For molybdenum(VI), the maximum value is shifted to the existence region of its anionic forms, i.e., into the region of low acidity. The maximum values of the distribution coefficients for Re(VII) and Mo(VI) in extraction from hydrochloric acid solutions are obtained if the concentration of the acid is less than 1 M. The maximum extent of Re(VII) and Mo(VI) recovery from nitric acid solutions is achieved for even less acid solution than in the case of hydrochloric acid. The observed positions of the maximum extents of recovery of rhenium(VII) and molybdenum(VI) are in a rather good agreement with the series of extrastability of HBTA and mineral acids used to create the acidity of the medium. Because the difference in the extrastability of rhenium(VII) and molybdenum(VI) with HBTA is most completely manifested in extraction from sulfuric acid solutions, it is appropriate to separate these metals in solutions of this acid.

The effect of other parameters on the extraction of rhenium(VII) and molybdenum(VI) was studied under the conditions providing the maximum recovery of rhenium(VII), i.e., at a sulfuric acid concentration of 1.5 M.

Effect of the time of contact between the phases on the extraction of rhenium(VII) and molybdenum(VI) [concentration (M): H_2SO_4 1.5, Re(VII) 5.4×10^{-3}, Mo(VI) 20.8×10^{-3}; $V_{org} : V_{aq} = 1 : 1$; 0.3 M solution of HBTA in kerosene]

3	1.40	0.038	20.06	5.88	14	154	93.5	99.4
5	1.36	0.038	20.10	5.88	15	156	93.7	99.4
10	1.57	0.038	19.89	5.88	13	154	92.7	99.4
30	1.59	0.038	19.87	5.88	13	155	92.6	99.4

The rate of extraction is one of the most important parameters. The experimental data (see table) demonstrate that the process of extraction of rhenium(VII) and molybdenum(VI) from solutions of sulfuric acid with HBTA solutions in kerosene has a rather slow kinetics. To attain an extraction equilibrium for Re(VII) and Mo(VI), the phases should be in contact for no less than 5 min. In this case, the recovery E of Mo(VI) and Re(VII) is 93–94 and 99.4%, respectively. Consequently, it is advisable to perform extraction in nearly equilibrium conditions to achieve the maximum recovery and separation of rhenium(VII).

The effect of temperature on the recovery of rhenium(VII) and molybdenum(VI) into the organic phase was considered. It was found that, as the temperature of extraction increases, the extent of recovery of rhenium(VII) and molybdenum(VI) decreases. The temperature dependence $\log D_M - 1/T$ was used to evaluate the enthalpy and entropy of extraction of the metals (Fig. 2). The processing of the results by the least-squares method yielded dependences described by the following equations:

$\log D_{Re(VII)} = 2112/T + 4.98$, correlation coefficient 0.96;

$\log D_{Mo(VI)} = 555.6/T + 0.734$, correlation coefficient 0.99.

For rhenium(VII), $\Delta H^{org} = 40.44 \pm 3.97$ kJ and $\Delta S^{org} = 11.47 \pm 1.12$ J mol^{-1} K^{-1}; for molybdenum(VI), $\Delta H^{org} = -10.64 \pm 1.01$ kJ and $\Delta S^{org} = 1.69 \pm 0.11$ J mol^{-1} K^{-1}. These heat effects of extraction of rhenium(VII) and molybdenum(VI) are in an agreement with the dependence of the heat effects on the distribution constants in extraction of acids, which decrease in the order hydrochloric > rhenic > nitric > sulfuric > molybdenic [10].

Isotherms of rhenium(VII) and molybdenum(VI) extraction with HBTA from aqueous sulfuric acid solutions were measured (Fig. 3). Their run indicates that rhenium(VII) and molybdenum(VI) can be concentrated in the organic phase.

The experimental data on the distribution of rhenium(VII) and molybdenum(VI) were processed by

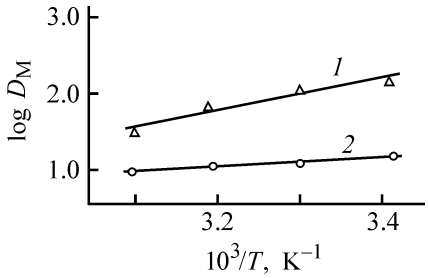

Fig. 2. Distribution coefficient D_M for (*1*) rhenium(VII) and (*2*) molybdenum(VI) vs. temperature T. H_2SO_4 concentration 1.5 M; the same for Figs. 3, 4.

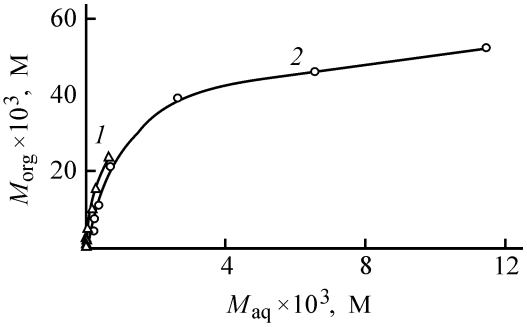

Fig. 3. Isotherms of extraction of (*1*) rhenium(VII) and (*2*) molybdenum(VI). (M_{org}, M_{aq}) Concentrations of Re(VII) and Mo(VI) in the organic and aqueous phases, respectively.

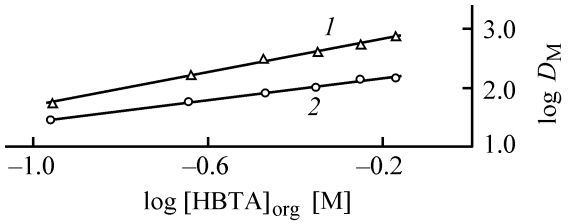

Fig. 4. Effect of the HBTA concentration on the extraction of (*1*) rhenium(VII) and (*2*) molybdenum(VI).

the least-squares method. This yielded the following equations for the extraction isotherms:

$$[Re]_{org} = (156 \pm 14)[Re]_{aq},$$

$$[Mo]_{org} = (29 \pm 2)[Mo]_{aq}.$$

Thus, the concentration constant for the extraction with HBTA is 156 ± 14 for rhenium(VII) and 29 ± 2 for molybdenum(VI).

The composition of the compounds of rhenium(VII) and molybdenum(VI) with HBTA, extracted in the experiments, was determined by the method of the equilibrium shift. The dependence of the distribution coefficients for rhenium(VII) and molybdenum(VI) on the HBTA concentration in extraction from 1–2 M sulfuric acid solutions (Fig. 4) was processed by the least-squares method to give the following equations:

$$\log D_{Re} = (1.41 \pm 0.13)\log[HBTA]_{org} + (3.12 \pm 0.05),$$

$$\log D_{Mo} = (0.93 \pm 0.08)\log[HBTA]_{org} + (2.35 \pm 0.03),$$

where $[HBTA]_{org} = [HBTA]_{in} - q[HReO_4]_{org} - [H_2MoO_2(SO_4)_2]_{org} - [H_2SO_4]_{org}$.

The correlation coefficients for both the equations are 0.99. It follows from the equations that the solvation number is 1.41 ± 0.13 for rhenium(VII) and 0.93 ± 0.08 for molybdenum(VI). These values indicate that rhenium(VII) is presumably extracted as a mixture of a monosolvate and disolvate, and molybdenum(VI), as a monosolvate. It should be kept in mind that, as the concentration of the extracting agent in the organic phase increases, the phase stratification starts to take a noticeably longer time. This somewhat restricts the possibility of using concentrated HBTA solutions for extraction.

Certain conclusions concerning the interactions that occur in the course of extraction can be made on the basis of the whole set of changes in the IR absorption spectra in the range from 4000 to 400 cm^{-1}, in which the characteristic vibrations of metal anions and bonds in the molecule of the extraction agent occur. Therefore, to identify the spectra of the solvates, a comparative analysis of the vibration spectra of solutions of the extracting agents used and of the spectra of extracts containing compounds of rhenium(VII) and molybdenum(VI) with HBTA was made. The samples were studied in a thin layer.

IR spectra of a 0.3 M solution of HBTA in carbon tetrachloride and those of extracts saturated with rhenium(VII) or molybdenum(VI) were analyzed. The extracts were obtained by recovery of the corresponding metal compound from an aqueous solution containing 3 M of hydrochloric acid and 0.08 M of rhenium(VII) or 0.21 M of molybdenum(VI).

The IR spectra of the 0.3 M solutions of HBTA in carbon tetrachloride contain the absorption band ν(P=O) at 1150–1180 cm^{-1}. In the IR spectra of the HBTA extracts saturated with rhenium(VII), this band is shifted to longer wavelengths, 1100–1150 cm^{-1}. A strong absorption band at 905 cm^{-1}, associated with triply degenerated antisymmetric vibrations of the perrhenate ion ReO_4^- having a tetrahedral structure, appears in the IR spectra of the HBTA extracts saturated with rhenium(VII). The fact that this band is not split points to the predominantly ionic nature of bonding between the cationic and anionic parts of the complex being extracted. The IR spectra of the HBTA extracts saturated with molybdenum(VI) contain absorption bands at 930 and 900 cm^{-1}, which correspond to antisymmetric and symmetric stretching vibrations of the Mo=O bond. In addition, the IR spectra of the HBTA extracts with rhenium(VII) and molybdenum(VI) contain bands at 3550–3200 cm^{-1} (antisymmetric and symmetric stretching vibrations of O–H) and 1630–1600 cm^{-1} (deformation vibrations of H–O–H), which belong to water molecules contained in the complexes being extracted. This confirms the assumption that the extraction of rhenium(VII) and molybdenum(VI) occurs by the hydration-solvation mechanism.

The whole body of the data obtained, combined with published evidence [11–13], makes it possible to represent the extraction of rhenium(VII) and molybdenum(VI) with HBTA by the following equations:

$$nS_{org} + H_3O^+ + ReO_4^- + mH_2O \rightleftarrows [H_3O \cdot mH_2O \cdot nS]^+(ReO_4)^-_{org},$$

$$nS_{org} + H_3O^+ + A^{n-} + MoO_2^{2+} + mH_2O \rightleftarrows [H_3O \cdot mH_2O \cdot nS]^+\{MoO_2^{2+}(A^{n-})\}^{(n-2)-}_{org},$$

where S denotes the molecule of the extracting agent, and A^{n-}, the anion of a mineral acid (i.e., SO_4^{2-}, NO_3^-, Cl^-).

CONCLUSIONS

(1) Hexabutyltriamide of phosphoric acid is an effective extracting agent for recovery of rhenium(VII) and molybdenum(VI) from sulfuric acid, hydrochloric acid, and nitric acid solutions.

(2) Solutions of hexabutyltriamide of phosphoric acid in kerosene can be used for extractive separation of rhenium(VII) and molybdenum(VI) from solutions with a high content of sulfuric acid.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Recovery of Rhenium(VII) with Triisooctylamine from Sulfuric Acid Solutions

A. G. Kasikov and A. M. Petrova

Tananaev Institute of Chemistry and Technology of Rare Elements and Mineral Resources, Kola Scientific Center, Russian Academy of Sciences, Apatity, Murmansk oblast, Russia

Received March 23, 2006

Abstract—Extraction recovery of rhenium(VII) with triisooctylamine from model sulfuric acid solutions was studied. The effect of the composition of the organic and aqueous phases on the recovery of rhenium(VII) was analyzed, and the composition of rhenium(VII) complexes in the organic phase was determined. The possibility of effective re-extraction of rhenium(VII) from triisooctylamine with ammonia solutions was demonstrated.

DOI: 10.1134/S1070427206060097

Rhenium is one of the most needed rare elements; the demand for rhenium has markedly increased recently because of its larger-scale consumption in manufacture of refractory alloys [1, 2]. The main sources of rhenium are solutions of washing sulfuric acid, in which rhenium concentrated is in catching of roaster gases formed in pyrometallurgical processing of molybdenum, copper, and copper-nickel ores [2–5].

The method of liquid extraction is widely used in practice for recovery of rhenium(VII) from industrial washing sulfuric acid solutions, with mixtures containing trialkylamine used as extracting agents in most cases [2–8]. The extraction of rhenium(VII) with tertiary amines of normal structure was also studied in [9–14].

Data on application of tertiary amines of branched structure, which are industrial extracting agents [15], for recovery of rhenium(VII) are exceedingly scarce [5, 16].

In view of the fact that the extracting capacity of branched amines may markedly differ from that of similar compounds of normal structure [17–19] and sulfuric acid solutions are frequently used in practice, the present study was aimed to examine the extraction of rhenium(VII) from H_2SO_4 solutions with mixtures containing triisooctylamine.

EXPERIMENTAL

As extracting agent served solutions containing 5–30 vol % industrial triisooctylamine (TIOA) of Hostarex A 324 brand (no less than 95% main substance and up to 5% primary and secondary amines) in a Escaid 100 diluent with addition of 20–70 vol % isomeric aliphatic alcohols (1-octanol or 2-ethyl-hexanol-1 of pure grade).

The extracting agent was preliminarily converted into the salt form via contact with a H_2SO_4 solution of the same concentration as a solution of rhenium, from which the extraction was performed.

Model rhenium-containing solutions were prepared by dissolution of ammonium perrhenate in distilled water, with addition of a necessary amount of chemically pure sulfuric acid. The concentration of rhenium(VII) was varied from 0.001 to 0.036 M, and that of sulfuric acid, from 0.1 to 9 M.

The extraction was performed in separatory funnels at a volume ratio of the organic to aqueous phase equal to 1 : 25 at room temperature in the course of 5 min, which provided that equilibrium was attained by the system.

The content of rhenium(VII) in the aqueous phase was determined spectrophotometrically from the coloration intensity of the thiourea complex of rhenium(IV), formed in the presence of Sn(II) as reducing agent. The light absorption was measured with a KFK-3 photoelectric colorimeter at a wavelength λ = 390 nm [20] or by the atomic-emission method on a Plazma 400 spectrometer. The content of rhenium in the organic phase was calculated as the difference of its contents in the aqueous phase before and after extraction.

Industrial extracting agents based on tertiary amines are solutions of amine in a nonpolar organic solvent (commonly, kerosene), with addition of a modifier that precludes formation of a third phase. Changing the relative amounts of components in organic mixtures of this kind strongly affects their extraction capacity, and, therefore, the effect of the composition of the organic phase on the recovery of rhenium(VII) was studied in the first place.

Apparently, the extraction capacity of a mixture is most affected by the content of the active component in it. For example, it is known that, if tributylphthalate (TBP) is diluted, its extraction capacity for rhenium(VII) considerably decreases [10]. For extracting agents belonging to the class of tertiary amines, published data are contradictory [7, 9–11]. The present study demonstrated that, as the content of TIOA in the extracting mixture is raised from 5 to 30%, the distribution coefficient D_{Re} of rhenium(VII) steadily increases (Fig. 1). Consequently, more effective recovery of rhenium(VII) requires mixtures with higher amine concentration. However, concentrated solutions of the sulfate salt of TIOA are highly viscous and, therefore, organic mixtures with TIOA content not exceeding 35% can be recommended for practical application, whereas the extracting agents presently used to recover rhenium(VII) from industrial solutions commonly contain no more than 10% tertiary amine [7, 8].

The type and content of a modifier in the extracting mixture also largely determine its properties. As a rule, polar organic solvents (higher alcohols, ketones, TBP, etc.) are used as modifiers. In this study, isomers of octyl alcohol served for this purpose.

High-molecular-weight aliphatic alcohols, as a rule, suppress extraction of metals [21], which is due to solvation of a part of amine salt anions with alcohol molecules. At the same time, just this process diminishes the association of the amine salt, thereby raising its solubility and precluding formation of a third phase in the extracting agent [22]. In addition, aliphatic alcohols can themselves recover rhenium(VII) from sulfuric acid solutions with a rather high distribution coefficient [23, 24]. As shown experimentally, the volume ratio amine : octyl alcohol in the extracting mixture based on TIOA should be no less than 2 : 1. The structure of an alcohol affects the extraction capacity of TIOA for rhenium(VII) as follows: 1-octanol suppresses the extraction of rhenium(VII) to a greater extent than does 2-ethyl-1-hexanol (Fig. 1). This is probably due to the fact that, being a more electrophilic reagent, 1-octanol, an alcohol of linear structure, more strongly solvates anions of TIOA sulfate [22] as compared with octyl alcohol with a hydrocarbon radical of branched structure. On the whole, an increase in the concentration of an alcohol in the extracting mixture only slightly diminishes the distribution coefficient for rhenium(VII) via solvation of amine molecules (Fig. 2).

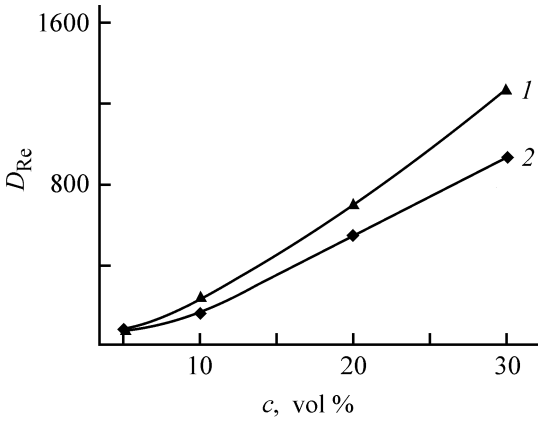

Fig. 1. Effect of the TIOA content in the organic phase on the distribution coefficient of rhenium(VII). (D_{Re}) Distribution coefficient of Re(VII) and (c) content of TIOA. Starting aqueous phase: Re(VII) 200 mg l^{-1}, H_2SO_4 4 M. Composition of the extracting agent (vol %): 5–30 TIOA and (*1*) 20 2-ethyl-1-hexanol or (*2*) 20 1-octanol.

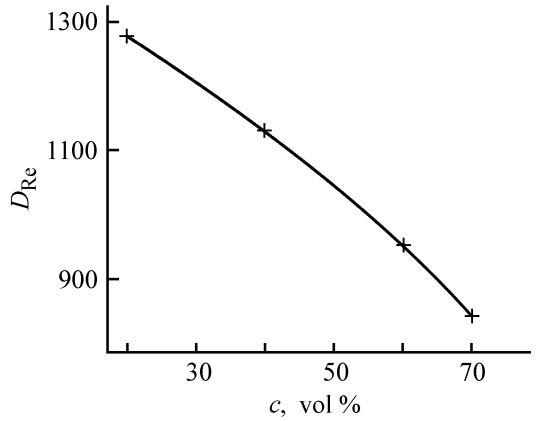

Fig. 2. Effect of the content c of 2-ethyl-1-hexanol in the organic phase on the distribution coefficient D_{Re} of rhenium(VII). Composition of the extracting agent (vol %): 30 TIOA and 20–70 2-ethyl-1-hexanol.

In addition, it was found that the concentration of a modifier in the extracting agent affects the composition of rhenium(VII) solvates formed in the organic phase in extraction with TIOA. The solvation numbers determined by the method of the equilibrium shift [10] from the slope of the straight lines corresponding to

Table 1. Solvation numbers of rhenium(VII) in the organic phase in recovery with extracting mixtures of various compositions, containing 5–30 vol % TIOA

Composition of the extracting agent	Solvation number n	Composition of the extracting agent	Solvation number n
TIOA + 20 vol % 1-octanol in Escaid 100	1.45	TIOA in 1-octanol	1.25
TIOA + 20 vol % 2-ethyl-1-hexanol in Escaid 100	1.68	TIOA in 2-ethyl-1-hexanol	1.37

the dependence $\log c_{TIOA}$–$\log D_{Re}$ (Fig. 3) for organic complexes of rhenium(VII) in extraction with mixtures containing different amounts of alcohols are listed in Table 1. As the content of octyl alcohol in the mixtures increases, the ratio TIOA : Re in the solvate decreases from ~1.5 to ~1.3. Consequently, the degree of polymerization of the TIOA salt in the extracting agent decreases as the content of the modifier becomes lower.

It should be noted that similar values of the solvation numbers were obtained in another way, by the saturation method, for extracting mixtures containing 30% TIOA and 20 or 70% 1-octanol (~1 and ~1.4, respectively).

In addition to the composition of the extracting agent, the factors that strongly affect the equilibrium of the extraction process include its conditions and the composition of the aqueous phase.

One of the most important technological parameters of the extraction process is the ration between the volumes of the organic and aqueous phases. It is known that the phase volume ratio affects the efficiency of extraction of rare-earth elements with TBP [25]. No published data of this kind are available for extracting agents belonging to the class of tertiary amines. Therefore, a set of experiments were performed, which demonstrated that the distribution coefficient of rhenium(VII) varies with the Org : Aq ratio in extraction of the metal with a mixture of TIOA and 1-octanol. As, in particular, the volume ratio of the organic and aqueous phases is changed from 1 : 1 to 1 : 100 for a 30% solution of TIOA in octyl alcohol, D_{Re} decreases by approximately a factor of 5 (Fig. 4), which corresponds to a decrease in the recovery of ReO_4^- into the organic phase from 99.8 to 51.2%. However, the value of D_{Re} remains large (about 100) even at Org : Aq = 1 : 100, which enables practical use of TIOA in a wide range of Org : Aq ratios, with extracts with high concentration of rhenium obtained.

The parameters of rhenium(VII) extraction with solutions of tertiary amines are noticeably affected by the composition of the aqueous phase [7, 9–11, 16]. The largest contribution to this process is made by the acidity of the starting aqueous phase [2, 7, 9–11, 22]. This can be probably attributed to the ability of extracting agents of this kind to extract the acid from solutions, in addition to rhenium(VII) [24, 26]. How-

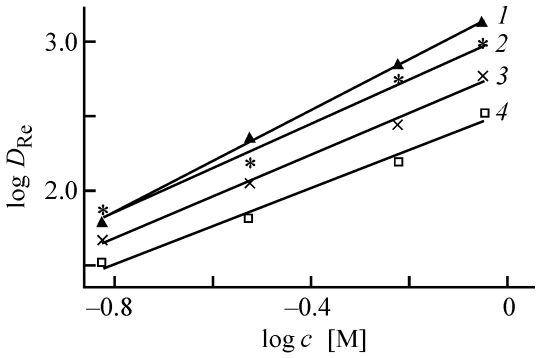

Fig. 3. Distribution coefficient D_{Re} of rhenium(VII) vs. concentration c of TIOA in the organic phase, plotted in the log–log coordinates for extracting agents of various compositions. Composition of the extracting agent (vol %): 5–30 TIOA and (*1*) 20 2-ethyl-1-hexanol or (*2*) 10 1-octanol in (*3*) 2-ethyl-1-hexanol or (*4*) 1-octanol.

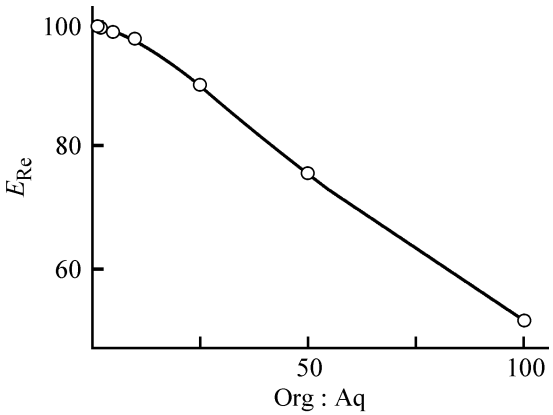

Fig. 4. Effect of the Org : Aq ratio on the recovery E of rhenium(VII) in extraction with 30 vol % TIOA in 1-octanol. Starting aqueous phase: Re(VII) 1.3 g l^{-1} and H_2SO_4 4 M. Composition of the extracting agent: 30 vol % TIOA in 1-octanol.

Table 2. Effect of the phase ratio and concentration of NH_4OH on the recovery E of rhenium(VII) from a 30% solution of TIOA in 2-ethyl-1-hexanol, washed with water to remove H_2SO_4 [$c(Re)_{org}$ = 2.85 g l^{-1}, $c(Re)_{re\text{-}extr}$ is the concentration of Re in the re-extract]

	E, %	$c(Re)_{re\text{-}extr}$, g l^{-1}	pH of the re-extract	E, %	$c(Re)_{re\text{-}extr}$, g l^{-1}	pH of the re-extract
1 : 5	95.9	0.55	10.7	97.61	0.56	11.1
1 : 1	90.6	2.58	9.9	92.28	2.63	10.5
2 : 1	88.4	5.03	9.1	89.68	5.10	10.1
5 : 1	0.08	0.024	7.52	0.92	0.13	8.06

ever, the relevant published data are contradictory, with authors reporting incomparable dependences of D_{Re} on the concentration of sulfuric acid in extraction with tertiary amines [7, 9–11, 16, 22].

The present study demonstrated that, as the H_2SO_4 concentration in the starting solution increases from 0.1 to 9 M in extraction with 30% TIOA, the distribution coefficient of rhenium(VII) decreases, with this decrease being the most pronounced at 0.1–1 M H_2SO_4 (Fig. 5). Similar results were obtained in [7, 27] in the case of Re(VII) extraction with tri-*n*-octylamine (TOA).

The decrease in D_{Re} on passing from weakly acidic to more concentrated solutions is probably due to a change in the state of the TIOA salt in the organic phase under conditions of an increasing concentration of H_2SO_4 in the aqueous phase. For example, it has been reported [26] that three forms of TOA sulfate exist at the equilibrium concentration of the acid in the aqueous phase equal to 0.1–0.5 M, and virtually the whole amount of TOA is converted into the hydrosulfate form at a sulfuric acid content of 2–3 M. The strongest decrease in D_{Re} can be attributed to differences in the extraction capacities of different sulfate forms of the amine for rhenium(VII). As for the gradual decrease in the distribution coefficient of Re(VII) with further increase in the concentration of sulfuric acid, it can be readily accounted for by the competing extraction of the acid by the amine, which hinders the extraction of rhenium(VII).

D_{Re} is affected not only by the acidity of the aqueous phase, but also by the concentration of ReO_4^- in the starting solution. It was found that raising the concentration of rhenium(VII) in the starting solution from 200 mg l^{-1} to 7 g l^{-1} in extraction with 30% TIOA leads to a more than fivefold decrease in the distribution coefficient. Accordingly, the degree of recovery falls from 93 to 23% (Fig. 6). Probably, such a dependence is due to a limited capacity of the extracting agent for rhenium(VII).

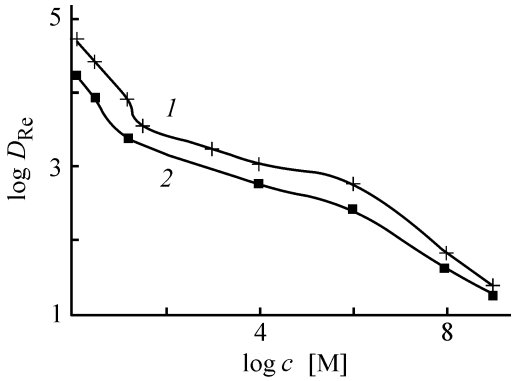

Fig. 5. Effect of the concentration c of sulfuric acid in the starting aqueous phase on the distribution coefficient D_{Re} of rhenium(VII). Starting aqueous phase: Re(VII) 200 mg l^{-1} and H_2SO_4 0.1–0.9 M. Composition of the extracting agent (vol %): (*1*) 30 TIOA + 20 2-ethyl-1-hexanol and (*2*) 2-ethyl-1-hexanol.

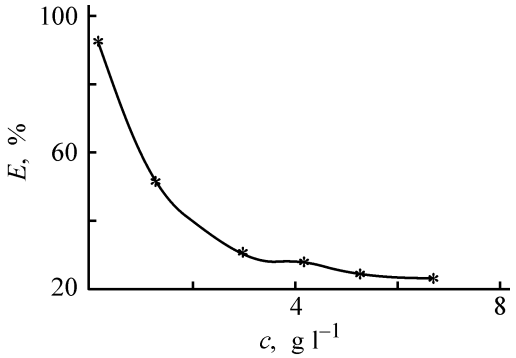

Fig. 6. Effect of the concentration of rhenium(VII), c_{Re}, in the starting aqueous phase on its recovery E from acid sulfate solutions. Starting aqueous phase: Re(VII) 0.2–6.7 g l^{-1} and H_2SO_4 4 M. Composition of the reagent: 30 vol % TIOA in 1-octanol.

An additional important characteristic of an extracting agent is its regeneration capacity. Rhenium(VII) is commonly re-extracted from tertiary amines of normal structure with ammonia solutions [20]. It was found that efficient re-extraction of rhenium(VII) from TIOA with ammonia solutions occurs, after its washing to remove sulfuric acid, under conditions providing a pH of no less than 9 in the re-extracts. It can be seen in Table 2 that, depending on the process conditions, a degree of re-extraction of up to 97.6% can be reached in a single stage to give solutions containing up to 5 g l^{-1} of rhenium.

Apparently, the concentration of rhenium(VII) can be additionally raised in the case of a counterflow re-extraction, and the solutions obtained can be further used to obtain ammonium perrhenate.

CONCLUSIONS

(1) Organic mixtures based on TIOA are effective extracting agents of rhenium(VII) from a sulfuric acid medium in a wide range of concentrations of both the organic and aqueous phases. ReO_4^- is best recovered from weakly acid solutions of rhenium(VII) with extracting mixtures that contain the maximum amount of TIOA (30–35 vol %) and the minimum amount of a modifier (15–20 vol % octyl alcohol).

(2) The distribution coefficient of rhenium(VII) in extraction with TIOA grows as the concentration of rhenium(VII) in solution decreases and the ratio between the organic and aqueous phases increases.

(3) The composition of the complex being extracted depends on the type and concentration of octyl alcohol. The complex contains 1.2–1.7 TIOA molecules per each perrhenate ion, and the solvation number decreases as the alcohol concentration becomes higher.

(4) Deep ammonia re-extraction of rhenium(VII) from TIOA can be performed to give concentrated solutions of ammonium perrhenate.

SORPTION AND ION-EXCHANGE PROCESSES

Interaction of Heavy Metal Ions with Ammonium Humates

Abstract—Sorption properties of ammonium humates with respect to Fe(III), Cu(II), Al(III), Ni(II), Pb(II), and Zn(II) are studied. The effect of the metal ion concentration on the ammonium humate consumption is examined and the corresponding dependences are analyzed using regression equations. The IR spectra of brown coal humic acids, ammonium humates, as well as Fe, Cu, Ni, Zn, Pb, and Al humates are presented.

DOI: 10.1134/S1070427206060103

Humic acids (HAs) are polyfunctional high-molecular-weight compounds with fairly high reactivity caused by the presence of the carboxy, hydroxy, amino, carbonyl, and other groups in their structure. These compounds can form stable complexes with heavy metal ions and, therefore, can be used for recovery of heavy metals from galvanic and metallurgic wastewaters.

In this study, we examined the interaction of ammonium humates with Fe(III), Cu(II), Al(III), Ni(II), Pb(II), and Zn(II), using IR spectroscopy and chemical analysis.

EXPERIMENTAL

The starting material for preparation of ammonium humates was oxidized brown coal from the Gusinoozersk deposit. The HA content in this coal ranges from 70 to 90%. Humic acids were extracted with 1% aqueous NH_4OH (s : l = 1 : 20).

To study the interaction of ammonium humates with metal ions, we used solutions prepared from $FeCl_3 \cdot 6H_2O$, $CuSO_4 \cdot 5H_2O$, $Ni(NO_3)_2 \cdot 6H_2O$, $Zn(CH_3COO)_2 \cdot 2H_2O$, $Pb(NO_3)_2$, and $KAl(SO_4)_2 \cdot 12H_2O$ [concentration 100–1000 mg l^{-1} (in terms of the metal)] and aqueous ammonium humate (20 g l^{-1}). Sorption was carried out in the static mode with stirring for 15 min at 20°C. A precipitate of ammonium humate was separated by filtration trough a paper filter and washed with a small amount of distilled water. The volume of the filtrate was adjusted to a fixed value (resulting filtrate was a transparent yellowish solution). The metal ion concentration in the mother liquor was determined photocolorimetrically [1]. The weak coloration of the mother liquor virtually did not interfere with the photometric determinations.

The degree of recovery of the metals, X (%), was estimated from the difference between the initial and equilibrium concentrations:

$$X = (c_0 - c_{eq})/c_0,$$

where c_0 and c_{eq} are the initial and equilibrium concentrations of the metal ions, respectively (mg l^{-1}).

In this study, we examined the dependence of the optimal consumption of the humate on the metal ion Fe(III), Cu(II), Al(III), Ni(II), Pb(II), and Zn(III), concentrations at pH 1–2. As the optimal consumption P we regarded the minimum amount of the sorbent required to recover metal ions to the maximum extent under given conditions. The results are summarized in the table.

Sorbent consumption at various concentrations of Fe(III), Cu(II), Al(III), Ni(II), Zn(II), and Pb(II)

1000	48.0	96.35	1000	8	87.10

The experimental data obtained in these experiments were processed by the least-squares method [2]. Over the metal concentration range 100–1000 mg l^{-1}, the experimental dependences are linear with a 99.0% probability (Fig. 1).

The sorption capacity of ammonium humate with respect to metal ions is as follows: Fe(III) 58 mg g^{-1} (3.1 mg-equiv g^{-1}), Cu(II) 31 mg g^{-1} (0.97 mg-equiv g^{-1}), Ni(II) 35 mg g^{-1} (1.2 mg-equiv g^{-1}), Zn(II) 36 mg g^{-1} (1.1 mg-equiv g^{-1}), Pb(II) 119 mg g^{-1} (1.15 mg-equiv g^{-1}), and Al(III) 24 mg g^{-1} (2.7 mg-equiv g^{-1}). Note that adsorption of the metal ions is accompanied by neutralization of the acidic solutions.

The humate provides a high degree of recovery (96–99%) of Al(III) and Fe(III) from water. The recovery of lead is 87%, while that of copper, nickel, and zinc is slightly lesser (70–78%). Thus, the recovery of the metal ions decreases in the order Fe(III) > Al(III) > Pb(II) > Ni(II) > Zn(II) > Cu(II). In the case of an iron-containing solution, water was completely clarified with the humate, whereas in the presence of other cations, some coloration remained, caused by the formation of water-soluble metal humates through chelation with electron-donor groups of the humate. The FTIR spectra of the humic acids and metal humates (Fig. 2) confirm the formation of metal humate complexes.

The spectra of brown coal humic acids and humates of ammonium and heavy metals show the ab-

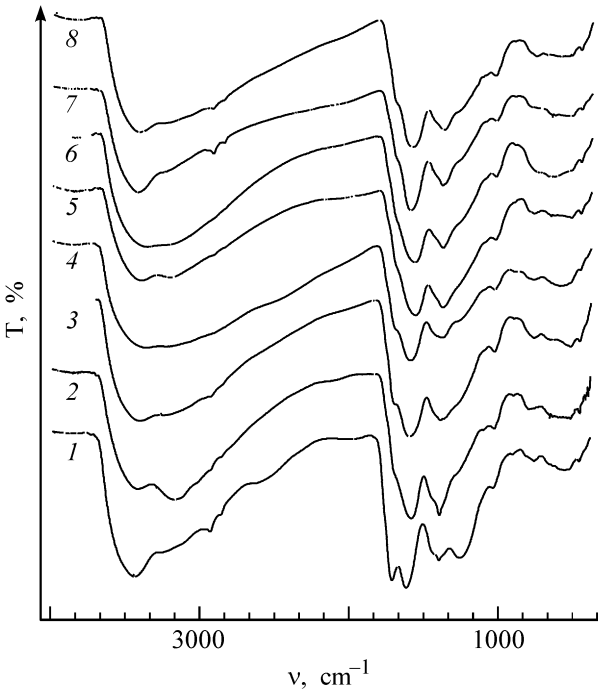

Fig. 2. IR spectra of (*1*) humic acids from the Kholbol'dzhinskoe deposit and humates of (*2*) ammonium, (*3*) iron, (*4*) aluminum, (*5*) lead, (*6*) nickel, (*7*) zinc, and (*8*) copper. (T) Transmittance and (ν) wavenumber.

sorption band at 3450–3300 cm^{-1} (H-bonded hydroxy groups) (Fig. 2). In the range 690–400 cm^{-1}, the samples of the humic compounds show weak absorption bands, presumably associated with the mineral fraction, but not organic structures [3]. The signature of aromatic structures is observed as the bands near 1600 (C=C skeleton vibrations) and at 773 (C–H out-plane bending vibrations). The bands at 1050–910 cm^{-1} are assigned to ether clay minerals or some phenoxy structures (aromatic CCH moieties in ordinary or condensed rings, or substituted phenolic and hydrocarbon structures). Asymmetric and symmetric stretching vibrations of the $-CH_2$ groups are observed at 2925–2935 and 2855 cm^{-1}. As a shoulder, these bands are found in the spectra of iron, ammonium, and lead humates. In the spectra of nickel and aluminum humates, these bands are unnoticeable or concealed by the broad absorption band of the hydroxy groups.

In the spectra of humic acids, the characteristic bands at 1720–1700 (vibrations of the carbonyl groups) and 1250–1270 cm^{-1} (C–O stretching vibrations or OH bending vibrations) are assigned to the carboxy groups.

Treatment of humic acid with ammonium hydroxide resulted in predictable changes in the IR spectra, caused by the conversion of free carboxy groups into the carboxylate form. The IR spectrum of ammonium humate shows a new strong band at 3174 cm^{-1} as well as a band at 1400 cm^{-1} whose intensity is higher than in the spectrum of humic acid. These bands are assigned to the N–H vibrations of ammonium. The bands of the carboxy groups (1714 and 1267 cm^{-1}) disappear, which is generally due to their transformation into the carboxylate groups. In this case, new bands of carboxylate appear at 1610–1550 and 1420–1300 cm^{-1}, which are not resolved because of the superposition with other bands. Additionally, the band at 1616 cm^{-1} shifts to 1589 cm^{-1} (C=C skeleton vibrations in arenes), which can be attributed to the superposition with a new band of carboxylate. The expected band of carboxylate at 1400 cm^{-1} is not resolved because of the superposition with the strong band due to N–H vibrations in the ammonium cation.

The spectra of the heavy metal humates show a low-frequency shift and decrease in the intensity of the band at 1400 cm^{-1} (symmetric stretching vibrations of COO^-). The band at 1589 cm^{-1} (asymmetrical stretching vibrations of COO^-) shifts also, suggesting the substitution of the ammonium ions by heavy metal ions in the carboxylate. The slight splitting of the bands at 1379–1398 cm^{-1} in Fe, Zn, and Cu humates, and of the band at 1569–1570 cm^{-1} in the Pb salt can be assigned to vibrations in the metal carboxylate COOMe (Me is a heavy metal) and carbonyl group, weakened by the resonance between the C–O–M and C=O...M structures [4]. It is quite possible that the metal humate structures contain β-diketone fragments ($-CO-CH_2-CO-$) whose carbonyl groups are coordinated to the metal cations. The appearance of the band near 3200 cm^{-1} in the spectra of Fe, Pb, and Al humates can be attributed to the formation of coordination polymers. These metal ions tightly cross-link the humate macromolecules to give poorly soluble metal humates, providing efficient water treatment. In the spectra of Cu, Ni, and Zn humates, this band appears as a shoulder. Evidently, the resulting polymeric associates are less stable than those of Fe, Al, and Pb.

CONCLUSIONS

(1) In treating water to remove Fe(III), Cu(II), Al(III), Ni(II), Pb(II), and Zn(II), the consumption of ammonium humate linearly increases with increasing metal ion concentration.

(2) The maximum decontamination efficiency with humates is 96–99% for Fe(III) and Al(III), 87% for Pb(II), and 70–78% for Cu(II), Zn(II), and Ni(II). The recovery of the metal ions decreases in the order Fe(III) > Al(III) > Pb(II) > Ni(II) > Zn(II) > Cu(II).

(3) The IR spectra of the metal humates show that Fe, Al, and Pb form more stable polymeric associates as compared to Zn, Cu, and Ni, providing an explanation for the observed higher efficiency of decontamination to remove Fe(III), Al(III), and Pb(II).

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Effect of Electrochemically Synthesized Polymethylolamide Coatings on the Corrosion Resistance of Steel in Seawater

Abstract—The effect of coatings based on a copolymer of acrylamide, *N*,*N*'-methylenebisaxcrylamide and formaldehyde deposited by electrochemical polymerization on the corrosion resistance of 08Kh18N10T stainless steel (field studies at sea) and low-carbon steel (laboratory experiments) was examined.

DOI: 10.1134/S1070427206060115

The problem of protection of metals from biogrowth and corrosion in seawater is a matter of acute current interest, because corrosion processes lead to a large-tonnage loss of metals and failure of ships, devices, and equipment working in marine conditions and in coastal regions. Solution of this problem would prolong the service life of high-cost objects and save metals and alloys. However, no versatile methods that could forever close the issue of article protection from biogrowth and corrosion have been developed so far. Therefore, the necessity for continuation of investigations in this area is quite apparent.

Commonly, various metallic coatings or polymer and paint-and-varnish layers, or combinations of these, are used as protective materials. In recent years, increasingly close attention has been given to polymer coatings. Apparently, the advances in application of polymer materials are determined both by the level of understanding of their physicochemical and biochemical properties and by the development of new materials and progressive technologies for deposition of polymer coatings on metal surfaces. A particular place among technologies of this kind is occupied by the electrochemical polymerization method [1]. This method makes it possible to control the properties of polymers deposited on metallic substrates both by varying the composition of the starting monomeric formulations and by immobilization of fillers of varied nature, which impart new special properties to the coatings, into the polymer matrix directly in the course of electrolysis. In addition, the electrochemical polymerization method can control the quality and thickness of coatings by varying the electrolysis modes. Control over the electrolysis potential also makes it possible to vary the polymerization mechanism and obtain (co)polymers of prescribed composition. The simplicity of the technique, combined with the high rate of formation of polymer layers and the valuable properties of (co)polymers, make apparent the advisability of a study of the protective properties of electrically synthesized polymer coatings.

The evidence concerning the method and mechanism of electrochemical polymerization of acryl monomers and formaldehyde and possible application areas of the polymethylolamine coatings obtained was the most completely represented in [2]. It has been shown that formaldehyde contained in the starting monomeric formulation is incorporated, in the course of electrochemical polymerization, into the macromolecular chain of a polymer (methylolamide groups) [3]. In addition, it is well sorbed in pores and on the surface of a polymer film. Being the main toxic component of the starting solution and of the material being formed, formaldehyde imparts bactericidal properties to the polymer film [4]. The presence in the polymer of such a highly toxic compound, whose threshold content is only 1×10^{-4}%, should exert a sterilizing influence on microorganisms, including those corrosion-hazardous. As a result coatings of this kind can protect equipment used in natural water from biogrowth and corrosion. However, no

investigations of this kind have been performed until now.

The aim of this study was to examine the influence exerted by poly(acrylamide-*N*,*N*-methylenebisacrylamide–formaldehyde) coatings electrochemically deposited on metals on the corrosion activity of the marine environment with respect to St.3 low-carbon steel and on the corrosion resistance and formation of micro- and macroovergrowths on the surface of special steels that are stable against general corrosion in seawater, but are damaged by biogrowth.

EXPERIMENTAL

Acrylamide (AA) and *N*,*N*'-methylenebisacrylamide (MBAA) of Reanal brand (without additional purification), formaldehyde (F) in the form of a 29.3% aqueous solution, and zinc chloride of chemically pure grade were used in the study. The concentrations of these reagents in the aqueous electrolysis bath were as follows (M): AA 3, MBAA 0.1, F 7, and $ZnCl_2$ 0.1.

Prior to experiments, in accordance with the procedure described in [5], steel plates were marked, their edges were trimmed, and the plates were ground, degreased with ethanol, and weighed on a VLR-200-M analytical balance.

Polymer coatings were formed on $80 \times 40 \times 2$ mm samples of 08Kh18N10T high-alloyed steel and $40 \times 20 \times 1$ mm samples of St.3 steel (cathodes) in quarts glass cells in the potentiostatic electrolysis mode. Aluminum foil was used as anodes. An EVL-1M3 silver chloride electrode equipped with a Luggin capillary filled with a working solution served as reference. Solution temperature 20–25°C, electrochemical polymerization potential E = –1.16 V, electrolysis duration 5 min. The metallic electrodes were treated before experiments by techniques commonly accepted in electropating [6]. Part of the plates were electroplated with zinc under conditions similar to those used in electrochemical polymerization (c_{ZnCl_2} = 0.1 M, τ = 5 min).

Some of the samples with a polymer coating were twice washed, after electrolysis, with 100 ml of distilled water for 30 min, whereas the rest were used without washing.

Seawater was used in the laboratory experiments.[1] The temperature of water in nature was 7–8°C. Freshly taken water was used in all the experiments, with its temperature gradually, in the course of several hours, elevated to room temperature (20–23°C).

The laboratory experiments included two sets. In the first set, glass vessels were filled with 0.5 l of pretreated seawater and three coated samples were suspended on Kapron threads in each vessel. In the second set, samples without coatings were exposed, with addition of a certain amount of a formamide solution to the test corrosive media. The duration of the tests was seven days.

The study included the following tests: (1) seawater + steel samples (control); (2) seawater + F (M): 1×10^{-3} (trace concentration), 1×10^{-2} (concentration of fixation of bacteria), and 1×10^{-1} (excess of formaldehyde), coated steel samples; (3) seawater + steel samples modified with a polymer film (a) without treatment with water and (b) washed with water; and (4) seawater + steel samples coated with zinc metal.

After the completion of experiments in the test and control media with natural seawater, the biological response to a changed state of the medium was studied by measuring the abundance of four physiological groups of bacteria: saprophytes (S), iron bacteria (IB), sulfate-reducing bacteria (SRB), and putrefactive anaerobes (PA) [8]. In parallel, the pH value of the medium and the concentration of dissolved oxygen were determined [9]. Steel samples were removed from exposure and weighed, the loss of mass was evaluated, and the corrosion rate was calculated by the equation

$$K = (P_1 - P_2)/S\tau,$$

where K is the corrosion rate (g m^{-2} h^{-1}); P_1, initial sample mass (g); P_2, sample mass after tests (g); S, sample area (m^2); and τ, test duration (h).

In tests under natural conditions, steel samples-plates (control and coated) were submerged in seawater in the near-shore part of the Golden Horn Bay (Vladivostok port) at a depth of 2.5–3 m. The tests were commenced during the period (last days of June) of mass settling of larvae of Balanus barnacles (BB) and continued for 120 days without interruptions.

After the samples were taken away from testing, the biological film formed during the whole time of exposure was subjected to microbiological analysis. Samples of the film were taken with a sterile spatula from different parts of the surface: (I) from under barnacles, no corrosion; and (II) the same, but with

[1] The water was taken at the Rynda Bay (Japan Sea, water area of the Amur Bay), whose water corresponds in the main hydrochemical parameters to that in the open Japan Sea [7]. Water was taken at a distance of 10–15 from the shoreline at a depth of 1 m.

corrosion. A bacterial suspension was formed and seeded onto nutrient media. The abundance of S was counted on fish-peptone agar; IB, on Kalinenko medium; PA, on Morris medium; and SRB, on Van Delden medium [8]. The species composition of the community of microscopic overgrowers and their raw biomass were studied. The intensity of steel disintegration under BB was expressed as the ratio between the number of BB with recorded corrosion sites under them and the total number of settled BB. The mass loss by a sample was determined.

Potentiostatic electrolysis in AA–F–MBAA–$ZnCl_2$ solutions at $E = -1.1\ldots-1.3$ V enables formation of two-layer Zn/polymer coatings on the cathode surface [2]. The results obtained in determining in laboratory conditions the biocide effect of coatings of this kind, without pretreatment with distilled water and with double washing, on the bacteriocenosis in the test media are listed in Table 1. The analysis performed demonstrated that metallic zinc, which belongs to toxic heavy metals, gradually dissolves during the exposure of the samples under study. As can be seen from Table 1, exposure of St.3/Zn samples in the test media results in that the abundance of the physiological groups of bacteria decreases by a factor of 1.5–3.5 as compared with the control media. A similar suppressive bacteriostatic effect was observed in test media with formaldehyde added in amounts recommended for fixation of bacteria (0.1–1.0 M of a 40% solution [10]). As shown by the experiments, even trace amounts of formaldehyde strongly suppress the development of bacteria (Table 1), and this suppression is the most pronounced for saprophytes. Their abundance decreases by a factor of 35, whereas that of IB, SRB, and PA, by factors of 10, 2, and 2.6, respectively. An increase in the formaldehyde concentration to 1×10^{-2} M completely eliminates any vital activity of bacteria and microorganisms present in seawater.

Exposure of steel samples with a Zn/polymer coating in test media gives results similar to those obtained in the presence of 1×10^{-2}–1×10^{-1} M of formaldehyde. Irrespective of whether untreated or water-washed samples are used, their inhibiting action is manifested in full measure, which terminates the vital activity of microorganisms. This result is a consequence of a joint toxic effect of Zn and formaldehyde incorporated into the polymer matrix.

Thus, the biological response of the natural marine medium is totally suppressed in laboratory experiments owing to the complex effect of two-layer composite Zn/polymer layers deposited on test metallic substrates.

Further studies were aimed to examine the corrosion resistance of metals coated with polymethylolamide films and to analyze factors that govern the corrosion processes. Table 2 lists the pH values and oxygen contents in the control and test media. The data obtained indicate that there is, on the whole, only a little change in these parameters in the course of the process. The insignificant decrease in the pH value both in test media with fixed steel plates and in solutions with addition of formaldehyde can hardly serve as in important corrosion factor, especially if the fact that the accuracy of pH measurements is an order of magnitude poorer than that in determining the oxygen concentration [9] is taken into account. It is known that the rate of oxygen supply to a corroding surface governs the corrosion rate of the majority of metals. The observed minor increase, with respect to the control values, in the oxygen concentration in the test

Table 2. Concentration of dissolved oxygen, corrosion loss by St.3, and pH value in the test media

1×10^{-3}	2.38	7.76	0.0104	0.039
1×10^{-2}	3.32	8.04	0.0114	0.042
1×10^{-1}	3.37	7.96	0.0111	0.041

media may be due to absence of, or decrease in, the consumption of O_2 for respiration by microorganisms because of their death or suppression of their vital activity. Therefore, it may be assumed that the corrosion loss by steel samples will also depend on the biological activity of a medium.

At the same time, there exist a number of reasons why corrosion processes are hindered and, consequently, the corrosion rate decreases. One of these is the method of electrochemical deposition of one metal onto another, exceedingly widely used in modern technology [11]. This technique provides cathodic protection of the base metal from disintegration. Just this result was obtained in the present study: the corrosion rate of zinc-plated St.3 samples decreases by 40% (Table 2).

The results obtained demonstrate that the mass loss by the test samples also considerably decreases (by 25–30%) after certain amounts of formaldehyde, the known adsorbing organic inhibitor [12], are introduced into seawater. A similar result was observed after polymer coatings were deposited onto steel by electrochemical polymerization of AA, *N*,*N*'-MBAA, and F, in which case the corrosion processes are hindered by combination of several factors: antiseptic properties of the films, inhibiting action of residual formaldehyde, and cathodic protection by zinc.

Because attainment of a passive state is virtually impossible for iron, cast iron, and medium-alloyed steels in seawater [13], the corrosion of these materials occurs at a permanently high rate. A visual inspection of the surface of the steel samples during their exposure in test media demonstrated that the corrosion of the control sample starts virtually immediately after the beginning of an experiment. In media with formaldehyde, changes on the steel surface were observed after 1–1.5 h. The most stable were samples with polymer and Zn coatings, on which no corrosion products could be seen during several hours. Further, the corrosion pattern was the same for all the samples, with a continuous bulky loose mass formed on their surface. It should, however, be mentioned that polymer films in a swollen state shielded the sample surface during the entire experiment.

Thus, it was found that, without any treatment in water after electrochemical synthesis or being twice washed with distilled water, copolymers of acrylamide, *N*,*N*'-methylolbisacrylamide, and formaldehyde exhibit biocide properties, with the microflora of the test media totally eliminated, and effectively reduce the corrosion loss.

The influence exerted by electrochemically synthesized (AA–*N*,*N*'-MBAA–F) copolymers on the formation of micro- and macrogrowths and the corrosion resistance of steel was further studied in summer–autumn (July–October) in the field conditions of the Golden Horn Bay, which is a typical port harbor with anthropogenic contaminations of both organic and inorganic origin. As practice shows, this permanently acting ecological factor predetermines the specific type of formation of the bacteriocenosis and community of overgrowers, with their transformation toward development of certain physiological groups of organisms stimulated [14, 15].

In performing field tests, it is necessary to take into account that, in the case of open water, when samples exposed are permanently washed with fresh water, the concentration of formaldehyde will rapidly decrease and this will diminish its overall biocide effect. In this case, the corrosion resistance of samples will depend to a greater extent on formation of micro- and macrogrowths on the surface of high-alloyed steel, which is known to be damaged under biogrowth.

Table 3. Abundance *B* of microorganisms on different areas on the surface of 08Kh18N10T high-alloyed steel (exposure duration 120 days)

Steel sample	Surface area	*B*, thousand cells per square centimeter, for indicated microorganisms

Control	I	104.0	106.2	0.8	35.6
	II	143.0	136.6	2.5	17.1
Samples with polymer coating	I	250.8	249.0	1.47	3.1
	II	269.5	164.0	1.45	7.6

* Areobes.

** Anaerobes.

Table 4. Parameters of biogrowth and local damage to 08Kh18N10T steel under barnacles (sample exposure duration 120 days)

Type of the steel surface	Raw mass of biogrowth, kg m^{-2}	Total abundance of barnacles, sp m^{-2}	Number of corrosion sites under barnacles per square meter	Corrosion intensity, %	Corrosion rate, g m^{-2} h^{-1}
Control	13.85	10516	1875	17.85	0.017
Polymer films	16.21	10781	1106	10.99	0.023
Deposit of metallic zinc		11953	703	5.88	0.0105

Table 3 lists the results obtained in counting the abundance of all the groups of bacteria under study on the surface of test and control samples under bases of barnacle shells. It can be seen from Table 3, that the number of saprophytes and iron bacteria on plates with polymer coatings exceeds by a factor of 2–2.5 the number of microorganisms of these physiological groups on the control. The abundance of SRB also tends to increase. However, the abundance of putrefactive anaerobes decreases by an order of magnitude. The decrease in the number of putrefactive anaerobes on plates with polymer coatings may be due to sensitivity of the microorganisms of this group to the biocide action of formaldehyde and polymethylolamide or to other factors, which require a more detailed study.

According to [16], the vital activity of bacteria on a metallic surface coated with a layer of adsorbed organic substances is markedly enhanced. Therefore, the presence on the metal surface of an additional organic source of nutrients in the form of the polymer matrix with removed toxic component activates to an even greater extent the reproductive capacity of the bacteria, which is manifested in the noticeable difference in their abundance on the experimental and control samples.

The sharply increasing number of bacteria colonizing the substrate surface predetermines the large volume of the biological film, which, in turn, attracts larvae of micro-overgrowers. This relationship can be considered confirmed both by the results of this study and by previous investigations [17]. The experiments demonstrated that the macro-overgrowth of the test plates is exceedingly abundant, multilayer, and continuous, and is predominantly represented by *Balanus improvisus* and *Balanus crenatus* barnacles, sludge worms, bivalves (mussels) *Mytilus trossilus*, hydroids *Obelia longissima*, and by single specimens of sea squirts *Ascidia de.sp* and amphipods. No differences in the species composition and climax phase of the overgrowers' community on the control and test samples are observed. However, the raw mass of overgrowers per sample on steel surfaces exceed in quantitative regard that on the control samples (Table 4). The present communication gives averaged data on biogrowth on samples with polymer coatings.

After removal of the biogrowth, the local damage to the surface of steel samples was observed under barnacle shells and, occasionally, between these shells at places of their mass accumulation. No corrosion damage was found under other types of overgrowers.

The maximum number of barnacles was observed on samples with a zinc deposit. However, the intensity of steel disintegration and the corrosion rate are the lowest on these samples.

On samples with polymer coatings, the total abundance of barnacles is close to that on the control. Nevertheless, the absolute number of damages sites on these surfaces is nearly twice lower than that on the control, with the result that the corrosion intensity decreases by a factor of 1.5–2, as in the case of the zinc coating. At the same time, it was found that the corrosion rate of the control sample is 1.5 times lower than that on polymer-coated samples. This is possibly due to the weaker biogrowth on the control samples, whereas on the samples with polymethylolamide films deposited by electrochemical polymerization, the abundant mass of biogrowth and the denser settlement of barnacles restrict the supply of oxygen to the surface and hinder formation of a passivating film on steel, with the result that the corrosion rate of these samples increases.

CONCLUSIONS

(1) A study of the influence exerted by electrochemically synthesized copolymer coatings based on acrylamide and formaldehyde on the corrosion resistance of St.3 steel and 08Kh18N10T stainless steel in natural seawater revealed that corrosion in a limited volume of a corrosive medium is hindered by the biocide action of the polymer, its components, and zinc sublayer. As a result, the loss of mass by St.3 steel is reduced by 25–30%.

(2) An increase in the corrosion rate of modified stainless steel samples was observed in field tests at sea. It was demonstrated that the corrosion disintegration of steel in open water is controlled by the biological factor of the medium. This may occur because the polymer layer on the metal surface can serve as an additional organic source of nutrients for microorganisms.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Acid–Base Interactions and Adhesion Capacity in the System Constituted by an Epoxy Coating and a Metal

V. Ya. Kustovskii, I. A. Starostina, and O. V. Stoyanov

Kazan State Technological University, Kazan, Tatarstan, Russia

Received February 1, 2005; in final form, December 2005

Abstract—Free surface energy and acidity parameter of solid surfaces of polyepoxides used as anticorrosive coatings were measured. Formulations of epoxy resins with various curing agents were studied. The adhesion capacity of epoxy films to various metallic surfaces was evaluated.

DOI: 10.1134/S1070427206060127

The presently widely used three-layer (epoxy primer, polyolefin-based thermoplastic melt-adhesive, and polyethylene) anticorrosive coatings (ACC) for steel pipes combine high adhesion properties of polyepoxides with good mechanical properties and high chemical resistance of polyolefins. As, however, the temperature is elevated and working time made longer, the adhesion capacity of ACC decreases. The performance of these coatings can be markedly improved by varying the composition of an epoxy formulation and the set of design elements of a three-layer ACC. This type of anticorrosive coatings is an interesting object of study and matter for further development, because a high adhesion between the constituent layers is to be achieved.

As is known, the phenomenon of adhesion consists in various kinds of interaction between molecules of the contacting phases. For an adhesion interaction to occur, it is necessary that bonds between molecules of the adhesive and active centers on the substrate surface should be formed. The existing thermodynamic approaches are based on the results obtained in studying the energy of interphase tension, wetting angles at the substrate–adhesive interface, and adhesive spreading angles at phase boundaries, with account of various contributions of intermolecular forces [1].

Recently, the approach according to which an important role in bonding between the contacting phases is played by acid–base interactions has gained wide acceptance [2]. In this context, the best properties should be observed for an adhesion joint in which one side shows acidic (by Lewis) properties, and the other, basic properties. In view of the aforesaid, a study of surface characteristics of all components of a coating is a matter of strong current interest. Further purposeful modification of the layers, aimed to enhance their acid–base interaction, could improve the properties and extend the service life of ACC.

The surface characteristics that allow prognostication of the capacity of a material for adhesion interaction include, in the first place, the surface energy with two components, dispersion and acid–base (previously named polar), and the acidity parameter [3], or reduced acidity parameter [4], which is the difference of the acidity parameters of the adhesive and substrate. The acidity parameter gives information about the acid–base properties of a surface under study and, consequently, about its capacity for an acid–base interaction in an adhesion joint.

The aim of our study was to reveal and assess the relationship between the above-mentioned characteristics and the adhesion capacity in the system constituted by an epoxy coating and a metal, which is highly important for a multilayer coating and ensures its adhesion to the metal and resistance to cathode flaking.

EXPERIMENTAL

We used in the study ED-20 epoxydiane resin and PEF-3A low-molecular weight epoxyurethane

caoutchouc. The formulation was cured with diethylenetriamine (DETA), polyethylenepolyamine (PEPA), AF-2M aminophenol, and DTB-2 curing agent, which is formed in the reaction of diethylenetriamine and butylmethacrylate in the presenece of a catalyst, a solution of boron trifluoride in diethylene glycol. The curing agent was taken in the stoichiometric amount with respect to the epoxy resin.

Copper, titanium, brass, steels (St. 10, St. 20, EP696, and Ya1T brands), and duralumin alloys (D16T, D16ATV, and D16AM brands) served as metallic substrates.

To evaluate the surface properties, film samples of epoxy formulation were formed on glass substrates and cured in air at room temperature (cold method) and in an oven at 80°C for 2 h (hot method).

We evaluated the components of the free surface energy (FSE) by measuring the wetting angles for test fluids on the sample surface with a KM-6 cathetometer and calculated them graphically, with processing by the least-squares method with the use of Microsoft Excel software.

As test fluids served water, aniline, phenol, formamide, glycerol, dimethylformamide, dimethyl sulfoxide, saturated aqueous solution of K_2CO_3, methylene iodide, and α-bromonaphthalene. Their parameters are listed in Table 1 [1, 3].

We calculated the acidity parameter by the Berger method [3], which consists in the following. If we use the known Owens–Wendt equation [5]

$$\gamma_{lv}(1 + \cos\Theta)/2 = (\gamma^d_{lv}\gamma^d_s)^{1/2} + (\gamma^p_s\gamma^p_{lv})^{1/2},$$

which can be brought to the form

$$W_a/2(\gamma^d_{lv})^{1/2} = (\gamma^d_s)^{1/2} + (\gamma^p_s\gamma^p_{lv})^{1/2}/(\gamma^d_{lv})^{1/2}$$

(γ^{ab}_1 and γ^d_1 are the acid–base and dispersion components of the FSE of the test fluids; W_a, thermodynamic work of adhesion of a fluid on the surface under study; γ^d_s and γ^{ab}_s, dispersion and acid–base components of the FSE of the surface under study) and plot, using a linear approximation, a curve in the coordinates $(\gamma^{ab}_1/\gamma^d_1)^{1/2}$–$W_a/2(\gamma^d_1)^{1/2}$, then the coordinate of the intersection point of the curve and the ordinate axis will be $(\gamma^d_s)^{1/2}$ and the slope of the straight line, $(\gamma^{ab}_s)^{1/2}$. The sum of the values of γ^d_s and γ^{ab}_s, graphically found in this way, is the geometric-mean approximation of the free surface energy of the material.

Table 1. Free surface energy γ_1 of model fluids and its acid–base (γ^{ab}_1) and dispersion (γ^d_1) components

Figure 1 shows as an example a plot in the coordinates $(\gamma^{ab}_1/\gamma^d_1)^{1/2}$–$W_a/2(\gamma^d_1)^{1/2}$ for one of the surfaces studied, that of a film based on the PEF-3A + PEPA formulation. Figure 1 demonstrates the strong deviations from linear behavior are observed for some of the fluids. This refers to all of the surfaces studied and indicates that values of γ^{ab}_s depend on the nature of a test fluid. These deviations furnish information about the acid–base interaction.

In the method used, we calculated values of γ^{ab}_s for the surfaces we studied from their individual interaction with each of two test Lewis acids and two test bases. The test acids and bases used have

EP 696	22.2	19.2	41.4	1.3

rather close, in pairs, values of γ_1^{ab} and γ_1^d (these are phenol and aniline, and glycerol and formamide). The differences in surface energy between the members of the above pairs are insignificant (Table 1). The aniline base has a somewhat higher FSE than the phenol acid, and the formamide base, a somewhat lower FSE than the acidic glycerol. The base having a lower FSE (formamide) in one pair should compensate for the influence of the acid with a lower FSE (phenol) in the other. If there were no acid–base interaction, these pairs would have approximately equal wetting angles on the surface under study and virtually coinciding points in the plot mentioned above. The values of γ_s^{ab} would be same for aniline and phenol, and glycerol and formamide. However, this is not the case. The occurrence of an acid–base interaction leads to the deviations of the points from the straight lines, mentioned above. In Fig. 1, the values of γ_s^{ab} for phenol and glycerol lie below the straight line. This means that the acids interact with the surface under consideration to a substantially lesser extent than it follows from the geometric mean and that preference is given to interactions with bases. Consequently, the surface has acid properties. In other words, if both bases wet the surface under study better than the acids do, it can be considered acidic.

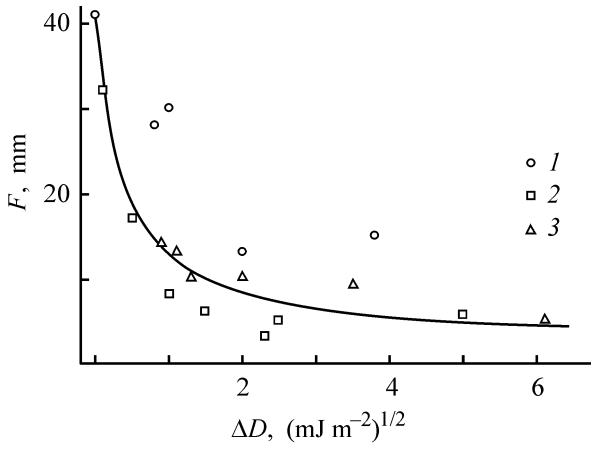

Fig. 2. Resistance to cathode flaking, F, vs. reduced acidity parameter ΔD for adhesion pairs constituted by a metal and an epoxy ACC. (*1*) ED-20 + PEPA, (*2*) ED-20 + AF-2M, and (*3*) ED-20 + DTB-2.

The difference between the values of γ_s^{ab} for acids and bases, calculated by the formula

$$D = 2\{[\gamma_s^{ab}(\text{aniline})]^{1/2} + [\gamma_s^{ab}(\text{formamide})]^{1/2}\} - 2\{[\gamma_s^{ab}(\text{phenol})]^{1/2} + [\gamma_s^{ab}(\text{glycerol})]^{1/2}\},$$

gives the measure of the acidity of the surface. And just this is the physical meaning of the acidity parameter.

The adhesion capacity of an epoxy coating to a metal was judged from the diameter of a defect produced in cathode flaking in a 0.1 N solution of sodium chloride at room temperature and voltage of 6 V during 8 h from the "seed" defect 3 mm in diameter.

According to the approach under consideration, a most important role in the interphase adhesion interaction is played by acid–base binding of the interacting surfaces. In three-layer ACC, particular attention is given to enhancement of the interaction at the interface between a metal and an epoxy primer.

Data on surface characteristics of a cured epoxy primer are listed in Table 2. As follows from the results obtained, the surface properties of films based both on the epoxydiane resin and on epoxyurethane caoutchouc strongly depend on the nature of a curing agent. For both primers, the acid properties increase in the order DTB-2 < AF-2M < PEPA < DETA. The full free surface energy of cured ED-20 is about 40 mJ m^{-2}, with the main contribution to this energy coming from the dispersion component of FSE, γ_s^d. The acid–base component is small ($\leq$10 mJ m^{-2}). The acidity par-

ameter D is positive, which points to the acid nature of the surfaces, and reaches the highest values for ED-20 + DETA and ED-20 + PEPA produced by cold curing.

We made a comparative estimate of the surface parameters of a primer cooled by the cold and hot methods. It was found that curing at elevated temperatures leads to a decrease in the acidity parameter for all the samples. This is presumably due to a slow rate of the curing reaction at low temperatures, so that amine reacts with atmospheric moisture and carbon dioxide to give an ammonium salt that is a Lewis acid.

To obtain coatings with the optimal adhesion properties, it is necessary to possess information about the surface (and, primarily, acid–base) properties of a metal. Therefore, we studied these parameters for various metallic surfaces. The experimental data obtained are listed in Table 3.

According to the acid–base approach, the best adhesion capacity should be observed between surfaces with the largest reduced acidity parameter ΔD. To confirm this suggestion, we evaluated the adhesion interaction of epoxy ACC with various metals by the method of cathode flaking (Fig. 2). Each of the dependences presented in the figure demonstrates that the intensity of interaction between these surfaces increases with the difference of their functionalities, and this is manifested in that the defect diameter decreases.

Previously, a dependence of this kind has been observed for ACC of modified low-pressure polyethylene, deposited on various metallic surfaces [4].

Thus, the analysis we made suggests that the films based on epoxy resins, we studied, exhibit acid properties, which are enhanced in the case of cold curing. The surface properties of the metals used in the study rather widely vary as regards the acidity (from nearly neutral for titanium to high for St. 10 steel). The best adhesion capacity, evaluated by the resistance to cathode flaking, is observed for the following adhesion joints: (ED-20 + PEPA)–titanium (ΔD = 4.6), (ED-20 + AF-2M)–St. 10 steel (ΔD = 5.1), and (ED-20 + DTB-2)–St. 10 steel (ΔD = 6.1).

CONCLUSIONS

(1) A relationship was revealed between the adhesion capacity of epoxy films to various metallic surfaces and the reduced acidity parameter for the elements of the adhesion joint, involved in the interaction.

(2) It was shown that application of the acid–base approach to the problem of improvement of the adhesion interaction between contacting phases and can be used in design of particular coating systems based on polyepoxides.

Abstract—Barrier-discharge plasma treatment of real surface water to remove organic pollutants was studied. Plasma treatment decreases the potential toxicity of snowmelt and rainfall runoff containing ammonium and chloride ions, oil products, phenols, and carboxylic acids (as recalculated for CH_3COOH).

DOI: 10.1134/S1070427206060139

Recent trends toward increasing contamination of natural surface and ground water make urgent water treatment to satisfy the potable water quality standards and to remove persistent organic pollutants, among which phenols are typically classified as criterial pollutants as well [1]. Along with adsorption and electrochemical methods, plasmochemical methods and, in particular, those using low-temperature barrier-discharge plasma (BDP) [2], rank among the most promising for water treatment to remove organic compounds. However, plasmochemical methods do not have widespread application now, probably, because the processes involved in treatment of real water need to be adequately understood, and the implementation of these methods, to be developed in more detail.

This study was aimed to elucidate the physicochemical relationships in the BDP treatment of wastewater to remove phenol, as well as to identify the most effective process parameters, based on the yield of the least toxic final products of oxidation of the pollutant.

EXPERIMENTAL

The experiments were carried out on the setup we described in [3]. The volumetric flow rate of the water to be treated was varied from 0.02 to 0.56 $cm^3\ s^{-1}$. Technical-grade oxygen (99.8 vol % pure, main impurities N_2 and Ar) at a flow rate $\leq 3.2\ cm^3\ s^{-1}$ served as the plasma-forming gas.

A barrier discharge was excited from a high-voltage transformer (current frequency 50 Hz); the interelectrode gap was 2 mm.

The voltage applied to the electrodes, measured with a V7-47 high-voltage voltmeter, was constant in all the experiments, 16 kV, which corresponded to the specific power input to the discharge, $W = 0.8\ W\ cm^{-3}$. The current in the secondary circuit was monitored oscillographically (C 1-55) from the voltage drop across the resistor (the discharge current was constant, 1.7 μA).

The time of contact of the solution with the plasma zone, τ_c, s, was calculated by the formula

$$\tau_c = \frac{S_{flow} h \tau_{tr}}{V_{tr} \times 1000}, \quad (1)$$

where S_{flow} is the area of the ring of the liquid layer in which the treatment is performed (in a layer of a hydrophilic material), cm^2; h, size of the discharge zone, cm; V_{tr}, volume of the solution being treated, ml; and τ_{tr}, time required for treatment of the given volume of the solution, s.

Our experiments were performed with prefiltered samples of real surface water (rainfall and snowmelt runoff) taken in the central, most urbanized, part of the city of Ivanovo; the runoff composition is presented in Table 1. Also, we carried out experiments with model solutions, namely, aqueous solutions of phenol and potassium chloride: model solution no. 1 (M1), $c_{phenol} = 4.2\ mg\ l^{-1}$ (or 268.1 μM the content of atomic carbon in the C_6H_5OH molecule); $c_{KCl} = 33.6\ mg\ l^{-1}$ (451 μM in terms of the content of atomic chlorine in the KCl molecule); model solution no. 2 (M2), $c_{phenol} = 3.97\ mg\ l^{-1}$ (253.4 μM in terms of the content of atomic car-

Σ PT_i			2343		1693		5578		3868

* The potential toxicity of the surface runoff was estimated from the $PT = c_i/MPC_{fish.i}$ ratio, where c_i is the concentration of the pollutant, mg l^{-1}, and $MPC_{fish.i}$, the maximum permissible concentration of the pollutant in a water basin used for fishing purposes, mg l^{-1}.

bon in the C_6H_5OH molecule), $c_{KCl} = 2.52$ mg l^{-1} (33.8 μM in terms of the content of atomic chlorine in the KCl molecule), this solution contained 123.74 μM of dissolved CO_2 (in terms of the content of atomic carbon in the CO_2 molecule); and model solution no. 3 (M3), $c_{phenol} = 10.0$ mg l^{-1} (or 638 μM in terms of the content of atomic carbon in the C_6H_5OH molecule).

The qualitative indicators (including pH) characterizing the composition of the initial and treated water (Table 1) were determined by standard techniques used for analysis of surface water and wastewater [4, 5].

Table 1 shows that the total efficiency of plasmochemical treatment of the surface runoff tends to decrease with increasing initial concentration of the water components that are monitored in the experiments. For example, treatment of storm and snowmelt runoff decreases the content of difficultly biochemically oxidizable organic compounds (COD) by factors of 3.8 and 1.8, respectively, the content of easily oxidizable organic compounds (BOD), by factors of 2.7 and 3.8, respectively, the content of oil hydrocarbons, by factors of 19 and 11, respectively, the content of volatile phenols, by factors of 1.4 and 1.8, respectively, and the content of carboxylic acids, by a factor of 1.3 in the snowmelt runoff only.

It should be noted that, despite the high initial concentrations (relative to MPC_{fish}) of organic compounds, the efficiency of decomposition for most of them remains sufficiently high, namely, 91–95 for oil products, 45–73 and 73–74 for reduction of COD and BOD, respectively, 30–46 for phenols, and up to 24 wt % for carboxylic acids.

These figures suggest that, during the BDP treatment of real snowmelt and rainfall runoff, phenols and carboxylic acids are formed once again, now as intermediates in decomposition of more complex organic compounds and, in particular, oil hydrocarbons.

We carried out a chromatomass-spectrometric analysis of the surface runoff (an extract in hexane) and interpreted the chromatograms using the library of mass spectra. We found that, along with typical compounds classified as oil products (ethylbenzene, *p*-xylene, 1,2-dimethylbenzene, propylbenzene, isopropylbenzene, 1-methyl-3-ethylbenzene, 1-methyl-2-ethylbenzene, 1,2,3-trimethylbenzene, propylbenzene, ethyldimethylbenzene, *o*-isopropenyltoluene, tetramethylbenzene, dimethylstyrene), the water also contained

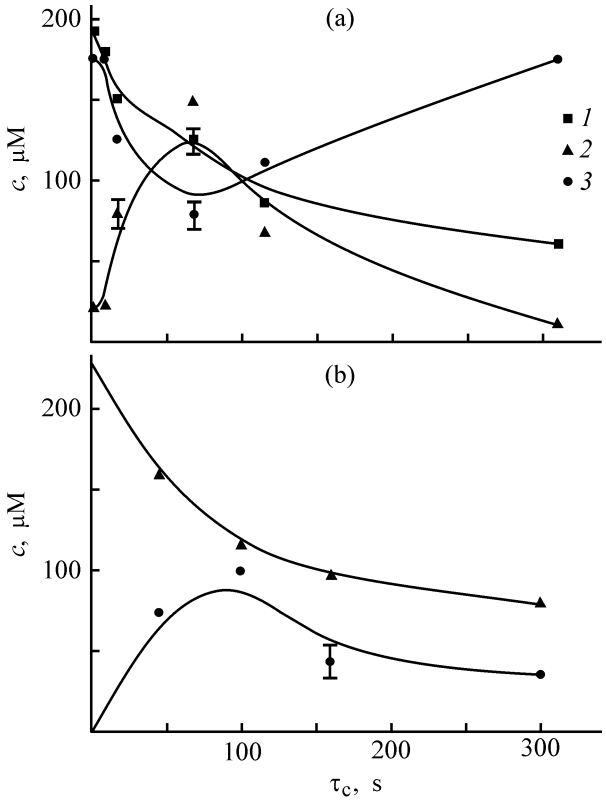

Fig. 1. Variation of the concentration of organic compounds, c (in terms of the content of atomic carbon in the molecule), in plasmochemical treatment of (a) the surface snowmelt runoff and (b) solution M1, with the contact time τ_c. (*1*) Oil products, (*2*) phenols, and (*3*) carboxylic acids (*points*, experiment; *lines*, calculation).

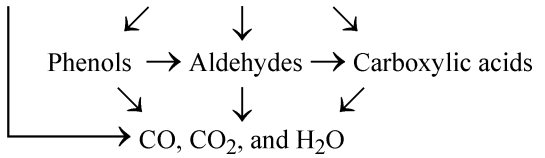

complex [4-(2-methyl-1,3-dioxalane-2-yl)benzonitrile, 1-methyl-2,8,9-trioxa-5-aza-1-silabicyclo[3,3,3]undecane] and, in particular, polycyclic (naphthalene, benzocycloheptatriene) and halogenated (1,2,3-trimethylbromobenzene) compounds, as well as triethanolamine, 1-phenylisoquinoline, dibutyl phthalate, and bis(2-ethylhexyl) phthalate. Probably, decomposition of these organic compounds can be an additional source of low-molecular-weight oxidation products occurring in the BDP-treated water.

Assessment of the potential toxicity of the initial and BDP-treated waters shows that, after plasma treatment, the PT decreases by a factor of 1.4 on the average, irrespective of the initial content of the organic compounds in water (Table 1). Thus, even taking into account the residual content of pollutants of various nature in the water treated, BDP seems promising for treatment of at least rainfall and snowmelt runoff.

The formation and decomposition of intermediate and final oxidation products of complex organic compounds in an oxygen medium can be represented by the following simplified schemes:

Complex derivatives of aromatic compounds → benzene → phenols → aldehydes → carboxylic acids → carbon and hydrogen oxides

Oil products (including aromatic hydrocarbons)

Our experiments showed that the rate of decomposition of phenols is, evidently, much lower than that of their accumulation as intermediates, as suggested by the peak in the kinetic curve describing variation of the phenol concentration (Fig. 1). Probably, specifically the efficiency of decomposition of the initial organic impurities makes the deciding contribution to the total efficiency (to reduction of the content of organic compounds) of the wastewater treatment.

In plasmochemical treatment, one of the main decomposition pathways for molecules of organic compounds (which is usually considered under the model experiment conditions) is their oxidation in reactions involving active species of the oxygen plasma (in particular, electronically excited O_2 molecules and oxygen atoms in the ground state), including those yielded by O_3 [6]. Ozone can react with diverse organic, organomelement, and inorganic compounds, and, thermodynamically, these reactions can go to completion [7]. A limiting factor is the low rate of the reactions in the final stages of decomposition. It should be noted that O_3 is a strong, but selective oxidant. For example, it is known that ozone very rapidly oxidizes phenols and unsaturated organic compounds, and fairly slowly, saturated acids and ketones (acetone) [7].

The specific features of the reactions of O_3 with various organic compounds account for, in part, the observed relationships in transformation of organic compounds whose content was monitored during our experiments. However, the results of our measurements suggest the necessity for taking into account the action of an additional oxidizer (Table 1), active chlorine (e.g., in the form of HClO or ClO^-) which can be yielded in natural waters by inorganic salts, e.g., potassium chloride. For example, an increase in the time of contact of water with the plasma zone is accompanied by conversion of chloride ions to an ac-

tive form (Fig. 2); the kinetic relationships in the formation of active chlorine from chloride anions, observed in the experiments with model solutions, were independent of the initial KCl concentration and identical for the M1 and M2 solutions.

Unlike ozone, radicals formed in the discharge by the scheme

$$HClO + ClO^- \rightarrow ClO^\bullet + Cl^- + OH^\bullet,$$

can effectively react with all the substances in solution that are capable of oxidation.

Radicals $ClO^\bullet$ can be involved participate in formation of atomic oxygen and $OH^\bullet$ [8]:

$$ClO^\bullet + ClO^- + OH^- \rightarrow 2Cl^- + OH^\bullet + 2O.$$

The appearance of strong oxidizers in the system is also indirectly confirmed by the change in pH of the solution from 7.23 to 6.65 during the experiments.

Chloride ions are formed in water, above all, via dissociation of inorganic salts, e.g., potassium chloride, which is widely used for elimination of the ice cover on roads and, probably, occurrs in the surface snowmelt runoff in city territories. Also, we cannot rule out possible occurrence in the water we studied of other, both inorganic and organic, chlorinated compounds, whose decomposition can yield chlorine in the form of ions and radicals capable, in turn, of reacting not only with the impurities occurring in water but also with one another.

We estimated the apparent rate constants of decomposition of the organic compounds occurring in the real runoff and in the model solution, based on the data in Fig. 1 by solving the problem of parametric and structural identification of the models of the kinetics of complex chemical reactions. To this end, we utilized the approach taken in [9]; we obtained the most likely estimates of parameters by the Gauss–Newton method and represented the step-by-step schemes of the processes of transformation of the organic compounds in the systems examined as follows:

for model solution

$$C_6H_6O\ (F) \xrightarrow{k_1} CH_3COOH\ (A) \xrightarrow{k_2} CO_2 + H_2O,$$

for surface runoff

$$\text{Oil products} \xrightarrow{k_3} C_6H_6O \xrightarrow{k_1} CH_3COOH$$
$$\searrow^{k_4} \qquad\qquad \swarrow_{k_2}$$
$$CO_2 + H_2O$$

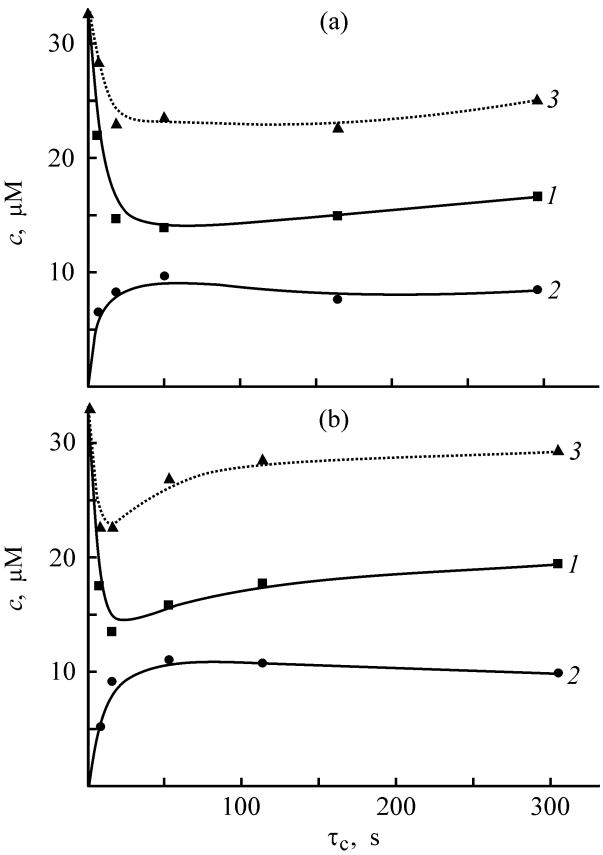

Fig. 2. Variation of the concentration of the chloride ions and active chlorine, c, in (a) M2 solution and (b) snowmelt runoff with the contact time τ_c. (*1*) Chloride ions, (*2*) active chlorine, and (*3*) total chlorine (*points*, experiment; *lines*, calculation).

The results of calculation in terms of these models are graphically represented in Fig. 1, and the calculated apparent rate constants of the reactions are listed in Table 2. The tabulated data suggest that the apparent rate constant of oxidation of phenol, k_1, is weakly dependent on its initial concentration and on the composition of the solution being treated.

Table 2 confirms the validity of the previous assumption that the rate of decomposition of phenol, k_1, though being comparatively high, is nevertheless lower than that of its accumulation in oxidation of more

complex organic compounds, k_3, during BDP treatment of real systems.

Under BDP exposure of the model solutions, the rate of accumulation of carboxylic acids is lower than that of their decomposition, whereas in treatment of real waters the situation is the reverse. This can be accounted for by the fact that, in the case of the BDP treatment of real waters, there are additional pathways for formation of alkyl radicals (decomposition products of alkoxy radicals) which, eventually, yield a significant proportion of low-molecular-weight products, such as aldehydes, ketones, acids [10].

To identify the limiting step of the plasmochemical processes, we analyze the characteristic lifetime τ^* of the molecules of the substances occurring in the solution, with phenol as an example (Table 3): (1) the time of contact of the liquid with the electrodes, τ_c; (2) diffusion time of movement of the molecules toward the electrode in the liquid phase, $\tau_d \sim h^2/D$, where h is the thickness of the liquid layer ($h \approx 0.05$–0.1 cm), D is the diffusion coefficient in the liquid phase, $cm^2\ s^{-1}$ (e.g., $D = 0.77 \times 10^{-5}$ $cm^2\ s^{-1}$ for resorcinol [11]), $\tau \approx 325$–1299 s; and (3) lifetime τ_p based on the oxidation rate (the rate constants are taken equal to those calculated by numerical modeling), $\tau_p = 1/k_1$.

Thus, if the real thickness of the liquid layer is 1 mm, the diffusion lifetime of the phenol molecules is the largest among all the parameters considered. Evidently, specifically this step of the processes of interest can be regarded as the limiting in this case. If the thickness of the liquid layer is smaller (which is closer to reality), we can consider directly the chemical reaction in solution as the limiting step of the process. This is more probable in view of the behavior of the water film in strong electric fields.

Table 4 presents the change in the contents of the main products of decomposition of organic com-

pounds in the model solutions and the real surface runoff. Also presented is the estimated balance for the carbon atoms; it is satisfied accurately to within 5–13 mol % in the case of treatment of an aqueous solution of phenol. The disagreement in the carbon balance for the phenol solution lies within the accuracy of measurement for the compounds listed in Table 4. This suggests that all the main products of decomposition of phenol are measured and any other compounds and, in particular, those more toxic than phenol, are unlikely to be formed. This assumption is confirmed by the fact that the disagreement in the carbon balance is the smaller, the larger the time of contact of the solution with the plasma zone. When potassium chloride was added to the phenol solution, the disagreement in the carbon balance increased (33–41 mol %) and went beyond the accuracy of measurements for the compounds of interest. Hence, any other compounds that are not monitored in our experiments can be formed along with those monitored.

Similar conclusions are suggested by the results we obtained for a real surface runoff (the disagreement in the carbon balance was 35–37 mol %, and that for chlorine compounds, 13–21 mol %). The appearance of additional decomposition products both in the model solution and in the real runoff, when exposed to BDP, is, probably, due to formation of an additional amount of active species (in particular, active chlorine), which can be responsible for a change in the decomposition mechanism for the organic compounds on the whole.

Despite certain advantages offered by the plasmochemical treatment of wastewater, there is residual, unchanged, ozone at the reactor output in the gas phase [12]. Its amount was 9.4–42.3 g m^{-3}, which substantially exceeded the maximum permissible one-time concentration for atmospheric air (0.16 mg m^{-3}). Our experiments showed that, when a cartridge with a commercial catalyst, such as GTT,[1] was placed at the reactor output, ozone was not detected within the sensitivity of the method of measurement, i.e., its concentration at the output was under 0.1 g m^{-3} (the efficiency of removal of O_3 was not lower than 98.9–99.8 wt %). Thus, with a catalyst like GTT the ozone emission can be reduced to the permissible level.

CONCLUSIONS

(1) Barrier-discharge plasma treatment in the gas-liquid system is suitable for removing organic compounds from surface rainfall and snowmelt runoff.

(2) The degrees of decomposition of phenol in plasma treatment of its model solutions (99 wt %) and real surface waters (95 wt%) are comparable, like the corresponding apparent rate constants of decomposition of phenol (2.43×10^{-3} and 2.92×10^{-3} s^{-1} for the model solution and real runoff, respectively).

(3) Plasma treatment of the model solutions of phenol and real surface waters leads to formation of carboxylic acids as basic products of plasmochemical oxidation, as well as of CO_2 and HCO_3^-; the yield of these latter is 81 mol % for the model phenol solutions and 64 vol % for the real surface waters.

(4) In plasma treatment of the model phenol solutions and surface waters to remove organic compounds, the limiting step of the process is the reaction of the active species of plasma, predominnantly O_3, with the molecules of organic compound (phenol), as well as formation of the final decomposition products.

(5) Plasma treatment reduces the potential toxicity of wastewater by a factor of no less than 1.4.

Abstract—Synthesis of lower pefluoroalkanes, tetrafluoromethane, hexafluoroethane, octafluoropropane, and decafluorobutane, in a high-temperature reaction of graphite with fluorine in a reactor with a vertical ascending gas-dust flow was studied.

DOI: 10.1134/S1070427206060140

Tetrafluoromethane (TFM), hexafluoroethane (HFE), octafluoropropane (OFP), and decafluorobutane (DFB) are large-tonnage products used in processing (etching) of silicon in the semiconductor industry [1].

Tetrafluoromethane is produced in a high-temperature reaction of an immobile (fixed) bed of graphite with fluorine [2]. The rest of the above-listed perfluorocarbons are industrially manufactured by various methods, mainly with the use of ozone-hazardous chlorine-containing raw materials [1]. At the same time, TFM, HFE, OFP, and DFB can be synthesized from graphite and fluorine [3].

The primary goal of this study, which continues earlier investigations [3], is to search for conditions of carbon fluorination in which a mixture of perfluoroalkanes, containing HFE, OFP, and DFB in commercial amounts, is formed.

A study of the process of fluorination of graphite with a mixture of fluorine and nitrogen (or argon) in a fluidized bed [3] at various concentrations of fluorine in the gas phase enabled a conclusion that synthesis of CF_4, C_2F_6, C_3F_8, and C_4F_{10} at a temperature of about 600°C occurs in accordance with the two-stage scheme in which synthesis of a solid carbon polyfluoride $(CF_x)_n$ is followed by its thermal decomposition. The composition of the products formed in thermal decomposition of carbon polyfluoride depends on presence of gaseous fluorine in the decomposition zone. An increase in its amount makes smaller the fraction of fluorocarbons with a longer carbon chain. Therefore, spatial separation of the synthesis zone from the zone of thermal decomposition of carbon fluoride can lead to an increase in the fraction of hydrocarbons with the number of carbon atoms exceeding unity in the gaseous reaction products.

It was impossible to achieve a stable separation of the zone of $(CF_x)_n$ synthesis and decomposition in a reactor with a fluidized bed. Therefore, it was suggested to study synthesis of perfluoroalkanes from graphite and fluorine in a reactor in which $(CF_x)_n$ is synthesized in a vertical ascending gas-dust flow and decomposed in a fixed bed of a powder at a higher temperature.

To study the fluorination of graphite in a gas-dust flow, a laboratory installation schematically shown in Fig. 1 was created. The installation comprises an ejector *1*, uptake pipe *2* (inner diameter 9 mm, length 1.2 m), separator *3*, and down pipe *4* of diameter 20 mm. Filter *5* and solid-phase-expenditure meter *6* are installed in the separator of the reactor. Pipes *2* and *4* are equipped with electric heaters and with immersion-type and wall thermocouples.

The basic part of the installation is ejector unit *1*, which forms a gas-dust flow of a prescribed composition from nitrogen and graphite. The working principle of this unit is based on mixing of, and energy exchange between, two flows with different pressures to give a mixed flow with an intermediate pressure.

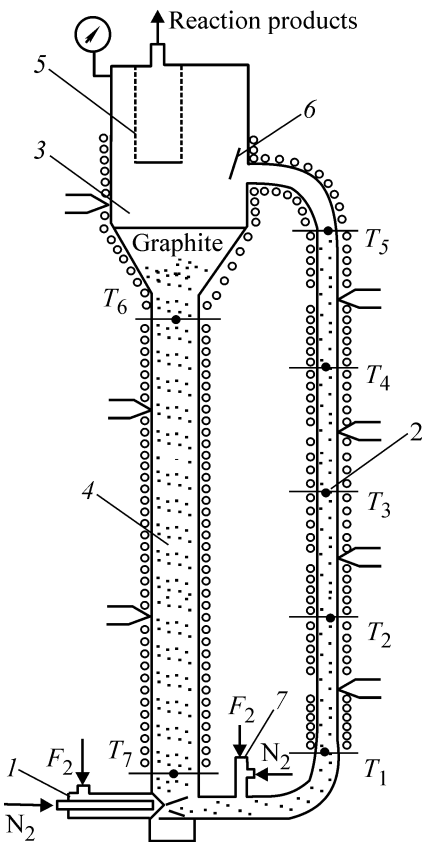

Fig. 1. Schematic of the laboratory reactor for fluorination of graphite in a vertical ascending gas-dust flow: (*1*) ejector, (*2*) uptake pipe, (*3*) separator, (*4*) down pipe, (*5*) filter, (*6*) expenditure meter, and (*7*) nozzle. T_1–T_7, thermocouples.

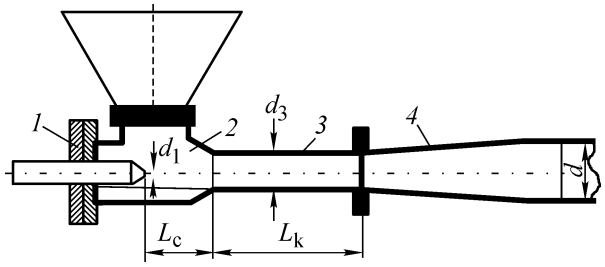

Fig. 2. Schematic of the unit for graphite ejection: (*1*) working nozzle, (*2*) receiving chamber, (*3*) mixing chamber, and (*4*) diffuser. d_1 = 1.5, d_2 = 8, and d = 9 mm.

The design of unit *1* is shown in Fig. 2. The main elements of the apparatus are the working nozzle, receiving chamber, mixing chamber, and diffuser. Their parameters were chosen on recommendations given in [4].

Nitrogen is fed into ejector unit *1*, and a gas-dust flow is formed in it.

A loose graphite powder is delivered to receiving chamber *2*. The gas jet outflowing at a high linear velocity from the working nozzle *1* carries away the graphite powder and imparts to it a part of its kinetic energy. The mixture of the gas and graphite is delivered to chamber *3*, where the velocity field of the moving flow becomes uniform and pressure partly increases. Then, this mixture is fed into diffuser *4*, where the pressure of the moving flow increases further. Leaving the diffuser, the flow is delivered to the uptake pipe under a certain excess pressure.

Fluorine is introduced by nozzle *7* into the gas-dust flow moving upwards in a heated vertical pipe *2* (uptake pipe). In this unit, carbon polyfluoride is formed, with complete consumption of fluorine.

In separator *3*, the gas and powder are separated. Filter *5* serves to remove fine particles from the gas. Expenditure meter *6*, which is an electrostatic capacitor with a movable plate, is installed in the separator opposite the inlet of the uptake pipe. Under the action of the flow, the plate deviates, with the electric capacitance of the capacitor changed, which is recorded with a digital meter. The extent to which the plate deviates and, consequently, the capacitance of the capacitor depend on whether or not the solid phase is present in the flow.

The powder separated from the gas is directed into down pipe *4*, in which it moves downwards in a constricted state under the action of the gravity force. Pipe *4* is equipped with an electric heater, which makes it possible to set a temperature necessary for decomposition of carbon polyfluoride.

Thus, the graphite powder circulates in the installation, being delivered successively into the zone of synthesis of carbon polyfluoride (pipe *2*) and that of its decomposition (pipe *4*).

Gaseous perfluorocarbons are discharged from the separator together with the flow of nitrogen, with the excess pressure in the reactor not exceeding 0.5 atm.

In the first stage of the study, the physicomechanical characteristics of the installation were analyzed: conditions for stable formation of a gas-dust flow (gas flow rate and the corresponding expenditure of the powder), residence time of the powder in uptake pipe *2* and down pipe *4*, and coefficient of heat transfer from the gas-dust flow to the wall of the uptake pipe. A graphite fraction with a particle size less than 1 mm was used.

A conclusion that a stable mode of powder circulation is attained was made using readings of the capacitive transducer *6*: the signal from the transducer subjected to the action of a gas flow is 8–10 times smaller that that in the case of a gas-dust flow.

Table 1. Expenditure of the solid phase (W_C) and the residence time of the powder in pipe *2* (t_2) and pipe *4* (t_4) in relation to the gas flow rate

Nitrogen flow rate, $cm^3 s^{-1}$, T_f = 500°C	Expenditure of graphite, $g s^{-1}$	Residence time, s		Powder circulation mode
		in uptake pipe	in down pipe	
32	–	–	–	No circulation
47	6.7	0.6	43	
52	5.7	0.6	50	Unstable
52	4.0	0.6	71	Stable
54	3.8	0.5	75	
55	5.0	0.5	57	
60	4.2	0.5	68	
62	4.7	0.5	61	
81	4.0	0.4	71	
90	4.0	0.3	71	
95	4.2	0.3	68	
118	4.0	0.3	71	
118	4.3	0.3	66	

The expenditure of the powder was determined in two ways: (i) by direct sampling of the powder, with removed upper cover of separator *3* and interrupted circulation, and (ii) from change in the temperature of the powder upon its heating in pipe *2*, with the cover and circulation circuit closed.

Table 1 lists the results obtained in measuring the expenditure of the solid phase and the residence time of the powder in pipe *2* and pipe *4* in relation to the gas flow rate. It follows from these data that no ejection of the graphite powder occurs at a nitrogen flow rate less than 60 $cm^3 s^{-1}$. At a higher flow rate of the gas, a stable gas-dust flow is formed and the expenditure of the solid phase is virtually independent of the gas flow rate.

At a nitrogen flow rate of 60 $cm^3 s^{-1}$, the residence time of the powder in pipe 2 is 0.5 s at the reactor temperature of 500°C, which is sufficient, according to [3], for complete binding of fluorine with carbon at a temperature exceeding 500°C.

The coefficient α of heat transfer from the gas-dust flow to the wall of pipe *2* was found from the rise in the temperature of the gas-dust flow in the region between the 1st and 5th thermocouples (T_5–T_1) at different wall temperatures of the uptake pipe. The heat-transfer coefficient was 120–180 $W m^{-2} K^{-1}$ in the working range of flow rates.

In the second stage of the study, the composition of the gaseous products formed in the reaction between fluorine and graphite in the reactor was examined (Fig. 1).

The reaction of fluorine with graphite to give $(CF_x)_n$ leads to heat release, with the heat effect of the reaction equal to 198 kJ mol^{-1} [5]. Table 2 lists the results of calculation of the adiabatic warming-up of the gas-dust flow in relation to the flow rate of fluorine.

In order that the temperature of the gas-dust flow from pipe *2* should not exceed 600–650°C at the initial temperature of 500–600°C, the flow rate of fluorine was maintained in the experiments within the range 4–8 $cm^3 s^{-1}$.

In the experiments performed, fluorine was delivered via injector *7*, and the flow rate of nitrogen was set to be about 60 $cm^3 s^{-1}$. The temperature of the powder in pipes *2* and *4* was varied.

Table 2. Parameters of the reaction between fluorine and graphite to give $(CF_x)_n$: adiabatic warming-up of the gas-dust flow (ΔT), heat release (ΔQ), ratio of the flow rate of fluorine to expenditure of carbon ($G_F G_C^{-1}$), and concentration of fluorine in the mixture with nitrogen (c_F) in relation to the flow rates of fluorine (G_F) and nitrogen (G_N) and expenditure of graphite (G_C)

C_F, $cm^3 s^{-1}$	G_N, $cm^3 s^{-1}$	G_c, $g s^{-1}$	c_F, vol %	$G_F G_C^{-1}$, %	ΔQ, $J s^{-1}$	ΔT, °C
15	60	2	20	1.2	250	160
8	60	2	12	0.6	130	90
4	60	2	6	0.3	65	45
2	60	2	3	0.1	33	23

Table 3. Composition of the gaseous products formed in the reaction between fluorine and graphite at different temperatures in the zones of synthesis and decomposition of carbon polyfluoride

T_5	T_6	CF_4	C_2F_6	C_2F_4	C_3F_8	C_3F_6	C_4F_{10}
°C		vol %					
580	600	57.6	20.6	1.5	10.4	3.5	6.5
570	600	52.3	24.8	1.8	10.6	2.4	8.1
550	570	53.2	25.8	–	10.5	1.7	8.8
530	580	53.0	27.8	–	10.6	–	8.7

In all the experiments, there was no breakthrough of fluorine across the zone of $(CF_x)_n$ synthesis.

Table 3 lists, in relation to the temperature at the outlet of pipe *2* (T_5) and to that in pipe *4* (T_6), the composition of the gaseous products formed in fluorination of graphite by the procedure described above.

According to the data in Table 3, the content of TFM is 50–55 vol %, which is approximately 15–20% lower than that in experiments on fluorination of graphite in a fluidized bed [3]. C_2F_4 and C_3F_6, absent in the case of fluorination in a fluidized bed, were found in the gaseous reaction products.

These facts suggest that carbon polyfluoride decomposes in the absence of fluorine in the gas phase. Thus, the use of the procedure for fluorination of carbon by the two-stage scheme in the installation shown in Fig. 1 made it possible to spatially separate the zone of synthesis of $(CF_x)_n$ and that of its thermal decomposition and to raise the yield of perfluoroalkanes with more than one atom of carbon.

It should be noted that the technological processing of the gas produced in fluorination of graphite is to include the stage of fluorination of unsaturated compounds with, e.g., cobalt trifluoride. This is necessary in order to rule out appearance of trace amounts of perfluoroisobutylene, which is extremely toxic [1], in the products formed. In doing so, tetrafluoroethylene and hexafluoropropylene will be fluorinated to give HFE and OFP, which will raise the yield of the last two products.

CONCLUSIONS

(1) It was shown that use of the ejection principle provides a stable formation of the nitrogen–fluorine–graphite gas-dust flow.

(2) The composition of the gaseous products formed in fluorination of graphite by the scheme including synthesis of $(CF_x)_n$ in a gas-dust flow and thermal decomposition of $(CF_x)_n$ in a fixed bed was determined (wt %): tetrafluoromethane 35–40, hexafluoroethane 25–30, octafluoropropane 15–20, and decafluorobutane 15–20.

(3) It was found that, in synthesis of the above-listed perfluoroalkanes from graphite and fluorine in a reactor with spatial separation of stages, the achievable yield of tetrafluoromethane is 15–20% lower than that of the reaction performed in a reactor in which both the stages occur within the same space.

(4) It was shown that the products formed in fluorination of graphite in a reactor with spatially separated stages contain tetrafluoroethylene and hexafluoropropylene, in contrast to the case of a reactor with spatially combined stages.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Kinetics of Heterogeneous Hydrodynamic Coagulation of Microscopic Drops

V. V. Tarasov, N. E. Kruchinina, S. A. Shilin, and N. I. Shchedrova

Mendeleev Russian University of Chemical Technology, Moscow, Russia

Received October 5, 2005; in final form, January 2006

Abstract—A prototype reactor for heterogeneous hydrodynamic coagulation of emulsions was developed and tested. The efficiency of coagulation of water emulsions of some organic liquids was studied in relation to process conditions.

DOI: 10.1134/S1070427206060152

Development of new methods for separation of emulsions into constituent phases is a topical task. Stable emulsions are the main reason for considerable loss in oil production and for contamination of the environment with oils, fats, and oil products. Separation of dilute emulsions of the "oil-in-water" type, i.e., raffinates produced in extraction of nonferrous, precious, rare, and radioactive elements, is also a complicated problem. This is so because emulsions with particles of submicrometer and micrometer size ("medusas"), formed in radiochemical industry, show high sedimentation and aggregative stability. Their separation requires application of special methods [1]. Separation of the dispersed phase from the dispersion medium occurs via coagulation (aggregation) of drops with their subsequent coalescence.

The method of heterogeneous hydrodynamic coagulation (HHC), we suggest here, is implemented in a batch installation (Fig. 1) [2, 3]. The stainless steel reactor *1* of volume 500 cm^3 and inner diameter of 80 mm, mounted on support *2*, was charged with 450 cm^3 of emulsion via opening *3* in cover *4*. An electric motor set in motion shaft *5* with plastic discs *6* attached to it. The rotation frequency of the discs was maintained constant in each set of experiments. To preclude formation of a whirlpool, four cylindrical reflector partitions *7* of diameter 4 mm were installed in the reactor. Samples were taken at certain intervals of time via opening *3*. Upon completion of an experiment, the contents of the reactor were discharged via bottom pipe *8*. The experiments were performed with 5 or 10 plastic discs of diameter 57 mm with smooth and corrugated surface, with the distance between the discs equal to 10 and 5 mm, respectively. All the experiments were carried out at 25°C. The apparatus in Fig. 1 is shown without a thermostating jacket. The unit maintaining the stable rotation of the discs was of the PE-8310 type. The discs were rotated by an electric motor at a strictly constant to within 10% prescribed speed in the range 200–3500 rpm.

The coagulation and coalescence in the reactor we developed necessarily involve immobile solid bodies (reflector partitions and reactor walls) [2, 3]. Because the emulsion is composed of at least two fluids, the process suggested here is to be regarded as occurring in a fluid–fluid–solid system (i.e., heterogeneous coagulation is meant). Moreover, the method being described is performed in a system of moving fluids,

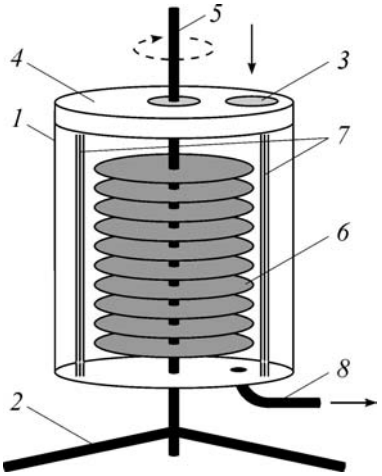

Fig. 1. Schematic of the installation for hydrodynamic heterogeneous coagulation. For explanations see text.

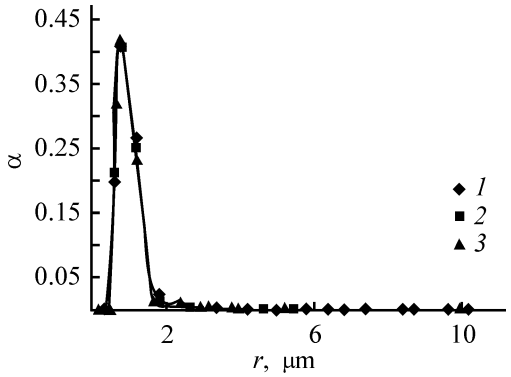

Fig. 2. Normalized size distribution of the counted number of drops in an emulsion of I-40 oil at disperser rotation speed of (*1*) 8000, (*2*) 9500, and (*3*) 13 500 rpm. (α) Fraction of drops of a certain size and (r) drop radius.

whence follows the term "hydrodynamic heterocoagulation."

Because moving fluids may have a considerable velocity relative to immobile bodies (e.g., walls) and high gradients of numerous properties are created near these bodies, a considerable acceleration of coagulation and coalescence would be expected in this case.

Thus, the aim of our study was to reveal how motion of fluids affects the kinetics of separation of comparatively stable emulsions in the presence of walls and other immobile bodies.

EXPERIMENTAL

The experiment comprised the following stages: (1) preparation of stable emulsions; (2) heterogeneous hydrodynamic coagulation, coalescence; and (3) analysis of the dispersion composition of the emulsions and determination of the efficiency of their separation.

We mean by stable emulsions those changing their optical transparence by 10–15% in 24 h.

To prepare an emulsion of this kind, we placed 200 ml of distilled water and 2–3 ml of a substance being dispersed ("oil") in the vessel of an MPW-303 homogenizer and vigorously agitated the mixture with an impeller at a rate of up to 8000 rpm. Also, an IKA DI 25 disperser equipped with an S 25 N-18G spraying unit having a rotor rotation speed of up to 25 000 rpm and fluid pulsation frequency of 4000 Hz. The emulsions formed under these conditions had well-reproducible light-absorption characteristics and possessed a strictly specified dispersion composition.

The vessel of the disperser was cooled from its outer surface with flowing water to preclude heating of its contents. After the agitation was terminated, the resulting emulsion was placed in a separation funnel and subjected to prolonged settling for 10 h to remove "coarsely dispersed" oil drops. In this way we prepared comparatively concentrated emulsions, which were further diluted with water containing 0.8–1.5 g l^{-1} of sodium chloride. These emulsions acquired more unchangeable properties, including light absorption. The oil particle size was 1–5 μm after a preliminary settling of the emulsion. This diminished to a minimum the probability of collisions between drops and their coagulation in the bulk of the fluid.

We were interested in such properties of the emulsions prepared as light absorption and particle distribution over size and volume. The absorption of light was measured in the spectral range 460–590 nm on a photoelectrocolorimeter. At a content of the dispersed phase of 0.8–1.5%, the Bouger–Lambert–Beer law was obeyed; the direct proportionality between the light absorption by an emulsion and the percentage content of the dispersed phase in it made it possible to measure the concentration of the dispersed phase.

To study the particle distribution over size, area, and volume, we developed a computer complex intended to obtain micrographs of emulsions and their processing. The number of drops on a single photograph was from several units to several hundred. Tens of photographs had to be taken for strongly diluted emulsions. The minimum recordable drop size was 0.6 μm.

Figure 2 shows as an example a normalized size distribution of counted drops of I-40 oil. At rotations rate of the disperser rotor in the range 8000–13 500 rpm, the distributions virtually completely coincide. Figure 2 can be used to determine the averaged drop radius ($r \approx 1$ μm); the curve in Fig. 2 is the closet to a logarithmically normal distribution.

To study the HHC process, we chose the method of rotating disks. The material of the inner surface of the apparatus walls was exceedingly important, as also that of the reflector partitions. In the experiments described in this communication, we used only stainless steel (reactor) and plastic discs and reflector partitions. The choice of discs as agitating devices was due to the fact that they create no excess turbulence in the emulsion and do not favor drop disintegration. At the same time, they form emulsion flows perpendicularly directed toward the reactor walls, where drops collide and the velocity vectors of the flows strongly change.

We used as fluids being dispersed Midel 7131 transformer oil, I-40 machine oil, olive oil, and decane. Midel 7131 has a density of 0.97 g cm^{-3}, which is extremely close to that of water. It is very important to keep this feature in mind when discussing the role of centrifugal forces. In addition it is necessary to take into account the not-too-high coefficient of kinematic viscosity (μ = 56 mm^2 s^{-1}) and rather considerable polarity (~12) of Midel 7131. The I-40 oil is a viscous mixture ($\mu \approx 80$ mm^2 s^{-1}, density 0.89 g cm^{-3}) of saturated hydrocarbons frequently used in practice as lubricants. The olive oil ($\mu \approx$ 60 mm^2 s^{-1}, density 0.87 g cm^{-3}) contains unsaturated fatty acids of medium polarity, which are widely used in food industry. Decane is an analogue of diesel fuel, a typical contaminant contained in wastewater from oil refineries and gas-filling stations, which has a viscosity close to that of water and density of 0.73 g cm^{-3}.

As a criterion characterizing the degree of recovery of an organic fluid from emulsions serves the quantity E (%) defined by the formula

$$E = 100(1 - A_\tau/A_0),$$

where A_0 and A_τ are the light absorptions by the initial emulsion and that at instant of time τ, respectively.

The Deryagin–Landau–Verwey–Overbeek (DLVO) theory [4] serves as a basis for the concepts of HHC. The kinetic energy of the flows created by rotating discs can be used by drops to overcome the potential barriers that appear in the DLVO curve when drops approach one another. The agitation of the emulsion by the discs has the following specific feature: it gives rise to flows perpendicular to the cylindrical wall and guarantees collision of these flows. The volume of the fluid between the discs is poorly agitated, and drops formed at and on the wall move upwards and then are removed from the process in the form of separate coarse drops and clusters of these. The organic phase is accumulated in the upper (immobile) part of the reactor (Fig. 1) and is virtually not subjected to repeated disintegration if the rotation rate of the discs is not too high. Nevertheless, repeated dispersion occurs and its extent is the more noticeable, the higher the degree of purification.

The agitation of the "oil-in-water" emulsion by the discs in the HHC installation leads to formation of transparent phases. This indicates that the coagulation, which is the rate-determining stage, culminates in coalescence. Calculations show that the separation of the emulsion into phases occurs at a rate exceeding that of natural sedimentation by a factor of 100–200. Indeed, several days are necessary in the latter case to reach the same separation as that we readily observe in the prototype reactor.

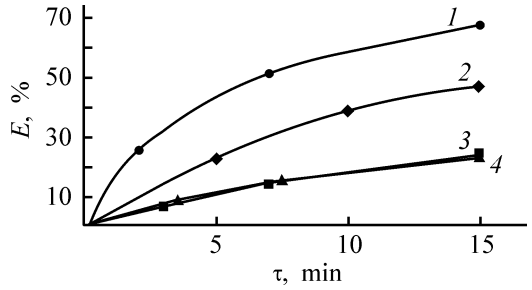

Fig. 3. Degree of clarification, E, of an emulsion vs. the process duration τ at a disc rotation rate n = 700 rpm. Emulsion composition: (*1*) decane, (*2*) Midel 7131, (*3*) I-40 oil, and (*4*) olive oil.

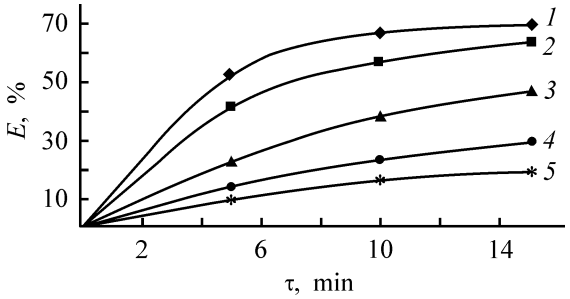

Fig. 4. Degree of clarification, E, of the emulsion with Midel 7131 vs. the process duration τ at different disc rotation rates n. n (rpm): (*1*) 2200, (*2*) 1100, (*3*) 700, (*4*) 500, and (*5*) 400.

Figure 3 shows kinetic curves of HHC separation of emulsions of various organic fluids at a disc rotation rate of 700 rpm. The highest coagulation rate is observed in the case of processing of the decane emulsion. The coagulation rate of organic fluids decreases in the order decane > Midel 7131 > I-40 oil > olive oil; however, there is no strong correlation of the HHC rate with such quantities as viscosity, interphase tension, and density of the dispersed phase. Although the difference between the fluid densities in the system with Midel 7131 is record-breaking small (only 0.03 g cm^{-3}), the coagulation in this system is two times faster than that in systems with olive oil and I-40 oil. This indicates that centrifugal forces do not play any noticeable role. I-40 oil and olive oil exhibited virtually the same coagulation rates despite that they have different densities and viscosities. Apparently, the kinetics of the process is governed by a set of factors, among which physicochemical surface-related quantities, such as wetting angles and dynamics of drop spreading, are important.

Figure 4 shows how the agitation intensity affects the transparence of the emulsion with I-40 oil at its in-

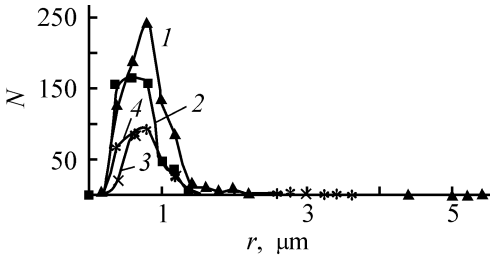

Fig. 5. Evolution of the drop size distribution for the emulsion with I-40 oil. (*N*) Counted number of drops and (*r*) drop radius. Process duration (min): (*1*) 0, (*2*) 10, (*3*) 30, and (*4*) 45.

variable dispersion composition, expressed as the number of drops of a given size related to the total number of drops.

The necessity for simulation and optimization of the HHC process is apparent. The simulation is all the more important because we observed a noticeable influence exerted by the number of discs and their design on the rate of purification of the aqueous phase to remove microscopic drops. For example, reducing the number of discs to five even led to a certain increase in the degree of purification. Replacement of smooth discs with corrugated ones also improved the phase separation.

Let us call attention to the "saturation" of the coagulation process, which is especially clearly manifested at high disc rotation rates and high degrees of purification. This phenomenon can be attributed to reversibility of the HHC process. The fact that it is impossible to reach high degrees of I-40 removal (>70%) means that repeated disintegration of drops becomes the key process. To obtain higher degrees of purification, it would be necessary to remove part of the upper fluid or perform continuous counterflow coagulation, rather than carrying out the batch HHC. In general, the dependence of the degree of clarification of an emulsion on the agitation intensity passes through a maximum at high degrees of purification, which also indicates that simulation and optimization of the process are necessary. The apparent reason for the existence of the maximum is the secondary disintegration of drops.

Another reason why the dependence of the rate of phase separation on the disc rotation rate levels-off and even passes through a maximum is caused by exhaustion of drops that can coagulate [5], rather than being due to reversibility. The aforesaid is confirmed by the type of evolution of the drop size distribution with the time of emulsion processing by the HHC method (Fig. 5). The last fractions of drops, seemingly having a similar distribution, are not "removed" on making the process longer.

Thus, we can suggest the following model of HHC: transport of oil drops to the surface of an immobile solid body (reactor walls); formation of guiding centers in interaction between drops of the organic phase and the reactor surface; surface coagulation of fine drops with the guiding centers and, possibly, coalescence; detachment of coarsened drops or their clusters from the surface of a solid body under the action of the incident vortices and pulsations; rise of coarse drops (clusters) and their removal from the agitation zone.

The results we obtained indicate that HHC may become an efficient method for purification of emulsions to remove drops of the dispersed phase. This technique may prove especially efficient in the case of moderately diluted emulsions and suspensions, and also very "fine" dispersed systems stable against sedimentation. The method requires no reagents or heating.

CONCLUSIONS

(1) An installation for performing the process of heterogeneous hydrodynamic coagulation simultaneously with coalescence was designed and tested.

(2) It was shown that the heterogeneous hydrodynamic coagulation leads to purification of the aqueous phase to remove microscopic drops, with the rate of this process exceeding that of gravitational sedimentation by a factor of 100–200.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Induced Bromination of Aromatic Hydrocarbons with Alkali Metal Bromides in the Presence of Oxidants

Abstract—The features of induced bromination of aromatic hydrocarbons in the NaBr(KBr)–HX–H_2O_2(NaOCl) system were studied.

DOI: 10.1134/S1070427206060164

Halogen derivatives of arenes are widely used for preparing drugs, dyes, fire-resistant composites, etc. At present, chloro- and bromoaromatic compounds are produced on the industrial scale by substitution halogenation of benzene derivatives with appropriate halogens [1, 2]. However, the selectivity of this process with respect to monohalo derivatives is low, and a certain fraction of halogens is lost in the formation of hydrogen halides, which require additional efforts for their utilization. Higher yields of monobromo derivatives of aromatic hydrocarbons are attained with alkali metal bromides and various oxidants, and almost all bromide anions are consumed in the course of the process.

Some data on oxidation of HCl and HBr with H_2O_2 were presented in [3], and the use of HCl + H_2O_2 and HBr + H_2O_2 oxidation system for preparing aliphatic halohydrins [4–6] and haloaromatic hydrocarbons [7–12] was studied. It was found [13, 14] that the bromide anion is incorporated into the substrate upon oxidation of aromatic hydrocarbons in the presence of Co(III) and Mn(III) bromide catalysts. At the same time, bromination of arenes, especially that of toluene and isomeric xylenes, predominantly occurs in the side chain. Benzyl bromide and its derivatives are formed either by ligand transfer of bromine atoms in the intermediate benzyl radicals or through steps of electron transfer [13]. Analogous data on oxidation of 2,4-dichlorotoluene were given in [14]. In [15], accumulation of bromoarene in the oxidate in the presence of cobalt(II) salts and bromine was analyzed assuming that an intermediate is formed by the following reaction:

$$[Co^{2+}\cdots L\cdots BrH]\cdot RH + 2O_2 \rightarrow [Co^{2+}\cdots L] + RBr + 2HO_2^{\cdot}.$$

It was found that, in the case of oxidation systems consisting of equimolar amounts of alkali metal bromides and hydrogen peroxide, the reaction direction shifts toward substitution bromination of alkylaromaic hydrocarbons via substitution of hydrogen atoms in the benzene ring [16–20]. In this case, bromination involves hypobromous acid and molecular bromine, whose formation was noted previously in oxidation of *p*-xylene and toluene in the presence of cobalt(II) bromide [21, 22]. Taking into account that, in contrast to polyvalent metal bromides, alkali metal bromides are not involved in the formation of intermediate complexes, ligand transfer of bromine atom in bromination of the initial hydrocarbons in their presence should be excluded. However, nascent bromine can participate in the process initiation. In [22], the oxidation of *p*-xylene, pseudocumene, and durene with $CoAc\cdot 4H_2O$–NaBr–*N*-bromosuccinimide system was interpreted assuming the following reaction scheme with the participation of bromine radical:

$$>NBr \rightarrow >N^{\cdot} + Br^{\cdot},$$

$$Br^{\cdot} + RH \rightarrow R^{\cdot} + HBr,$$

$$HBr + >NBr \rightarrow >NH + Br_2,$$

$$Br_2 + R^{\cdot} \rightarrow RBr + Br^{\cdot},$$

$$R^{\cdot} + O_2 \rightarrow RO_2^{\cdot} \text{ etc.}$$

In this case, only hydrogen atoms in the side chains are substituted. In the above papers, the formation of bromoarenes in the presence of polyvalent metal bromide catalysts and various oxidants was studied under the conditions in which aromatic acids are produced, and this reaction direction is strongly different from that of the induced bromination of arenes.

In this study, we examined the features of substitution bromination of alkylarenes in the presence of alkali metal bromides.

EXPERIMENTAL

The experiments were carried out in a standard glass reactor equipped with a reflux condenser, a system for reagent supply, and a magnetic stirrer. The reactor was placed in a thermostat with automatic temperature control. The required amounts of an aromatic hydrocarbon and of an aqueous solution of NaBr (or KBr) were placed in the reactor, and then the required amounts of H_2SO_4 (or HCl) and 28–30% aqueous hydrogen peroxide or 18.5–26% aqueous solution of sodium hypochlorite (110–115 g-ion l^{-1} content of available chlorine) were added dropwise.

After the experiment was complete, the organic layer was separated, neutralized with a solution of sodium bicarbonate, washed with water, dried with $CaCl_2$, and distilled. The reactions of induced bromination of aromatic hydrocarbons were monitored by gas-liquid chromatographic analysis for the amounts of unchanged arene and the isomeric composition of the resulting bromo derivatives, using an LKhM-7 chromatograph. The products of bromination of benzene, toluene, and xylenes were analyzed on a column (300 × 0.3 cm) packed with Silichrom-2 impregnated with 10 wt % $CoCl_2$ at (150°C column temperature); and of ethyl-, isopropyl-, and ethoxybenzene, on a column (300 × 0.3 cm) packed with Chromaton N-AW-DMCS impregnated with 5 wt % XE-60 at a column temperature of 150°C and a flow rate of helium carrier gas of 40 ml min^{-1}. In some cases, the individual bromo derivatives of aromatic compounds were prepared by the Sandmeyer reaction [23]. The consumption of hydrogen peroxide was monitored by permanganate titration [3], and the content of Br_2 and NaOCl in the reaction mixture was determined by iodometric titration [24]. The ^1H NMR spectra were recorded in CCl_4 on a Tesla BS-484B spectrometer (80 MHz) with hexamethyldisiloxane as internal reference. The IR spectra of liquid bromoarenes were recorded on a Specord-80 spectrometer in the 4000–400 cm^{-1} range (thin layer between KBr windows). The initial reaction rates were calculated by a differential procedure, using the kinetic curves of accumulation of the desired products at various temperatures [25].

The induced bromination of benzene and its alkyl and alkoxy derivatives was performed in a heterophase system, because arenes are insoluble in aqueous solutions of NaBr (or KBr) and H_2O_2 (or NaOCl). The main reaction products are the corresponding monobromo derivatives formed by the following reactions:

$$MBr \xrightarrow{HX} A \underset{-H_2O\ (NaCl)}{\overset{H_2O_2 \text{ or NaOCl}}{\rightleftarrows}} B \underset{-A}{\overset{C}{\rightarrow}} D, \qquad (1)$$

where M = Na or K; A = [HBr]; B = [HOBr] or [Br_2]; C = $R_1R_2ArH_m$, R_1 = R_2 = H; m = 4, 5; R_1 = H, R_2 = Me, Et, *i*-Pr, EtO; R_1 = R_2 = Me; D = $R_1R_2ArH_{m-1}Br$; X = Cl^-, SO_4^{2-}, RSO_3^- (R = Me/C_6H_4).

Since the formation of HOBr and Br_2 and the induced bromination of arenes proceed in aqueous and organic phases, respectively, stirring of the reaction mixture is one of the decisive factors affecting the yield of the reaction products. Without stirring of the reaction mixture, the yield of bromoarenes is as low as 15–20%. Stirring facilitates the transfer of HOBr and Br_2 from aqueous into the organic phase, and at a stirring rate of 600–700 rpm, the yield of bromo derivatives reaches 63–96%. It was found that, as the stirring rate is raised from 100 to 800 rpm, the initial rate w of formation of monobromotoluenes (at 293 K) increases from 1.45×10^{-3} to 9.14×10^{-3} mol l^{-1} s^{-1} (Fig. 1a). Further increase in the stirring rate does not significantly affect the reaction rate, and thus the stirring rate of 600–700 rpm ensures the kinetic control of the reaction.

Special experiments showed that, when the initial reagents are charged into the reactor simultaneously, the formation of bromine by the above scheme proceeds faster than in the induced bromination of arenes. The yield of the products of induced bromination of hydrocarbons can be controlled by the rate of the oxidant supply. In particular, at simultaneous charging of toluene and aqueous solutions of alkali metal bro-

mides and oxidants (Fig. 2a), monobromotoluenes are formed at 303 K at the initial rate of 1.25×10^{-2} (H_2O_2 oxidant) and 9.53×10^{-3} mol l^{-1} s^{-1} (NaOCl oxidant), and the yield of the desired product is 68%. Such a low yield of bromoarenes in the case of a simultaneous addition of H_2O_2 or NaOCl and the other reagents is apparently due to consumption of H_2O_2 and NaOCl in side reactions in the presence of HOBr and Br_2:

$$2MBr + 2HX + H_2O_2 \rightarrow Br_2 + 2MX + 2H_2O, \quad (2)$$

$$Br_2 + ArH \rightarrow ArBr \rightarrow HBr, \quad (3)$$

$$2HBr + H_2O_2 \rightarrow Br_2 + 2H_2O, \quad (4)$$

$$HBr + H_2O_2 \rightarrow HOBr + H_2O, \quad (5)$$

$$HOBr + ArH \rightarrow ArBr + H_2O, \quad (6)$$

$$H_2O_2 + Br_2 \rightarrow 2HBr + O_2, \quad (7)$$

$$HOBr + H_2O_2 \rightarrow H_2O + HBr + O_2. \quad (8)$$

Introduction of arenes into the reaction mixture and further gradual supply of the oxidant prevent nonproductive consumption of H_2O_2 and NaOCl by reactions (7) and (8) and thus provide a high yield of monobromoarenes.

To gain further insight into this process, we studied the oxidation of NaBr and HBr of various concentrations with H_2O_2 and NaOCl in the absence of arene. We found that no free bromine was formed in the presence of catalytic amounts (0.22 M) of HBr and NaBr. However, bromine was formed as the concentration of NaBr or HBr was raised from 0.65 to 5.26 M (Fig. 1b).

As can be seen from Fig. 1b, that raising the NaBr or HBr concentration in the above range makes higher the rate of their oxidation; the initial rate of bromine formation increases to 1.25×10^{1} mol l^{-1} s^{-1}, i.e, by more than an order of magnitude.

It should be noted that H_2O_2 and NaOCl decompose not only by reactions (7) and (8), but also through formation of hypobromous acid, which is less stable than NaOCl and H_2O_2 [3]:

$$\left.\begin{array}{l} H_2O_2 + HBr \\ NaOCl + HBr \end{array}\right\} \xrightarrow[-NaCl]{-H_2O} HOBr \rightarrow HBr + \frac{1}{2}O_2. \quad (9)$$

As can be seen from reaction (1), formation of intermediate HOBr and Br_2 is a reversible process, whereas the reactions of bromine or BrO^- anion with arenes are irreversible. No induced bromination occurs in the absence of H_2O_2 and NaOCl, because NaBr (KBr) or HBr are not involved in the electrophilic substitution in the aromatic ring. Thus, the induction in the above system only provides in situ formation of more reactive intermediates, which then effectively participate in the arene bromination.

Accumulation of the intermediate electrophilic reagent in the system probably occurs by the following scheme:

$$H_2O_2 + HBr \rightleftarrows H{-}\underset{\vdots}{O}{-}O{-}H \underset{-H_2O}{\rightleftarrows} HOBr, \quad \begin{matrix} \\ \vdots \\ HBr \end{matrix} \quad (10)$$

$$NaOCl + HBr \rightleftarrows Na{-}\underset{\vdots}{O}{-}Cl \underset{-NaCl}{\rightleftarrows} HOBr. \quad \begin{matrix} \\ \vdots \\ HBr \end{matrix}$$

With increasing concentrations of MBr or HBr, the rate of bromine formation grows [4]:

$$HOBr + HBr \rightleftarrows H_2O + Br_2. \quad (11)$$

In contrast to the formation of Br_2 and HOBr, bromination of arenes proceeds by the ionic mechanism [reactions (3) and (6)].

Both the yield of monobromoarenes and the rate of their formation increase with the content of NaBr (or KBr) in the system, which is due to increasing concentration of intermediate bromine and hypobromous acid. For example, at a NaBr concentration of 0.65 M, the yield of bromine in the first 15 min from the reaction start is 10% (Fig. 1b), and it increases to 72 wt % with the NaBr concentration increasing to 5.26 M. Hence, at a high concentration of MBr or HBr at beginning of the process, the bromination is predominantly effected by bromine formed in situ, and in further stages, by the BrO^- anion. The concentrations of MBr or HBr affect only the rate of induced bromination, whereas the process selectivity with respect to monobromoarenes is independent of this factor. With the NaBr concentration increasing from 15 to 43 wt %, the initial rate of monobromotoluene formation grows from 4.87×10^{-3} to 3.25×10^{-2} mol l^{-1} s^{-1} (Fig. 2b).

This rise in the bromination rate of arenes with increasing concentration of the above compounds is due not only to the easier formation of the intermediate brominating agent, but also to involvement of H_2O_2 and HBr molecules in the step of Br_2 and HOBr activation and to better solvation of the transition state:

$$Br^+{-}Br^- \cdots H{-}Br, \quad Br^+{-}Br^- \cdots H{-}O{-}H, \quad H{-}\underset{\vdots}{O}{-}Br^+. \quad \begin{matrix} \\ \\ HBr \end{matrix}$$

Various reaction parameters were studied in order to select the optimal reaction conditions. The yield of monobromoarenes and the process selectivity strongly depend on the ArH : NaBr : H_2O_2(NaOCl) molar ratio. The presence of electron-donor substituents in the benzene ring facilitates induced bromination. With the NaBr : H_2O_2(NaOCl) : arene molar ratio increasing from 1 : 1 : 1 to 4 : 1 : 1, the yield of bromoaromatic compounds grows from 38 to 64% (C_6H_5Br), from 82 to 98% ($CH_3C_6H_4Br$), from 64 to 94 ($C_2H_5C_6H_4Br$), from 52 to 69 (*iso*-$C_3H_7C_6H_4Br$), from 83 to 97 [1,2-$(CH_3)_2C_6H_3Br$), from 89 to 98 [1,3-$(CH_3)_2C_6H_3Br$), and from 89 to 98 [1,4-$(CH_3)_2C_6H_3Br$). Further increase in this ratio does not noticeably affect the yield of the desired product. With the molar ratio of benzene or its alkyl derivatives to the oxidant increasing from 1 to 4, the yield of the corresponding monobromoarenes grows from 5 to 15% per mole of converted hydrocarbon. However, in the case of ethyl- and isopropylbenzenes, we observed partial substitution of alkyl fragments with bromine (i.e., dealkylation and further bromination), with the formation of bromobenzene. In this case, the yield of bromobenzene increases from 1 to 23 and from 2 to 22% in the case of ethylbenzene and isopropylbenzene, respectively (Figs. 3a and 3b).

In this case, no dibromo derivatives are formed. The data of gas-liquid chromatography and IR and NMR spectroscopy showed that the content of a particular compound in the reaction products changes with temperature and nature of substituents in the aromatic

ring. For example, with the temperature increasing from 293 to 323 K, the yield of monobromobenzene grows from 54 to 75%. Under similar experimental conditions, the yields of monobromo derivatives of toluene, ethylbenzene, and isopropylbenzene grow from 91, 90, and 95 to 96, 97, and 97%, respectively. The same trend is observed in induced bromination of individual isomeric xylenes. In particular, 1,2-dimethylbenzene yields two isomers: 3-bromo- and 4-bromo-1,2-dimethylbenzene and, with the temperature increasing from 293 to 323 K, their total yield grows from 91 to 99%. Under similar conditions, 1,3- and 1,4-dimethylbenzene give only one isomer, and its yield increases from 94 and 88 to 98 and 94%, respectively.

Hence, we observed in the course of induced bromination of alkylbenzenes only substitution of the proton in the aromatic ring, whereas hydrogen atoms of the alkyl radical are not involved in the reaction.

To obtain comparable data on the reactivity of aromatic compounds in induced bromination, we performed special experiments with each hydrocarbon, with simultaneous charging of the starting reactants under similar conditions. From the data given in Figs. 4a, 4b, 4c, and 4d, we calculated the initial rates of formation of bromoarenes. These data show that the rate of substitution of hydrogen atoms in the aromatic ring of methyl-, ethyl-, and isopropylbenzenes in the *ortho* position is lower than that in the *para* position. With increasing size of the alkyl group, the difference between these rates becomes more pronounced (Table 1). For example, the rates of formation of 2-bromotoluene and 2-bromoethyl- and 2-bromoisopropylbenzenes in the presence of NaOCl are smaller than those of formation of 4-bromomethyl-, 4-bromoethyl-, and 4-bromoisopropylbenzenes by factors of 3.7, 5.2, and 10.2, respectively, and in the case of H_2O_2 oxidant, these rates differ by a factor of 1.2, 3.7, and 10.1, respectively. The activation energies are independent of the oxidant and decrease with increasing size of substituents (e.g., on passing from toluene and isopropylbenzene). However, due to a decrease in the activation entropy in the above series of aromatic compounds, the rate of formation of the *ortho* isomer decreases. A similar dependence was observed for catalytic chlorination of arenes in the liquid phase, which is due to the fact that formation of the σ complex with the *ortho* orientation of the aromatic ring becomes more hindered with increasing size of substituents [27]. Based on the isomer composition and using the equations given in [28], we calculated the partial rate factors and the selectivity [29] of induced bromination in the *ortho*

Table 2. Composition of isomers, partial rate factors *f*, and the selectivity S_f of induced bromination of aromatic compounds (293 K)

ArBr	Isomer	Isomer content, wt %	f_2	f_4	S_f
Me–Ph–Br	2-	10.2	0.54	10.0	2.73
	4-	80.5			
Et–Ph–Br	2-	24.2	0.895	14.7	3.1
	4-	65.3			
i-Pr–Ph–Br	2-	4.2	0.023	11.2	3.4
	4-	90.4			
1,2-$(Me)_2$Ph–Br	3-	40.5	1.85*	22.8	1.1
	4-	50.6			
EtO–Ph–Br	2-	8.5	0.143	10.7	2.18
	4-	78.6			

* Value corresponding to f_3.

and *para* positions for Me–Ph, Et–Ph, and *i*-Pr–Ph and in the *meta* and *para* positions for 1,2-$(Me)2C_6H_4$ (Table 2). It can be seen that the partial rate factor of induced bromination of methyl-, ethyl-, isopropyl-, and ethoxybenzenes is 0.54, 0.895, 0.023, and 0.143 for the *ortho* (f_2) isomers and 10, 14.7, 11.2, and 10.7 for the *para* (f_4) isomers. In the case of 1,2-dimethylbenzene, the following results were obtained: 1.85 for the *meta* (f_3) and 22.8 for *para* (f_4) isomers. These partial rate factors show that, in comparison with benzene, the *para* positions of the above compounds are activated to a greater extent than the ortho and *meta* positions. For monosubstituted derivatives, the reaction selectivity increases in the following order EtO–Ph < Me–Ph < Et–Ph < *i*-Pr–Ph. Using the known Brown–Nelson equation [29], we determined the relationship between the intra- and intermolecular selectivities of aromatic compounds studied and found that this system is characterized by an extremely low intramolecular selectivity but a very high intermolecular selectivity, i.e., it exhibits a high selectivity with respect to the *para* position of the aromatic ring.

CONCLUSIONS

(1) Induced bromination of arenes with metal bromides in the presence of H_2O_2 and HOCl proceeds by the radical-ion mechanism that involved in situ formed bromine and hypobromous acid, through substitution of a hydrogen atom in the benzene ring exclusively.

(2) Bromination is highly selective with respect to monobromo derivatives in the *para* position of the aromatic ring. With increasing molar content of ethyl- and isopropylbenzenes, formed by the yield of bromobenzene increases to 23% due to partial substitution of the alkyl groups with bromine atoms.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Calculation of Densities of Organic Compounds from Contributions of Molecular Fragments

A. A. Kotomin and A. S. Kozlov

St. Petersburg State Technological Institute, St. Petersburg, Russia

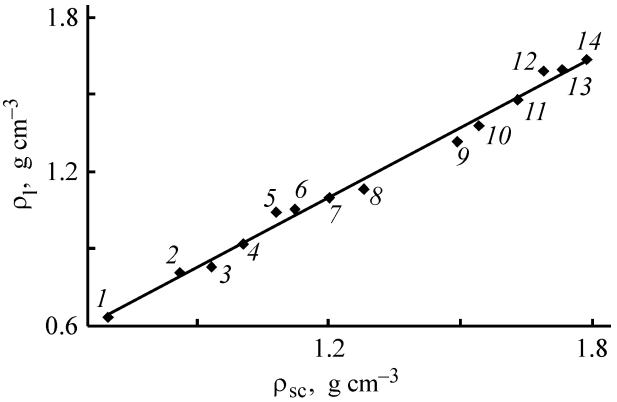
Received October 28, 2005

Abstract—A method for calculating the densities of organic compounds from the contributions of molecular fragments was suggested. A correlation between the densities of solid and liquid substances at 20°C was examined.

DOI: 10.1134/S1070427206060176

Density is one of the main characteristics of substances. It is connected with the fundamental physicochemical properties of substances and performance of materials produced from them. Along with performing a molecular design, it is necessary to forecast the properties of organic compounds to be synthesized, including density, which is required to design the production process. Therefore, the development of the most general and precise methods of density calculations is an topical problem, especially for high-energy-capacity substances whose density largely determines the efficiency, detonation power, sensitivity, and tendency for passing from combustion to detonation. Density is used in calculations of the detonation rate, explosion energy, burning rate, detonation critical diameter, and parameters of the impact of the explosion on the environment [1–8].

All the known methods of density calculation can be divided into three groups.



Theoretical methods. Molecular mechanics methods of Stine and Keddy allow calculation of the density of a substance from the basic physical characteristics of the molecules, such as van der Waals atomic radius, interatomic distances and angles, etc. In so doing, principles of simulation of the molecular structure of solids and molecular crystal packing for various steric configurations are used [9–12].

Empirical methods. The Smirnov, Tarver, Immirizi, and Perini methods are additive and allow calculation of the molar volume and substance density using atomic or group contributions, and also correction and other factors calculated directly from the measured densities of various types of organic compounds [13, 14].

Semiempirical methods. Piacenza, Jacob, Graindorge, Blaive, and Gallo methods include both physical characteristics of molecules and empirical coefficients [10].

The majority of methods estimating the density through the atomic and group contributions operate with a limited set of these and hence are insufficiently general or have poor accuracy. For solid substances, the theoretical, semiempirical, and empirical methods give average relative calculation errors of 5.0–6.0, 3.0–3.5, and 2.0–3.0%, respectively. Therefore, studies of correlations between the density and chemical structure of the compounds and the development of modern calculation methods are of interest.

We suggested a calculation method based on contributions of molecular fragments. A complex system of contributions to the molar volume was developed for solid substances: aliphatic, alicyclic, aromatic, and heteroaromatic compounds, including annelated and skeleton compounds, and for combined structures consisting of alicyclic and aromatic (heteroaromatic) rings. The corrections for fragment interaction, structure type, and bonding between rings, allowing finer consideration of the structural features, were found. The contributions and corrections were derived from the experimental densities and, correspondingly, from the molar volumes of more than 6000 organic substances [15–34]. The molar volume of each fragment was calculated for 15–25 compounds containing this fragment.

Correlation between the densities of aliphatic compounds in the solid (ρ_{sc}) and liquid (ρ_l) states. (*1*) *N*,*N*,*N*-Trimethylnitramine, (*2*) butanol, (*3*) diethyl acetal, (*4*) 2,2-difluoropropane, (*5*) 1-nitroethane, (*6*) *N*,*N*-diethylnitramine, (*7*) ethyl nitrate, (*8*) 3-nitrobutanol, (*9*) triethylene glycol dinitrate, (*10*) diethylene glycol dinitrate, (*11*) ethylene glycol dinitrate, (*12*) bis-(fluorodinitroethyl) formal, (*13*) glycerol trinitrate, and (14) nitroisobutylglycerol trinitrate.

In this method, the structural components are molecular fragments whose contributions take into account the interaction of the elements within the fragments and with the nearest atoms. Such fragments are functional groups and, for certain structures, atoms. Division of molecules into fragments is performed step by step from larger to smaller fragments. Initially, the molecule is divided into larger fragments, and then, the residual part of the molecule is divided into smaller fragments, and the probable residue, into atoms. The sum of the molecular weights of the fragments is equal to the molecular weight of the compound.

The molar volumes and molecular weights of the molecular fragments of solid organic compounds and the above corrections are listed in Tables 1–9. The structural fragments into which molecule of various classes should be divided are shown in Tables 1, 3, and 6.

Interaction of electronegative groups, H bonding, and steric factors were considered both in the fragment contributions dependent on the surrounding and in various corrections. Special attention was paid to high-energy-capacity substances. The densities of salts, coordination compounds, and crystal hydrates can also be calculated. Such compounds can contain C, H, N, O, S, F, Cl, Br, I, Na, K, Fe, and Co atoms.

Using mathematical methods of analysis [35], we found linear correlations between the densities of organic compounds of various classes in the solid and liquid states at 20°C, which allow prediction of the densities of liquid organic substances. For example, such a correlation for aliphatic compounds is shown in the figure: along the abscissa are the densities of solid compounds calculated by our method, and along the ordinate, the experimental densities for the liquid state. The correlation coefficient is 0.99.

The method developed allows calculation of densities at the standard temperature of 20°C with the average relative error of 1.5% for solid substances and 2.5% for liquids. The maximal error does not exceed 3.5%. The method can be used in scientific research and for express estimation of the densities of new high-energy-capacity and other organic compounds in the step of synthesis planning. The density of a solid organic compound is determined as

$$\rho_{sc} = M/V,$$

where $M = \Sigma M_i$; $V = \Sigma V_i + \Sigma \delta_i$; ρ_{sc}, density of a single crystal of an organic substance; M, molecular weight of the compound; M_i, molecular weight of the fragment; V, molar volume of the compound; V_i, molar volume of the fragment; and $\Sigma \delta_i$, sum of corrections for fragment interactions, structure type, and bonding between rings.

The density of a liquid organic substance is given by

$$\rho_l = k\rho_{sc},$$

where ρ_l is the density of a liquid substance and k, coefficient (k = 0.92 for aliphatic and alicyclic compounds; k = 0.88 for aromatic and heteroaromatic compounds, and k = 0.90 for combined structures including alicyclic and aromatic or heteroaromatic rings).

The calculated density of a liquid substance at 20°C can be recalculated to another temperature by the methods described in [36, 37].

Three examples of calculations of the density of various organic compounds are presented below.

(1) Aliphatic compound: glycerol trinitrate (nitroglycerol), $C_3H_5O_9N_3$, M = 227.09, liquid substance, mp 13.5°C:

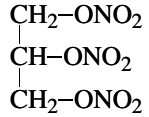


Table 1. Fragment contributions for calculation of the molar volume of aliphatic compounds

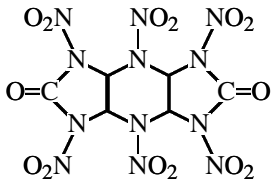
Cubane	+38.24

Notes: (1) For alicyclic compounds, the molar volume includes the sum of contributions of the ring (Table 3), corrections for their interaction (Table 4), and correction for structure type (Table 5). For side chains and fragments between rings, the contributions for aliphatic compounds (Table 1) are used. For polycyclic and framework structures, the molar volume includes the sum of corrections for structure type for all the rings in the compound.

(2) Atom in parentheses is not included in the fragment molar volume (A_c denotes any atom of the ring). When the fragment is not connected with an atom in parentheses, it is connected with any atom of the side chain or any other ring.

The molar volume of nitroglycerol includes fragment contributions (Table 1) and corrections for fragment interaction (Table 2).



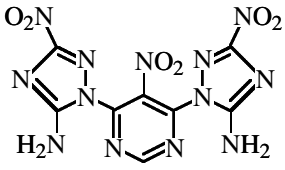
The molar volume is calculated as the sum of the fragment contributions and corrections:

$$V = \Sigma V_i + \Sigma \delta_i = 46.77 \times 2 + 39.24 + 0.42 \times 2$$

$$= 133.62 \text{ cm}^3 \text{ mol}^{-1}.$$

Density of solid nitroglycerol $\rho_{sc} = M/V = 227.09/133.62 = 1.70$ g cm^{-3} (experimental value: 1.73 g cm^{-3}). Density of liquid nitroglycerol: $\rho_l = k\rho_{sc} = 0.92 \times 1.70 = 1.57$ g cm^{-3} (experimental value: 1.60 g cm^{-3}).

(2) Condensed alicyclic compound: 2,6-dioxo-1,3,4,5,7,8-hexanitrodecahydro-1*H*,5*H*-diimidazopyrazine (Hexanitroglycoluryl), $C_6H_4O_{14}N_{12}$, $M = 468.18$, solid compound:



The molar volume of Hexanitroglycoluryl includes fragment contributions (Table 3), corrections for fragment interaction (Table 4), and corrections for structure type (Table 5).

$$V = \Sigma V_i + \Sigma \delta_i = 14.34 \times 4 + 21.22 \times 6 + 13.34 \times 2$$

$$+ 2.29 \times 4 + 3.54 \times 2 = 227.60 \text{ cm}^3 \text{ mol}^{-1}.$$

The density of Hexanitroglycoluryl $\rho_{sc} = M/V = 468.18/227.60 = 2.06$ g cm^{-3} (experimental value: 2.07 g cm^{-3}).

(3) Polycyclic heteroaromatic compound: bis-2,4-(3-nitro-5-aminotriazol-1-yl)-3-nitropyrimidine (DANTNP), $C_8H_5O_6H_{13}$, $M = 379.22$, solid substance:

The molar volume of DANTNP includes fragment contributions (Table 6) and corrections for the bond between rings (Table 7).

$$V = \Sigma V_i + \Sigma \delta_i = 34.80 + 28.68 \times 2 + 25.78 \times 3$$

$$+ 11.74 \times 2 + 7.96 + 1.16 \times 2 = 203.26 \text{ cm}^3 \text{ mol}^{-1}.$$

|			

Notes: (1) For aromatic and heteroaromatic compounds, the molar volume includes the contributions of rings and substituents (Table 6) and correction for bonding between rings (Table 7). For side chains, including ions, the contributions for aliphatic compounds are used (Table 1). When ring contributions in Table 6 are lacking, they can be estimated through the atom contributions (Table 8). The heterocycle contribution is taken as independent of the presence and sign of the charge.

(2) Atom in parentheses is not included in the fragment molar volume (A_c denotes any atom of the ring). When the fragment is not connected with an atom in parenthenes, it is connected with any atom.

(3) For annelated aromatic (heteroaromatic) compounds, the molar volumes of rings are calculated through atomic contributions (Table 9); $C_{(as)}$ and $N_{(as)}$ are common atoms belonging to neighboring rings.

(4) For polycyclic compounds of the combined type consisting of aromatic (heteroaromatic) and alicyclic rings, the molar volume includes the contributions for aromatic structures from Tables 6, 8 (for annelated compounds, Table 9); contributions of fragments for alicyclic structures (Table 3) excluding atoms composing aromatic structure (for annelated compounds); and sum of corrections for structure type for all alicycles in the compound (Table 5).

The density of DANTNP single crystal $\rho_{sc} = M/V = 379.22/203.26 = 1.87$ g cm^{-3} (experimental value: 1.86 g cm^{-3}).

CONCLUSIONS

(1) A method for calculating densities of organic compounds (including high-energy-capacity substances) from the contributions of molecular fragments was suggested. The complex system of contributions of molecular fragments to the molar volume for aliphatic, alicyclic, aromatic, and heteroaromatic compounds (including annelated and skeleton compounds) and combined structures consisting of alicyclic and aromatic (heterearomatic) rings was developed. Corrections for fragment interaction, structure type, and bonds between rings, allowing more precise consideration of the structural features, were found.

(2) A correlation between the densities of the organic compounds of various classes in the solid and liquid states at 20°C was found.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Relationship between the Molar Volume and Enthalpy of Formation, Polarizability, and Ionization Potential of CHNO-containing Organic Substances

Yu. E. Zevatskii and S. S. Lysova

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received March 1, 2006

Abstract—A new approach to revealing a relationship between various physicochemical properties of organic compounds is suggested. The basic principle of this approach consists in that deviations of experimental values of various molecular parameters from linear dependences for the constituent elements are due to intramolecular forces of the same nature.

DOI: 10.1134/S1070427206060188

The precision achieved in calculation of physicochemical parameters of substances still remains a key issue in chemistry and physics. Despite the existence of a wide variety of additive methods, which make it possible to calculate with a small error the properties of molecules with various structures, their number continues to grow. The general principle of the known calculation procedures is that the value of a property (enthalpy of formation, polarizability, volume of a molecule, etc.) is regarded, in accordance with the additivity rule, as a sum of partial properties of separate fragments of the molecule. Atoms, chemical bonds, functional groups, etc. can be chosen as fragments of this kind.

In calculating the density of substances, the molar volume is determined on the basis of the molecular elements suggested by Stine [1], by the Cady method [2] with the use of Van der Waals radii; in addition, procedures with certain refinements and corrections were reported in [3–6].

The additive methods for calculation of the enthalpy of formation of substances can be divided into three groups [7]. The first of these is based on the additivity principle for bond energies, developed by Pauling, Tatevskii, Leidler, and others. The second group employs dependences of the thermochemical properties of substances on other thermodynamic parameters (methods of Karas and Handrick). To the third group belong methods based on the principle of additivity of the thermochemical properties of various structural groups contained in a molecule (reports by Esterman and Raikova).

Modern methods for calculation of the polarizability of molecules were described in [8, 9]. The review [9] is devoted to a critical analysis of experimental and calculated data on the static polarizability of more than 650 molecules of various classes of substances. In [10], the previously suggested [11] empirical method for calculation of the molecular polarizability from parameters of "atomic hybrids" was further developed. The results obtained in calculation of the mean polarizability, anisotropy, and principal components of the polarizability were compared with calculations based on the polarizability of bonds [12] and groups [13], and the possibility of passing from the "hybrid parameters" suggested by the authors to other empirical parameters was demonstrated.

The methods for calculation of the ionization potentials of molecules are based on the generalized Koopmans' theorem in the form of certain approximations [14]. The effect of substituents is taken into account using the principle of linearity of free energies, with a distinction made between the inductive, resonance, and polarization effects linearly appearing in the expression for the ionization potentials [15, 16]. Dependences of the ionization potentials on linear dimensions have been obtained only for atoms, with attempts to establish a relationship of this kind for nonpolar molecules undertaken only recently [18].

Some of the methods mentioned above have a number of advantages and disadvantages, compared with other techniques, but all of them give deviations from experimental values. The discrepancies are not large, but they can in no way be attributed to errors in measurement of the relevant parameters, even if the statistical nature of the measurement process is taken into account.

We assume in this study that the deviations of physicochemical parameters calculated by empirical additive methods from the corresponding experimental values are inevitable. Taken by themselves, the deviations have a certain physical meaning and are due to intramolecular forces of the same nature. A consequence of this concept is that the above deviations for different molecular constant should be linearly interrelated.

A fact supporting our hypothesis was first reported in [19]. It was found that there is a linear relationship between the enthalpy of atomization and the experimentally determined molecular polarizability minus the polarizabilities of the atoms constituting the molecule within the same homological series of organic substances. The method suggested is a generalization of this approach and it can be extended to calculation of other molecular parameters.

The enthalpy of formation, molecular polarizability, and molar volume of substances were chosen for demonstration of the practical applicability of the method for the following reasons. The enthalpy of formation belongs to the main thermodynamic potentials of substances. The polarizability is a parameter of a substance subjected to a strong perturbing action. The ionization potential is a parameter of a substance that is measured for a strongly perturbed molecule. The molar volume is a quantity that can be readily obtained with high reliability by a chemist experimenter from the density and structural formula of a substance under study. In addition, published data on the densities of substances are well consistent.

Calculation procedure. We determined the molar volume of substances by the formula

$$V = M/\rho, \tag{1}$$

where M is the molecular weight of a substance, and ρ, its density in the condensed state, determined at atmospheric pressure and constant temperature, further taken to be 20°C [20]. Then, depending on whether the substance is in the liquid or solid state under the conditions specified, we used indices l or s. We define the molecular-volume defect ΔV as the difference of the molecular volume and atomic volumes of atoms constituting the molecule of the substance:

$$\Delta V = \frac{V}{N_A} - \frac{4}{3}\pi \Sigma g_i r_i^3, \tag{2}$$

where r_i is the covalent radius of ith atom, found using the data of [21]; g_i, number of ith atoms in the molecule; and N_A, Avogadro number. We use the value of the molecular polarizability as a coefficient η relating the polarization P of the molecule of a substance in a uniform external electrostatic field to the field strength E:

$$P = \eta \varepsilon_0 E, \tag{3}$$

where ε_0 is the permittivity of free space. We define the molecular-polarizability defect similarly to (2):

$$\Delta\eta = \eta - \Sigma g_i \eta_i, \tag{4}$$

where η_i is the polarizability of ith atom [22]. We used the notion of the enthalpy of atomization of a substance, as in [19], on the per-molecule basis:

$$\delta H = (\Delta_f H^0 - \Sigma g_i \Delta_f H_i^0) N_A^{-1}, \tag{5}$$

where $\Delta_f H^0$ is the standard enthalpy of formation of the substance, and $\Delta_f H_i^0$, standard enthalpy of formation of ith atom [23]. We defined the ionization-potential defect of a substance for the first ionization potentials of the molecule, U, and of its constituent atoms, U_i, as

$$\Delta U = U - \Sigma g_i U_i. \tag{6}$$

We calculated the molecular-volume defect by Eq. (2) for 72 substances, molecular-polarizability defect by Eq. (4) for 49 substances, enthalpy of atomization by Eq. (5) for 66 substances, and ionization-potential defect By Eq. (6) for 67 molecules. It should be emphasized that the enthalpy of atomization was measured in units of 1 eV per molecule. The ionization potentials were taken from [24]. The results of our calculations are listed in Table 1.

It was found that the molecular-volume, molecular-polarizability, and ionization-potential defects and the enthalpies of atomization, calculated by Eqs. (2), (4)–(6) linearly depend on one another:

$$\Delta\eta = \alpha_\eta \Delta V + \Delta\eta_0, \tag{7}$$

$$\delta H = \alpha_H \Delta V + \delta H_0, \tag{8}$$

$$\Delta U = \alpha_U \Delta V + \Delta U_0, \tag{9}$$

with the coefficients α_η, α_H, α_U, $\Delta\eta_0$, δH_0, and ΔU_0 being constant within certain broad classes of CHNO-containing organic substances. The dependences (7)–(9) are graphically shown in the figure for substances from the classes chosen. The classes of organic substances with the above-mentioned coefficients and correlation coefficients are listed in Table 2. If no correlation coefficients are given, this means that we reconstructed the dependence from two points.

Polarizability defect $\Delta\eta$, enthalpy of atomization δH, and ionization-potential defect ΔU vs. the volume defect ΔV.

Analysis of the data obtained shows an insignificant, compared with the difference in free terms ($\Delta\eta_0$, δH_0, ΔU_0), scatter of the linear coefficients α for virtually all of the substance classes considered. Noteworthy is the fact that the correlation coefficients obtained in statistical processing of the dependences (7)–(9) are close to unity: the coefficients are no less than 0.9940 for enthalpies, 0.9898 for polarizabilities, and 0.9749 for ionization potentials. The best correlation achieved for the dependence of the enthalpy of atomization on the volume defect is, in all probability, accounted for by the fact that more advanced and precise methods are used to determine the enthalpy.

Thus, we can determine, with high reliability, the polarizability, enthalpy of formation, and first ionization potential of a substance from its known structure and density:

$$\eta = \Sigma g_i\eta_i + \alpha_\eta\left(\frac{M}{\rho N_A} - \frac{4}{3}\pi\Sigma g_i r_i^3\right) + \Delta\eta_0, \quad (10)$$

$$\Delta_f H^0 = \Sigma g_i \Delta_f H_i^0 + \alpha_H\left(\frac{M}{\rho} - \frac{4}{3}\pi N_A \Sigma g_i r_i^3\right)e + N_A e\,\delta H_0, \quad (11)$$

$$U = \Sigma g_i U_i + \alpha_U\left(\frac{M}{\rho N_A} - \frac{4}{3}\pi\Sigma g_i r_i^3\right) + \Delta U_0, \quad (12)$$

where e is the elementary charge. The resulting dimensionalities for the quantities in the left-hand parts of formulas (10)–(12) are cubic angstroms, joules per mole, and electronvolts, respectively.

Table 3 lists the results obtained in calculation by formulas (6), (8), and (9) for a number of heterocyclic compounds. The experimental values were taken from [23]; the calculated ionization potentials are given in Table 3 in parentheses. The choice of these compounds for prognostication of their physicochemical properties is due to the fact that, despite the strong scientific interest and large number of publications, data on the enthalpy of formation and ionization potentials in the authoritative reference literature [25] are rather scarce. Closing this gap may be of practical importance for assessing the ability of substances to enter electrophilic and nucleophilic reactions.

A natural continuation of the study of the method we suggested is verification of its applicability to calculation of other physicochemical properties, e.g., protonation energy, chemical potential, specific heat, electron affinity, dipole moment, transfer coefficients, etc. Of particular interest is elucidation of the physical meaning of the linear coefficients: dimensionless α_η and also α_H and α_U with dimensionality of electronvolts per cubic angstroms. In addition, certain useful results can be furnished by analysis of hypothetical values of the volume, polarizability, and ionization-potential defects obtained in the limit of zero enthalpy of atomization for various classes of substances.

CONCLUSIONS

Linear relationships between the molar volume, enthalpy of formation, polarizability, and ionization potential were revealed within various classes of CHNO-containing organic substances. High correlation coefficients were obtained. The method developed was used to calculate the first ionization potentials from the enthalpies of formation for several heterocyclic compounds.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Oxidation of Soap Chips and Antioxidative Stabilization with Phenolic Inhibitors

St. Petersburg State Technological Institute, St. Petersburg, Russia

Received November 17, 2005

Abstract—The initiation of free radicals and oxidizability of soap chips were studied by the methods of inhibited and initiated oxidation. A scheme accounting for the effect of phenolic inhibitors (with Ionol and 2-ethylhexyl gallate as examples) was suggested. The kinetic parameters of the main reactions determining the inhibiting activity of these additives were found.

DOI: 10.1134/S107042720606019X

Recently there has been an increased interest in the oxidation and stabilization of detergents and, in particular, of toilet soaps. This is caused by the fact that requirements to consumer properties of soaps (preservation of the external appearance and odor provided by fragrant additives) become more and more stringent. The requirements to stabilizers added to cosmetics and soaps also increased [1]. Toilet soap is produced from soap chips with appropriate additives. The main components of soap chips are sodium salts of C_8–C_{20} fatty acids; the content of unsaturated acids can reach 28–42%. During the production and storage, toilet soap undergoes oxidation on coming in contact with atmospheric oxygen to form labile oxygen-containing intermediates, peroxides. Peroxides decompose into free radicals and more stable products: alcohols, carbonyl compounds, etc. [2–4].

Free radicals accelerate the oxidation, and some of the forming oxygen-containing compounds impair the consumer properties of soap, imparting to it an unpleasant odor and altering its color and structure.

Ample data have been accumulated on the liquid- and solid-phase oxidation of organic materials and on their stabilization under the conditions of artificial aging [5, 6]. However, as applied to detergents, the available data on their oxidation and stabilization are scarce.

The lack of kinetic data on the oxidation and stabilization of detergents and on the mechanism of action of various antioxidants gives no way of predicting the shelf life of commercial products and making a substantiated choice of the most promising stabilizers for detergents and toilet soap.

This paper deals with the kinetics of oxidation of soap chips and their stabilization with phenolic antioxidants.

We examined three samples of soap chips (Nevskaya Kosmetika Private Company) without additives; the fatty acid composition of the samples is given in Table 1.

The soap chips were oxidized in a gasometric installation at 130–160°C at an oxygen pressure of

Table 1. Fatty acid composition of soap chip samples

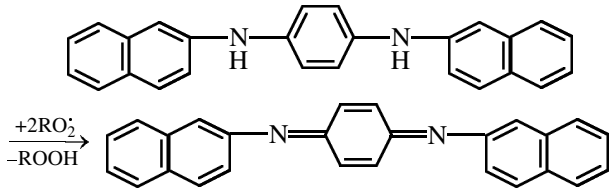
The oxidation course was monitored by the oxygen uptake.

Table 2. Kinetic parameters of chain initiation in oxidation of various soap chip samples

Soap chip sample no.	$k_{0i} \times 10^6$, l mol^{-1} s^{-1}		E_{0i}, kJ mol^{-1}	
	T = 155°C	T = 145°C	T > 150°C	T < 150°C
1	1.10 ± 0.06	0.51 ± 0.06	49 ± 8	105 ± 8
2	1.26 ± 0.06	0.73 ± 0.06	50 ± 8	94 ± 8
3	0.50 ± 0.06	0.22 ± 0.06	74 ± 8	116 ± 8



The results are shown in Fig. 1.

It can be seen from Fig. 1 that the oxidation of soap chips occurs autocatalytically. An inflection in kinetic curves *1–4* is due to accumulation of peroxy compounds, which are sources of free radicals. The inflection point is followed by the section corresponding to the steady-state process, when the rate of generation of free radicals (species leading the chain process) from peroxides is constant.

Thus, the oxidation of soap chips is a typical autooxidation process; it can be characterized by the rate constants of chain initiation (k_{0i}), chain propagation (k_p), chain termination (k_t), and degenerate chain branching (k_i), and also by the oxidizability $k_p/k_t^{0.5}$.

To determine the rate constants of chain initiation and degenerate branching, we used the method of inhibitors [5, 7].

When determining the rate constant of chain initiation, we used as peroxy radical scavenger *N*,*N*'-di-β-naphthyl-*p*-phenylenediamine (DNPD), which is highly reactive toward peroxy radicals:

The chain initiation rate was determined from the amount of the reaction product, quinone diimine (determined spectrophotometrically, λ = 490 nm, ε = 1.03×10^4 l mol^{-1} cm^{-1}). We found that the chain initiation in the oxidation of soap chips in the temperature range 130–160°C is a second-order reaction with respect to the substrate (Fig. 2).

The trimolecular reaction of chain initiation can be represented by the following equation:

$$2C_nH_{2n-1}COOM + O_2 \xrightarrow{r_{0i}} 2^{\bullet}C_{4n}H_{2n-2}COOM + H_2O_2.$$

Trimolecular reactions of chain initiation are characteristic of the oxidation of unsaturated compounds with weak C–H bonds (D_{R-H} = 330–340 kJ mol^{-1}) [5]. Apparently, salts of unsaturated acids play an important role in the chain initiation in oxidation of soap chips. Taking into account the amount of oxygen dissolved in the reaction mixture, we calculated the rate constants and kinetic parameters of chain initiation for various chip samples (Table 2).

The chain initiation rate is the highest in the oxidation of sample no. 2, which contains salts of not only monoenoic, but also di- and trienoic fatty acids.

The determination of the apparent activation energy gave interesting results. Figure 3 shows that the dependence of the logarithm of the chain initiation rate on reciprocal temperature is nonlinear, with a break at about 150°C. It is difficult to account for this fact; it may be due to variation of the viscosity and structural characteristics of the soap solution with temperature.

Thus, our results suggest that unsaturated monocarboxylic acid salts are the most reactive components of soap chips in the step of chain initiation.

The apparent activation energies and rate constants of chain initiation can be used for predicting the shelf life of the soap and for determining the optimal concentration of an antioxidant introduced into soap chips.

With the progress of soap oxidation, peroxides, as already noted, become an additional source of free radicals. We found that, at the concentration of peroxides in the soap chip oxidate (sample no. 1) of 5×10^{-3} M and lower, their decomposition at 75–85°C follows the first-order law with an apparent activation energy of 94 ± 8 kJ mol^{-1}. The results are listed in Table 3 and Fig. 4.

As already noted, an important kinetic parameter is the oxidizability, i.e., the ratio of the rate constants of the chain propagation and termination $[k_p/(2k_t)^{0.5}]$, which depends on the structures of the compounds being oxidized and radicals leading the chain process. The oxidizability of soap chips was evaluated by the method of initiated oxidation in *o*-dichlorobenzene at 70–90°C and atmospheric pressure in the presence of an initiator, azobis(isobutyronitrile) (AIBN).

Our experiments showed that, in the AIBN concentration range 1.0×10^{-2}–1.0×10^{-1} M and soap concentrations below 0.6 M, the dependence of r_{O_2}/r_i on $1/r_i^{0.5}$ (Fig. 5) follows the rate equation

$$r_{O_2}/r_i = A + k_p c_{RCOONa}/[(2k_i)^{0.5} r_i^{0.5}],$$

where r_{O_2} is the soap oxidation rate (mol l^{-1} s^{-1}); r_i, rate of initiated oxidation (mol l^{-1} s^{-1}); and A, coefficient taking into account the oxygen consumption in the steps of chain initiation and termination.

The linearization of the kinetic curves in the coordinates r_{O_2}/r_i–$1/r_i^{0.5}$ is a kinetic indication that peroxy radicals are involved in square-law chain termination.

80	9.1 ± 0.1	
85	13.0 ± 0.1	

Table 4. Kinetic parameters of the initiated oxidation of soap chip samples (AIBN initiator; 80°C; $r_i = 2.1 \times 10^{-6}$ mol l^{-1} s^{-1})

Soap chip sample no.	Chain length ν	$k_p/(2k_t)^{0.5} \times 10^2$, $(l\ mol^{-1}\ s^{-1})^{0.5}$	$E_p - 0.5E_t$, kJ mol^{-1}
1	6	2.5 ± 0.5	36 ± 4
2	5	3.3 ± 0.5	30 ± 4
3	6	2.2 ± 0.5	40 ± 4

The oxidizabilities of the three soap chip samples are listed in Table 4. They differ insignificantly, which is quite natural if we take into account similar composition of the samples.

The oxidizability of soap chips is close to that of individual unsaturated monocarboxylic acids [8]. The oxidizability of saturated fatty acids is approximately two orders of magnitude lower than that of unsaturated carboxylic acids. Thus, it can be concluded that the oxidizability of soap chips is determined by the presence of unsaturated carboxylic acid salts.

The antioxidants commercially used for stabilization of detergents and toilet soap are phenol derivatives and aromatic and aliphatic amines.

In this study, we used phenolic antioxidants: Ionol and 2-ethylhexyl gallate. Experiments on inhibited oxidation of soap chips were performed on a gasometric unit in *o*-dichlorobenzene at 75–90°C in the presence of AIBN initiator. Oxidation of soap chips in the presence of the initiator in the mode of a radical-chain reaction at low initiator conversion occurs at a constant rate, r_i = const.

Addition of an inhibitor, Ionol or 2-ethylhexyl gallate, leads to deceleration of the initiated oxidation of soap chips (Fig. 6).

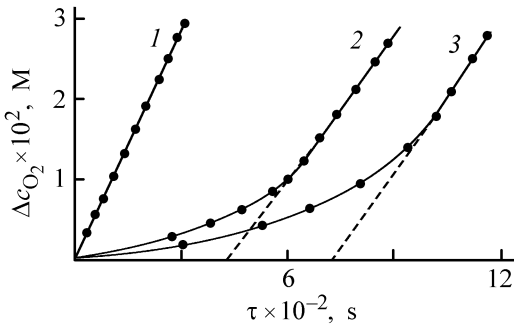

Fig. 6. Oxygen uptake Δc_{O_2} in oxidation of soap chips in the initiated mode. (τ) Time. $r_i = 2.1 \times 10^{-6}$ mol l^{-1} s^{-1} at 80°C, $c_{RCOONa} = 0.6$, $c_{InH} = 3 \times 10^{-3}$ M. Additive: (*1*) none, (*2*) ionol, and (*3*) 2-ethylhexyl gallate.

We found that the antiradical capacity of 2-ethylhexyl gallate is higher than that of Ionol, which is attibutable to the involvement of three hydroxy groups of 2-ethylhexyl gallate in the reaction with peroxy radicals; as a result, the induction period increases as compared to Ionol. The antioxidative effect of the inhibitor depends on the rate of key reactions involving it [4, 5], e.g.,

$$RO_2^{\bullet} + InH \xrightarrow{k_{InH}} ROOH + In^{\bullet},$$
$$RO_2^{\bullet} + In \xrightarrow{k_{In}} ROOIn,$$
$$RH + In^{\bullet} \xrightarrow{k_{RH}} R^{\bullet} + InH.$$

This inhibition scheme in the initiated oxidation of a substrate (RH) is described by the rate equation

$$r_{O_2} = r_\infty + k_p[RH]^{0.5}\sqrt{\frac{k_{RH}r_i}{f k_{InH}k_{In}[InH]}},$$

where r_∞ is the oxidation rate at $[InH] \to \infty$, equal to $(k_{RH}/k_{In})[RH](r_i)^{1/2}$ (mol l^{-1} s^{-1}); r_i, initiation rate (mol l^{-1} s^{-1}); [RH] and [InH], substrate and inhibitor concentrations, respectively (M); f, stoichiometric coefficient of inhibition.

Figure 7 shows the dependence of the oxidation rate of soap chips on the inhibitor concentration to

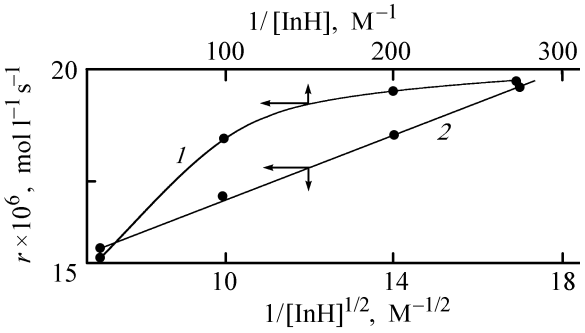

Fig. 7. Oxidation rate r (mol l^{-1} s^{-1}) of soap chips (sample no. 2) at 80°C vs. the inhibitor concentration to the power (*1*) –1 and (*2*) –1/2. $r_i = 2.1 \times 10^{-6}$ mol l^{-1} s^{-1}; c_{RCOONa} = 0.6 M.

the powers –1 (curve *1*) and –1/2 (curve *2*) at a constant initiation rate.

The linear dependence of the oxidation rate on the inhibitor concentration to the power –1/2 indicates that there is no linear chain termination at inhibitor molecules. Radicals generated from the inhibitor are involved in the chain termination and propagation in accordance with to the above scheme; the intercept on the ordinate axis ([InH] $\to \infty$) indicates that oxyphenyl radicals are involved in the chain propagation; these radicals, apparently, react with the allyl C–H bonds in acid molecules.

The involvement of phenols in the chain propagation is uncommon for inhibited oxidation. Apparently, the relatively high viscosity of soap solutions and possible occurrence of the substrate in the colloidal state decrease the mobility of phenoxyl radicals; as a result, the probability of their involvement in the chain propagation increases.

A graphic solution of Eq. (1), carried out with account of published data on k_{RH} and k_{In} [9], allowed us to estimate the $k_p/(fk_{InH})$ ratio characterizing the performance of the inhibitors (Table 5).

Table 5 shows that the phenolic inhibitors Ionol and 2-ethylhexyl gallate show approximately the same performance in stabilization of soap chips.

EXPERIMENTAL

Oxidation of soap chips in *o*-dichlorobenzene was performed on a manometric unit and was monitored by measuring the volume of oxygen taken up, with the pressure in the system maintained constant [10]. In experiments on initiated oxidation, we used azobis(isobutyronitrile) (AIBN) recrystallized from CH_3OH (mp 102–103°C) as a source of free radicals.

The fatty acid composition of soap chip samples was analyzed according to GOSTs (State Standards) 790 and 25219.

2-Ethylhexyl gallate was prepared by esterification of gallic acid with 2-ethylhexanol in *p*-xylene in the presence of *p*-toluenesulfonic acid as catalyst and was purified by recrystallization from diethyl ether.

o-Dichlorobenzene was purified before use by treatment with sulfuric acid, followed by distillation.

Table 5. Parameters of the initiated oxidation of soap chips (sample no. 2) in the presence of inhibitors (80°C; $r_i = 2.1 \times 10^{-6}$ mol l^{-1} s^{-1})

Inhibitor	$k_p/fk_{InH} \times 10^3$, mol l^{-1} s^{-1}	$E_p - 0.5E_{InH}$
Ionol	2.90 ± 0.03	32 ± 5
2-Ethylhexyl gallate	2.17 ± 0.03	25 ± 5

CONCLUSIONS

(1) Oxidation of soap chips consisting of sodium salts of saturated and unsaturated C_8–C_{20} aliphatic monocarboxylic acids occurs autocatalytically. Initially, the chains are initiated by a trimolecular reaction, and in the developed oxidation process, labile peroxides become an additional source of free radicals.

(2) The oxidizability, characterized by the ratio of the rate constant of chain propagation to the square root of the rate constant of chain termination, is largely determined by the presence of unsaturated acid salts in soap chips.

(3) Phenolic inhibitors, Ionol and 2-ethylhexyl gallate, inhibit the oxidation. The inhibitor effect is due not only to its involvement in the chain termination reactions by the nonlinear mechanism, but also to chain propagation by the reaction of oxyphenyl radicals with molecules of sodium salts of fatty acids.

ORGANIC SYNTHESIS AND INDUSTRIAL ORGANIC CHEMISTRY

Polysiloxane Xerogels Containing Arch-fixed Urea Groups

Abstract—A sol–gel procedure was suggested for preparing polysiloxane xerogels containing arch-fixed urea groups. The presence of these groups was confirmed by IR spectroscopy. The surface layer of the xerogels prepared exhibits enhanced hydrolytic stability in nonoxidizing acids.

DOI: 10.1134/S1070427206060206

Functional materials based on silica are well known and are widely used in many areas, including chromatography, heterogeneous catalysis, and sorption processes [1–4]. A frequently used method of their preparation involves modification of a surface with chloro or alkoxy derivatives of silicon, which allows formation of a surface layer with required properties. However, this method does not allow preparation of materials with a high and controllable content of functional groups. Furthermore, the hydrolytic and thermal stability of functional surface layers prepared by this method is, as a rule, relatively low. The low stability may be caused by the fact that, with traditional modifiers (e.g., trifunctional silanes), a large amount of structural units of type $-Si(OR)_2R'$ (T^1) is formed (R = H or alkyl; R' is a functional group being introduced) [5]. In this case, the functional group is linked to the matrix surface by a single siloxane bond, $\equiv Si-O-Si(OR)_2R'$, and the silicon atom bearing the functional group also contains alkoxy and/or silanol groups.

An alternative pathway is based on the sol–gel method; it allows one-step preparation of functionalized polysiloxane xerogels [6, 7] containing mainly structural units of types $=Si(OR)R'$ (T^2) and $\equiv SiR'$ (T^3) on the surface. In addition, an increase in the number of spacers (hydrocarbon chains) linking the functional group with the surface of the polysiloxane framework and leading to formation of arch structures should also enhance the hydrolytic and thermal stability of the surface layer.

The goal of this study was to develop sol–gel procedures for preparing xerogels containing arch-fixed functional groups in the surface layer. As functional groups we chose urea groups, which are efficient in recovery and separation of rare-earth metal ions [8] and in preparation of membranes [9] and wear-resistant protective coatings on the surface of lenses made of organic polymers [10].

EXPERIMENTAL

As starting compounds we used diethylenetriamine $H_2N(CH_2)_2NH(CH_2)_2NH_2$ (DETA, Aldrich, 99%); 1,4,10-trioxa-7,13-diazacyclopentadecane (TDCPD, Aldrich, 99%); tetraethoxysilane $Si(OC_2H_5)_4$ (TEOS, Aldrich, 98%); bis[3-(trimethoxysilyl)propyl]amine $[(CH_3O)_3Si(CH_2)_3]_2NH$ (BTMPA, Fluka, ≥97%); 3-isocyanatopropyltriethoxysilane $(C_2H_5O)_3Si(CH_2)_3 \cdot NCO$ (IPTES, Aldrich, 95%); NH_4F (Fluka, 98%). Nonaqueous solvents (>99% pure) were dehydrated by the standard procedures. All the manipulations preceding the sol–gel syntheses were performed in a dry nitrogen flow, using the standard Schlenk technique.

The elemental analysis was performed with a Carlo Erba EA 1108 analyzer. The IR spectra of the alkoxysilanes were recorded on a Nicolet Nexus FTIR spectrometer in the transmission mode (NaCl windows), and those of the xerogels, on a Thermo Nicolet Nexus FTIR spectrometer in the reflection mode (4000–400 cm^{-1}); for this purpose, samples were ground with preliminarily calcined KBr in a 1 : 20 ratio. The ^1H NMR spectra were measured on a Bruker AC-300 spectrometer, using tetramethylsilane as reference. The mass spectra were taken on a Finnigan SSQ 710 mass spectrometer. The thermal analysis was performed with a Q-1500D in an air flow (temperature

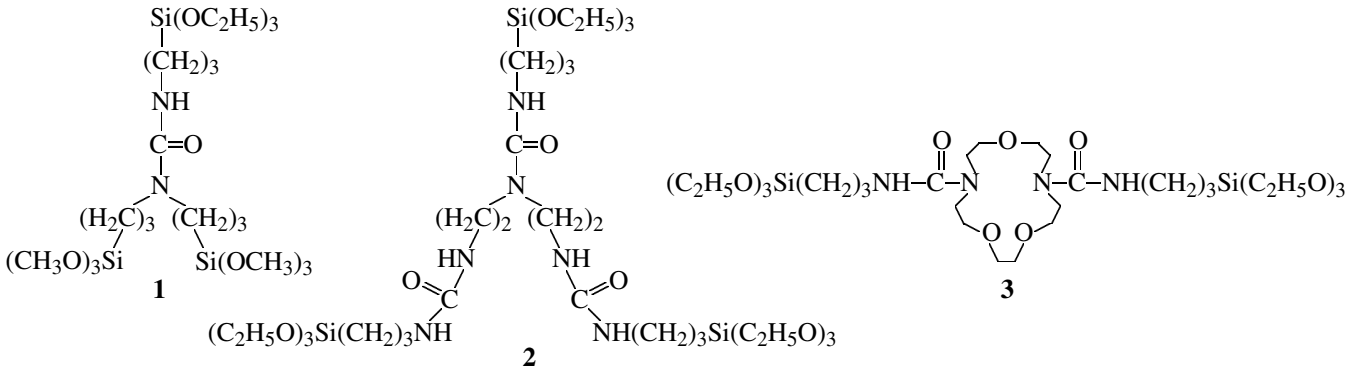
range 20–800°C, heating rate 5 deg min^{-1}). The thermobalance sensitivity was ±0.1 mg. Electron micrographs of samples in the scanning mode (SEM) were obtained with a Tesla BS301 device. To eliminate the electrostatic effect, samples were coated with a thin gold or platinum film using a Polaron SC 7640 device. Electron micrographs in the transmission mode (TEM) were obtained with a Tesla BS 540 device. Platinum–carbon replicas were preliminarily obtained for the samples studied. Low-temperature nitrogen adsorption isotherms were measured with an ASAP-2405N device (Micromeritics). Samples were preliminarily degassed in a vacuum at 150°C for 2 h.

Trifunctional silane $(C_2H_5O)_3Si(CH_2)_3NHC(O)N\cdot[(CH_2)_3Si(OCH_3)_3]_2$ (1). A 0.025-mol portion of IPTES was added dropwise with continuous stirring to a solution of 0.025 mol of BTMPA in 10 ml of methanol. An exothermic reaction occurred. After stirring for 1 h, the solution was allowed to stand for 18 h at room temperature, after which the solvent was removed under isothermal conditions. The residue (virtually colorless oil) was kept for several hours in a vacuum. ^{1}H NMR spectrum ($CDCl_3$), δ, ppm: 0.49 m ($SiCH_2$), 1.09 t (CH_3CH_2O), 1.51 m ($SiCH_2CH_2$), 3.01–3.10 m (CH_2N), 3.43 s (CH_3O), 3.69 q (CH_2O), 4.83 t (NH). MS, *m*/*z* (%): 160 (18), 192 (28), 202 (12), 340 (38), 439 (15), 543 (62), 557 (100), 559 (28), 588 (82), 600 (52), 618 (16). IR spectrum, cm^{-1}: 3365 (ν_{NH}); 2974, 2942, 2882, 2842 (ν_{CH}); 1631 (ν_{CO}); 1533 (ν_{CNH}).

Xerogel A. Silane **1** (0.025 mol) was dissolved in 20 ml of ethanol; the solution was cooled on an ice bath. To this solution, a solution of 0.75 mmol of ammonium fluoride in 0.2125 mol of water was added with vigorous stirring. After the mixture became fully transparent, 0.05 mol of TEOS precooled on an ice bath was added. After 3 min, the stirring was stopped, and 2 min later a transparent gel started to form. After standing for 24 h, the gel was crushed and dried in a vacuum at 70/80/90°C (2 h at each temperature). Then the xerogel was washed with 500 ml of water and again dried in a vacuum at 90°C for 6 h. Yield 14.0 g; white product.

Trifunctional silane $[(C_2H_5O)_3Si(CH_2)_3NHC(O)\cdot NH(CH_2)_2]_2NC(O)NH(CH_2)_3Si(OC_2H_5)_3$ (2). A solution of 0.0167 mol of DETA in 10 ml of ethanol was added dropwise with vigorous stirring to a solution of 0.05 mol of IPTES in 20 ml of *n*-hexane. After stirring for 2 h at room temperature, the solvents were removed under isothermal conditions. The residue (highly viscous oil) was kept in a vacuum for several hours with intermittent heating to 40–50°C. ^{1}H NMR spectrum ($CDCl_3$), δ, ppm: 0.60 m ($SiCH_2$); 1.17 t (CH_3CH_2O); 1.55 m ($SiCH_2CH_2$); 3.10 m [$Si(CH_2)_2\cdot CH_2N$]; 3.20, 3.27 m [$N(CH_2)_2N$]; 3.77 q (CH_2O); 5.29 m [$NH(CH_2)_2N$]; 5.85 m [$NH(CH_2)_3$]; 6.36 m [NHC(O)N]. MS, *m*/*z* (%): 202 (100), 218 (14), 246 (28), 320 (10), 333 (16), 423 (10), 555 (30), 625 (10), 799 (12), 846 (16). IR spectrum, cm^{-1}: 3358, 3320 sh (ν_{NH}); 2975, 2928, 2886 (ν_{CH}); 1644 sh, 1618 (ν_{CO}); 1569 (ν_{CNH}).

Xerogel B. Silane **2** (0.0167 mol) was dissolved in 40 ml of ethanol; the solution was cooled on an ice bath, and a solution of 0.75 mmol of ammonium fluoride in 0.2088 mol of water was added with vigorous stirring. After the mixture became fully transparent, 0.0668 mol of TEOS precooled on an ice bath was added. The mixture was stirred for several minutes, after which the stirring was stopped, and the transparent solution was allowed to stand at room temperature. A slight opalescence appeared, and a gel formed in 3 h. After standing for 24 h, the elastic gel was crushed and dried in a vacuum at 60/70/80°C for 2 h at each temperature. Then the xerogel was washed with 1000 ml of water and again dried in a vacuum at 80/90/105°C (2 h at each temperature). Yield 13.0 g; white product.



Trifunctional silane $[(C_2H_5O)_3Si(CH_2)_3NHC(O)\cdot N]_2C_{10}H_{22}O_3$ (3). The starting TDCPD (0.005 mol) was dissolved in 25 ml of ethanol, and a solution of 0.01 mol of IPTES in 5 ml of ethanol was added dropwise with vigorous stirring. An exothermic reaction occurred. After stirring for 3 h at room temperature, the solvent was removed under isothermal conditions. The residue (pale yellow oil) was kept for 48 h in a vacuum. ^{1}H NMR spectrum ($CDCl_3$), δ, ppm: 0.61 m ($SiCH_2$), 1.20 t (CH_3CH_2O), 1.56 m ($SiCH_2\cdot CH_2$), 3.13 m (CH_2N), 3.13 m [$O(CH_2)_2O$], 3.57 m (OCH_2CH_2N), 3.69 t (OCH_2CH_2N), 3.78 q (CH_2O), 5.76 m (NH). MS, *m*/*z* (%): 202 (18), 219 (12), 466 (25), 667 (100), 668 (45), 713 (22), 742 (8). IR spectrum, cm^{-1}: 3364 (ν_{NH}); 2975, 2927, 2885 (ν_{CH}); 1640 (ν_{CO}); 1538 (δ_{CNH}).

Xerogel C. Silane **3** (0.005 mol) was dissolved in 10 ml of ethanol, and a solution of 0.15 mmol of ammonium fluoride in 0.035 mol of water was added with vigorous stirring. The resulting solution was cooled on an ice bath, and 0.01 mol of TEOS was added with stirring. The stirring was continued for 10 min, after which the transparent solution was allowed to stand at room temperature. After standing for 48 h, the elastic gel was crushed and dried in a vacuum at 50/60/70°C for 2 h at each temperature. Then the xerogel was washed with 100 ml of water and

50 ml of ethanol and again dried in a vacuum for 2 h at 70°C and 4 h at 80°C. Yield 2.85 g; white product.

RESULTS AND DISCUSSION

To prepare the starting trifunctional silanes **1**–**3** containing a urea functional group >N–C(O)–N<, we used the well-known reaction of primary or secondary amines with isocyanates. As a rule, this reaction readily occurs even at room temperature, often with a quantitative yield. Since we used IPTES containing a triethoxysilyl group as the starting isocyanate, the new trifunctional silanes contained two or three such groups:

In the synthesis of **3**, we used as the starting amine a macrocycle containing two secondary amino groups. Thus, the pathway we suggest can be an alternative to the synthesis of alkoxysilyl-substituted macrocycles reported in [11].

All the trifunctional silanes prepared are oils. A particularly viscous oil is obtained in the case of alkoxysilane **2**; therefore, in [9], this compound was obtained and subsequently used as a 70% solution in 2-propanol. The alkoxysilanes obtained were identified by mass spectrometry and by IR and ^{1}H NMR spectroscopy. Since the purity of alkoxysilanes **1**–**3** was no less than 95%, according to the IR and NMR data, they were brought into the subsequent reaction without additional purification. The possibly present traces of the residual solvent do not prevent the hydrolytic polycondensation to give xerogels (the more so as the solvent used in this step was the same, ethanol). As the condensation catalyst we used ammonium fluoride (F^-/Si ratio from 1/130 to 1/150). We chose this catalyst because an acid catalyst could react with the functional group, and use of alkaline media frequently leads to formation of xerogels with a low specific surface area, especially when the trifunctional silanes contain bulky functional groups [7].

To prepare gels, we used a two-component system; along with alkoxysilanes containing urea functional groups we used tetraethoxysilane as cross-linking agent. The TEOS : trifunctional silane ratio was 2 : 1 (in the case of xerogel **B**, 4 : 1). The amount of water added was half that required for complete hydrolysis of all the ethoxy groups. Further treatment of the gels to prepare xerogels was performed similarly to [7]. The xerogels prepared are white substances readily forming aerosols. The analytical data and the content of functional groups, calculated from these data, are listed in Table 1. The calculated content of functional groups is fairly high, 1.2–1.6 mmol g^{-1}.

Table 1. Analytical data and content of functional groups in the xerogels prepared

Sample	C	N	H	C : N : H	$c_{f.\,gr}$,* mmol g^{-1}	Total loss of organics, wt %
	wt %					
A	30.5	4.4	6.2	8.2 : 1 : 20	1.6	41.1** (38.4)***
B	22.6	9.4	5.0	2.8 : 1 : 7.5	1.2	37.0 (35.4)
C	32.4	7.9	6.4	4.8 : 1 : 11.4	1.5	46.7 (47.4)

Table 2. Main absorption bands in the IR spectra of the xerogels synthesized and their assignment

Sample	ν(NH)+ν(OH)	ν(CH)	ν(CO)	δ(CNH)	ν(SiO)
	cm^{-1}				
A	3630, 3513, 3439, 3291	2973, 2939, 2886	1630	1539	1143, 1056
B	3630, 3517, 3330	2978, 2939, 2882	1656	1560	1195, 1082
C	3626, 3504, 3330	2939, 2869	1630	1543	1200, 1082

The modification of the silica surface does not allow a high content of functional groups to be reached, even when performed in the liquid phase [12]. It should be noted also that xerogel **B** contains three urea groups per unit. Thus, the actual amount of ligand centers in this case is three times larger: 3.7 mmol g^{-1}. The analytical data (Table 1) also show that the content of C and H is somewhat higher than that calculated assuming complete hydrolysis of all the ethoxy groups in the starting alkoxysilanes. This is not unexpected for hydrogen, because the samples may contain silanol groups and certain amount of water; as for carbon, its increased content suggests the presence of a small amount of unchanged alkoxy groups.

The presence of urea functional groups in the xerogels prepared is also confirmed by IR spectroscopy, namely, by the presence of characteristic absorption bands in the ranges ~3380–3400 and 1530–1640 cm^{-1} (Fig. 1). A strong broadened band in the first range is due to the stretching vibrations ν(NH) of the –NH–C(O)–NH– or –NH–C(O)–N= (in the case of secondary amine) fragment. This band apparently overlaps with the ν(OH) band. In the second range, there are two strong and sharp, but somewhat broadened bands assigned to ν(CO) and δ(CNH) [13, 14] (also termed amide I and amide II bands, Table 2). The strongest band in the IR spectra of all the xerogels is observed at 1050–1130 cm^{-1}; it has a shoulder (or shoulders) on the high-frequency side (Table 2). This band is indicative of the formation of a siloxane framework [15].

All the xerogels prepared were studied by thermal analysis; the curves obtained for xerogel **A** are shown as an example in Fig. 2. It is seen that all the samples exhibit a high thermal stability. In the range 100–150°C, there is an endothermic effect accompanied by a small weight loss: 5.5, 3.8, and 2.7% for xerogels **A**, **B**, and **C**, respectively. This effect can be attributed to the removal of water and residual solvent. At higher temperatures, there are exothermic effects caused by thermal oxidative degradation of the organic functional groups. The first exothermic effect is observed for all the matrices at 380–430°C; it can be assigned to

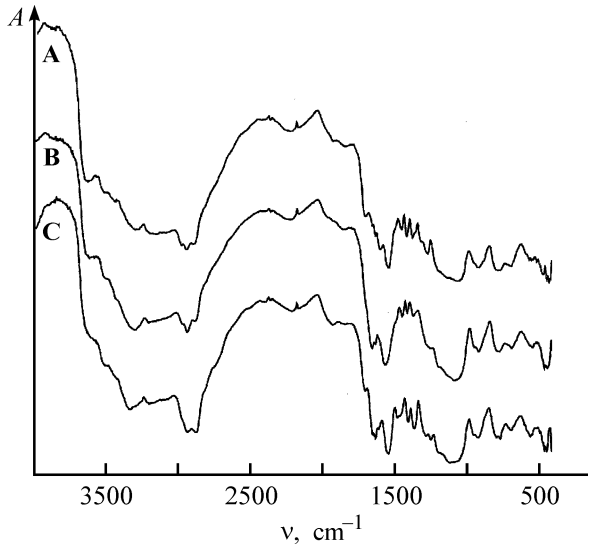

Fig. 1. IR spectra of xerogels: (*A*) reflection and (ν) wavenumber.

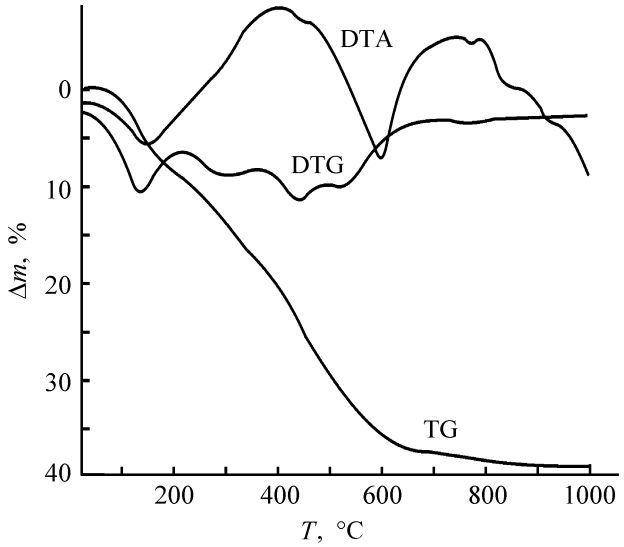

Fig. 2. Thermal analysis curves of xerogel **A**: (Δ*m*) weight loss and (*T*) temperature.

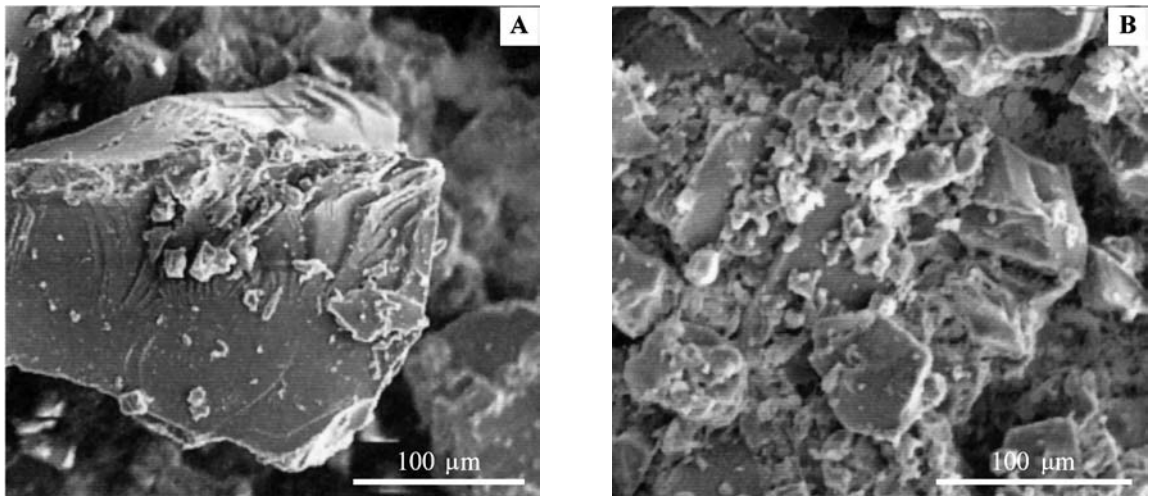

FIg. 3. SEM images of xerogels **A** and **B**.

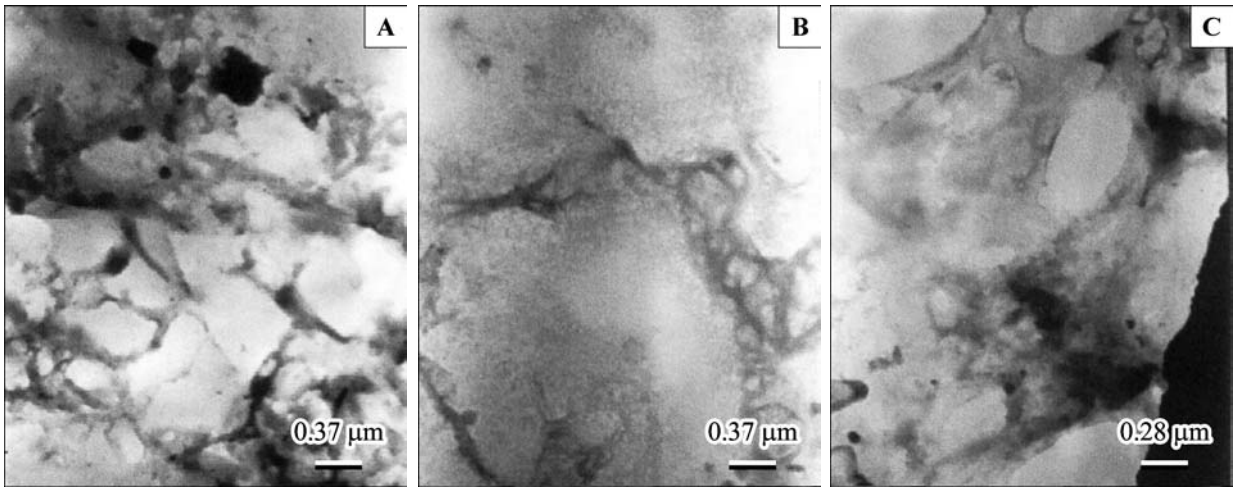

Fig. 4. TEM images of xerogels **A**, **B**, and **C**.

decomposition of structurally similar fragments. We believe that these are the >N–C(O)–N< fragments. The second effect is observed at different temperatures decreasing in the order **A** (750°C) > **B** (720°C) > **C** (620°C), i.e., with an increase in the structural strain. The total weight loss for all the samples is consistent with the analytical data (Table 1).

The hydrolytic stability of the surface layer of the xerogels obtained was evaluated by stirring 1 g of a sample in 25 ml of 0.1 N HCl for 4 h. After that, the sample was filtered off and dried at 120°C for 6 h. The IR spectra of the thus treated xerogels are identical to those recorded before the acid treatment, i.e., the surface layer is hydrolytically stable under these conditions. Furthermore, the weight loss estimated by the evaporation of the filtrate was less than 0.5 wt %.

The specific surface area of the xerogels, determined by low-temperature adsorption of nitrogen, is less than 2–3 $m^2 g^{-1}$, i.e., they are nonporous, which is typical of xerogels containing bulky functional groups [7].

Figure 3 shows the SEM images of the xerogels. They are typical of such materials and indicate that the xerogels consist of particles of irregular shapes and different sizes. The TEM images (Fig. 4) suggest that the xerogels prepared do not have a globular structure and are similar to organic polymers. Therefore, their pore structure parameters are low.

CONCLUSIONS

(1) Alkoxysilanes containing urea functional groups were prepared by the reactions of primary and

secondary amines with 3-isocyanatopropyltriethoxysilane.

(2) Xerogels containing 1.2–1.6 mmol g^{-1} functional groups were prepared by hydrolytic polycondensation catalyzed by fluoride ions.

(3) It was demonstrated that the synthesized xerogels with arch-fixed urea functional groups exhibit fairly high thermal and hydrolytic stability.

Abstract—The influence of peat humic acids on the aerobic reduction of Chrome Green Anthraquinone dye with sodium hydroxymethanesulfinate and thiourea dioxide in alkaline solutions was studied.

DOI: 10.1134/S1070427206060218

Textile dyeing with water-insoluble vat dyes necessarily involves the stage of temporary reductive transfer of the dye into solution, followed by its back oxidation on a fiber. The reduction of vat dyes is based on reversible quinone/hydroquinone reaction [1], which requires that not only strong reductants such as hydroxymethanesulfinate (HMS) or thiourea dioxide (TUDO), but also a catalyst should be used. The most widely employed catalysts for this purpose are synthetic anthraquinones [2], which are generally components of commercial vat dyes. In some cases, the catalysts are directly introduced into the printing dye. In these cases, the most commonly used catalysts are cobalt dioximates [3–5]. Naturally, some part of the indicated compounds, along with the unfixed dye, is rejected to wastewater of textile mills.

It has been demonstrated that absolutely nontoxic and environmentally friendly humic acid (HAs) can be used as a full-value alternative to the synthetic reduction catalysts. These acids can be readily extracted from peat [4].

Since the reduction of vat dyes is caused by only the presence of the quinoid groups in them, it becomes possible to study this process with model compounds readily soluble in water. Such model compounds can be anthraquinone dyes.

In this study, we examined the influence of peat humic acids on the kinetics of reduction of Chrome Green Anthraquinone (CGA) (CI Acid Green 27) with two sulfur-containing reducing agents, HMS and TUDO.

EXPERIMENTAL

In the experiments, we used an aqueous solution of HA salt obtained by alkaline extraction from peat, using the standard procedure [4]. HMS was purified by recrystallization of the commercial product. TUDO was synthesized as in [5]. CGA dye was purified to constant extinction coefficient [6].

The rate of CGA reduction by an excess amount of the reductant was determined by measuring the optical density at the absorption peak of the oxidized dye (λ_{max} = 612 nm, ε = 10 870 l mol^{-1} cm^{-1}). It was demonstrated in the preliminary experiments that this peak is well resolved from the absorption peak of the reduced dye.

The rate of dithionite formation by decomposition of TUDO under aerobic conditions was also determined spectrophotometrically at 315 nm (ε = 8043 l mol^{-1} cm^{-1} [7]) on a Specord M-40 instrument. The kinetic curves of reduction of CGA with HMS and TUDO are shown in Fig. 1.

The CGA reduction is described by a first-order kinetic equation [8], which suggests that the initial CGA molecule is involved in the reaction, i.e., that the reaction is kinetically controlled by the dye concentration [9]:

$$\mathrm{Dye(CO)_2} + \mathrm{HOCH_2SO_2^-} \rightleftarrows \mathrm{DyeCOCOH^-} + \mathrm{SO_2} + \mathrm{CH_2O}. \quad (1)$$

The reaction of the dye with sulfoxylate ions (active reducing species formed in decomposition

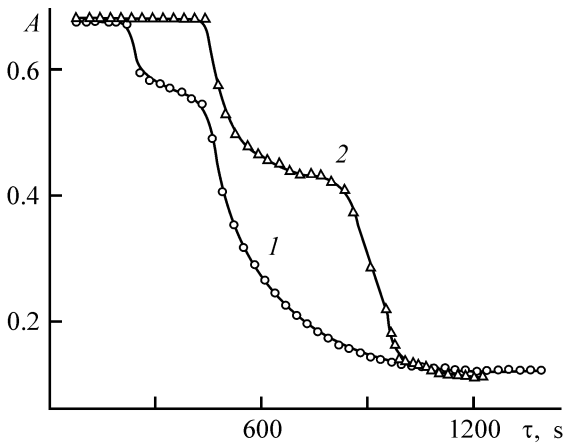

Fig. 1. Kinetic curves of CGA reduction with (*1*) HMS at 65°C and (*2*) TUDO at 20°C. Reagent concentrations (M): CGA 5.98×10^{-5}, HMS 2.37×10^{-2}, TUDO 1×10^{-3}, and NaOH 0.1; the same for Fig. 2. (*A*) Optical density of the CGA solution and (τ) time; the same for Fig. 2.

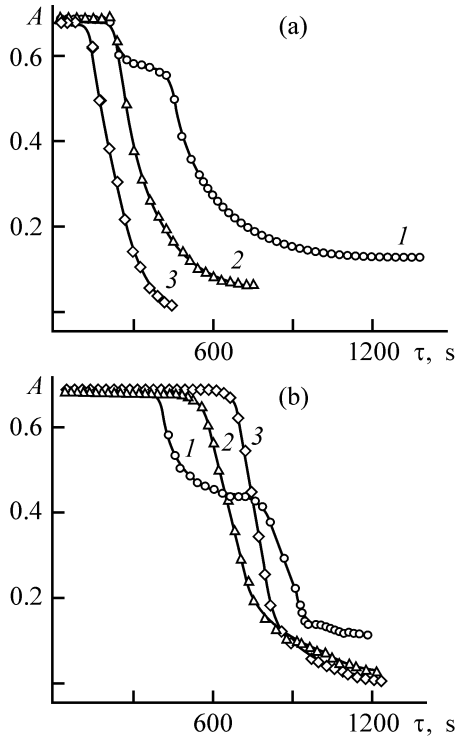

Fig. 2. Influence of HAs on the kinetics of CGA reduction with (a) HMS at 65°C and (b) TUDO at 20°C. Rate constants (s^{-1}): (a) $k_1 = 0.009$, $k_2 = 0.010$, and $k_3 = 0.092$ and (b) $k_1 = 0.0018$, $k_2 = 0.0021$, and $k_3 = 0.0025$.

of HMS [9]) also contributes significantly to the overall process:

$$HOCH_2SO_2^- + OH^- \rightleftarrows SO_2^{2-} + CH_2O + H_2O, \quad (2)$$

$$Dye(CO)_2 + SO_2^{2-} \rightleftarrows Dye(CO)_2^{2-} + SO_2. \quad (3)$$

This conclusion is based on the fact that the curve of CGA reduction with HMS shows an induction period, which, as is well known, is typical of only aerobic reactions, and is caused by the reaction of sulfoxylate with oxygen occurring in the solution [9, 10]:

$$SO_2^{2-} + O_2 \rightarrow SO_2^- + O_2^-, \quad (4)$$

$$SO_2^- + O_2 \rightarrow SO_2 + O_2^-. \quad (5)$$

Thus, the CGA reduction with HMS involves both the initial reductant molecule and the sulfoxylate ion, a reactive product of its decomposition [reactions (1) and (3)].

The kinetics of CGA reduction with TUDO, unlike that with HMS, is independent of the dye concentration, being described by a zero-order equation [8]. The reaction is kinetically controlled by the generation of the SO_2^{2-} ion as a reactive reducing species [11]:

$$(NH_2)_2CSO_2 + 2OH^- \rightarrow SO_2^{2-} + (NH_2)_2CO + H_2O. \quad (6)$$

This is demonstrated by the occurrence of an induction period in the initial reduction stage, which is considerably longer in the case of TUDO (Fig. 1, curve *2*) as compared to HMS (Fig. 1, curve *1*). The reasons are the lower reaction temperature and the lack of any reduction pathways other than the reaction with sulfoxylate.

It has been demonstrated in special experiments that the second induction period in the kinetic curves of dye reduction with both reductants is caused by the accumulation of oxygen reduction products, such as superoxide (O_2^-) formed by reaction (4) [12].

The influence of humic acids on the kinetics of CGA reduction with both reductants is shown in Fig. 2.

In the case of HMS (Fig. 2a), addition of HAs resulted in the following changes in the kinetic features: (i) the second induction period is completely vanishes (with account of the aforementioned reasons for its appearance [12], this suggests that, in the presence of HAs, the oxygen reduction products are either not accumulated or transformed); (ii) the yield of CGA reduction increases by about 20%; (iii) the reduction rate increases (the rate constant increases by more than an order of magnitude with the HA concentration increasing from 0 to 0.1 $g\,l^{-1}$); (iv) the slope of the kinetic curves decreases, suggesting a decrease in the contribution of reaction (1) and increase in the contribution of (3) to the overall process; and (v) the first induction period becomes shorter.

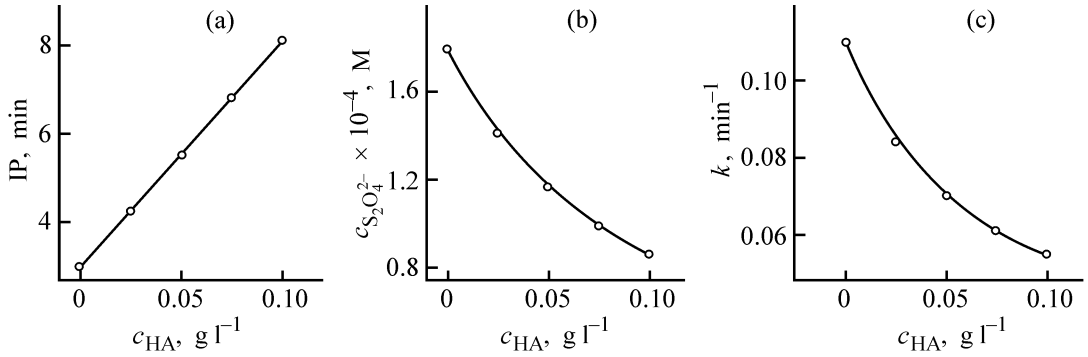

Fig. 3. Kinetic parameters of TUDO decomposition with the formation of $S_2O_4^{2-}$ ions as influenced by the HA concentration c_{HA}. $c_{TUDO} = 1.0 \times 10^{-3}$ M and $c_{NaOH} = 0.5$ M; $T = 20$°C. (a) (IP) Induction period, (b) $c_{S_2O_4^{2-}}$ concentration of $S_2O_4^{2-}$ ions, and (c) (k) rate constant of dithionite accumulation.

In CGA reduction with TUDO (Fig. 2b), the first three effects are the same (the second induction period vanished, the reaction yield increased by 20%, and the rate constant, by a factor of 2). The differences were that, firstly, HAs do not alter the reduction mechanism (kinetic curves are linear both in the presence and in the absence of HAs). Secondly (and most importantly), the first induction period is not only reduced, as with HMS, but even becomes considerably longer.

To analyze the last of the two indicated features, we examined in separate experiments the influence of HAs on the kinetics of anaerobic decomposition of TODO [reaction (6)]. The appearance of sulfoxylate ions in the system was judged from the absorption spectra of dithionite ions ($S_2O_4^{2-}$) formed from the sulfoxylate ions by reaction (7) and having a well-resolved peak in the near UV region [11]:

$$2SO_2^- \rightleftarrows S_2O_4^{2-}. \quad (7)$$

The influence of the HA concentration on the kinetics of accumulation of the dithionite ions is shown in Fig. 3. It is seen that the duration of the induction period linearly increases with the HA concentration (Fig. 3a) and with the content of dissolved oxygen [11]. Therefore, as in the case of oxygen, HAs entirely react with sulfoxylate ions. Among the diverse functional groups present in the HA molecules, only carbonyl groups can be reduced under mild conditions, the reaction being reversible [13–15]:

$$HA(C{=}O)_n + nS_2O_4^{2-} \rightleftarrows HA(C{-}O)_n^- + 2nSO_2. \quad (8)$$

Other groups (amide, imine, anhydride, and ester) are reduced at high temperature and pressure [16]. In addition to the carbonyl groups, the reduction of transition metal ions, primarily Fe(III), in the HA structure is also quite probable:

$$HA(Fe^{3+})_n + nS_2O_4^{2-} \rightleftarrows HA(Fe^{2+})_n + 2nSO_2. \quad (9)$$

The reversible redox reaction of iron (without rupture of its bonds with the organic fraction of the HA molecule) is comprehensively considered in the literature [17].

The interaction of HAs with sulfoxylate ions by reactions (8) and (9) results in a decrease in the equilibrium concentration of $S_2O_4^{2-}$ (Fig. 3b) and the process rate constant (Fig. 3c). However, as mentioned above, the rate and completeness of CGA reduction increase in this case. Therefore, the reduction of the dye involves not only sulfoxylate ions [reaction (3)], but also HAs reversibly reduced by sulfoxylate:

$$2HA(C{-}O)_n^- + n\text{Dye}(CO)_2 \rightleftarrows 2HA(C{=}O)_n + n\text{Dye}(CO)_2^{2-}, \quad (10)$$

$$2HA(Fe^{2+})_n + n\text{Dye}(CO)_2 \rightleftarrows 2HA(Fe^{3+})_n + n\text{Dye}(CO)_2^{2-}. \quad (11)$$

This mechanism is operative in reduction of CGA with TUDO. In the case of HMS, as demonstrated above, the process involves not only sulfoxylate ions, but also the molecular form of the reductant. Undoubtedly, the latter also can reduce HAs, since the redox potential of HAs under the experimental conditions is as low as 70–120 mV:

$$HA(C{=}O)_n + nHOCH_2SO_2^- \rightleftarrows HA(C{-}O)_n^- + nSO_2 + nCH_2O, \quad (12)$$

$$HA(Fe^{2+})_n + nHOCH_2SO_2^- \rightleftarrows HA(Fe^{3+})_n + nSO_2 + nCH_2O. \quad (13)$$

Evidently, it is these reactions that are responsible for the observed considerably more effective accelerating effect of HAs on the CGA reduction with HMS (Fig. 2a) as compared to TUDO (Fig. 2b).

The high catalytic activity of peat HAs in reduction of the quinone groups of the dyes, observed with an example of the model water-soluble dye, was verified in the laboratory and industrial tests in printing textiles with water-insoluble vat dyes [18]. Introduction of small amounts of HAs into the vat dyes for printing cotton fabrics reduces by half of the time of water-steam treatment and allows a simultaneous increase the adsorption of the dye on the fibers by 2–9%. In this case, the color fastness, as well as the color purity, are not deteriorated, which is virtually impossible with the common synthetic catalysts.

CONCLUSIONS

(1) Small additions of peat humic acids have a considerable catalytic effect on the reduction of Chrome Green Anthraquinone dye with sodium hydroxymethanesulfinate in alkaline solutions.

(2) Comparison of the effect of peat humic acids on the kinetics of reduction of the anthraquinone dye with two sulfur-containing reductants (sodium hydroxymethanesulfinate and thiourea dioxide) and also on the kinetics of accumulation of the dithionate ions in aerobic decomposition of thiourea dioxide in solutions reveals that the catalytic action of humic acids occurs by the mechanism of redox catalysis.

(3) Humic-acid catalysis of the reduction of the carbonyl groups in the molecules of organic dyes, observed for the example of the water-soluble acid dye, also virtually impossible under conditions of printing textiles with water-insoluble vat dyes. In industry, this can save material resources and energy supply.

Abstract—Homogeneous copolymerization of acrylamide and sodium 2-acrylamido-2-methylpropanesulfonate was carried out in water–ethanol mixtures at pH 9 in the presence of potassium peroxosulfate as promoter in the temperature range 40–70°C. The copolymerization kinetics and molecular characteristics of the copolymers formed were studied in relation to the composition of water–ethanol mixtures, reagent concentrations, temperature, and degree of monomer conversion.

DOI: 10.1134/S107042720606022X

Owing to numerous useful properties, water-soluble polymers are widely applied in various fields of modern industry. Synthesis and use of these polymers involve no toxic, inflammable, and dangerously explosive solvents, and no risk of pollution. Water-soluble copolymers of acrylamide (AA) and sodium 2-acrylamido-2-methylpropanesul-fonate (Na-AMS) deserve a special attention because of their wide application as thickeners, stabilizers, and flocculants in petroleum production, well-boring, and water treatment [1–3].

It is known [4] that the radical copolymerization of water-soluble monomers significantly depends on the kind of solvent. Therefore, the use of binary solvents of variable composition allows efficient control over copolymerization. Copolymerization of AA and Na-AMS in aqueous salt solutions [5], and in water–dimethyl sulfoxide [6] and water–dimethylformamide [7] mixtures has been studied peviously. In this study, we examined the kinetics of homogeneous radical copolymerization of AA and AMS monomers in water–ethanol mixtures in the presence of potassium peroxosulfate as initiator at 40–70°C.

EXPERIMENTAL

2-Acrylamido-2-methylpropanesulfonic acid (HAMS), mp 185°C, was purchased from the Lubrizol (England). Na-AMS was prepared by potentiometric titration of aqueous HAMS with aqueous NaOH to pH 9. Acrylamide, mp 84.5°C, was purchased from Mitsubishi Chem Ind. Ltd. (Japan). Potassium peroxosulfate (PP), chemically pure grade, was twice recrystallized from water. The main substance content in potassium persulfate, determined by redox titration, was 97.8%. All other chemicals were of chemically pure grade.

The copolymerization of AA and Na-AMS was carried out to small degrees of conversion ($x < 2.5\%$) in a 8.4-cm^3 glass dilatometer and to higher degrees of conversion in 50-cm^3 weighing bottles. The copolymerization experiments were performed as follows. The aqueous HAMS monomer or its solution in the water–ethanol mixture was neutralized under cooling with aqueous alkali to pH 9, and then aqueous PP and AA solutions were added. The resulting mixture was transferred with a long-needle syringe into a dilatometer or a weighing bottle and kept in a thermostat (45–70°C) at a temperature control accuracy of ±0.05°C. The copolymerization kinetics was studied by dilatometry. In these experiments, both the copolymerization conditions and the dilatometric technique were identical to those reported in [8]. The initial rate of copolymerization, v_0, at low degree of conversion (<2.5%) was determined from the slope of the initial linear portion of the kinetic curve.

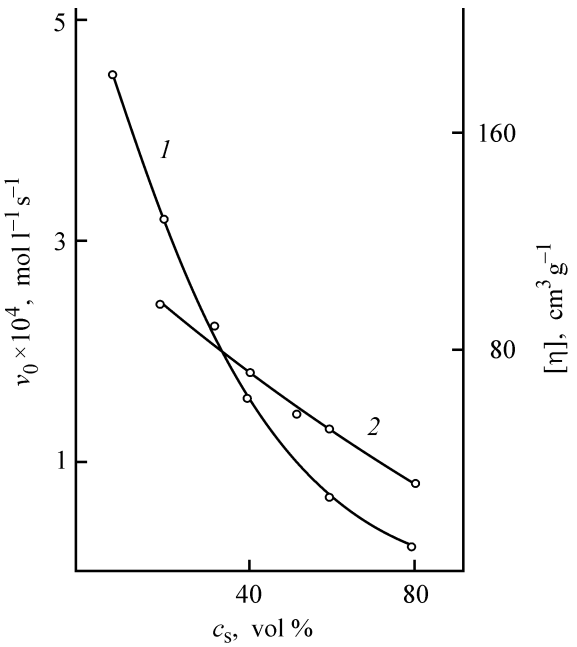

Fig. 1. Dependence of (*1*) initial rate of copolymerization of AA and Na-AMS, v_0, in the water–ethanol mixture ($H_2O : C_2H_5OH$ = 3 : 1) and (*2*) intrinsic viscosity of the copolymer, [η], on the ethanol content in the reaction mixture, c_s. $[M_1] + [M_2]$ = 20%; $[M_1]/[M_2]$ = 1.

After the copolymerization completion, the resulting copolymer was precipitated from the reaction mixture by adding a large excess of acetone. This procedure allowed separation of the target copolymer from the unchanged monomers. The isolated copolymer was washed with acetone and dried in a vacuum to constant weight. Its yield was determined gravimetrically. The sulfur content of the copolymer was determined by the method described in [9].

The molecular weight of the AA–Na-AMS copolymer was estimated from its intrinsic viscosity [η] determined from the concentration dependence of the reduced viscosity (η_{sp}/c) of the copolymer solution in 0.5 M aqueous NaCl at 30°C:

$$[\eta] = \lim(\eta_{sp}) \text{ at } c \to 0.$$

The viscosity was measured with a VPZh-3 capillary viscometer (d_c = 0.56 mm).

The pH was measured using a pH-121 pH-millivoltmeter equipped with an ESL-63-07 glass electrode and an EVL-1M3 silver chloride reference electrode.

The copolymerization of AA and Na-AMS was carried out in aqueous solution or water–ethanol mixtures at ethanol-to-water volume ratios of 4 : 1, 3 : 1, 1.5 : 1, 1 : 1, 1 : 1.5, and 1 : 4 in the presence of PP (3×10^{-4} M) at 60°C. The AA and Na-AMS content of all the reaction mixtures was 20%. To ensure homogeneity of the reaction mixture in the course of the copolymerization, the ethanol content of the water–ethanol mixtures did not exceed 80%. At higher ethanol concentrations, the reaction mixture gave a precipitate. To stabilize the activating effect of PP [10] at the ionic strength of the reaction mixture varying with the initial Na-AMS monomer concentration and Na-AMS consumption in the course of polymerization, pH 9 of the reaction mixture was maintained [11]. Under these conditions, both the imidization of the Na-AMS amido groups [12] and hydrolysis of this salt [3] were suppressed. We found that AA and Na-AMS copolymerize only in the presence of an initiator (PP).

Figure 1 shows the rate of copolymerization of AA and Na-AMS in relation to the composition of water–ethanol mixtures. It is seen that, with increasing water content, both the copolymerization rate v_0 and the intrinsic viscosity [η] of the copolymer increase. These effects are due to the fact that the mobile protons and the hydroxy groups of water molecules prevent chain transfer to ethanol molecules. Our results are consistent with the data on copolymerization of AA and Na-AMS in aqueous-organic media, reported in [13], which showed that the number of hydrogen bonds between H_2O molecules and the CO groups in the AA and Na-AMS monomers increases with the water content of the water–ethanol mixture. As a result, the electron density on the double bonds of both monomers decreases and their reactivity increases. Therefore, an increase in the water content in the reaction mixture leads to a rise in both the copolymerizaion rate v_0 and the yield of the copolymer (Table 1). Table 1 also shows that the AA–Na-AMS copolymers are formed in high yield.

Table 1. Yield of AA–Na-AMS copolymer in copolymerization of AA and Na-AMS in water–ethanol mixtures of varied composition ($[M_1] + [M_2]$ = 20%; $[M_1]/[M_2]$ = 1)

Water–ethanol ratio, vol %	Yield in 1 h, %
25 : 75	78
40 : 60	81
50 : 50	81
60 : 40	83
80 : 20	84

Figure 2 shows how the Na-AMS content of the water–ethanol mixture ($H_2O : C_2H_5OH = 3 : 1$) affects the copolymerization rate, and the intrinsic viscosity [η] and yield of the copolymer, other factors being the same. It is seen that, with increasing relative content of Na-AMS in the reaction mixture, both v_0 and [η] decrease in parallel. Thus, on enrichment of the reaction mixture with AA, the copolymerization is accelerated. These data indicate that AA is more reactive in copolymerization than Na-AMS.

Figure 3 shows the correlation between the Na-AMS concentration in the initial reaction mixture and content of Na-AMS units in the AA–Na-AMS copolymers obtained at low degrees of conversion ($x < 2.5\%$). Curve *2* refers to copolymerization in water, and curve *1* to that in the water–ethanol mixture ($H_2O : C_2H_5OH = 3 : 1$). S-shaped curve *2* has an azeotropic point at the Na-AMS mole fraction 0.35, whereas the AA–Na-AMS copolymers obtained in water within the entire Na-AMS concentration range, are enriched in AA units. The relative reactivity of AA and AMS monomers toward like and different macroradicals [ratio of the probability of formation of AA–AA (11), AA–Na-AMS (12), and Na-AMS–Na-AMS (22) fragments in a copolymeric chain in the course of AA and Na-AMS copolymerization] is characterized by the ratio of the corresponding rate constants: $r_1 = k_{11}/k_{12}$ and $r_2 = k_{22}/k_{21}$. The r_1 and r_2 parameters were calculated from the relation $m_2 = f(M_2)$ by the Mayo–Lewis, Fineman–Ross, and Kelen–Tudos methods. All these methods gave close r_1 and r_2 values which are as follows: water, $r_1 = 1.31 \pm 0.09$ and $r_2 = 0.11 \pm 0.01$ [6]; and water–ethanol mixture ($H_2O : C_2H_5 = 3 : 1$), $r_1 = 0.78 \pm 0.12$ and $r_2 = 0.31 \pm 0.01$. These results show that, for AA and Na-AMS copolymerization in water, $r_1 > r_2$, i.e., AA is more reactive than Na-AMS. In copolymerization of AA and Na-AMS in the water–ethanol mixture, $r_1 < 1$ and $r_2 < 1$, i.e., formation of the AA–Na-AMS fragments is preferential.

Comparison of curves *1* and *2* at $m_2 = \text{const}$ (Fig. 3) shows that, with increasing water content, the copolymers become enriched in the AA units because of an increase in r_1 and a decrease in r_2.

Figure 4 shows the plots of the reduced viscosity η_{sp} of solutions prepared from identical AA–Na-AMS copolymer samples in water (curve *1*) and water–ethanol mixtures of varied composition (curves *2–4*) against the copolymer concentration. These plots are typical of polyelectrolyte solutions whose rheological

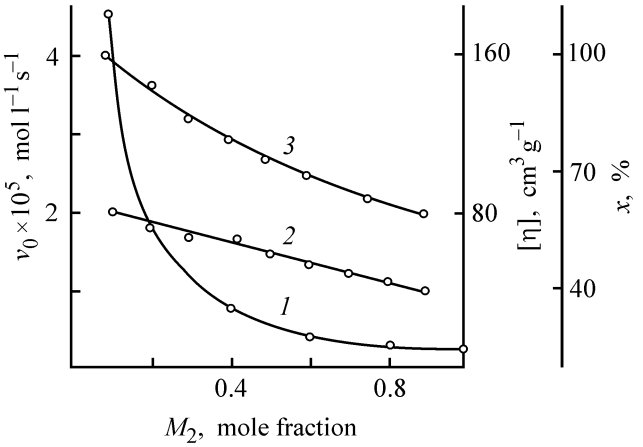

Fig. 2. Dependence of the (*1*) initial rate of copolymerization of AA and Na-AMS v_0, (*2*) intrinsic viscosity of the copolymer [η], and (*3*) yield of the copolymer x on mole fraction M_2 of the Na-AMS monomer in the initial water–ethanol mixture ($H_2O : C_2H_5OH = 3 : 1$).

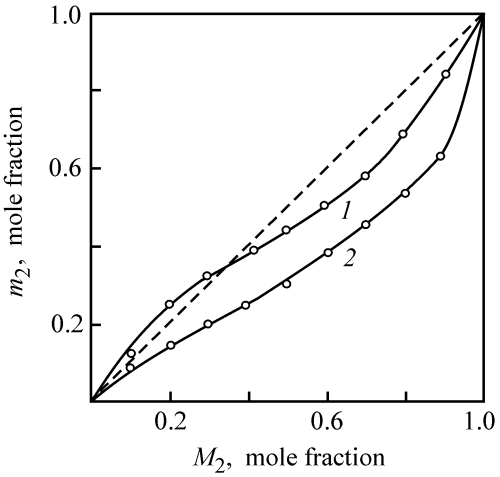

Fig. 3. Dependence of the content of Na-AMS units in AA–Na-AMS copolymers m_2 prepared at low degrees of conversion ($x < 2.5\%$) on the mole fraction of Na-AMS monomer M_2 in (*2*) water and (*1*) water–ethanol mixture ($H_2O : C_2H_5OH = 3 : 1$).

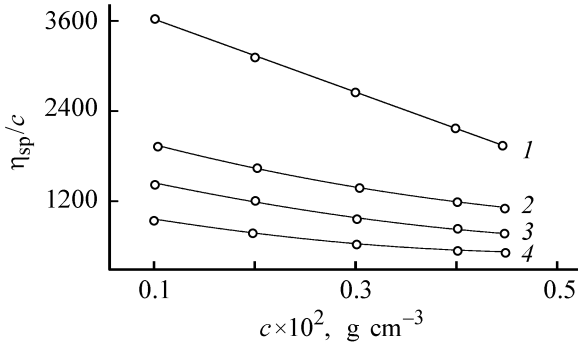

Fig. 4. Dependence of the reduced viscosity of solution of AA–Na-AMS copolymer ([η] = 96 cm^3 g^{-1}, content of Na-AMS units 24 mol %) on its concentration in (*1*) water and (*2–4*) water–ethanol mixtures with water : ethanol ratios of (*2*) 3 : 1, (*3*) 1 : 1, and (*4*) 1 : 3 at 30°C.

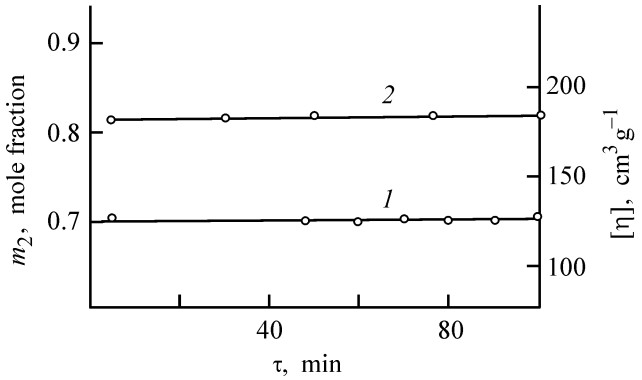

Fig. 5. Dependence of (*1*) [η] and (*2*) content of Na-AMS units in the copolymer (m_2) on the copolymerization time τ in water–ethanol mixture (water : ethanol = 3 : 1). M_2 = 0.9.

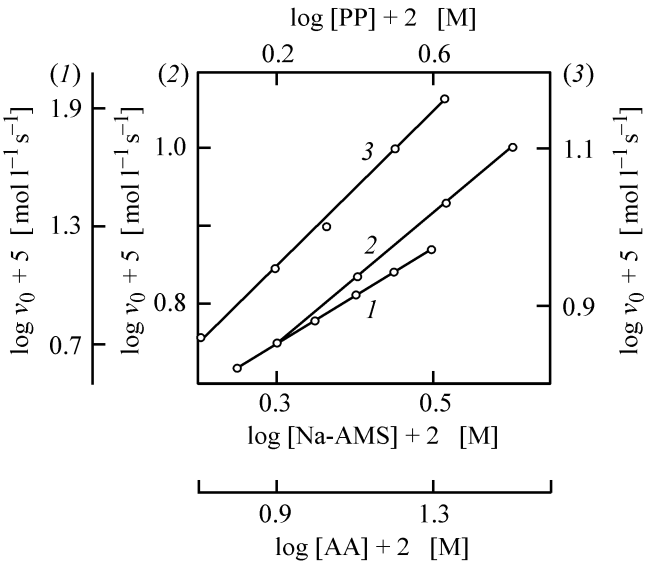

Fig. 6. Logarithmic plot of the initial rate of AA and Na-AMS copolymerization v_0 in the water–ethanol mixture (water : ethanol = 3 : 1) vs. (*1*) AA, (*2*) Na-AMS, and (*3*) PP concentrations. (*1*) [Na-AMS = 0.66 M, [PP] = 3.2×10^{-3} M; (*2*) [AA] = 0.66 M, [PP] = 3.2×10^{-3} M; and (*3*) [Na-AMS] = [AA] = 0.66 M.

behavior is controlled by the electrostatic effects. On adding water to AA–Na-AMS copolymer in ethanol, both the polarity of the medium and the degree of ionization of Na-AMS ionic groups increase. The increase in the polarity enhances repulsion between like-charged sulfonate anions situated along the polymeric chain. Therefore, in going from the reaction mixture with the lowest water content (curve *4*) to water (curve *1*) at c = const, the macromolecular globules of copolymers become bulkier and the viscosity of the solutions increases. With increasing water content in the reaction mixture, the electrostatic repulsion between the like-charged Na-AMS units and macroradicals with terminal Na-AMS units also becomes stronger. This repulsion decreases the rate constant k_{22} and, as it is seen from comparison of curves *1* and *2* (Fig. 3), the copolymer becomes depleted of Na-AMS units. On adding water to ethanol, the charge of copolymer chains increases. This factor makes lower the local concentration of Na-AMS monomer in the vicinity of the Na-AMS reaction centers, which causes depletion of the copolymer in Na-AMS units.

Figure 5 shows how the intrinsic viscosity [η] of AA–Na-AMS copolymers in the water–ethanol mixture ($H_2O : C_2H_5OH$ = 3 : 1) and the Na-AMS unit content of the copolymer depend on the conversion. It is seen that both [η] and the Na-AMS content remain constant in the course of copolymerization. Similar results have been obtained preliminarily for homopolymerization of AA and N-vinylpyrrolidone [14, 15] and copolymerization of AA and Na-AMS in water [16]. These results can be attributed to micelle formation. The bulkier Na-AMS monomers penetrate into micelles to the propagating macroradical more difficultly than smaller AA monomers do. Therefore, the ratio of Na-AMS and AA monomers within micelles remains constant in the course of copolymerization. Under these conditions, the copolymer composition is virtually independent of the degree of conversion.

The copolymerization kinetics of AA and Na-AMS monomers in the water–ethanol mixture ($H_2O : C_2H_5$ = 3 : 1) was studied in relation to the concentrations of the monomers and PP, all other factors being the same (Fig. 6). It is seen that, with increasing concentration of the monomers and PP, v_0 grows. The order of the copolymerization reaction with respect to both the monomer and initiator was determined from the slopes of the corresponding plots in Fig. 6. Based on these data, the following empirical equation for the rate of AA and AMS copolymerization in the presence of PP was derived

$$V = k_c[\text{AA}]^{1.4}[\text{Na-AMS}]^{0.8}[\text{PP}]^{0.5},$$

where k_c is the rate constant of AA and Na-AMS copolymerization.

In this equation, the reaction order with respect to the initiator is 0.5, which indicates a bimolecular mechanism of termination of propagating polymeric chains.

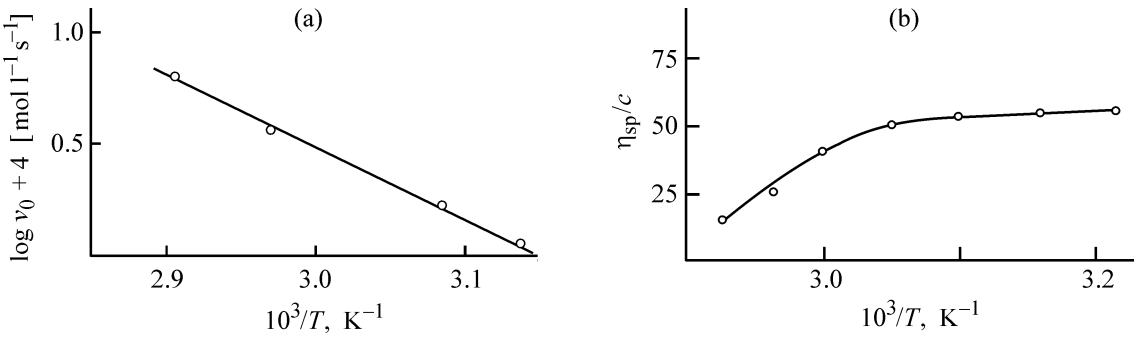

Fig. 7. Dependence of (a) initial copolymerization rate v_0 in the water–ethanol mixture ($H_2O : C_2H_5OH$ = 1 : 3) and (b) reduced viscosity η_{sp} of the copolymer solution ([η] = 182 cm^3 g^{-1}, Na-AMS unit content 8.4 mol %) on the reciprocal temperature. (b) Solvent : water–ethanol mixture (3 : 1), c = 0.5%.

Table 2 shows that AA–Na-AMS copolymers are formed in a the water–ethanol mixture in high yield. With increasing comonomer concentrations, the intrinsic viscosity [η] of the copolymers and their yield grow.

The influence of temperature on the copolymerization was studied within the temperature range 40–70°C. The plot of log v_0 vs. reciprocal temperature (Fig. 7) shows that, with increasing temperature, v_0 grows. The apparent overall activation energy of the copolymerization is 30 kJ mol^{-}1. We believe that a decrease in η_{sp}/c with temperature (Fig. 7b) is caused by contraction of the macromolecular globules. The reason for this contraction is a decrease in the degree of Na-AMS ionization with increasing temperature. This factor weakens the electrostatic repulsion between like-charged Na-AMS units situated along the copolymeric chain. This decrease in the electrical charge is also accompanied by an increase in the local concentration of Na-AMS monomer in the vicinity of Na-AMS reactive centers of propagating macromolecular chains. As a result, the copolymerization accelerates with temperature.

Table 2. Dependence of the intrinsic viscosity [η] of the reaction mixture and the yield of AA–Na-AMS copolymers on the comonomer concentration in the water–ethanol mixture ($H_2O : C_2H_5OH$ = 3 : 1)

Monomer	c, M	Yield in 1 h, %	[η], cm^3 g^{-1}
AA	0.60	39	187
	0.63	51	253
	1.20	62	300
Na-AMS	1.60	70	349
	0.90	22	98
	1.20	28	101
	1.40	36	125
	1.70	48	180

CONCLUSIONS

(1) In radical copolymerization of AA and Na-AMS monomers in the water–ethanol mixture, high-molecular-weight copolymers of varied molecular structure are formed.

(2) With increasing water content of the reaction mixture, the initial copolymerization rate v_0, intrinsic viscosity [η], and content of AA units in the copolymer become higher due to increasing r_1 and decreasing r_2. Neither [η] nor the copolymer composition change with the conversion.

(3) Both [η] and the yield of copolymers increase with the total comonomer concentration in the reaction mixture. At $[M_1] + [M_2]$ = const, v_0 and [η] increase with the AA content in the reaction mixture. The copolymerization of AA and Na-AMS is accelerated with increasing initiator concentration and temperature.

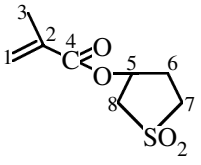
Abstract—Radical copolymerization of *N*-vinylpyrrolidone with 3-methacryloyloxytetrahydrothiophene 1,1'-dioxide in the bulk and in dimethyl sulfoxide in the range of low conversions was studied. The kinetic features of copolymerization were examined. The relative activities of monomers and the structure and some characteristics of the copolymers were determined.

DOI: 10.1134/S1070427206060231

Poly-*N*-vinylpyrrolidone (PVP) is of prime importance among other macromolecular compounds. A combination of practically valuable characteristics of PVP: solubility in water and in most of organic solvents, absence of toxicity, biological compatibility, immune inactivity, and also clearly pronounced capability for complex formation with a wide variety of inorganic and organic compounds and biological systems, allows use of this compound as a disintoxication agent and prolongation agent for drugs [1, 2]. Copolymers of *N*-vinylpyrrolidone (VP) have a still wider set of valuable characteristics. The copolymerization reactions allow modification of PVP characteristics and therefore acquire growing practical importance. Copolymers based on VP are components of a great number of drugs, act as carriers of biologically active substances, and are the base of membranes, sorbents, coagulants, flocculants, etc. [3–7]. Copolymers of VP with 3-methacryloyloxytetrahydrothiophene 1,1'-oxide (MAHTO) can be of some interest for medical purposes. MAHTO is nontoxic, has clearly pronounced antimicrobial, antiphlogistic, and wound-healing effects, and enters into the composition of the medicinal glue widely used in surgery for gluing of soft tissues of a living body [8, 9]. It is well known that MAHTO is highly active in radical homo- and copolymerization with vinyl monomers, methyl methacrylate, methacrylic acid, and styrene [10, 11]. There are no published data on copolymerization of MAHTO with VP; at the same time, it is our opinion that copolymerization of VP with MAHTO could widen the set of valuable characteristics and the range of application of copolymers based on VP in medicine and biotechnology.

Our aims were to study the copolymerization of VP with MAHTO, namely, to determine the activities of monomers and to examine the kinetic features of the reaction and some characteristics of the resulting copolymers.



EXPERIMENTAL

N-Vinylpyrrolidone of chemically pure grade was dried with potassium hydroxide and distilled in a vacuum. For polymerization we used the fraction with bp 65°C at a pressure of 200 Pa, n_D^{20} 1.5117.

3-Methacryloyloxytetrahydrothiophene 1,1'-oxide was synthesized by the procedure described in [12]. The purity was monitored by the elemental analysis, determination of the content of double bonds, and ^{13}C NMR.

Found (%): C 47.25, H 6.11, S 15.41, C=C 11.80.
Calculated (%): C 47.06, H 5.88, S 15.69, C=C 11.76.

Chemical shifts δ (ppm) and multiplicity of signals for the indicated atoms are presented below.

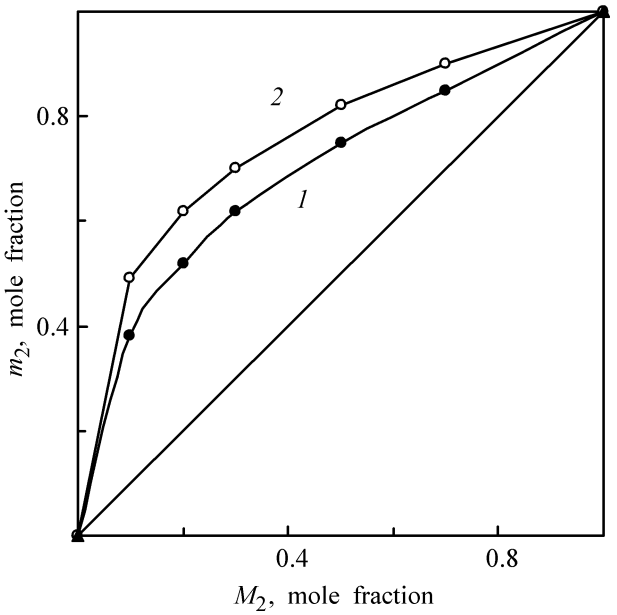

Fig. 1. Composition of copolymers of VP with MAHTO vs. the composition of the initial monomer mixture. [AIBN] = 3.05×10^{-2} M, T = 55°C; the same for Fig. 2. (M_2) MAHTO content in the initial mixture, and (m_2) MAHTO content in the copolymer. (*1*) In the bulk and (*2*) in DMSO, $[M_1 + M_2]$ = 3.2 M; the same for Fig. 2.

Azobis(isobutyronitrile) (AIBN) of chemically pure grade was thrice recrystallized from methanol and dried in a vacuum at room temperature to constant weight, mp 103°C with decomposition.

Dimethyl sulfoxide (DMSO) and acetone after purification by standard procedures corresponded in their characteristics to published data.

Copolymerization of VP with MAHTO was performed in a vacuum to low conversions in the bulk and in a DMSO solution in the presence of AIBN initiator at 55°C. The process kinetics was monitored dilatometrically. The initial rate was evaluated from the initial portions of the kinetic curves (at ≤7% conversions). When the required degree of conversion was reached, the polymerization was terminated by cooling and subsequent precipitation of the copolymer. The copolymers were purified by twofold reprecipitation from DMSO solutions in acetone. The purified polymers were dried in a vacuum at 50°C to constant weight.

Table 1. Effective constants of copolymerization of VP (M_1) with MAHTO (M_2) AIBN, 55°C

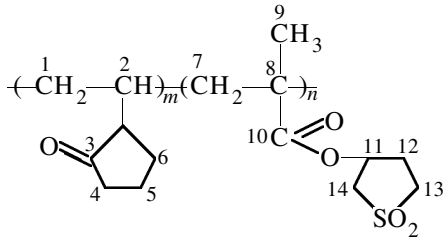
Medium	r_1	r_2
In bulk	0.05 ± 0.01	1.20 ± 0.30
DMSO	0.01 ± 0.005	2.72 ± 0.32

The composition of the copolymers was determined from the results of elemental analysis. The effective copolymerization constants were evaluated by the Mayo–Lewis [13] and Kelen–Tudos [14] methods.

The ^{13}C NMR spectra were recorded on a Bruker AM-300 spectrometer operating at 75.46 MHz. DMSO-d_6 was used as a solvent, and tetramethylsilane, as an internal reference.

The intrinsic viscosity of the copolymers was measured on an Ubbelohde viscometer (DMSO, 25°C).

The parameters of acute toxicity of copolymers of VP with MAHTO were determined on outbred white mice of both sexes with a weight of 18–22 g, by the procedure described in [15]. The bactericidal activity was studied on three samples of conditionally pathogenic strains (*Staphylococcus aureus*, strain 906; *Staphylococcus saprophiticus*, strain 15305; *Micrococcus luteus*, strain 4698) by two-fold dilution method [16]. DMSO was used as a solvent for the copolymer in screening.



A thermomechanical testing was performed on powder-like samples compacted in pellets (pressure 185 MPa, pressing duration 5 min). The measurements were performed by permanent loading of the samples with linear heating at a rate of 2.5 deg min^{-1}.

Thermal gravimetric measurements were performed in air on a MOM Q 1000 derivatograph at a heating rate of 5.0 deg min^{-1}.

The studies showed that, irrespective of the reaction conditions (in the bulk or in solution), copolymerization of VP with MAHTO yields copolymers with a random distribution of monomeric units in the macrochain. The dependence of the copolymer composition on the composition of the initial mixtures (Fig. 1) and the effective copolymerization constants (Table 1) suggest that MAHTO (r_2) has a significantly higher activity in comparison with VP ($r_2 >> r_1$) and, irrespective of the reaction conditions, the copolymers are significantly enriched in MAHTO units throughout the entire range of the copolymer ratios in the initial mixture.

Table 1 shows that the relative activity of VP in the reaction in DMSO is significantly lower than that in copolymerization in the bulk, which is apparently caused by associative interactions of the components in the polar system: electron-donor DMSO, being associated with a propagating radical having a MAHTO

Table 2. Chemical shifts and multiplicity of signals in the ^{13}C NMR spectra of VP–MAHTO copolymer

C_1	C_2	C_3	C_4	C_5	C_6	C_7	C_8	C_9	C_{10}	C_{11}	C_{12}	C_{13}	C_{14}
30.99 t	43.29 d	174.55 s	30.96 t	17.58 t	43.94 t	40.96 t	43.70 s	19.20 q	174.56 s	70.26 d	28.24 t	48.96 t	55.73 t

terminal unit, displaces VP from the solvation layers of the propagating chains.

A study of kinetic features of the reaction at low conversions showed that an increase in the MAHTO fraction in the initial monomer mixture results in acceleration of the reaction both in the bulk and in DMSO (Fig. 2). The reaction rate in the bulk is significantly higher than that in DMSO.

In copolymerization in DMSO, the reaction orders with respect to the sum of the monomers (at their equimolar ratio) and initiator are 1 and 0.5, respectively, which suggests that the common relationships of radical polymerization with biomolecular mechanism of the termination of the propagating chains are obeyed.

The structure of copolymers was found by ^{13}C NMR (Table 2).

Copolymers of VP with MAHTO are white powders. The solubility of the copolymers depends on the ratio of the comonomer units in the polymer chain. At any ratio of the monomers, the copolymers are soluble in DMSO and DMF, and at the content of MAHTO units in the copolymer less than 10 mol %, they are soluble in water and methanol. The copolymers show film-forming properties; flexible transparent films can be prepared by casting from solutions. The intrinsic viscosity of VP–MAHTO copolymer of the equimolar composition is 1.4 dl g^{-1} (DMSO, 25°C), which suggests a high molecular weight of the copolymer.

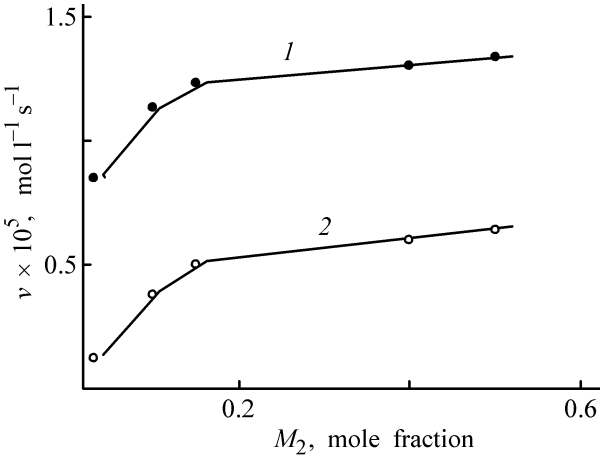


Fig. 2. Initial rate of copolymerization of VP with MAHTO v vs. the composition of the initial monomer mixture, M_2.

The toxicity tests on mice showed that VP–MAHTO copolymers belong to hazard class 4 (in stomach administration LD_{50} >> 3000 mg per 1 kg) and can be used for medical purposes.

The studies of the bactericidal activity showed that VP–MAHTO copolymer of the equimolar composition exhibits pronounced bactericidal effect with respect to *Staphylococcus aureus* and *Staphylococcus saprophiticus* in a concentration of 62.5 μg ml^{-1} and to *Micrococcus luteus* in a concentration of 32.2 μg ml^{-1}.

The glass transition point of the copolymer (at the equimolar ratio of VP units and MAHTO) is 68, flow point 170, and onset point of intense decomposition 264°C.

CONCLUSIONS

(1) Radical copolymerization of *N*-vinylpyrrolidone with 3-methacryloyloxytetrahydrothiophene 1,1'-dioxide was studied. The optimum reaction conditions are the reaction in the bulk at 55°C in the presence of $(3.0–3.1) \times 10^{-2}$ M azobis(isobutyronitrile).

(2) The resulting copolymers are nontoxic, belong to hazard class 4, have pronounced antimicrobial ac-

tivity with respect to gram(+)-microflora, and can be used in production of drugs and in biotechnology.

MACROMOLECULAR CHEMISTRY AND POLYMERIC MATERIALS

Synthesis and Properties of Water-Soluble Derivatives of Fullerene C_{60}

I. F. Gun'kin, V. N. Tseluikin, and N. Yu. Loginova

Saratov State Technical University, Saratov, Russia

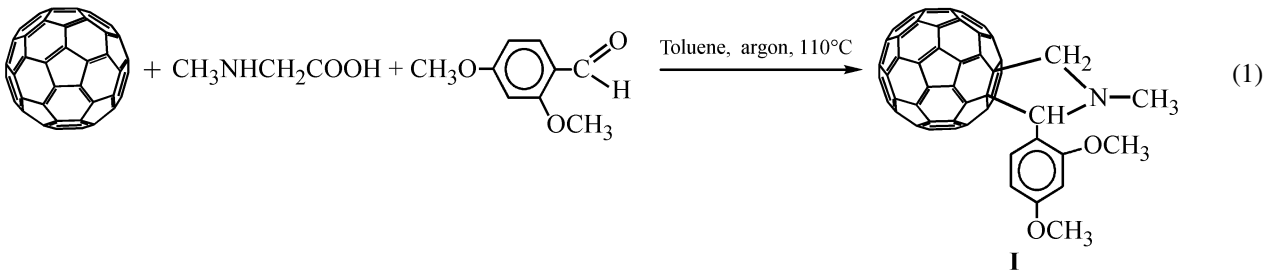
Received September 19, 2006

Abstract—Procedures for synthesized of water-soluble forms of fullerene C_{60} and its derivatives were developed.

DOI: 10.1134/S1070427206060243

Development of methods for synthesis of functionalized derivatives of fullerene C_{60} is imported for preparation of new materials and biologically active compounds. Compounds intended for biological application should be water-soluble. However, C_{60} is hydrophobic. Its solubility in water is as low as 1.3×10^{-11} mg ml^{-1} [1].

A search for ways to raise the water-solubility of C_{60} and its derivatives is a topical task. A study of reactions of fullerenes in water is also of separate interest for applied chemistry. In principle, there are several procedures for raising the solubility of fullerene C_{60} and its derivatives in water.

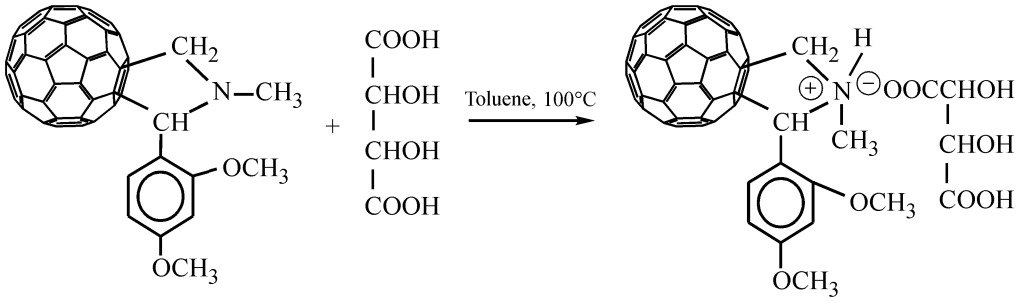


The first is modification of the C_{60} sphere. It is known [2] that the 6–6 bonds of a fullerene molecule are unsaturated and dienophilic. Hence, dienes and nucleophilic agents containing various hydrophilic substituents can be attached to these bonds to form adducts whose solubility in water is higher that that of the initial fullerene C_{60}. Physiologically active fullerenes can be prepared by grafting of pharmacophore groups.

To raise the solubility of fullerene C_{60}, its complexes with various water-soluble polymers, e.g., with polyvinylpyrrolidone (PVP) can be prepared [3–7]. The polymer partially envelops fullerene molecules, which leads to partial solubilization and to increase in its solubility in water.

The third procedure is to prepare colloidal C_{60}. It is known that surfactants can convert water-insoluble organic compounds into colloids or solubilize them. For example, colloid solutions of C_{60} in water are formed in the presence of sodium dodecyl sulfate.

Using these methods, we prepared water-soluble derivatives of fullerene C_{60}.



The fullerene sphere was modified by the Plato procedure [8]. The reaction of fullerene C_{60} with *N*-methylglycine (sarcosine) and 2,4-dimethoxybenzaldehyde in refluxing toluene under Ar atmosphere yields *N*-methyl-1-[2,4-dimethoxyphenyl]fullereno-C_{60}[1,9*c*]pyrrolidine (**I**) [reaction (1)]:

(1)

I

To raise the solubility of compound **I** in water, the pyrrolidine ring should be substituted with additional hydrophilic groups. For this purpose, we performed reaction of compound **I** with mesotartaric acid to form the corresponding pyrolidinium tartrate (**II**) [reaction (2)].

I **II**

(2)

Unlike fullerene C_{60}, tartrate **II** is soluble in a water–DMSO mixture (3 : 1).

To obtain water-soluble derivatives of fullerene C_{60}, we prepared its complexes with PVP. These complexes were reported in [3–7]. However, it should be noted that we failed to prepare PVP solutions with high concentrations of fullerene C_{60} by the procedure described in [3]. This is due to the following reasons. When pure toluene is used, problems caused by its low polarity arise, whereas the solubility of fullerene C_{60} in more polar solvents (a chloroform–toluene mixture) is insufficient. An analysis of previous studies [3–7] showed that water-soluble PVP–C_{60} complexes with a high fullerene concentration should be prepared in a single-component polar solvent which readily dissolves both C_{60} and PVP. We suggested that chlorobenzene is a suitable solvent. The dielectric constant of chlorobenzene is $\varepsilon = 5.6$, i.e., it is more polar than chloroform ($\varepsilon = 4.8$). The solubility of fullerene C_{60} in chlorobenzene (5.7 mg ml^{-1} [1]) is an order of magnitude higher than that in a toluene–chloroform mixture. PVP is also readily soluble in chlorobenzene. The use of chlorobenzene allowed us to significantly improve the procedure for preparing complex **III** and to raise the fullerene content in the complex. Complex **III** is water-soluble. The C_{60} content in the complex reaches 1.6%, i.e., it is a factor of 2 higher that than obtained in [3]. The UV spectrum of an aqueous solution of complex **III** contains two bands at 255 and 330 nm. The complex is fairly stable at room temperature but gradually decomposes in an aqueous solution. At 80°C, the complex gradually decomposes in an aqueous solution to form fullerene C_{60}. Decomposition of complex **III** is complete within 70 h. The solubility of complex **III** and the fullerene content were determined both gravimetrically and from the absorption at 255 and 330 nm.

Our third procedure developed for raising the solubility of fullerene C_{60} in water was to prepare a C_{60} colloid, using sodium dodecyl sulfate as a stabilizer. A colloid solution of C_{60} in water was prepared by evaporation of organic solvents from a toluene–acetone–water mixture in the presence of sodium dodecyl sulfate. In the course of evaporation, a dispersion of fullerene C_{60} in water stabilized with sodium dodecyl sulfate is formed. The average size of colloid particles in water, determined from a turbidity spectrum, was 24 nm. The C_{60} content in the dispersion ranged from 0.01 to 0.5 g l^{-1}. The color of these dispersions changed from yellow to dark brown as the fullerene concentration increased.

The stabilizing effect of sodium dodecyl sulfate is caused by adsorption of its molecules on the surface of the fullerene sphere by the hydrocarbon radicals, so that the polar groups form an external layer preventing coagulation. In an aqueous solution, the polar groups partially dissociate to form colloidal C_{60} particles whose structure can be described by the formula

$$\{n[C_{60}]mC_{12}H_{25}SO_4(m - x)Na^+\}xNa^+.$$

Thus, water-soluble derivatives of fullerene C_{60} were prepared by different methods that can be used in chemical industry.

EXPERIMENTAL

The IR spectra of fullerene C_{60} and compounds **I** and **III** (Nujol of hexachlorobutadiene mulls, or KBr

pellets) were recorded on a Specord-80 spectrophotometer. The UV spectra of these compounds in $CHCl_3$ and water were recorded on an SF-26 spectrophotometer.

The TLC analysis was performed on Silufol UV-254 plates, using hexane–toluene (1 : 1) mixture as the eluent. The chromatograms were developed with an iodine vapor.

Fullerene C_{60} (99.5% main compound) was purchased from Merck and used as received, R_f 0.9. UV spectrum ($CHCl_3$), λ_{max}, nm (ε): 258 (86 000), 328 (11 000), 401 (13 000), shoulder 490–500. IR spectrum, ν, cm^{-1}: 528, 576, 1180, 1428.

Sarcosine and 2,4-dimethoxybenzaldehyde were recrystallized prior to use. The physicochemical properties of these compounds were consistent with the published data.

***N*-Methyl-1-[2,4-dimethoxyphenyl]fullereno-C_{60}-[1,9*c*]pyrrolidine (I)**. To a solution of fullerene C_{60} (0.072 g) in toluene (100 ml), sarcosine (0.0267 g) and 2,4-dimethoxybenzaldehyde (0.0332 g) (molar ratio of the reactants 1 : 3 : 2, respectively) were added. The reaction mixture was refluxed under Ar for 8 h, cooled, and washed with several portions of water. The reaction mixture was evaporated to a volume of ~4 ml in a vacuum under Ar. The residue was placed in a column packed with SiO_2. The column was eluted with hexane to remove the unchanged fullerene C_{60}. Compound **I** was eluted with a hexane : toluene (1 : 1) mixture. The eluent was removed. The yield of compound **I** was 15%. R_f 0.1. IR spectrum, ν, cm^{-1}: 528, 550, shoulder 560–580, 670, 725, 770, 850, 915, shoulder 930–950, 970, 1150, 1170, 1210, 1360, 1370, 1450, 1460, 1500–1600, shoulder 1650–1670. 1680, 1700–1750, 2856, 2924, 2960. UV spectrum ($CHCl_3$), λ_{max}, nm (ε): 260 (36 058), 350 (2163), 425 (721), 475–485 shoulder, 525–535 shoulder.

***N*-Methyl-1-[2,4-dimethoxyphenyl]fullereno-C_{60}-[1,9*c*]pyrrolidinium mesotartrate (II)**. To a solution of compound **I** (4 mg) in toluene (10 ml), a solution of mesotartaric acid (0.9 mg) in ethanol (reactant molar ratio 1 : 1) was added. The reaction mixture was refluxed under argon for 1.5 h. The solvent was removed in a vacuum in an argon atmosphere. The yield of compound **II** was 4.9 mg. A single spot was observed at the start on the TLC pattern of this compound. Unlike the initial fullerenopyrrolidine **I**, compound **II** is soluble in aqueous DMSO at ~30–40°C.

Complex PVP–C_{60} (III). The synthesis was performed in anhydrous chlorobenzene. PVP (Enterodez pharmaceutical trademark, molecular weight 12 600 ± 2700) was dried in a vacuum at 80°C for 50 h. To PVP (0.7529) in chlorobenzene (20 ml), C_{60} (0.0231 g) in chlorobenzene (10 ml) was added. The reaction mixture was stirred, heated at 60°C for 5 h, cooled to room temperature and then to 0°C, and kept at room temperature for 50 h. Chlorobenzene was removed in a vacuum at 60°C. The residue was dried in a vacuum, powdered to completely remove the residual chlorobenzene, and dried to constant weight at 60°C in a vacuum. Analysis showed the absence of chlorobenzene in the product. Complex **III** is soluble in water. Its UV spectrum contains bands at 255 and 330 nm. IR spectrum, ν, cm^{-1}: 578, 844, 894, 933, 1077, 1227, 1266, 1375, 1490, 1630, 1687, 1703, 2127, 2395, 2575, 2922, 3329, 3493, 3800, 3943.

Aqueous dispersions of fullerene C_{60}. Fullerene C_{60} was dissolved in toluene to give a 1 mg ml^{-1} solution. A 5–20 mM solution of stabilizer (sodium dodecyl sulfate) in an acetone-water mixture (1 : 3) was prepared. The toluene solution of fullerene C_{60} was added dropwise to the solution of the stabilizer, with vigorous stirring on a magnetic stirrer. The resulting yellow homogeneous solution was distilled under atmospheric pressure with vigorous stirring. The first fraction was acetone, and the second, a toluene–water azeotrope. In the course of azeotrope distillation, an aqueous fullerene dispersion stabilized with sodium dodecyl sulfate was gradually formed. After complete evaporation of the organic solvent from the reaction mixture, only the water fraction with a refractive index n_D^{20} 1.3330 was distilled off. The thus obtained solution was a colloid solution of fullerene C_{60} with a particle size of 24 nm.

CONCLUSIONS

(1) Fullerenopyrrolidine was prepared by functionalization of fullerene C_{60}. Fullerenopyrrolidinium tartrate soluble in a water–DMSO mixture (3 : 1) was prepared by the reaction of this compound with mesotartaric acid.

(2) Procedures for preparing water-soluble derivatives of fullerene C_{60} were developed. These derivatives can be used for preparing composite electrochemical coatings and can exhibit biological activity.

Abstract—Distribution of scattering centers (filler particles and pores) in films of an ultra-high-molecular-weight polyethylene xerogel was studied by IR spectroscopy and optical microscopy.

DOI: 10.1134/S1070427206060255

Preparing new polymeric composites, studying their structure and properties, and searching for their new application areas are important problems of modern science and technology. Polymeric composites can be prepared by various processes and, among them, the gel-casting process shows much promise. In this process, the polymeric matrix is filled with both organic and inorganic fillers in the initial stage of the solution preparation before its conversion into the gel and then into the xerogel (solvent-free gel). Since solutions used in the gel preparation are often relatively dilute, a very high degree of filling can be attained upon substitution of the solvent with an appropriate filler. IR spectroscopy is a powerful tool for studying porous structure of xerogel films, because it allows determination of the total porosity of a sample [1] and the average diameter of pores on the micrometer scale [2, 3]. Also, IR spectra furnish information about how the filler affects the xerogel porous structure [4, 5].

In this study, we developed an IR spectroscopic procedure for studying the size distribution of pores and filler particles in a filled polymeric composite.

EXPERIMENTAL

In the tests, we used films of xerogels of ultra-high-molecular-weight polyethylene (UHMWP) with an average molecular weight of 4.0×10^6, filled with particles of micrometer size and various shapes (sphere, tetrahedron, fiber, and flat flake) of vermiculite, strontium ferrite, zeolite, talc, Kopan (modified Nitron fiber), and montmorillonite.

The filled films of 60-μm thickness were prepared by the procedure given in [4, 5]. The degree of filling was varied in the 0–90% range. The IR spectra were recorded on an Equinox 55 Fourier IR spectrometer.

The total porosity of the xerogel films was determined from the absorption coefficient ε_ν of the most intense band in the IR spectra [1, 3]. For polyethylene, we used the absorption band at 730 cm^{-1}, which belongs to rocking vibrations of CH_2 groups in the crystalline phase.

Analysis of scattering and its effect on the IR spectra of a sample allows evaluation of such parameters as the average pore diameter and pore size distribution [3]. As a rule, the bending point in the IR spectrum of a porous material corresponds to the average pore diameter. To evaluate the size distribution function of the scattering centers (pores or filler particles), we recorded IR spectra of a monolithic film of high-density polyethylene with an average molecular weight of 1.5×10^5, prepared from the melt, and of a filled film of the same thickness, prepared from solution by gel-casting (Fig. 1a, curves *1*, *2*). Then, by subtracting the spectra of the porous film from those of the monolithic sample, we obtained the difference spectrum characterizing the dependence of the scattering *S* on the wavenumber (Fig. 1b), which is represented by an S-shape dependence with a characteristic bending point. Then, by assuming that the strongest scattering is observed in the case of coincidence of the scattering particle size and the wavenumber of incident light (so-called diffraction scattering), by passing from wavenumber to the wavelength, and by differentiating this

diffraction curve, we obtained the size distribution curve of the scattering centers (for pores and filler particles combined) (Fig. 1c) [6].

The composite structure was studied independently by optical microscopy. Photomicrographs of the filled films were recorded on an Neophot 30 optical microscope equipped with a digital camera. The size distribution of the filler particles in the sample was evaluated with the Image Pro program, and the diameters of the filler particles were calculated from the areas of their cross sections on the surface photomicrographs.

It was found [4, 5] that, with the filler concentration increasing to 50%, the total porosity of the sample increases, whereas in some cases, at higher degrees of filling, the sample porosity decreases. The dependences of the absorption coefficient ε_{730} of the UHMWP xerogel films on the degree of filling with various fillers are shown in Fig. 2. Actually, the total porosity increases with the degree of filling for all the fillers studied, and the strongest changes are observed in the initial stage (up to 20%). Since the slope of the curve at the initial point varies with the filler, we can control the dynamics of growth of the total porosity of a polymeric composite and, thus, its properties by using appropriate filler. A certain increase in the absorption coefficient ε_{730} at high degrees of filling (more than 50%) is in some cases indicative of an insignificant decrease in the sample porosity at high degrees of filling, which well agrees with the data reported in [4, 5].

The IR transmission spectra of UHMWP xerogel films with various degrees of filling with strontium ferrite are shown in Fig. 3. It can be seen that, with

increasing degree of filling, the characteristic bending point is shifted toward larger wavenumbers due to scattering of IR light on pores and filler particles. By subtracting the IR spectra of the porous film from the IR spectra of the monolithic film and differentiating the difference spectra with respect to wavelength (Fig. 1) [6], we obtained the size distribution curves of the scattering centers (pores and filler particles) (Fig. 4). It can be seen that, with increasing degree of filling, the average diameter of the scattering centers increases and the size distribution curve of the pores and filler particles becomes significantly broader. Actually, the electron microscopic data on these polymeric films showed that, with increasing degree of filling with strontium ferrite particles, coarser aggregates are formed.

The dependences of the average diameter of the scattering centers (pores and filler particles) on the filler content are shown in Fig. 5. The average diameters of the scattering centers were calculated from the peaks the size distribution curves, similar to those given in Fig. 4. As can be seen from Fig. 5, the most pronounced increase in the average diameter of the scattering is observed with strontium ferrite, and the least pronounced, with Kopan. This indicates that the filler type directly affects the pore diameter and ability to form filler aggregates in the polymeric composite. Obviously, ferromagnetic strontium ferrite should show the strongest tendency to form aggregates. Hence, by adding various fillers in a polymeric composite, we can significantly change its morphology and the mechanical, sorption, and other properties.

In accordance with the Babinet principle [7], the scattering of electromagnetic radiation on holes (pores) is identical to that on the solid particles. Thus, it is rather difficult to distinguish the contributions of pores and filler particles to the overall pattern of light scattering with a porous composite using the IR data only. For this purpose we used an independent method, optical microscopy, which allows evaluation of the size distribution function of only particles that occur on the sample surface. The size distribution curves of the scattering centers (pores and filler particles) in the UHMWP xerogel films filled with strontium ferrite, evaluated by two above methods, are shown in Figs. 6a and 6b. Curve *1* illustrates the size distribution of the filler particles obtained by optical microscopy, and curve *2* (IR data), the size distribution of both pores and filler particles. As seen, at a 10% degree of filling the size distribution curves of the scattering centers are similar (Figs. 6a and 6b) and are only slightly shifted with respect to each other. This fact suggests that, at a small content of the strontium ferrite filler (≤10%), the size distri-

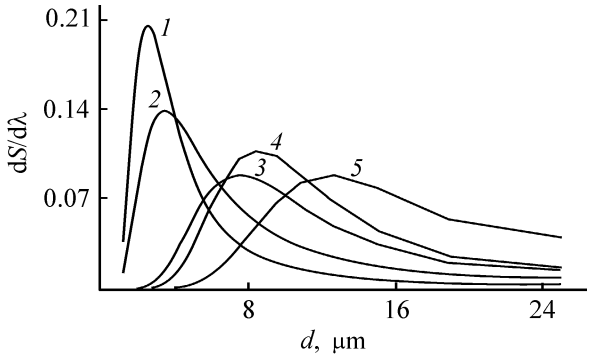

Fig. 4. Size distribution of the scattering centers (pores and filler particles) of the UHMWP xerogel films with degree of filling with strontium ferrite of (*1*) 0, (*2*) 10, (*3*) 30, (*4*) 50, and (*5*) 70%. (*d*) Average pore diameter; the same for Fig. 6.

bution functions of the filler particles and pores in the xerogel film are similar. With increasing filler content (Fig. 6b), the contribution of scattering on pores grows, and the difference in the size distribution curves obtained by optical microscopy and IR spectroscopy becomes more pronounced; simultaneously, the shift between these curves also increases. This shift is due to the increasing porosity of the film; it is related to the growth of the pore size rather than to that of the pore concentration. This increase in the film porosity with increasing filler content well agrees with the results presented in [4, 5] and can be attributed to changes in the crystallization conditions at formation of the xerogel film. Thus, combined use of optical microscopy and IR spectroscopy furnishes rich information on the aggregation of the filler particles and formation of the porous structure of UHMWP xerogel films.

CONCLUSUIONS

(1) The dependences of the total porosity and average diameter of the scattering particles of ultra-high-molecular-weight polyethylene on the content and type of filler were evaluated by IR spectroscopy; the filler type strongly affects the porosity and aggregation of the filler particles.

(2) A study of the dependences of the size distribution functions on the degree of filling of ultra-high-molecular-weight polyethylene with strontium ferrite filler demonstrated that, at high degrees of filling, the effect of the pore scattering on the distribution function is decisive.

Abstract—The migration of plasticizers [EDOS, di(2-ethyl hexyl) *o*-phthalate, di-*n*-butyl *o*-phthalate] from unfilled and chalk-filled polyvinyl chloride films plasticized with individual and binary plasticizers was studied by gravimetric analysis and IR spectroscopy. The intermolecular interaction of components in model systems was studied by IR spectroscopy and isothermal calorimetry.

DOI: 10.1134/S1070427206060267

EDOS plasticizer attracts attention of researchers and producers of polymer materials as a substance allowing partial or complete replacement of expensive phthalate plasticizers [1–4]. EDOS is prepared from large-volume isoprene production waste and is a mixture of dioxane alcohols and their high-boiling derivatives [5].

The properties of polyvinyl chloride (PVC) materials plasticized with EDOS were compared in [1, 2] with the properties of the same materials plasticized with commercially used di(2-ethylhexyl) *o*-phthalate (DOP) and di-*n*-butyl phthalate (DBP). It was shown that complete (with DOP) or partial (with DBP) replacement of phthalate plasticizers with EDOS is appropriate. However, the high volatility of EDOS can lead to its substantial loss in the course of processing of PVC formulations.

It is also known [6–9] that the release from PVC materials of such plasticizers as DOP, DBP, dibutoxyethyl adipate, or dibutyl sebacate can be controlled both by the volatility of the plasticizers themselves and by their diffusion in a polymer matrix, depending on the temperature, chemical structure of the plasticizer, its initial content in the sample, and other factors. In this connection, various procedures can be considered for decreasing the migration of plasticizers from polymeric materials with the aim to ensure their environmental safety and stability of service parameters. Data on the mechanism of EDOS migration from polymer formulations are lacking; therefore, it is interesting to study its migration from PVC compounds in comparison with the formulations plasticized with DOP and DBP.

EXPERIMENTAL

Experiments were performed with PVC films simulating linoleum prepared by rolling and calendering; both filled and unfilled films were tested. The formulations were prepared from the following commercial components: S-70 suspension PVC; EDOS, DOP, and DBP plasticizers; and MTD-2 chalk (filler). All the formulations were stabilized with calcium stearate and urea. Samples for gravimetric experiments had the following composition (weight proportion): PVC 100, plasticizer 64, chalk 0 or 245, Ca stearate 0.9, and urea 0.45. Samples were prepared as films by rolling on laboratory rolls at 140°C for 10 min. The film thickness was about 1 mm. Experiments were started approximately 1 month after the sample preparation.

Samples for studying the thermodynamics of component interaction in PVC formulations containing up to 50% plasticizer were rolled as films. Formulations containing more than 50% plasticizer were prepared by adding strictly the required amount of the same plasticizer to samples containing 50% plasticizer, followed by heating at 50°C in sealed glass calorimetric ampules to complete homogenization.

Model polymer-containing systems for studying intermolecular interaction by IR spectroscopy were prepared as films from 3% solutions in tetrahydrofuran (THF) on a glass support. Tetrahydrofuran was evaporated at room temperature, and the films were kept for 9 h at 70°C to remove the residual solvent; the process was monitored spectroscopically.

The weight loss of the samples in air at atmospheric pressure under isothermal conditions at room temperature and 90°C was monitored gravimetrically.

The qualitative composition of substances released from the films to air and the kinetics of their release at 90°C in a dynamic vacuum (residual pressure about 30 Pa) were studied by the previously developed procedure [9, 10] based on IR spectroscopy, using a thermovacuum chamber (TVC).

The intermolecular interactions of components in the films were evaluated from changes in the absorption bands of functional groups in the IR spectra of model systems plasticizer–polymer, plasticizer–filler, and plasticizer–plasticizer. The IR spectra were recorded on a Specord 75-IR spectrometer.

The thermodynamics of the interactions in PVC formulations was studied by isothermal calorimetry. The enthalpies of mixing of the plasticizers, PVC, and PVC formulations with a solvent (THF) at 25°C were measured with a Calvet calorimeter (cell sensitivity 0.22 V W^{-1}). The enthalpy of wetting of chalk with EDOS plasticizer was also determined. The error of the calorimetric measurements did not exceed 5%.

The enthalpy of mixing of a polymer with an individual or mixed plasticizer was calculated in accordance with the Hess law:

$$\Delta H^m = \omega_1 \Delta H_1 + \omega_2 H_2 - \Delta H_3, \quad (1)$$

where ω_1 and ω_2 are the weight fractions of the plasticizer and polymer in the formulation; ΔH^m, enthalpy of mixing of the polymer with an individual or mixed plasticizer per gram of PVC formulation; ΔH_1, ΔH_2, and ΔH_3, enthalpies of solution of the plasticizer, polymer, and formulations in excess solvent.

When analyzing the enthalpies of mixing of PVC with plasticizers, it should be taken into account that at room temperature PVC is in the glassy state; therefore, the measured enthalpies of solution of the formulations and individual polymer are integral quantities and involve two contributions: that from intermolecular interaction of the components and that from the breakdown of the glassy structure of the polymer [11, 12]:

$$\Delta H^m = \Delta H_{int} + \Delta H_g. \quad (2)$$

The contribution from the component interaction is calculated in accordance with the Flory–Huggins theory as follows:

$$\Delta H_{int} = \chi RT \varphi_1 \varphi_2, \quad (3)$$

where φ_2 is the volume fraction of the polymer in the formulation; φ_1, volume fraction of the plasticizer in the formulation; and χ, Flory–Huggins interaction parameter. The contribution associated with the glassy state of the polymer is determined in accordance with the semiempirical model of polymer solution suggested in [12] as

$$\Delta H_g = \varphi_v^0 \varphi_2 \varepsilon_{22} (1 - \varphi_2^{[(1/\varphi_v^0) - 2)]}), \quad (4)$$

where φ_v^0 is the fraction of metastable vacancies in the initial polymer sample and ε_{22} is the cohesion energy density of the polymer chain units.

By interpolation of the experimental data on the enthalpies of solution, using Eqs. (1)–(4), we calculated the enthalpies of the interaction and glassy structure for the PVC–DOP and PVC–EDOS systems for the entire concentration ranges. For EDOS, the mean molecular weight and mean van der Waals volume of the plasticizer were calculated taking into account the structures and amounts of its components.

To calculate the enthalpies of mixing of components of the DOP–EDOS plasticizing mixture, we also used the thermochemical cycle and Eq. (1). In this case, ω_1 and ω_2 are the weight fractions of the plasticizer in the mixture; ΔH_1 and ΔH_2, enthalpies of solution of the individual plasticizers in THF; and ΔH_3, enthalpy of solution of the mixed plasticizer of a definite composition in excess solvent.

The weight loss of the unfilled and chalk-filled PVC films containing the individual plasticizers at room temperature (T_r) and 90°C under atmospheric pressure is shown in Fig. 1 (curves *1–3*). It is seen that the weight loss of the EDOS-containing films is larger than that of the DOP- and DBP-containing films, except the weight loss of the filled films at 90°C; in the latter case, with DBP the weight loss is larger than with EDOS. In the substances released from the samples, we detected by IR spectroscopy only the plasticizers present in the films. Since the samples contain stabilizers, release of HCl at 90°C (and, the more so, at T_r) does not occur, and the weight loss is exclusively due to the plasticizer migration and not to the PVC degradation. The weight loss data were

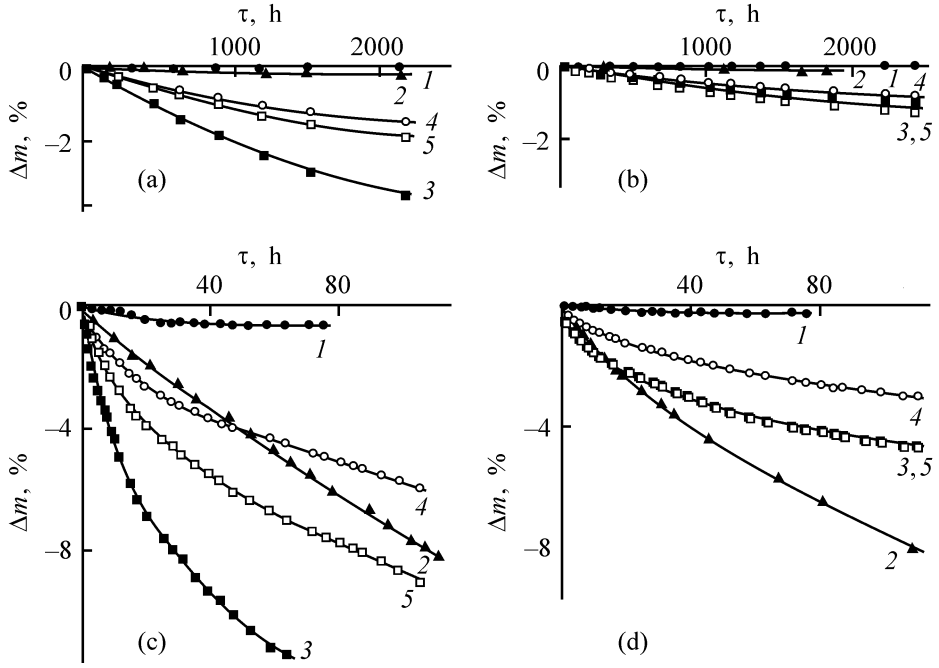

Fig. 1. Weight loss Δm vs. time τ. Temperature: (a, b) T_r and (c, d) 90°C. PVC films: (a, c) unfilled and (b, d) filled with chalk. plotted in the coordinates $M_\tau/M_\infty = f(\tau^{1/2})$ [9], where M_τ is the amount of the plasticizer released by the moment τ, assumed to be equal to the sample weight loss, and M_∞ is the initial content of the plasticizer in the sample. The initial linear portions in the plots obtained suggest that in these periods the release of the plasticizers to the atmosphere is controlled by their diffusion in the sample. This fact allows calculation of the diffusion coefficients (Table 1), which are apparent quantities (especially for EDOS) characterizing the migration rate.

The weight loss of some samples containing DOP and DBP (Table 1) during the experiment is small, which does not allow any reliable conclusions about the shape of the $M_\tau/M_\infty = f(\tau^{1/2})$ dependences. However, according to [6, 8], at room temperature the release of DOP and DBP from PVC formulations is limited by the volatility of the plasticizers, whereas the release of DOP at 90°C is limited by the diffusion of the plasticizer in the polymer matrix.

For the EDOS-containing samples at room temperature, during the first 15 days after the sample preparation, the $M_\tau/M_\infty = f(\tau^{1/2})$ dependence is nonlinear, suggesting that the release of the plasticizer is controlled by its volatility. In the subsequent period, the dependence becomes linear, which indicates that the plasticizer diffusion becomes the limiting step. The D values calculated from this dependence are listed in Table 1. At 90°C and atmospheric pressure, the release of EDOS, like that of DOP, is controlled by the plasticizer diffusion (in both unfilled and filled PVC films), even in the initial steps of the desorption. The results obtained with DOP are consistent with

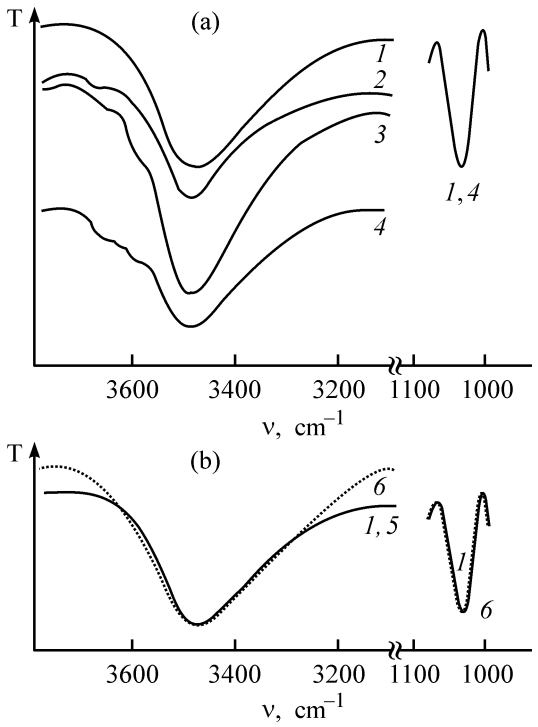

Fig. 2. IR spectra of (a, b) (*1*) EDOS, (a) (*2–4*) PVC–EDOS films, and (b) (*5*, *6*) chalk–EDOS mixtures in the range of the EDOS absorption bands ν_{OH} and ~1030 cm^{-1}. (T) Transmission and (ν) wavenumber. Weight ratio of components in the films and mixtures: (*1*) 0 : 100, (*2*) 100 : 100, (*3*) 100 : 60, (*4*) 100 : 25, (*5*) 10 : 100, and (*6*) 40 : 100.

the data of [6, 9]. For unfilled films containing DBP, the dependence was nonlinear throughout the experiment, i.e., the DBP release is controlled by its volatility. However, in the filled films with DBP plasticizer, its diffusion in the film becomes the limiting step. The results obtained with DBP are consistent with the data of [8, 10]. In particular, Dedov and Nazarov [8] indicate that the limiting step of the DBP release from PVC films depends on the initial content of DBP in the sample. The diffusion control in the release of DBP and EDOS from the filled compounds under the examined conditions also follows from a comparison of the weight loss curves for the filled samples containing DBP and EDOS ($\Delta m_{DBP} > \Delta m_{EDOS}$, Fig. 1d), volatility of these plasticizers ($v_{DBP} < v_{EDOS}$, Table 1), and their diffusion coefficients ($D_{DPB} > D_{EDOS}$, Table 1).

The migration of the plasticizers from the samples was also studied at 90°C under the conditions of forced removal of the plasticizers from the surface. To this end, we performed experiments in a dynamic vacuum (TVC). The IR spectra of the released products confirm that the released substances are the plasticizers initially present in PVC films. The kinetic data on the release of the plasticizers were plotted in the coordinates $A_\tau/A_\infty = f(\tau^{1/2})$ [10], where A_τ is the optical density of the chosen absorption band in the IR spectra of the released substances by the instant of time τ (~1720 cm^{-1} for DOP and DBP; ~1030 cm^{-1} for EDOS), and A_∞ is the optical density of this absorption band corresponding to the initial plasticizer content. The band at ~1720 cm^{-1} is the stretching vibration band of the carbonyl groups in DOP and DBP [13]. The band at ~1030 cm^{-1} for EDOS is common for all the EDOS components. It can be assigned to bending vibrations ($\delta_{C–OH}$) of the OH groups of primary alcohols and to stretching vibrations ($\nu_{C–O}$) of the C–O groups of primary alcohols and ethers [13, 14].

After the establishment of the temperature in the TVC, the initial portions of the desorption curves for all the samples are linear, suggesting that the release of the plasticizers is controlled by their diffusion in the samples. The *D* values calculated from the linear portions of the dependences are listed in Table 1. It is seen that in the unfilled and filled films *D* increases in the order DOP < EDOS < DBP. Introduction of chalk as a filler leads to an increase in *D*, which is consistent with the data of [10] for the phthalate plasticizers (DOP, DBP). The difference in the diffusion coefficients of the plasticizers may be caused, along with the steric factors, also by the difference in their interaction with the polymer macromolecules and filler particles [9, 10, 15, 16]. We showed previously by IR spectroscopy [9, 10] that DOP and DBP interact with the polymer, forming H bonds with the CHCl groups of PVC via the C=O groups [17]. In addition, a donor–acceptor interaction may arise between the π electrons of the benzene ring of the plasticizers and the vacant 3*d* orbitals of the Cl atoms of PVC macromolecules [18]. Safronov and Somova [19] indicate that the contribution of dispersion interactions in the systems PVC–phthalate plasticizer should also be taken into account. The total enthalpy of interaction of PVC with DOP is higher than with DBP [19], which is consistent with the lower diffusion coefficient of DOP, compared to DBP, as we determined in this study.

Figure 2a shows the IR spectra of the EDOS plasticizer and PVC–EDOS films in the range of OH stretching vibrations (ν_{OH}) of the hydroxyl-containing EDOS component [5, 13] and the ~1030 cm^{-1} band of EDOS at varied concentration of the polymer in the film. The position of the ν_{OH} maximum in the spectrum of pure EDOS (~3480 cm^{-1}) and the half-width of this band ($\Delta\nu_{1/2}$ ~290 cm^{-1}) (Fig. 2a, curve *1*) are

indicative of the association of EDOS molecules through OH···C–O and OH···OH hydrogen bonds [20, 21]. In going to the plasticized PVC film (curves *2–4*), the band intensities are redistributed in favor of the higher-frequency components, suggesting the decomposition of EDOS associates. However, the H bonding between the EDOS C–O groups and CHCl groups of PVC (of the type C–O···CHCl) is quite possible, taking into account high electron-donor power of dioxane (DN_{SbCl_5} = 28.2 [22]). These two processes exert opposite (and hence mutually compensating) effects: the decomposition of the associates should increase ν_{C-O} and decrease δ_{C-OH}, whereas the H bonding should decrease ν_{C-O} and increase δ_{C-OH} [20]; as a result, the EDOS band at ~1030 cm^{-1} undergoes no appreciable changes.

The interaction of PVC with EDOS and DOP also follows from the thermodynamic data. The experimentally measured enthalpies of solution of PVC, plasticizers, and plasticized PVC formulations in THF are given in Table 2.

From the experimental data, we calculated by Eq. (1) the enthalpies of mixing of PVC with the plasticizers. These quantities are negative throughout the composition range. The calculated contributions of intermolecular interactions to the enthalpies of mixing of PVC with the EDOS and DOP in the whole composition range are plotted in Fig. 3. Figure 3 shows that EDOS interacts with PVC more weakly than does DOP, which correlates with its higher diffusion coefficient compared to DOP (Table 1).

In the filled systems, the filler can interact with the plasticizer. It is known that chalk does not interact with PVC and does not noticeably interact with phthalate plasticizers [10, 18, 23]. Data on the interaction of chalk with EDOS are lacking. We determined the heat of wetting of chalk with EDOS: –2.3 J g^{-1}. This value differs from the heats of wetting of chalk with DOP and DBP, which are close to zero [18]. The wetting of chalk with EDOS is consistent with the fact that both EDOS (its components, in contrast to DOP and DBP, appreciably dissolve in water [4]) and carbonates (carbonates are wetted with water better than with nonpolar hydrocarbons [24]) are hydrophilic. Figure 2b shows the IR spectra of EDOS with additions of chalk. Introduction of chalk (40 wt % relative to EDOS) leads to a slight broadening of the plasticizer bands ν_{OH} and ~1300 cm^{-1}, suggesting certain interaction between the components. Presumably, the interaction of the filler with EDOS may lead to a nonmonotonic dependence of *D* on the filler content in PVC films, in contrast to the phthalate plasticizers [10].

Table 2. Enthalpies of solution in THF of PVC–plasticizer formulations and of PVC and plasticizers taken separately

ω_{PVC}	ΔH_s, J g^{-1}	
	PVC–EDOS	PVC–DOP
1.00	–41.3	–41.3

0.41	–8.0	–
0.23	–4.9	–
0.25	–	–4.5
0.17	–	–4.0
0.13	–	–3.0
0.08	–	–2.8
0	–3.0	–2.2

We also studied the PVC films containing mixed plasticizers (DOP + EDOS), because it is known [1] that partial replacement of DOP with EDOS improves the service characteristics of PVC finishing materials (the use of DBP–EDOS mixtures is not appropriate because of possible ester interchange of dibutyl phthalate with dioxane alcohols in the course of storage of PVC materials [1]). Figure 1 (curves *4*, *5*) shows data on the mass transfer in unfilled (Figs. 1a, 1c) and chalk-filled (Figs. 1b, 1d) PVC films plasticized with DOP–EDOS mixtures, measured at room temperature or 90°C and atmospheric pressure. The formulations containing the mixed plasticizers occupy an intermediate position between the formulations with the individual plasticizers. The IR spectra of the released substances are attributable to the plasticizers initially present in the formulations. Data on the release of the plasticizers under the conditions of forced removal of the plasticizers from the film surface (90°C, TVC) allowed us to calculate *D* of the plasticizer mixtures

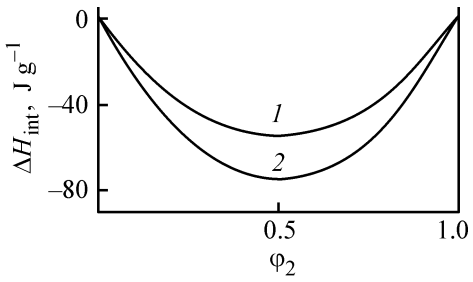

Fig. 3. Concentration dependence of the contribution from the component interaction ΔH_{int} to the enthalpy of mixing of PVC with (*1*) EDOS and (*2*) DOP. (φ_2) Volume fraction of the polymer at 25°C.

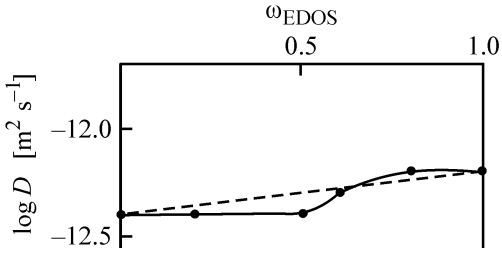

Fig. 4. Diffusion coefficient D of the DOP–EDOS mixed plasticizer in unfilled PVC films at 90°C in a vacuum vs. the EDOS weight fraction in the mixed platicizer. PVC : plasticizer weight ratio 100 : 50.

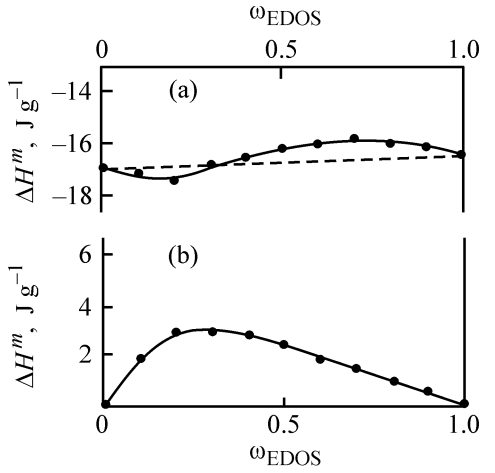

Fig. 5. Enthalpy of mixing ΔH^m (a) of PVC with DOP–EDOS mixed plasticizer and (b) of DOP with EDOS vs. of the EDOS weight fraction ω_{EDOS} in the DOP–EDOS mixture. (a) PVC : plasticizer weight ratio 100 : 50.

in the initial steps of the desorption. The values of D for the DOP–EDOS mixtures were evaluated using the absorption band at ~1030 cm^{-1}, which is common for EDOS and DOP (a weak band at ~1030 cm^{-1} is present in the spectrum of DOP [25]), and the DOP band at ~1720 cm^{-1}. Previous experiments showed that the calculations of D from data of the same experiment but using different absorption bands gave similar results.

Figure 4 shows the dependence of D on the composition of the DOP–EDOS plasticizing mixture. It is seen that D grows with an increase in the EDOS content in the plasticizing mixture and that the dependence of D on the mixture composition shows no strong deviations from the additivity. In Fig. 5a the enthalpy of mixing of PVC with the DOP–EDOS mixed plasticizer (50 wt % relative to PVC) is plotted vs. the ratio of the plasticizer components. This dependence well correlates with the dependence of the diffusion coefficient on the composition of the mixed plasticizer. At a low EDOS content, ΔH^m is more negative and D is lower than the additive value, whereas at a high EDOS content ΔH^m becomes less negative and D exceeds the additive value. On the whole, however, the deviations from the additivity are small; this fact can be accounted for by the absence of specific interactions between the components of the mixed plasticizer [26].

Figure 5b shows the dependence of the enthalpy of mixing of DOP with EDOS on the component ratio. In the entire composition range, the mixing is endothermic, i.e., the energy of the interaction of the different molecules is lower than that of the interaction of the like molecules. This fact is also confirmed by IR spectroscopy. On adding DOP to EDOS, the ν_{OH} maximum shifts toward higher frequencies, i.e., the decomposition of EDOS associates prevails:

ω_{EDOS}	1.0	0.8	0.6	0.5	0.4	0.2	0
ω_{OH}, cm^{-1}	3482	3490	3496	3500	3507	3529	–

Monitoring at ~1030 (EDOS) and 1720 cm^{-1} (DOP) is complicated by overlap of the absorption bands of the plasticizers.

The absence of preferential interaction of EDOS with DOP in the plasticizer mixture is apparently responsible for the fact that the diffusion coefficient of the mixed plasticizer and the enthalpy of mixing of PVC with the mixed plasticizer are approximately linear functions of the plasticizing mixture composition.

CONCLUSIONS

(1) The release of EDOS from plasticized polyvinyl chloride films of the examined composition into air at room temperature and at 90°C is mainly controlled by the EDOS diffusion in the polymer matrix, rather than by its volatility.

(2) Replacement of di(2-ethylhexyl) *o*-phthalate and di-*n*-butyl phthalate with EDOS in unfilled films is not appropriate because of the large loss of the plasticizer in air, especially on heating.

(3) Filling of polyvinyl chloride films with chalk can reduce the weight loss. For the filled films, complete replacement of di-*n*-butyl phthalate or partial replacement of di(2-ethylhexyl) phthalate with EDOS is appropriate, provided that the other service characteristics will be preserved.

(4) The characteristics of migration of the plasticizers from polyvinyl chloride formulations correlate with the thermodynamics of interaction of the components.

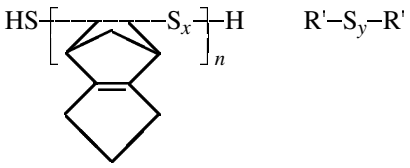
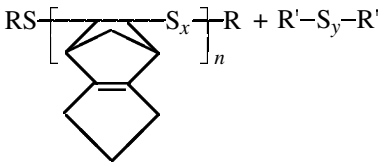
Abstract—The performance of new polyfunctional additives containing bis(2,6-di-*tert*-butyl-4-hydroxyphenyl) polysulfide and dicyclopentadiene–sulfur copolymer was studied with respect to SKI-3 and vulcanizates thereof. These additives act not only as stabilizers but also as vulcanizing agents improving a number of physicomechanical characteristics of the vulcanizates.



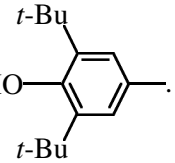
DOI: 10.1134/S1070427206060279

Polyisoprene rubber SKI-3 is widely used in the polymer industry. This is a highly unsaturated and, thus, easily oxidizable compound [1], which makes urgent its stabilization during storage, processing, and exploitation.



Today, aging of SKI-3 is prevented by antioxidants (AOs) from among aromatic amines and substituted phenols [2]. Despite a wide diversity of the available AOs, active studies aimed at finding new and more rationally using the existing AOs are still under way [3]. Of much significance in the future will be polyfunctional AOs and mixed compositions of stabilizers exhibiting a synergistic antioxidative effect [4–6].

Of no less importance for the polymer industry is development of an effective system for vulcanization of rubbers based on SKI-3 [7]. Elemental sulfur is typically used as vulcanizing agent [1, 8]. Polysulfide oligomers, Thiokols, are used for these purposes less frequently [9], though sulfuring-up on the vulcanized rubber surface occurs with them to a much lesser extent than with sulfur.



Previously, we have developed a method for synthesis of dicyclopentadiene–sulfur cooligomers (DCPD-S_x) with controlled sulfidity and bis(2,6-di-*tert*-butyl-4-hydroxyphenyl) polysulfide (SHP-S_y) [10, 11], as well as a one-step method for preparation of complex additives with various sulfidities (DCPD-S_x : SHP-S_y) [12].

DCPD-S_x SPH-S_y

DCPD-S_x : SPH-S_y

where R = H, R'; R' = 

.

The structure of the ingredients of the (DCPD-S_x : SHP-S_y) complex additives make them suitable as AOs for rubbers owing to the presence of a compound with sterically hindered phenol moiety and a vulcanizing agent. The function of the latter can be performed by a polysulfide oligomeric component.

This study examines the performance of the (DCPD-S_x : SHP-S_y) additives synthesized as stabilizers for SKI-3 rubber, as well as their influence on the rheological and physicomechanical characteristics of SKI-3-based vulcanized rubbers.

Table 1. Designations and main physicochemical characteristics of the additives

Designation	Average number of sulfur atoms in the polysulfide fragment		Total sulfur content, wt %	Content of –SH groups, wt %	Upper MWD limit
	x	y			
DCPD-S_4 : SHP-S_y	4	2–4	46.0	0.08	6000
DCPD-S_2 : SHP-S_y	2	2–4	33.20	0.12	10000
DCPD-S_4	4	–	49.28	0.90	6000
DCPD-S_2	2	–	32.20	0.65	10000
SHP-S_y	–	2–4	20.95	–	–

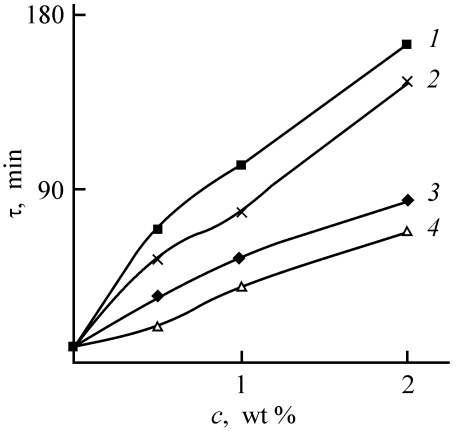
Composition of the polymer introduced	Amount of the stabilizer relative to rubber		τ, min	Composition of the polymer introduced	Amount of the stabilizer relative to rubber		τ, min
	wt %	$C\times 10^3$, mol			wt %	$C\times 10^3$, mol	
No additive	–	–	10	$DCPDS_4$	2.0	8.4	85
Diaphene PP	0.3	1	80	DCPD-S_4 : SHP-S_y	2.0	32	165
$DCPDS_2$	2.0	10	75	SHP-S_y	0.3	1	55
DCPD-S_2 : SHP-S_y	2.0	64	150				

EXPERIMENTAL



The procedure for preparation of DCPD-S_x : SHP-S_y allows the content of the SHP groups, as well as the sulfidity of the oligomer, to be widely varied. In this study, we used the $DCPDS_x$: SHP-S_y products containing 10 wt % SHP-S_y ingredient with the sulfidities x = 2 and 4.

To elucidate the role and performance of the components of the DCPD-S_x : SHP-S_y complex additive, we separately prepared (DCPD–S) cooligomers with different sulfidities and bis(2,6-di-*tert*-butyl-4-hydroxyphenyl) polysulfide (SHP-S_y) by the techniques described in [10, 11].

Table 1 lists the main physicochemical characteristics of the additives synthesized.

In the first stage of the study, the antioxidative performance of the additives synthesized was estimated from the induction period of oxidation of SKI-3 rubber at 135–140°C in an oxygen atmosphere [13]. Testing consisted in determining by the manometric method the period before the polymer begins to take up oxygen. SKI-3 was preliminarily thrice reprecipitated (with toluene as solvent and acetone as precipitating agent) to remove low-molecular-weight products [14]. Our experiments showed that, with a complex stabilizer DCPD-S_x : SHP-S_y, the induction period τ in oxidation of SKI-3 can be significantly prolonged relative to the DCPD-S_x additives without SHP-S_y. This can be evidently attributed to the synergistic antioxidative effect. Table 2 shows that the induction period in oxidation of SKI-3 in the presence of DCPD-S_x : SHP-S_y exceeds that of the rubber containing a commercial antioxidant like Diaphene PP (*N*,*N*'1-diphenyl-1,4-phenylenediamine).

When the oligomeric additives, both with and without SHP-S_y, are introduced in concentrations within 0.5–2.0 wt %, the induction periods in oxidation of SKI-3 tend to linearly increase (see figure).

Induction period τ in oxidation of SKI-3 rubber vs. the concentration c relative to rubber, of the additive introduced at p_{O_2} = 250 mm Hg, T = 140°C. (*1*) DCPD-S_4 : SHP-S_y, (*2*) DCPD-S_2 : SHP-S_y, (*3*) DCPD-S_4, and (*4*) DCPD-S_2.

10	0	7.0			

In the next stage, the additives synthesized were introduced into the rubber stocks based on SKI-3. The rubber stocks were prepared on a laboratory mixer of the Brabender plasticorder (see Table 3 for the formulation and mixing mode).

In preparation of the rubber stock, a part of the vulcanizing agent, sulfur, was replaced with DCPD-S_x : SHP-S_y with a step of 0.5 wt % (Table 4).

The influence of DCPD-S_x : SHP-S_y on the vulcanization kinetics of the rubber stocks was studied on a Monsanto Reometr-100S rheometer. From the resulting rheograms, we derived the rheological and vulcanization characteristics of the stocks: the minimal ($M_{min)}$ and maximal ($M_{max)}$ torques, the torque level in vulcanization ΔM, the torque at the optimal vulcanization point M_{90}, the time of attainment of the vulcanization optimum T_{90}, and the vulcanization rate V_C. Table 5 lists the results of analysis of the rheometric curves.

Table 5 shows that the replacement (partial or complete) of sulfur with DCPD-S_x : SHP-S_y in the rubber stock decreases the viscosity of the stock, characterized by $M_{min.}$ This suggests an increase in the plasticity of the resulting rubber stocks. This holds for the copolymer with both disulfide and tetrasulfide bridges. At the same time, replacement of sulfur with

the DCPD-S_x : SHP-S_y copolymer in the vulcanizing system leads to decrease in the maximal torque M_{max}. On the whole, the torque level in vulcanization of the polymer (ΔM) is slightly lower than that of the reference sample. Polysulfide additives DCPD-S_x : SHP-S_y do not cause scorching of the rubber stocks based on SKI-3, but with increasing content of DCPD-S_x : SHP-S_y the time of attainment of the vulcanization optimum tends to increase. Deceleration of the vulcanization of the rubber stock occurring by the radical mechanism can be attributed to the ability of the SHP-S_y component to react with radicals [15] with chain termination.

We studied the physicomechanical characteristics of the vulcanized rubbers, taking into account the time of attainment of the vulcanization optimum equal to 25 min at 150°C. Tables 6 and 7 present the results.

A study of the strength properties of the vulcanizates [16] showed that the nominal tensile strength of the samples containing 0.5–2.5 wt % DCPD-S_x : SHP-S_y increases insignificantly. Introduction of 3.0 wt % DCPD-S_x : SHP-S_y sharply raises the nominal strength. This is probably due to the synergistic effect of DCPD-S_x : SHP-S_y and elemental sulfur introduced simultaneously. With a further increase in the amount of DCPD-S_x : SHP-S_y introduced, the nominal strength of the vulcanizates decreases; this also holds for the true strength. The increase in the relative elongation of the vulcanized rubber at break and in the relative elongation set at break is, evidently, due to the change in the structure of the vulcanization network.

CONCLUSIONS

(1) Introduction of DCPD-S_x : SHP-S_y increases the oxidation period of SKI-3 rubber. The induction period linearly grows with the amount of the additive introduced in the range 0.5–2.0 wt %.

(2) DCPD-S_x : SHP-S_y blends decrease the viscosity and rigidity of the rubber stocks, i.e., they exhibit plasticizing properties.

(3) The time of attainment of the vulcanization optimum increases relative to the reference sample.

(4) When introduced in amounts of up to 3.0 wt %, DCPD-S_x : SHP-S_y enhances the physicomechanical parameters. Further increase in the content of the additive is unreasonable because of the deterioration of the physicomechanical properties.

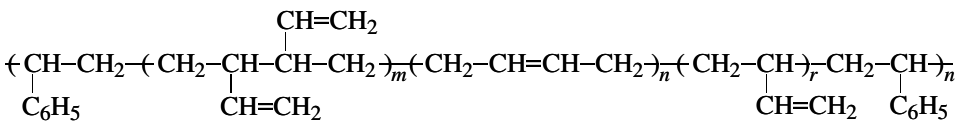
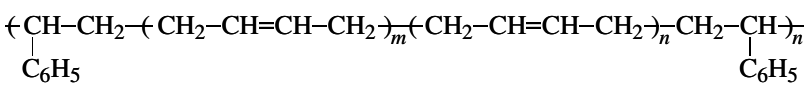
Abstract—Mechanical and structural-rheological properties of oxidized bitumen modified with styrene–butadiene–styrene copolymers side vinyl groups in their butadiene fragment were studied. A comparative analysis of the modified and unmodified bitumen composites was performed.



DOI: 10.1134/S1070427206060280

The problem of modification of oxidized bitumen with polymers of varied chemical nature, to improve its structural and rheological characteristics, was overviewed in our previous publications [1–3]. Among the existing variety of polymers recommended for modification of bitumen, only two kinds have found wide use, namely, thermoplastic elastomers based on styrene–butadiene–styrene (SBS) block copolymers and thermoplastics based on ethylene–vinyl acetate copolymers (EVA) [4]. However, research is being conducted primarily on modification of residual bitumen, whose group composition differs considerably from that of the oxidized bitumen used in both Belarus and Russia. Characterization of bitumens is performed by the methods included into the quality standards for bitumens. Numerous studies and wide experience of practical applications of bitumens characterized using standard parameters often reveal some inconsistency between these values and the behavior of bitumens in road pavements. Standard parameters do not characterize the structure of bitumens, can be considered only as some arbitrary values for comparison of bitumens under given testing conditions [5]. Structural changes are adequately characterized by the rheological parameters (softening and melting points), which are governed by the structure of the bitumen composite [6, 7].

A novel class of block copolymers, SBS, has been developed, which differs in the structure of the polymer chain from the previously existed ones. In this study, we examined the effect of SBS copolymers with modified butadiene block on the structural and rheological properties of oxidized bitumens.



EXPERIMENTAL

In the experiments, we used BND 90/130 paving bitumen from Novopolotsk Oil Refinery with the following characteristics: ring and ball softening temperature 43°C, penetration at 25°C (0.1 mm) 98; and a linear block copolymer with modified central block [Kraton D-1192 (**1**)]. Unlike the SBS copolymer described previously [Kraton D-1101 (**2**)], the polymer chain of **1** is characterized by the presence of side vinyl groups in the polybutadiene fragment and also by the lower number of double C=C bonds in the macromolecular chain.

Kraton D-1192

1

Kraton D-1101

2

Two brands of Kraton D-1192 copolymer were used: Kraton D-1192 ES represents porous granules dustcoated with amorphous SiO_2, and Kraton D-1192 EM, a powder treated with amorphous SiO_2.

Bitumen formulations with 3% polymer content were prepared by mixing components in a cylindrical reactor equipped with an anchor stirrer (250 rpm) and a heating jacket providing a homogeneous heating throughout the reactor volume. After attaining temperature of 150°C, Kraton was added in small portions with stirring. Kraton D-1192 EM powder is readily (in 1.5–2 h) dissolved at 160°C, while dissolution of the granulated product takes 5–6 h at about 180°C. The completeness of dissolution was controlled by the homogeneity of the bitumen-polymer film using a Rheotest-2 rotary viscometer.

We determined the mechanical characteristics of the bitumen–polymer formulations (BPFs), such as the softening and Fraas (brittle) points, needle penetration depth (penetration), impact resistance, adhesion to mineral matrix, elasticity, and extensibility using standardized procedures (STB 1220–2000). The aging of samples was performed by heating at 163°C for 300 min in accordance to the GOST (State Standard) 18 180–72 [ST SEV (COMECON Standard) 4543–84].

The viscosity was measured on a Rheotest-2 rotary viscometer using a cone–plate working unit over the shear rate range 11.1–4860 s^{-1}. The measurements were carried out at 70 and 130°C, to model conditions of preparation and laying of the road concrete mix.

Table 1 summarized data on mechanical characteristics for the initial bitumen and BPFs before and after aging.

The results show that SBS copolymers taken at a concentration of 3%, regardless of the structure of their polymer chain, form a 3*D* network in the bitumen dispersion medium. When sorbing the oil components of bitumen, the polymer network, formed by the styrene domains, increases in volume, but preserves its continuity, thus imparting elasticity to bitumen and decreasing the brittleness at low temperatures. It should be pointed out that, despite different structures of the polymer chain, the elasticities and extensibility of the investigated copolymers are practically the same.

High content of the vinyl fragments (40 wt %) decreases the total chain length, thus decreasing the viscosity of BPFs, as demonstrated by data on the needle penetration depth. It should be pointed out that BPFs obtained with Kraton D-1192 are aging-resistant. Their

mechanical characteristics only slightly changed after heat treatment, remaining meeting the requirements of STB 1220–2000. Such a resistance to thermooxidative degradation can be attributed to the fact that oxidation of the vinyl bond in the side fragment only slightly changes the molecular structure, since the backbone of the molecule remains intact, keeping on playing the role of a constituent of the 3*D* network. If a double bond is in the backbone, as in the case of BPFs based on Kraton D-1101, the oxidation results in its breakdown, thus distorting the 3*D* network and deteriorating mechanical properties.

It follows from Table 1 that, the standard tests of the investigated bitumen–polymer formulations, obtained by modification of bitumen with SBS copolymers with different structure of the polymer chain, revealed no significant differences in their mechanical characteristics.

Tables 2 and 3 and Fig. 1a represent data on the structural and rheological characteristics of BPFs with Kraton D-1192 and Kraton D-1101, measured at 70 and 130°C.

The results show that the structural viscosity of the samples with Kraton D-1101 is twice that of BPFs

Flow curves for SBS-modified bitumens at (a) 70 and (b) 130°C. (τ) Shear stress and (D_r) shear rate. (a): (*1*) Bitumen, (*2*) bitumen + Kraton D-1192 EM, (*3*) bitumen + Kraton D-1192 ES, and (*4*) bitumen + Kraton D-1101 (3%); and (b): (*1*) bitumen + Kraton D-1192 ES, (*2*) bitumen + Kraton D-1192 EM, and (*3*) bitumen + Kraton D-1101 (3%).

with Kraton D-1192. For the formulations with Kraton D-1101, the conditional static elastic limit P_{k1}, characterizing the resistance to deformation, is higher by a factor of 4 than that for BPFs with Kraton D-1192. The rheological characteristics of the samples with Kraton D-1192, unlike BPFs with Kraton D-1101, only slightly differ from those of the initial bitumen. Modification with Kraton D-1192 copolymer does not considerably change the viscosity, which is an important factor in preparation of a road concrete mix and emulsified polymer–bitumen formulations. Estimation of P_{k2} characterizing the elastoplastic properties of bituminous materials allowed characterization of the efficiency of the modifying action of the copolymers studied. The polymer-bitumen composites prepared with Kraton D-1101 are characterized by higher P_{k2} as compared to those with Kraton D-1182 (by a factor of 8 and 20 for Kraton D-1192 EM and Kraton D-1192 ES, respectively), although the standard tests revealed practically no differences in their elasticity and extensibility. The increase in the elastoplastic characteristics in the formulations with Kraton D-1101 can be attributed to the fact that molecules of this polymer contain a polybutadiene chain formed through anionic polymerization of *cis*-1,3-butadiene and contain about 90% of double bonds. These bonds impart elastoplastic properties, typical of polybutadiene (glass-transition temperature –95°C), to the polymer. Because of lower content of double bonds in the polymer chain of Kraton D-1192, the elastoplastic characteristics of BPFs with this copolymer are worse. The estimated P_m/P_{k1}, characterizing the structural strength, do not virtually change for Kraton D-1192, suggesting that the size of structural elements in the dispersion medium remains unchanged in the bitumens modified with Kraton D-1192, while in the case of Kraton D-1101, this parameter increases by a factor of 1.7. Therefore, the increase in the viscosity of BPFs modified with Kraton D-1101 can be attributed to both formation of a strong 3*D* structure and increase in the size of the structural units.

Tables 2 and 3 and Fig. 1b also include data obtained at 130°C. At this temperature, bitumen and the modified samples have practically the same static elastic limit. Differences from the initial bitumen are found with increasing shear rate, which is reflected in increase in P_m and P_{k2}. It should be pointed out that the structural viscosity in BPFs based on the polymers with the modified polybutadiene block falls in the same range as that in the initial bitumen. This opens the door for application of such BPFs to preparation of bitumen emulsions using the modes accepted for the unmodified bitumens.

CONCLUSIONS

(1) Introduction of the modified polybutadiene block into the polymer molecule changes both mechanical and structural and rheological characteristics of bitumen, like that in the case of the use of the unmodified styrene–butadiene–styrene copolymer. The polymer formulation based on Kraton D-1192 demonstrate high aging resistance. However, standard mechanical tests of the investigated bitumen–polymer formulations revealed no significant differences.

(2) In modification of bitumen with styrene–butadiene–styrene copolymer containing side vinyl groups, the size of structural units of the dispersion medium remains unchanged, and no considerable increase in the viscosity is observed, compared to the unmodified polymer, thus improving the performance characteristics of the bitumen–polymer formulation based on Kraton D-1192.

(3) Characterization of bitumen–polymer formulations using science-based rheological parameters opens the door for their application in various road construction technologies.

BRIEF COMMUNICATIONS

Kinetics of the Reaction between the Active Paste from the Positive Electrode of a Dead Nickel–Iron Battery and Sulfuric Acid

A. I. Demidov and M. S. Kokhatskaya

St. Petersburg State Polytechnic University, St. Petersburg, Russia

Received May 24, 2006

Abstract—The kinetics of dissolution of a powdered active paste from the positive electrode of a worked-out nickel–iron battery in 0.1 N sulfuric acid at 25, 50, and 75°C was studied by measuring the electrolyte resistance.

DOI: 10.1134/S1070427206060292

In continuation of previous publications [1, 2], we present the results obtained in studying the reaction between a powdered active paste from the positive electrode of a worked-out nickel–iron (NI) battery and sulfuric acid in the temperature range 25–75°C. The active paste was taken from worked-out NI battery of the TNZh-250-U2 type, the particle size of the powder did not exceed 200 μm.

The overall reaction that occurs in charging and discharge of a NI battery can be represented by the equation:

$$2NiOOH + Fe + 2H_2O = 2Ni(OH)_2 + Fe(OH)_2, \quad (1)$$

It follows from this equation that the worked-out active paste from the positive electrode should contain $Ni(OH)_2$ and NiOOH. An X-ray diffraction analysis revealed graphite and dispersed nickel hydroxide $Ni(OH)_2$ in the active paste. An X-ray diffraction pattern of the powdered active paste from a worked-out NI battery is shown in Fig. 1.

In hydrometallurgical processing of worked-out electrodes, it is necessary to know the content of sodium or potassium carbonate and hydrocarbonate remaining in pores of the active paste, because their amount affects the expenditure of sulfuric acid for processing of worked-out positive electrodes contain-

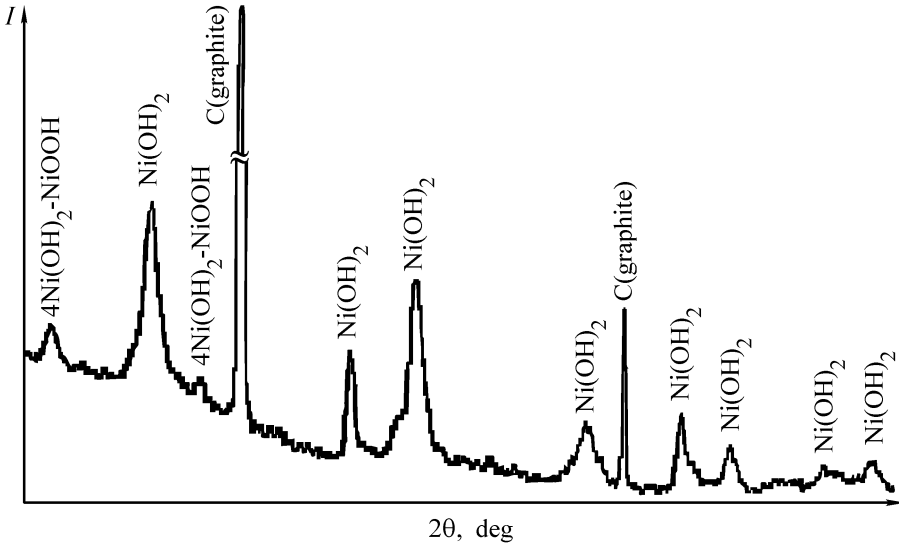

Fig. 1. X-ray diffraction pattern of the powdered active paste from the positive electrode of a worked-out TNZh-250-U2 nickel–iron battery. (*I*) Intensity and (2θ) Bragg angle.

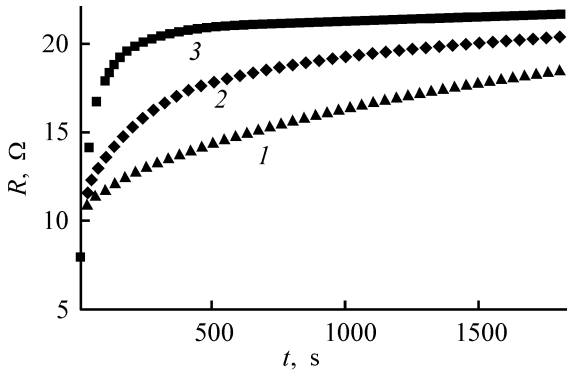

Fig. 2. Variation of the resistance R with time t in dissolution of the powdered active paste from the positive electrode of a worked-out NI battery in 0.1 N sulfuric acid at different temperatures. Temperature (°C): (*1*) 25, (*2*) 50, and (*3*) 75; the same for Fig. 3.

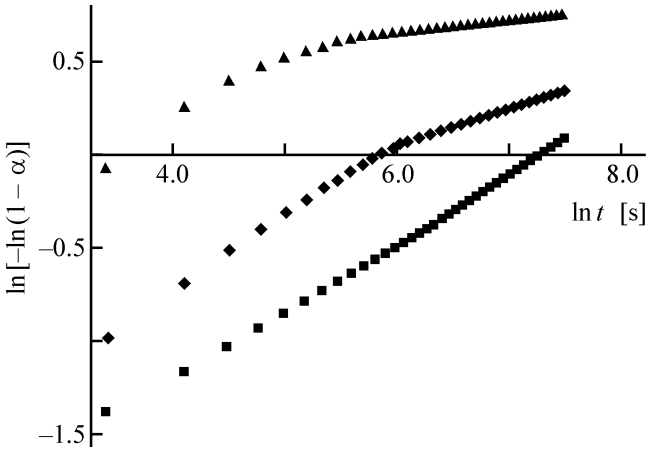

Fig. 3. Dependence of $\ln[-\ln(1-\alpha)]$ on $\ln t$ in dissolution of the powdered active paste from a worked-out NI battery in 0.1 N sulfuric acid at different temperatures.

ing nickel hydroxide. A conductometric titration showed that, after its prolonged storage in air, the worked-out active paste contains sodium carbonate and hydrocarbonate whose content varies with time. Sodium carbonate is converted into hydrocarbonate, with the result that the content of carbonates in the active paste decreases, and that of hydrocarbonates increases [2].

The kinetics of the reaction of the active paste with sulfuric acid was studied in a thermostated conductometric cell, with vigorous agitation of a solution with magnetic stirrer. Changes in the resistance were measured with an E7-15 immitance meter, with the use of graphite electrodes, during 30 min at intervals of 30 s. The variation of the resistance with time in the course of the dissolution of the powdered active paste from the positive electrode in a 0.1 N sulfuric acid at 25, 50, and 75°C is shown in Fig. 2.

Two portions can be distinguished in the curve describing the variation of the resistance in dissolution of the active paste from the positive electrode in sulfuric acid. In the first of these, sodium carbonate and hydrocarbonate remaining in the pores of the active paste after its prolonged storage in air are neutralized, and in the second, nickel hydroxide contained in the worked-out active paste reacts with sulfuric acid. The reaction of nickel(II) hydroxide with sulfuric acid results in that the type of charge carriers changes. The rather mobile hydrogen ions are replaced with less mobile nickel ions. As a result, the electrical conductivity of the solution changes in the course of the process [1].

The data obtained were processed using the Erofeev–Kholmogorov equation

$$\alpha = 1 - \exp(-kt^n), \qquad (2)$$

where α is the fraction of the reacted substance; k, rate constant; t, time; and n, exponent that accounts for a change in the surface area in the dissolution of the powdered active paste.

The applicability of Eq. (2) can be verified by the existence of a linear dependence $\ln[-\ln(1-\alpha)] = f(\ln t)$ obtained by twice taking the logarithm of the initial equation. The fact that the curves plotted (Fig. 3) using experimental data are linear shows that the Erofeev–Kholmogorov equation can be used to describe the dissolution kinetics of the powdered active paste from the positive electrode of a worked-out NI battery in sulfuric acid.

Further, the straight lines obtained were processed by the least-squares method to give the value of $\ln k$, from which the rate constant was found by taking the antilogarithm and the activation energy of the process was calculated. The calculation was done using the formula:

$$\Delta E = \frac{RT_1T_2 \ln \dfrac{k_2}{k_1}}{T_2 - T_1}, \qquad (3)$$

where R is the universal gas constant (8.314 J mol^{-1} K^{-1}) and k_1, k_2 are the rate constants at temperatures T_1 = 298.15 and T_2 = 348.15 K, respectively.

It was found that the neutralization of sodium carbonate and hydrocarbonate occurs in the temperature range 25–75°C in the mixed region (ΔE = 23.9 kJ mol^{-1}), and the dissolution of nickel hydrox-

ide in sulfuric acid, in the kinetic region (ΔE = 52.7 kJ mol^{-1}).

To determine the degree of nickel recovery from the active paste, a sample was taken after completion of each test, and the content of nickel that passed into solution was determined by titration with Trilon B, as described in [3]. The degree of nickel recovery in dissolution of the powdered active paste from the positive electrode in 0.1 N sulfuric acid at 25, 50, and 75°C was 66, 75 and 88%, respectively.

CONCLUSION

The dissolution of a powdered worked-out active paste from the positive electrode in sulfuric acid occurs as follows. First, sodium carbonate and hydrocarbonate, and then, nickel hydroxide react with sulfuric acid. The neutralization of sodium carbonate and hydrocarbonate in the range 25–75°C occurs in the mixed region, and the dissolution of nickel hydroxide, in the kinetic region.

A Study of the Diffusion Permeability Coefficient of a Tubular Membrane Unit in an Aqueous Solution of Sodium Sulfate

S. I. Lazarev, V. L. Golovashin, V. V. Mamontov, and S. V. Kovalev

Tambov State Technical University, Tambov, Russia

Received December 8, 2005

Abstract—Experimental data on the diffusion permeability coefficient of sodium sulfate in a fluoroplastic membrane were obtained and analyzed.

DOI: 10.1134/S1070427206060309

Mathematical simulations of the operation of a membrane apparatus are commonly based on the self-diffusion coefficient of water and diffusion coefficient of a substance in the membrane [1]. However, it is difficult to determine these parameters experimentally, and, therefore, the coefficients of diffusion and osmotic permeability are used in calculations. With a knowledge of the diffusion permeability coefficient, we can evaluate the contribution of the diffusion flux to the mass transfer. The coefficients of diffusion and osmotic permeability can be determined experimentally. This is done in membrane cells of various types. The simplest cell is the flat-chamber cell [2]. A disadvantage of this cell is that it does not reflect the hydrodynamics of real apparatus, e.g., of tubular type. This disadvantage is not characteristic of the installation schematically shown in Fig. 1.

The installation comprises a membrane unit *1*, thermostated vessels with pumps for a solution under study (*2*) and distilled water (*3*), and a set of valves *4*. The temperature of the solutions in tubes and intertubular space is monitored with Chromel–Copel thermocouples *5* connected to potentiometers *6*, *7*.

This installation is intended for studies of the diffusion and osmotic permeability of polymeric membranes for two-, three-, and multiple-component solutions. It can also be used for experiments aimed to examine the influence exerted by various kinds of turbulators on the hydrodynamics of the annular channel and the effect of externally applied magnetic and temperature fields on a solution being separated. The membrane unit used in the process is shown in Fig. 2. It comprises the following elements: cylindrical case *1* with flanges *2*; porous tube *3* with mem-

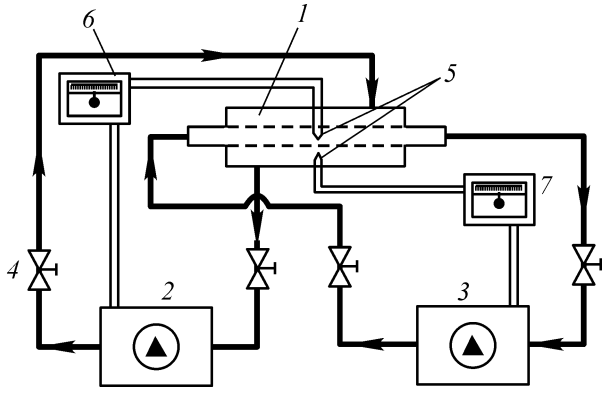

Fig. 1. Schematic of a tubular flow-through installation. For explanations see text; the same for Fig. 2.

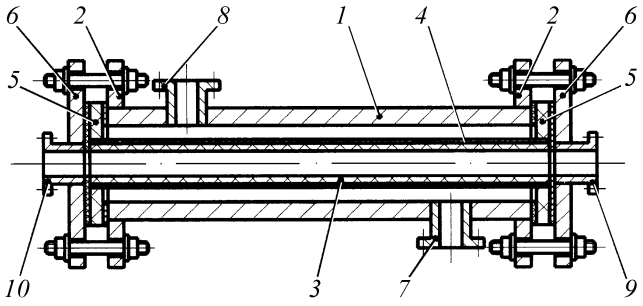

Fig. 2. Schematic of the tubular membrane unit.

brane *4* on its outer surface, supported by tube sheets *5* fixed between flanges *2* and *6*; and inlet and outlet pipes for the starting solution (*7*, *8*) and distilled water (*9*, *10*).

The diffusion permeability coefficient was calculated by the formula [2]:

$$P_d = c_2 V_2 \delta / [(c_1 - c_2) S_\tau], \quad (1)$$

where P_d is the diffusion permeability coefficient ($m^2\ s^{-1}$); c_1, concentration of the solute in the initial solution ($kg\ m^{-3}$); c_2, concentration of the solute that passed across the membrane ($kg\ m^{-3}$); V_2, volume of the solution under study (m^3); δ, membrane thickness (m); S, working area of the membrane (m^2); and τ, duration of an experiment (s).

The experiments aimed to determine the coefficients of diffusion permeability P_d were performed on a fluoroplastic membrane for an aqueous solution of Na_2SO_4 with initial concentrations of the salt in solution equal to 0.5, 1.0, 2.0, and 5.0 $kg\ m^{-3}$, at temperatures of 22, 25, 32, and 45°C. The experimental data obtained are presented in Fig. 3.

When analyzing the concentration dependence of the diffusion permeability coefficient (Fig. 3), we should keep in mind the fact that the solute can diffuse within the membrane both via the pore space filled with the solution and via amorphous regions of membrane swelling. As the concentration of the sodium sulfate solution increases, the pores in the membrane are first constricted and then clogged because of the sorption, which leads to a decrease in the diffusion permeability coefficient [3]. Apparently, the sodium sulfate solution does not plasticize the membrane, or does so only slightly, and, therefore, the diffusion permeability coefficient decreases over the entire range of concentrations of this solution.

It was found that, as the temperature of the sodium sulfate solution increases, the diffusion permeability coefficient becomes larger. This conforms to the generally accepted concept of the effect of temperature on the diffusion permeability coefficient in polymers [2, 4].

Because the dependences of the diffusion permeability on the solution concentration and temperature are gradual, it seems appropriate to consider an approximating dependence of the type

$$P_d = A \exp(Bc)(T/T_0)^m, \quad (2)$$

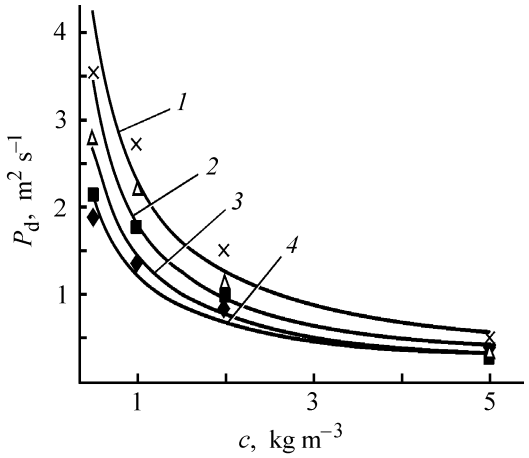

Fig. 3. Diffusion permeability coefficient P_d vs. the initial concentration c of the salt in the solution. Temperature (°C): (*1*) 22, (*2*) 25, (*3*) 32, and (*4*) 45.

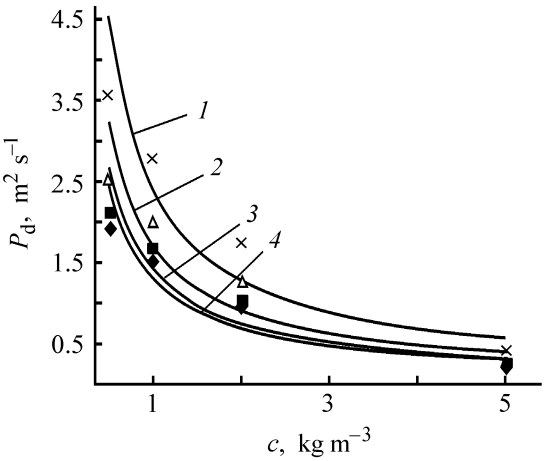

Fig. 4. Approximating dependence of the diffusion permeability coefficient P_d vs. the initial concentration c of the salt in the solution. Temperature (K): (*1*) 295, (*2*) 298, (*3*) 305, and (*4*) 318.

where P_d is the diffusion permeability coefficient ($m^2\ s^{-1}$); c, concentration of the solute in the initial solution ($kg\ m^{-3}$); T, working temperature (K); T_0, initial temperature (K); and A, B, and m, empirical coefficients obtained by calculation.

The approximating dependences are shown in Fig. 4.

A comparison of the experimental and calculated values of the diffusion permeability of a sodium sulfate solution, shown in Figs. 3 and 4, demonstrated that the calculation error is within admissible limits (±15%).

CONCLUSIONS

It was found that the diffusion permeability coefficient decreases as the initial concentration of sodium sulfate in a solution becomes higher and increases as the solution temperature is elevated.

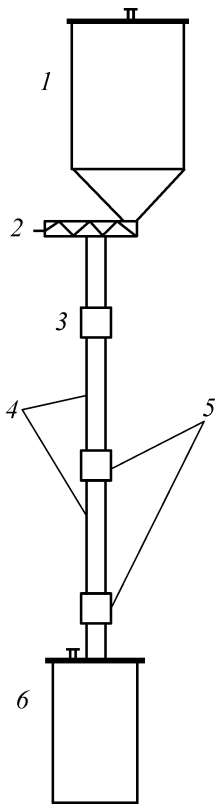
Abstract—Reaction between fluorine and graphite in a reactor with a free-falling bed of graphite was studied in relation to the temperature in the reaction zone, ratio of the feeding rates of fluorine and graphite, and dilution of fluorine with an inert gas.

DOI: 10.1134/S1070427206060310

Tetrafluoromethane, hexafluoromethane, octafluoromethane, and decafluoromethane are large-tonnage products used in etching of silicon in semiconductor industry [1].



The present paper reports on a continuation of previous studies [2, 3], whose main goal was to search for conditions of carbon fluorination in which a mixture perfluoroalkanes is produced and this mixture contains hexafluoroethane, octafluoropropane, and decafluorobutane in commercial amounts.

A study of graphite fluorination with a mixture of fluorine and nitrogen (or argon) in a fluidized bed and in an ascending gas-dust flow [2, 3] led to a conclusion that synthesis of CF_4, C_2F_6, C_3F_8, and C_4F_{10} at a temperature of about 600°C occurs by a two-stage scheme: synthesis of a solid carbon polyfluoride $(CF_x)_n$ and thermal decomposition of $(CF_x)_n$. The composition of the products formed in thermal decomposition of carbon polyfluoride depends on whether or not gaseous fluorine is present in the decomposition zone. An increase in the amount of gaseous fluorine in the decomposition zone makes smaller the fraction of fluorocarbons with a longer carbon chain. Therefore, spatial separation of the zone in which fluorine reacts with graphite to give carbon polyfluoride and the zone in which carbon fluoride undergoes thermal decomposition leads to an increase in the fraction of fluorocarbons with the number of carbon atoms greater than unity in the gaseous reaction products.

In performing the fluorination of graphite in a fluidized bed, it is impossible to spatially separate the zones of synthesis and thermal decomposition of carbon polyfluoride [2]. The reactor with an ascending gas-dust flow also has a number of disadvantages: it is necessary to use an inert gas (approximately nine volumes per volume of fluorine) to create as gas-dust flow; it is virtually impossible to vary the feed rate of graphite; there occur uncontrollable disruptions of powder ejection in the device forming the gas-dust flow.

Therefore, it was suggested to examine the possibility of using a reactor with a free-falling powder bed to obtain perfluoroalkanes by fluorination of carbon, as it has been done in synthesis of sulfur tetrafluoride from elements [4]. In this reactor, powdered graphite is delivered by a screw conveyor into the upper part of a hollow vertical tube, within which graphite particles move in the free-fall mode. Fluorine is also fed into the upper part of the tube. The reaction between fluorine and graphite (which is present in a large excess) yields carbon polyfluoride at a complete conversion of fluorine. Thermal decomposition of carbon polyfluoride is performed in the fixed powder bed in the lower part of the reactor.

The process in a reactor with a free-falling bed has a number of advantages over that in reactor with a fluidized bed or a gas-dust flow. The most important distinctive features of the reactor with a free-falling bed are as follows: reagents are delivered separately and in controlled way by a screw conveyor [5], which should provide stable formation of the gas-dust flow (falling bed) of prescribed composition; the zones in

Schematic of a free-fall reactor: (*1*) feeding bunker, (*2*) screw conveyor, (*3*) fluorine input unit, (*4*) reaction tube, (*5*) control unit, and (*6*) receiving bunker.

which fluorine is absorbed and carbon polyfluoride decomposes are separated; application of a screw may diminish (or make unnecessary) the use of an inert gas; and the technology of isolation of target products is simplified.

EXPERIMENTAL

Fluorination in the reactor with a free-falling graphite bed occurs in the vertical tube to give carbon polyfluoride, under the conditions of a free fall of a graphite particle at a temperature lower than 600°C in a large excess of graphite, with fluorine completely bound. $(CF_x)_n$ is decomposed in the receiving bunker at a temperature exceeding 600°C.

The laboratory reactor (see figure) comprises the following elements: feeding bunker *1* with graphite (diameter 120 mm, volume 2100 ml); screw conveyor *2*; fluorine input unit *3*; reaction tubes *4* (diameter 12 mm, length 300 mm); control units *5* for monitoring the temperature and presence of fluorine in the reaction zone; and receiving bunker *6* (diameter 120 mm, volume 2400 ml. The required temperature of the feeding bunker *1*, reaction tubes *4*, and receiving bunker *6* is maintained by electric heaters. To enable variation of the time of contact between fluorine and the carbon material, the reaction tube is fabricated in the form of interchangeable parts connected by the control units. Bunker *6* is equipped with a filter for gas cleaning to remove fine particles and with a sampling line serving to take samples for chromatographic analysis.

The screw conveyor *2*, fabricated on the basis of the recommendations given in [5], has the form of a rigid spiral screw with a pitch of 8 mm, placed in a cylindrical channel 12 mm in diameter and 8 mm long. The screw is rotated by an electric motor with variable rotation rate, which enables variation of the graphite feed.

The reactor is used in experiments as follows. Powdered graphite is charged into heated bunker *1* and the temperature of the carbon material is brought to 450–500°C by electric heaters. Then, screw *2* delivers heated graphite into the reaction tube, in whose upper part unit *3* for input of gaseous fluorine is situated. Under the action of the gravity force, graphite moves downwards along the reaction tube in the free-fall mode. The gaseous fluorine fed into the reactor reacts with particles of free-falling graphite to give $(CF_x)_n$. In the course of $(CF_x)_n$ synthesis, the powder warms-up to a temperature of about 550–600°C, and arrives to receiving bunker *6*, in which $(CF_x)_n$ decomposes to give perfluoroalkanes.

To choose the feed rate of graphite and fluorine, the dependence of the heat release and adiabatic warming-up of falling graphite particles on the feed rates of the components delivered into the reactor was calculated on the condition that $(CF_x)_n$ is formed, using the data of [6] (Table 1).

Table 2. Composition of the gaseous products formed in the reaction between fluorine and graphite in the reactor with a free-falling graphite bed

	vol %					
100	85	8	0.05	5	0.2	1
50	60	20	0.3	10	2	5

For perfluoroalkanes to be synthesized by the scheme comprising synthesis of $(CF_x)_n$, followed by thermal decomposition of $(CF_x)_n$, the temperature of graphite should be 450–550°C at the inlet of the fluorination reactor, and the temperature of the powder at the reactor outlet, about 550–600°C. At the feed rate of graphite fixed at about 1 g s^{-1}, the interval of possible variation of the flow rate of fluorine will be 5–10 cm^3 s^{-1}. Thus, the duration of a single experiment will be, at a completely filled feed bunker *1* (see figure) and the chosen feed rate of graphite, 30–35 min.

Experiments on fluorination of powdered graphite were performed on the laboratory setup with a reactor with a free-falling graphite bed. The fluorination was performed at a temperature of 400–500°C in the zone of reaction between fluorine and graphite and 550–600°C in the zone of decomposition of carbon polyfluoride. The temperature of 550–600°C is sufficient for complete thermal decomposition of carbon polyfluoride [2, 3] in several seconds to tens of seconds.

The 0.2–1-mm fraction of the graphite powder was isolated for use in the study. The feed rate of graphite in the experiments performed was 1 g s^{-1}. The fluorination was done using a fluorine–argon mixture with fluorine content of 50 vol % or gaseous fluorine with dilution with an inert gas.

The flow rate of the fluorine–argon mixture was 8–10 cm^3 s^{-1}, and that of undiluted fluorine, 5–6 cm^3 s^{-1}. The theoretical heat release under adiabatic conditions in the reaction between fluorine and graphite at a given ratio of the feed rates will lead to a rise in the powder temperature by 100°C. The true rise in the temperature of the falling flow of graphite particles, caused by the heat of the reaction, is 50–60°C. Table 2 presents the averaged composition of the gaseous reaction products.

An analysis of values of the parameter $\Sigma S_{CF}/S_N$, whose physical meaning was described in detail in [2, 3], led to a conclusion that carbon polyfluoride formed in the reaction of fluorine and graphite completely decomposes.

Experiments with various inert gases, fluorine diluents, were carried out on the laboratory setup with a reactor with free-falling graphite bed. As inert gases served argon and tetrafluoromethane. The compositions of gaseous perfluorocarbons obtained in fluorination of graphite with mixtures containing 50 and 80 vol % fluorine were studied. In the case of a fluorinating mixture composed of 50 vol % CF_4 and 50 vol % fluorine, the composition of the gaseous reaction products was the following (with tetrafluoromethane coming into the gas mixture together with fluorine disregarded) (wt %): tetrafluoromethane, about 38–40; hexafluoroethane, 24–26; octafluoropropane, 19–21; and decafluorobutane, 10–12.

CONCLUSIONS

(1) It was shown that, in synthesis of perfluoroalkanes from graphite and fluorine under laboratory conditions in a reactor with a free-falling graphite bed by the scheme comprising synthesis of carbon polyfluoride and its thermal decomposition, the reaction products of the following composition can be obtained (wt %): tetrafluoromethane, about 38–40; hexafluoroethane, 24–26; octafluoropropane, 19–21; and decafluorobutane, 10–12.

(2) It was demonstrated, on a laboratory model of a reactor with free-falling powder bed, that a screw conveyor provides a stable formation of a gas-dust flow of fluorine and graphite in a wide range of feed rates of the components. In turn, the stable delivery of the components provides and maintains those temperature conditions of synthesis and thermal decomposition of carbon polyfluoride which are close to the optimal, as regards the composition of the gaseous reaction products, conditions.

(3) It was shown that use of a reactor with a free-falling graphite bed makes it possible to reduce the concentration of an inert gas in its mixture with fluo-

rine, compared with reactors with a fluidized bed and ascending gas-dust flow.

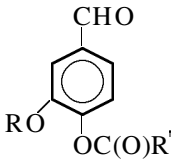
BRIEF COMMUNICATIONS

New Esters of Vanillin and Vanillal with Some Alkane- and Arenecarboxylic Acids

E. A. Dikusar



Institute of Physicoorganic Chemistry, National Academy of Sciences of Belarus, Minsk, Belarus

Received February 13, 2006

Abstract—Previously unknown esters were synthesized by the reaction of vanillin and vanillal with carboxylic acid chlorides.

DOI: 10.1134/S1070427206060322

Natural plant aldehydophenols, vanillin and vanillal (**Ia**, **Ib**), are available precursors for preparing fragrance compounds and food aromatizers [1–3], medical products, and biologically active compounds [4–8]:

IIa–**IIh**, **IIIa**–**IIIv**

where **II**, R is Me, R' is (**a**) $(CH_2)_7Me$, (**b**) $(CH_2)_{14}Me$, (**c**) cyclo-C_6H_{11}, (**d**) $(CH_2)_2C_6H_5$, (**e**) $CBrCCl{=}CCl_2$, (**f**) $(CH_2)_2C(O)OMe$, (**g**) $C(CN){=}CHC_6H_5$, and (**h**) 3,5-$C_6H_3(NO_2)_2$; **III**, R is Et, R' is (**a**) $(CH_2)_4Me$, (**b**) $(CH_2)_5Me$, (**c**) $(CH_2)_6Me$, (**d**) $(CH_2)_7Me$, (**e**) $(CH_2)_8Me$, (**f**) $(CH_2)_{11}Me$, (**g**) $(CH_2)_{14}Me$, (**h**) $(CH_2)_{16}Me$, (**i**) cyclo-C_6H_{11}, (**j**) $CH_2C_6H_5$, (**k**) $(CH_2)_2C_6H_5$, (**l**) $CH_2CHMeC_6H_5$, (**m**) *trans*-$CH{=}CHC_6H_5$, (**n**) $CBrCCl{=}CCl_2$, (**o**) $CHBrCHBrC_6H_5$, (**p**) $(CH_2)_2C(O)OMe$, (**q**) $C(CN){=}CHC_6H_5$, (**r**) 2,4-$C_6H_3C_{12}$, (**s**) 2,4-$CH_2OC_6H_3C_{12}$, (**t**) 3-$C_6H_5NO_2$, (**u**) 4-$C_6H_5NO_2$, and (**v**) 3,5-$C_6H_3(NO_2)_2$.

Here we describe a convenient procedure for preparing new esters of vanillin and vanillal with a number of alkane- and arenecarboxylic acids (**IIa**–**IIh** and **IIIa**–**IIIv**).

Esters **IIa**–**IIh** and **IIIa**–**IIIv** were prepared by simpler, more convenient, and more practically feasible procedure in comparison with that described previously for similar compounds [1–3].

Esters **IIa**–**IIh** and **IIIa**–**IIIv** were synthesized by the reaction of vanillin and vanillal (**Ia**, **Ib**) with chlorides of the corresponding alkane- and arenecarboxylic acids in anhydrous benzene in the presence of pyridine. We used the stoichiometric ratio of the reactants, 1 : 1 : 1. As a result of this reaction, the initial aldehydophenols **Ia** and **Ib** were converted to the corresponding esters **IIa**–**IIh** and **IIIa**–**IIIv** with a yield of 90–96%.

Vanillin and vanillal esters **IIa**–**IIh** and **IIIa**–**IIIv** are colorless viscous liquids or crystalline substances (crystallized from a mixture of benzene and hexane) (see table). The esters do not require additional purification, distillation, or recrystallization.

The structure and composition of vanillin and vanillal esters **IIa**–**IIh** and **IIIa**–**IIIv** were confirmed by elemental analysis, cryoscopic determination of the molecular weight (see table), and ^{1}H NMR, IR, and UV spectra. According to the ^{1}H NMR data, the purity of the resulting compounds was $98 \pm 1\%$.

In the IR spectra of vanillin and vanillal esters **IIa**–**IIh** and **IIIa**–**IIIv**, there are the following characteristic absorptions bands, ν, cm^{-1}: 3100–3000 (CHAr), 2990–2795 (CHAlk), 2740 ± 5 (CH of CHO group), 1720–1770 (C=O of ester group), 1695–1705 (C=O of CHO group), 1600–1350 (vibrations of aromatic system), 1300–1000 (C–O vibrations), and 800–600 (CHAr) [1, 3].

In the UV spectra of vanillin and vanillal esters **IIa**–**IIh** and **IIIa**–**IIIw**, there are the following absorption peaks, λ_{max}, nm (ε): 206 (9000), 224 (15 000), 260 (8000), and 310 (3000), caused by the presence of the 4-alkanoyloxy-3-alkoxybenzaldehyde fragment

[1]. In addition, the UV spectra of esters of functionality substituted and aromatic carboxylic acids (**IId**, **IIe**, **IIg**, **IIh**, **IIIj**–**IIIo**, and **IIIq**–**IIIv**) contain absorption bands typical of the corresponding fragments of these acids [3].

In the ^{1}H NMR spectra of vanillin derivatives **IIa**–**IIh**, the MeO group gives a singlet in the range 3.90–3.96 ppm, and in the ^{1}H NMR spectra of vanillal derivatives **IIIa**–**IIIv** the EtO group gives a triplet at 1.40–1.45 ppm (Me) and a quartet at 4.08–4.18 ppm (CH_2). The aromatic protons of esters **IIa**–**IIh** and **IIIa**–**IIIv** (C_6H_3) give a multiplet in the range 7.10–7.60 ppm, and the aldehyde proton of the CHO group gives a singlet in the range 9.95–10.0 ppm. The ^{1}H NMR spectra of compounds **IIa**–**IIh** and **IIIa**–**IIIv** contain characteristic signals of ester fragments [1, 3].

EXPERIMENTAL

The IR spectra were recorded on a Protege-460 Nicolet Fourier spectrophotometer in thin layer or

in KBr. The UV spectra of 1×10^{-4} M solutions in methanol were recorded on a Specord UV-Vis spectrophotometer. The ^{1}H NMR spectra were recorded on a Tesla BS-587A spectrometer operating at 100 MHz (5% solutions in $CDCl_3$, TMS internal reference). The molecular weights were determined cryoscopically in benzene.

Carboxylic acid chlorides were synthesized by refluxing the corresponding carboxylic acids with a 1.5-fold excess of $SOCl_2$ in benzene. Freshly distilled carboxylic acid chlorides and anhydrous benzene and pyridine were used.

Vanillin and vanillal alkanoates IIa–IIh and IIIa–IIIv. To a solution of 0.02 M of vanillin or vanillal (**Ia**, **Ib**) and 0.02 mol of alkene- or arenecarboxylic acid chlorides in 50 ml of benzene, a solution of 0.02 mol of pyridine in 10 ml of benzene was added with shaking. The vessel with the reaction mixture was hermetically sealed and the mixture allowed to stay for 10–12 h at 20–23°C with intermitted careful shaking. Then it was placed in a separating funnel, thoroughly washed with water and 20% NaCl for suppression of emulsion formation, and washed 2–3 times with 5% $NaHCO_3$. The organic layer was separated and filtered through a paper filter. Benzene was removed in a vacuum, with heating of the residue above 30°C avoided. Compounds **IIb**–**IIh**, **IIIf**–**IIIi**, **IIIk**, **IIIm**–**IIIo**, and **IIIq**–**IIIv** were crystallized from a mixture of benzene and hexane.

CONCLUSIONS

(1) An improved procedure was developed for preparing vanillin and vanillal esters with a yield of 90–96%.

(2) Some of the resulting compounds may be of interest as components for perfume and food industry and can serve as accessible precursors in synthesis of biologically active substances and medicinals.

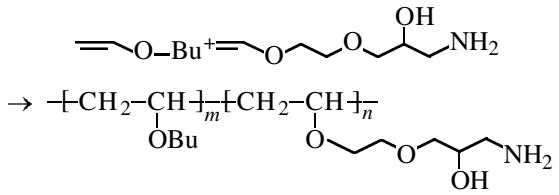
Received January 11, 2006

Abstract—Butyl vinyl ether–1-amino-3-[2-(vinyloxy)ethoxy]-2-propanol cooligomer was prepared and studied as a stabilizer of mazut–coal blended fuel.



DOI: 10.1134/S1070427206060334

Vinyl polymers (copolymers of *N*-vinylpyrrolidone with ethylene glycol vinyl-OCH_2CH_2O-glycidyl ether and butyl vinyl ether of various molar compositions, and homopolymers of these monomers) can be used as stabilizers of a promising fuel, mazut–coal blends [1].

In this study, we prepared butyl vinyl ether–1-amino-3-[2-(vinyloxy)ethoxy]-2-propanol cooligomer and studied this compound as a stabilizer of a mazut–coal blended fuel.

Cooligomerization of butylvinyl ether with 1-amino-3-[2-(vinyloxy)ethoxy]-2-propanol was performed by heating an equimolar mixture of these monomers in the presence of azobisisobutyric acid dinitrile [2]. The cooligomer was isolated by precipitation from an ethanol solution with diethyl ether; it was a light yellow viscous resin soluble in organic solvents and water.

The absence of the bands of vinyloxy group (820, 1320, 1645, 1625, 3120 cm^{-1}) and the presence of the bands of methyl group of butyl vinyl ether (1380, 1460, 2960 cm^{-1}) and amino and hydroxy groups (3310, 3446 cm^{-1}) in the IR spectrum of the oligomer confirm oligomerization via opening of the double bond and the presence of both monomeric units in the oligomer. The molar ratio of the monomeric units in the oligomer is 32 : 68 (mol %). The intrinsic viscosity in water is 0.12 dl g^{-1}. The weight-average molecular weight is 1100.

where m = 32, n = 68 mol %.

The stabilizing effect of the oligomer was studied by the known procedure [1, 3].

The stability and viscosity of the suspension at different concentrations of the stabilizer are listed in the table.

Among the known copolymers of *N*-vinylpyrrolidone with ethylene glycol vinyl glycidyl ether and butyl vinyl ether of various molar compositions and the homopolymers of these monomers, the best results were obtained with *N*-vinylpyrrolidone-butyl vinyl ether copolymer. The stability of the mazut–coal blend containing 20% coal and 0.3–0.5% stabilizer at 70°C was 96–100 in 24 h and 75.7–80.2% in 1 month, respectively, depending on the copolymer composition [1]. As can be seen from the table, the stabilizing effect of the copolymer is noticeably stronger than that

Stability and viscosity of a mazut–coal blend at 70°C

Cooligomer content in mazut–coal blend, %	Viscosity, Pa s^{-1}	Stability, %	
		in 24 h	in 1 month
0	0.585	11.2	0
0.02	1.492	74.6	22.7
0.03	1.651	80.1	37.4
0.04	2.432	88.2	49.8
0.08	2.826	98.2	88.9
0.10	3.117	100.0	98.2
0.15	3.994	100.0	99.1
0.20	4.252	100.0	100.0
0.30	7.107	100.0	100.0

of known stabilizers. The stability of a mazut–50% coal blend containing 0.1% copolymer in 24 h and 1 month at 70°C was 100 and 98.2%, respectively.

EXPERIMENTAL

Butyl vinyl ether–1-amino-3-[2-(vinyloxy)ethoxy]-2-propanol cooligomer. A mixture of butyl vinyl ether (100.2 g, 1 mol), 1-amino-3-[2-(vinyloxy)ethoxy]-2-propanol (161.2 g, 1 mol), and azobisisobutyric acid dinitrile (2 g) was heated at 80°C for 60 h. To remove unchanged monomers, the cooligomer was precipitated from an aqueous solution with diethyl ether and then dried in a vacuum (5 mm Hg). The cooligomer yield was 72.4 g. The butyl vinyl ether : 1-amino-3-[2-(vinyloxy)ethoxy]-2-propanol molar ratio determined by GLC analysis of a solution of the reprecipitated product is 68 : 32, i.e., the ratio of the monomer units is 32 : 68%.

Found (%): C 57.01, H 10.09, N 6.73.

$(C_6H_{12}O)_{0.32}(C_7H_{15}NO_3)_{0.68}$.

Calculated (%): C 56.63, H 9.99, N 6.72.

The mazut–coal blend was prepared from coal with the particle size smaller than 70 μm, 6.9% ash content and the water content of about 6% and M-100 mazut with viscosity of 70 cP at 70°C and the water content of 4.0%. The suspension was prepared in a DS-106 disintegrator (the linear collision speed of particles with the rotor fingers is 120 m s^{-1}). The coal content in all blends used in this study was 50 wt %. The stabilizer concentration ranged from 0.02 to 0.30 wt %.

The viscosity of the mazut–coal blend was measured on a Hoeppler viscometer using a 10.0172-g ball 13.5 mm in diameter. To determine the stability of the mazut–coal blend, its was controlled thermostatically at 70°C in sedimentation cylinders [3] for 24 h and 30 days. The stability of the suspension was determined gravimetrically from the carbon content in the upper layer. A sample (1/3 of the whole volume) of the upper part of the suspension was taken, and washed with toluene. The coal was separated by centrifugation and dried. The stability (Y, %) was calculated by the equation

$$Y = m_c \times 100/(m_s c),$$

where m_s is the weight of the suspension sample (g); m_c, weight of coal recovered from the suspension sample (g); and c, weight fraction of coal in the initial suspension.

CONCLUSIONS

(1) Butyl vinyl ether–1-amino-3-[2-(vinyloxy)ethoxy]-2-propanol cooligomer with molar ratio of the monomeric units of 32 : 68 (mol %) was prepared.

(2) The stability of a mazut–coal blend containing the cooligomer in an amount of 0.1% and more, evaluated upon heating at 70°C for 24 h and 1 month, is 100 and 98.2–100%, respectively. The stabilizing effect of the cooligomer is substantially stronger than that of the known stabilizers derived from vinyl monomers.

OBITUARY

Valentin Borisovich Aleskovskii (1912–2006)

DOI: 10.1134/S1070427206060346

On January 29, 2006, passed away, at the age of 93 after short illness, Valentin Borisovich Aleskovskii, a known scientist-chemist, one of the patriarchs of domestic solid-state chemistry, Honored scientist of the Russian Federation, participant of the Great Patriotic War, corresponding member of the Russian Academy of Sciences, doctor of chemical science, and professor of the chair of chemistry at the chemical faculty of St. Petersburg State University.

V.B. Aleskovskii was born on July 3, 1912, in the town of Mary in Turkmenia.

Having graduated from Leningrad Technological Institute in 1937, Aleskovskii became a post-graduate student at the chair of sorption technology and defended his candidate dissertation in 1940.

In June 1941, Valentin Borisovich volunteered to the frontline. He was wounded in action near Pulkovo at the end of 1943.

After returning from the front to the Institute, Aleskovskii defended his doctoral dissertation in 1952. He was appointed rector of Leningrad Technological Institute in 1965. In 1967, he founded the first chair of solid-state chemistry in the country and headed this chair. In 1972, Aleskovskii was elected a corresponding member of the Academy of Sciences of the USSR.

Aleskovskii's pedagogical, scientific, and organizational activities had been associated with Leningrad State University since 1975, when he was appointed rector of the University. Occupying this position, Aleskovskii modernized the structure of the University and transformed it into an educational-scientific center comprising two complexes, on the Vasil'evskii Island in St. Petersburg and at Petrodvorets at the outskirts of the city, which include faculties of the University and the corresponding scientific institutes.

Aleskovskii was among those who gave birth to solid-state chemistry in our country. In 1977, he organized at the chemical faculty of Leningrad University the chair of solid-state chemistry, headed by him till 1986, and later held the position of a professor of

this chair. The main area of Aleskovskii's scientific interests was study of the nature and chemical transformations of solids and development of a technology of new inorganic materials. He was the author of more than 450 scientific publications, including 12 monographs and textbooks, and made more than 150 inventions.

Most widely known are Aleskovskii's works of the 1960s, in which he created (by a certain analogy with DNA replication) methods for chemical assembly and, in particular, for synthesis of solid compounds of reproducible composition by the molecular layering technique. Abroad, this technique (known as atomic layer epitaxy) was developed 20 years later. At present, molecular layering is one of the most promising methods for synthesis of nanomaterials for electronics and other areas of solid-phase materials science.

Aleskovskii developed the concept of chemistry of supramolecular compounds (early 1990s) and later reconsidered it with account of the results of his own theoretical and experimental studies and published data in the field of supramolecular chemistry (J.-M. Lehn, 1989). This allowed him to suggest

the concept of chemistry of highly organized substances (1993).

Numerous results of studies and inventions by Aleskovskii and his pupils have been implemented in practice, a new effective and economically efficient material Anod for electrochemical power cells has been put into production, an electrochemical generator autonomously working in seawater has been developed on the basis of a novel material Mikrovors, and the new sorbing materials created in the 1980s by the molecular layering technique have been successfully used in instrument engineering for more than 20 years, with the quality and reliability of aircraft improved.

Aleskovskii was a talented pedagogue. He trained a pleiad of specialists in solid-state chemistry, who are working in our country and abroad, and created a highly productive scientific school "Chemistry of highly organized substances." There are several tens of doctors of science and more than 100 candidates of science among his pupils.

He was a member of the Supreme Soviet of the Russian SFSR (Soviet Federative Socialist Republic) and made an important contribution to the development of higher school in Russia by heading not only the leading higher-school institutions of the country, but also the Commission for education of the Supreme Soviet of the Russian SFSR.

During a number of years, Aleskovskii was a member of the Editorial board of *Zhurnal Prikladnoi Khimii* (Russian Journal of Applied Chemistry) published by the Russian Academy of Sciences.

The following conferences are regularly held in the framework of activities of the scientific school: International Conference "Chemistry of Highly Organized Substances and Scientific Foundations of Nanotechnology" (at St. Petersburg State University: 1st in 1996, 2nd in 1998, 3rd in 2001, and 4th in 2004); All-Russia Conference with foreign participation "Surface Chemistry and Nanotechnology" (at St. Petersburg State Technological Institute: 1st in 1999, 2nd in 2002, and 3rd to be held on September 2006).

For his scientific and educational-pedagogic activities, Aleskovskii was decorated with honorary titles and government awards.

The illness untimely terminated the vigorous scientific activities of the scientist, who remained faithful to his scientific interests till the end of his days and was agitated by problems associated with the development of highly organized substances, of the chair he organized, and of the chemical faculty of St. Petersburg University. To proceed with his deeds is the duty of his pupils and the best way to preserve his memory.

BOOK REVIEWS

L. D. Khegai, *Svintsovye akkumulyatory. Sostoyanie, problemy, resheniya* (Lead Batteries: State of Affairs, Problems, Solutions), Vladivostok: Dal'nauka, 2005, 256 pp.

DOI: 10.1134/S1070427206060358

Despite that lead batteries appeared about 150 years ago, no real alternative to their use in various vehicles has been found so far. The steady increase in the number of automobiles, especially characteristic of some regions of Russia, requires that the production of lead batteries should be raised, with their quality simultaneously improved. At present, 70 to 80% of the world's output of lead is consumed by battery industry. The geopolitical changes at the end of the XX century resulted in that the battery plants of the former Soviet Union, mostly concentrated on the territory of Russia, virtually lost their resources of raw materials. By 1990, Russia produced no more than 10% of the whole amount of lead manufactured in the USSR, whereas the leading position was occupied by Kazakh SSR.

The service life of the majority of lead batteries is, in the case when all exploitation requirements are satisfied, 3–5 years (starter batteries), after which they should be obligatorily utilized. At present, no less than 55% of the world's production of lead is based on processing of secondary raw materials, and scrap lead batteries in the first place. Measures are undertaken all over the world to organize an efficient system for collection of batteries and to improve the technology of their utilization. These problems are of not only economical, but also ecological importance, because lead and its compounds are highly toxic for living organisms.

The book by L.D. Khegai comprises an introduction, two parts (each dived into chapters), conclusion, and reference lists for the first and second parts separately (18 and 142 reference to various publications, respectively). In the brief introduction of most general nature (p. 3), some figures given without any reference seem to be questionable. In particular, the author states that "the present-day yearly output of lead batteries is 12 million batteries and will increase by 5 million in the near future." These data seem to be strongly overestimated and too optimistic.

The first part of the book (pp. 4–77) contains general evidence concerning lead batteries, description of the electrochemical behavior of the positive and negative electrodes (chs. 1–3), data on the electrolyte and separators (chs. 4, 5), information about design features and basic parameters of various-purpose lead batteries (ch. 6), brief description of the technology of their production (ch. 7), working conditions of lead batteries (chs. 8, 9), and prospects for further development of this kind of secondary power sources (ch. 10). The possibility of improving the performance of batteries is related by the author to application of new lighter materials for fabrication of their separate parts. Such a way to improve batteries as doping of lead-antimony alloys with various elements is only briefly mentioned when discussing the possible impurities in the metallic fraction of lead battery scrap.

The second part of the book (pp. 78–242), which also comprises ten chapters, is devoted to problems of integrated utilization of worked-out lead batteries. The author discusses a wide variety of problems: composition of the battery scrap, its fractionation and reparation for pyrometallurgical processing (chs. 1, 2); utilization of the electrolyte (ch. 3); remelting of the metallic fraction of battery scrap (ch. 4); pyrometallurgical, electrochemical, and hydrometallurgical methods for production of secondary lead (chs. 5–7); refining of raw lead (ch. 8); separation of lead-antimony alloys into components (ch. 9), and methods for production of various salts of lead, red lead, and oxidized lead powder from wastes formed in battery production (ch. 10). A number of critical remarks concerning the second part of the book should be made.

Until recently, a substantial part of studies in processing of lead battery scrap have been performed at Gintsvetmet Institute under general supervision of A.V. Tarasov and A.D. Besser. They suggested and implemented at the Ryaztsvetmet plant (Ryazan) a technological scheme for processing of battery scrap, which is based on soda-free electrosmelting. This technological procedure has been described in quite a number of publications and in the monograph *Metalurgicheskaya pererabotka vtorichnogo svibntso-*

vogo syr'ya (Metallurgical Processing of Secondary Lead-containing Raw Materials) (Tarasov, A.V., Besser, A.D., Mal'tsev, V.I., and Sorokina, V.S., Tarasov, A.V., Ed., Moscow: Gintsvetmet, 2003). Unfortunately, these domestic achievements found no reflection in Khegai's book. There are rather numerous annoying inaccuracies in description of quite a number of technological operations. For examples, discharged electrolyte (sulfuric acid) should in no way be delivered to the apparatus in which desulfation (desulfurization) of the oxide-sulfate fraction of lead battery scrap is carried out with the use of sodium hydroxide or carbonate (Fig. 2.6, p. 101). It is hardly appropriate to describe, in a serious book, the calculation of the amount of soda ash necessary for neutralization of sulfuric acid (p. 107). The description of the express method for determining the content of antimony in alloys with lead is unsatisfactory (p. 129). Figure 2.14 can only illustrate crystallization of a pure component or eutectic mixture. The electrochemical behavior of lead in ionic melts was considered in detail in the monograph *Elektrokhimiya svintsa v ionnykh rasplavakh* (Electrochemistry of Lead in Ionic Melts) (Morachevskii, A.G., Vaisgant, Z.I., and Demidov, A.I., St. Petersburg: Khimya, 1994). Unfortunately, this book failed to draw attention of the author of the book being refereed. Table 2.29 (p. 190) is extremely poorly compiled: all values in it should have been negative. Table 2.32 (p. 193) requires comments. It is unclear what is understood by the degree of interaction.

The author erroneously considers that the method for separation of lead and antimony by introduction of aluminum is new. More than 40 years ago, this method was described in ample detail in the book *Proizvodstvo vtorichnykh tsvetnykh metallov i splavov* (Manufacture of Secondary Nonferrous Metals and Alloys) (Tsyganov, A.S., Moscow: Metallurgizdat, 1961). It should be noted that the method based on interaction of aluminum with antimony dissolved in lead was not considered new in those years, either.

The presence of conclusions (pp. 243–246) in a book that is an industrial-technological publication is hardly at all appropriate. It would be more correct to only make a conclusion containing necessary recommendations. The author pays a considerable attention to description of various apparatus and technological equipment. Not quite successful are those parts of the book in which Khegai employs notions of electrochemistry or chemical thermodynamics. A large body of reference data contained in the book should be used with caution. For example, the melting point of lead(II) chloride is given as 1091°C (p. 86), 495°C (p. 215), and 508 ± 5°C (p. 217). The same thermodynamic function should not be differently named within the same book: isobaric-isothermal potential, free energy, Gibbs energy. Numerous critical remarks can be made concerning the reference list, especially that for the second part of the book, in which there are numerous departures from the commonly accepted rules for reference lists.

The manuscript of the book should have been refereed with closer attention and subjected to better-qualified scientific editing. Khedai's book, and especially its second part, is devoted to a problem that is topical for Russia, but the ways to tackle with this issue, suggested by the author, are rather questionable. Most part of domestic publications of recent years remained out of author's sight. Separate industrial-technological sections of the book may be of interest to engineers and technicians working in manufacture of lead batteries and processing of secondary lead raw materials.

BOOK REVIEWS

K. K. Kalnin'sh, and L. I. Pavlova, *Voda – rodnik zhizni. Monographiya* (Water, A Spring of Life: Monograph),

St. Petersburg: Inst. Vysokomol. Soedin. Ross. Akad. Nauk, 2005, 293 pp.

DOI: 10.1134/S107042720606036X

The central place in the fascinating monograph written by known scientists, K.K. Kalnin'sh and L.P. Pavlova, is occupied by studies of the fundamental role of water in vital processes. The authors for the first time consider water as a catalyst of biochemical reactions, which can serve to explain, from purely scientific standpoint, many properties of water and to subject to critical analysis various pseudoscientific hypotheses.

The book comprises authors' address to readers, introduction, seven chapters, afterword, and supplement. Each chapter, afterword, and supplement are provided with reference lists. The address to readers notes that such a unique property of water as catalytic activity has been discovered, and a method for its measurement has been developed by one of the authors of the book, Kalnin'sh, during his many-years investigations at the Institute of Macromolecular Compounds, Russian Academy of Sciences, in St. Petersburg. The co-author of the book, Pavlova, studies the catalytic properties of water and performs biological investigations at St. Petersburg State University.

In the introduction (pp. 9–12), the authors describe in a rather condensed form the contents and specific features of the monograph, emphasize that the book presents a new interpretation of both the very notion of chemical catalysis and the catalysis in water as applied to biological enzymatic processes, and note the important role of the electron-proton effect in analysis of catalytic processes. This previously unknown physical phenomenon[1] exceedingly strongly lowers energy barriers and thereby facilitates a complex train of biochemical reactions.

In the small first chapter (pp. 13–23), the authors discuss the exceedingly important role of water in various processes in Earth's biosphere on the basis of works of Academician V.I. Vernadskii (1863–1945). The second chapter (pp. 24–55), devoted to analysis of the relationship between water and living organisms, also pays a considerable attention to works by Vernadskii [*Zhivoe veshchestvo* (Living Substance) (Moscow: Nauka, 1978)], Academician A.I. Oparin (1894–1980) [*Materiya. Zhisn', Intellect* (Matter, Life, Intelligence) (Moscow: Nauka, 1977)], and a number of other scientists (E.S. Bauer, B.P. Tokin). Particular attention is given by the authors to analysis of studies that considered to any extent the involvement of electronically excited states in biological processes.

The third chapter (pp. 56–79) substantiates the novel concept suggested by the authors. According to this concept, water is an active participant and catalyst of biochemical processes, with the catalytic function of water being of a fundamental nature and making possible to asses, from a new standpoint, the role of water in the formation of the biogeosphere of our planet at all stages of its development. The fourth chapter (pp. 80–104) presents the evidence, obtained by the authors by calculation, that water molecules are directly actively involved in the principal bioenergetic process, splitting of the molecule of adenosine triphosphoric acid (ATP).

In the fifth chapter (pp. 105–133), the authors introduce and discuss in detail the notion "activity of water." According to the concepts developed in the monograph, the degree of activity of water is determined by its ability to accelerate or decelerate chemical reactions whose elementary stage involves transfer of an electron and a proton. To reactions of this kind belongs majority of biochemical processes and numerous chemical reactions involving organic substances. In the authors' opinion, the new parameter they suggested for evaluation of the quality of water, activity, is an important characteristic of water of any origin and purpose.

In the sixth chapter (pp. 134–186), Kalnin'sh and Pavlova subject to constructive criticism the concepts of the "information" role played by the struc-

[1] Kalnin'sh is the author of the monograph *Elektronnoe vozbuzhdenie v khimii* (Electronic Excitation in Chemistry) (St. Petersburg, 1998).

ture of water and "memory" of water, and discuss the widely accepted concepts of "alive" and "dead" water. The fluid water having a labile instantaneously rearranging structure cannot serve for writing, storage, and transmission of information. The problem of the "memory" of water and effect on water of various external treatments is considered. In the final part of the chapter, the authors emphasize that water possesses a unique dissolving ability. Dissolved molecules of various chemical compounds affect the shortlived instantaneous structure of water.

The seventh chapter (pp. 187–239) considers facts and hypotheses associated with the medicinal and some other properties attributed to water from various sources or to that subjected to certain treatments. In particular, the medicinal properties and the probable mechanism of action of "silica" and "shungite" water, "alive" and "dead" water produced by electrolysis, and "silver" water are discussed. Special attention is given to properties of thaw water and water subjected to magnetic treatment ("magnetized water"). The authors make an attempt to explain the observed effects in scientific terms, primarily taking into account the concept of catalytic properties of water.

The afterword to the book is entitled "From Myths to Reality," which is rather symbolic. The authors realize that the issue of water is a matter of acute current interest and gives rise to active discussions on pages of popular-science publications and mass media. Frequently, this occurs in the form of incorrect statements and pseudoscientific hypotheses. The desire to distinguish between the myths and reality and to scientifically substantiate the real, verified facts is a notable achievement of the authors.

The supplement to the monograph (pp. 248–292) describes the essence of the electron-proton effect and its role in various physical and chemical processes. It is particularly important for catalysis.

In the book, a vast material is collected and analyzed and rather valuable evidence of practical nature is contained. The monograph is very well written, and a considerable part of the material is presented in a form understandable for a wide audience of readers. Unfortunately, only 600 copies of the book have been printed, and, what is more, the existing system of distribution of the scientific literature is far from being perfect.

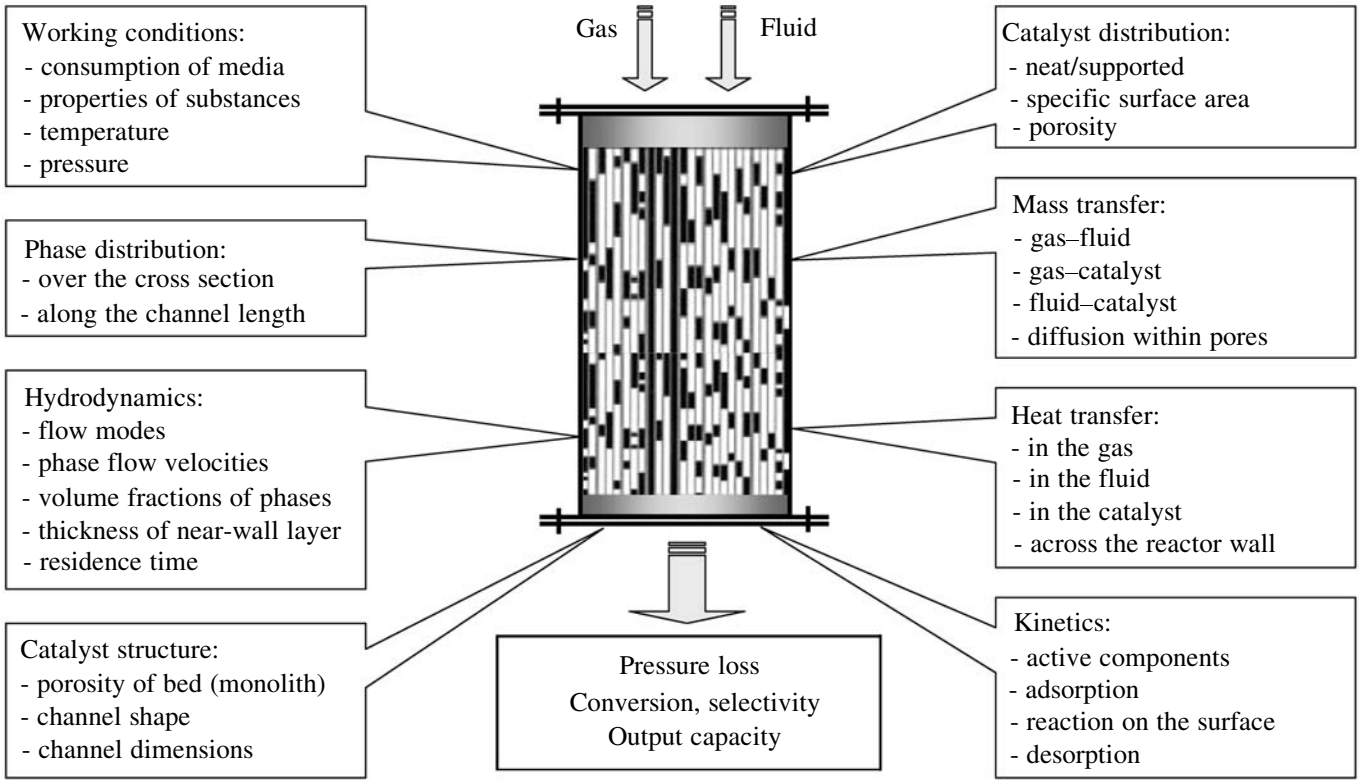
Abstract—The review discusses the present-day state of research, industrial experience, and prospects for application of reactors with a multichannel catalyst for gas–fluid catalytic reactions.

DOI: 10.1134/S107042720607019

INTRODUCTION



Optimization of the existing chemical processes is one of key requirements put forward by modern industry with the aim to achieve technological efficiency and environmental safety [1, 2]. This problem can be successfully solved by developing new apparatus and processes of chemical industry that would fundamentally improve the efficiency of the processes and save energy. In the technology of multiphase reactions, application of the so-called structured reactors with a "monolithic" (multichannel[1]) catalyst (Monolith reactors) instead of the conventional apparatus, such as reactors with a suspended catalyst or a fixed catalyst bed arranged in a disordered way, is a very promising alternative.

New designs and methods are being developed with the claimed goal of process intensification. Stankiewicz and Moulijn [3] defined this notion as fundamental improvement of an apparatus or a process as regards their scale, energy consumption, and environmental impact. A significant decrease in the dimensions of an installation can lead to additional improvement of the process safety (for example, miniature heat exchangers with a volume of 1 cm^3 and heat-transfer capacity of up to 20 kW and reactors of similar dimensions have already been developed at the Research Center in Karlsruhe, Germany).

Heterogeneous catalytic gas–fluid reactions are performed in numerous petrochemical installations, in manufacture of many materials and substances, in fine chemical technology, in pharmaceutical industry, and in biotechnology. Reactors with impellers, bubbling reactors (including those of airlift type) [4], and reactors with a chaotically arranged (disordered) fixed catalyst bed [5] have found the widest application in hydrogenation, oxidation, and (since recently) biological reactions. The most important requirement in design and operation of these reactors is that a large phase contact area should be provided in order to achieve highly intense mass transfer. An inhomogeneous phase distribution or nonuniform wetting of the catalyst leads to a nonuniform mass transfer, which adversely affects the overall reaction rate and the selectivity of the reaction process. The result is known: loss of product quality, lower output capacity of the reactor, and its poorer safety. Similar phenomena have been observed in an apparatus with a similar hydrodynamic situation, ion-exchange apparatus with a fixed resin bed [6]. The temperature distribution in exothermic reactions could be made more uniform by using a catalyst based on a nickel–aluminum support reinforced with a stainless steel grid [7]. The conventional reactors for the gas–fluid–solid systems are also very difficultly scaled because the flow fields of the fluid and gas, parameters of bubbles, and properties of phases, including the catalyst, are not proportional to the reactor dimensions [8].

In [9], steam conversion of methane with a catalyst of regular structure in the form of a plane-parallel packing was studied. It was shown that, for the given process, the working volume of the apparatus is approximately three times smaller than that of reaction tubes in a Kellogg methane-reforming furnace, which are filled with a granulated catalyst, and two orders

[1] Both the terms, monolithic and multichannel, will be used in this review.

Scheme 1.

of magnitude smaller than the total volume of the furnace.

The review [10] noted the advantages of catalysts with irregularly shaped grains (stars, tubes, tri- and quarterfoils, multichannel tubes, etc.): increased accessible grain surface area, a certain rise in the porosity of the bulk bed, lower hydraulic resistance, higher degree of utilization, and longer service life of a grain. Investigations aimed to develop new catalysts with irregularly shaped grains are being conducted at Yarsintez Research Institute Open Joint-Stock Company.

The processes that occur when carrying out multiphase reactions can be intensified by improving the contact in the gas–fluid–solid system in such a way that the diffusion length becomes shorter (i.e., the fluid film on the catalyst surface becomes thinner) and the agitated volume of the fluid in the reactor decreases. The studies performed in recent years have shown that directed introduction of the fluid phase into catalyst channels having a certain shape can be a successful way to achieve a highly intense and uniform mass transfer. A parallel connection of channels of this kind results in an ordered and structured multichannel (monolithic) catalyst [11]. This catalyst with active components on the channel surface is fixed within the reaction volume. Owing to the regular arrangement of the channels and their identical sizes, a rather simple scaling is possible, because an increase in the flow section and in the active surface area of the catalyst means in the given case that only the number of parallel channels becomes larger. However, an engineering task of developing a reliable device for distribution of the gas and fluid among all the channels remains topical in designing and scaling of apparatus [12].

Having better characteristics of energy consumption, smaller dimensions, and improved safety at an, at a minimum, equal output capacity, reactors with a multichannel catalyst can oust the conventional three-phase reactors [13]. However, the elementary processes occurring in reactors with a multichannel catalyst (Scheme 1) affect one another in a complicated way and have not been completely accounted for as yet. Here we discuss the current state of research and the experience of industrial use of reactors with a multichannel catalyst for gas–fluid catalytic reactions.

1. COMPARISON WITH CONVENTIONAL MULTIPHASE REACTORS

Catalytic gas–fluid reactions are performed in reactors with impellers, whose design has not changed

significantly until now. The hydrodynamic and agitation processes in these reactors are exceedingly complex and, despite the considerable efforts made by researchers, are still difficult to describe. Neither rigid inserts in the form of reflecting partitions, nor the improved design of impellers can completely eliminate the problem of the quality of agitation. Noninvasive (i.e., not affecting a system under study) studies of the hydrodynamics of apparatus with impellers, performed using radioactive tracers (Computer-Automated Radioactive Particle Tracking, CARPT), revealed a great difference in velocities within each phase, inhomogeneous distribution of the gas and fluid phases, strongly limited nature of circulation zones, and presence of stagnant zones [14]. As the reactor volume increases, these agitation-related problems become more severe.

Many chemical processes employ bubble columns. Their significant advantage over apparatus with impellers is the possibility of working at a high content of the solid phase, commonly up to 30 vol %. However, similar problems associated with the phase distribution and with achieving a large specific area of contact between phases arise in bubble columns. Density measurements by computer tomography with γ-radiation revealed that the gas content decreases in the direction from the reactor axis toward its walls [15].

Despite the use of the most recent measurement techniques and modern software for flow simulation by the method of finite elements (Computational Fluid Dynamics, CFD), complex processes of mixing in reactors with a suspended catalyst have not been fully described so far.

A possible alternative to apparatus of the above kind are reactors with disordered packing with the catalyst: trickle-bed reactors with upflowing gas and downflowing fluid (Rieselbettreaktoren) and upflow packed-bed reactors (Sumpfphasenreaktoren). The reactors with disordered packing with a catalyst are mostly used in petrochemistry to perform reactions that involve hydrogen. The reactors with a fixed catalyst bed are not sufficiently versatile as regards a change of a catalyst or product, but show a comparatively low production expenditure. Because of the incomplete wetting of the catalyst surface, difficulties associated with the optimal utilization of the catalyst and heat removal in the case of exothermic reactions may be encountered in reactors with disordered packing, which is indicated by tomographic studies [16, 17].

Reactors with a multichannel (monolithic) catalyst have a number of decisive fundamental advantages over the conventional multiphase reactors. Compared with reactors with a fixed bed, they have a very low hydraulic resistance, large specific surface area, and virtually full wetting of the catalyst surface. Compared with reactors with a suspended catalyst, reactors with a monolithic catalyst show high mechanical strength of the catalyst and rule out any possibility of crushing and carry-over of the expensive catalyst. The studies performed by the time of publication of this review revealed advantages of reactors with a multichannel catalyst in mass-transfer, selectivity, and output capacity [18–21]. The rise in output capacity is primarily due to a closer contact between the gas, fluid, and solid phases within the ordered monolithic multichannel structure and to a shorter diffusion length across the thin phase boundary [22].

It should be noted that no direct experimental comparison of the output capacities of the reactors with an appropriate comparison criterion has been carried out so far. An integral characteristic of the output capacity at the appropriate working parameters typical of each kind of apparatus could serve as a criterion of this kind. Analysis of the economical efficiency with account of energy expenditure and installation cost could supplement such a comparison and thereby reveal the reasonable fields of application of new catalysts.

2. FUNDAMENTAL ASPECTS OF REACTORS WITH A MULTICHANNEL (MONOLITHIC) CATALYST

2.1. Manufacture and materials. The monolithic catalysts have a cellular structure constituted by a large number of parallel, regularly arranged, and separated channels. The most important characteristics of the multichannel catalysts are cell density (number of channels per unit area of the apparatus cross section), hydraulic diameter of a channel, porosity of the cross section (fraction of a free cross section), and partition strength [23].

The catalyst support is prepared by extrusion of a forming paste with the subsequent drying and sintering or by rolling over corrugated metallic sheets. The monolith may be wholly composed of the active component, or this component is deposited onto a ceramic forming paste. Both methods yield a solid catalyst with a very high degree of saturation with the active component.

The most frequently used method is coating of a ceramic skeleton with a supporting substance making

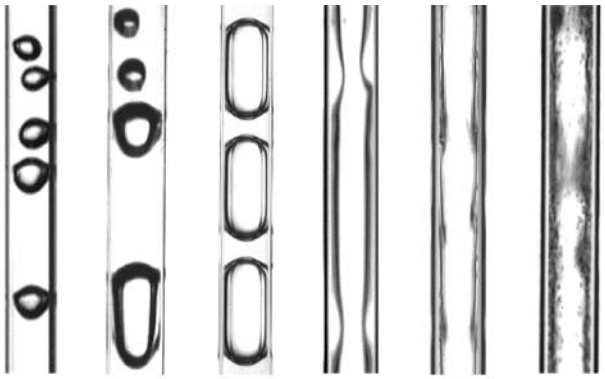


Fig. 1. Flow modes in a square-cross-section capillary with a hydraulic diameter of 1.0 mm [26]. Flow: (a) bubble mode, (b) transition from bubble to slug mode, (c) slug mode, (d) transition from slug to film mode, (e) film mode, and (f) "explosive" emulsion mode.

larger the specific surface area (washcoat). Typical supporting materials are aluminum oxide, aluminum silicate, silicic acids, and carbon. A supporting material can be deposited by introducing it into the porous structure of the ceramic skeleton or by creating a thin coating layer on the ceramic skeleton. The active components (Pt, Pd, etc.) can be introduced into the fine structure by impregnation, ion exchange, or precipitation [24].

The general requirement to a method for coating deposition is that it should yield a large and uniform specific surface area, strong binding of all the components, and homogeneous distribution of the catalytically active components within the monolith or on its surface. In view of the large longitudinal dimensions and the structure of the monolithic bodies, their coating with the active components is a more complicated task than that in the case of the conventional forms of the catalyst.

Use of catalyst-coated supports is recommended for reactions that occur at a high rate with a comparatively slow mass transfer (i.e., diffusion-controlled reactions). The integral characteristic of the output capacity of a catalyst, the overall performance, depends in this case on the specific surface area and, to a lesser extent, on the amount of the catalyst. At a comparatively low reaction rate (i.e., for kinetically controlled reactions), a neat monolithic catalyst [e.g., activated carbon or iron(III) oxide] should be used. The catalyst may be wholly composed of the active component, or this component is homogeneously distributed in the ceramic skeleton.

2.2. Hydrodynamics. The hydrodynamics strongly affects the mass and heat transfer in multiphase processes and thereby largely determines the output capacity of reaction apparatus. Of particular importance is the intense contact of the phases with one another and with the solid catalyst. As regards the reaction technology, preference should be given to large phase contact areas and to as thin as possible boundary layers. In multiphase systems, these parameters are directly or indirectly related to hydrodynamic parameters of the flow mode, fraction of phases, film thickness, quality of catalyst wetting, residence time, dispersion, and pressure loss. A detailed knowledge of these parameters is necessary for deep understanding of the working principles of these reactors and their putting into industrial practice [25].

The hydrodynamics of reactors with a multichannel catalyst is governed by the flow mode of the gas–fluid medium in separate channels. The flow modes of the gas–fluid medium in narrow channels depend on the flow section, catalyst material, and channel properties (Fig. 1). Until now, of particular interest for the reaction technology have been the slug and film flow modes in multichannel catalysts. The slug flow is characterized by sequence of elongated gas bubbles and fluid drops along the channel. In this flow mode, the ratio of flow rates of the gas and fluid varies from 0.2 to 2.0. As regards the reactor technology, the advantages of the slug mode are the very small thickness of a fluid film between the cylindrical part of gas bubbles and the porous catalyst wall and the uniform agitation within each fluid drop (the later is determined by the Taylor diffusion).

At very low fluid flow velocities (<0.01 m s^{-1}), a transition to a film flow may occur in the case of a downflow in narrow channels. In this mode, the gas phase flows in the same direction as the fluid or is oppositely directed. The film flow mode is of particular interest if a large conversion (related to the fluid flow rate) should be achieved or the process requires a counterflow of the phases, as, e.g., in reactive evaporation in stripping columns.

An important criterion of reliable and adequate description and calculation of reactors is the homogeneous distribution of the fluid and gas, because approximately the same conditions and stable flow modes occur in all the channels. However, such optimal working conditions are difficult to achieve in practice. A study of the gas and fluid distribution along the flow direction by NMR tomography [27] demonstrated that there is a clearly pronounced difference in gas distribution between the channels. Also, the bubble sizes within separate channels are strongly different, so that a nonuniform bubble distribution can

be inferred. Similar results characterizing an inhomogeneous phase distribution have been obtained in studies of the fluid and gas distribution over the cross section of a monolithic catalyst by capacitance tomography [28] and γ-ray computer tomography [29]. It was stated in these publications that, depending on the distribution of the fluid and gas and on the phase flow rate, various contents of the phases both over the cross section and along the reactor axis can be obtained. This suggests that each of the distributing systems can operate in the optimal mode only at certain phase flow rates.

The following distributing devices have demonstrated good performance in experimental practice: spraying nozzles [30] and ejectors [31] for the downflow of gas–fluid systems and static mixers [32] for the upflow.

For better understanding of the fundamental aspects of flow within monolithic reactors, studies in glass capillaries of round and square cross sections, in which any influence of the uniformity of phase distribution is excluded, have been carried out. Examples of the flows formed in this case and the transition regions were obtained by photographing and video recording and then analyzed as regards the type of flow, distribution and flow velocity of phases, phase boundaries, etc. [33, 34]. These experimental data are used for precise determination of the corresponding model parameters, which should be taken into account in the mathematical model of the reactor (mostly in mass and energy balance equations).

It should be noted that most part of the studies have been performed in the water–air system under atmospheric conditions in glass capillaries of round cross section. It seems hardly probable that the data obtained and correlation equations can describe with sufficient accuracy the predominant industrial conditions. That is why two-phase flows in the so-called mini channels (with a hydraulic diameter of about 1 mm) are being intensively studied at the Institute of Process Engineering and Environmental Technology, Technical University of Dresden (Institut für Verfahrenstechnik und Umwelttechnik der TU Dresden) with account of the real industrial conditions and material systems.

2.3. Mass transfer. A distinctive feature of monolithic reactors is that they exhibit improved mass-transfer characteristics, compared to those having an irregular filling with a fixed catalyst. An advantageous mode in this case is the so-called slug (piston) flow constituted by a sequence of gas bubbles and fluid drops. As shown in Fig. 2, the flow mode characteristically involves three stages of mass transfer: (i) at the gas–fluid interface, from the semispherical nose of a bubble and from its end part into the fluid; (ii) at the gas–solid interface, from the cylindrical part of a bubble across a thin fluid film to the catalyst; and (iii) from the fluid itself and from the gas dissolved in the fluid to the catalyst at the fluid–solid interface. In addition, the reagents should also diffuse into the catalyst pores to the active centers. Particularly high rates of mass transfer are achieved in the case of the piston flow owing to the circulation currents within fluid drops and to the small thickness of the fluid film between the gas bubble and the catalyst. In this case, the mass transfer is a very complex process largely determined by the gas and fluid flow velocities, bubble length, and fluid film thickness.

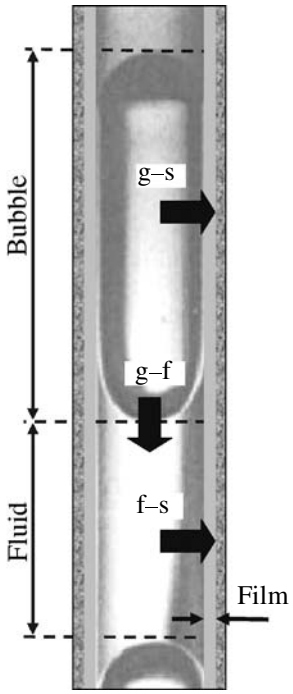

Fig. 2. Stages of mass transfer in unit cells: gas–catalyst (g–s), gas–fluid (g–f), and fluid–catalyst (f–s). Characteristic hydrodynamic dimensions: fluid drop length, bubble length, and fluid film thickness.

At very low fluid flow rates and a hydraulic channel diameter exceeding 2.0 mm, a film-type flow occurs. In this mode, an exceedingly long residence time of liquid reagents in the reactor and a high ratio of gas and fluid flow rates can be achieved.

Theoretical analysis demonstrated that mass transfer is improved as the fluid flow velocity decreases. The effect of the fluid flow velocity is more pronounced in the piston mode, compared to the film

flow. The reason is that the film thickness decreases, which leads to a significant improvement of the mass transfer. Another advantage of low fluid flow velocities is that, in this case, the pressure loss is small.

To exclude any influence of the nonuniformity of distribution among the catalyst channels and to set the necessary hydrodynamic parameters, mass transfer is frequently studied in glass capillaries of round or square cross section [35, 36]. However, the adequacy and applicability of the results obtained in this case seem to be questionable for the following two reasons. First, the occurrence of a certain flow mode is strongly affected by the system of gas and fluid distribution, so that different experimental capillary setups give markedly dissimilar results. Second, in monolithic (multichannel) structures there exist, as described in the section devoted to hydrodynamics, such distributions of gas bubbles and fluid drops which can hardly be reproduced in experiments performed in capillaries. The existing correlations on mass transfer are not dimensionless and require that the bubble and drop lengths should be known. Hence follows that evaluation of mass-transfer characteristics in monolithic reactors is a very complicated task, and experimental and theoretical studies should be performed to resolve this issue.

The mathematical models of two-phase flows can be further improved using the results obtained in [37–39]. It seems appropriate to develop mathematical models that would describe phase distribution among monolith channels and formation of bubbles and drops in capillaries.

2.4. Application fields. Monolithic catalysts were originally developed for use in reactions in gas–solid systems to treat automobile exhaust fumes. These catalysts have also been successfully used in processing of industrial gases (e.g., in power engineering), in selective catalytic reduction of NO_x, and in catalytic combustion systems. The widely diverse application fields of monolithic catalysts in the reaction technology of gas–solid systems have been reviewed by Heck et al. [40].

In the 1980s, studies of the applicability of monolithic catalysts in heterogeneous catalytic processes in the gas–solid system were commenced. The first of these were carried out at the Chalmers Technical University (Sweden). The hydrogenation of nitroaromatic compounds [41, 42], 2-ethylhexenal [43], anthraquinone [44], acetylene, thiophene, and dibenzothiophene [45] was examined.

Based on these data, Eka Chemicals Company developed the so-called anthraquinone process for manufacture of hydrogen peroxide using monolithic catalysts. At present, Akzo Nobel Company successfully employs numerous large-scale installations of this kind all over the world [46].

In recent years, extensive studies, both fundamental and those oriented toward industrial application of monolithic catalysts in multiphase reactions, have been carried out at the Delft University of Technology (the Netherlands). The hydrogenation of styrene [47], α-methylstyrene [48], benzaldehyde [49], and 3-methyl-1-pentyn-3-ol [50] has been studied on a pilot installation. In addition, cyclohexanone has been oxidized in a monolithic reactor [51]. It has been shown, when examining the Fischer–Tropsch synthesis, that monolithic reactors may become a good alternative to the conventional types of multiphase reactors, with the requirements of a high selectivity, low pressure loss, and good heat removal, etc., satisfied [52].

At the University of Tulsa (the United States), "wet" oxidation of acetic acid [53] and glucose and cellulose [54] has been performed in an upflow monolithic reactor, and various substances have been manufactured from cellulose and biomass [55].

A research group from the University of Birmingham (the United Kingdom) studied the hydrogenation of 2-butene-1,4-diol in a downflow monolithic reactor [56].

Recently, Air Products and Chemicals Inc. developed, together with a catalyst manufacturer Johnson Matthey Company, a technique for manufacture of monolithic catalysts for fine chemical technology. In this connection, Air Products and Chemicals Inc. designed a pilot monolithic reactor. The same company has successfully tested hydrogenation of nitroaromatic compounds [57] and sorbitol [58].

Corning Inc. has tested hydrogenation of vegetable oil in a monolithic reactor [59] and hydrogenation of alkenes in a monolithic channel with various configurations [60, 61].

The number of studies devoted to the potentialities of monolithic reactors in biological conversion of substances is growing. Airlift reactors have been used to study the biological decomposition of 2,4-dichlorophenol with immobilized cells of *Achromobacter sp.* [62] and that of quinoline with *Burkholderia pickttii* bacteria [63]. Recently, the formation of a biological film in monoliths has been studied experimentally and theoretically [64].

Selected applications of monolithic reactors

Reaction	Active component, support	Direction of flows	References
Hydrogenation of anthraquinone	Silica gel	Downwards	[44]
Hydrogenation of α-methylstyrene	1.8 wt % Pd, γ-Al_2O_3	Downwards	[48]
Oxidation of cyclohexanone	Carbon	Downwards	[51]
Oxidation of glucose and cellulose	0.26 wt % Pt, Al_2O_3	Upwards	[54]
Hydrogenation of 2-butene-1,4-diol	1.0 wt % Pd, α-Al_2O_3	Downwards	[56]
Hydrogenation of nitroaromatic compounds	Co–Mo, γ-Al_2O_3	Downwards	[57]
Hydrogenation of vegetable oils	2.0 wt % Pd	Downwards	[59]
Biological decomposition of quinoline	*Burkholderia pickttii*	Upwards	[63]

Monoliths have been tested in numerous application fields of reactors (see table). As follows from the data presented, monolithic reactors find use in fast reactions, e.g., in hydrogenation and oxidation. Together with having high output capacity and selectivity, reactors of this kind possess one more advantage of being compatible with other basic processes. For example, monoliths can be used for the reaction process of pressure flotation (Strippen) [65] and reactive distillation [66, 67]. One more application opportunity of interest is combination of a chemical reaction with agitation in a monolithic reactor [68], in which the conventional mixer is replaced with a monolith. The advantage of such a mixer is that the catalyst is fixed within the reaction shell, which saves the catalyst by preventing its carry-over.

Another interesting way to intensify chemical processes with monolithic reactors is the so-called built-in monolithic reactor [69]. In this reactor design, delivering reagents via pipes to other apparatus of the process scheme can be combined with performing a chemical reaction. A simulation of the reactor, carried out by DSM Research Company, demonstrated that use of this reactor can lead to a significant decrease in the installation dimensions. Irrespective of the reactor configuration, the possibility of application of the new types of reactors has been so far studied only at moderate loads. To extend the applicability range, the Institute of Process Engineering and Environmental Technology, Technical University of Dresden (Germany) has developed, in cooperation with Sigmar Mothes Hochdrucktechnik Company, an installation for study of multiphase reactions in reactors with a fixed bed at pressures of up to 100 bar.

3. PRACTICAL CONCLUSIONS

The possibility of independent variation of the dimensions and shape of channels and of the wall thickness in order to satisfy requirements imposed by various multiphase processes is an important advantage in performing the optimal design of monolithic reactors. The conventional monolithic reactors, such as, e.g., trickled-bed reactors (Rieselbettreaktoren) and upflow packed-bed reactors (Sumpfphasenreaktoren), have a lesser number of degrees of freedom.

In monolithic reactors, the efficiency of interaction in the gas–fluid–solid system and the concentration of reagents in the fluid film are directly determined by the structure of the monolith (square, triangular, rounded, etc.). In this case, the shape of the channel predetermines the uniformity of fluid distribution over the catalyst surface. It has been shown that no stagnant zones are formed in rounded channels and a high rate of mass transfer is achieved because of the small thickness of the film on the catalyst surface [60]. Development of new techniques for coating of predominantly square monolith channels to make them rounded would be an important stage in further improvement of their efficiency.

Gas–fluid flows in separate mini channels can be regarded as approximately independent of the flow direction. At comparatively high phase flow velocities, the hydrodynamic situation in monolithic reactors is also the same throughout a reactor. At low phase flow velocities, the distribution of the gas and fluid over the cross section of a bed in an upward flow occurs with certain difficulties and, in the case of a nonuniform distribution, may adversely affect the output capacity of a reactor. It should be added here that studies of reactions revealed a higher output capacity in the upflow [61].

Monolithic reactors can find use in industrial practice in the following way: (1) by replacing the fixed grained bed in the existing reactors with a monolithic catalyst, (2) by supplementing the design of the existing reactors with an additional monolithic reactor, and (3) by creating separate monolithic reactors. Presum-

ably, the first way can only be followed with strong limitations. The main obstacle is that the loads by the gas and fluid are different. The slug flow with intense mass transfer requires that the fluid flow velocity should be comparatively high (no less than 0.1 m s^{-1}), whereas trickle-bed reactors operate at a velocity of about 0.01 m s^{-1}. In the case of hydrogenation reactions requiring an excess of hydrogen, the slug flow mode can hardly be used, since an insufficient amount of hydrogen may be present in the mixture because of the small gas/fluid flow rate ratio. This flow mode is advantageous if the component being hydrogenated has a low concentration and a high process selectivity should be achieved.

Another interesting application opportunity furnished by the good mass-transfer characteristics of the monolithic reactor is associated with catalytic reactions in fluid–fluid and gas–fluid–fluid systems with two mutually insoluble fluids. Operation of the reactor in the film mode, which is similar to the trickle mode in a reactor with a fixed grained bed, could be its additional possible application. However, the problems of film flow have been studied by only few researchers. Moreover, a uniform distribution of the gas and fluid over the cross section of the monolith is much more difficult to be achieved in this mode [30]. Replacement of the grained catalyst with a monolithic one requires a new organization of the process.

Monolithic reactors may become an efficient supplement to reactors with a suspended catalyst, whose life in the industrial practice was short. Thus, a monolithic catalyst can replace the suspended one. The necessary additional equipment may have the form of a reactor with a fixed bed (monolith) or an impeller with monoliths fixed on it, or a reactor with a differential circulation contour (reactor with a fixed catalyst bed and recycled liquid components) [70]. An additional advantage in this case is that a catalyst can be rapidly replaced, which is particularly important at a short operation cycle characteristic of, e.g., pharmaceutical industry. This concept allows a simple reconstruction of the existing reactors with a suspended catalyst, which leads to an economically efficient increase in the output capacity of the existing production facilities and to a predictable financial risk: replacement of a suspended catalyst in a reactor with an external monolith can diminish the reconstruction expenditure even at a preserved output capacity.

4. CONCLUSION

The results of studies published before August 2005 suggest that monolithic reactors can find wide application. However, numerous fine processes mentioned in the review are rather complex and insufficiently understood, which hinders optimization of this kind of reactors. It was also demonstrated that, as regards processes intensification, the monolithic reactor is rather promising because it has a high output capacity, high selectivity, low pressure loss, and a number of design advantages over the conventional types of multiphase reactors. It should be admitted that, at present, there is deficiency of data obtained on semicommercial installations, which could open up new application fields. This is mostly due to the excess output capacity of the existing large installations and insufficient preparedness of industrial managers to take a certain risk. It can be predicted with confidence that monolithic reactors can very soon be successfully used in manufacture of expensive products in fine chemical technology and pharmaceutics, where the production process is small-tonnage and can be readily reconstructed. Long-term planning should be oriented to use of these reactors also in the Fischer–Tropsch synthesis for manufacture of synthetic fuels from natural gas, as well as in the presently evolving biotechnology, in which new methods of deep substance conversion will be developed.

ACKNOWLEDGMENTS

The authors thank the Rossendorf Research Center (Forschungszentrum Rossendorf) for the support of videographic studies of the two-phase flow in capillaries, Corning Inc. for provision of monoliths in connection with an interesting technical discussion, and Prof. Dr. Muthanna Al-Dahhan and Dr. Shaibal Roy from Washington University in St. Louis for helpful discussion in the course of preparation of this review.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Effect of Mechanochemical Activation on the Synthesis and Sintering of Solid Solutions Based on ZrO_2

Received December 19, 2005; in final form, April 2006

Abstract—The effect of mechanochemical activation on the synthesis of tetragonal solid solutions in the systems ZrO_2–Y_2O_3 and ZrO_2–Y_2O_3–CeO_2 and also the possibility of preparing the substances in amorphous and nanocrystalline states were studied.

DOI: 10.1134/S1070427206070020

Achievements of the last decade in the field of ceramics processing and sintering theory clearly show that the possibilities for the development of new ceramic materials based on oxides and their compounds are far from being exhausted. Presently there is an increased interest in ultradispersed powders (particle size up to 150 nm) in the processing of structural ceramics, caused by their high activity allowing compact products to be obtained at relativelly low sintering temperatures (1400°C).

Structural ceramics based on partially stabilized zirconium dioxide belongs to new advanced kinds of ceramics with a unique combination of properties: high melting point, reagent and corrosion resistance, high hardness and strength, resistance to thermal shock, and low thermal conductivity [1].

To obtain ultradispersed powders, precursors of stabilized zirconium dioxide, chemical methods of synthesis (coprecipitation [2–5], decomposition of solutions by evaporation [6, 7], and the sol–gel method [8–10]) are widely used.

The sol–gel method and chemical precipitation make it possible to synthesize nanopowders (3–5 nm) of stabilized ZrO_2; however, these methods are rather labor- and time-consuming; they and also require special research and a choice of optimal conditions for each particular system. Such powders tend to form many-particle agglomerates negatively affecting the densification in the course of compaction and sintering of ceramic materials.

At present the method of mechanochemical activation (MA) is used to accelerate syntheses of solid solutions and compounds in oxide systems, and also to prepare ultradispersed powders. This method is highly competitive with liquid-phase synthetic methods and allows chemical processes to be performed at relatively low temperatures when the formation of a perfect crystal structure is complicated. This opens up a way to the synthesis of substances in nanocrystalline and amorphous states. The MA method is characterized by simplicity and low cost; thus, it can be considered as an alternative to modern chemical synthetic methods.

Its essence consists in carrying out solid-phase reactions in grinding devices (mills and disintegrators). A joint mechanical treatment leads to crushing and plastic deformation of substances, acceleration of mass transfer, and efficient mixing of the components. The mean particle size of ceramic materials obtained by MA is as small as 30–150 nm at a contamination of no more than 0.05 wt %; the advantages of the solid-phase synthesis in this case are preserved [11].

The aim of this work was to study the effect the mechanochemical activation on the synthesis and sintering of the tetragonal solid solutions $(ZrO_2)_{0.97} \cdot (Y_2O_3)_{0.03}$ and $(ZrO_2)_{0.92}(Y_2O_3)_{0.03}(CeO_2)_{0.05}$ and to prepare compact ceramic materials based on them.

EXPERIMENTAL

Zirconium, yttrium, and cerium nitrates: $ZrO \cdot (NO_3)_2 \cdot nH_2O$ (analytically pure grade), $Y(NO_3)_3 \cdot 6H_2O$ (chemically pure grade), and $Ce(NO_3)_3 \cdot 5H_2O$ (analytically pure grade) were chosen as starting reagents for the study.

The use of hydrated nitrates is caused by the fact that their hardness is several times lower than that of the anhydrous compounds, which allows us to reduce

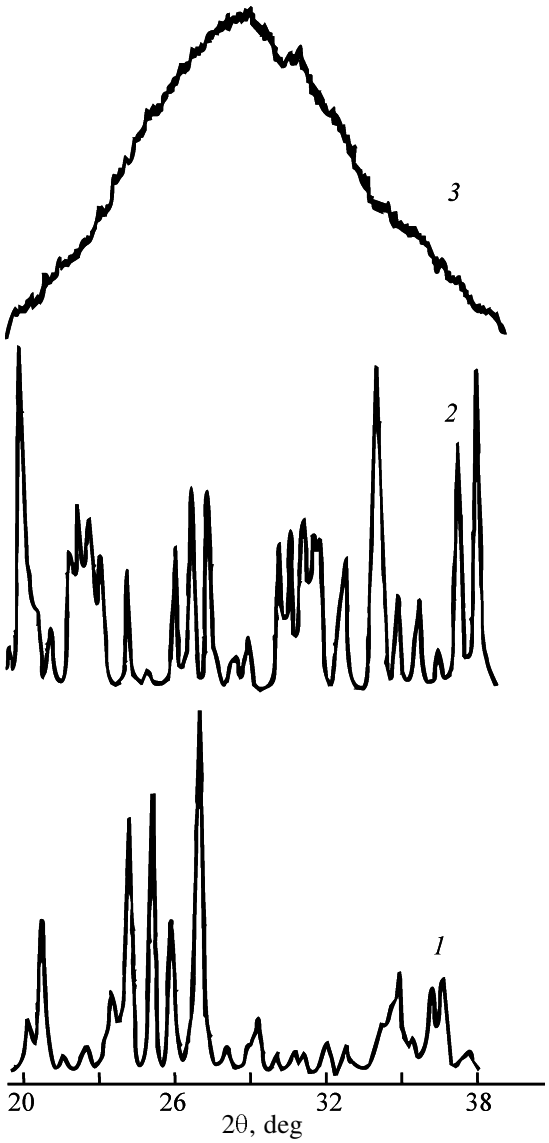

Fig. 1. X-ray patterns of the starting reagents (*1*) $ZrO(NO_3)_2 \cdot nH_2O$, (*2*) $Y(NO_3)_3 \cdot 6H_2O$, and (*3*) MA powder with the stoichiometric composition $ZrO_2 : Y_2O_3 = 97 : 3$ (the pattern for the ZrO_2–Y_2O_3–CeO_2 system is similar). (2θ) Bragg angle; the same for Figs. 2, 4, and 5.

the mechanical load and to avoid the contamination of the resulting products by the material of milling balls.

The mechanochemical activation of powder mixtures with specified stoichiometric contents of oxides in the systems ZrO_2–Y_2O_3 and ZrO_2–Y_2O_3–CeO_2 was carried out on a Fritsch planetary mill in electrocorundum beakers (with Al_2O_3 balls as a milling material) in air. It should be noted that all the starting reagents were preliminarily heat-treated at 100°C to remove water adsorbed on the surface of crystal hydrates (as shown by the gravimetric analysis, the water loss is approximately 10–12%) and to avoid sticking of activated salts on the beaker walls and milling balls. The duration of the mechanical treatment was 1, 2, and 4 h.

During MA, particles of salts were exposed to impacts and frictional forces; the dose of the absorbed energy varied from 5 to 20 kJ mol^{-1}.

Powder X-ray phase analysis of samples was carried out on a Siemens D-500/HS diffractometer in the range of angles 2θ 15°–65° at room temperature in air using CuK_α radiation and a nickel filter. The scanning rate was 1 deg min^{-1}.

The average size of crystallites of the forming phases was calculated from the X-ray diffraction data. The X-ray patterns obtained in the digital form were processed with a WINFIT 1.2.1. program [12] using the Fourier transform of peak profiles. For the calculation we chose the diffraction peak (111) of the ZrO_2 phase, whose profile was preliminarily corrected for instrumental distortion and approximated by Voigt's pseudo-function [13].

The differential thermal analysis (DTA) was carried out on a Q-1000 derivatograph (MOM, Hungary) in air in the range 20–800°C.

The heat treatment of samples under study was carried out in a Silit furnace with silicon carbide (SiC) heaters in the range 400–1500°C. Depending on the sintering temperature, the heating rate varied from 350 to 450 deg h^{-1}.

The ceramic samples were examined by electron microscopy using the method of cellulose–coal replicas. The replicas were taken from the surface of fresh chips of the samples. Morphological studies were carried out on an EM-125 transmission electron microscope at an accelerating voltage of U = 75 kV.

The apparent density and open porosity were determined in accordance with GOST (State Standard) 473.4–81 [14]. The relative density of samples ρ (%) was calculated by the formula $\rho = \rho_a/\rho_0$, where ρ_a is the apparent density (g cm^{-3}) and ρ_0 is the theoretical density calculated from the X-ray data. The Vickers microhardness H_V was determined with a PMT-3 microhardness meter [15]. The procedure of the determination of the critical coefficient of stress intensity, crack resistance K_{IC}, of the samples has been described in [16].

Structural transformations resulting from MA in a mixture of nitrates were monitored by X-ray phase analysis. We found that, as the mechanical treatment duration increases (from 1 to 4 h), starting components are gradually destroyed and X-ray amorphous phases are formed in the systems (Fig. 1).

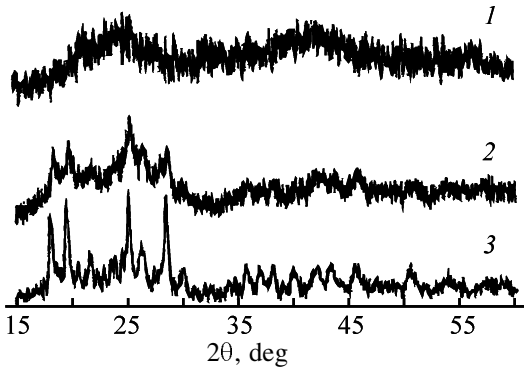

Fig. 2. Effect of air (20°C) on the structure of fresh MA powder. Contact duration (h): (*1*) 0, (*2*) 1, (*3*) 2, and (*4*) 4.

A study of the behavior of fresh mechanically activated powders in certain oxide systems by IR and ESR spectroscopy [11, 17, 18] revealed the appearance of vibrationally and electronically excited states of interatomic bonds, formation of radical ions, and ionization of particles. The authors have concluded that the valence-unsaturated bonds arising during the mechanochemical activation enhance the reactivity of MA powders.

An X-ray phase analysis we made in this study revealed structural changes in the ZrO_2–Y_2O_3 and ZrO_2–Y_2O_3–CeO_2 systems on contact of fresh MA powders with air. Apparently, valence-unsaturated bonds arising upon the mechanical activation initiate the uptake of oxygen, carbon oxides, and H_2O vapor from air, which results in the disappearance of the X-ray amorphous phase and formation of new crystalline phases (Fig. 2). Therefore, it is necessary to make the time interval between the MA process and the use of activated powders as short as possible.

The thermal decomposition of the MA powders in the range 20–500°C was studied by differential thermal analysis. The DTA curves for MA powders in the ZrO_2–Y_2O_3–CeO_2 system before the activation and after the mechanical treatment for 1, 2, and 4 h are shown as an example in Fig. 3.

In each of the DTA curves two characteristic effects are detected: an endothermic dehydration effect and an exothermic effect caused by transformation of the MA powder from the X-ray amorphous to crystalline state.

The DTA data show that both the MA process proper and its duration affect the thermal decomposition of MA powders. The shift of the endothermic peaks to lower temperatures is attributable to the fact that the increase in the duration of the mechanical treatment weakens the bonds between the molecules of nitrates and water of crystallization, which, in turn,

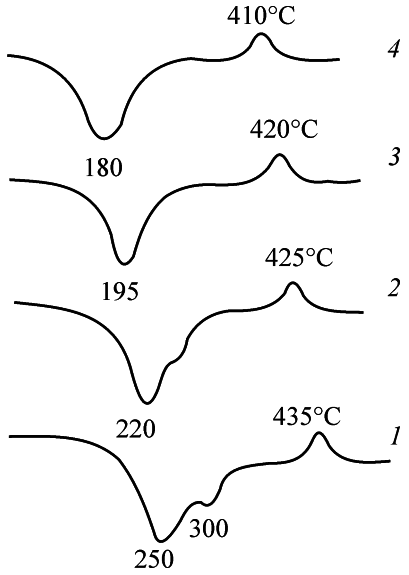

Fig. 3. DTA curves of MA powder of the stoichiometric composition $ZrO_2 : Y_2O_3 : CeO_2 = 92 : 3 : 5$ in the range 20–500°C. Mechanical treatment duration (h): (*1*) 0, (*2*) 1, (*3*) 2, and (*4*) 4.

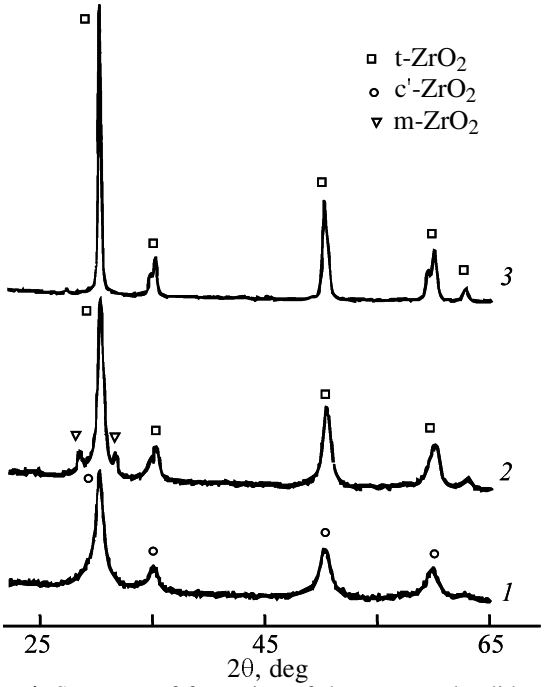

Fig. 4. Sequence of formation of the tetragonal solid solution based on ZrO_2 for the ZrO_2–Y_2O_3 and ZrO_2–Y_2O_3–CeO_2 systems. Calcination temperature, °C: (*1*) 400, (*2*) 800, and (*3*) 1300.

facilitates the dehydration of MA powders. It was found by X-ray phase analysis that the exothermic effects in the DTA curves in the range 400–430°C correspond to the crystallization of solid solutions based on ZrO_2 in the cubic metastable modification (c'-ZrO_2) (Fig. 4). As the duration of the mechanical

Average size of crystallites d, relative density ρ_a/ρ_0, open porosity P, microhardness H_V, and crack resistance K_{IC} of the solid solutions $(ZrO_2)_{0.97}(Y_2O_3)_{0.03}$ and $(ZrO_2)_{0.92}(Y_2O_3)_{0.03}(CeO_2)_{0.05}$ in the range 1200–1500°C

Sample	T, °C	d, nm	ρ_a/ρ_0, %	P, %	H_V, GPa	K_{IC}
$(ZrO_2)_{0.97}(Y_2O_3)_{0.03}$	1200*	81	97	3	10	5
	1300	95	98.5	<1	12	6
	1400	110	97.5	3	10	–
$(ZrO_2)_{0.92}(Y_2O_3)_{0.03}(CeO_2)_{0.05}$	1300*	98	95	5.5	–	–
	1400	115	99	1	11	14
	1500	133	98	1.5	10	13

* Temperature of the formation of t-ZrO_2 single-phase solid solutions.

treatment increases, the temperature at which the phase of the stabilized ZrO_2 solid solution is formed decreases by 25°C, owing to increased reactivity of MA powders [11]. The average size of the crystallites of this phase is 8–10 nm (calculated by the Fourier transform method).

According to the X-ray data, at temperatures above 500°C the c'-ZrO_2 solid solution transforms into the tetragonal modification (t-ZrO_2), as indicated by splitting of the diffraction maxima in the range 2θ = 34°–36° (Fig. 5).

The average size of t-ZrO_2 crystallites at 600°C is 15 nm for the $(ZrO_2)_{0.97}(Y_2O_3)_{0.03}$ solid solution and 20 nm for the $(ZrO_2)_{0.92}(Y_2O_3)_{0.03}(CeO_2)_{0.05}$ solid solution.

Figure 4 shows the sequence of formation of the tetragonal solid solutions $(ZrO_2)_{0.97}(Y_2O_3)_{0.03}$ and $(ZrO_2)_{0.92}(Y_2O_3)_{0.03}(CeO_2)_{0.05}$. When MA powders are heat-treated at temperatures above 600°C, a small amount (~9–10%) of the monoclinic phase (m-ZrO_2) is detected in the X-ray patterns. This phase coexists with the t-ZrO_2 phase in a wide temperature range, up to 1000–1100°C. At 1200°C and higher temperatures, single-phase solid solutions based on t-ZrO_2 are formed. The half-width of diffraction maxima corresponding to the t-ZrO_2 phase decreases in the range 600–1200°C, which indicates that the average size of crystallites of this phase increases (from 15 to 85 nm).

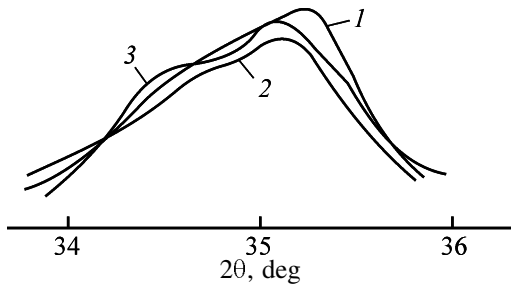

Fig. 5. Fragments of the X-ray pattern of a solid solution based on ZrO_2, sintered at (*1*) 500, (*2*) 550, and (*3*) 600°C.

We studied sintering of tetragonal solid solutions in the ZrO_2–Y_2O_3 and ZrO_2–Y_2O_3–CeO_2 systems using samples in the form of pellets (d = 12 mm and h = 4 mm) prepared by semidry pressing at 150 MPa of MA powders preliminarily heat-treated at 450°C. A 10% aqueous solution of polyvinyl alcohol was used as a binding agent. The calcination was carried out in the range 1200–1500°C; the duration of isothermal heating at each temperature was 2 h. Characteristics of the tetragonal solid solutions in the ZrO_2–Y_2O_3 and ZrO_2–Y_2O_3–CeO_2 systems are presented in the table.

The table shows that the densest samples of the $(ZrO_2)_{0.97}(Y_2O_3)_{0.03}$ and $(ZrO_2)_{0.92}(Y_2O_3)_{0.03}\cdot(CeO_2)_{0.05}$ solid solutions were obtained at 1300 and 1400°C, respectively.

We have studied the microstructure of sintered samples by transmission electron microscopy. We found that the microstructure of the ceramic sample of $(ZrO_2)_{0.97}(Y_2O_3)_{0.03}$ (T = 1300°C) is characterized by close packing of well developed crystalline grains with a smooth surface (Fig. 6a). As the temperature is increased to 1400°C, small cracks appear on intercrystallite boundaries (Fig. 6b). An electron-microscopic examination shows that 1300°C is the optimal temperature for sintering of dense ceramic materials based on the $(ZrO_2)_{0.97}(Y_2O_3)_{0.03}$ solid solution. Properties of the ceramics sintered at this temperature are better compared to 1400°C (see table).

The microstructure of samples of the $(ZrO_2)_{0.92}\cdot(Y_2O_3)_{0.03}(CeO_2)_{0.05}$ solid solution was studied similarly. We found that these ceramic materials reach a high degree of sintering at 1400°C, whereas at 1500°C cracks are formed, affecting the porosity of samples, their microhardness, and crack resistance (see table).

To sum up, we can conclude that the mechanochemical activation provides efficient mixing of the

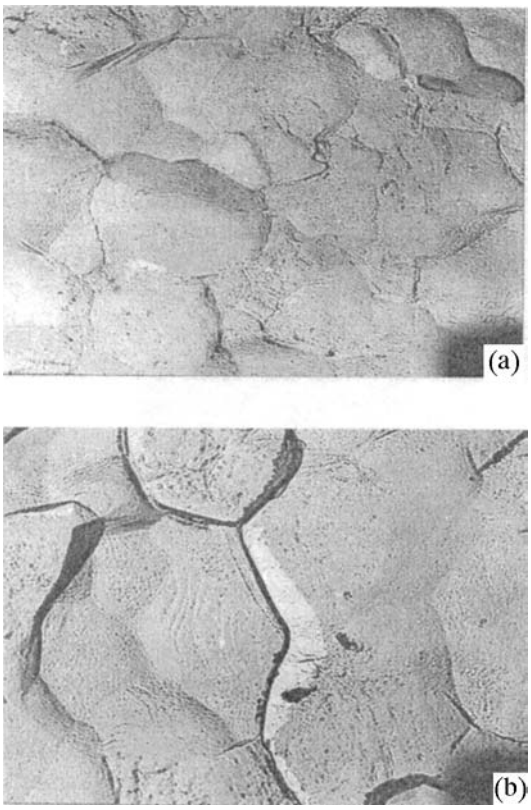

Fig. 6. Microstructure of a sample of the $(ZrO_2)_{0.97} \cdot (Y_2O_3)_{0.03}$ solid solution sintered at (a) 1300 and (b) 1400°C. Magnification 40000.

reactants in the ZrO_2–Y_2O_3 and ZrO_2–Y_2O_3–CeO_2 systems and enhances their reactivity; it allows preparation of precursor powders based on zirconium dioxide in the nanocrystalline state (particle size as small as 10 nm); it intensifies sintering of solid solutions based on ZrO_2, increases their phase stability, and allows preparation at 1200–1400°C of dense ceramic materials based on the tetragonal solid solution of zirconium dioxide.

CONCLUSIONS

(1) Mechanochemical activation extends the potential of the standard ceramic method and makes it possible to synthesize ceramic materials with specified properties under milder conditions.

(2) The particle size of the resulting ceramic materials varies from 10 to 130 nm in the range 400–1500°C.

(3) Studies in the field of the mechanochemical synthesis of oxide materials allow us to develop and improve the mechanonochemical ceramic technology, which can be incorporated in complex processes when necessary.

INORGANIC SYNTHESIS AND INDUSTRIAL INORGANIC CHEMISTRY

Extraction of Ce(III) with Naphthenic Acid from Nitrate Solutions

D. E. Chirkst, T. E. Litvinova, V. S. Starshinova, and V. I. Kuchina

St. Petersburg State Mining Institute, St. Petersburg, Russia

Received November 2, 2005; in final form, February 2006

Abstract—Extraction of Ce(III) with naphthenic acid from nitrate solutions was studied. The composition of solvation complexes, extraction constants, and Gibbs energies of extraction were found from the dependences of the distribution coefficients on pH and compositions of the aqueous and organic phases.

DOI: 10.1134/S1070427206070032

Tri-*n*-butyl phosphate (TBP) is a traditional extractant for recovery of rare-earth metals (REM) from nitrate media. However, leaching with sulfuric [1] and hydrochloric acids [2] is usually used for processing of lean and technogenic raw materials. In these media, REM mainly exist in the form of charged complexes $[M(An)_z]^{3-zx}$, where An is an acid residue and x, its charge (x = 1 or 2) [3]. In this case, TBP is inefficient for REM recovery and separation [4], and ion-exchange extractants, e.g., carboxylic acids (in particular, oleic) are widely used [5].

Previously, we studied extraction of Ce(III) with naphthenic acid [6]. The goal of this study is detailed examination of the extraction within the pH 3–5 range and more precise elucidation of the extraction equation. At pH > 5, the system represents a difficultly settling emulsion.

Cerium(III) extraction was studied using model aqueous solutions with a Ce(III) content of 0.01 mol kg^{-1}, which corresponds to the concentration of hydrometallurgical solutions of REM extractive recovery from lean or technogenic raw materials. The solution of naphthenic acid in dodecane was used as extractant. The average molar weight of the naphthenic acid fraction studied was 226 g mol^{-1}, and the acid dissociation constant pK_d = 5.1 [7].

The cerium(III) concentration in the equilibrium aqueous phase and in the initial solution was determined photometrically with Arsenazo III [8].

The Ce(III) content in the organic phase was determined as the difference between the concentrations in the initial and equilibrium aqueous phases with regard to the difference in the phase volumes (or weights):

$$c_{org} = [(c_0 - c_{aq})m_{aq}]/m_{org}, \quad (1)$$

where c_{org} and c_{aq} are the equilibrium concentrations of the metal ions in the organic and aqueous phases, respectively (mol kg^{-1}); c_0, initial REM content in the aqueous phase (mol kg^{-1}); m_{aq}/m_{org}, weight ratio of the aqueous and organic phases, which was 40 : 2.6 at the organic phase density of 0.86 ± 0.01 g cm^{-3}.

The distribution coefficient was calculated by the formula

$$D = c_{org}/c_{aq}. \quad (2)$$

Within the framework of our goals, we measured the dependences of the Ce(III) distribution coefficient on pH of the aqueous phase at a constant concentration of naphthenic acid, 0.5 M (Table 1), and on

Table 1. Cerium(III) distribution coefficient D_{Ce} at various pH. Initial Ce(III) concentration 0.014 mol kg^{-1}

0.2	2.17	2.55	11.55
0.25	1.83	3.45	18.85
0.5	2.86	11.69	40.9

the naphthenic acid concentration at a constant pH (Table 2).

In separate experiments, we showed that nitrate ions are not incorporated in the extractable solvate. Therefore, the extraction reaction is as follows:

$$M^{3+}_{aq} + zH_2O + (3 - z)R^-_{org} \rightleftarrows M(OH)_zR_{(3-z)org} + zH^+_{aq}, \quad (3)$$

where R^- is naphthenate ion.

The equilibrium constant is

$$K = \frac{a_{Ce^{3+}_{org}} a^z_{H^+_{aq}}}{a_{Ce^{3+}_{org}} a^{3-z}_{R^-_{org}}} = \frac{\gamma_{\pm org} c_{Ce^{3+}_{org}} a^z_{H^+_{aq}}}{\gamma_{\pm aq} c_{Ce^{3+}_{org}} \gamma^{3-z}_{\pm org} [R^-]^{3-z}_{org}}$$
$$= \frac{c_{org} a^z_{H^+_{aq}}}{c_{aq}\gamma_{\pm aq}[R^-]^{3-z}_{org}} = \frac{D a^z_{H^+_{aq}}}{\gamma_{\pm aq}[R^-]^{3-z}_{org}}, \quad (4)$$

where $\gamma_{\pm aq}$ is the mean ionic activity coefficient of Ce^{3+} in the equilibrium aqueous phase.

The equilibrium concentration of cerium(III) nitrate in the aqueous phase was 0.0030 ± 0.0016 mol kg^{-1}, and the ionic strength, 0.018 ± 0.010 mol kg^{-1}. The activity coefficient was taken equal to that for lanthanum chloride at an ionic strength of 0.70 ± 0.05 [9]. Then, $\log \gamma_{\pm aq} = -0.16 \pm 0.03$. The mean ionic activity coefficient of the component in the organic phase was taken equal to unity because of the use of a nonpolar solvent (dodecane). The concentration of naphthenic acid anions $[R^-]^{3-z}_{org}$ depends on pH:

$$[R^-]^{3-z}_{org} = [HR]K_d/a_{H^+}, \quad (5)$$

where K_d is the dissociation constant of naphthenic acid.

The concentration of the nondissociated acid species is

$$[HR] = c_{extr} - (3 - z)c_{org} - [R^-]^{3-z}_{org}, \quad (6)$$

where c_{extr} is the total concentration of the extractant in the organic phase and c_{org}, REM concentration in the organic phase.

Dissociation of naphthenic acid can be considered as a heterogeneous process described by the equation

$$HR_{org} \rightleftarrows H^+_{aq} + R^-_{org}, \quad (7)$$

because H^+ cations are hydrated and completely pass into the aqueous phase, whereas the hydrophobic molecules of nondissociated acid and acid anions remain in the organic phase. Nominally, this process can be considered as a sum of the following equilibria:

$$HR_{org} \rightleftarrows HR_{aq}, \quad (8)$$

whose equilibrium constant is $k_8 = [HR]_{aq}/[HR]_{org}$, i.e., is inversely proportional to the distribution coefficient of naphthenic acid between dodecane and aqueous phase, D^{-1}_{HR}.

$$HR_{aq} \rightleftarrows H^+_{aq} + R^-_{aq}. \quad (9)$$

The equilibrium constant of this process is the dissociation constant of naphthenic acid in the aqueous phase.

$$R^-_{aq} \rightleftarrows R^-_{org}. \quad (10)$$

The equilibrium constant of process (10) is the distribution coefficient of naphthenate anion D_{R^-}.

Thus, the equilibrium constant of heterogeneous process (7) is

$$K = (K_d D_{R^-})/D_{HR} \cong K_d. \quad (11)$$

The distribution coefficients of naphthenic acid and naphthenate anion can be considered to be approximately equal, because, in accordance with Duclot–Traube rule, the hydrophobicity is determined by the organic radical.

The concentration of naphthenic acid anions depends on pH as follows:

$$[R^-]_{org} = [HR]_{org}K_d/a_{H^+_{aq}}, \quad (12)$$

where K_d is the dissociation constant of naphthenic acid, and the concentration of nondissociated naphthenic acid in the organic phase is

$$[HR]_{org} = c_{extr} - (3 - z)c_{org} - [R^-]_{org}, \quad (13)$$

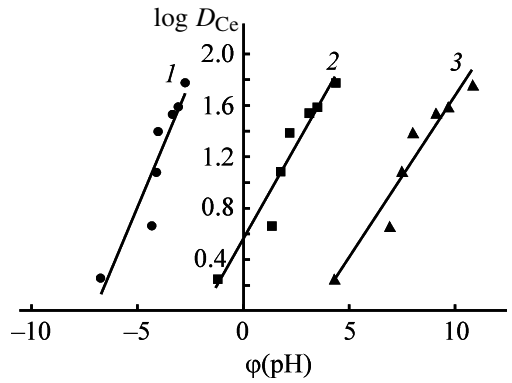

Fig. 1. Logarithm of Ce(III) distribution coefficient $\log D_{Ce}$ vs. the function of pH. Solvation number z: (*1*) 0, (*2*) 1, and (*3*) 2.

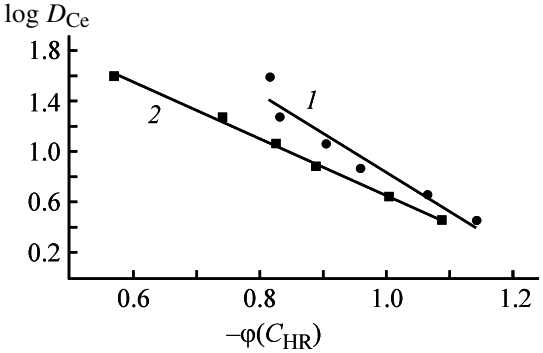

Fig. 2. Logarithm of Ce(III) distribution coefficient $\log D_{Ce}$ vs. the function of extractant concentration $\varphi(c_{HR})$ at z (*1*) 0 and (*2*) 1.

where c_{extr} is the total concentration of the extractant in the organic phase, and c_{org}, REM concentration in the organic phase.

Thus, naphthenate bound into the solvate complex was considered. The equilibrium concentration of free naphthenate anion in the organic phase was determined by combined solution of Eqs. (12) and (13):

$$[R^-]_{org} = [c_{extr} - (3 - z)c_{org}](1 + a_{H^+_{aq}}/K_d)^{-1}. \quad (14)$$

After substitution in Eq. (4), we obtain

$$K = \frac{D a^z_{H^+_{aq}} (1 + a_{H^+_{aq}}/K_d)^{3-z}}{\gamma_\pm [c_{extr} - (3 - z)c_{org}]^{3-z}}. \quad (15)$$

The logarithm of the distribution coefficient is

$$\log D = \log K + z\text{pH} - (3 - z)\log(1 + a_{H^+_{aq}}/K_d)^{3-z} + (3 - z)\log[c_{extr} - (3 - z)c_{org}] + \log\gamma_\pm. \quad (16)$$

The dependences of $\log D$ on the argument

$$\varphi(\text{pH}) = z\text{pH} + (3 - z)\log[c_{extr} - (3 - z)c_{org}] - (3 - z)\log(1 + a_{H^+_{aq}}/K_d) \quad (17)$$

for various probable values of the solvation number z were plotted using data of Table 1 (Fig. 1).

For cerium(III) these dependences are linear at z 0–2 and in accordance with Eq. (16) are described by the equations

$$\log D = 0.4\varphi(\text{pH}) + 2.75 \quad (z = 0), \quad (18)$$

$$\log D = 0.3\varphi(\text{pH}) + 0.56 \quad (z = 1), \quad (19)$$

$$\log D = 0.25\varphi(\text{pH}) - 0.83 \quad (z = 2), \quad (20)$$

with the correlation coefficient $R^2 = 0.93$.

The constants of the extraction equilibrium and Gibbs energies were calculated using the absolute term of Eqs. (18)–(20) with regard to Eq. (16):

$$\log K = 2.75 \ (z = 0), \ \Delta_r G = -15.7 \text{ kJ mol}^{-1};$$

$$\log K = 0.56 \ (z = 1), \ \Delta_r G = -3.2 \text{ kJ mol}^{-1};$$

$$\log K = -0.83 \ (z = 2), \ \Delta_r G = 4.7 \text{ kJ mol}^{-1}.$$

For $z = 2$, the constant of the extraction equilibrium and Gibbs energy contradict the experimental data (fairly high distribution coefficient), so this model is inadequate.

Cerium can be extracted in the form of both Ce^{3+} cations and $CeOH^{2+}$ hydroxo complexes. In this case, the slope of the logarithmic dependence of the Ce(III) distribution coefficient on the function of the extractant equilibrium concentration $\varphi(c_{HR}) = \log[c_{extr} - (3 - z)c_{org}]$ should be equal to 3 (for $z = 0$) or 2 (for $z = 1$). These dependences are shown in Fig. 2 for z 0 and 1.

As seen, linear dependences are observed for both cases and are described by the equations

$$\log D = 3.9\varphi(c_{HR}) + 3.1 \text{ at } zG = 0, \quad (21)$$

$$\log D = 2.2\varphi(c_{HR}) + 2.9 \text{ at } zG = 1, \quad (22)$$

with $R^2 = 0.95$.

For $z = 0$, the slope does not correspond to the model taken. For $z = 1$, the slope corresponds to the model; however, the logarithm of the equilibrium constant [calculated from the absolute term of the dependence in accordance with Eq. (16)] and Gibbs energy $\log K = -13$ ($z = 1$) and $\Delta_r G = 7.4$ kJ mol^{-1}

contradict experimental data (fairly high distribution coefficient).

Therefore, we suggested that both Ce(III) species participate in the extraction in proportion with their content in the equilibrium aqueous phase:

$$[CeOH]^{2+}_{aq} + H_2O + 2R^-_{org} = CeOHR_{2org} + H^+_{aq}, \quad (23)$$

$$Ce^{3+}_{aq} + 3R^-_{org} = CeR_{3org}. \quad (24)$$

The IR spectra of Ce(III) extracts (Table 3) confirmed the existence of $CeOHR_2$ species in the organic phase (bands at 1400–1500 cm^{-1} are observed, which, in accordance with [10–12], belong to OH groups in the metal complex; they are absent in the spectrum of naphthenic acid).

Mathematical simulation with various z within the range 0–1 gave the best results for $z = 0.67$ (Figs. 3 and 4).

The dependences shown in Figs. 3 and 4 are described by the following equations, for which the logarithms of the equilibrium constants and the Gibbs energies were calculated from the absolute terms:

$$\log D = 0.35\varphi(pH) + 1.31, \ \log K = 1.31,$$

$$\Delta_r G = -7.47 \text{ kJ mol}^{-1}; \quad (25)$$

$$\log D = 2.43\varphi(pH) + 3.14, \ \log K = 1.04,$$

$$\Delta_r G = -5.93 \text{ kJ mol}^{-1}. \quad (26)$$

Thus, the thermodynamic parameters of Ce(III) extraction with naphthenic acid obtained by two independent methods are satisfactorily consistent with each other. The average values of the extraction constant and Gibbs energies are $K_{extr} = 1.18$ and $\Delta_{extr}G = -6.7$ kJ mol^{-1}, respectively.

The overall equation of Ce(III) extraction with naphthenic acid can be represented as follows:

$$Ce^{3+}_{aq} + 0.67H_2O + 2.33R^-_{org} \rightleftarrows CeOH_{0.67}R_{2.33org} + 0.67H^+_{aq}. \quad (27)$$

With regard to the thermodynamic characteristics of Ce(III) hydrolysis, for which the Gibbs energy $\Delta_h G$ calculated from reference data [13] is 53.98 kJ mol^{-1}, the Gibbs energy of solvation can be calculated as the difference between the Gibbs energies of extraction and hydrolysis with regard to the slope of the dependence $\log D = \varphi(pH)$: $\Delta_{solv}G = \Delta_{extr}G - 0.67\Delta_h G = -36.2 \pm 1.7$ kJ mol^{-1}.

Table 3. IR spectra of naphthenic acid and cerium naphthenate

Naphthenic acid		Cerium naphthenate	
ν, cm^{-1}	optical density	ν, cm^{-1}	optical density
1080	0.1	1076	0.2
1200	0.09	1263.7	0.36
1300	0.22	1310.1	0.47
1410	0.1	1373.4	0.91
1700	0.88	1424.1	1.64
2370	0.1	1470.5	0.78
2660	0.2	1546.4	1.7
2850	2.13	1685.6	0.42
2870	2.1	1732.1	0.11
2900	2.05	2680	0.19
2950	1.75	2732.1	0.23
		2852.3	0.46

The results obtained are compared in Table 4 with the data on cerium(III) nitrate extraction with a 20% solution of tributyl phosphate (TBP) in *o*-xylene, a 0.5 M solution of trialkylbenzylammonium nitrate

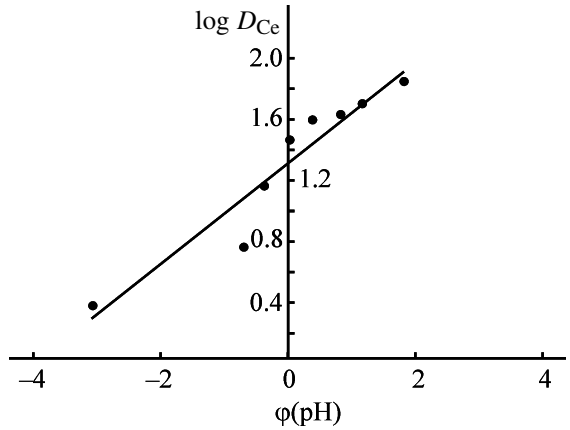

Fig. 3. Logarithm of Ce(III) distribution coefficient $\log D_{Ce}$ vs. the function of pH at $z = 0.67$.

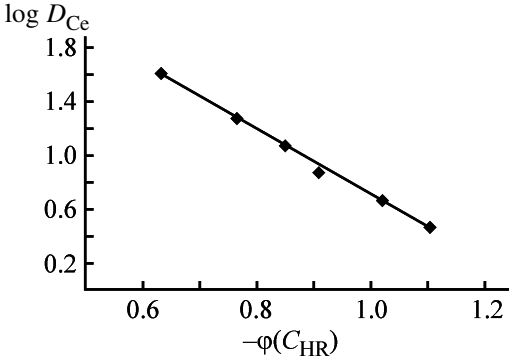

Fig. 4. Logarithm of Ce(III) distribution coefficient $\log D_{Ce}$ vs. the a function of extractant concentration $\varphi(c_{HR})$ at $z = 0.67$.

Table 4. Comparison of parameters of Ce(III) extraction with various extractants

Extractant	pH	D	$-\Delta_r G^0_{298}$, kJ mol^{-1}
TBP [4]	5	9.0 ± 0.4	5.92 ± 0.03
TABAN [3]	3	35 ± 4	8.9 ± 0.3
Oleic acid	5	100 ± 3	58.6 ± 1.7
Naphthenic acid	5	39 ± 0.5	36.2 ± 1.3

(TABAN), and a 0.5 M solution of oleic acid in dodecane.

As seen, the Ce(III) extraction from nitrate solutions at pH 5 is the most efficient when oleic or naphthenic acid is used as extractant. This fact confirms the existence of Ce(III) at such pH as positively charged hydroxo complexes. In the more acidic media (pH 3), Ce(III) exists in the form of negatively charged anionic complexes, which ensures its preferred extraction with salts of quaternary ammonium bases.

CONCLUSIONS

(1) Extraction of cerium(III) with carboxylic acids from nitrate solutions is the most efficient at pH of formation of metal hydroxo complexes.

(2) The extraction involves transfer of Ce^{3+} and $[Ce(OH)]^{2+}$ cations into the organic phase in the 1 : 2 molar ratio.

(3) The equilibrium constant and Gibbs energy of solvation of these species were determined.

Abstract—The hydrolysis of graphite hydrosulfate prepared in the system aqueous solution of sodium dichromate–sulfuric acid was studied, and the composition of gases evolving from the solid phase during the hydrolysis was determined. The effects of the duration of the graphite hydrosulfate hydrolysis on the expansion factor and also on the morphology and particle size of the final product, residual graphite hydrosulfate, was studied.

DOI: 10.1134/S1070427206070044

A highly efficient procedure for preparing residual graphite hydrosulfate (RGH) has been developed previously [1]. This procedure involves successive treatment of natural flaky graphite with a saturated aqueous solution of sodium dichromate and concentrated sulfuric acid, hydrolysis of the resulting graphite hydrosulfate (GH), washing of the final product with water, and drying at 100–110°C. This procedure allows preparation of high-quality RGH at the total consumption of reagents in the stage of graphite oxidation of about 60–80 wt % relative to graphite. The resulting product effectively expands at a relatively low temperature (400–500°C), it is characterized by low values of the sulfur content (1.5–1.0 wt %) and pH of the aqueous extract (2.5–3.5). In previous studies the main attention was paid to the influence of conditions of graphite oxidation on the thermal properties of the final product, though it was noted that conditions of the oxidized graphite hydrolysis also exert a substantial effect.

In this study we examined changes in the morphology of GH particles as a result of their treatment with water and the influence of hydrolysis conditions on the properties of the final product (RGH).

We used in the experiments GSM-1 grade natural flaky graphite (Zaval'e, Ukraine) with ash content of about 0.1 wt % with the average particle size of 0.200–0.315 mm, a 67.7 wt % aqueous solution of sodium dichromate, and concentrated chemically pure grade sulfuric acid (concentration 95.8 wt %).

The synthesis of RGH was carried out at room temperature in a glass reactor by the following technique. An aqueous solution of sodium dichromate (1.5 cm^3) was added with stirring to 10 g of the starting graphite. After 10 min, 4.4 cm^3 of sulfuric acid was added, and the reaction mixture was stirred for an additional 10 min. The resulting mixture was stirred in the reactor with 200 cm^3 of distilled water for 1–2 min and then washed with water either directly after the synthesis (direct washing) or with an intermediate keeping of the suspension for the hydrolysis to occur. The oxidized graphite was washed with distilled water on a paper filter until the wash water became colorless. To carry out the hydrolysis, the aqueous suspension of the oxidized graphite was transferred into a mixture of water with ice and left without stirring for graphite hydrosulfate to be hydrolyzed. The hydrolysis duration was varied from 0.5 to 18 h. In all the cases, the final products were dried at 100–110°C to constant weight.

The granulometric composition of the final product (RGH) was determined using a standard set of sieves and a Fritsch Analisette 3 Pro laboratory vibrating screen.

The thermal expansion factor K_V ($cm^3\,g^{-1}$) of the products obtained was determined at 500 and 900°C by two methods: in cold (K_V^{cool}) and heated (K_V^{hot}) cells. The swelling was carried out in a 100-g cylindrical cell made of stainless steel.

The expansion in a heated cell was carried out as

Effect of the GH hydrolysis duration on the RGH expansion factor at 500 and 900°C in cold and heated cells

follows. The cell was placed in a muffle and kept there for 10 min. Then an RGH weighed portion of m = 0.20–0.25 g was placed quickly in the cell and kept there until the expansion was complete. The duration of heating in the muffle was 120 s at 500 and 60 s at 900°C.

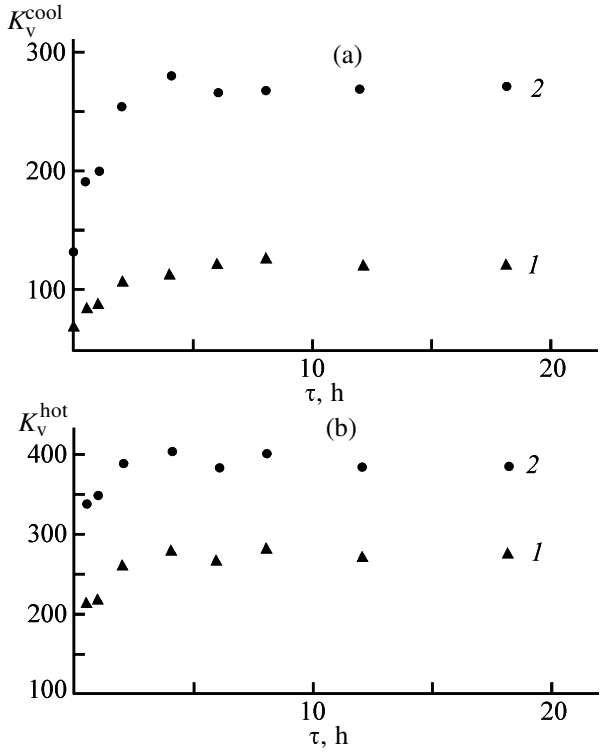

Fig. 1. Effect of duration of graphite hydrosulfate hydrolysis τ on the expansion factor K_v of residual graphite hydrosulfate in (a) cold and (b) heated cells. Temperature, °C: (*1*) 500 and (*2*) 900.

In the case of expansion in a cold cell, a weighed portion of m = 0.40–0.42 g was introduced in a cell at room temperature, then the cell with the sample was placed in a preheated muffle. The cell with the sample was kept in the muffle for 300 s at 500°C and for 120 s at 900°C.

The cell with expanded graphite was taken from the muffle, the expanded graphite was carefully transferred in a graduated glass cylinder, and the volume of expanded graphite V (cm^3) was measured. The expansion factor was determined from the relationship $K_v = V/m$ as an arithmetic mean of three replicate measurements. The relative error did not exceed 5%.

The morphology of RGH particles was studied by scanning electron microscopy (SEM) using a JEOL JSM-T300 scanning electron microscope.

The qualitative composition of gaseous products evolved from the reaction mass in various steps of the RGH synthesis was studied by gas chromatography, using an LKhM-8M chromatograph with a thermal conductivity detector and a stainless-steel column of length 2 m packed with AG-3 activated carbon (fraction 0.2–0.315 mm). The temperature of the columns was 60°C; the carrier gas was helium. Components of the gas mixtures were identified by comparison of their retention times with those of the pure gases.

It was noted previously that gases intensively escape from a layer of oxidized graphite when a suspension of oxidized graphite in water is kept without stirring. It was assumed that these gases are carbon oxides formed in the GH interlayer space as a result of oxidation-hydrolytic processes involving a carbon matrix, an intercalating compound, and intercalated particles. In this study we proved experimentally that the liberated gases contain CO and CO_2. We found that the evolution of carbon oxides is absent if the graphite powder is wetted with a solution of sodium dichromate and it begins in the stage of treating the reaction mass with concentrated sulfuric acid. The gas evolution continues throughout the time of the GH contact with water and stops only after drying the final product (RGH) at 100–110°C.

The effect of the GH hydrolysis duration on the final product expansion factor at 500 and 900°C in cold and heated cells is shown in the table. The same data in the graphic form are presented in Figs. 1a and 1b.

These data show that the expansion factors for all the studied RGH samples in a heated cell are higher by a factor of 1.5–2.5 than in a cold cell. The expan-

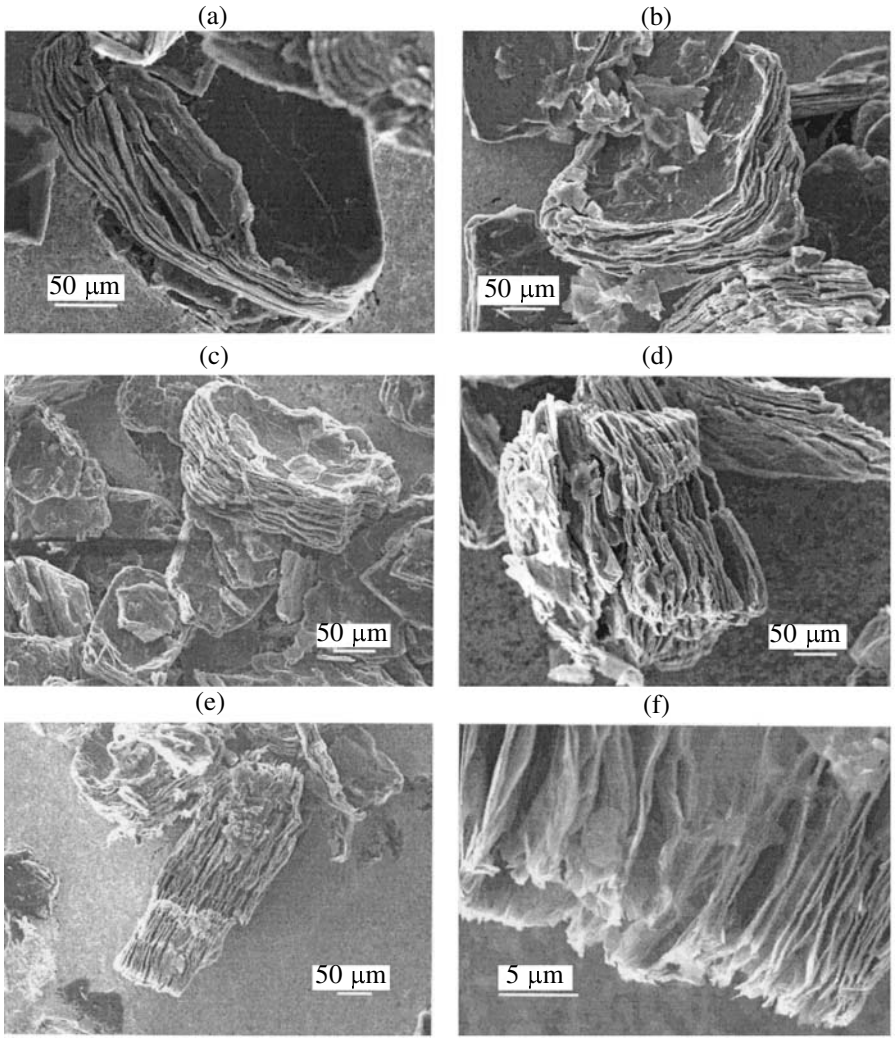

Fig. 2. Variation of the shape of residual graphite hydrosulfate particles with the hydrolysis time. (a) Direct washing; hydrolysis duration, h: (b) 0.5, (c) 1, (d) 4, and (e, f) 24.

sion factors are the lowest for the sample obtained by direct washing of GH with water, i.e., without the hydrolysis stage. As the duration of the hydrolysis stage increases, the expansion factor of the final product increases and flattens out at the hydrolysis duration of 4–5 h.

The data on the granulometric composition of RGH obtained from GSM-1 graphite with a particle size of 0.200–0.315 mm at the duration of the hydrolysis stage of 18 h are given below:

Size of mesh aperture, mm	Fraction content, wt %
–0.630+0.400	1.5
–0.400+0.315	31.3
–0.315+0.200	49.1
–0.200+0.160	10.0
–0.160+0.100	6.8
–0.100+0.063	0.3

The final product contains about 17% of particles smaller than 0.200 mm. It appeared unexpectedly that the product contains not only smaller particles, but also about 30% of particles larger than 0.315 mm, and only about 50% of particles have sizes in the range 0.200–0.315 mm. The possibility of breakdown of graphite particles during oxidizing intercalation is rather obvious, but the formation of a significant amount of larger particles seems unusual. This result stimulated us to study the effect of the hydrolysis on the morphology of particles in more detail.

The SEM photomicrographs showing the variation of the morphology of RGH particles in the course of the hydrolysis are given in Figs. 2a–2f. They show that the hydrolysis causes expansion of RGH flakes along the *c* axis, their bursting, stratification, and fragmentation with the formation of particles with

smaller diameters and thicknesses. The appearance of particles larger than the starting particles seems to be due both to their expansion along the *c* axis and to the increase in their diameter along the *a* axis owing to the formation of radial cracks and incomplete fragmentation of the flakes.

We have found that, as in the case with graphite compounds with chromium sesquioxide Cr_2O_3 [2], the hydrolysis of thus obtained oxidized graphite is accompanied by so-called ashtray effect, which is manifested as swelling of a flat flake of an intercalation compound with the formation of a flake in the form of an ashtray with deformed peripheral region. The end surface of such particles has a structure reminiscent of the honeycombed structure of thermally expanded graphite. During the further hydrolysis, the swelling front gradually moves to the center of the flake, which leads to the disappearance of the ashtray shape and to the formation of an evenly swollen particle in the final process stages. At the hydrolysis time of 4–5 h, the flakes already have approximately equal thickness both on edges and in centers, being similar in the outwards appearance to the particles of thermally expanded graphite at a low degree of expansion.

The data obtained allow us to assume the following mechanism of the RGH formation. Most likely, when concentrated sulfuric acid is added to the reaction mass containing graphite particles and concentrated aqueous solution of sodium dichromate distributed over their surface, an intercalating solution is formed. It contains hydrosulfate anions solvated by sulfuric acid molecules, sulfuric and chromic acids, and also chromosulfuric acid, H_2CrSO_7, and its anions $HCrSO_7^-$. Chromic acid plays a role of an oxidant of the graphite matrix and provides the formation of graphene macrocations. As positive charges appear on the graphene planes of a graphite matrix, anionic species present in the intercalating solution start to penetrate into the interlayer space. Simultaneously anionic species of two types, HSO_4^- and $HCrSO_7^-$, solvated by sulfuric acid intercalate in the interlayer space to form compounds of bi- and(or) cointercalation containing hydrosulfate and hydrochromosulfate anions. The possibility for the formation of chromosulfuric acid in mixtures of concentrated sulfuric and chromic acids has been shown in [3–5], and the formation of similar compounds was detected experimentally during the electrochemical oxidation of a graphite intercalation compound with chromic anhydride in concentrated sulfuric acid [6].

When the graphite compound obtained is brought in contact with water, its molecules penetrate into peripheral regions of the carbon matrix interlayer space and enter into oxidation-hydrolytic reactions with the graphite matrix and intercalated species. Gases liberated in this process give rise to a slight initial expansion of the compound. Water molecules gradually diffuse further and further into the central part of the interlayer space, and the swelling front also gradually moves from a flake periphery to its center. In the course of the further hydrolysis, the central part of a graphite flake swells, which results in the disappearance of the ashtray shape and in the formation of evenly swollen particles within 4–5 h.

Most likely, oxygen-containing functional groups of the graphite oxide type [7] are formed simultaneously with moving of the front of oxidation-hydrolytic processes from the periphery of the interlayer space to its central part. Extremely reactive $OH^{\bullet}$ radicals formed by the oxidation of water with chromic or chromosulfuric acid [8, 9] can be responsible for the process. Apparently, it is the formation of such oxygen-containing functional groups that ensures high thermal expansion factors K_v and a low temperature of the onset of final product expansion (about 220°C). Possibly, the formation of such functional groups in the interlayer space of the graphite matrix is almost finished at the duration of the starting GH hydrolysis of 4–5 h.

CONCLUSIONS

(1) The liberation of carbon oxides (CO and CO_2) begins in the stage of treatment of the reaction mass with concentrated sulfuric acid. The evolution of gases continues throughout the time of graphite hydrosulfate hydrolysis and ceases only after drying of the final product.

(2) As the hydrolysis duration increases, the expansion factor of the final product increases and flattens out within 4–5 h.

(3) A significant amount of both larger and smaller particles, as compared to the starting graphite particles, appear in the product.

(4) A probable mechanism of the formation of residual graphite hydrosulfate has been suggested. Its key step is the formation of a compound of bi- and(or) cointercalation of graphite with sulfuric and chromosulfuric acids.

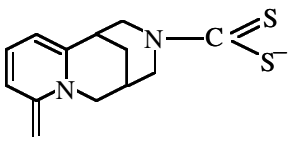
Abstract—The heat of solution in water and the heat capacity in the range 173 K–T_m of triethylammonium, sodium, and potassium dithiocarbamates derived from cytisine were studied by calorimetry. The heats of combustion and melting and the standard enthalpies of formation of the compounds were calculated.

DOI: 10.1134/S1070427206070056



The researcher's interest in natural compounds considerably increased recently in the context of the modification and preparation on their basis of highly effective drugs.

Cytisine alkaloid is very interesting in this respect, because it enters into various chemical reactions and in the form of a 0.15% solution is used in medical practice under the brand Cytiton [1]. More than 200 cytisine derivatives of various structures are known. The scientists from the Institute of Organic Synthesis and Coal Chemistry (Karaganda) showed that a number of phosphorus-containing cytisine derivatives [Cytaphat, Cybunat] exhibit hepatoprotective properties. Cytisine dithiocarbamates are characterized by a broad spectrum of biological action and by low toxicity, which gives grounds to recommend them as drugs, preservatives, pesticides, etc. [2–5].

To estimate the reactivity with respect to molecules of different nature, it is of theoretical and practical significance to study the thermodynamic characteristics of these compounds. Therefore, the heat capacity in the range 173K–T_m and the enthalpy of solution in water of triethylammonium, sodium, and potassium dithiocarbamates derived from cytisine were studied by the dynamic and isothermal calorimetry. The standard enthalpy of formation and the heats of combustion and melting of the compounds were also determined.

EXPERIMENTAL

Cytisine-derived dithiocarbamates of triethylammonium $C_{18}H_{29}N_3OS_2$ (**I**), sodium $C_{12}H_{13}N_2OS_2Na$ (**II**), and potassium $C_{12}H_{13}N_2OS_2K$ (**III**) were synthesized, purified to the level of analytical purity, and studied calorimetrically.[1] The compounds under study have the following structural formulas:

X^+,

where X^+ is $HN(C_2H_5)_3$ (**I**), Na^+ (**II**), and K^+ (**III**).

The enthalpies of solution of the compounds in water was measured at dilutions (here and hereinafter, salt : water molar ratios) of 1 : 18000, 1 : 36000, and 1 : 72000 on a DAK-1-1A isothermal differential automated calorimeter. The calorimeter measures the integral heat flow passed from the ampule with substances through differentially connected thermal batteries and a massive central block of the microcalorimeter. The heats of solution were determined in the automated heat compensation mode. The thermal effects were recorded with a KSP-4 recording potentiometer and an IP-4 precision integrator. The

[1] The samples were synthesized by staffmembers of the Institute of Organic Synthesis and Coal Chemistry (Karaganda).

sample was placed into a thermostat preheated to a prescribed temperature and kept there for 2 h. Prior to testing, the device was calibrated by the Joule heat. To do this, a reference voltage was applied to a built-in heater, and the liberated power was measured. The calibration was checked by measuring the heat of solution of triply recrystallized potassium chloride at dilutions of 1 : 1600, 1 : 2400, and 1 : 3200. Five replicate measurements were made at each dilution, and the results were averaged. The average heat of solution of KCl in water at 298.15 K and the above dilutions (17.780 ± 2.62 kJ mol^{-1}) is in good agreement with the recommended reference value [6] (17.577 ± 0.340 kJ mol^{-1}) and with the reference data of [7] on the enthalpy of KCl solution at the indicated dilutions.

The experimental errors and the uniformity of their variance were treated by mathematical statistics using the Student and Bartlett criteria [8].

The results of the calorimetric measurements of the heats of solution of triethylammonium, sodium, and potassium dithiocarbamates derived from cytisine at various dilutions, where ΔH_s^m is the enthalpy of solution of a compound at a definite dilution, taking into account the molar weight of the solute, are presented in Table 1.

The heat capacities of the compounds were measured on an IT-s-400 calorimeter. Liquid nitrogen was used as a coolant. The specific heat capacity was measured at a step of 25 K, according to the technical characteristics. The time of the measurement, including the treatment of the experimental data, did not exceed 2.5 h. The standard admissible deviation of the device was ±10% according to the certificate.

The samples under study were placed into a metallic ampule of the measuring cell. Then they were continuously heated by a heat flow through the heat meter. The delay of the ampule temperature with respect to the temperature of the base was measured at 25 K intervals.

First, the heat meter was calibrated by the thermal conductivity K_t [9]. To do this, five replicate experiments, both with and without the copper sample in the ampule, were performed. As in the calibration, five replicate experiments were made at each tempertuare (25 K step) for each compound under study, with the results obtained averaged and treated by mathematical statistics [8].

At each measured temperature, the root-mean-square deviation $\bar{\delta}$ was calculated for the average value of the specific heat capacity and the random error $\mathring{\Delta}$, for the molar heat capacities.

Table 1. Enthalpies of solution of triethylammonium ($C_{18}H_{29}N_3OS_2$), sodium ($C_{12}H_{13}N_2OS_2Na$), and potassium ($C_{12}H_{13}N_2OS_2K$) dithiocarbamates derived from cytisine in water at various dilutions

Compound	Dilution	ΔH_{dis}^m, kJ mol^{-1}
$C_{18}H_{29}N_3OS_2$	1 : 18000	12.63 ± 0.18
	1 : 36000	14.89 ± 0.13
	1 : 72000	18.22 ± 0.21
$C_{12}H_{13}N_2OS_2Na$	1 : 18000	18.47 ± 0.33
	1 : 36000	19.88 ± 0.34
	1 : 72000	21.74 ± 0.33
$C_{12}H_{13}N_2OS_2K$	1 : 18000	15.72 ± 0.11
	1 : 36000	17.73 ± 0.33
	1 : 72000	19.30 ± 0.27

The work of the device was checked by measuring the heat capacity of α-Al_2O_3: the measured C_p^0 value of α-Al_2O_3 (298.15 K), equal to 76.0 J mol^{-1} K^{-1}, is in satisfactory agreement with the recommended value of 79.0 J mol^{-1} K^{-1} [10].

The experimental specific and molar heat capacities of the compounds are presented in Table 2.

To calculate the standard enthalpy of formation of the compounds, we determined their standard heats of combustion at 298.15 K by the Karash and Frost methods [11]. The heat of melting ΔH_m of cytisine dithiocarbamates was estimated from the empirical equation [12].

The experimentally determined enthalpies of solution of $C_{18}H_{29}N_3OS_2$, $C_{12}H_{13}N_2OS_2Na$, and $C_{12}H_{13}N_2OS_2K$ at various dilutions were then used for calculating ΔH^0 at infinite (standard) dilution. The mathematical treatment of the experimental data showed that, as in [13], the dependences of the enthalpy of solution ΔH_s^m (kJ mol^{-1}) on the molal concentration $m^{1/2}$ are described by the following equations:

$$\Delta H_s^m(C_{18}H_{29}N_3OS_2) = 23.30 - 198.22m^{1/2}, \quad (1)$$

$$\Delta H_s^m(C_{12}H_{13}N_2OS_2Na) = 24.76 - 116.26m^{1/2}, \quad (2)$$

$$\Delta H_s^m(C_{12}H_{13}N_2OS_2K) = 22.87 - 129.30m^{1/2}, \quad (3)$$

The standard enthalpies of solution of $C_{18}H_{29}N_3 \cdot OS_2$, $C_{12}H_{13}N_2OS_2Na$, and $C_{12}H_{13}N_2OS_2K$ in water at standard (infinite) dilution, obtained from these equations, are 23.3 ± 0.27, 24.76 ± 0.41, and 22.87 ± 0.30 kJ mol^{-1}, respectively.

Table 3. Calculated values of thermal chemical characteristics of compounds

Compound	$-\Delta H_{comb}^0$	ΔH_m	$-\Delta_f H^0(298.15)$, kJ mol^{-1}	
	kJ mol^{-1}		liquid	solid
$C_{18}H_{29}N_3OS_2$	10694 ± 313	320.2	1135	1455
$C_{12}H_{13}N_2OS_2Na$	6335 ± 314	177.6	1053	1231
$C_{12}H_{13}N_2OS_2K$	6335 ± 314	200.1	1025	1225

The experimental heat capacities were used to obtain the equations for the temperature dependences of the heat capacity of the compounds (J^{-1} mol^{-1} K^{-1}):

$$C_p^0(C_{18}H_{29}N_3OS_2) = -(68.52 \pm 4.93) + (1455.5 \pm 104.8) \times 10^{-3}T + (4.26 \pm 0.31) \times 10^5 T^{-2}, \quad (4)$$

$$C_p^0(C_{12}H_{13}N_2OS_2Na) = (34.25 \pm 2.51) + (566.06 \pm 41.55) \times 10^{-3}T - (16.6 \pm 1.22) \times 10^5 T^{-2}, \quad (5)$$

$$C_p^0(C_{12}H_{13}N_2OS_2K) = -(475.05 \pm 31.16) + (2586.4 \pm 169.7) \times 10^{-3}T + (36.69 \pm 2.41) \times 10^5 T^{-2}. \quad (6)$$

The Karash and Frost methods [12], which are the most suitable to take into account the contribution of different groups, were used to calculate the heat of combustion of the compounds. The average values of the enthalpy of combustion of the compounds in the liquid and solid states are given in Table 3.

Using the equations

$$2C_{18}H_{29}N_3OS_{2(l)} + 53.5O_{2(g)} = 36CO_{2(g)} + 29H_2O_{(l)} + 3N_{2(g)} + 4SO_{2(g)} - \Delta H_{comb}^0, \quad (7)$$

$$2C_{12}H_{13}N_2OS_2Na_{(l)} + 22O_{2(g)} = 24CO_{2(g)} + + 13H_2O_{(l)} + 2N_{2(g)} + 4SO_{2(g)} + Na_2O_{(s)} - \Delta H_{comb}^0, \quad (8)$$

$$C_{12}H_{13}N_2OS_2K_{(l)} + 22O_{2(g)} = 24CO_{2(g)} + 13H_2O_{(l)} + 2N_{2(g)} + 4SO_{2(g)} + K_2O_{(s)} - \Delta H_{comb}^0, \quad (9)$$

we calculated $\Delta_f H_{298.15}^0$ of the compounds in the liquid states (Table 3). The required values of $\Delta_f H_{298.15}^0$ $CO_{2(g)}$, $H_2O_{(l)}$, $N_{2(g)}$, $SO_{2(g)}$, $Na_2O_{(s)}$, and $K_2O_{(s)}$ were taken from [14].

Because at the standard temperature (298.15 K) the compounds considered are crystalline, we calculated $\Delta_f H_{298.15}^0$ for their solid state. To do this, we esti-

mated ΔH_m of the compounds from the empirical equation [12]

$$\Delta H_m/T_m = 20.72 \times 10^{0.00324M}. \quad (10)$$

The ΔH_m values calculated by Eq. (10) are presented in Table 3. Then, we calculated, using the equations

$$\Delta_f H^0(C_{18}H_{29}N_3OS_{2(s)}, 298.15) = \Delta_f H^0(C_{18}H_{29}N_3OS_{2(l)}, 298.15) - \Delta H_m, \quad (11)$$

$$\Delta_f H^0(C_{12}H_{13}N_2OS_2Na_{(s)}, 298.15) = \Delta_f H^0(C_{12}H_{13}N_2OS_2Na_{(l)}, 298.15) - \Delta H_m, \quad (12)$$

$$\Delta_f H^0(C_{12}H_{13}N_2OS_2K_{(s)}, 298.15) = \Delta_f H^0(C_{12}H_{13}N_2OS_2K_{(l)}, 298.15) - \Delta H_m, \quad (13)$$

the standard enthalpies of formation of crystalline triethylammonium, sodium, and potassium dithiocarbamates derived from cytisine (Table 3).

CONCLUSIONS

The standard enthalpies of solution in water, enthalpies of combustion and melting, and standard heats of formation in liquid and solid states were determined for triethylammonium, sodium, and potassium dithiocarbamates derived from cytisine. The equations describing the temperature dependence of the heat capacity in the range studied were derived for each compound.

PHYSICOCHEMICAL STUDIES OF SYSTEMS AND PROCESSES

Choice of an Extractive Separating Agent for the 1-Pentanol–Cyclohexanone Binary Mixture

E. P. Myul'khi, M. S. Khristenko, and M. V. Andryukhova

Received July 11, 2005; in final form, January 2006

Abstract—Phase equilibria in binary and ternary systems formed by the components to be separated (1-pentanol, cyclohexanone) with extractive separating agents (methyl Cellosolve, butyl Cellosolve, aniline, acetophenone, ethylene glycol) were studied.

DOI: 10.1134/S1070427206070068

Catalytic synthesis of ε-caprolactam involves formation of a waste which is a multicomponent mixture containing solvents [1-butanol, cyclopentanone, 3-methyl-1-butanol, 1-pentanol (PL)] and target components of the main process [cyclohexanone (CON) and cyclohexanol]. Phase equilibria in binary [1] and ternary [2] subsystems of this mixture were studied previously. Fractional distillation [3] allows recovery of an alcoholic PL–CON fraction from this mixture. The phase equilibria in this system were studied in [4]; this system showed tangential zeotropy [5], which was confirmed by the shape of the *K* lines (*K* is the distribution ratio) and data on the azeotropy at different pressures. Such mixtures cannot be separated into components by common fractional distillation, because the required number of separation steps and reflux ratio are so large that the process becomes unfeasible. Therefore, we examined a specific separation method, extractive distillation.

The goal of this study was to choose an efficient separating agent (SA) for the PL–CON mixture. This task involves construction of a new system of higher dimension than the base system, with a definite type of the phase diagram, in which the relative fugacity of components of the base mixture would increase. The following strategy of choosing the best separating agent seems to be appropriate [5, 6]: (1) choice of a group of potential separating agents, (2) comparison of their selectivity by instrumental methods (prompt analysis [7, 8] and classical methods for studying liquid–vapor equilibria), and (3) experimental check and choice of the most efficient separating agent.

Components of the base mixture belong to different classes of organic compounds: 1-pentanol is an alcohol and cyclohexanone is a cyclic ketone. These compounds can be involved in various kinds of intermolecular interactions. When choosing an SA for such systems, it is advisable [5, 6] to use high-boiling homologs of the less volatile component. As possible agents for separating alcohol–ketone mixtures it is suggested [5] to use esters and glycols.

Taking into account these recommendations and the physicochemical properties and molecular structure of the components, we tested the following SAs for the PL–CON system: methyl Cellosolve (2-methoxyethanol, ethylene glycol monomethyl ether), butyl Cellosolve (2-butoxyethanol, ethylene glycol monobutyl ether), ethylene glycol (1,2-ethanediol), acetophenone (methyl phenyl ketone), and aniline. These polar solvents belong to different classes of organic compounds: glycols, ethylene glycol ethers, aromatic amines, and aromatic ketones. Their choice was governed by the fact that ethylene glycol and its monoethers are capable of forming three-dimensional networks of strong hydrogen bonds; primary amines (aniline) contain an active H atom and a donor –N atom; ketones (acetophenone) contain no active H atoms but are capable of hydrogen bonding via donor –O atoms.

EXPERIMENTAL

To assess the efficiency of the separaing agents chosen, we studied experimentally the liquid–vapor phase equilibria in binary and ternary systems formed by the components (PL, CON) with the suggested SAs. Experiments were performed at atmospheric pressure following the known procedures and using

Table 1. Parameters of the Antoine equation for the separating agents

Component	T_b, °C	A	B	C
Methyl Cellosolve (MC)	124.3	8.2655	1543.735	162.03
Butyl Cellosolve (BC)	170.6	7.6194	1639.863	175.00
Aniline (AN)	184.5	7.2500	1677.180	200.00
Ethylene glycol (EG)	197.0	8.7945	2615.394	244.75
Acetophenone (AC)	202.3	7.0600	1643.940	192.00

a Gillespie device [5, 9] for homogeneous mixtures and a modified Smirnova–Morachevskii device [10] for mixtures with phase separation. The boiling point was measured with a mercury thermometer (accuracy 0.1°C), with the correction for the protruding mercury column [11].

The compositions of the vapor and liquid phases were determined with an LKhM-80 chromatograph equilled with a flame ionization detector. We used metal columns 3 m long and 3 mm in diameter; as a stationary phase we used polyethylene glycol 1000, 30 wt % on Tsvetokhrom support. Measurement conditions: detector temperature 150°C, column temperature 120–140°C, flow rates: H_2 500, O_2 250, and N_2 (carrier gas) 10–50 ml min^{-1}. The mixture compositions were determined using internal normalization with calibration coefficients.

The mathematical description of the experimental data in the binary systems was made using the Wilson equation [12], by minizing the $(T_{calc} - T_{exp})^2$ functional by Barker's method with the program developed at NIIneftekhim (Ufa). The compositions of the equilibrium phases were calculated assuming ideal behavior of the components in the vapor phase. The temperature dependence of the vapor pressure was described by the Antoine equation

$$\log P = A - B(T + C),$$

where P is the vapor pressure (mm Hg); T, temperature (°C); and A, B, and C, constants of the Antoine equation.

The Antoine's constants for the SAs and their boiling points are given in Table 1; for PL and CON, these quantities are given in [1]. The temperature range to which these constants are applicable corresponds to the vapor pressure range 10–1500 mm Hg, i.e., it corresponds to the vapor pressure range used in industrial distillation processes.

Data on the phase equilibria in the binary systems are given in Table 2.

The results of the mathematical description of the experimental data on the binary systems are given in Table 3 in the form of the Wilson equation parameters λ_{12} and λ_{21} and the average and maximal deviations of the temperature. The binary interaction parameters ("large parameters") obtained are dimensionless.

From data on the phase equilibria in the binary systems, we can calculate the selectivity of the separating agents, $S = \alpha_{SA}/\alpha$, where α_{SA} and α are the relative fugacity coefficients of the PL–CON system averaged over the whole range of their concentrations, measured in the presence and in the absence of the separating agent, respectively [5]. The high selectivity is one of major requirements to an agent for extractive distillation. There are indications [13, 14] that of practical value are SAs that increase α from 1.0–1.1 to 1.5 and more, i.e., agents whose selectivity is higher than 1.5. The selectivity was calculated using the mixing functions Φ_{1S} and Φ_{2S} by the formulas [5]

$$\log S = (\Phi_{1S} - \Phi_{2S})/(1 - X_{SA}),$$

$$\Phi_{1S} = X_1 \log \gamma_1 + (1 - X_1) \log \gamma_{SA},$$

$$\Phi_{2S} = X_1 \log \gamma_2 + (1 - X_2) \log \gamma_{SA},$$

where X_1, X_2, X_{SA}, γ_1, γ_2, and γ_{SA} are, respectively, the mole fractions and activity coefficients of PL, CON, and separating agent.

The values of S, α, and α_{SA} at X_{SA} = 90 mol % are listed in Table 4.

The binary interaction parameters obtained allow simulation of the phase equilibria in multicomponent systems. When choosing the investigation objects, we took into account the fact that only two agents, acetophenone and ethylene glycol, exerted the positive effect, increasing the relative fugacity of the base components, $\alpha_{SA} > \alpha$. Therefore, we studied experimentally the phase equilibria in two systems: PL–CON–EG and PL–CON–AC. The X–Y–T dependences (X, liquid phase composition; Y, vapor phase compo-

Figures 1a and 1b and Table 2 show that methyl Cellosolve and butyl Cellosolve exhibit negative deviations from the ideality ($\gamma < 1$) in the interaction with 1-pentanol, which is due to association of the components with each other. In the interaction with cyclohexanone, there are weak positive deviations; as a result, the relative fugacity of 1-pentanol in the presence of methyl Cellosolve and butyl Cellosolve decreases, and that of cyclohexanone increases.

Aniline (Fig. 1c) is also inefficient and shows a similar pattern; according to experimental data, cyclohexanone and aniline form a minimal heteroazeotrope with a boiling point of 152.6°C.

Acetophenone and ethylene glycol (Figs. 1d, 1e), in contrast to the separating agents mentioned above, increase the fugacity of 1-pentanol, providing positive changes in the relative fugacity; ethylene glycol is apparently more efficient.

Thus, our results lay the foundation for further quantitative studies aimed to elucidate the relationships of the extractive distillation and determine the optimal process parameters of the separation.

CONCLUSIONS

(1) Acetophenone and ethylene glycol are efficient as extractive separating agents for the 1-pentanol–cyclohexanone mixture.

(2) Nine binary mixtures formed by 1-pentanol and cyclohexanone with separating agents are zeotropic.

(3) In the cyclohexanne–aniline system, a minimal heteroazeotrope with a boiling point of 152.6°C was revealed.

(4) The Wilson equation adequately reproduces the features of the liquid–vapor equilibria in the binary and ternary systems under consideration.

Abstract—Thermodynamic compatibility in the polymeric system cellulose nitrate–cellulose acetate is studied by reversed-phase gas chromatography. The excess enthalpy ΔH_{ji}^E, entropy ΔS_{ji}^E, and Gibbs energy ΔG_{ji}^E of mixing of the components, and also the Flory–Huggins interaction parameter χ_{ji} are estimated.

DOI: 10.1134/S107042720607007X

Mixing of two or more polymers of different chemical nature shows promise as a way to design composite materials surpassing the individual polymers in performance characteristics. Study of cellulose nitrate–cellulose acetate (CN–CA) blends is of interest from the standpoint of improving performance and extending application area of such practically important products as technical films, paint-and-varnish materials, and slow-burning powder composites.

Prediction of properties of such products is based on the thermodynamic data characterizing the interaction between components of the blend. Thermodynamic characteristics of polymer blends can be derived from experimental data obtained by reversed-phase gas chromatography (RGC) [1, 2]. The theory of the method has been developed for the case of ideal gas chromatography, i.e., it is valid for an infinitely dilute solution of a sorbate in the stationary phase on the condition of the establishment of the sorption–desorption equilibrium. Such equilibrium is observed in the case of a sufficiently fast diffusion of the solvent molecules to the polymer, which is realized, e.g., in polymers in the hyperelastic state at a temperature 50° above the glass-transition point. Our test subject, CN, cannot be brought to the hyperelastic state by heating, and the experimental temperature range is bound by thermal degradation of the polymer. Nevertheless, despite all the factors distorting the experimental results, RGC was successively used to study polymers in the glassy state [3, 4]. Yampol'skii and Durgar'yan [3] observed an exothermic effect in mixing glassy polyvinyltrimethylsilane with low-molecular-weight organic compounds (sorbates), as well as a strong dependence of the excess functions of mixing on the molar volume of the sorbate. Based on these and published data, the authors concluded that the observed trends are general in the sorption on glassy polymers. Data of [4] reveal that the retained volume, the basic parameter to be determined in the experiment, is influenced by the thickness of the polymeric film and the amount of the sorbate introduced into the chromatographic column. Results obtained in this study were also obtained after optimization of the experimental conditions (film thickness, volume of the sorbate sample, and carrier gas flow rate) for the CN–CA system.

EXPERIMENTAL

In the study we used commercial CN (nitrogen content 12%; viscosity-average molecular weight in ethyl acetate M = 72 500) and laboratory CA samples obtained by homogeneous acetylation (acetate group content 51.0%; viscosity-average molecular weight in acetone M = 57 000).

The thermodynamics of interaction of the components in the CN–CA system was studied by RGC on a Khrom-4 chromatograph with a thermal conductivity detector. Helium was used as a carrier gas. We used Teflon columns 0.6 m long and 5 mm in diameter. As an inert support we used diatomite with a particle size of 0.2–0.4 mm. Samples of the individual polymers and polymer blends were deposited onto the support by evaporation from 5% solution in

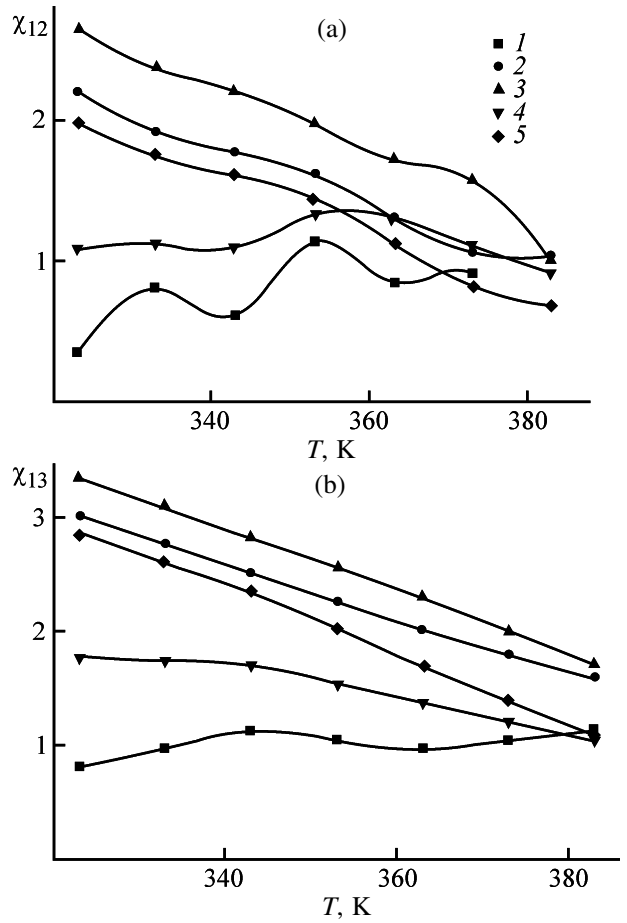

Fig. 1. Flory–Huggins interaction parameters χ_{ij} of the sorbates with (a) CN and (b) CA. (*T*) Temperature. (*1*) Methanol, (*2*) chloroform, (*3*) CCl_4, (*4*) ethanol, and (*5*) hexane.

acetone [1]. In all cases, the content of the polymer phase was 10% relative to the inert support weight. Such a content provided full coverage of the support surface with a polymer film, allowing establishment of the sorption–desorption equilibrium by virtue of the accessibility of the functional groups of the polymer for the sorbate. The measurements were carried out at 323–383 K. The CA content in the blends was 3–97%.

As sorbates we selected a series of low-molecular-weight organic solvents including hexane, methanol, ethanol, benzene, toluene, ethyl acetate, chloroform, and carbon tetrachloride with close boiling points near 60–80°C.

The sorbates (0.1 μl) were introduced into the column using a microsyringe. It was demonstrated in the preliminary experiments that the sorbate concentration in the experiments corresponded to infinite dilution, i.e., to the initial part of the sorption isotherm.

From the retained volume of the sorbates on the individual polymers and their blends we estimated the activity coefficients γ_1^∞ and Flory–Huggins parameters χ_{1k} over the entire temperature range using the equations suggested in [1]. The excess thermodynamic functions (enthalpy ΔH_{1k}^E, entropy ΔS_{1k}^E, and Gibbs energy ΔG_{1k}^E) of mixing of the individual polymers and their blends with the sorbates were estimated by Eqs. (1)–(3):

$$\Delta G_{1k}^E = RT\ln\gamma_1^\infty, \quad (1)$$

$$\Delta H_{1k}^E = R[\partial\ln\gamma_1^\infty/\partial(1/T)], \quad (2)$$

$$\Delta S_{1k}^E = (\Delta H_{1k}^E - \Delta G_{1k}^E)/T, \quad (3)$$

where the index k refers to the polymer phase.

Then we estimated the excess molar thermodynamic functions of mixing of two polymers ΔG_{23}^E, ΔG_{23}^E, ΔG_{23}^E, and χ_{23}, as the differences between the parameters of retention of the sorbate on the individual polymers and their blends [2].

Reversed-phase gas chromatography is among the methods allowing quantitative characterization of the thermodynamic compatibility of polymers in binary composites. Generally, the compatibility is characterized by the sign and value of ΔG_{23}^E and χ_{23} [1, 2, 5].

The interaction parameter is influenced by a variety of factors, the major of which are the natures of the polymers and sorbates [6, 7]. The problem of selection of the sorbate was discussed in [4, 6, 7]. Most often, the authors recommend taking an ideal solvent demonstrating equal affinity for both polymers, to eliminate the effect of the sorbate on the thermodynamics of the interaction in the system. However, it is practically impossible to find such a solvent for a giver pair of solvents. Therefore, the decision on the sorbate is restricted to low-molecular-weight solvents, which, equally interacting with both polymers, have a minimal effect on the experimental results.

The interaction of the polymers with the sorbates was characterized by the Flory–Huggins interaction parameters χ_{12} (CN–sorbate) and χ_{13} (CA–sorbate) (Fig. 1). In this case, we focused primarily on the closeness of χ_{12} and χ_{13}. The condition $(\chi_{12} - \chi_{13}) \approx 0$, suggesting the same interaction of the sorbate with both polymers, is met to the maximal extent for hexane and carbon tetrachloride over the entire temperature range. Additionally, we analyzed the temperature dependences of the interaction parameters. The temperature dependences of χ_{12} and χ_{13} are linear with the correlation coefficients of 0.99 and 0.96

for CCl_4 and hexane, respectively. However, the molar volume is higher for hexane (136 against 100 cm^3 mol^{-1} for CCl_4), which negatively affects its ability to penetrate the structure of the cellulose esters. Therefore, carbon tetrachloride could be recommended as the optimal sorbate for the system in hand.

The concentration dependences of ΔG_{23}^E and χ_{23} in the CN–CA system, determined from the experimental data on the retention of CCl_4, are given in Figs. 2 and 3.

Figure 2 shows that the concentration dependences of the Gibbs energy of mixing are in the region of negative values over the entire temperature range studied, suggesting that CN and CA are thermodynamically compatible. The dependences are convex-concave in shape, which is typical of systems with phase separation. The second derivative of the Gibbs energy with respect to the composition $\partial^2 \Delta G_{23}^E / \partial w_3^2$ (w_3 is the mass fraction of CA in the system) more than once changes its sign as the CA concentration in the system increases, suggesting that the stability of the system with respect to diffusion is strongly influenced by the composition [8].

Our analysis shows that the negative Gibbs energy of mixing in the CN–CA system is provided by the entropy factor. The increase in the absolute value of ΔG_{23}^E with the temperature and the fulfillment of the inequalities $(\partial^2 \Delta H_{23}^E / \partial w_3^2)_T < 0$ and $(\partial^2 \Delta S_{23}^E / \partial w_3^2)_T < 0$ allows classification of the investigated system with polymer blends with upper critical point of mixing [8], for which the thermodynamic compatibility increases with the temperature.

One of the criteria of thermodynamic compatibility of polymers in blends is a negative or nearly zero value of χ_{23} [9]. Figure 3 shows that this condition is not met for the blend with c_{CA} = 50% over the entire temperature range and for the blends with c_{CA} = 60 and 80% at 373 K.

The lowest χ_{23} values, i.e., the maximal compatibility of the components, are obtained for the blends with the CA concentration of 3, 7, 93, and 97%. At c_{CA} from 10 to 90%, χ_{23} is close to zero, being only slightly dependent on the temperature and composition.

In addition to experimental determination, we estimated the thermodynamic functions of mixing using the Flory–Huggins theory [2]. According to this theory, at the total volume of the mixture V, the Gibbs energy of mixing can be determined by Eq. (4)

$$\Delta G_{23}^E = (RTV/v_r)[(\varphi_2/r_2)\ln\varphi_2 + (\varphi_3/r_3)\ln\varphi_2 + \chi_{23}\varphi_2\varphi_3], \quad (4)$$

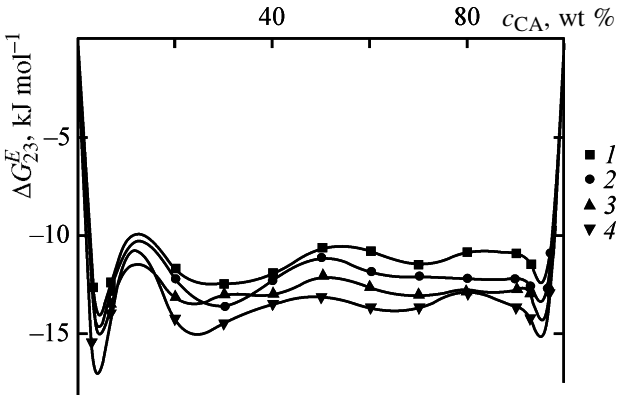

Fig. 2. Gibbs energy of mixing ΔG_{23}^E as a function of the component concentration c_{CA} in the CN–CA system over the temperature range 323–383 K, as determined by RGC. Temperature (K): (*1*) 323, (*2*) 343, (*3*) 363, and (*4*) 383; the same for Figs. 3, and 4.

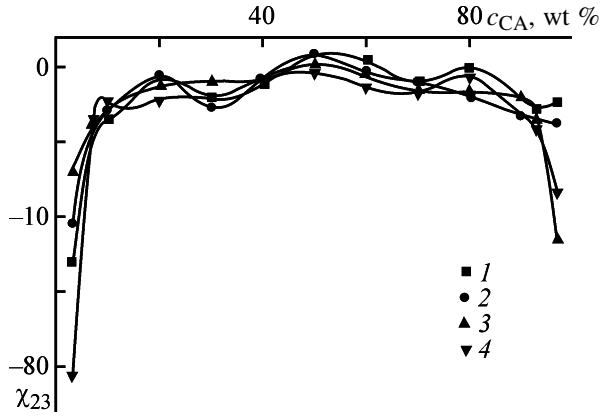

Fig. 3. Interaction parameter χ_{23} as a function of the component concentration c_{CA} in the CN–CA system over the temperature range 323–383 K.

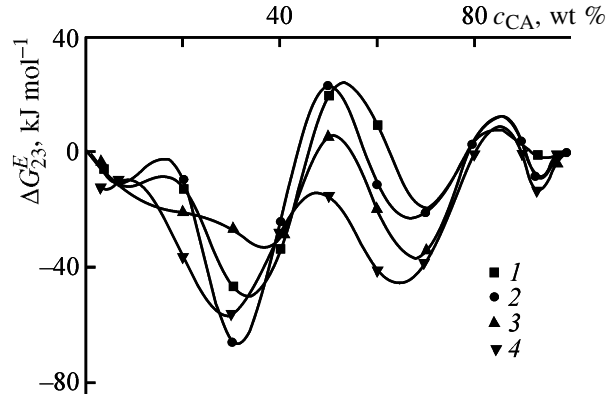

Fig. 4. Gibbs energy of mixing ΔG_{23}^E as a function of the component concentration c_{CA} in the CN–CA system, as estimated by the Flory–Huggins theory.

where v_r is the segment volume equal to the volume of the repeated unit of the chain (this parameter is taken the same for both polymers); r_2 and r_3 are the numbers of segments in polymer nos. 2 and 3; and

φ_2 and φ_3, volume fractions of the polymers in the blend.

Comparison of the Gibbs energies of mixing obtained from the experimental retention volume of the sorbate (Fig. 2) and by Eq. (4) with the experimental χ_{23} (Fig. 4) shows that the Flory–Huggins theory can be used as only a qualitative model of the interaction between the components in the CN–CA system.

CONCLUSIONS

(1) Carbon tetrachloride is the optimal sorbate for studying cellulose nitrate–cellulose acetate blends.

(2) The components of the cellulose nitrate–cellulose acetate system are thermodynamically compatible at 323–383 K. The system is unstable with respect to the diffusion, the entropy factor being responsible for the negative Gibbs energies of mixing.

(3) The compatibility in the cellulose nitrate–cellulose acetate system increases with increasing temperature and with decreasing fraction of one of the component to below 10%.

SORPTION AND ION-EXCHANGE PROCESSES

Adsorption and Luminescence Properties of Tb^{3+}-Modified Perfluorosulfonic Acid Membrane

K. A. Gavronskaya, A. A. Petushkov, S. M. Shilov, and V. N. Pak

Herzen Russian State Pedagogical University, St. Petersburg, Russia

Received March 1, 2006

Abstract—After treatment of perfluorosulfonic acid membrane MF-4SK with an aqueous solution of $TbCl_3$, the protons in sulfo groups are completely replaced by the hydrated terbium cations. Specific features of the water adsorption and its influence on the luminescence of the modified membrane were examined.

DOI: 10.1134/S1070427206070081

High chemical stability of the fluorocarbon skeleton, combined with developed pore structure, high transparency, and pronounced cation-exchanging power, make Nafion perfluorosulfonic acid membranes (PFSMs) suitable as carriers for preparation of a broad spectrum of polyfunctional composite materials [1–8]. Possible applications of modified PFSMs include development of fuel cells [1, 2], catalysts [3, 4], optically active media, in particular, intercalation compounds of aromatic substances [5], fluorescent dyes [6], and compounds of transition metals [7, 8]. At the same time, the prospects for preparation of film luminophores incorporating compounds of rare-earth elements from PFSMs still remain to be elucidated. In this connection, we carried out in this study modification of a polyfluorosulfonic acid membrane with terbium(III) and examined the adsorption and luminescence properties of the resulting material.

EXPERIMENTAL

Our study was concerned with 0.25-mm-thick perfluorosulfonic acid membranes MF-4SK produced in Russia. They were purified by boiling in concentrated nitric acid for 2–3 h and thoroughly washing with distilled water to negative reaction for NO_3^- anions. The quality of purification of the membranes was judged from the transparency in the visible and near UV ranges, as well as from the lack of luminescence excited with nitrogen laser. The content of the accessible sulfo groups was determined by the following procedure. The membranes with the known weight were immersed in an aqueous solution of NaOH for 1 day so that all the protons in the sulfo groups be replaced by sodium cations. Next, the alkali was titrated with hydrochloric acid and, from the difference in the solution concentrations before and after contacting the PFSM, the content of the sulfo groups [$–SO_3H$] was determined. The membranes were modified by keeping in 0.003–0.01 M aqueous solutions of terbium(III) chloride. The establishment of equilibrium and the content of the cations fixed in the membrane were judged from the decrease in the optical density of the impregnating solution (Fig. 1) in the maximum λ_{max} = 219 nm of the narrow absorption band corresponding to the $4f^8 \rightarrow 4f^7 5d$ transition of terbium(III) [9], for which the extinction coefficient was preliminarily determined to be ε = 326.6 l mol^{-1} cm^{-1}. The amount of the sulfo groups [$–SO_3H$]* spent in the reaction was estimated from the change in pH of the impregnating solution. The modified membranes were washed with distilled water to complete removal of the excess impregnating solution and hydrochloric acid from the pore space. Given below are the results of the analytical and adsorption measurements for the modified membranes:

[$–SO_3H$], mmol g^{-1}	0.840
[$–SO_3H$]*, mmol g^{-1}	0.828
[Tb^{3+}], mmol g^{-1}	0.276
[$–SO_3H$]*/[Tb]	3
V_p, cm^3 g^{-1}	0.200
V_p^*, cm^3 g^{-1}	0.145
ΔV_p/[Tb^{3+}], nm^3 atom^{-1}	0.332
r^*, nm	0.43

humidity $p/p_0 = 0.1–0.95$ set in desiccators with sulfuric acid solutions. The samples were preliminarily dehydrated by keeping over phosphorus(V) oxide to constant weight, since the heat treatment of the membranes even at temperature near 100°C is accompanied by decreases in the pore volume and the number of the accessible sulfo groups [10].

The luminescence in the visible range and the lifetime of the excited state of the membranes before and after water adsorption was recorded in air-tight quartz cells at room temperature on a setup assembled on the basis of a KSVU-1 universal spectral-computing complex [11]. As the excitation source served an

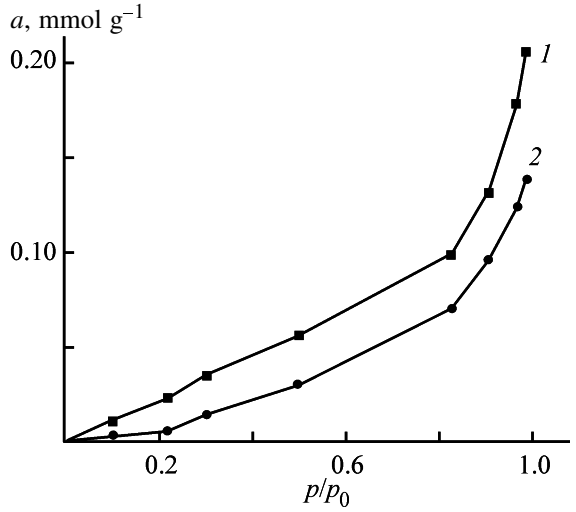

Fig. 2. Isotherms of water adsorption a by the (*1*) initial and (*2*) modified membranes. (p/p_0) Relative humidity.

LGI-21 pulsed nitrogen laser (λ = 337 nm, τ = 10 ns); the luminescence was recorded at an angle of 90° with respect to the laser beam.

Our analytical and adsorption data suggest that terbium sorption in the PFS membrane involves virtually all the accessible sulfo groups and follows the mechanism providing a definite stoichiometry: The experimentally determined molar ratio of the reacted sulfo groups to fixed terbium(III) [$–SO_3H$]* : [Tb^{3+}] was close to 3 in all the experiments. The predominant occurrence of the reaction by the scheme

$$3(–SO_3H) + TbCl_3 \cdot nH_2O \rightarrow (–SO_3–)_3Tb(H_2O)_n + 3HCl$$

with complete compensation of the charge of the Tb^{3+} cations, as we revealed, is determined, most likely, not only by the uniform distribution but also by certain mobility of the exchange centers in the PFSM: Flexible fluorocarbon chains connecting the sulfo groups with the polymeric σ skeleton [1–8] are able of additional orientation in the pore space of the membrane. The fact that the sorption kinetics is close to linear (Fig. 1) suggests that the process is controlled by diffusion of $TbCl_3$ in the pore space of the membranes. Rapid chemical stage and strong fixation of the cations, confirmed by their invariable content in the membrane after prolonged contact with water, suggest formation of a surface species of terbium(III) sulfonate with a low solubility, like its polycrystalline "analog" $Tb_2(SO_4)_3$ [9].

Replacement of the protons in the sulfo groups by terbium(III) cations significantly suppresses the water adsorption throughout the humidity range examined (Fig. 2). It should be noted that the bound water can-

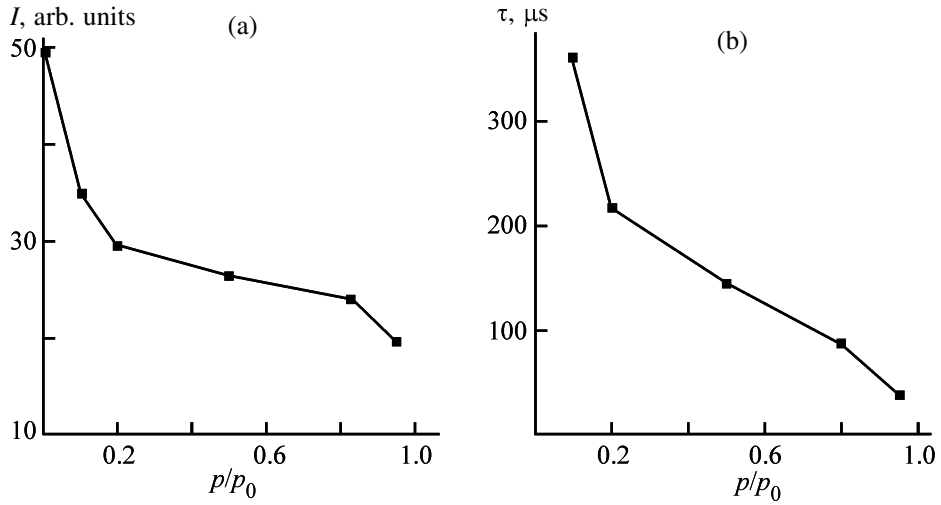

Fig. 4. (a) Intensity I of the band of the main transition $^5D_4 \rightarrow {}^7F_5$ in the luminescence spectrum of Tb^{3+} in the membrane and (b) lifetime of the excited state τ as a function of the relative humidity p/p_0.

not be completely removed by preliminary dehydration of the membranes under mild conditions. Most of the molecules that are strongly fixed in the coordination sphere of terbium(III) are preserved and serve as adsorption centers that are appreciably less reactive than the sulfo groups of the initial membranes. Notably, the sorption space of the PFSM after modification is strongly contracted (Fig. 2). The ratio of the parameter $\Delta V_p = (V_p - V_p^*) = 0.055$ cm^3 g^{-1}, estimated from the end points of the isotherms, to the terbium(III) content in the membrane gives the apparent volume $\Delta V_p/[Tb^{3+}]$ occupied by the hydrated cation, which, in the spherical model approximation, yields a reasonable value of its radius $r^* = 0.43$ nm.

The luminescence spectrum of the modified membrane dried over P_2O_5 (Fig. 3) exhibits five out of seven bands due to radiative transitions from the excited $^5D_4$ to the ground ^7F_j (j = 6, 5, 4, 3, 0) state of terbium(III) [9]. Good resolution of the spectrum suggests a high symmetry of the coordination surrounding of the central atom; the band with a maximum at 546 nm, having the maximal intensity, corresponds to the hypersensitive $^5D_4 \rightarrow {}^7F_5$ transition. It is well known that the water molecules coordinated to the rare-earth metal cations cause nonradiative degradation of the excitation energy via its transfer to high-frequency vibrations ν_{O-H} [9]. Nevertheless, despite low content of bound terbium(III) and the

presence of water in its coordination sphere, the modified membranes dried over P_2O_5 exhibit a visually observed bright green luminescence excited with a nitrogen laser. However, subsequent water adsorption significantly decreases the luminescence intensity (Fig. 3). Sharp simultaneous decreases in the intensity of the hypersensitive band and the lifetime of the excited state of terbium were recorded in a narrow range of the humidities $p/p_0 \leq 0.2$ (Figs. 3, 4). It should be noted in this connection that the ratio of the adsorption at $p/p_0 = 0.2$ to the content of terbium(III) in the membrane corresponds exactly to one water molecule per cation. This suggests that, in the initial stage of adsorption, formation of the nearest water surrounding is complete for most of the terbium(III) cations. Further monotonic quenching of the luminescence is due, most likely, to the gradual, sterically hindered hydration of the cations localized in difficultly accessible sites of the pore space of the membrane.

CONCLUSION

Attaining stable brightness parameters of luminescence of terbium(III)-modified perfluorosulfonic acid membranes requires protecting the luminescence centers against water adsorption. At the same time, the sensor properties of the resulting film luminophore with respect to water can be used in the luminescence control of systems and working items requiring dry atmosphere.

SORPTION AND ION-EXCHANGE PROCESSES

Isotherm of Exchange of Nickel and Sodium Cations on Iron–Manganese Nodules

Abstract—The isotherm of ion exchange of Ni^{2+} and Na^{+} cations on iron–manganese nodules was studied. The ion exchange was described by an equation similar to the Langmuir isotherm. The limiting sorption and the apparent ion-exchange constant were calculated.

DOI: 10.1134/S1070427206070093

Wastewater and spent process solutions containing nonferrous metal cations in amounts exceeding the maximum permissible concentration are presently treated by the reagent method. This method yields a large amount of precipitates with a rather high content of valuable metals, which are virtually irrevocably lost [1]. Other waste treatment techniques: electrocoagulation, electrodialysis, reverse osmosis, and ultrafiltration, are used only locally. Therefore, a particular importance is acquired by sorption and ion exchange, which allow effective recovery of nonferrous metals from waste solutions of various salt compositions [1].

It was shown in [2, 3] that iron–manganese nodules (IMNs) are a promising natural sorbent for treatment of natural and deep-well water used for drinking purposes and of wastewater and spent process solutions.

Deposits of iron–manganese nodules widely occur on the bottom of the Gulf of Finland in the Baltic Sea, being mostly found on the bottom surface [4].

Two types of deposits are found in the Gulf of Finland. Those of the first type lie at a depth of 60 m and more in the southern and northern parts of the gulf. Nodules in these deposits are spherical formations with grain size of 1–2 to 30 mm (predominant diameter 1–16 mm), strength of 100 kPa (1 kg cm^{-2}), and density of 1.6 g cm^{-3}. Tentative estimates of the nodule resources in this region yield 25–30 million tons, which corresponds to a mainland deposit of medium profitableness [5].

Another deposit lies at smaller depths of 25–30 m in the Kopor'e bay. The predominant nodule diameter is 3–5 mm, and less frequently up to 15–30 mm. In the summer of 2005, the first 2500 tons of a nodule-containing material was recovered from this deposit from depths of up to 30 m [5].

The technology of IMN recovery has been developed by Dobretsov and co-workers [5]. The possibility of utilization of spent nodules by the pyrometallurgical method at metallurgical plants by a technology involving the recovery of nonferrous metals (manganese, copper, cobalt, nickel) has been studied [6, 7].

An analysis of the substance composition of IMNs demonstrated [8] that the main part of the ore component is represented by iron and manganese hydroxides and nonferrous metals are in an isomorphic association with minerals of manganese and iron. A characteristic feature of IMNs is their hygroscopicity caused by the developed surface of the material (58% porosity). The environmentally safe IMN material has the form of ready-for-use rounded grains with a granulometric composition suitable for use in poured filters.

Table 1 lists the chemical composition (the most important components) of nodules from the Kopor'e bay, determined by X-ray fluorescence analysis, in comparison with that reported in [3]. Because the specific surface area of the nodules is 43.81 $m^2 g^{-1}$ [9], the content of MnO_2 in these nodules exceeds that in imported pyrolusite sorbents of the Aquamandix brand. The sorption capacity of IMNs for iron(II) is 46.34 to 123.56 g kg^{-1}, against 3.25 g kg^{-1} for the imported analog [9]. Granulation of IMNs with bentonite clays makes the capacity of the modified

Table 1. Chemical composition of nodules from the Kopor'e bay

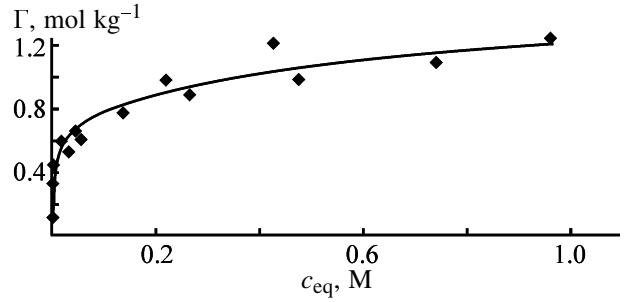
P_2O_5	–	2.70

nodules 2–3 times higher, which is due to an increase in the specific surface area in the course of grinding and granulation with the binder.



The large resources of IMNs, their comparatively large specific surface area and high sorption capacity, and the possibility of their utilization make application of IMNs in purification techniques economically efficient.

This study is concerned with the isotherm of exchange of sodium and nickel ions on the IMN surface.

Natural samples of iron–manganese nodules contain various exchange cations, and, therefore, the IMNs were converted prior to experiments into the sodium form, because sodium ions are displaced with any cations [8].

An air-dry IMN sample with a grain size of –0.25+0.10 mm was soaked in a NaOH solution (5 wt %) for 5 days with intermittent stirring. The alkali solution was daily replaced with a fresh one. The IMN conversion into the sodium form was considered complete when the activity of Na^+ cations after treatment of IMNs with an alkaline solution reached a constant value. The activity of Na^+ ions in alkaline solutions diluted upon contact with IMNs to concentrations of 0.001–0.01 mol kg^{-1} using a volumetric flask was measured with an ion-selective electrode and an Anion ion meter. After that, IMNs were washed many times with distilled water to pH 7 in a water extract and dried to an air-dry state. The ion exchange was studied on model aqueous $NiSO_4$ solutions with a Ni(II) concentration of 0.0107–1.0846 M at 298 K. The sorption value, Γ (mol kg^{-1}), of nickel cations was determined under static conditions at a ratio between the volume of the liquid phase and the weight of the solid phase V/m = 10 ml g^{-1} and a 5-g portion of IMNs from the difference of the concentrations of the starting (c_0) and equilibrium (c_{eq}) solutions by the formula

$$\Gamma = (c_0 - c_{eq})V/m. \quad (1)$$

Isotherm of sorption Γ of nickel(II) ions on the IMN surface. (c_{eq}) Equilibrium concentration of nickel(II) ions.

The nickel sulfate solution with a weighed portion of IMNs was agitated with a magnetic stirrer at a rate of 400 rpm to the equilibrium state. The equilibrium corresponding to a constant solution concentration was attained within 5–6 h; in the experiments, the time of phase contact was set to be no less than 10 h.

After an experiment, the solution was filtered through a blue-band filter, and the equilibrium concentration of sodium ions was measured with an ion-selective electrode and an Anion ion meter, and that of nickel(II) ions, by the photometric method [10]. This method is based on the formation of a colored nickel(II) complex with dimethylglyoxime (Chugaev reagent), occurring in an alkaline medium in the presence of an oxidizing agent.

Solution aliquots with volumes of 2 to 10 ml, depending on the content of nickel ions, were transferred into a 50-ml vessel. Then, 5 ml of an aqueous $Na_2S_2O_8$ solution (5 wt %), 5 ml of a solution of the Rochelle salt ($C_4H_4O_6KNa \cdot H_2O$) (20 wt %), and 5 ml of a solution of dimethylglyoxime in a sodium hydroxide solution (5 wt %) were added, and the mixture was brought to the mark with water. The content of nickel(II) in the solution under study was determined from the intensity of the absorption band associated with the nickel complex with dimethylglyoxime at a wavelength of 540 nm. This technique makes it possible to determine the content of nickel(II) in the range 2–20 μg in 25 ml of a solution. The determination is hindered by substances that have their own coloration and cations that form hydroxide precipitates in an alkaline medium (Fe^{2+}, Fe^{3+}, Al^{3+}, Mg^{2+}, Cu^{2+}, Mn^{2+}).

The figure shows the isotherm of sorption of nickel(II) cations on the IMN surface, plotted using the

data of Table 2: initial and equilibrium concentrations of nickel ions, c_0 and c_{eq}; sorption value of nickel ions, Γ; reciprocal sorption value of nickel ions, $1/\Gamma$; equilibrium concentrations of sodium ions, c_{Na^+}; and mean ionic activity coefficients $\gamma_\pm$ of Na_2SO_4 and $NiSO_4$ [11]. Measurements of the equilibrium concentration of sodium ions with an ion-selective electrode confirmed the equivalence of exchange of sodium ions for those of nickel. The isotherm presented in the figure is described by the Freundlich equation $\Gamma = 1.218\,c_{eq}^{0.195}$ with an approximation confidence $R^2 = 0.96$.

The ion exchange of nickel and sodium ions was thermodynamically described on the assumption that the solid phase is ideal, i.e., with the activity coefficients of ions in the sorbed state disregarded. The previously suggested [12] method of linearization of an analog of the Langmuir equation was used. The equation describing the mass action law for the ion-exchange reaction

$$2Na_s^+ + Ni_{aq}^{2+} \rightleftarrows 2Na_{aq}^+ + Ni_s^{2+}$$

has the form

$$K = \frac{\Gamma_{Ni^{2+}} a_{Na^+}^2}{\Gamma_{Na^+}^2 a_{Ni^{2+}}}, \quad (2)$$

where K is the apparent exchange constant; $\Gamma_{Ni^{2+}}$ and Γ_{Na^+}, sorption values of nickel and sodium ions (mol kg^{-1}); and a_{Na^+} and $a_{Ni^{2+}}$, activities of the ions in solution (mol kg^{-1}).

The limiting sorption capacity for the ions (Γ_∞, equiv kg^{-1}) is given by

$$\Gamma_\infty = \Gamma_{Na^+} + 2\Gamma_{Ni^{2+}},$$

where the sorption values of the ions are expressed in moles per kilogram.

Equation (1) can be brought to the form

$$K = \frac{\Gamma_{Ni^{2+}}[Na^+]^2\gamma_{\pm(Na_2SO_4)}^2}{\Gamma_{Na^+}^2[Ni^{2+}]\gamma_{\pm(NiSO_4)}} = \frac{\Gamma_{Ni^{2+}} c_{Na^+}^2 \gamma_{\pm(Na_2SO_4)}^2}{(\Gamma_\infty - 2\Gamma_{Ni^{2+}})^2 c_{eq}\gamma_{\pm(NiSO_4)}}. \quad (3)$$

Equation (2) was transformed to formula (4), which is similar to the equation of the Langmuir isotherm (3):

$$\Gamma = \Gamma_\infty Ka(1 + Ka)^{-1}, \quad (4)$$

$$\Gamma_{Ni^{2+}}^{1/2} = \Gamma_\infty(Kc_{eq})^{1/2}[c_{Na^+}(\gamma_{\pm(Na_2SO_4)}^2/\gamma_{\pm(NiSO_4)})^{1/2} + 2(\Gamma_{Ni^{2+}}Kc_{eq})^{1/2}]^{-1}. \quad (5)$$

The linear form of the equation has the following appearance:

$$1/\Gamma_{Ni^{2+}} = 2/\Gamma_\infty + c_{Na^+}(\gamma_{\pm(Na_2SO_4)}^2/\gamma_{\pm(NiSO_4)})^{1/2} \times [\Gamma_\infty(K\Gamma_{Ni^{2+}}c_{eq})^{1/2}]^{-1}. \quad (6)$$

which is similar to the linear Langmuir equation:

$$1/\Gamma = 1/\Gamma_\infty + 1/(\Gamma_\infty Ka).$$

The dependence of the reciprocal sorption value of nickel ions, $1/\Gamma_{Ni^{2+}}$, on the argument

$$f(c) = c_{Na^+}(\gamma^2_{\pm(Na_2SO_4)}/\gamma_{\pm(NiSO_4)})^{1/2}(\Gamma_{Ni^{2+}}c_{eq})^{-1/2}$$

is approximated by the linear equation

$$1/\Gamma_{Ni^{2+}} = 1.190 + 0.403f(c),$$

with an approximation confidence $R^2 = 0.99$. This equation was used to calculate the limiting sorption capacity for the ions, $\Gamma_\infty = 1.68$ equiv kg^{-1}, the apparent ion-exchange constant $K_{Na^+/Ni^{2+}} = 2.18$, and the Gibbs energy of exchange of nickel ions for those of sodium on the IMN surface, $\Delta G^0_{298} = -1.932$ kJ mol^{-1}.

The limiting sorption capacity for strontium ions on the IMN surface $\Gamma_\infty = 0.97$ equiv kg^{-1} [13], which exceeds by a factor of 1.73 that for nickel ions, $\Gamma_\infty = 1.68$ equiv kg^{-1}. Apparently, this is due to the fact that the landing site for Ni^{2+} ions is smaller. The specific surface area of IMNs, $S_{sp} = 43.1$ m^2 g^{-1} [9] and the limiting sorption capacity for nickel ions of 0.84 mol kg^{-1} were used to estimate the landing site area for Ni^{2+} ions (m^2):

$$S_M = \frac{S_{sp}}{\Gamma_\infty N_A} = \frac{43.81 \times 10^3}{0.84 \times 6.02 \times 10^{23}} = 8.66 \times 10^{-20},$$

where N_A is the Avogadro number.

Hence follows that the radius of a sorbed Ni^{2+} ion is 166 pm. This value exceeds the crystallographic radius of Ni^{2+} by Bokii (74 pm) [11]. The experimentally determined radius of the nickel ion is to be regarded as the mean effective radius of hydrated Ni^{2+} ions.

The resulting value of the radius of Ni^{2+}_{aq} on the IMN surface is smaller than the radius of the Sr^{2+}_{aq} cation sorbed on IMNs (219 pm) [13] and smaller than the radius of hydrated Fe^{3+} ions on clay (348 pm) [12].

The radius of strontium ions sorbed on clay (302 pm) [14] coincides with the Stokes radius of hydrated ion (309 pm) [11]. Consequently, the strontium ion is sorbed in the totally hydrated form on clay and is partly dehydrated on IMNs. The hydrated radius of the nickel(II) ion should by larger than that of strontium because of the stronger polarizing action resulting from the smaller crystallographic radius of the nickel ion at the same ion charges ($r_{Sr} = 120$ pm and $r_{Ni} = 74$ pm [11]). This assumption is also confirmed by the lower equivalent electrical conductivity of the strontium ion ($\lambda_{0,Ni^{2+}} = 1.080 \times 10^{-2}$ and $\lambda_{0,Sr^{2+}} = 1.188 \times 10^{-2}$ S m^2 equiv^{-1} [11]). Because the radius of the hydrated Ni^{2+} ion, equal to 166 pm, is smaller than that of the Sr^{2+} ion (219 pm), the nickel(II) ion is more strongly dehydrated on IMNs and is more firmly bound to IMNs than the strontium ion.

The cations under study are arranged, as regards the Gibbs energies of ion exchange, in the following order of displacement powers, which correlates with the increase in the ionic potential z/r of the cations, where z is the charge and r the crystallographic radius of the cations by Bokii [11] ($r_{Na} = 97$, $r_{Sr} = 120$, $r_{Ni} = 74$, $r_{Fe} = 80$ pm):

	Na^+	$< Sr^{2+}$	$< Ni^{2+}$	$< Fe^{3+}$
ΔG^0_{298}, kJ mol^{-1}		–0.78	–1.93	–8.85
$(z/r) \times 10^3$, pm^{-1}	10.31	17.86	28.99	42.25

The ionic potential of the Ni^{2+} ion is higher and, consequently, nickel(II) ions will displace Na^+ and Sr^{2+} ions from the IMN surface.

CONCLUSIONS

(1) The isotherm of ion exchange of Na^+ and Ni^{2+} ions on iron–manganese nodules was described by an equation similar to the Langmuir equation and can be represented in the linear form with an approximation confidence $R^2 = 0.99$.

(2) The apparent ion-exchange constant $K = 2.18$ and the Gibbs energy of exchange of nickel ions for those of sodium on the surface of iron–manganese nodules, $\Delta G^0_{298} = -1.932$ kJ mol^{-1}, were determined. The area of the landing site for nickel ions was estimated to be 8.66×10^{-20} m^2. The radius of the sorbed ion, equal to 166 pm, indicates that its binding to the iron–manganese nodule is stronger.

SORPTION AND ION-EXCHANGE PROCESSES

Extraction of Carpathian Menilite Shales with Organic Solvents

Abstract—Extraction of Carpathian menilite shales with 18 solvents at 20°C was examined.

DOI: 10.1134/S107042720607010X

Oil shales are used as power-plant fuel to only a small extent but are regarded as potential power resources for the future. This concerns especially shales with a fairly high content of organic substances, such as Estonian, Australian, some Chinese shales, and shales from the Green River deposit in the United States. At the same time, a number of applications were suggested for resins obtained from shales by pyrolysis or extraction with organic solvents: transformation into motor fuel [1], coke [2], adhesives, surfactants, etc. It should be specially mentioned that the resin of Estonian shales contains alkylresorcinols used in a number of industries, for example, in preparation of epoxy resins or synthetic tanning agents that are difficult to obtain synthetically [3]. Therefore, a number of studies [4, 5] were devoted to the properties and possible applications of oil shales.

Pyrolysis to obtain resins makes sense only if shales contain no less than 20% organic substance, which yields up to 10% liquid fractions and also certain amount of fuel gases [6]. At a lower content of organic components, the power consumed in pyrolysis is too large, which makes more reasonable extraction of the shale with organic solvents at room or elevated temperature, followed by blowing off the residual solvents from the shale. For example, heating the shale containing 12.8% carbon with a tetralin–water mixture to 374°C at a pressure of 6.8 MPa allows 85% recovery of organic components of the mineral [7].

The Carpathian menilite shales from the Sinevidne deposit typically contain less than 10% organic components and, hence, the yield of the resin in pyrolysis is several per cents of their weight only. Therefore, it is more reasonable to recover resins by extraction with organic solvents. However, this requires choosing solvents with the best extraction properties.

Previously [8] we studied extraction of these shales with a number of organic solvents. The content of carbon in the sample examined was 12.0%, and the calcination loss, 26%. Such experiments on extraction are typically carried out in a Soxhlet apparatus. Since our study was aimed at comparing the performances of the extracting agents under identical conditions, extraction was carried out at room temperature by keeping the shale sample in excess solvent for 24 h with intermittent stirring. This eliminates both the interference of the temperature factor in extraction and possible partial tarring of high-boiling extracting agents. Such a procedure does not ensure complete extraction of the organic component, but more than 90% of soluble substances passes into solution even in the first extraction run, as shown by Kröger [9] in a study of extraction of coals.

Since the shale extract contains phenols and carboxylic acids [10], it could be expected that the amount of the extract Q will depend on the basicity of the extracting agent. However, there exists no definite relationship between Q and the Gutmann donor number DN of the solvents (Fig. 1), although these parameters show similar trends in variation. Also, there exists no correlation between Q and the Hildebrand solubility parameter δ. All these facts suggest a complex interaction of the solvents with the substance being extracted. We attempted previously [8] to describe the relationship between the physicochemical characteristics of the solvents and the apparent equilibrium constant of dissolution P (i.e., the ratio of the amount of the extract to that of the residue) in terms of the linear free energy relationship. To this end, we used a multiparameter equation which takes into account the capability of the extracting agent for specific and nonspecific interactions. However, those results

Amount Q and W of the extractable substances recovered from shales by 1 mol of the solvent with the donor number DN

* The data for these solvents were eliminated from the total calculation.

cannot be considered as satisfactory: For 18 solvents the multiple correlation coefficient R was as low as 0.800.

When treating extraction as an equilibrium physicochemical process governed by interaction of the dissolved substance with the solvent, it is more reasonable to assume that the free energy of the process ΔG will be proportional to the logarithm of the constant of the equilibrium between the solvated and nonsolvated substrate species, $\log K$. The molecular weight of the extracted (dissolved) resins is typically unknown, but in more recent studies on extraction of coals [11] we found that, with sufficient accuracy, $\log K$ can be replaced by the logarithm of the weight W of the substrate fraction dissolved in 1 mol of the extracting agent. Therefore, in this study we recalculated the data from [8] in this context. The table presents the amounts (in per cent Q and grams per mole of the extracting agent W) of the substance recovered with various solvents. Similar to [11], these data were correlated using a six-parameter equation

$$\log W = a_0 + a_1 f(n^2) + a_2 f(\varepsilon) + a_3 B + a_4 E_T + a_5 \delta^2 + a_6 V_M, \quad (1)$$

where n and ε are the light refractive index and dielectric permittivity of the solvents, respectively, i.e., the parameters related to the polarizability and polarity of the solvents, responsible for nonspecific solvation of the extract; B and E_T, Palm basicity and Reichardt acidity, respectively, determining the capability of the extracting agents for specific solvation [12]; δ^2, squared Hildebrand solubility parameter proportional to the cohesion energy of the solvents; and V_M, molar volume of the solvents.

The characteristics of the solvents were taken from [13], and the calculational procedure, from IUPAC recommendations [14].

For all the 18 solvents the parameter R was unsatisfactorily low, 0.880, though higher than that given in [8]. As shown in [14], successive exclusion of data for several most outlying extracting agents yields equations with higher R parameters: After elimination of

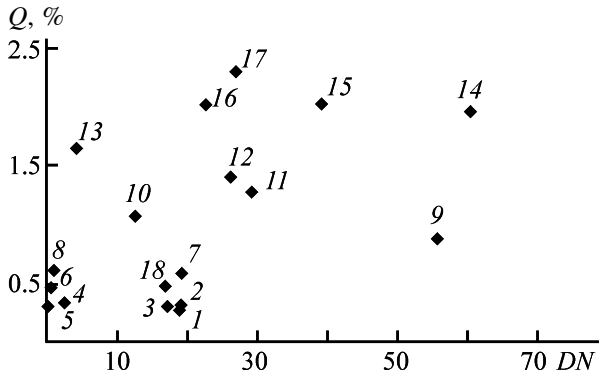

Fig. 1. Yield of the extract Q vs. the donor number DN of the extracting agents. Figures at points correspond to solvent nos. in the table; the same for Fig. 2.

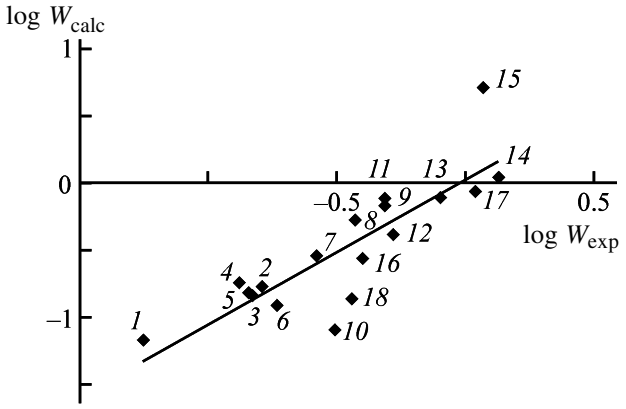

Fig. 2. Relationship between the experimentally determined and calculated [Eq. (3)] amounts of the extractable substances W, recovered with 1 mol of the extracting agent.

the data for acetic acid, quinoline, and acetone, R increased to 0.915, 0.935, and 0.960, respectively, which is acceptable according to the recommendations from [14]. Thus, we obtained with an acceptable accuracy Eq. (2) relating the yield of the extract to the physicochemical characteristics of the extracting agents:

$$\log W = -4.230 + (7.42 \pm 1.01) f(n^2) + (1.84 \pm 0.64) f(\varepsilon) + (1.42 \pm 0.18) \times 10^{-3} B + (0.73 \pm 1.06) \times 10^{-2} E_T - (0.42 \pm 0.25) \times 10^{-3} \delta^2 + (6.60 \pm 2.47) \times 10^{-3} V_M, \quad (2)$$

$N = 15$, $R = 0.960$, rms deviation $S = \pm 0.109$.

The pair correlation coefficients between $\log W$ and individual parameters r, which were estimated at 0.432, 0.059, 0.527, 0.225, 0.235, and 0.501, respectively, suggest the lack of unambiguous quantitative correlation between $\log W$ and any of the parameters used, taken alone. Evidently, extraction is governed by a combination of several factors, among which the most significant will be, probably, the basicity and the molar volume of the extracting agents, as judged from the r values. Therefore, we elucidated in more detail the significance/insignificance of individual terms of the equation: Following the recommendations from [14], these terms were successively excluded and the parameter R was determined for every resulting equation with a smaller number of the terms. If R decreases insignificantly, the eliminated term will be of little significance. In this way, we established insignificance of the electrophilic solvation parameter E (R decreased to 0.959 only) and relatively little significance of the δ^2 term. The dependence of the yield of the extract on the properties of the extracting agent can be adequately described by a four-parameter equation

$$\log W = -4.020 + (7.43 \pm 1.11) f(n^2) + (1.68 \pm 0.48) f(\varepsilon) + (1.45 \pm 0.20) \times 10^{-3} B + (6.19 \pm 1.81) \times 10^{-3} V_M, \quad (3)$$

$$R = 0.951, \; S = \pm 0.120.$$

The parameters $\log W$ calculated by Eq. (3) and their deviations from the experimental data $\Delta \log W = \log W_{calc} - \log W_{exp}$ are also presented in the table. It is seen that these deviations are less or only insignificantly larger (formamide, DMSO, chloroform) than the rms deviation $S = \pm 0.120$. More substantial deviations are observed only for the solvents excluded from consideration. Figure 2 shows the relationship between $\log W_{calc}$ and $\log W_{exp}$.

Further exclusion of any term of Eq. (3) yields expressions with unacceptably low parameters R [without $f(\varepsilon)$ or V_M, R decreases to 0.917], or completely breaks the correlation: Without $f(n^2)$ or B terms, the parameter R becomes equal to 0.77 or 0.73, respectively.

Equation (3) shows that the yield of the extractable substances from Carpathian menilite shale is governed by the solvation power of the solvents, which is above all connected to the polarizability and basicity of the solvents. This is easily understood in view of the presence of acid groups and aromatic moieties in the organic substance of the shales. The two other factors, polarity and molar volume of the extracting agents, affect the yield of the extract less significantly.

Thus, solvents with high basicities (amines, amides) and, desirably, enhanced polarizabilities will be the best extracting agents. This is generally consistent with our experimental data (see table), though the sequence of the performance of the extracting agents represented in mass fractions of the extractable substances will naturally differ from that of the solubilities in 1 mol of the solvent. Technologically, it is also necessary to take into account some other properties such as thermal stability, boiling point which should desirably be low, etc. Among the extracting agents examined, the best performance will be exhibited by formamide, *N*-methylpyrrolidone, and triethylamine.

CONCLUSIONS

(1) Experimental yields of the extractable substances from menilite shales, represented as the amounts of the substance recovered by 1 mol of the

extracting agent, can be adequately correlated with the physicochemical characteristics of the organic solvents.

(2) The extracting power of the solvents is determined, above all, by their basicity and polarity.

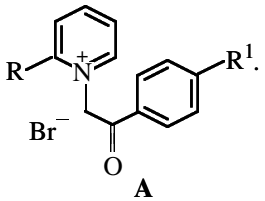
APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Anticorrosive Properties of *N*-Acetylmethylpyridinium Bromides

R. I. Yurchenko, I. S. Pogrebova, T. N. Pilipenko, and T. E. Shubina

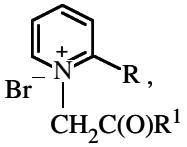


Kiev Polytechnic Institute, National Technical University of Ukraine, Kiev, Ukraine

Received October 25, 2005; in final form, February 2006

Abstract—The inhibiting action of *N*-acetylmethylpyridinium bromides on the corrosion of low-carbon steel in a 3 M sulfuric acid solution at 20, 40, 60, and 80°C was studied. The mechanism of their protective action was examined using electrochemical methods. Compounds exhibiting high anticorrosive properties at elevated temperatures were found.

DOI: 10.1134/S1070427206070111



It has been shown previously [1] that *N*-phenacylmethylpyridinium bromides (**A**) are effective inhibitors of the acid corrosion of steel and their protective properties depend on the nature of the substituents R and R^1:

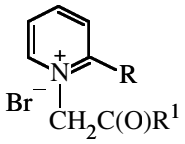
A

It was found, by varying R and R^1, that the coefficients γ of steel corrosion hindrance for these compounds at 20 and 40°C correlate with the σ_c^0 constants characterizing the combined action of the mesomeric and π-induction effects of the substituents R and with the induction σ_I constants of R^1 groups. As temperature increases, their anticorrosive action is significantly enhanced, but, in this case, the correlation between the corrosion hindrance factors and the electronic characteristics of the substituents is broken.

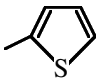
This study is concerned with the anticorrosive properties of pyridinium bromides containing a CH_3 or NH_2 group in position 2 and methylacyl groups with CH_3, *t*-Bu, 1-Ad, and 2-thienyl substituents at the nitrogen atom (compounds **Ia**–**Id**, **IIa**–**IId**):

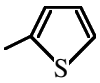
where R = CH_3 (**I**), NH_2 (**II**); R^1 = CH_3 (**a**), *t*-Bu (**b**), 1-Ad (**c**), 2-thienyl (**d**).

The pyridinium bromides necessary for the study were synthesized by the standard procedure involving the reaction of 2-methyl- or 2-aminopyridine with the corresponding bromomethyl ketones.



EXPERIMENTAL





The anticorrosive properties of the compounds studied were evaluated at inhibitor concentrations of 1×10^{-2} M by the corrosion hindrance factors γ and degrees *Z* of corrosion protection of 08KP steel in a 3 M sulfuric acid solution at 20, 40, 60, and 80°C. The corrosion tests were carried out using the conventional gravimetric method [1]. Voltammetric measurements were performed in the potentiodynamic mode, after a free corrosion potential E_c of steel is attained, at a potential sweep rate of 2 mV s^{-1}.

The results obtained in the corrosion tests demonstrated that compounds **Ia**–**Id** and **IIa**–**IId** exhibit a stronger inhibiting effect than their phenacyl analogs **Ie** and **IIe** (Table 1). For compounds **Ie** and **IIe** at 20°C, the steel corrosion hindrance factors are 15.50 and 23.70, respectively [1]; and for compounds **Ia**–**Id** and **IIa**–**IId**, 19.60–39.60. As temperature increases, the anticorrosive effect of the compounds studied is enhanced, and at 60°C the hindrance factors are approximately 200–560 and 200–860 for compounds **Ia**–**Id** and **IIa**–**IId**; for their phenacyl analogs, the hindrance factors do not exceed 200 units.

It is known that, owing to the methylene group separating the pyridinium and phenacyl moieties, the compounds under study exhibit a conformational lability, which allows them to occupy, depending on conditions, a position on the steel surface that is the

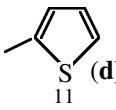
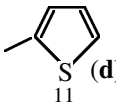
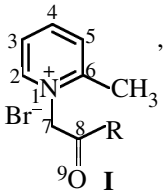
most favorable for adsorption. As also in pyridinium bromides **Ie, IIe** [1], the most probable reaction center responsible for adsorption of the compounds under study at room temperature is the pyridinium moiety of the molecule, which gives rise to a positive adsorption-related step of the potential and hinders corrosion by the energy mechanism of inhibition. At the same time, the carbonyl group contained in these compounds is responsible for chemisorption of the compounds, which becomes more pronounced as the solution temperature increases [2].

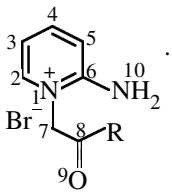
It was found that compounds **Ia**–**Ic**, **Ie**, **IIa**–**IIc**, and **IIe** at 20°C show linear relationships between $\log\gamma$ and the induction σ* constants of the substituents R^1:





$$\log\gamma = 1.30 - 0.174\sigma^*R^1, \quad r = 0.999, \qquad (1)$$





$$\log\gamma = 3.45 - 0.455\sigma^*R^1, \quad r = 0.991. \qquad (2)$$

The coefficients (0.174 and 0.455) in Eqs. (1) and (2) point to different sensitivities of the adsorption centers in compounds **Ia**–**Ic**, **Ie** and **IIa**–**IIc**, **IId** to the induction effect of the substituents R^1. This may be due to difference in the induction and mesomeric effects of the methyl and amino groups on the polarizability of the compounds and, consequently, on their adsorbability on the steel surface. It should also be noted that compounds **Id** and **IId** are not described by the dependences obtained and their inhibiting effect is considerably stronger than that expected with account of only the strength and type of the induction effect of the 2-thienyl radical. Such a behavior of inhibitors **Id** and **IId** can be attributed on the assumption that not only the main adsorption centers, but also the thiophene ring directly interact with the steel surface, as previously observed in [3]. As temperature increases, the linear relations $\log\gamma$–σ^*R^1 cease to be valid, which may occur for various reasons: transition from physical sorption to chemisorption; change of the mechanism of the protective action of the inhibitors; high rate of steel dissolution, which hinders their adsorption on the metal; and some other factors. In this case, the correlation coefficients decrease to 0.939, 0.936 at 40°C and 0.877, 0.886 at 60°C.

Quantum-chemical calculations of the charge distribution within the molecule were carried out for compounds **Ia**–**Ie** and **IIa**–**IIe** (Table 2). The molecular configurations were optimized by the B3LYP method [4] with the standard 6-31G basis set, using the GAUSSIAN software package [5]. All the stationary points were characterized via a complete analysis

of the normal modes of harmonic vibrations, in which NIMAG = 0 corresponds to minima on the potential energy surface for all of the optimized structures. The calculations demonstrated that, as the substituents R^1 in the compounds studied are varied, the effective charges on the respective atoms within each series remain virtually the same and change only slightly on passing from **Ia–Id** to **IIa–IId**. The only exception are charges on α-carbon atoms of the pyridine ring (C^6), which strongly differ between the series **I** and **II**. This is due to the different electronegativities of the carbon and nitrogen atoms in the CH_3 and NH_2 groups.

The results obtained (Table 1) suggest that an important role in the inhibiting action of acylmethylpyridinium bromides is played by steric factors. In the series of compounds **Ia–Ic** and **IIa–IIc** with CH_3, *t*-Bu, and 1-Ad groups, for which the steric constants E_s^c are, respectively, 0.00, –2.40 [6], and –2.68 [7], a correlation between the corrosion hindrance factors and the steric effect exerted by these substituents is observed.

The plots of the dependences $\log K_m$–$1/T$ (K_m is the gravimetric corrosion index, and T, absolute temperature) in Fig. 1 indicate that *N*-acylmethylpyridinium bromides affect the effective activation energy of corrosion. In the temperature range 20–40°C, the effective activation energies W_c increase in the presence of compounds **Ia–Ie** and **IIa–IIe** from 81.69 kJ mol^{-1} (no inhibitor) to 86.16–102.44 kJ mol^{-1}, which points to the activation mechanism of the inhibiting effect. At higher temperatures, a deviation from the linear dependences $\log K_m$–$1/T$ is observed and inflections appear, which are probably due to transition from the physical (specific) adsorption of the compounds to chemisorption. The effective activation energy of corrosion decreases to 58.88–26.33 kJ mol^{-1} in the presence of compounds **Ia–Ic**, **Ie** and to 19.15 and 9.57 kJ mol^{-1} for compounds **Id** and **IId**, respectively. This indicates that the inhibition mechanism changes as the temperature increases and the diffusion limitations appearing when reacting particles penetrate across the adsorbed film of an inhibitor play an important role. For these compounds, a noticeable aftereffect is observed, which consists in that their protec-

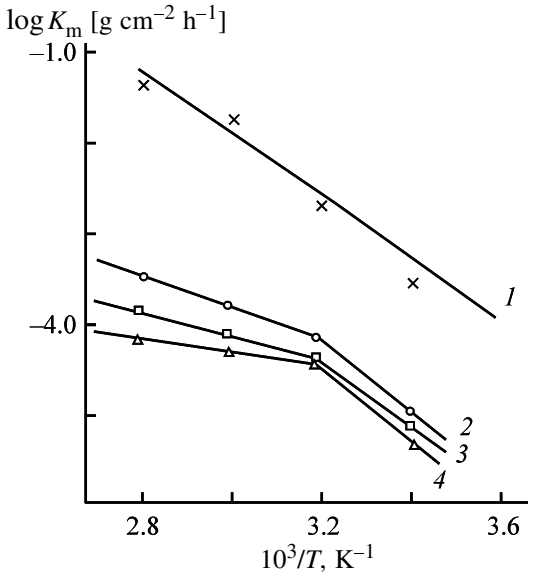

Fig. 1. Temperature dependence of the corrosion rate of 08KP steel in a 3 M H_2SO_4 solution in the presence of 1×10^{-2} M *N*-acylmethylpyridinium bromides. (K_m) Gravimetric corrosion index and (*T*) absolute temperature. Inhibitor: (*1*) none, (*2*) **Ie**, (*3*) **Id**, and (*4*) **IId**.

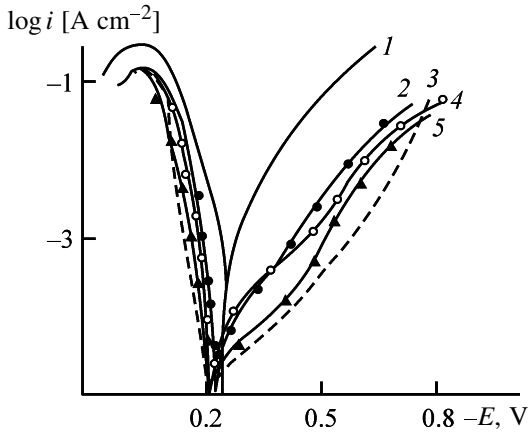

Fig. 2. Anodic and cathodic polarization curves measured on 08KP steel in a 3 M H_2SO_4 solution at 20°C in the presence of 1×10^{-2} M of the compounds under study. (*i*) Current density and (*E*) potential (vs. SHE); the same for Fig. 3. Inhibitor: (*1*) none, (*2*) **Ic**, (*3*) **IIc**, (*4*) **Id**, and (*5*) **IIb**.

tive action is preserved after metal samples are removed from the inhibiting medium. For example, the corrosion of steel in a 3 M H_2SO_4 solution at 60°C in the presence of 1×10^{-2} M **Ic** and **Id** is hindered by factors of 317 and 560, respectively, and that after their being kept in the same solutions for 1 h, washed with distilled water, and submerged in the acid solution without inhibitor at the same temperature, by factors of 30 and 38, respectively.

Voltammetric measurements demonstrated that both the cathodic reaction of hydrogen evolution and the anodic reaction of iron ionization are hindered in the presence of compounds **Ic**, **Id**, **IIb**, and **IId** (Fig. 2). The presence of these compounds in 3 M H_2SO_4 solutions affects only slightly the slopes of the cathodic and anodic polarization curves, i.e., has virtually no effect on the mechanism of partial reactions involved in corrosion. Only at weak cathodic polarizations of steel the curves show poorly pronounced regions of limiting current, which are possibly due to the occurrence of concurrent reactions of oxygen ionization or partial reduction of the compounds under study. A stronger change in the slope of the cathodic curve is observed in the presence of compound **Id**, which possibly indicates that the sulfur atom of the thiophene ring is involved in adsorption. The appearance, in its presence, of a narrow hysteresis loop (Fig. 3) is probably due to hindered desorption from the steel surface of inhibitor molecules or of products formed in partial chemical transformations of the inhibitor on the electrode. However, the hindrance factors calculated from the polarization curves satisfactorily coincide for all the compounds with the hindrance factors found in more prolonged gravimetric tests. This indicates that no noticeable chemical transformations of the inhibitors occur at the steel surface at 20°C.

The results of the calculations in Table 3 demonstrated that the corrosion of steel at 20°C in the presence of compounds **Ia**, **Ic**, **Id** and **IIa**, **IIc**, **IId** is hindered by the energy-related and blocking inhibition mechanisms with the predominant contribution of the energy effect. However, the effect of blocking of the metal surface dominates at 60°C, which is indicated by the fact that γ_{exp} markedly exceeds $\gamma_{\Delta\psi 1}$ calculated assuming an energy-related inhibition mechanism.

Table 3. Experimentally found (γ_{exp}) and calculated ($\gamma_{\Delta\psi 1}$) corrosion hindrance factors of 08KP steel in a 3 M H_2SO_4 solution for *N*-acylmethylpyridinium bromides **Ia**, **Ic**, **Id**, **IIa**, **IIc**, and **IId**

1.6×10^{-3}	20	45	16.91	13.33	1.27
6.4×10^{-4}	20	22	4.45	3.54	1.25
2.56×10^{-4}	20	4	1.28	1.26	1.02
IId, 1×10^{-2}	20	50	24.30	17.78	1.37
Ic, 1×10^{-2}	60	10	317.13	1.93	164.31

Note: It was taken in the calculations [8] that $\gamma_{exp} = \gamma_{\Delta\psi 1}\gamma_\theta$, where $\gamma_{\Delta\psi 1}$ and $\gamma_{\Delta\psi 1}$ are, respectively, the energy-related and blocking hindrance factors; $\gamma_{\Delta\psi 1} = 10^{K\Delta\psi 1}$; $K = b_c/b_0(b_a + b_c)$, $\Delta\psi 1 = \Delta E_c/[1 - b_c b_a/b_0(b_a + b_c)]$; ΔE_c, shift of the free corrosion potential, caused by the inhibitor; b_c and b_a, Tafel slopes of the cathodic and anodic polarization curves in a 3 M H_2SO_4 solution; and $b_0 = 2.3RT/F$.

It is also not improbable that the steel corrosion is hindered by the compounds studied by a more complex mechanism, e.g., with a possible reduction of the carbonyl group they contain and subsequent formation of chemisorbed protective films on the metal surface [9].

CONCLUSIONS

(1) The *N*-acylmethylpyridinium bromides studied are highly effective inhibitors of acid corrosion of steel, especially at elevated temperatures.

(2) The presence in the acyl moiety of the molecule of groups that can be directly involved in an interaction with the steel surface or have a considerable volume markedly enhances the anticorrosive effect of the compounds studied. The hindrance factors at 60°C are as large as 414–865 units in separate cases, and the degree of corrosion protection of steel exceeds 99.5% for all of the compounds studied.

APPLIED ELECTROCHEMISTRY AND CORROSION PROTECTION OF METALS

Composite Coatings Based on Copper Oxides Electrodeposited from Solutions and on Polymers

Abstract—The possibility of obtaining composite coatings consisting of metal oxides deposited from solutions with an asymmetric ac current and of a polymer was studied. Protective properties of the composite coatings were examined.

DOI: 10.1134/S1070427206070123

Of particular interest among composite coatings are metal–polymer coatings (MPCs) in which fluoropolymers are used as the polymer component [1–3]. Incorporation of fluoropolymer particles in the metallic matrix imparts to an MPC antistatic, antiadhesive, and anticorrosive properties, but it retains metallic properties (high thermal and electrical conductivity and wear resistance) and has a good adhesion to the substrate.

Much promise is shown by composite MPCs in which oxides obtained using an asymmetric ac current serve as the matrix. Application of a nonstationary method of electrodeposition of metals opens up wide opportunities in control over the structure and, accordingly, properties of deposited metallic films [4].

The goal of the study was to obtain composite MPCs on the surface of St.3 steel and to examine the protective properties of these coatings. A composite MPC had the form of a porous matrix composed of copper oxide formed by deposition from solution with an asymmetric ac current, rather than by oxidation of the base metal in the course of electrolysis, and was filled with fluoroplastic.

Copper oxides were deposited from solutions containing copper(II) sulfate, chromium(VI) oxide, boric acid, and 1,4-butanediol under polarization with an asymmetric ac current of mains frequency in the form of two half-sinusoids with different amplitudes. A device [5] that comprised two diodes connected in parallel and conducting current in different directions via adjustable resistors served as a current source. As the cell served a glass vessel in which the St.3 steel working electrode with a surface area of 12 cm^2 was placed together with lead (or copper) counter electrodes in sheaths, thermometer, and magnetic rabble. The electrode surface was prepared using the standard stirrer [6]. However, a contact exchange may occur when samples are submerged in the sulfuric acid electrolyte, determined by the relative values of the potentials of these metals (0.34 V for copper and –0.44 V for steel). To suppress the contact exchange in surface treatment, a passivation stage was introduced.

The structure and phase composition of MPCs were determined by transmission electron microscopy (TEM) on a JEOL LEM-100cx electron microscope (Japan) at an accelerating voltage of 100 kV, by X-ray phase analysis (XPA) on a DRON-2 X-ray diffractometer (filtered CuK_α radiation), and by cathodic chronopotentiometry in a 1.0 M solution of $LiBF_4$ in dimethylformamide [7–9]. In the cathodic chronopotentiometry, a sample was polarized with dc current, with the time dependence of the potential recorded.

A preliminary XPA study of the samples demonstrated that the MPC on the samples has a mixed amorphous-crystalline structure, and, therefore, to perform XPA, the samples were calcined in an inert gas (helium).

The adhesion of the MPC was determined by the method of a grid cut. The electrical resistance of samples with MPC was measured with a V7-16A versatile voltmeter by pressing a graphite electrode against the surface of a sample under study with a constant force of 100 g. The resistance was found

Table 1. Conditions of the experiment, experimental results, and design matrix*

* $\overline{Y}_{exp}$, average experimental value of the resistance; $\hat{Y}_c$, calculated value.

at ten different points and the average value was taken. The porosity was studied by the chemical method [10]; accelerated corrosion tests were made in conformity with GOST (State Standard) 9.313–89. The optimal conditions for obtaining copper oxide on the surface of St.3 steel were determined using the method of mathematical experiment design using first-order designs and a fractional factorial experiment (FFE) [11].

Because pure copper has a high electrical conductivity (59.1 MS m^{-1}) and a very low resistance (1.5×10^{-6} Ω), the resistance of MPC should increase upon formation of copper oxides on the steel surface. Therefore, the electrical resistance of MPC (Y) was taken as the optimization parameter. As independent variables were chosen the average anode current J_a (mA) (X_1), average cathode current J_c (mA) (X_2), and the concentrations of the electrolyte components (g l^{-1}): copper(II) sulfate $CuSO_4 \cdot 5H_2O$ (X_3), chromium(VI) oxide (X_4), and 1,4-butanediol (X_5). The temperature, content of boric acid, and quantity of passed anodic electricity were maintained constant.

The coefficients of the linear regression equation

$$\hat{Y} = b_0 + b_1x_1 + b_2x_2 + b_3x_3 + b_4x_4 + b_5x_5$$

were found using quarter-replicates of a 2^5 FFE with the following generating relations: $X_4 = X_1X_2X_3$, $X_5 = -X_1X_2$. The experimental conditions and results and the design matrix are presented in Table 1.

According to the calculations, the regression equation has the form

$$Y = 8.36 + 3.84X_3 + 6.63X_4 - 3.91X_5. \quad (1)$$

The adequacy of Eq. (1) to the experiment was checked using the Fisher test F:

$$F = S^2_{ad}/S^2_{rep} = 11.42/15.08 = 0.75$$

The tabulated value $F_{tab} = 5.3$ and $F < F_{tab}$, and, therefore, the regression equation is adequate to the experiment. Thus, a rise in the MPC resistance is favored by an increase in the content of copper(II) sulfate and chromium(VI) oxide in the electrolyte and by a decrease in that of 1,4-butanediol. The insignificance of the rest of the coefficients in the regression equation means that the values of the variable factors are chosen near the optimum point.

As a result of generalization of the data on the influence exerted by the significant coefficients in Eq. (1) on the electrochemical deposition of copper oxide from solution, a steep ascension was performed. This made it possible to determine the optimal conditions of copper oxide deposition onto the surface of St.3 steel by nonstationary electrolysis.

The results of analyses of the phase composition and structure of MPC confirmed that copper oxide is deposited onto the steel surface in the case of polarization with an asymmetric ac current. The XPA data for the coatings obtained demonstrate that the main phases in MPC are CuO, compounds of the spinel type ($CuFe_2O_4$), and trace amounts of Cu_2O and Cu (Fig. 1).

A suggestion can be made on the basis of Fig. 1 that the MPC substance has poor crystallinity and high dispersity.

A study of the composition of oxide MPCs by cathodic chronopotentiometry is based on cathodic

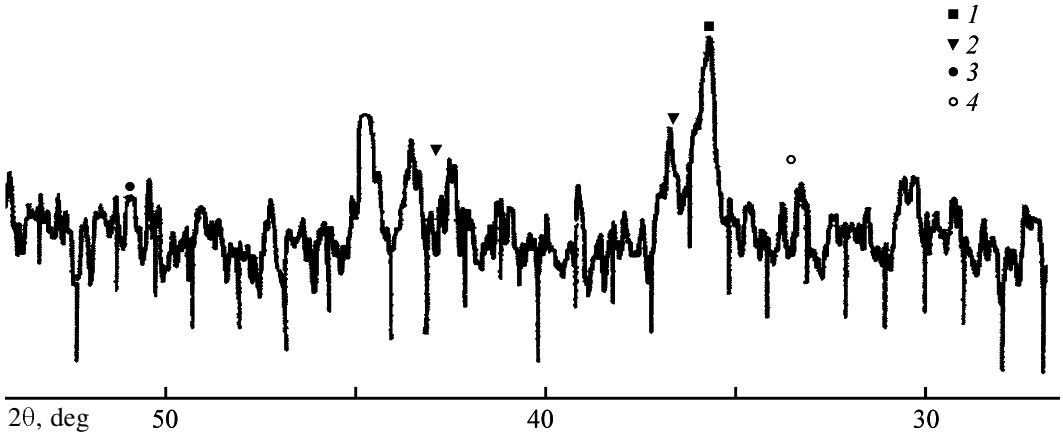

Fig. 1. X-ray diffraction pattern of the surface of oxidized samples. (2θ) Bragg angle. (*1*) $CuFe_2O_4$, (*2*) CuO, (*3*) Cu, and (*4*) Cu_2O.

intercalation of lithium ions from aprotic organic electrolytes

$$Cu_xO_y + zLi^+ + ze \rightarrow Li_2Cu_xO_y.$$

The process ends in the formation of lithium intercalation compounds of variable composition. The fundamental aspects of this process are determined by structural features of the phases under study, degree of oxidation of the metal, and number of point structural vacancies via which ions of intercalated lithium diffuse.

Figure 2 shows that the potentials of the horizontal portions of the chronopotentiograms widely differ between the samples. Comparison of the chronopotentiograms of MPCs with that of pure CuO shows that this phase is characteristic of sample nos. 2 and 5. The rest of the samples have lower potentials in the range 2.2–2.4 V. This can be interpreted as intercalation of Li^+ ions into a phase with a lower degree of copper oxidation, i.e., Cu_2O. The conditions of MPC deposition onto the samples were the same except that they differed in the duration of passivation in the course of surface pretreatment (Fig. 2). Thus, passivation furnishes an additional opportunity of control over the coating properties.

Electron microscopy made it possible to determine not only the qualitative, but also quantitative composition of the MPC substance. The results of calculation of electron diffraction patterns of MPC particles from sample nos. 2 and 5 (Table 2) confirmed the results of XPA and chronopotentiometry.

Table 2 shows that the electron diffraction pattern simultaneously contains lines of pure copper and copper oxide. No electron diffraction patterns of only pure copper or only pure copper oxide were observed.

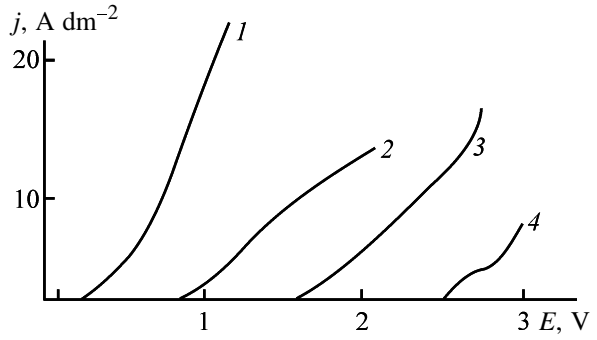

Fig. 4. Anodic polarization curves of samples in 3% NaCl. (*j*) Current density and (*E*) potential. Sample: (*1*) St.3, (*2*) copper oxide, (*3*) copper oxide and polyurethane latex, and (*4*) copper oxide combined with a fluoroplastic-containing formulation.

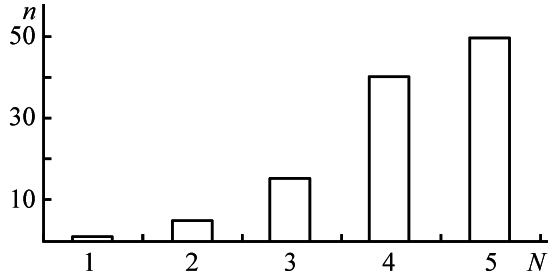

Fig. 5. Comparison of the protective capacities of the samples. (*n*) Number of cycles and (*N*) sample number. Sample: (*1*) St.3; copper oxide: (*2*) with lead counter electrodes, (*3*) with copper counter electrodes, (*4*) combined with a fluoroplastic formulation, and (*5*) with F32LN fluoroplastic and in combination with polyurethane latex.

This means that all coating particles are copper particles enveloped by copper oxide. An exceedingly weak reflection with an interplanar spacing $d = 3.00$ Å was also observed in the electron diffraction pattern. This reflection corresponds to copper(I) oxide. The phase composition determined by analysis of the data obtained is as follows (wt %): copper 50.0, copper(II) oxide 35.0–45.0, and copper(I) oxide ≤5.

The coating has nonuniform thickness and structure (Fig. 3) The thickness varies from 4 to 12 μm. Two regions, upper and lower, of a coating vary in thickness. The lower region, adjacent to the metallic substrate, has a thickness of 7–8 μm and is composed of discrete particles. The upper surface also shows separate layered islands. The high adhesion of the MPC to the substrate is provided by the intermediate sublayer composed of the $CuFe_2O_4$ spinel. This sublayer is formed in the course of cycling, but the MPC is porous in this case. The pores are formed during the cathodic period via discharge of hydrogen ions.

A fluoroplastic-containing formulation and polyurethane latex were deposited onto an oxidized surface of St.3 steel by heteroadagulation, and an F32LN fluoroplastic, by rubbing. The protective properties of the resulting composite coatings after their polymerization drying were assessed by measuring polarization curves in a 3% NaCl solution (Fig. 4). An analysis of these curves demonstrated that copper oxide formed on the steel surface markedly improves the corrosion resistance of steel, and modification of the surface with fluoroplastic substantially hinders the corrosion of the substrate.

The results of express corrosion tests (Fig. 5) are in full agreement with the conclusions made upon analysis of the polarization curves. The express corrosion tests of the composite MPC were terminated after 50 cycles because it still was a long way before the beginning of corrosion owing to the virtually total nonwettability of the coating.

The composite MPC exhibits a good adhesion because of the anchor fixation of the polymer within pores of the metallic matrix in polymerization drying.

CONCLUSIONS

(1) The possibility of obtaining copper oxides on the surface of St.3 steel by their deposition from solution under polarization with an asymmetric ac current was demonstrated.

(2) The optimal conditions of deposition of copper oxide from a copper(II) sulfate solution were found.

(3) The phase composition and structure of the coating substance were determined, and the presence of copper oxide in the coating was thereby confirmed.

(4) The conditions of substrate passivation and the nature of a counter electrode affect the phase composition and structure of a coating.

(5) The substrate corrosion is substantially diminished by copper oxide.

(6) Modification of a coating with fluoroplastic makes it hydrophobic and thereby strongly hinders the substrate corrosion.

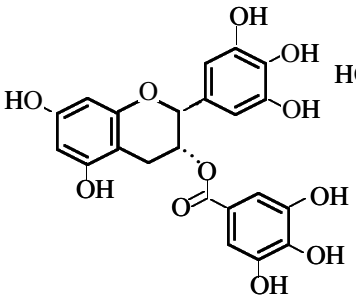
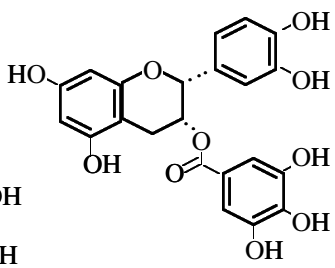
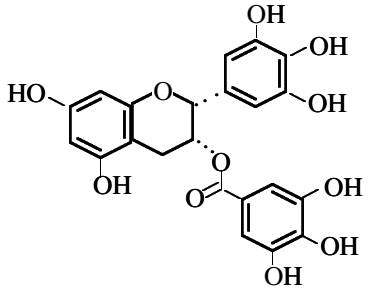
Abstract—Conditions for electrophoretic separation of tea phenolic enantiomers, (+)-catechin and (–)-epicatechin, by capillary (zone) electrophoresis using β-cyclodextrin as a component of the working electrolyte are developed. Optimization is made of the conditions for separating a multicomponent mixture of ionic and neutral polyphenols from various tea samples in the mode of micellar electrophoretic chromatography using sodium dodecyl sulfate as a micelle-forming agent and urea as an additive to the phosphate buffer.



DOI: 10.1134/S1070427206070135



Tea flavanols are classed with the group of compounds known as catechins. These are water-soluble colorless compounds, which are readily oxidized (especially in alkaline solutions) and react with a variety of other compounds [1]:



Catechin (C)

Epicatechin (EC)

Epigallocatechin (EGC)

Gallocatechin gallate (GCG)

Epicatechin gallate (ECG)

Epigallocatechin gallate (EGCG)

The characteristic chemical feature of tea flesh is high content of polyphenols.

Tea polyphenols demonstrate a strong antioxidant activity, scavenging free radicals in biological fluids of human body [2]. It was demonstrated experimentally that catechins have the anticarcinogenic, antisclerotic, and antiviral effects, and that tea caffeine acts as a stimulant [1–4].

The common methods for determination of organic compounds, primarily catechins, in tea are gas and liquid chromatography, spectrophotometric and chemiluminescence methods, and NMR [5]. However, in recent years, such methods as reversed-phase HPLC and capillary electrophoresis, namely, capillary (zone) electrophoresis (CE) and micellar electrokinetic chromatography (MEKC) with UV detection, are more and more often used for quantitative and qualitative analysis of tea [1, 4, 5–8].

In this study we tested MEKC as a method for simultaneous determination of tea polyphenols and caffeine. Among the advantages of this method is a small time required for analysis and the possibility of simultaneous determination of both ionic and neutral analytes.

Here we examined the effects of the surfactant [sodium dodecyl sulfate (DDS)] and organic additives (urea, acetonitrile, and methanol) on the resolution factor and selectivity of separation of bioflavanoids.

EXPERIMENTAL

The electrophoretic determinations were carried out on a Kapel' 105R capillary electrophoresis system with a spectrophotometric detector, equipped with a quartz capillary [75 μm i.d.; effective length 50 cm (total length 60 cm)] with a polyimide external coating. The operating temperature was 20°C. The detector operated at a wavelength of 200 nm.

(+)-Catechin, (–)-epicatechin, (–)-epicatechin gallate, (–)-epigallocatechin, (–)-gallocatechin gallate, (–)-epigallocatechin gallate, and gallic acid were purchased from Fluka and Sigma.

The stock buffer electrolyte solutions were prepared from standard reagents $Na_2B_2O_4 \cdot 10H_2O$ (chemically pure grade), $Na_2HPO_4 \cdot H_2O$ and $NaH_2PO_4 \cdot 12H_2O$ (REATEK), HCl (chemically pure grade), NaOH (chemically pure grade), β-cyclodextrin (Sigma), DMSO (chemically pure grade), DDS (chemically pure grade), urea (chemically pure grade), acetonitrile (ultrapure grade), and methanol (Merck).

In the determinations of tea polyphenols we used the working electrolyte containing 25 mM phosphate buffer (pH 7.0), 50 mM DDS, and 5 wt % acetone. Samples were injected hydrodynamically at 600 mbar s^{-1}. Electrophoretic separations were performed at +25 kV. Before use, the quartz capillary was washed with 1 M HCl and distilled water for 10 min and then conditioned with 0.5 M NaOH and distilled water for 10 min. Between the analyses, it was washed with the working electrolyte for 3 min.

The electrophoretic mobility of the analytes μ_{total}, resolution factor R_s, capacity factor, and separation selectivity and efficiency were estimated by Eqs. (1) and (2):

$$\mu_{tot} = (L_{eff} L_{tot})/U t_{migr}, \quad (1)$$

$$R_s = 1.77(t_2 - t_1)/(w_1^{0.5} - w_2^{0.5}), \quad (2)$$

where L_{eff} and L_{tot} are the effective and total length of the capillary (cm); U is the voltage (25 kV); t_{migr}, analyte migration time (min); t_1 and t_2 are the migration times of the first and second components; and $w_1^{0.5}$ and $w_2^{0.5}$, widths of the peaks at half-height (min).

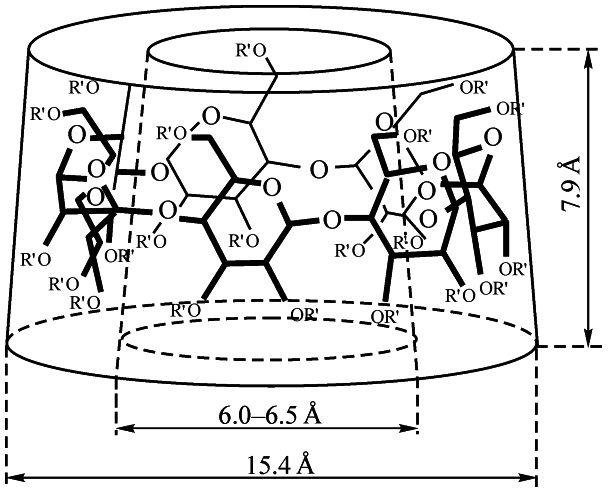


Fig. 1. Structure of cyclodextrin.

It is known that catechins are polyphenols which can be negatively charged at pH > 8 by virtue of the phenolic hydroxy groups in the analyte molecules, so that they can be separated as anions in the CE mode.

When optimizing the electrophoretic separation conditions, we varied the compositions and concentrations of the buffer electrolyte and complexing agent (β-cyclodextrin).

For CE determinations of the catechins, we selected the borate buffer (pH 9.0) containing 4 mM β-cyclodextrin and 10 mM NaOH.

The structure and hydrophobic inner cavity of cyclodextrins allow them to form inclusion complexes with a variety of organic and inorganic compounds via penetration of bulky hydrophobic fragments of analytes to the cavity and interaction of the secondary hydroxy groups of the macrocycle with polar groups of the guest molecule (Fig. 1).

Since β-cyclodextrin is a chiral selector, its introduction into the buffer electrolyte increased the selectivity of separation of the stereoisomers [(+)-catechin and (–)-epicatechin] by virtue of formation of different diastereomeric complexes between the chiral additive and analytes (Fig. 2).

However, even the introduction of the complexing agent, influencing the resolution factor, into the buffer electrolyte did not provide complete separation of the mixture of six most significant polyphenols

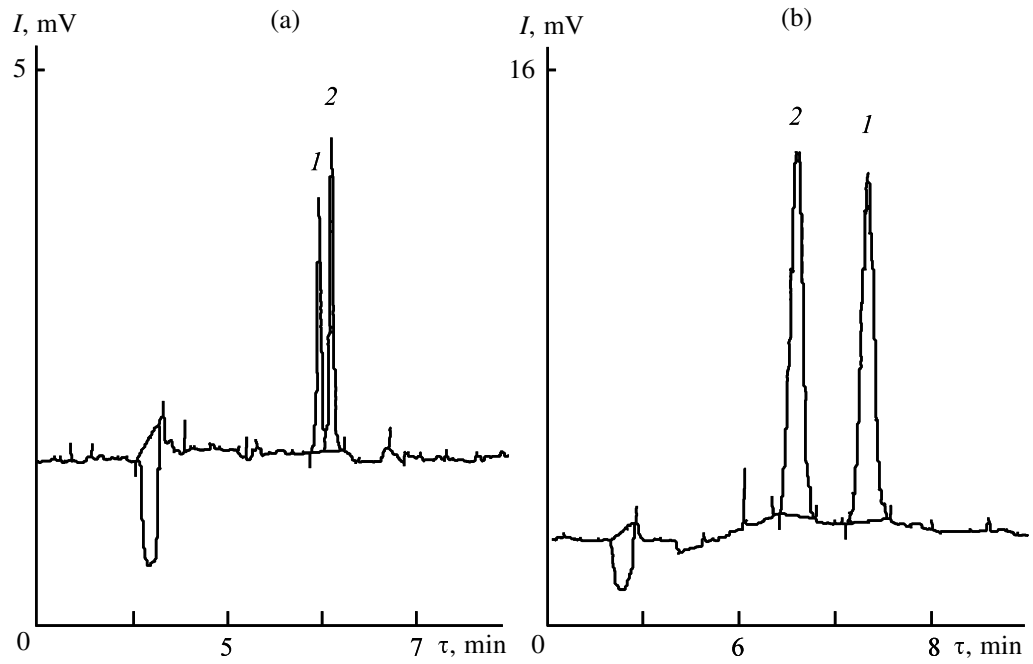

Fig. 2. Electrophoregram of a model mixture of (*1*) catechin and (*2*) epicatechin, obtained in the CE mode. Separation conditions: Kapel' 105R system (UV detection at 200 nm); capillary: 75 μm i.d., L_{eff} = 50 cm, and L_{tot} = 60 cm; injection: 30 mbar, 10 s, 20 kV. Working electrolyte: (a) 5 mM sodium tetraborate (pH 9.0) and (b) 5 mM sodium tetraborate (pH 9.0) + 4 mM β-cyclodextrin + 10 mM NaOH. (*I*) Intensity and (τ) time; the same for Figs. 3 and 5.

[(+)-catechin, (–)-epicatechin, (–)-epicatechin gallate, (–)-epigallocatechin, (–)-epigallocatechin gallate, and (+)-gallocatechin gallate] in the CE mode.

To increase the separation selectivity, we selected the MEKC mode. Additional argument in favor of using this method was that it allows simultaneous determination of catechins and caffeine, which is practically impossible by CE.

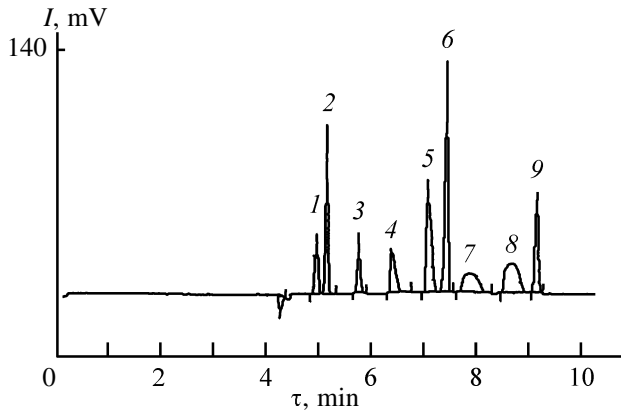

Fig. 3. Electrophoregram of a model mixture containing (*1*) caffeine, (*2*) catechin, (*3*) epigallocatechin, (*4*) epigallocatechin gallate, (*5*) epicatechin, (*6*) gallic acid, (*7*) gallocatechin gallate, (*8*) epicatechin gallate, and (*9*) benzoic acid. Working electrolyte: 25 mM phosphate buffer (pH 7.0) + 20 mM DDS + 10 mM urea; the same for Fig. 5.

Sodium dodecyl sulfate (DDS) is the most widely used anionic surfactant [4]. Above CMC (8 mM), DDS forms micelles representing a pseudostationary phase, thus increasing the separation selectivity as compared to the CE mode by virtue of analyte distribution between the micelles and buffer electrolyte.

Based on the results of preliminary experiments, for the determination of polyphenols we selected 25-mM phosphate buffer (pH 7.0) containing 15 mM DDS. To study the possibility of quantitative determination of tea polyphenols, we introduced benzoic acid as an internal reference. This made it necessary to change the initial separation conditions: we increased the surfactant concentration and additionally introduced urea in a concentration of up to 50 mM. The competitive interaction of urea with the micelles with formation of hydrogen bonds increased the separation selectivity (Fig. 3).

It was demonstrated that the resolution factors and electrophoretic mobilities of the analytes depend on the DDS and urea concentrations in the working electrolyte.

With increasing DDS concentration, the electrophoretic mobilities of the gallate and benzoate anions only slightly change as compared to the neutral analytes migrating to the detector in the form of micellar

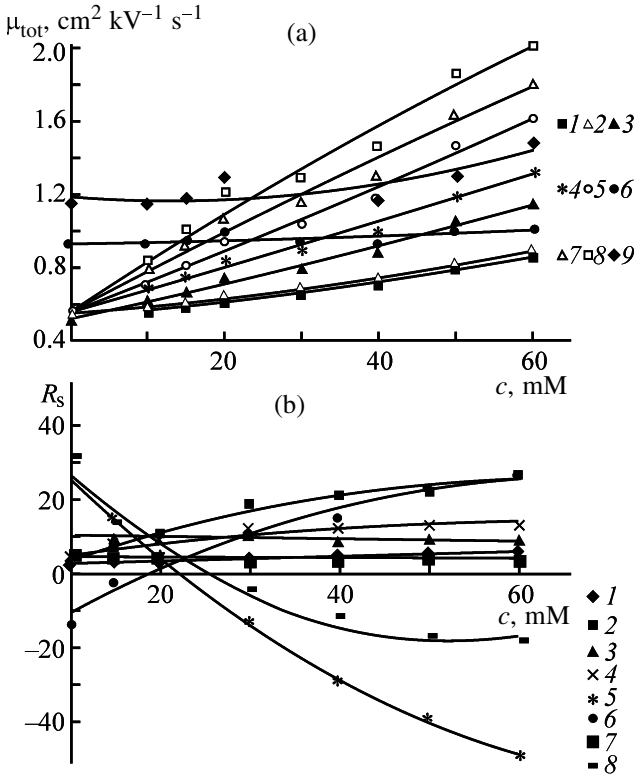

Fig. 4. Effects of the DDS concentration c in the working electrolyte on (a) electrophoretic mobility μ_{tot} of analytes and (b) resolution factors R_s: (a) (*1*) caffeine, (*2*) catechin, (*3*) EGC, (*4*) EGCG, (*5*) EC, (*6*) gallic acid, (*7*) GCG, (*8*) ECG, and (*9*) benzoic acid; (b) (*1*) caffeine/catechin, (*2*) catechin/EGC, (*3*) EGC/EGCG, (*4*) EGCG/EC, (*5*) EC/gallic acid, (*6*) gallic acid/GCG, (*7*) GCG/ECG, and (*8*) ECG/benzoic acid.

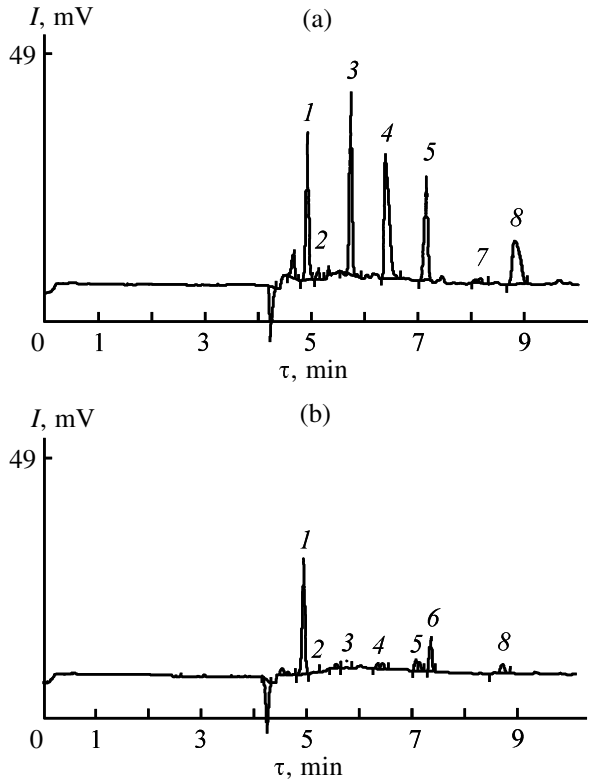

Fig. 5. Electrophoregram of actual aqueous extracts from (a) green and (b) black tea samples: (*1*) caffeine, (*2*) catechin, (*3*) EGC, (*4*) EGCG, (*5*) EC, (*6*) gallic acid, (*7*) GCG, and (*8*) ECG.

complexes (Fig. 4a). In this case, the resolution factors R_s of the pairs EC/gallic acid and ECG/benzoic acid considerably decrease. The R_s values increase for the pairs gallic acid/GCG and C/EGC, which can be attributed to the structural features of their molecules (Fig. 4b).

We also studied the effect of urea on the electrophoretic mobilities of the analytes and resolution factors. The electrophoretic mobilities of all the analytes decrease with increasing urea concentration. However, the resolution factors for the pairs EC/gallic acid and ECG/benzoic acid increase, which is probably due to the effect of urea on the distribution of EC and ECG between the micelles and buffer electrolyte.

Under the optimal conditions determined with the model mixtures, we performed MEKC analysis of the aqueous extracts from green (Fig. 5a) and black tea (Fig. 5b) samples (200-mg tea sample was treated with 20 ml of hot water). Our results showed that the polyphenol content is considerably higher in green tea.

CONCLUSIONS

(1) Conditions of chiral electrophoretic separation of tea polyphenols, (+)-catechin and (–)-epicatechin, in the capillary (zone) electrophoresis mode using β-cyclodextrin as a component of the buffer electrolyte are optimized.

(2) Optimization is made of electrophoretic separation of the multicomponent mixture of catechins in the mode of micellar electrokinetic chromatography. The electrophoretic mobility and resolution factors of the analytes are influenced by the concentrations of a micelle-forming agent (sodium dodecyl sulfate) and organic modifier (urea).

Abstract—The influence of preparation procedure on the nature of active centers, surface chemistry, and catalytic characteristics of FeZSM-5 zeolite in selective oxidation of benzene to phenol using N_2O as an oxidizing agent was studied.

DOI: 10.1134/S1070427206070147

Phenol is produced on the industrial scale by the multistage cumene process [1]. Its main drawbacks are significant environmental hazard, high power consumption, and low selectivity [1, 2]. Therefore, substitution of this process by single-stage selective catalytic oxidation of benzene with N_2O as an oxidizing agent opens an opportunity for the development of economically beneficial procedure of phenol production [1]. The most efficient catalyst for this reaction is ZSM-5 zeolite (structural type MFI) containing Fe^{3+} ions in the structure and steam-treated at 773–973 K (steaming) [1, 3]. The need in such a treatment makes the single-stage synthesis of phenol considerably less attractive, which stimulates the search for alternative solutions. In addition, the activity and selectivity of the catalysts of this type can significantly depend on the procedure of their preparation [4, 5]. However, despite a great deal of publications in this field, this problem is not adequately studied.

These facts stimulated us to perform a detailed study of the relation between the procedure of preparation of catalysts based on ZSM-5 zeolite and their catalytic characteristics in selective oxidation of benzene.

EXPERIMENTAL

The FeZSM-5 samples were prepared by incorporation of Fe^{3+} ions into the crystal lattice during the synthesis [6] and also by ion exchange in the medium of Fe^{3+} ions generated *in situ* [7, 8], by common procedure [9] or solid-phase ion exchange [10]. The catalyst containing structural Fe^{3+} ions (Si/Fe = 130) was synthesized by the procedure described in [6, 11] using the reaction mixture TEOS : TPAOH : Fe_2O_3 : $H_2C_2O_4$ = 1.0 : 0.312 : 0.00385 : 0.0254. First 10.24 g of tetraethyl orthosilicate (TEOS) was added to 15.0 g of structuring agent (tetrapropylammonium hydroxide, TPAOH, 20% aqueous solution), and the mixture was stirred for 20 h. Then, 5.0 ml of an aqueous solution containing 0.147 g of $Fe(NO_3)_3 \cdot 9H_2O$ and 0.152 g of $H_2C_2O_4 \cdot 2H_2O$ was added dropwise to this solution with stirring. The resulting gel was placed into a steel autoclave with a Teflon insert and kept for 5 days at 443 K. The crystalline phase was washed with water and dried at 383 K. TPAOH sorbed in zeolite pores was removed by calcination in an N_2 flow for 8 h at 823 K and a heating rate of 1.0 K min^{-1} and then in a flow of dry air for 4 h at the same temperature. The catalyst thus prepared is denoted as FeZSM-5(FW). The [Fe, Al]ZSM-5(FW) sample containing iron and aluminum ions in the structure (Si/Fe = 130, Si/Al = 40) was synthesized similarly using the following reaction mixture (g): 10.24 TEOS, 15 TPAOH, 0.147 $Fe(NO_3)_3 \cdot 9H_2O$, 0.444 $Al(NO_3)_3 \cdot 9H_2O$, and 0.644 $H_2C_2O_4 \cdot 2H_2O$. A part of the FeZSM-5(FW) and [Fe, Al]ZSM-5(FW) samples was steamed at 973 K, 10% H_2O/90% Ar for 3 h.

For the ion exchange in the medium of Fe^{3+} ions generated *in situ* [7, 8], 2.0 g of NH_4ZSM-5 zeolite (atomic ratio Si/Al 20, 40; Akzo-Nobel) was sus-

FeZSM-5(SE)	40	0.50	0.263	390	0.120

pended at 298 K in 200 ml of a 0.06 M HCl solution containing 0.10 or 0.73 g of metallic iron powder (Fluka). This suspension was kept without stirring for 72–80 h at 298 K in an argon flow (20 $cm^3\ min^{-1}$), after which the solid phase was filtered, washed with ethanol, and dried in a vacuum at 373 K. The prepared catalysts are denoted with the IE index.

For the ordinary ion exchange [9], NH_4ZSM-5 (Si/Al = 40) was treated three times with a 1.0 M $Fe(NO_3)_3 \cdot 9H_2O$ solution (solid : liquid = 1 : 50) for 6 h at 333 K, then washed with distilled water to negative reaction for NO_3^- ions, separated by filtration, and dried at 383 K for 16 h. This catalyst is denoted as CE. The solid-phase ion exchange ($FeCl_2$ + NH_4ZSM-5 $\rightarrow$ FeZSN-5 + NH_4Cl [10]), FeZSM-5(SE) sample, was performed by the procedure described in [10] by impregnation of NH_4ZSM-5 (Si/Al = 40) with a $FeCl_2/C_2H_5OH$ solution with a concentration corresponding to the ratio Fe/Al = 0.26.

The content of iron ions in the catalysts studied was determined by the ICP-AES method (Perkin–Elmer Optima, DV-3300, ICP-AES Instrument). The X-ray analysis was performed with a Rigaku RINT-2000 diffractometer (CuK_α radiation, λ = 1.54178 Å) in the range of Bragg angles 2θ = 5°–50°. The electronic diffuse reflection (EDR) spectra (190–800 nm) were recorded on a Shimadzu UV 2401 spectrophotometer, reference $BaSO_4$. The IR spectra were recorded on a Nicolet Avatar 360 FT-IR spectrophotometer; the samples were pelletized with thoroughly dried KBr (ratio 1 : 60). The ^{27}Al NMR MAS spectra were recorded on a Bruker Avance 500 spectrometer at 130 MHz and MAS rate of 12.5 KHz with a saturated $Al(NO_3)_3$ solution used as a reference. The curves of temperature-programmed reduction of the catalysts with hydrogen (TPH) were obtained using a flow reactor connected with a heat conductivity detector. For reduction we used a hydrogen–argon mixture (66% H_2) fed at a rate of 20 $cm^3\ min^{-1}$. The temperature range was 298–1073 K, and the heating rate, 5 deg min^{-1}. The isotherms of nitrogen adsorption–desorption at 77 K (Micromeritics ASAP 2010 installation) were obtained on preliminarily evacuated samples (5 h, 673 K, 10 Pa). The isotherms were analyzed using Langmuir equation, BET theory, and Dubinin–Astakhov method [3].

The catalytic tests were performed in a flow-type reactor at 623 K, $C_6H_6 : N_2O$ = 1 : 4 vol % in a helium flow, flow rate of 100 ml min^{-1}, and space velocity of 30000 h^{-1}. The composition of the reaction mixture was determined with a Hewlett–Packard GC-5890 gas chromatograph (OV1 column, flame ionization detector) and a Balzers TPG-420 mass spectrometer. In so doing, the conversion of benzene and N_2O, selectivity with respect to N_2O (amount of oxygen atoms generated from N_2O and entering into composition of phenol), selectivity with respect to benzene (C_6H_6 fraction converted into benzene), and productivity with respect to phenol were determined. The matter balance with respect to carbon and nitrogen was 98 and 99%, respectively. Before the reaction, the catalysts were heated in a helium flow (100 ml min^{-1}) at 823 K for 3 h.

The X-ray powder patterns of the samples isomorphically substituted with Fe^{3+} and Al^{3+} cations contain all basal reflections typical for ZSM-5 (structural type MFI) [12]. In this case, the content of Fe^{3+} and Al^{3+} practically coincides with that in the reaction mixture used for their synthesis (Table 1). The Fe^{3+} ions are localized predominantly in the crystal lattice of the zeolite, which is suggested by the presence of an absorption band in their IR spectra at approximately 650 cm^{-1}, assigned to the stretching vibrations in the structural fragments ≡Si–O–Fe= [6]. This band practically completely disappears after steaming due to decomposition of these fragments and subsequent

migration of Fe^{3+} ions to the outer surface of zeolite pores [13]. In this case, the crystal structure does not significantly change, since there are no noticeable differences in the X-ray patterns of the initial and steamed samples. In addition, ion exchange does not appreciably affect the zeolite structure, irrespective of its procedure. Nevertheless, in the case of FeZSM-5(IE) catalysts prepared by the ion exchange in strongly acidic medium, the coordination state is altered and the surrounding of a part of Al^{3+} ions is distorted. This follows from a comparative analysis of the ^{27}Al NMR spectra of the NH_4ZSM-5 and FeZSM-5(IE) samples (Fig. 1). In the latter case, there is an insignificant shift of the NMR signal of tetrahedrally coordinated Al^{3+} skeleton ions (approximately 54 ppm) [14] and also weak signals of octahedrally coordinated out-of-framework Al^{3+} cations (approximately 8.0 and 0.3 ppm) appear [14]. The amount of these ions is in direct proportion to the content of aluminum(III) in the zeolite, as seen from a comparison of the intensities of these signals for the samples with different atomic ratio Si/Al (Fig. 1). The steamed sample [Fe, Al]ZSM-5(FW) also contains a significant amount of out-of-framework Al^{3+} ions, which is suggested by its ^{27}Al NMR spectrum. In the spectra of catalysts prepared by ordinary or solid-phase ion exchange, no signals characteristic of such Al^{3+} ions are observed.

As known, the electronic diffuse reflection (EDR) spectroscopy furnishes data on the coordination, oxidation, and aggregative states of iron ions or iron oxides [15]. In the EDR spectra of the FeZSM-5(FW) and [Fe, Al]ZSM-5(FW) samples (Fig. 2), there is a band in the region of 250 nm, reflecting the ligand-to-metal charge transfer [15, 16]. Since this band characterizes the coordination state of Fe^{3+} ions as tetrahedral [15, 16], it can be suggested that at least a part of these ions is localized in the zeolite structure. A similar conclusion can be made from the analysis of the spectra in the range of *d–d* transitions (300–500 nm). However, in the [Fe, Al]ZSM-5(FW) sample the content of these cations is lower, as seen from a comparison of the intensities of the bands at approximately 350 and 415 nm (Fig. 2). This can be explained by a competition between aluminum and iron ions in formation of the crystal structure of zeolite [17], resulting in that a noticeable part of Fe^{3+} ions occupies out-of-framework positions. Steaming of these samples results in a noticeable decrease in the intensity of the bands at 350 and 415 nm (isolated Fe^{3+} ions [18]) due to rupture of the Si–O–Fe bond. Simultaneous shift of the band at approximately 250 nm to longer wavelengths suggests alteration of the coordination state of iron ions from tetrahedral to octahedral and formation of oxide clusters Fe_xO_y [15]. In this case, the aggregated Fe_2O_3 phase is not formed since in the spectra of these samples there is no typical absorption in the range $\lambda > 400$ nm [18]. These results allows a conclusion that steamed samples contain iron mainly in the form of individual finely dispersed clusters Fe_xO_y localized outside zeolite skeleton.

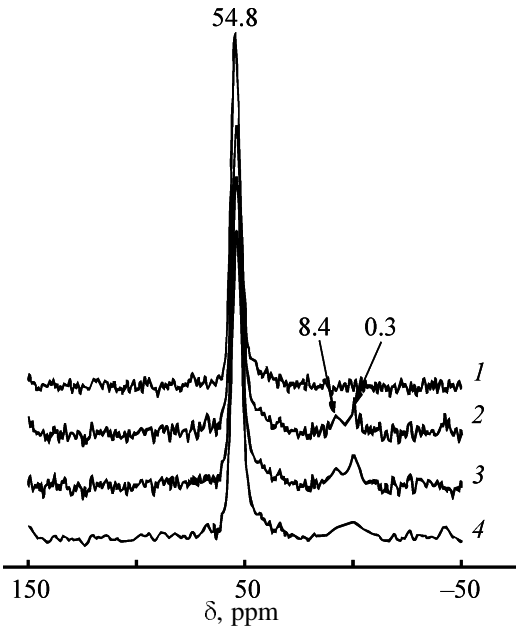

Fig. 1. ^{27}Al NMR spectra of the samples. (δ) Chemical shift. (*1*) NH_4ZSM-5; (*2*) FeZSM-5(IE), Si/Al = 40; (*3*) FeZSM-5(IE), Si/Al = 20; and (*4*) [Fe,Al]ZSM-5(FW) after steaming.

In the catalysts prepared by the ion exchange in the medium of iron ions generated in situ, formation of aggregated Fe_xO_y particles is not observed either, which follows from the absence of characteristic bands in the EDR spectra of FeZSM-5(IE) (Fig. 3). In this case, iron occurs predominantly in the double-charged state, since in the corresponding spectra the absorption bands of Fe^{3+} ions, namely at 224, 278, 350, and 485 nm [8, 15], are absent. For catalysts prepared by the ordinary procedure or solid-phase ion exchange, the pattern is cardinally different. In their EDR spectra (Fig. 3), there are bands with maxima at 230 and 238 nm, a peak or shoulder at 353 nm, and a broad absorption band in the range $\lambda > 400$ nm. This pattern is typical for tetra- and octahedrally coordinated Fe^{3+} ions forming aggregated oligomeric oxide clusters $(Fe_xO_y)_n$ [8], most of which is localized at the outer surface of zeolite crystals [15, 18].

Temperature-programmed reduction in hydrogen medium (H_2 TPR) furnishes data on the composition

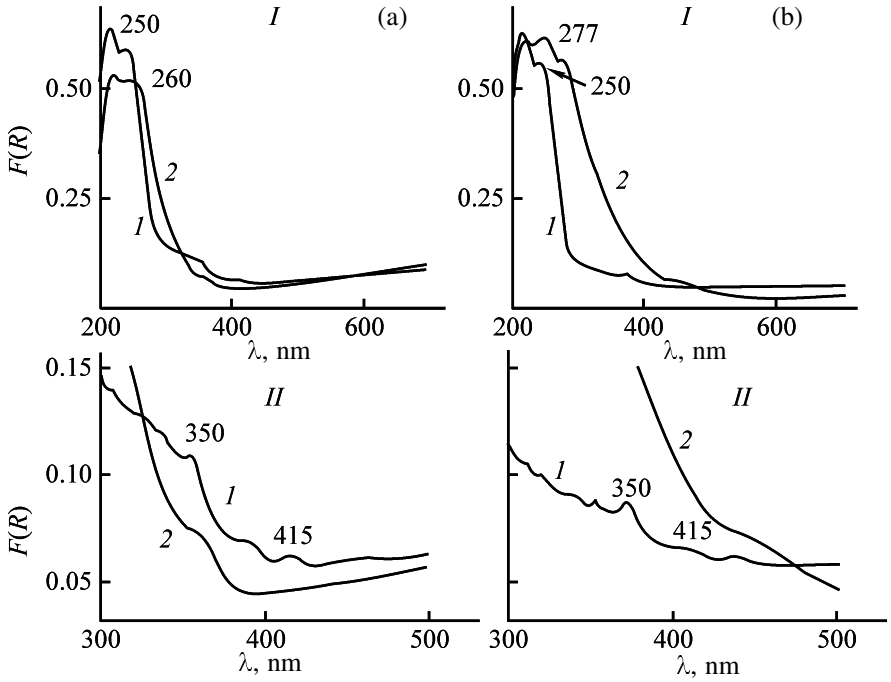

Fig. 2. EDR spectra of (a) FeZSM-5(FW) and (b) [Fe, Al]ZSM-5(FW) samples. [F(R)] Kubelka–Munk function and (λ) wavelength; the same for Fig. 3. (*I*) Entire range and (*II*) range of *d*–*d* transitions. Sample: (*1*) initial and (*2*) after steaming.

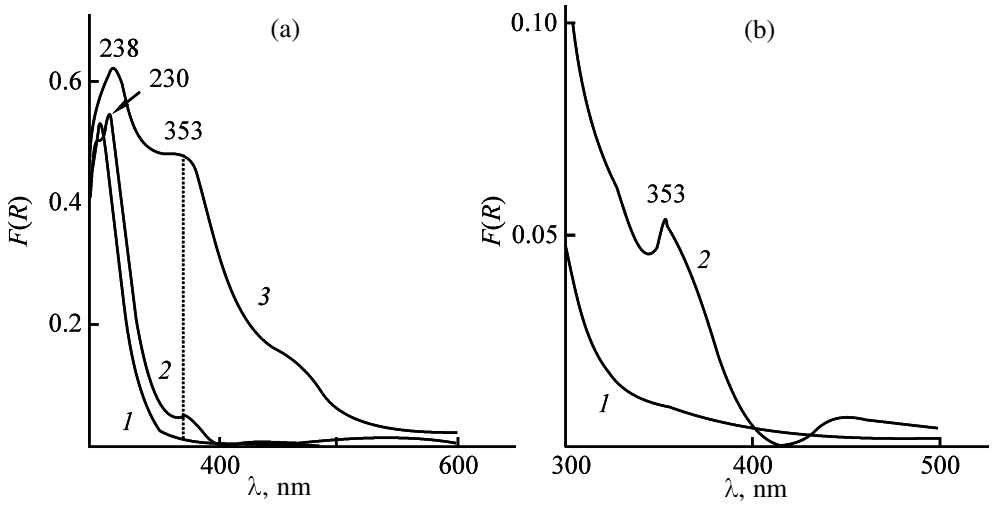

Fig. 3. EDR spectra of the FeZSM-5 samples. (a) Entire range and (b) range of *d*–*d* transitions. (*1*) FeZSM-5(IE) (0.53 wt % Fe^{n+}), (*2*) FeZSM-5(CE), and (*3*) FeZSM-5(SE).

of the metal oxide phase and also, indirectly, on the strength of its interaction with the catalyst surface [19]. The H_2 TPR curves of the samples isomorphically substituted with iron ions contain a broad peak of hydrogen uptake with a maximum at approximately 720 K corresponding to the reduction of Fe^{3+} apparently localized in the zeolite structure to Fe^{2+} (Fig. 4). This is supported by the shift of the temperature maximum and also by narrowing of this peak for the steamed sample (Fig. 4). As shown above, these materials contain iron in the form of highly dispersed Fe_xO_y clusters localized outside the zeolite skeleton. For the FeZSM-5(IE) catalysts, there is one broad peak of hydrogen uptake; however, the temperature of the onset of reduction is significantly higher (approximately 840 K) than that for the other materials (Fig. 4). The maximum of this peak is observed at 1020 K; it corresponds to the reduction of Fe^{2+} to Fe^0 [19], which additionally proves the presence of iron ions predominantly in the double-charged state.

The H_2 TPR curves of the samples prepared by the ordinary ion exchange or exchange in the solid phase

contain a strong peak of hydrogen uptake with a maximum at 675 and a shoulder at approximately 735 K (Fig. 4). This shape of the H_2 TPR spectrum is most probably caused by the differences in localization and dispersity of oxide clusters formed by the Fe^{3+} ions [20]. The hydrogen uptake in the range of higher temperatures (approximately 735 K) can reflect reduction of clusters located in the zeolite pores and separated clusters. In both cases, reduction occurs at a higher temperature in comparison with the oxide phase or oxide clusters localized at the outer surface of zeolite crystals. The H_2 TPR curve of the FeZSM-5(CE) sample contains also a weak peak at approximately 1027 K (Fig. 4), which is typical for the reduction $Fe^{2+} \rightarrow Fe^0$ [21]. It should be noted that, for all the catalysts prepared by ion exchange, the temperature of the maximum of the H_2 uptake is lower in comparison with their isomorphically substituted analogs. Since reduction of iron(III) bound in the structural fragments Fe–O–Si requires higher temperature than that of cations, this fact also proves that at least a part of Fe^{3+} ions is fixed in the crystal lattice of the catalysts.

Additional data on localization of iron compounds in the structure of the catalysts in hand were obtained using nitrogen adsorption [20]. For all the samples, the experimental adsorption isotherms can be classed with type I according to the IUPAC classification [22], which suggests their microporous structure typical for zeolites of the MFI type [23]. The BET method based on the polylayer model of N_2 adsorption inadequately describes adsorption processes occurring in zeolite channels because of the small size of their entrances (<0.7 nm). This follows from the negative value of the coefficient C in the BET equation, obtained for all the samples studied. Therefore, the isotherms were analyzed using the Langmuir and Dubinin–Astakhov equations. Owing to the similar synthesis conditions, the parameters of pore structure of the samples isomorphically substituted with Fe^{3+} ions differ insignificantly (Table 1). Steaming of these materials results in noticeable increase in the specific surface area and micropore volume (Table 1) as a result of an increase in their size. The most probable cause of this fact is migration of iron and aluminum ions from the structural positions to the outer surface. Lower values of the specific surface area and micropore volume of the FeZSM-5(IE) samples in comparison with the initial NH_4ZSM-5 (Table 1) suggest localization of iron ions and iron oxide clusters within zeolite pores. The decrease in these parameters for FeZSM-5(CE) and FeZSM-5(SE) can be explained by blocking of a part of their micropores with coarser

oligomeric oxide clusters $(Fe_xO_y)_n$ whose presence was shown by EDR spectroscopy.

The FeZSM-5(FW) sample prepared by incorporation of Fe^{3+} ions into the crystal lattice during synthesis was practically inactive in selective oxidation of benzene (Fig. 5). As a result of steaming its activity increases only insignificantly. At the same time, this treatment results in significant increase in the activity of the [Fe,Al]ZSM-5(FW) catalyst. These results are in good agreement with the concept that the Fe–O–Al clusters formed in steaming are active centers of the selective oxidation of benzene [3, 13, 24].

Table 2. Conversion X and selectivity S of the benzene oxidation to phenol

Catalyst	Benzene, %		N_2O, %		Benzene, %		N_2O, %	
	X	S	X	S	X	S	X	S
	5 min				240 min			
FeZSM-5(FW) after steaming	9	12	1	35	4	5	1	2
[Fe,Al]ZSM-5(FW) after steaming	36	67	16	42	6	98	3	55
FeZSM-5(IE) (0.53 wt % Fe^{n+})	18	71	8	41	5	82	3	49
FeZSM-5(IE) (0.07 wt % Fe^{n+})	23	77	4	100	6	100	1	100
FeZSM-5(CE)	15	58	2	100	0.5	38	3	2
FeZSM-5(SE)	22	48	5	50	0.2	6	1	0.4

In the course of the reaction, this catalyst is significantly deactivated, and the activity flattens out within approximately 3 h after the beginning of its operation. In the initial period (5 min), the selectivity of benzene conversion into phenol is approximately 70% (Table 2), which suggests partial conversion of C_6H_6 into other products. These are not only macromolecular compounds ("coke") adsorbed at the catalyst surface but also carbon dioxide and water. During further process, the selectivity of benzene conversion significantly increases (95–99%); however, this is accompanied by an abrupt decrease in its conversion (to 7%). In this case, the selectivity with respect to nitrous oxide is significantly lower, which can be explained by participation of N_2O in coke oxidation at the catalyst surface. The similar pattern is observed in the case of the FeZSM-5(IE) sample with a similar iron content (0.53 wt %, Fe/Al = 0.26) (Fig. 5). At the same time, an increase in the amount of Fe^{2+} ions to 0.07 wt % results in a significant increase in the activity and selectivity of the FeZSM-5(IE) catalyst, especially with respect to N_2O conversion (Table 2). This result can be explained as follows. The latter materials contain mainly double-charged iron ions, which pass into triple-charged state, being oxidized with nitrous oxide. In this case, the amount of Fe^{n+} ions plays a decisive role in formation of macromolecular by-products (coke). At increased concentration of these ions, the rate of side reactions increases, which is manifested as decreased selectivity of benzene conversion, observed for the samples containing 0.53 wt % Fe^{n+}. Since N_2O is also expended for coke oxidation, with an increase in its content a larger amount of nitrous oxide will participate in this process, which will result in decreasing selectivity of conversion along the main reaction pathway.

The steady-state activities of the FeZSM-5(IE) and steamed [Fe, Al]ZSM-5(FW) samples are the same (Fig. 5). This suggests the similar nature of active centers of these catalysts. As shown above by NMR spectroscopy, the samples prepared by ion exchange in the medium of Fe^{2+} ions generated in situ contain out-of-framework aluminum(III). In the steamed [Fe, Al]ZSM-5(FW) sample, there are also out-of-framework Al^{3+} ions. In both cases, they can occupy positions neighboring with Fe^{n+} ions and, hence, can participate in formation of Fe–O–Al clusters acting as active centers of the selective oxidation of benzene [3, 24]. The initial and steady-state activity of the catalysts prepared by ordinary and solid-phase ion exchange is significantly higher than that of the FeZSM-5(IE) samples (Fig. 5). The rate of deactivation of these catalysts, especially of the material prepared by solid-phase ion exchange is significantly higher than that of the FW and IE samples. This distinction in the behavior of the catalysts containing iron cations in exchange positions can be explained by the influence of various factors. First of all, these materials contain iron in the form of aggregated oligomeric oxide clusters of the $(Fe_xO_y)_n$ type, formed by tetra- and octahedrally coordinated Fe^{3+} cations, most of which are localized on the outer surface of the ZSM-5 crystals. Because of low dispersity of these centers, their specific activity will be significantly lower compared to the FeZSM-5(IE) catalysts containing iron mainly in the form of separated ions and highly dispersed oxide clusters. In addition, as shown by NMR, the catalysts prepared by the ordinary or solid-phase ion exchange do not contain out-of-framework Al^{3+} ions. This fact significantly decreases the probability of formation of Fe–O–Al clusters, i.e., active centers of the reaction in hand. Hence, the increased dispersity of the active centers formed predominantly by double-charged iron ions is responsible for a high activity of the catalysts prepared by the ion exchange in the medium of iron ions generated in situ.

CONCLUSION

The whole set of the results obtained suggests that the preparation procedure significantly affects the nature of active centers and chemical characteristics of the surface of Fe-containing ZSM-5 zeolite. Ion exchange in the medium of Fe^{2+} ions generated in situ allows preparation of active and selective catalysts for benzene oxidation to phenol using N_2O as an oxidizing agent. These catalysts can be used in this process without pretreatment at a high temperature, which makes the process significantly more feasible.

PROCESSES AND EQUIPMENT OF CHEMICAL INDUSTRY

Energy Approach to the Extraction Kinetics

E. V. Ivanov

Received December 7, 2005

Abstract—A method for description of the process kinetics is suggested on the basis of processing of a vast body of experimental data on the kinetics of extraction of target components from vegetable raw materials in apparatus with an intensive hydrodynamic mode. The method takes into account the input energy and type of hydrodynamic action on porous particles.

DOI: 10.1134/S1070427206070159

Hydromechanical methods for intensification of extraction of target components (TCs) from porous particles are aimed at partial replacement of the diffusion mass transfer with that of the convective type. An extracting agent moves within coarse pores when the process is performed under conditions of low-frequency pressure pulsations, under the action of pressure pulses near the surface of particles, or as a result of their mechanical deformation. In fine pores, mass transfer occurs exclusively as a result of molecular diffusion of the extracting agent and TCs, so that, on the whole, the extraction mechanism in apparatus with intensive hydrodynamic mode (in apparatus with a fast stirrer, in those of pulsatory and vibrational types, and in apparatus with vacuum-boiling, "explosive" boiling, and suspension subjected to ultrasonic treatment, electric discharges, etc.) can be regarded as that of diffusion-convective type. The theory of diffusion extraction has been developed in sufficient detail [1, 2], whereas for that of diffusion-convective extraction this is still to be done and the related publications are few in number [3–8].

Apparently, the rate of convective mass transfer in porous particles and the completeness of TC extraction depend on the intensity and duration of hydrodynamic treatment of particles and, in the end, on the amount of input energy and method of action on the particles.

The aim of this study was to develop a method for description of the extraction kinetics in apparatus with intensive hydrodynamic mode that would take into account the energy expenditure and the technique used for hydrodynamic action on the porous particles.

Processing of a vast body of experimental data on the kinetics of extraction from vegetable raw materials in apparatus with intensive hydrodynamic mode [9–13] demonstrated that, beginning with a certain instant of time, they are well approximated by the relations [5, 6]

$$\mu = a \ln E_{sp} + b, \quad (1)$$

where μ is the yield of TC in the extraction process (%); a and b, empirical coefficients dependent on the type of a raw material, method and mode of energy supply to a suspension being processed, apparatus type, and average concentration of TC in the bulk of the extracting agent (%); $E_{sp} = N_{br}\tau/V$ or $E_{sp} = N_{br}\tau/V\rho_l$, specific (related to the volume or mass of the suspension) input energy (J m^{-3} or J kg^{-1}); N_{br}, consumed power (W); τ, time (s); V, suspension volume (m^3); and ρ_l, density of the suspension being processed (kg m^{-3}).

Relation (1) can only be used within the interval $0 \le \mu \le 100$. A specific feature of this approximation consists in that, in the same hydrodynamic modes, but at different levels N_{br} of consumed power, the kinetic curves $\mu = f_1(\tau)$ are described by the same dependence $\mu = f_2(E_{sp})$. The results obtained can be explained as follows. The extraction rate, $d\mu/d\tau$, increases in the diffusion-convective mode with the intensity of the hydrodynamic impact on porous particles, and the hydrodynamic impact, in turn, becomes stronger as the specific power $N_{sp} = N_{br}/V$ delivered to the suspension being processed is raised. At the same time, the process rate decreases in an approximately inverse proportion to the extraction duration $\tau = E_{sp}/N_{br}$, because the surface layers of particles get depleted of TC. Hence follows

$$d\mu/d\tau \sim N_{sp}\tau, \quad d\mu \sim (N_{sp}\,d\tau)/\tau, \quad d\mu \sim (N_{sp}\,dE_{sp})/E_{sp},$$

$$\mu \sim N_{sp}\int (dE_{sp}/E_{sp}),\ \mu = a\ln E_{sp} + b.$$

The parameter N_{br} is implicitly included in the empirical coefficients a and b, which makes them dependent on the method of hydromechanical treatment of particles. Because E_{sp} is a dimensional quantity, it is more correct to use the relation

$$\mu = a\ln(E_{sp}/E_{0sp}), \quad (2)$$

where $E_{0sp} = \exp(b/a)$ is the specific input energy corresponding to $\mu = 0$ (J m^{-3} or J kg^{-1}).

An approximation of type (2) cannot describe the kinetics of the process in its initial stage and is only applicable when $E_{sp} > E_{0sp}$, and, naturally, kinetic curves based on (2) do not pass through the point $\tau = 0$, $\mu = 0$ ($\mu = 0$ at $\tau = \tau_0 > 0$). However, the experimental data on the extraction kinetics in this stage of the process are not found in the literature, which is due to difficulties is taking representative samples of the extract or raw material for analysis for the content of TC at time intervals of less than 2–5 min. After an extracting agent is mixed with the raw material, the extracting agent starts to penetrate into particles and to dissolve TC. Apparently, the rate of TC extraction is insignificant during a certain time ($0 \le \tau \le \tau_0$), and, therefore, the kinetic curves formally emerge from the point $\tau = \tau_0$, $\mu = 0$.

The consumed power is commonly a power function of one or several variables $N_{br} = cx_1^k x_2^l x_3^m$, where c is a coefficient; x_1, x_2, x_3, ..., variables on which the consumed power depends; and k, l, m, ..., exponents. Therefore, processing of experimental data can give approximations other than (1) and (2):

$$\mu = a\ln(g x_1^s x_2^i x_3^j), \quad (3)$$

where g is an empirical coefficient, and s, i, and j, empirical exponents.

Using (2) and (3), relations describing the change in the TC yield ($\Delta\mu$) caused by a change, all other conditions being the same, in the specific input energy from E_{1sp} to E_{2sp} (or in the power from N_{1sp} to N_{2sp} and in the variables from $x_{1,1}$, $x_{2,1}$, $x_{3,1}$, to $x_{1,2}$, $x_{2,2}$, $x_{3,2}$,...) during the same time:

$$\Delta\mu = a\ln(E_{2sp}/E_{1sp}) = a\ln(N_{2sp}/N_{1sp}), \quad (4)$$

$$\Delta\mu = a\ln[(x_{1,2}/x_{1,1})^s (x_{2,2}/x_{2,1})^i (x_{3,2}/x_{3,1})^j ...]. \quad (5)$$

It follows from expressions (4) and (5) that the extraction process is only intensified in its initial stage, and further (when samples are commonly taken for analysis), the kinetic curves run at approximately the same distance, equal to $\Delta\mu$, from one another. Apparently, the diffusion-convective mechanism of extraction is operative in the first stage of the process, and the inner-diffusion mechanism, in the second stage. Large energy expenditure is only effective in the first stage. In the second stage of extraction, it can (and should) be diminished by, e.g., lowering the frequency of pressure oscillations in pulsatory apparatus, temperature head in vacuum-boiling apparatus, stirrer rotation speed, etc. This has nearly no effect on the TC yield, but makes it possible to lower the energy expenditure for the process.

Let us illustrate the aforesaid with examples of processing of experimental data on the extraction kinetics for vegetable raw materials of varied anatomical structure in apparatus with intensive hydrodynamic mode. Semagina et al. [13] reported on the extraction kinetics of biologically active substances from pine needles with 25 and 40% aqueous solutions of ethanol under the action of an ultrasound with a frequency of 20–22 kHz and specific power N_{sp} = 2–3 MW m^{-3}. The intensity of the process was evaluated by a change in the TC content c (%) of the extracts. Values of c are related to those of μ by a constant proportionality factor, which could not be determined using the data of [13]. Processing of the experimental data demonstrated that they are satisfactorily described by the expression $c = 0.64\ln(3.6 \times 10^{-8} E_{sp})$.

The monograph by Balabudkin [12] presented the results obtained in extraction of tannin from galls in a rotary-pulsatory apparatus. The author reported neither the technical parameters of the apparatus used, nor any evidence concerning the volume of a suspension being processed. The consumed power was proportional to the rotor rotation speed n_{rot} raised to a certain power γ [12], and, therefore, the experimental data were approximated with the expression $\mu = a\ln(g n_{rot}^{\gamma}\tau)$.

At rotor rotation frequencies of 720, 940, and 1460 rpm, the experimental points (Fig. 1, dependence *1*) rather well fall on a straight line

$$\mu = 11.8\ln(6.71 \times 10^{-3} n_{rot}\tau), \quad (6)$$

where n_{rot} is the rotor rotation speed (rpm), and τ is time (min).

At the same time, the experimental points at a rotor rotation speed n_{rot} = 2960 rpm are grouped around the straight line $\mu = 8.1\ln(491.5\tau)$ (Fig. 1, dependence *2*), which indicates that the hydrodynamic impact on porous particles differs in this case from that at rotation speeds of 720–1460 rpm.

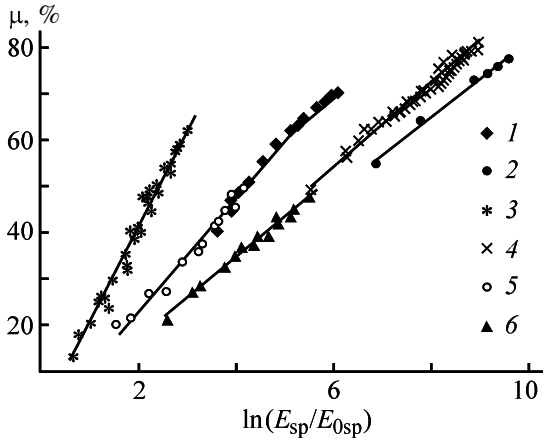

Fig. 1. Degree μ of TC extraction vs. $\ln(E_{sp}/E_{0sp})$ in the course of extraction. (E_{sp}) Specific input energy (J m^{-3}) and (E_{0sp}) specific input energy at μ = 0 (J m^{-3}). (*1, 2*) Tannin from gals in a rotary-pulsatory apparatus at rotor rotation frequencies of 72–1460 and 2960 rpm, (*3*) flavonoid compounds from hawthorn fruits in an oscillating vacuum-boiling mode, (*4*) flavonoid compounds from everlasting flowers in a vacuum-boiling mode at various temperature heads, and (*5, 6*) mushroom proteins in a pulsatory apparatus and that with a fast stirrer, respectively.

The extraction in the oscillating vacuum-boiling mode occurs under adiabatic conditions, in which the heat expended for boiling-up of the liquid is returned into the suspension being processed. For this purpose, the volume of the temperature-controlled system, constituted by the suspension being processed and vapor of the extracting agent, is periodically changed. As the volume of the system is raised, the pressure in it becomes lower, which causes intense boiling-up of the extracting agent and leads to formation of steam bubbles in the system. As the volume of the system decreases, the pressure increases, the bubbles collapse, and the heat of vaporization (condensation) is returned into the system. If the period of variation of the system volume is shorter than the time in which the bubbles rise to the surface, their collapse generates shock waves and thereby initiates filtration mass transfer in porous particles.

The useful consumed power is unknown because the process is complex and poorly understood. Apparently, it is proportional to the total power expended for agitation (transfer) of the suspension:

$$N_{sp} \sim \Delta P W,$$

where ΔP is the pressure difference (Pa), and W is the flow rate (m^3 s^{-1}).

Because the process is fast, ΔP could not be found experimentally. Calculations based on the thermal energy scheme of growth of a steam bubble in an overheated liquid [14] and on experimental data on the kinetics of bubble growth in the oscillating vacuum mode demonstrated that at boiling-up frequencies of 1–7.5 s^{-1} the pressure difference is insignificant, 310 kPa. As the boiling-up frequency ν increases, ΔP decreases following a nearly power-law dependence. Because the suspension flow rate is proportional to the amplitude A of suspension oscillations in the extractor, multiplied by the frequency ν, experimental data on the extraction kinetics were processed using the relation

$$\mu = a \ln(g A^{\alpha} \nu^{\beta} \tau), \quad (7)$$

where A is the amplitude of liquid oscillations in the extractor (m); ν, frequency of boiling-up (oscillations) of the liquid (s^{-1}); and α and β, empirical coefficients.

The experimental data on the extraction kinetics of flavonoid compounds (in terms of rutin) from noncrushed hawthorn fruits with a 40% aqueous solution of ethanol at 70°C and $0.035 \le A \le 1.75$ grouped around the straight line $\mu = 20.5 \ln[9.38 \times 10^{-3} (A\nu\tau)^{1/2}]$ (Fig. 1, dependence *3*).

The method of extraction in the vacuum-boiling mode was first suggested by Lysyanskii [15]. Since then, this technique has been repeatedly used and studied on laboratory and semicommercial installations [1, 9, 11, 16]. The experimental results obtained demonstrated that boiling under a vacuum markedly accelerates the extraction process. Lysyanskii believes that steam bubbles create, when moving across the layer of a material, identical conditions at all points of the layer, favor energetic mutual motion of particles and liquid, and thereby accelerate the external mass exchange. However, this is not the only intensifying factor. In the case of spontaneous growth of bubbles in the common boiling mode, the pressure gradient at local points exceeds 50 MPa m^{-1}, and the rate gradient in a direction perpendicular to that of the microflow, 10^{-5} s^{-1} [17, 18]. The forming shock waves exert dynamic influence on particles of the raw material with the result that molecular diffusion within these particles partly gives way to convective (filtration) mass transfer.

Despite the large number of publications devoted to this method, there is no published evidence about how the extraction rate is affected by the intensity of suspension agitation. This intensity can be defined as the flow rate of steam across unit area of the free surface of the liquid [19], or, if the heating surfaces are distributed within the apparatus volume, as a flow rate

of steam through unit volume of the suspension being processed:

$$I_V = q_h F / r_{st} \rho_{st} V_{st}.$$

where I_V is the agitation intensity ($m^3\ s^{-1}\ m^{-3}$); q_h, specific heat flux ($W\ m^{-2}$); F, heating surface area (m^2); r_{st}, heat of steam formation ($J\ kg^{-1}$); ρ_{st}, steam density ($kg\ m^{-3}$); and V, liquid (suspension) volume (m^3).

The specific power expenditure for agitation in a vacuum-boiling apparatus is given by

$$N_{sp} = q_h F / V.$$

The specific heat flux is proportional to the temperature head: $q_h \sim (\Delta t)^{\varphi}$ [14], where $\Delta t = t_s - t_l$ is the temperature head; t_s, temperature of the heating surface; t_l, temperature of the liquid; and φ, exponent ($\varphi = 3$ for water under atmospheric pressure). Therefore, in the same apparatus at the same filling with the liquid and at the same temperature,

$$I_V \sim (\Delta t)^{\varphi} \text{ and } N_{sp} \sim (\Delta t)^{\varphi}.$$

The temperature head of boiling onset, Δt_{0h}, is affected by a wide variety of factors: pressure, properties of the liquid, roughness and material of the heating surface, etc. Water starts to boil at a pressure P = 100 kPa at $\Delta t_{0h} \sim 5$–6°C and specific heat flux $q_{0h} \sim 6 \times 10^3\ W\ m^{-3}$ [14]. For ethanol at P = 100 kPa, the temperature head of boiling onset is Δt_{0h} = 15°C [20].

Processing of the experimental data on extraction of flavonoid compounds (in terms of rutin) from everlasting flowers with a 40% aqueous solution of ethanol at a boiling temperature of the extracting agent of about 70°C (t_1 = 68.4–72.5°C), pressure of 62 kPa, and temperature heads Δt = 6.5, 13.4, and 25.2°C demonstrated that the process kinetics is sufficiently precisely described by the expression $\mu = 9 \ln(2.09 \Delta t \tau)$ (Fig. 1, dependence *4*).

The power expenditure for the process in a pulsatory apparatus is largely determined, as in the apparatus of oscillating vacuum boiling, by the energy expenditure for suspension transfer. Therefore, a formula similar to (7) was used to process experimental data at the same pressure differences. Dependence *5* in Fig. 1 illustrates the fundamental kinetic aspects of protein extraction with a 0.11 M buffer solution with pH 9.0 from finely divided (particle size 1–5 mm) fruit bodies of a *Lactarius rufus Fr.* mushroom at pressure oscillation frequencies ν = 3–6 s^{-1}. The straight line is described by the expression $\mu = 11.5 \ln[2.95 \times 10^{-3} (\nu\tau)^{1/2}]$.

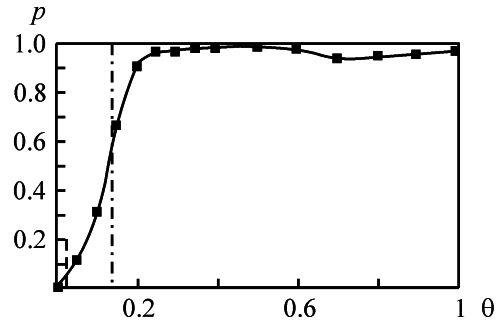

Fig. 2. Frequency p of satisfactory approximations vs. dimensionless extraction time θ.

Stirred vessels are the most frequently used reactors for extraction processes. In this case, the power expended for suspension agitation is $N_{sp} \sim n_{mix}^3$, where n_{mix} is the stirrer rotation speed (rpm). The experimental data on the kinetics of protein extraction from finely divided fruit bodies of a *Lactarius rufus Fr.* mushroom in a vessel with a fast stirrer (n_{mix} = 1500–3500 rpm) are well approximated by the expression $\mu = 8.67 \ln(5.94 \times 10^{-4} n_{mix} \tau)$ (Fig. 1, dependence *6*).

It is noteworthy that the exponent in the approximating dependence obtained for the extraction kinetics of tannin from galls is $\gamma = 1$. If the process were affected by the whole amount of energy expended by a rotary-pulsatory apparatus, the exponent would be $\gamma \approx 3$ [12]. The same can be said about the formula for the extraction kinetics of flavonoids from everlasting flowers in a vacuum-boiling apparatus. In this case, $\varphi = 1$ instead of $\varphi \approx 3$ [14]. Presumably, the parameter E_{sp} in relations (1) and (2) corresponds only to the "useful" part of the input energy, expended for initiation of the diffusion-convective mass-transfer mechanism, rather than to its whole amount. There is an apparent analogy with the dependence of the mass-transfer coefficient β on the specific energy dissipation ε, e.g., in dissolution of solid particles of size exceeding 60–100 μm in a stirred vessel, $\beta \sim \varepsilon^{0.25}$ [21, 22], and in dissolution of pellets in a vibration apparatus, $\beta \sim \varepsilon^{0.37}$ [23].

Figure 2 shows frequencies at which relations (1) and (2) satisfactorily (with an rms error less than 2.5%) approximate 90 kinetic curves of TC extraction from vegetable raw materials with various anatomical structures in apparatus with intensive hydrodynamic modes. As dimensionless time θ was taken the ratio between the running time and the time in which an "apparent" equilibrium is attained, when the process of TC extraction from the raw material still continues, but at an exceedingly low rate. The area under the curve, equal to 0.8, characterizes that part of the ex-

perimental data (with respect to the number of kinetic curves and the extraction time), which are satisfactorily described by formulas (1) and (2). Because there are no experimental data to the left of the curve (no samples were taken for technical reasons), the actual fraction of satisfactory approximations is 0.96. The average dimensionless time corresponding to $\mu = 0$ in the approximating relations (1) and (2) is $\theta_0 = 2.2 \times 10^{-2}$; this time is shown in Fig. 2 by a vertical dashed line. The average dimensionless time of first sampling, $\theta_1 = 0.14$, is denoted in Fig. 2 by a vertical dot-and-dash line. The average value of the ratio θ_0/θ_1 is 0.19. The approximation precision is somewhat deteriorated as the "apparent" equilibrium is approached, at dimensionless extraction times longer than 0.6.

CONCLUSION

The method suggested for processing of experimental data make it possible to describe with a sufficient precision the kinetics of TC extraction from porous particles in apparatus with an intensive hydrodynamic mode, reveal specific features and existence limits of hydrodynamic modes, analyze the utilization efficiency of the input energy, and find ways to diminish the energy expenditure for the process.

Abstract—A mathematical model for calculation of the dynamics of liquid-phase adsorption in a fixed sorbent bed is constructed on the basis of material balance equations solved by numerical integration on the assumption of a constant mass-transfer coefficient and a limiting inner-diffusion resistance.

DOI: 10.1134/S1070427206070160

Adsorption separation of mixtures is one of the most efficient mass-exchange processes.

The primary goal of mathematical simulation of the operation of an adsorption column is the opportunity to calculate the adsorption dynamics, i.e., to plot the curve of variation of the concentration of an impurity being adsorbed in the purified flow (raffinate) leaving the column: the breakthrough curve or adsorption isoplane. This makes it possible to calculate the most important working characteristics of the column: dynamic activity of the adsorbent with respect to the impurity being extracted till its conditional (admissible) breakthrough into the raffinate, length of the mass-exchange zone, duration of column operation till conditional breakthrough of the impurity into the raffinate, etc.

An analysis of the adsorbate sorption, based on an integral or differential approach to solution of the problem, underlies the numerous existing methods for calculation of the adsorption dynamics. In the case of the integral approach, the dynamics equations have the form of algebraic equations with coefficients that characterize the adsorbate mass transfer in the adsorbent–adsorbate system [1]. The authors of numerous publications devoted to the adsorption dynamics assign to these coefficients different meanings (kinetic coefficient [2–4], partial mass-transfer coefficient in the liquid [5] and solid [6] phases, mass-transfer coefficient, etc.). The coefficients in question are not constants and commonly strongly depend on the nature of a component being sorbed and sorbent, concentration of a substance being sorbed in the feed, and flow rate of the feed in the column and markedly differ in processing of the results of the same experiment by different methods for calculation of the adsorption dynamics [7]. The equations of the adsorption dynamics in the differential form require that numerical calculation methods should be used and contain a number of numerical parameters: diffusion and thermodiffusion coefficients, barrier resistance, etc. [8, 9]. Finding the coefficients that appear in the adsorption dynamics equations requires special labor-consuming and prolonged experiments under dynamic conditions, with the subsequent construction of additional dependences of the kinetic coefficients on the flow rate and on the concentration of the impurity being adsorbed in the flow. Because the dimensions of research adsorption columns and their process modes markedly differ from those in the industrial conditions, extrapolation of experimental dependences beyond the investigation range leads to a gross error in simulations. Moreover, calculations of the adsorption dynamics require information about the potential activity of the sorbent in the form of an adsorption isotherm, which is also found experimentally. The necessity for a large number of results of laboratory and pilot experiments leads to a search for less labor-consuming ways to solve this problem.

The present study makes an attempt to directly calculate the adsorption dynamics in a column with a fixed zeolite bed from liquid-phase flows on the basis of data on the adsorption kinetics with account of the specificity of this process. The basic assumption of the model developed is that the limiting diffusion resistance in impurity adsorption from the flow of a liquid-phase feed is concentrated within micropores of the zeolite sorbent and the diameter of inlet windows through which molecules being adsorbed pen-

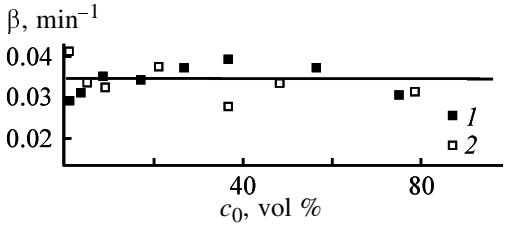

Fig. 1. Overall volume mass-transfer coefficient β vs. the content c_0 of the component being extracted in the feed in sorption of (*1*) benzene and (*2*) toluene with NaX zeolites from a solution in *n*-heptane.

etrate into voids of the crystal structure only slightly exceeds the critical size of the molecules. Such a behavior is typically observed, in particular, in separation of hydrocarbons with zeolites. Motion of molecules within the wide transport pores of the adsorbent and, the more so, in the space between adsorbent grains with linear dimensions of pores hundreds and thousands of times larger than the size of the molecules is provided at a significantly lower diffusion resistance, so that the outer-sphere diffusion can be neglected in this case. As a result, information obtained in studies of the adsorption kinetics can be used in developing a model of adsorption dynamics.
